Anti-Nerve Growth Factor Therapy Attenuates Cutaneous Hypersensitivity and Musculoskeletal Discomfort in Mice with Osteoporosis Miyako Suzuki*[1], Magali Millecamps[1], Seiji Ohtori[2], Laura S. Stone[1]. [1]The Alan Edwards Centre for Research on Pain, Faculty of Dentistry, McGill University, Canada, [2]Department of Orthopaedic Surgery, Graduate School of Medicine Chiba University, Japan

Introduction. The prevalence of osteoporosis is increasing with the aging global population. In addition to increased risk of fracture, osteoporosis is associated with chronic pain. We previously reported that improvement in bone mineral density is not sufficient to reduce osteoporotic pain in an ovariectomy (OVX)-induced mouse model of osteoporosis, highlighting the need for new treatments. Targeting of Nerve Growth Factor (NGF) with sequestering antibodies is a promising new direction for the treatment of musculoskeletal pain including low back pain and arthritis. Its efficacy is currently unknown for osteoporotic pain. The aim of this study was to examine the efficacy of anti-NGF antibody therapy against behavioural indices of osteoporotic pain and on sensory neuron plasticity in a mouse model of OVX-induced osteoporosis. Methods. Ovariectomy (OVX, n=20) - and sham-operated (n=10) female C57BL6 mice at 5-7 week of age were assigned to receive either anti-NGF antibody or vehicle (OVX/anti-NGF, OVX/Vehicle, and Sham/Vehicle; n=10 per group) at 8 weeks after surgery. Evaluation of the vertebral and femoral bone mineral density (BMD) were performed prior to the behavioral testing and after anti-NGF treatment. Animals received 2 injections of anti-NGF antibody (Exalpha Biologicals Inc., Shirley, MA, USA, 10mg/kg, i.p) or vehicle (0.01 mL/g, i.p sterile saline), 2 weeks apart. Behaviors were monitored at baseline, and for a maximum of 2 months after the initial treatment. Behavior included measures of cutaneous hindpaw hypersensitivity (von Frey, acetone-evoked behavior, cold plate test and heat test), deep musculoskeletal discomfort (grip test assay) and physical function (rotarod and open-field tests). Sensory nervous system plasticity was evaluated by quantification of the sensory neuropeptide calcitonin gene-related peptide (CGRP)- and neuropeptide-Y-immunoreactivity (-ir) in dorsal root ganglia. Results. There was a significant loss in vertebral and femoral BMD of the OVX mice compared to the sham-operated controls. Anti-NGF treatment had no adverse effect on the vertebral or femoral BMD. Furthermore, anti-NGF treatment attenuated OVX-induced hypersensitivity to mechanical, cold and heat stimuli on the plantar surface of the hindpaw. The OVX-induced impairment in grip force strength, used here as a measure of deep musculoskeletal discomfort, was partially reversed by anti-NGF therapy. No changes were observed in the rotarod or open field tests for overall motor function and activity. Finally, anti-NGF treatment attenuated the increase in CGRP-immunoreactive dorsal root ganglia neurons observed in OVX mice.Discussion. We demonstrated anti-NGF efficacy in the OVX mouse model of osteoporosis-related pain. These data implicate NGF as a driver of long-term osteoporotic pain and suggest that anti-NGF treatment may be a useful therapy for this population.

Advanced Age Leads to Aberrant Wnt Pathway Expression and Bone Turnover in a Murine Model of Chronic Kidney Disease Elizabeth Terhune*, Ryan Clark, William Schroeder, Karen King. Department of Orthopedics, University of Colorado Anschutz Medical Campus, United States

Chronic kidney disease-mineral and bone disorder (CKD-MBD) is a common complication of CKD that includes disrupted serum mineral homeostasis, low bone density, vascular calcifications and increased fracture risk. Over half of individuals age >65 meet the clinical definition for CKD, and elderly individuals undergoing dialysis experience four times as many hip fractures as expected for their age. We investigated whether bone responds distinctly to CKD at older ages, and hypothesized that age may be an aggravating factor for CKD-MBD. To explore this hypothesis, we conducted a 5/6th nephrectomy or sham procedure in three age groups of male C57Bl/6 mice. Groups were Young CKD (3 months, n= 7), Young Control (n= 7), Adult CKD (15 months, n= 12), Adult Control (n= 10), Geriatric CKD (21 months, n= 14) and Geriatric Control (n= 10). Twelve weeks later, at study completion, we analyzed serum mineral and protein concentrations, and we measured gene expression in cleaned, femoral diaphyseal bone.Nephrectomized mice were determined to have mild to moderate CKD as defined by increased serum levels of urea, calcium, phosphorus, FGF23 and PTH (parathyroid hormone). Geriatric CKD mice showed increases in serum type I collagen propeptides (PINP) (p= 0.012) and type I collagen fragments (CTX-I) (p= 0.035), indicating high bone turnover. Young and Adult CKD mice showed modest increases in CTX-I, but not PINP.Gene expression of several mineralization markers were altered in the Young and Geriatric groups (Table 1). Geriatric CKD mice showed decreased levels of the Wnt inhibitor genes Sost (sclerostin) (p= 0.0046, Fold Change= 0.29 compared to age-matched control) and Dkk1 (p= 0.0233, Fold Change= 0.40) as well as Tnfrsf11b (osteoprogerin) (p= 0.1531, Fold Change= 0.53). Geriatric CKD mice also showed increased levels of Ager (RAGE) (p= 0.0021, Fold Change= 2.14). These changes were not significant in Young CKD mice. The Wnt ligands Wnt10 and Wnt16 differed between Young and Geriatric mice, but not CKD groups. Genes encoding major structural proteins of bone, including Col1a1 and Ibsp, did not differ between cohorts.Our results suggest that the bone of geriatric individuals may respond more severely to CKD. Understanding the cellular mechanisms underlying the bone's response to CKD in the elderly will aid in the development of clinical treatments for individuals experiencing increased rates of bone fractures and CKD-induced osteoporosis.

Oncostatin M is a key effector of heterotopic ossification following spinal cord injuries Hsu-Wen Tseng*[1], Kylie Alexander[1], Irina Kulina[1], Marjorie Salga[2,3], Beulah Jose[1], François Genet[2,3], Frédéric Torossian[4], Bernadette Guerton[4], Adrienne Anginot[4], Whitney Fleming[1], Susan Millard[1], Allison Pettit[1], Natalie Sims[5], Jean-Jacques Lataillade[4,6], Marie-Caroline Le Bousse-Kerdilès[4], Jean Pierre Levesque[1]. [1]Mater Research Institute-The University of Queensland, Brisbane, Queensland, Australia, [2]Service de Médecine Physique et de Réadaptation, Raymond Poincaré Hospital, Garches, France, [3]END:ICAP U1179 INSERM, UFR des Sciences de la Santé-Simone Veil, Université Versailles Saint Quentin en Yvelines, Montigny le Bretonneux, France, [4]Inserm UMR-S-MD1197, Paris 11 University, Paul Brousse Hospital, Villejuif, France., France, [5]St. Vincent's Institute of Medical Research and Department of Medicine, St. Vincent's Hospital, The University of Melbourne, Fitzroy, Victoria, Australia, [6]Centre de Transfusion Sanguine des Armées, L'Institut de Recherche Biomédicale des Armées, Clamart, France

Neurogenic heterotopic ossification (NHO) is traumatic brain injury or spinal cord injuries (SCI)-associated abnormal ectopic bones in soft tissues. NHO leads to reduction of joint movement and complication associated with blood vessel and nerve compression. There is no effective pharmaceutical treatment to prevent NHO due to poor understating of NHO etiology, and surgical resection might only be temporary as it can reoccur. To identify the pathogenic factors, we established a NHO mouse model, in which NHO is induced in genetically unmodified mice following a combination of SCI and cardiotoxin-induced muscle injury. While cardiotoxin-triggered inflammatory and muscle injury gradually repaired in the absence of SCI, macrophages remained abundant in damaged muscle and intercalated with ectopic bone foci three weeks post SCI. Macrophage depletion abolished NHO formation suggesting macrophages are required in NHO pathogenesis. Comparing mRNA expression of injured muscle from SCI and sham-operated mice showed an upregulation of several macrophage-related proinflammatory cytokines in SCI group, such as Tnf, Ccl2, Csf1 and Osm. Osm encodes Oncostatin M, which also regulates osteoblast activity and hematopoietic stem cell mobilisation, is expressed by macrophages and osteoblasts around NHO and highly accumulated in the injured muscle. Phosphorylation of STAT3, one downstream signalling pathway, was significantly higher in injured muscle of the SCI group than sham group. Moreover, OSM receptor deficiency significantly reduced NHO volume by 2.5 fold compared to WT mice. Likewise, treatment with inhibitor of JAK/STAT signalling significantly reduced NHO volumes. In agreement with NHO murine model, OSM concentration was significantly higher in patients developing NHO compared to healthy volunteers. Furthermore, conditioned media from macrophages isolated from patients' NHOs promoted mineralisation of patient muscle-derived stromal cells in vitro and this effect was inhibited by addition of neutralising anti-OSM antibody. In conclusion, we identified OSM as a key mediator of NHO pathogenesis; therefore, blocking OSM signalling pathway might prevent or retard NHO formation.

SUN-0157

Osteocyte markers and vascular health in kidney transplantation Yue Pei Wang*, Aboubacar James Sidibé, Roth-Visal Ung, Karine Marquis, Mohsen Agharazii, Fabrice Mac-Way. CHU de Québec Research Center, L'Hôtel-Dieu de Québec Hospital, Endocrinology and Nephrology Unit, Faculty and Department of Medicine, Université Laval, Canada

Introduction: New bone and vascular markers such as sclerostin, dickkopf-related protein 1 (DKK1), fibroblast growth factor 23 (FGF23) and α-klotho have been suggested to contribute to kidney transplant (KTx)-related bone and vascular disorders. We aimed to evaluate the evolution of these markers after kidney transplantation and whether they are associated with arterial stiffness.Methods: Longitudinal observational cohort study of all eligible patients for vascular assessment who underwent KTx at CHU de Québec between 2007 to 2011. Comorbidities and biochemical parameters were collected from patients' electronic records. Bone markers levels were measured by ELISA on plasma collected on the day of KTx, at 3 (M3) and 6 months (M6) where hemodynamic parameters, carotid-femoral (CFpwv) and carotid-radial (CRpwv) pulse-wave velocity were assessed using a Complior device. Associations between arterial stiffness (adjusted for mean blood pressure and/or heart rate) and bone markers were analyzed with generalized estimating equations in univariate and multivariate models (baseline arterial stiffness parameter, age, sex, smoking, diabetes and cardiovascular disease) using SPSS 20.0.Results: This study included 79 patients (69.6% male with a mean age of 50.2 ± 13.7). All bone markers decreased significantly after KTx compared to baseline (Figure 1). The changes in sclerostin levels (M3 and M6) correlated with changes in DKK1 (R=0.523 and 0.424, p<0.01) and FGF23 (R=0.301 and 0.334, p<0.01). Sclerostin levels were associated with CFpwv in univariate model and with pulse pressure (PP) amplification both in univariate (β=-0.259; CI95 [-0.412, -0.105]) and multivariate models (β=-0.180; CI95 [-0.330, -0.030]) at M3. Baseline sclerostin levels also predicted CFpwv at M3 (β=0.346; CI95 [0.080, 0.613]) and M6 (β=0.334; CI95 [0.082, 0.586]) in univariate analyses while sclerostin levels at M3 predicted CFpwv (β=1.850; CI95 [0.263, 3.437]) at M6. Furthermore, sclerostin levels at M6 were associated with central PP in all models (multivariate: β=9.717; CI95 [0.887, 18.547]) at M24. Sclerostin, DKK1 and FGF23 levels were associated with parathyroid hormone levels at baseline but not after KTx. Conclusion: Sclerostin, DKK1, FGF23 and α-klotho levels significantly decrease after kidney transplant. Sclerostin levels seem to be associated with arterial stiffness parameters and may therefore play a role in regulation of vascular health in this population.

Enhanced bone growth with lipoxinA4 Amy Koh*, Justin Do, Hernan Roca, Laurie Mccauley. University of Michigan, United States

LipoxinA4 (LXA4) is an eicosanoid lipid mediator derived from arachidonic acid metabolism and is one of the most abundant lipoxin molecules. LXA4 binds to its receptor ALX, a G protein coupled receptor expressed in a variety of cells, and mediates resolution of inflammation and wound healing. Bone is a dynamic tissue serving as a vital supply and disseminator of bone marrow cells. Macrophages (F4/80+) compromise ~15% of bone marrow cells, mediate bone formation, and facilitate anabolic actions of parathyroid hormone (PTH). PTH increases lipoxins in the bone marrow and studies of lipoxin action in bone are

of recent interest. The purpose of this study was to investigate LXA4 effects on growing bone, a phase of high bone activity that mimics an inflammatory state. METHODS: In vivo, C57Bl/6 mouse pups (5d old) were treated daily for 17 days with LXA4 (10ng/g, IP; n=7) or vehicle control (VEH; n=5) and sacrificed 24h after the last injection. Bone turnover markers TRAcP5b and P1NP were determined in serum and microCT analyses of tibiae performed. In vitro, an LXA4 dose response was investigated on M-CSF-1 and RANKL induced osteoclastogenesis in primary bone marrow cultures. RESULTS: After 17 days of LXA4 administration, microCT analyses revealed significantly increased bone volume/total volume (0.21 +/- 0.02 VEH vs. 0.28 +/- 0.02 LXA4; p<0.02). There was a significant increase in trabecular number (5.96 +/- 0.22 VEH vs. 7.15 +/- 0.34 LXA4; p<0.02) and BMD (124.29 +/- 6.60 VEH vs. 155.18 +/- 9.99 LXA4; p=0.03) and a trend of increased trabecular thickness and decreased trabecular spacing. With LXA4 administration, serum TRAcP5b, an indicator of osteoclast numbers, was decreased (13.12 +/- 1.49 VEH vs. 9.71 +/- 0.88 LXA4; p=0.07) while P1NP, an indicator of bone formation, was unchanged (p=0.13). In vitro, LXA4 dose dependently inhibited osteoclastic differentiation of primary bone marrow cell cultures, confirming a report previously shown with the RAW264.7 macrophage cell line. These data reveal the pro-resolving mediator, LXA4, increases bone growth at least in part via an inhibition of bone resorption.

In vivo Intramedullary Pressure Measurements and Femoral Bone Microarchitecture and Cortical Thickness in Young and Old Male Fischer-344 Rats David Lee*[1], Sunggi Noh[1], Jeong-Bong Lee[2], Rhonda Prisby[1]. [1]University of Texas, Arlington, United States, [2]University of Texas, Dallas, United States

Previous studies have demonstrated that increased and decreased bone intramedullary pressure (IMP) augments and diminishes bone mass, respectively. Since advancing age corresponds with declines in bone mass, we theorized that bone IMP would also be reduced. The purpose of the study was to examine in vivo IMP in the femoral canal of young and old male Fischer-344 rats in relation to bone volume. We hypothesized that IMP and bone volume would be reduced in the older vs. younger rats. Experiment 1: young (6 months; n=5) and old (24 months; n=6) male Fischer-344 rats were anesthetized (2% isoflurane to O2 balance) and the femoral shafts were catheterized. Following 1-hour of recovery, the catheter was connected to a pressure transducer and in vivo IMP (mmHg) was recorded (PowerLab, AD Instruments) for 15 minutes in conscious animals. The last 5 minutes of data were averaged and reported. Experiment 2: Left femora from young (6 months; n=5) and old (24 months; n=5) male Fischer-344 rats were dissected, fixed and scanned using an inspeXio SMX-100CT Micro-Focus X-Ray Computed Tomography System (Shimadzu, Japan) to determine trabecular bone microarchitecture (i.e., bone-volume to total-volume ratio [BV/TV,%], trabecular thickness [Tb.Th, µm], trabecular number [Tb.N /mm], and trabecular separation [Tb.Sp, µm]) in the distal femoral metaphysis and cortical thickness (Ct.Th, µm) at the midshaft. One-way ANOVAs were performed. Alpha level was set at p<0.05 a priori. Values represent Means±S.E. Intramedullary pressure did not differ between groups (young, 16±3 mmHg vs. old, 13±3 mmHg). Trabecular BV/TV (21±2% vs. 18±3%, respectively) did not differ between young and old rats; however, Tb.N (3.0 ± 0.2 /mm vs. 2.3±0.3 / mm, respectively) and Tb.Sp (273±24 µm vs. 375±41 µm, respectively) tended (p=0.08 and p=0.07, respectively) to differ. In addition, cortical thickness was higher (p<0.05) in old (820±24 µm) vs. young (652±10 µm) rats. No differences in IMP and trabecular bone volume were observed between the young and old rats; however, additional work is warranted.

SUN-0177

Primary Perturbations in the Myeloid Lineage, Including Neutrophils and the OsteoMac, Contribute to Cystic Fibrosis-Related Bone Disease John Stabley*[1], Jessica Hook[2], Shadaan Abid[1], Li Li[1], Megan Mead[1], Abraham Behrmann[1], Jessica Moreland[2], Dwight Towler[1], Raksha Jain[1]. [1]Department of Internal Medicine, UT Southwestern Medical Center, United States, [2]Department of Pediatrics, UT Southwestern Medical Center, United States

The increase in lifespan of our patients living with cystic fibrosis (CF) has revealed new challenges to bone health management. The elevated prevalence of osteopenia and osteoporosis in this setting – and potentially avascular necrosis – is collectively denoted as cystic fibrosis-related bone disease (CFBD). Flow cytometry of circulating polymorphonuclear leukocytes (PMN) reveals an elevated number of activated PMNs (reduced L-selectin) from CF patients with low bone mineral density (T-score < -2.0), accompanied by an increased RANKL/OPG ratio, thus suggesting a role for the myeloid lineage in driving CFBD. To better understand the role of the cystic fibrosis transmembrane conductance regulator (CFTR) in bone homeostasis, we assessed female Cftr+/- and Cftr-/- mice possessing an intestinal epithelial human CFTR transgene to mitigate the contribution of nutritional malabsorption to skeletal homeostasis. Immunohistochemistry and immunofluorescence demonstrate increased myeloid (neutrophil elastase) and osteoclastic (RANKL) markers in the tibial bone marrow of Cftr-/- mice vs. Cftr+/- controls. MicroCT analysis of bone indicates a geometrically disadvantaged cortical phenotype in the tibias of Cftr-/- mice when compared to Cftr+/- sibling controls (Ps.Pm: 3.56±0.16 vs. 3.91±0.24 mm, p<0.05; Tt.Ar: 0.79±0.08 vs.

0.87±0.03 mm2, p=0.06). Volumetric bone mineral density was unaltered. Primary calvarial osteoblast cultures from Cftr-/- mice, maintained under mineralization conditions, exhibit reductions in tissue-nonspecific alkaline phosphatase mRNA accumulation (80.6±4.3% decrease, p<0.01) and enzyme activity (54.5±0.01% decrease, p=0.06) vs. Cftr+/- controls as noted by others, along with other markers of osteogenic differentiation and significantly reduced Vegf expression. Intriguingly, Cftr-/- calvarial osteoblast cultures exhibit increased OsteoMac accumulation compared to Cftr+/- controls, first revealed by RT-qPCR analyses (% increases, F4/80: 3453±78%, p<0.00001; Cd11c: 2763±97%, p<0.001; Csf1r: 1225±369%, p<0.01). This was confirmed by increased numbers of F4/80 – positive cells in the tibial bone marrow of Cftr-/- vs. Cftr+/- mice, and in primary calvarial cell cultures (Cftr-/- vs. Cftr+/-; 17.7±1.7% vs. 4.7±0.3% of cells; p<0.01). These data point to a novel and primary role of marrow-derived neutrophils and OsteoMacs in the pathogenesis of CFBD, beyond the cell-autonomous synthetic deficiencies in the osteoblast lineage.

SUN-0178

Human obesity is associated with enhanced insulin signaling and accelerated differentiation of bone marrow stromal stem cell leading to premature skeletal aging Michaela Tencerova*[1,2], Morten Frost[1], Florence Figeac[1], Anders Kristian Haakonsson[1], Jens-Jacob Lauterlein[1], Tina Kamilla Nielsen[1], Dalia Ayesh Hafez Ali[1], Kurt Højlund[1,2], Moustapha Kassem[1,2]. [1]Department of Molecular Endocrinology, KMEB, University of Southern Denmark and Odense University Hospital, DK-5000 Odense C, Denmark, [2]Danish Diabetes Academy supported by the Novo Nordisk Foundation, Denmark

The effects of obesity and type 2 diabetes (T2D) on bone are paradoxical as these patients usually exhibit higher bone mineral density but increased risk of bone fragility fractures. Since obesity increases with aging, we hypothesized that bone fragility is caused by a premature aging phenotype of bone marrow (BM) microenvironment. Thus, we investigated in a case-control study of 54 men subdivided into lean (n=19), overweight (n=15) and obese (n=20) groups based on their body mass index, the metabolic and senescence phenotype of BM stromal (skeletal) stem cells (BM-MSC). We found accelerated differentiation of primary BM-MSC obtained from obese participants. This was supported by global RNA sequencing analyses demonstrating a shift of molecular phenotype of BM-MSC towards committed adipocytic and osteoblastic progenitors. Genes differently expressed encompassed many metabolic genes, particularly of the glycolytic pathway, and genes encoding enzymes with oxidoreductase activity. Interestingly, in paired samples of BM-MSC and peripheral adipose tissue (AT-MSC) insulin signaling measured by insulin-stimulated pAKT/totalAKT was impaired in AT-MSC but up-regulated in BM-MSC of obese individuals. In addition, analysis of cellular composition of BM-MSC of obese participants revealed a unique pattern of increased number of insulin receptor (IR+) and leptin receptor (LepR+) positive cells that exhibited ex vivo enhanced adipogenic differentiation and hyper-activated metabolic phenotype. Our data provide a potential molecular explanation to the "bone fragility paradox" of obese patients as it shows enhanced insulin signaling in BM microenvironment leading to a premature aging phenotype of BM-MSC, and to creation of senescent microenvironment conducive to bone fragility. Also this clinical study highlights the differences between the metabolic responses of bone and peripheral AT, which is an important factor to be considered in designing tailored treatment of obesity-associated metabolic bone disease.

Gene Expression Profiles Associated with Angiogenesis in Human Site-Specific Bone Marrow Stromal Cells (hBMSCs) Yifei Du *[1], Weina Zhou[2,3], Hongbin Jiang[1], Qisheng Tu[2], Jinkun Chen[2,4]. [1]Jiangsu Key Laboratory of Oral Diseases, Nanjing Medical University, Department of Oral and Maxillofacial Surgery, Affiliated Hospital of Stomatology, Nanjing Medical University, Nanjing,China, China, [2]Division of Oral Biology, Tufts University School of Dental Medicine, Boston, Massachusetts, United States, [3]Jiangsu Key Laboratory of Oral Disease, Nanjing Medical University, Nanjing, China, [4]Department of Developmental, Molecular and Chemical Biology Sackler School of Graduate Biomedical Sciences Tufts University School of Medicine, United States

Objectives: Bone marrow stromal cells (BMSCs) from iliac crest and craniofacial regions are candidate seeding cells with site-specific characteristics and bone regenerative properties. Previous studies suggested that craniofacial BMSCs might possess stronger potentials and osteogenic capabilities than that isolated from iliac crest. BMSCs have the ability to regulate new blood vessel formation, maintain its stability and functions via secreting angiogenic growth factors and cytokines in a paracrine fashion. This study was to characterize the changes of gene expression profiles associated with angiogenesis in these two kinds of human BMSCs (hBMSCs).Materials and Methods: Bone samples were obtained from the same individuals undergoing alveolar bone grafting using iliac bone. The samples were cultured and hBMSCs of iliac crest (I-hBMSCs) and maxillae (M-hBMSCs) were isolated, respectively. Total mRNA of the paired I-Hbmsc and M-hBMSCs was extracted, and reversely transcribed into cDNA. The expression profiles of angiogenesis marker genes were determined by a gene expression profile chip.Results: Among all the differential-

ly expressed genes, 49 genes were found to be related to angiogenesis. In I-hBMSCs, a total of 13 angiogenesis-related genes was significantly down-regulated comparing with that in M-hBMSCs. The most pronouncedly decreased genes were gremlin 1 (GREM1), angiopoietin 2 (ANGPT2) and prostaglandin I2 synthase (PTGIS), with a more than 50% reduction of expression (Figure 1 B). Besides, the expression of 36 angiogenesis-related genes was significantly higher in I-hBMSC than that in M-hBMSCs. The most up-regulated genes were tumor necrosis factor alpha-induced protein 2 (TNFAIP2), complement component 3 (C3) and thrombospondin 3 (THBS3). All these three genes were increasingly expressed two times than that in M-hBMSCs (Figure 1 C).Conclusions: The site-specific hBMSCs exhibit distinct expression profiles of angiogenesis-related genes, which could attribute to the angiogenic variations between I-hBMSC and M-hBMSCs. Among these differentially expressed genes, GREM1, ANGPT2, PTGIS, TNFAIP2, C3 and THBS3 are the most profound and significant. Their roles in the angiogenic variations between I-hBMSC and M-hBMSCs need to be further clarified. The gene chip technique was useful to detect the multi-gene different expression profile and features.

Osteal Macrophage Regulation of the Plasminogen System in Bone Laura Zweifler*, Amy Koh, Benjamin Sinder, Megan Michalski, Hernan Roca, Yuji Mishina, Laurie Mccauley. University of Michigan, United States

Macrophage phagocytosis of dead or dying cells is termed efferocytosis. This process plays an important role in development, homeostasis, and repair of the skeletal system. Apoptotic cell clearance occurs rapidly and at a high rate in the bone given the large turnover of marrow cells; however, it is unclear how macrophages respond specifically to apoptotic osteoblasts. The goal of this project is to address this question by studying the unique macrophage gene expression profile during uptake of apoptotic bone cells. Macrophages (Macs) were derived from 6-8 week-old primary murine bone marrow stimulated with macrophage-colony stimulating factor (M-CSF) for 1 week. Macs were then co-cultured with apoptotic bone marrow stromal cells (apBMSCs) to model a skeletal pre-osteoblastic cell and simulate efferocytosis in bone. We also used apoptotic thymocytes (apThym) as a control to simulate efferocytosis of non-skeletal cells. To understand mechanisms of skeletal tissue-specific efferocytosis, RNA was isolated and gene expression analyzed with an Affymetrix Mouse Gene 2.1 ST Array. Efferocytic co-cultures with non-skeletal apThym resulted in 101 differentially regulated genes compared to Macs alone. However, efferocytosis co-cultures with skeletal apBMSC's revealed 1219 significantly up- or down- regulated genes, suggesting efferocytosis of skeletal cells may be particularly impactful. Plasminogen activator inhibitor 2 (PAI2) was 9.69 fold higher in Macs+apBMSCs co-cultures compared to Macs alone, and was not increased in Macs+apThym co-cultures. This finding was confirmed with quantitative reverse-transcribed polymerase chain reaction (qRT-PCR). Additionally, PAI2 was not upregulated when Macs were co-cultured with apBMSCs at 4°C, which is a condition known to inhibit efferocytosis. Western blot analysis has shown that Macs+apBMSCs secreted significantly higher PAI2 compared to macrophages alone. PAI2 is a serine protease inhibitor that can bind to plasminogen activators, reducing plasmin concentrations. In bone, plasmin has been implicated in mechanisms to degrade the osteoid layer covering the bone surface, providing osteoclasts with access to bone for resorption. Given the roles for the fibrinolytic system in the bone microenvironment, PAI2 upregulation suggests that osteal macrophages are mediating a decrease in bone resorption. These data support a critical role for efferocytosis in bone cell signaling and regulation.

The Extracellular Matrix Protein Spondin-2 Induces Osteomimicry in Prostate Tumor Cells via Primary Cilia Activation Juan Ardura*, Bethan Kitchen, Irene Gutierrez-Rojas, Luis Álvarez-Carrión, Arancha R Gortazar, Veronica Alonso. Bone Physiopathology Laboratory, Departamento de Ciencias Médicas Básicas, Universidad San Pablo CEU. CEU Universities, Madrid (Spain), Spain

Prostate cancer cells preferentially metastasize to bone in part by acquiring a bone phenotype based on ectopic expression of bone-related genes. This process, known as osteomimicry, allows cancer cells to colonize and proliferate in the bone microenvironment. Primary cilia loss is associated to prostate tumor progression causing over activation of the bone modulating protein ß-catenin. The extracellular matrix protein spondin-2 is a member of a ß-catenin-activating family that has recently been described as an inductor of osteomimicry and is overexpresed in prostate tumors that metastasize to bone.We hypothesize that spondin-2 induces osteomimicry in prostate tumor cells via a primary cilia-depending pathway.A C57BL/6 mouse model of prostate cancer induction by orthotopic injection of adenocarcinoma TRAMP-C1 cells was used. TRAMP-C1 cells in the in vivo model and for in vitro experiments were silenced or not with 3 specific siRNAs targeted to spondin-2. We evaluated the presence of primary cilia and the expression of the primary cilia marker IFT88 and ectopic bone-related markers in the prostates of the mouse model and in TRAMP-C1 cells. TRAMP-C1 cell adhesion to collagen-coated surfaces was also assessed.TRAMP-C1-induced tumors showed overexpression of spondin-2, decreased number of primary cilia and downregulation of IFT88 gene expression in association to osteomimicry changes in the prostate tissue, namely overexpression of RANKL, OPG, Runx2 and osterix. In vitro, stimulation with spondin-2 decreased the percentage of primary cilia-presenting cells. Moreover, IFT88 silencing further promoted spondin-2-induced changes on the aforementioned bone-related genes in TRAMP-C1 cells. Both spondin-2 stimulation and IFT88 silencing enhanced TRAMP-C1 cell adhesion to collagen-coated plates.We propose that spondin-2 induces prostate tumor cell osteomimicry and adhesion by decreasing primary cilia expression.

LIGHT/TNFSF14 and RANKL: biomarkers and therapeutic targets of bone disease in multiple myeloma patients experiencing therapeutic regimens Giacomina Brunetti*[1], Rita Rizzi[2], Giuseppina Storlino[3], Sara Bortolotti[3], Graziana Colaianni[3], Lorenzo Sanesi[3], Luciana Lippo[3], Maria Grano[3], Silvia Colucci[1]. [1]Department of Basic and Medical Sciences, Neurosciences and Sense Organs, Section of Human Anatomy and Histology, University of Bari, Bari, Italy, [2]Department of Emergency and Organ Transplantation, Section of Hematology with Transplantation, University of Bari, Bari, Italy, [3]Department of Emergency and Organ Transplantation, Section of Human Anatomy and Histology, University of Bari, Bari, Italy

The two members of TNF superfamily, LIGHT and RANKL, are involved in physiological and pathological bone remodeling and implicated in newly diagnosed Multiple Myeloma (MM)-bone disease. Bone disease occurs in about 80% of MM patients at diagnosis, and up to 90% at relapse. Despite improvements in the depth and the duration of response, most patients eventually relapse, with the duration of response decreasing with each line of therapy. Patients with relapsed, or refractory, or progressive MM and active bone disease represent a therapeutic challenge to identify both new pharmacological approaches and biomarkers. Herein, we investigated whether LIGHT and RANKL have also a role in Multiple Myeloma (MM)-bone disease patients experiencing therapeutic regimens. We found that LIGHT is over-expressed by CD14+ monocytes of peripheral blood from MM-bone disease patient responders, at relapses, and in progressive disease similarly to newly diagnosed MM-bone disease (NDMM) patients. Moreover, T-cells isolated from the same patients also over-express the pro-osteoclastogenic cytokine RANKL. Consistently with all these findings, we also demonstrated that spontaneous osteoclastogenesis only occurs in cultures derived from PBMCs of MM-bone disease patient responders, at relapses, and in progressive disease as demonstrated in NDMM patients. Finally, we proved that increasing doses of RANK-Fc or anti-LIGHT neutralizing antibody induce a dose-dependent reduction of spontaneous osteoclastogenesis of MM-bone disease patients' responders, relapses and in progressive disease, supporting the involvement of RANKL and LIGHT in the spontaneous osteoclast formation. These ex-vivo and in vitro findings are supported by the high serum levels of TRAP5b and CTX, two markers of osteoclast activity, in MM-bone disease patients' responders, relapses and in progressive disease. In conclusion, our study points out the key role of LIGHT in osteoclast and immune cell crosstalk in the pathophysiology of MM-bone disease, suggesting that LIGHT could be a new therapeutic target in the active bone disease of MM.

HDAC Inhibitors Synergize with Standard-of-Care MAP Chemotherapeutics to Block Growth of Osteosarcoma Sarcospheres Leah Everitt*, Christopher Collier, Gabrielle Knafler, Deep Gandhi, James Buschbach, Patrick Getty, Edward Greenfield. Case Western Reserve University Department of Orthopaedics, United States

Standard-of-care for osteosarcoma patients has remained largely unchanged in the last thirty years due to scarcity of clinical trials and prohibitive costs of traditional drug discovery. Our goal is to repurpose drugs to block the growth of osteosarcoma lung metastases, the lethal disease process. We therefore screened the NCI-panel of 114 FDA-approved oncology drugs to identify agents that potently reduce growth of osteosarcoma spheroids (sarcospheres). We first developed a system to routinely generate large numbers of highly-uniform spherical sarcospheres with a 400um diameter (1/well), by a centrifugation-based method, using highly metastatic human cell lines (143B, MG63.3, and LM7). Sarcospheres most closely simulate micrometases of the lungs in vivo. Our primary drug screen (Z'-factor=0.70+0.10) measured effects of FDA approved oncology drugs on reazaurin reduction by sarcospheres in the presence and absence of MAP chemotherapy (methotrexate, doxorubicin, and cisplatin). Dose-response experiments with 13 of the most effective drugs confirmed initial results and allowed comparison with each drug's toxicity on normal human osteoblasts and normal small airway epithelial cells. Romidepsin, a HDACi (histone deacetylase inhibitor), had the most favorable toxicity/efficacy ratios (TD50/IC50=57-580, depending on cell line). The only other HDACi in the panel of FDA-approved drugs (vorinostat) also ranked highly in the primary screen. Since newer HDACi's may have improved toxicity/efficacy ratios, we compared romidepsin and vorinostat with the three other HDACi's that are FDA-approved (belinostat, panobinostat, and valproic acid) plus one that is in clinical trials (entinostat). Romidepsin (Cmax/IC50=36-360) and belinostat (Cmax/IC50=14-20) reduced sarcosphere growth at clinically-achievable levels, in the presence or absence of MAP. Importantly, both romidepsin and belinostat were synergistic with MAP (BLISS scores=5-15). Propidium iodide staining showed that romidepsin substantially induced cell death throughout the sarcospheres. Our results strongly support future studies to determine effects of romidepsin and belinostat on growth of lung metastases in vivo.
143B sarcospheres were treated with DMSO control or romidepsin for 48 hours then stained with propidium iodide for 2 hours to show dead cells. Images obtained using Lecia DMI6000, top images are brightfield and lower images obtained with a TRITC/RFP filter set (535/617 nm). Each set of images is 1 representative sarcosphere of 3 replicates.

SUN-0203

Estrogen receptor alpha is a novel tumor suppressor in osteosarcoma Susan Krum*, Gustavo Miranda-Carboni, Maria Angeles Lillo Osuna. UTHSC, United States

Osteosarcoma is a malignant tumor in the bone that originates from normal osteoblasts or osteoblast precursors. Normal osteoblasts express estrogen receptor alpha (ERα); however, osteosarcomas do not due to promoter DNA methylation. Treatment of 143B osteosarcoma cells with Decitabine (DAC, 5-Aza-2'-deoxycytidine) induced expression of ERα, leading to a decrease in proliferation and a concurrent induction of osteoblast differentiation, as marked by alkaline phosphatase expression and activity and expression of bone sialoprotein (BSP). 17β-estradiol (E2) further decreases the DAC-induced reduction in proliferation. Over-expression of ERα also inhibits proliferation and induces osteoblast differentiation and silencing of ERα prevents the effects of DAC, demonstrating that ERα is both necessary and sufficient for DAC-mediated suppression of osteosarcoma. In an orthotopic model of osteosarcoma in vivo, 143B cells were injected into the tibia of NSG mice and DAC inhibited tumor growth and metastasis. Together, these experiments suggest that the FDA-approved DNA methylation inhibitor DAC can be used to treat osteosarcoma patients to decrease proliferation and induce osteoblast differentiation.

Parathyroid hormone-related protein (PTHrP) regulates CSC/EMT in a human breast cancer model and administration of anti-PTHrP therapeutic monoclonal antibodies reduces tumor burden in bone Jiarong Li*, Louis Dore Savard , Guoming Xiong, Richard Kremer. RI MUHC, Canada

Parathyroid hormone-related protein (PTHrP) is dysregulated in advanced cancers where it causes malignancy-associated hypercalcemia and plays a major role in the progression of bone metastases. We have shown previously that PTHrP ablation delays tumor initiation and that it is preferentially expressed in triple negative breast cancer (TNBC).Here we investigated whether PTHrP can influence the phenotype of the human TNBC cell line MDA-MB231 in vitro and can be targeted in vivo with anti-PTHrP monoclonal antibodies (mAbs). First we used CRISPR/Cas9 TO construct a U6G RNA-Cas9-2A-red fluorescence protein (RFP) vector with a human PTHrP specific guide RNA directed to exon 4(knockout/ KO) or an empty vector as control. Single clones of PTHrP KO cells (RFP+) were isolated and several clonal cell lines with over 95% PTHrP ablation were used in the studies. In vitro cancer stem cell (CSC) characterization showed a 60% reduction in mammosphere formation and a significant reduction in CSC markers(ALDH1, CXCR4 and CD44high/ CD24low) in KO cells. Furthermore, cell morphology and cell surface markers of epithelial mesenchymal transition(EMT)including E-cadherin, CK8, CK18, N-cadherin, CK14 and vimentin showed a shift from a mesenchymal phenotype towards an epithelial phenotype in KO cells. Next, we examined the potential of therapeutic mAbs against PTHrP in an intra-tibial model of skeletal metastasis in female nude mice(n=10/group) transplanted with 1x105 MD-AMB-231 cells. Two hundred micrograms of mAbs were administered 3 times/ week intra-peritoneally two weeks post tumor transplantation and treated for three weeks. Bone imaging performed by PET scan and MRI showed a 40% reduction in tumor burden (P=0.012) in mAbs treated animals compared to controls. Overall our data show that PTHrP regulates TNBC towards a more aggressive phenotype and demonstrate the therapeutic efficacy of anti-PTHrP mAbs in vivo.

Runx2 promotes autophagy through enhancing cytoskeletal stability in bone metastatic breast cancer cells. Ahmad Othman*[1], Manish Tandon[2], Jitesh Pratap[1]. [1]Rush University Medical Center, United States, [2]KBI Biopharma, United States

Bone metastasis of breast cancer causes significant patient mortality. Recent studies suggest that metastatic cancer cells induce autophagy to survive metabolic and hypoxic stress. During autophagy, cytoplasmic components and damaged organelles are captured by autophagosomes followed by lysosomal fusion and degradation, releasing metabolites as energy sources to meet metabolic demands. Although the components of autophagy have been well characterized, the regulatory mechanism of autophagy in metastatic cancer cells in the bone microenvironment is still unknown. To examine autophagy during bone metastasis, we used a bone metastatic isogenic variant of breast cancer MDA-MB-231 cells isolated from a xenograft tumor mouse model of metastasis. Previously, we and others have shown that Runt-related transcription factor-2 (Runx2) promotes cell survival, cell migration and invasion, and tumor growth associated osteolysis. Therefore, we examined whether Runx2 regulates autophagy for increased cell survival in the bone microenvironment. Our results show that Runx2 enhances autophagy in metastatic breast cancer cells. Silencing of Runx2 causes accumulation of autophagic vesicles due to reduced turnover of autophagosomes. Live cell confocal microscopy and biochemical studies show that Runx2 enhances trafficking of autophagic vesicles and increases acetylation of α-tubulin (Ac-αTub) subunit of microtubules. Similar to cancer-related functions of Runx2, elevated levels of Ac-αTub have been linked with an invasive, migratory and metastatic phenotype in cancer cells. Ac-αTub is a marker of the stable fraction of the tubulin cytoskeleton which is utilized for vesicle trafficking. Our studies in Runx2 knockdown cells and treatments with microtubule depolymerizing agents such as Nocodazole and vinblastine showed that depolymerization of stable microtubule fraction decreases autophagic flux and that Runx2 is required for stable fraction of microtubules. These results suggest that Runx2 enhances autophagy through maintaining cytoskeletal stability which is critical for autophagosome trafficking. Furthermore, immunohistochemical analysis of an autophagy marker LC3B protein in clinical breast cancer specimens showed significant association between high Runx2 and low LC3B protein levels. Taken together, our studies reveal a novel function of Runx2 in cytostructure and provide molecular insights into the role of autophagy in bone metastatic cancer cells.

SUN-0206

The JNKs/XBP1s Signaling Cascade Regulates Bone Microenvironmental Support to the Progression of Myeloma Bone Disease Risheng Chen*[1], Guoshuang Xu[1], Wissam Beaino[1], Kai Liu[1], Xuemei Zeng[1], Nathan Yates[1], Rong Chong[1], Konstas Verdelis[1], G Roodman[2], Denise Toscani[3], Nicola Giuliani[3], Yan Lin[1], Carolyn Anderson[1], Hongjiao Ouyang[4]. [1]University of Pittsburgh, United States, [2]Indiana University School of Medicine, United States, [3]University of Parma, Italy, [4]Texas A&M University, United States

Spliced X-box binding protein-1 (XBP1s) is an endoplasmic reticulum (ER) stress signaling molecule and implicated in pathogenesis and drug resistance of cancer, e.g. multiple myeloma and breast cancer. However, every little is known as to its roles in regulating the tumor bone microenvironment properties in tumor bone diseases. In addition, while its mRNA splicing has been widely studied, it remains largely elusive as to how its post-translational modification occurs and whether and/or how XBP1s' post-translational modification impacts its pathophysiological functions. We previously reported that human XBP1s (hXBP1s) in bone marrow stromal cells is required for the bone marrow stromal support of the growth multiple myeloma bone disease (MMBD), the most prevalent and severe tumor-induced bone disease. Here we report that human XBP1s (hXBP1s) is a physiological and direct phosphorylation substrate of JNKs. This phosphorylation promotes hXBP1s protein degradation via enhancing its physical interaction with the E3 ubiquitin ligase, β-TrCP, resulting in the enhanced ubiquitination and 26s proteasome-mediated degradation of hXBP1s. Mutation of the JNK phosphorylation site of hXBP1s to alanine largely prevents JNK phosphorylation of hXBP1s and JNK-induced protein degradation of hXBP1s. Further, we found that bone marrow stromal cells (BMSCs) harboring the hXBP1s mutant resistant to JNK phosphorylation provided significantly greater support of MM growth and MM-induced osteoclastogenesis and bone destruction both in vitro and in vivo, compared with the counterparts expressing wild type (WT) hXBP1s. Finally, we, utilizing a custom-made antibody that specifically recognizes JNKs' phosphorylation of hXBP1s, observed that JNK-mediated phosphorylation of hXBP1s is associated with favorable therapeutic outcome of MM patients in response to a combination treatment of bortezomib, dexamethasone, thalidomide (and/or their derivatives), three MM drugs known to stimulate the JNKs activities. These results suggest p-hXBP1sJNK as a potential predictive biomarker for MM patients' response to the drug treatment. Taken together, our study provides the first evidence that hXBP1s is a novel physiological and direct target of JNK phosphorylation and demonstrates that the JNKs/XBP1s signaling cascade plays an essential role in mediating MM drug therapeutic effects on repressing bone microenvironment support of MM growth and MM-induced bone destruction.

Effect of Extracellular Vesicles Derived from Osteotropic Tumors on Bone Resident Cells Riccardo Paone*[1], Alexander Loftus[1], Christopher George[1], Kirsty Shefferd[1], Argia Ucci[1], Simona Delle Monache[1], Alfredo Cappariello[1,2], Maurizio Muraca[3], Anna Maria Teti[1], Nadia Rucci[1]. [1]Department of Biotechnological and Applied Clinical Sciences, University of L'Aquila, Italy, [2]Bambino Gesù Children Hospital, Rome, Italy, [3]Department of Women's and Children's Health, University of Padua, Italy

Extracellular vesicles (EVs) are membrane-bound cargos of biologically active molecules shed by cells, which are emerging as mediators of a range of pathological processes, including cancer. Their role in both primary and metastatic cancers of the bone has been poorly explored. We investigated EV-mediated effect of osteosarcoma cells (MNNG-HOS) or osteotropic breast cancer cells (MDA-MB-231) on bone resident cells, including osteoblasts, osteoclasts and endothelial cells. In mouse primary osteoblasts, HOS- and MDA-EVs inhibited the mRNA expression of Cyclin D1 (-75%, p=0.02) and of the osteoblast-related genes Alp (-35%, p=0.002) and Osx (-40%, p=0.06), whereas they enhanced the expression of Nos2 (15-fold, p=0.015), Lcn2 (4-fold, p=0.01) and Serpin b2(22-fold, p=0.049). An increase of IL-1β (12-fold, p<0.001), IL-6 (10-fold, p=0.05) and Rankl (1.5-fold, p=0.02) was also observed in tumour cell-EVs-treated osteoblasts, which was confirmed at protein level. ELISA and cytokine array assays on conditioned media (CM) from osteoblasts treated with HOS-EVs showed an increase of Pentraxin-3 (2-fold, p=0.045), a positive modulator of tumour-associated inflammation. Moreover, the chemokines CCL-2 and -5, CXCL-1 and -2 and LIX, which were undetectable in untreated osteoblasts, were expressed by HOS EV-treated osteoblasts. Similarly, MDA-EVs-treated osteoblasts presented with an increase of CCL-3, CXCL-2 and -11, and of the cytokines IL-5, -12p40, -13, -15 and -17. HOS-EV transcriptional profile showed the expression of genes involved in bone metabolism, such as Cathepsin K, CLCN7, CD40 and VEGFA. In line with this molecular profile, HOS-EVs significantly increased in vitro osteoclastogenesis (7fold, p=0.012) performed in the presence of suboptimal concentrations of RANKL. Moreover, HOS-EVs significantly increased endothelial cell chemotaxis (p=0.02, AUC) and in vitro tube formation (3-fold, p=0.007), evaluated by scratch assay and number of branching formed in HUVEC cell cultures. Consistently, in vivo angiogenesis, evaluated by the matrigel plug assay, was significantly enhanced by HOS-EVs (3.5fold, p=0.001; n.mice/group=5). In conclusion, these data elucidated i) the transcriptional profile of osteosarcoma and breast cancer derived EVs and ii) their impact on bone cells and endothelial physiology.

RANKL Increases Resistance to TRAIL Induced Cell Death in Oral Squamous Cell Carcinoma Tumor Cells Purushoth Ethiraj*, Yuvaraj Sambandam, Jessica Hathaway-Schrader, Azizul Haque, Chad Novince, Sakamuri Reddy. Medical University of South Carolina, United States

Oral squamous cell carcinoma (OSCC) is the most common malignancy among oral cancers. OSCC has potent osteolytic activity, resulting in local bone invasion. Tumor necrosis factor (TNF) family member, RANK ligand (RANKL) is a critical osteoclastogenic factor that resorb bone. We have recently shown that OSCC tumor cells express RANKL and the RANK receptor. We have also identified that RANKL expression is autoregulated in OSCC tumor cells. Furthermore, RANKL significantly increases OSCC tumor cell proliferation. TNF-related apoptosis inducing ligand (TRAIL) has been shown to induce apoptosis in a variety of tumor cells. However, OSCC cells are relatively resistant to TRAIL-induced apoptosis. Therefore, we hypothesized that RANKL increases resistance to TRAIL-induced cell death in OSCC tumor cells. TRAIL interacts with receptors DR4, DR5, DcR1 and DcR2. Real-time RT-PCR analysis showed high-level of DR4, DR5 and relatively low levels of DcR1 and DcR2 mRNA expression in OSCC cells. Further, SCC1 and SCC74A tumor cells stimulated with TRAIL (100 ng/ml) for 24 h showed increased levels of RANKL expression. In addition, we analyzed apoptosis in OSCC cells by labeling DNA strand breaks (TUNEL assay) by fluorescence microscopy. Interestingly, RANKL stimulation of SCC1 tumor cells treated with TRAIL showed increased resistance to TRAIL induced cell death. We further confirmed these results by analyzing apoptotic marker protein expression in OSCC tumor cells. These data suggest that blockade of RANKL expression in OSCC tumor cells may enhance the therapeutic potential of TRAIL to control OSCC tumor growth/progression.

CD44 Intracellular Domain interaction with RUNX2 regulates metastasis of prostate cancer cells to the bone. Linda T. Senbanjo*, Meenakshi A. Chellaiah. University of Maryland Dental School, United States

Prostate cancer (PCa) is the second leading cause of death in males in the western world. It is characterized by extensive metastasis leading to secondary lesions in the bone, lymph node, and brain. Bone is the most common site for PCa metastasis and it targets bone with osteoclastic and/or osteoblastic lesions due to the activity of osteoclasts (OC) or osteoblasts (OB), respectively. The goal of this study was to investigate the role of two key proteins involved in bone metastasis, CD44, a receptor that has been shown to increase the metastatic potential of cancer cells and RUNX2, a transcription factor required for bone formation in osteoblasts. CD44 and RUNX2 have roles in the expression of RANKL, a key protein involved in osteoclast (OC) differentiation and activation. In this study, we used prostate cancer cell lines derived from bone (PC3 and PCa2b) and lymph node (LNCaP) metastases along with control cell lines (HPR1 and BPH). We used semi-quantitative PCR, immunoblotting, and immunostaining analyses in our study. Our findings revealed the following: 1) CD44 is variably expressed in different PCa cell lines. A significant increase in the expression of CD44 was observed in PC3 cells derived from bone metastasis of a Caucasian patient. Neither PCa2b (derived from an African American patient) nor LNCaP demonstrated the expression of CD44. 2) CD44 is cleaved by y-secretase to generate CD44-Intracellular Domain (ICD).Co-localization of CD44-ICD with RUNX2 was observed in the nucleus of PC3 cells. 3) Expression of serial deletion constructs of CD44-ICD in PC3 cells demonstrated more interaction of CD44-ICD fragment with RUNX2 between amino acid sequences 671 and 706. 4) Knockdown (KD) of CD44 in PC3 cells decreased RUNX2 expression and RANKL expression. Hence conditioned medium from these cells failed to support osteoclast differentiation in vitro. Our results indicate that CD44 can be one of the key biological factors which contribute to prostate cancer health disparity. Future investigation of the differences in the expression of CD44 in PC3 and PCa2b will ultimately pave way for future studies to understand the role of this protein and its downstream targets in bone metastasis and metastasis-related events (osteolytic vs. osteoblastic).

Paracrine Actions of FGF23 on Bone-Metastatic Prostate Cancer Attaya Suvannasankha*, Douglas Tompkins, Colin Crean, John Chirgwin. Indiana University School of Medicine, United States

Osteocytes are the major source of circulating endocrine FGF23. Feng et al (Oncotarget, 2015) reported that FGF23 is also made by prostate cancers (PCs), functioning as an autocrine growth factor. We previously reported that intact FGF23 was not elevated in the serum of PC patients, a result confirmed by Vlot et al (Clin Chim Acta, 2018). These results do not address whether osteocyte FGF23 contributes to PC growth in bone. We found that PC cell lines secreted physiologically insignificant amounts of FGF23, while responding to exogenous factor by increasing EGR1 transcription factor and its target gene heparanase, which contributes to tumor colonization of bone. Responses to FGF23 were blocked with FGFR kinase inhibitor BGJ398, which has IC50s of ~1nM for FGFRs 1, 2 and 3.PC-3 and LNCaP PC cell lines were assayed for secretion of intact FGF23 (Kainos ELISA) in 48hr conditioned media of confluent cells. LNCaPs made 1.5 pg/ml, less than the level in normal

serum, and PC-3s were below the limit of detection. Cleaved C-terminal FGF23 was undetectable. Treatment of LNCaP and PC3 with 100ng/ml FGF23 significantly increased mRNA for EGR1 at 1hr, followed by heparanase mRNA at 8 & 24hrs - responses that were blocked by BGJ398. When 14d mouse calvariae were incubated with BGJ398, markers of osteoblasts (alkaline phosphatase & type 1 collagen) and osteocytes (PHEX, MEPE, & FGF23) were increased 2-5 fold & 3-8 fold, respectively; the osteoclast marker TRAP was increased less than 2-fold, while RANKL mRNA was unchanged. Changes were consistent with anabolic responses in mice treated with BGJ398 (Wöhrle et al, JBMR, 2013). When human PC cells were grown on mouse calvariae in ex vivo organ co-culture assays (EVOCA), 25nM BGJ398 effectively blocked growth of both LNCaP & PC-3 cell lines, while 100X higher concentrations of BGJ398 only marginally decreased growth of the cells in vitro.The results suggest that osteocyte-derived FGF23 contributes to PC growth in bone, independent of the intracrine growth role of the PC-expressed factor found by Feng et al. Blockade of FGFR signaling could effectively suppress growth of metastatic PC in bone, but not primary prostate cancer. Agents with bone-anabolic effects, such as BGJ398, which is in Phase II clinical trials for cancers with activated FGFR signaling, could be effective in prostate cancer patients with osteosclerotic bone metastases.

Targeting the Wnt/beta-catenin pathway in human osteosarcoma cells Jianning Tao*[1,2], Fang Fang[1], Ashley Vancleave[1], Ralph Helmuth[1], Jing Zhao[1], Kirby Rickel[1], Erliang Zeng[2]. [1]Sanford Research, United States, [2]University of South Dakota, United States

Osteosarcoma (OS) is the most common primary malignancy of bone in adolescents and young adults. The five-year survival rate for localized osteosarcoma is about 70% while patients with metastatic or recurrent disease suffer poorly with the rate approximately 30%. However, the outcome for either group of patients with OS has not changed in more than four decades. This highlights the need for the second-line treatment options for patients. Aberrant activation of Wnt signaling has been implicated in human OS, which provides a genetic vulnerability in OS treatment. Using deposited data from Next Generation Sequencing (NGS) studies, we analyzed somatic mutations and gene expression of components of Wnt/ β-catenin pathway. To prove a principle that Wnt activation is necessary for osteosarcoma growth, colony formation, invasion, and metastasis, we treated human OS cells with a small molecule inhibitor of Wnt/β-catenin, PRI-724 (an ICG-001 derivative), which suppresses Wnt/β-catenin-mediated transcription. We found that constitutive Wnt/β-catenin signal activation is common in human osteosarcoma while activating genetic mutations of Wnt pathway components in osteosarcoma are rare. We also found that increased protein levels of both active- β-catenin and CyclinD1 in five human OS cell lines. Treatment with PRI-724 was sufficient to inhibit 143B and SJSA1 cell proliferation. Suppressed Wnt signaling was confirmed by decreased protein levels of CyclinD1, the Wnt target. Moreover, we revealed significant inhibitory effects on cell migration, invasion and colony formation in those human OS cells. Taken together, our results illustrate the critical role of Wnt/β-catenin signaling in human osteosarcoma pathogenesis and growth, and Wnt inhibitors represent potential therapeutic agents for the treatment of human osteosarcoma.

Remineralization of Bone Lytic Lesions in high risk myeloma patients enrolled on total therapy five protocol (TT5); the Arkansas experience. Maurizio Zangari*[1], Shivang Desai[1], Meera Mohan[1], Frits Van Rhe[1], Sharmilan Thanendrarajan[1], Carolina Schinke[1], Faith Davies[1], Gareth Morgan[1], Larry Suva[2], Donghoon Yoon[1], Leo Rasche[1], Niels Weinhold[1], Shobhit Sharma[1], Manoj Kumar[1]. [1]University of Arkansas for Medical Sciences, United States, [2]College of Veterinary Medicine and Biomedical Sciences Texas A&M University, United States

We have previously reported treatment associated remineralization of lyticpelvic lesions in a subset of low risk multiple myeloma (MM) patients who experience median progression free survival of eight years. In this study, the effect of total therapy five protocol (TT5) on bone lytic lesions in patients with high risk disease and a median progression free survival of two years was assessed.The TT5 protocol enrolled high risk myeloma patients (GEP 70 Gene Expression Profile ≥0.66 or lactate dehydrogenase (LDH) ≥ 360) or other high risk clinical features. Treatment included induction, stem cell collection, and tandem autologous transplant followed by velcade revlimid / melphalan dexamethasone maintenance therapy for three years along with monthly bisphosphonate therapy. The single largest lytic lesion measuring more than 1 cm was identified on the baseline PET CT and serially followed. Remineralization of the lesion was defined as sclerotic changes within the identified lytic lesion from baseline, using the largest diameter on the axial plane. Percent healing was defined as 100 (initial lesion size – final lesion size)/ initial lesion size and categorized to 26-50%, 51-75%, 76-99% and 100% complete healing. Lesions with ≤ 25% remineralization were not considered in this analysis.Among the 95 patients enrolled, 66 presented with a lesion ≥1 cm and appropriate imaging (median follow-up 36 months; 58% male; median age 60 years, IgG disease 51%, IgA 24% light chain 23%). The average size of the lytic lesion was 3.21 cm (range of 1 to 9 cm). Pelvic bone lesions were observed in 50% of the patients.

One third of patient presented with more than 100 lytic lesions at the baseline PET–CT. Any grade of remineralization > than 25% from baseline was observed in 48 subjects (72.7%), sixteen patients (33%) achieved complete remineralization(100% healing), 25% of subjects achieved ? 75% healing and 41% of patient lesions achieved 25-50% reduction. In a cohort of patients with cervical vertebral lytic lesions, 33% (6/18) demonstrated complete remineralization during treatment. One important limitation is that the analysis focused only on the single largest lytic lesion in these patients. Ongoing efforts are examining treatment efficacy of the entire lytic compartment to ascertain if the repair process is affected by tumor heterogeneity.This retrospective analysis documents the first evidence of significant bone healing at lytic sites in high risk myeloma patients, with a significantly shorter survival compared to the overall myeloma population.

BMP2 signaling is required for postnatal maintenance of osteochondral tissues of the temporomandibular joint and knee Eliane Dutra*, Mara O'Brien, Po-Jung Chen, Sumit Yadav. University of Connecticut Health, United States

Introduction: Osteoarthritis (OA) of knee and temporomandibular joint (TMJ) is a growing epidemic that afflicts aging men and women not only in United States but across the globe. The osteochondral tissues of TMJ and knee have distinct developmental origins, and are made up of different types of cartilage, with matrices that differ in molecular composition, structure and mineral content. Bone Morphogenic Protein 2 (BMP2) plays an important role in cartilage growth and development. Chondrocyte differentiation and remodeling of the osteochondral tissue are the major functions regulated by BMP2. Objective: In this study, we sought to better identify the role of BMP2 in cartilage health, matrix synthesis and its ability to form calcified cartilage. Our aim was to compare and contrast the effects of BMP2 loss of function on the cartilage and subchondral bone of the TMJ and the knee. Methods: In vitro studies: The chondrocytes of TMJ from triple transgenic reporter mice (Col1a1XCol2a1XCol10a1) were treated with BMP2 and noggin for over a period of 2 weeks in a chondrogenic medium. In vivo studies: Three-week-old mice with floxed BMP2 and Cre-expression specific to the aggrecan (ACAN) promoter, and their Cre-negative littermates, were injected with tamoxifen (75 µg/kg body weight) for 5 days. The animals were euthanized after 1, 3 and 6 months following treatment with tamoxifen. Mice were injected with alizarin complexone and calcein before euthanization. EdU was injected at 2 days and 1 day before euthanization. Results: In vitro: In the TMJ cartilage cultures, BMP2 enhanced proliferation, differentiation and mineralization; whereas noggin decreased proliferation and differentiation of the chondrocytes. In vivo: Conditional deletion of BMP2 in the cartilage of TMJ from mice of all age groups examined led to a decrease in TRAP activity, decreased proliferation (EdU) and decreased differentiation. However, there was no appreciable difference in the proliferation and differentiation between the control and BMP2 deleted mice. We also observed an altered cellular morphology (loss of zonal architecture) and decrease in matrix synthesis with the conditional deletion of BMP2 in the cartilage of TMJ and knee. Conclusion: In summary, conditional deletion of BMP2 in ACAN-expressing cells can lead to cartilage breakdown and early development of osteoarthritis of the TMJ cartilage, whereas the effects observed in the articular cartilage of knee were not severe.

Novel TNFR2 Signaling in Osteoarthritis Wenyu Fu*, Young-Su Yi, Jyoti Joshi Mundra, Aubryanna Hettinghouse, Chuanju Liu. New York University Medical Center, United States

Purpose: TNFR1 primarily mediates inflammatory activity of TNFα and is responsible for cartilage degeneration and bone erosion in various diseases/conditions, particularly under inflammatory conditions. Growing evidences indicate that TNFR2 plays a protective and anti-inflammatory role in various disorders; however, the role of the TNFR2 pathway in the pathogenesis of osteoarthritis (OA) remains largely unknown. The current study aims to determine the role of anabolic TNFR2 pathway in cartilage homeostasis and OA.Materials & Methods: Both Rosa26-CreERT2 and Agc1CreERT2 strains were obtained from Jackson Laboratory. 14-3-3ε F/F mouse was obtained from Dr. Wynshaw-Boris at UCSF. Mass spectrometry and microarray analysis was employed to identify the binding partners and downstream mediators. CRISPR/Cas9 technology was used to knockout14-3-3ε in human chondrocytes. Signaling pathways, anabolic and catabolic reactions, as well as characterization and analysis of OA phenotypes were performed with either chondrocytes or OA animal models, accordingly.Results: Our previous genetic screen isolated TNFR2 as the PGRN-binding receptor (Tang, et al, Science, 2011). Remarkably, PGRN exhibits an approximately 600-fold higher binding affinity to TNFR2 than does TNFα. Additionally, PGRN-mediated protective effects against post traumatic osteoarthritis (PTOA) was also largely lost in TNFR2-/- mice (Zhao, et al, ARD, 2015), indicating that the PGRN/TNFR2 pathway plays a critical role in PGRN-stimulated chondro-protective effects. Interestingly, 14-3-3ε was identified as a novel component of TNFR2 receptor complex in response to PGRN stimulation in a proteomics screen (Fig1A-C). PGRN-activated signaling and anabolic activity was abolished in 14-3-3ε knockout human chondrocytes and PGRN-mediated protective effects was also largely lost in inducible 14-3-3ε knockout PTOA mouse model (Fig 1D-F). Further, Tgfbr1 and Tgfbr2 were isolated as the downstream mediators of PGRN

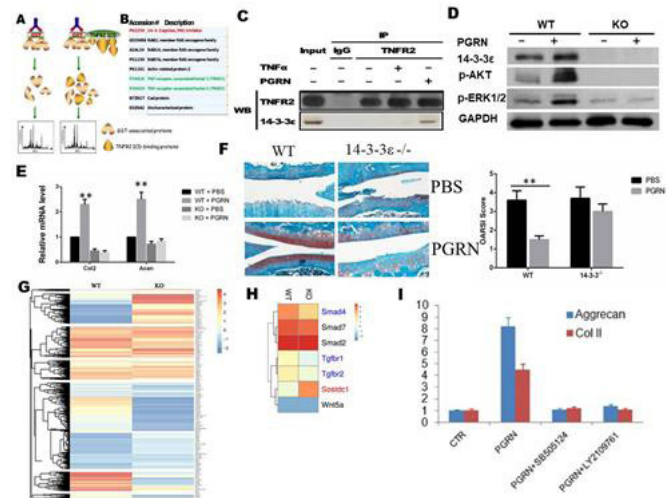
in a whole genome microarray (Fig1G,H), and blocking these receptors with their specific inhibitors also abolished PGRN's anabolic activity (Fig1I).Conclusions: Our results indicate that the PGRN/TNFR2/14-3-3ε/Erk-Akt/Tgfb axis plays a pivotal role in chondrocyte metabolism and OA. These findings not only advance our understanding of the TNFR2 pathway in cartilage homeostasis and degeneration, but may also lead to the development of novel interventions for OA.


Fig1. PGRN/TNFR2/14-3-3ε/Erk-Akt/Tgfb axis plays a pivotal role in chondrocytes and OA. (A) Scheme used to identify potential molecules binding to TNFR2 intracellular domains in response to PGRN stimulation. (B) Summary of the hits that were specifically recruited to TNFR2 complexes after treating chondrocytes with PGRN. (C) Co-IP assay showed 14-3-3ε binds to TNFR2 in chondrocytes. (D,E) WT or 14-3-3ε deficient human chondrocytes were treated with or without PGRN, western blot was used to determine the activation of signal molecules (D) and qPCR was performed to determine the mRNA level of Col2 and Acan (E). (F) Safranin O staining of knee joint obtained from ACLT WT or 14-3-3ε-/- mice treated with or without PGRN. n=8 (G) Genome microarray analysis of WT and PGRN KO mice. Differentially hierarchical clustering of the top 300 differentially expressed genes in KO as compared to WT. (H) DAVID gene oncology analyses identify the genes which are up-regulated (red) or down-regulated (blue) genes in KO mice. (I) PGRN-stimulated expressions of Collagen II and Acan in the absence or presence of specific inhibitor for Tgfbr1 (5µM, SB505124) or for Tgfbr2 (5µM, Ly2109761), assayed by real-time PCR.

Lin28a overexpression promotes chondrocyte reprogramming and protects from osteoarthritis in mice Yohan Jouan*[1,2], Joanna Sanna[1,2], Augustin Latourte[1,2,3], Pascal Richette[1,2,3], Hang-Korng Ea[1,2,3], Martine Cohen-Solal[1,2], Eric Hay[1,2,3]. [1]Paris Diderot University, Paris, France, [2]Inserm 1132, Paris, France, [3]Hopital Lariboisière, Paris, France

Purpose: Osteoarthritis (OA) affects all joint tissues including bone (osteophyte, subchondral bone sclerosis) in addition to cartilage degradation. In OA, activated chondrocytes have a reduced anabolism, whereas catabolism and apoptosis are increased. Cartilage matrix lesions are irreversible due to the poor regeneration abilities. Lin28a is a RNA binding protein involved in tissue repairing processes. Here we asked if Lin28a overexpression in cartilage could promote dedifferentiation of osteoarthritic chondrocytes and regenerate cartilage matrix. Methods: Ex vivo assays were performed using explant cultures of femoral head of 10 week-old transgenic CreCol2ERLin28ac(Tg) mice. Lin28a overexpression was induced by hydroxyl tamoxifen. After 24 hours, chondrocyte activation was induced by Wnt3a for 48 hours. Supernatant was collected for western blot analysis. Samples were processed for mRNA extraction or for histological analysis. In vivo assay, OA was induced by meniscus destabilization (DMM) in CreCol2ERLin28ac(Tg) or Lin28ac(Tg) as controls. Recombination was induced 1 week before DMM (preventive assay) or 4 weeks after DMM (regenerative assay). Left knee was sham-operated. Cartilage and bone were analyzed 4 and 8 weeks after surgery. Results: Ex vivo Wnt3a induces a decrease in Col2, Aggrecan, Sox9, PRG4 expression and a reduced matrix proteoglycan content, thereby increased MMP3-13 expressions. Lin28a overexpression totally abolished this effect. Moreover, Lin28a overexpressing-explants revealed reduced apoptosis and increased cell proliferation, concomitantly with an increase stem cell marker mRNA. In regenerative assay, chondrocyte activation led to cartilage lesions (increased MMP and reduced PRG4 expression) at 4 weeks post DMM. At bone level, osteophytes and bone sclerosis are already detectable. At 8 weeks, cartilage breakdown is more severe and PRG4 protein is totally absent in control mice, but stabilized in CreCol2ERLin28ac(Tg) to same level than week 4. At 8 weeks, PRG4 expression is reactivated, suggesting reprogramming of mature chondrocytes towards progenitors. Moreover, osteophyte size is remarkably increased without subchondral bone changes compared to controls. In preventive assay, Lin28a overexpression has the same protective effect. Conclusion: Our data suggest that targeting Lin28a could enhance cell reprogramming, thus reversing chondrocyte activation. This promotes the preservation of remaining osteoarthritic cartilage.

NFI-C is Required for Chondrocyte Proliferation in Growth Plate during Postnatal Cartilage Development Joo-Cheol Park*, Dong-Seol Lee, Yeoung-Hyun Park, Chul Son. Seoul National University, Republic of Korea

The nuclear factor I (NFI) gene family encodes site-specific transcription factors essential for the development of a number of organ systems. Our previous studies indicate that NFI-C is required for tooth root development and bone formation, but the exact function of NFI-C in cartilage development remains unknown. In this study, Nfic-/- mice revealed decreased growth-plate lengths compared to WT. In particular, the width of the proliferating and hypertrophic zone in the growth plate was dramatically reduced in Nfic-/- mice compared to WT. However, NFI-C disruption has no influence on prenatal cartilage development. In addition, cell proliferation rates of Nfic-/- chondrocytes were decreased approximately 40% at 3 days and 70% at 5 days compared to WT, respectively. PCNA-positive cells were significantly diminished in the proliferating zone of Nfic-/- mice compared to WT. In contrast, chondrocyte apoptosis was increased in the hypertrophic zone of Nfic-/- mice compared to WT. Nfic-/- chondrocytes exhibited increased p21 expression but decreased Cyclin D1 expression, strongly suggesting cell growth arrest due to the lack of Nfic activity. Further, Nfic-/- chondrocytes exhibited increased caspase-3 activation. These results indicate that NFI-C disruption results in decreased femur length caused by reduction in the width of the growth plate, decreased chondrocyte proliferation, and increased chondrocyte apoptosis.

Downregulation of Sox9 in growth plate hypertrophic zone promotes chondrocyte-osteoblast transdifferentiation Julian Lui*, Shanna Yue, Audrey Lee, Kevin Barnes, Jeffrey Baron. Section on Growth and Development, United States

Longitudinal bone growth is driven by endochondral ossification, a process in which cartilage tissue is generated by growth plate chondrocytes and then remodeled into bone by osteoblasts. In the postnatal growth plate, as hypertrophic chondrocytes approach the chondro-osseous junction, they either undergo apoptosis, or as recent findings suggest, transdifferentiate into osteoblasts. The molecular mechanisms governing this switch in cell lineage is poorly understood. In the current study, laser capture microdissection followed by real-time PCR demonstrated that Sox9 was downregulated as growth plate chondrocytes underwent hypertrophic differentiation whereas osteoblast-associated genes (Mmp9, Mmp13, Cola1, Sp7, and Ibsp) were modestly upregulated in the hypertrophic chondrocytes, even before they enter the metaphyseal bone. In transgenic mice that continue to express Sox9 at physiological levels in the hypertrophic zone, upregulation of these osteoblast-associated genes failed to occur (P<0.05). In these transgenic mice, we performed lineage tracing experiments. GFP expression was induced in chondrocytes (using a tamoxifen-inducible Col2a1-Cre transgene) at 4 days of age, and then the number of GFP-expressing osteoblasts were counted in a defined region of metaphyseal bone below the growth plate at 2 and 4 weeks of age. In transgenic mice expressing Sox9, the number of cells transdifferentiating from chondrocytes to osteoblasts was suppressed (4.3 vs 1.5 at age 2 wks; 6.9 vs 2.4 at age 4 wks; wild-type versus Sox9 transgenic, P < 0.01 at both time points). Collectively, our findings suggest that Sox9 downregulation in hypertrophic chondrocytes promotes subsequent transdifferentiation into osteoblasts.

Glutamine and Glucose Metabolism Controls Chondrocyte Function during Endochondral Ossification Steve Stegen*[1], Kjell Laperre[1], Guy Eelen[2], Gianmarco Rinaldi[3], Sophie Torrekens[1], Sarah-Maria Fendt[3], Peter Carmeliet[2], Geert Carmeliet[1]. [1]Clinical and Experimental Endocrinology, KU Leuven, Belgium, [2]Angiogenesis and Vascular Metabolism, Vesalius Research Center, VIB/KU Leuven, Belgium, [3]Cellular Metabolism and Metabolic Regulation, Vesalius Research Center, VIB/KU Leuven, Belgium

Endochondral ossification highly depends on proliferation and matrix deposition by growth plate chondrocytes, two energy-dependent anabolic processes. The avascularity of the growth plate requires controlled activity of hypoxia-inducible transcription factor HIF-1α that may alter chondrocyte metabolism. However, the type of metabolic adaptations and their importance for bone development are largely unknown.Here, we identify the HIF prolyl hydroxylase 2 (PHD2) oxygen sensor as a central gatekeeper of chondrocyte metabolism and cartilage matrix. Prolonged HIF-1α signaling in PHD2-deficient chondrocytes (Phd2chon-) leads to skeletal dysplasia by interfering with cellular bioenergetics and biosynthesis. Decreased glucose oxidation results in an energy deficit, which limits proliferation and reduces collagen synthesis. However, enhanced glutamine anaplerosis increases α-ketoglutarate (αKG) levels, which in turn increases collagen proline and lysine hydroxylation. This metabolically regulated collagen modification renders the cartilaginous matrix more resistant to protease-mediated degradation and thereby increases bone mass. To prove the specific contribution of the altered glutamine and glucose metabolism, we pharmacologically blocked the rate-limiting enzymes. Normalization of glucose oxidation in Phd-2chon- mice with dichloroacetic acid (DCA), a blocker of pyruvate dehydrogenase kinase (PDK), corrects the hypometabolic state and, consequently, matrix synthesis. DCA-treated Phd2chon- mice display a further accumulation of cartilage remnants and bone mass, likely because the high glutamine-derived αKG levels stimulate collagen modification. Accordingly, blocking glutaminase (GLS) in DCA-treated mice decreases αKG levels and thereby normalizes completely the cartilage and bone phenotype to the level of wild-type mice.Thus, chondrocytic HIF-1α signaling metabolically controls extracellular matrix properties and thereby regulates bone mass.

Salmon calcitonin exerts more preventive effects than celecoxib on cartilage degeneration, subchondral bone microarchitecture deterioration and tactile allodynia in a rat model of lumbar facet joint osteoarthritis Faming Tian*[1], Yu Gou[2], Liu Zhang[2]. [1]Medical Research Center, North China University of Science and Technology, China, [2]Department of Orthopedic Surgery, Hebei Medical University, China

Objective: To evaluate and compare the effects of salmon calcitonin (sCT) and celecoxib (CLX) on cartilage, subchondral bone and tactile allodynia in a rat model of lumbar facet joint (FJ) osteoarthritis (OA). Method: Forty 3-month-old male Sprague-Dawley rats were randomly divided into four groups: 30 received surgical collagenase (type II) injections in the right L3–L6 facet joints followed by 8 weeks of treatment with normal saline, CLX or sCT, and the other 10 received sham surgery. Tactile allodynia was evaluated using von Frey filaments. All rats were euthanized after completing treatment, and changes of the cartilage and subchondral bone of the L4–L5 FJs and serum biomarkers were analyzed. Results: sCT ameliorated cartilage lesions and significantly increased aggrecan expression and decreased caspase-3 and ADAMTS-4 expression, whereas CLX only significantly decreased caspase-3 expression. According to the micro-computed tomography (micro-CT) analysis, sCT significantly increased the BMD, BV/TV, and Tb.Th; decreased the Tb.Sp, SMI and micro-CT score; and inhibited articular process hypertrophy. sCT possessed a better analgesic effect than CLX on days 42 and 56 postoperatively. The sCT treatment reduced the elevated COMP concentration in rats injected with collagenase (type II). Additionally, the serum COMP concentration was significantly correlated with the histological and micro-CT scores. Conclusions: Both sCT and CLX exerted preventive effects on FJ OA caused by collagenase (type II), but sCT showed more protective effects, particularly on maintaining cartilage metabolism, restraining the deterioration of the subchondral bone microarchitecture and tactile allodynia, and reducing serum COMP concentrations.

NFAT1 Protects Articular Cartilage Against Osteoarthritis by Directly Regulating Transcription of Specific Anabolic and Catabolic Genes Mingcai Zhang*, Qinghua Lu, Theodore Budden, Jinxi Wang. Harrington Laboratory for Molecular Orthopedics, Department of Orthopedic Surgery, University of Kansas Medical Center, United States

Purpose: Mice lacking NFAT1, a member of the nuclear factor of activated T cells (NFAT) family of transcription factors, exhibit osteoarthritis (OA). The precise molecular mechanism for NFAT1 deficiency-induced osteoarthritic cartilage degradation remains to be elucidated. This study aimed to investigate if NFAT1 protects articular cartilage (AC)

Sunday Posters

against OA by directly regulating the transcription of specific catabolic and anabolic genes in articular chondrocytes.Methods: Through a combined approach of gene expression analysis and web-based searching of NFAT1 binding consensus DNA sequences, 25 candidate target genes that displayed aberrant expression in Nfat1-/- AC at the initiation stage of OA and possessed at least 4 NFAT1 binding sites in each promoter were selected and tested for NFAT1 transcriptional activities by chromatin immunoprecipitation (ChIP) and luciferase reporter assays using chromatins and chondrocytes isolated from AC of 3 to 4-month-old wild-type mice or Nfat1-/- mice with early OA phenotype. Normal mouse IgG and a pair of primers without NFAT1 binding sequences served as negative controls to verify the ChIP specificity. Results: ChIP assays revealed that NFAT1 directly bound to the promoter of 21 of the 25 tested genes encoding cartilage-matrix proteins, growth factors, inflammatory cytokines, matrix-degrading proteinases, and specific transcription factors (Figure 1). Luciferase reporter assays of representative anabolic and catabolic genes demonstrated that NFAT1-DNA binding functionally regulated the promoter activity of specific target genes in wild-type chondrocytes, but not in Nfat1-/- chondrocytes lacking functional NFAT1 protein. Conclusions: These results suggest that NFAT1 protects AC against OA by directly regulating the transcription of numerous target genes in articular chondrocytes. NFAT1 deficiency causes defective transcriptions of specific anabolic and catabolic genes in articular chondrocytes, leading to increased matrix catabolism and osteoarthritic cartilage degradation.

Effect of Doxycycline on Osteochondral Graft Chondrocyte Viability Ex Vivo
Brett Owens*, Li Yue. Brown University Alpert Medical School, United States

The surgical transplantation of fresh osteochondral (OC) grafts is an increasingly common procedure used to treat articular cartilage lesions. Fresh OC grafts have a limited window for transplantation, as chondrocyte viability significantly decreases after 14 days based on the current graft storage practices. Thus, it is critical to preserve fresh OC grafts without significant chondrocyte death. The antibiotic doxycycline has been shown to promote cartilage growth, disruptchondrocyte differentiation, and improve chondrogenesis of human bone marrow-derived mesenchymal stem cells. This suggests the potential use of doxycycline to improve cartilage repair and delay the onset of osteoarthritis. However, it is unknown whether doxycycline delays chondrocyte death in OC grafts. We hypothesized that doxycycline prolongs fresh OC graft chondrocyte viability. To test this hypothesis, the calf cartilages purchased from local slaughter were aseptically harvested within 4 hours of death, and were punched into the plugs with a diameter of 4 mm. The plugs were cultured in 48-well plates at 37oC or 4oC in the presence or absence of doxycycline (10, 2 or 1 μg/ml) for 9 weeks, while the medium was changed weekly. Chondrocyte viability in plugs was examined using the LIVE/DEAD Viability/Cytotoxicity kit with caldein acetoxymethyl for live cells and ethidium homodimer-1 for dead cells, respectively. We found that 1 μg/ml of doxycycline is the optimized concentration to increase chondrocyte viability. When cultured at 37oC, the chondrocyte viability was 82%, 65%, 62%, 54%, 53%, and 29% at d0, d14, d28, d48, d56, and d63, respectively. However, the viability of chondrocytes was 16%, 0.32% and 0% when the plugs were cultured at 4oC for 14, 28, and 48 days, respectively. Treatment of doxycycline caused a significant increase in the viability of chondrocytes, which was demonstrated by an increase of 17% on d14 and d48, 11% on d56, and 27.6% on d63 in OC plugs at 37oC culture. In addition, doxycycline treatment (1 μg/ml) at 37oC attenuated decreased glycosaminoglycan content and reduced increased empty lacunae through immunochemical staining in plugs during the culture duration. In conclusion, doxycycline at a concentration of 1 μg/ml under 37oC delays OC graft chondrocyte death. These findings

provide a potential approach to preserve fresh OC grafts for patients with articular cartilage lesions who wait for OC graft transplantation.

Hajdu Cheney Syndrome Mutants are Susceptible to Osteoarthritis
Stefano Zanotti*[1], Jennifer Wolf[2], David Bridgewater[1], Ernesto Canalis[1]. [1]UConn Health, United States, [2]University of Chicago, United States

Osteoarthritis is a degenerative disease of the joint characterized by compromised cartilage integrity, altered gene expression in articular chondrocytes and inflammation. NOTCH1 and NOTCH2 receptors and their ligand JAGGED1 are expressed by chondrocytes, and Notch plays a fundamental role in chondrocyte maturation. However, the role of Notch and its target genes in osteoarthritis has been controversial. Hajdu Cheney Syndrome (HCS) is a rare genetic disorder associated with NOTCH2 mutations in exon 34 that lead to the translation of a truncated and stable protein and NOTCH2 gain-of-function. Subjects afflicted by HCS have osteoporosis with fractures and inflammatory lesions of the distal phalanges that result in osteolysis. We created a mouse model (Notch2tm1.1Ecan) that reproduces the HCS mutation and manifests many aspects of the human disease. The availability of Notch2tm1.1Ecan mutants allowed us to determine whether HCS is associated with osteoarthritis. For this purpose, we destabilized the medial meniscus of 3-month-old Notch2tm1.1Ecan male mice and sex- and age-matched wild type littermates by resecting the medial meniscotibial ligament. Destabilized and sham-operated knees were analyzed for joint degeneration 2 months after the intervention. The expression of Notch target genes (Hey1, Hey2 and HeyL) was increased in the femoral heads of Notch2tm1.1Ecan mice, verifying enhanced NOTCH2 signaling. Microcomputed tomography and histological analysis of medial tibial plateaus revealed modest differences in periarticular bone structures and articular cartilage integrity between Notch2tm1.1Ecan mutants and control littermates subjected to sham interventions. Following destabilization of the medial meniscus, Notch2tm1.1Ecan mutants had a significant increase in osteophyte volume and thickened subchondral bone compared to wild type littermates. Moreover, Notch2tm1.1Ecan mutants, exhibited histological signs of moderate to severe cartilage degeneration, demonstrating that joints of Notch2tm1.1Ecan mutants are sensitized to osteoarthritis progression. Primary chondrocytes from Notch2tm1.1Ecan mutants cultured on JAGGED1-coated substrates expressed increased IL6 transcripts, possibly explaining the susceptibility of Notch2tm1.1Ecan mice to osteoarthritis. In conclusion, Notch2tm1.1Ecan mutant mice are sensitized to the development of osteoarthritis and NOTCH2 activation may play a role in the pathogenesis of the disease.

Associations between Circulating Osteoprogenitor (COP) cells, Parathyroid Hormone, Vitamin D and function in older adults
Ahmed Al Saedi*[1], Steven Phu[2], Gustavo Duque[1]. [1]Australian Institute for Musculoskeletal Science (AIMSS), The University of Melbourne and Western Health, St. Albans, VIC, Australia, [2]Department of Medicine-Western Health, Melbourne Medical School, The University of Melbourne, Australia

Associations between Circulating Osteoprogenitor (COP) cells, Parathyroid Hormone, Vitamin D and function in older adultsAuthors: Ahmed Al Saedi1,2, Steven Phu1,2, Piumali Gunawardene3, Sara Vogrin1,2, Damian Myers1,2 , Gustavo Duque1,3 Affiliations: 1 Australian Institute for Musculoskeletal Science (AIMSS), The University of Melbourne and Western Health, St. Albans, VIC, Australia2 Department of Medicine-Western Health, Melbourne Medical School, The University of Melbourne, St. Albans, VIC, Australia3 Sydney Medical School Nepean, The University of Sydney, Penrith, NSW, Australia Introduction: Circulating osteoprogenitor (COP) cells have been linked to bone formation and osteogenesis during the initial stages of fracture healing. Recent studies have shown a strong association between low percentages of COP cells (%COP) and frailty and disability.Additionally, increased levels of COP cells have been associated to low bone mineral density. However, the association between serum levels of Parathyroid hormone (PTH) and vitamin D remain unknown. In this study we aimed to identify the potential associations between COP cells, parathyroid hormone, vitamin D and their clinical significance in older adults.Methods: A random sample of community-dwelling individuals aged 65 and older enrolled in the Nepean Osteoporosis and Frailty (NOF) Study (mean age 82.8; N = 77; 70% female). COP cells were identified by flow cytometry using selective gating of CD45/OCN+ cells and by Mean Fluorescence Intensity (MFI). Logistic regression models estimated the relationship between the percentage of COP cells and prevalent disability and frailty.Results: There was a positive correlation between PTH levels and COP cells (p=0.003). A trend towards a negative correlation for vitamin D and COP cells was also evident (p=0.060). No correlations were found between COP cells and bone mineral density at the heel. Conclusions: COP cells were positively correlated with PTH levels in older adults. This may suggest involvement of COP cells in bone turnover in particular the formation and mineralisation of bone. Whether pathological states such as hyperparathyroidism and vitamin D deficiency are also associated with significant changes in %COP remains to be determined.

SUN-0270

Total adiposity as reflected in body weight, rather than specific fat compartments, predicts incident low-trauma fractures in healthy non-osteoporotic post-menopausal women Emmanuel Biver*, Jessica Pepe, Alessandro De Sire, Thierry Chevalley, René Rizzoli, Serge Ferrari. Division of Bone Diseases, Geneva University Hospitals and Faculty of Medicine, University of Geneva, Switzerland

Purpose: Despite higher bone mineral density (BMD), individuals with high fat mass have an increased fracture risk. Cortical microstructure at non-weight bearing bone sites has been suggested to be inversely associated with visceral fat. It remains however unknown whether higher fracture risk is specifically associated with fat mass compartments, such as android or visceral fat, independent of body mass index (BMI) or body weight. We investigated whether incident low-trauma major osteoporotic fractures (MOF) would be associated with levels of a specific fat mass compartment in a cohort of community-dwelling healthy non-osteoporotic postmenopausal women.Methods: Six hundred and forty-four non-osteoporotic (T-score spine or hip >-2.5SD) postmenopausal women (age 65.1 ± 1.5 yrs (mean ± SD), 15% with obesity defined as BMI<30kg/m2), enrolled in the Geneva Retirees Cohort, were prospectively evaluated over 5.7 ± 1.5 yrs for the occurrence of low-trauma MOF. At baseline, areal BMD and body composition were assessed by DXA, and FRAX fracture probability was calculated.Results: Thirty eight incident MOF (humerus n=13, wrist n=13, clinical and morphometric vertebral fractures n=9 and hip n=3) occurred in 34 women, while 534 women had no fracture. In Cox's proportional hazard models, MOF were positively associated with body weight, whole body fat mass, trunk and android fat compartments, and abdominal subcutaneous adipose tissue (HR per one SD increase of fat variable from 1.41 to 1.51, p<0.05 for all). Most associations with fat mass remained significant after adjustment for BMI, femoral neck BMD (Table) and FRAX (with BMD). However, they disappeared after adjustment for body weight (adjusted HR 0.87 to 1.19, p≥0.634 for all). In subgroups analyses, the associations were of higher magnitude in non-obese than in obese women [HR (95%CI) for trunk fat 1.99 (1.25, 3.17), p=0.004 vs 1.32 (0.34, 5.13), p=0.686, respectively].Conclusion: Whole body fat mass and trunk fat predict incident MOF independently of BMI, BMD and FRAX, but not of body weight, in non-osteoporotic women. These data do not support the hypothesis of a metabolic deleterious impact of a specific visceral fat compartment on bone fragility but suggest that total adiposity, as reflected in body weight, is the main contributor to fracture risk. These findings need however to be confirmed in larger populations including men and more hip fractures before generalization.

Table: Associations between fat mass compartments and the risk of incident low-trauma major osteoporotic fractures in healthy non-osteoporotic postmenopausal women.

	Crude associations		Adjusted for BMI		Adjusted for femoral neck BMD	
	HR (95%CI)	P-value	HR (95%CI)	P-value	HR (95%CI)	P-value
Body weight	1.51 (1.07, 2.14)	0.019	NA		1.67 (1.16, 2.40)	0.006

Overexpression of MitoNEET in osteoblasts leads to impaired bone mass and energy metabolism in mice Phuong Le*, Sheila Bornstein, Victoria Demambro, Clifford Rosen, Anyonya Guntur. MMCRI, United States

Osteoblasts during in vitro differentiation increase glycolytic ATP production rates in response to exogenous glucose supply. To study the role of the two major ATP generating pathways in vivo in osteoblasts we overexpressed MitoNEET a mitochondrial membrane protein generating a novel osteoblast specific overexpression mouse model. Previous work shows that overexpression of MitoNEET in adipocytes leads to decreased oxidative phosphorylation and a concomitant increase in glycolysis. In our overexpression model, mice containing the tetracycline responsive element fused to the MitoNEET ORF were crossed to Runx2 rtTA to generate osteoblast specific overexpression. Two groups of 4 week old male mice were generated and Doxycycline+Saccharin (Dox), and Saccharin (controls) were introduced through drinking water for 12 weeks. Tibiae from mice were isolated and qRT-PCR analysis performed showing a significant increase in MitoNEET expression in bone. Furthermore, we did not find any increases in MitoNEET gene expression in WAT, BAT or liver suggesting that the overexpression was specific for bone. Trabecular bone microarchitecture was assessed in the distal femoral metaphysis, whereas cortical bone morphology was assessed at the femoral mid-shaft with µCT analysis at 16 weeks of age. Dox treated male mice had significantly lower trabecular bone mineral density and trabecular thickness, along with lower cortical tissue mineral density (Ct.TMD, -0.7%), medullary area (Ma.Ar, -11.8%), total area (Tt.Ar, -10.7%), and minimum moment of inertia (Imin, -22%) compared to controls. Next, we performed indirect calorimetry to obtain energy expenditure (EE) and respiratory quotient (RQ) data. We found a significant increase in day time ener-

gy expenditure suggesting modulation in circadian rhythms. Interestingly, 24 hour RQ was significantly lower in the MitoNEET overexpressing animals, suggesting oxidation of fat (n=8-10, p=0.03). There was no difference in food consumption with the Dox group drinking significantly less amount of water (n=8-10, p=0.009). We also performed additional control experiments in metabolic cages on mice fed Saccharin and Saccharin+Dox and identified that the metabolic changes we observed were specific for MitoNEET overexpression. In sum, manipulating MitoNEET expression specifically in the osteoblast impairs bone mass and leads to decreased, energy expenditure and respiratory quotient in male mice potentially affecting whole body energy metabolism.

Energy metabolism in the bone is associated with histomorphometric changes in rats with hyperthyroidism Liao Cui*, Zhuoqing Hu, Minqun Du, Yajun Yang. Department of pharmacology, Guangdong Medical University, China

Hyperthyroidism led to a higher frequency of bone remodelling and net bone loss. With the development of proteomics, the molecular mechanisms of osteoblast and osteoclast biology have been identified through several proteomic analyses. Nevertheless, the underlying histological consequence of hyperthyroidism remains to be elucidated by bone proteomic analysis. Therefore, we assessed histomorphometric changes induced by thyroxine (T4, 250 µg/kg/day) in 3-month-old hyperthyroid male rats and examined whether the potential mechanism of these changes is related to bone changes by using isobaric tags for relative and absolute quantification(iTRAQ). Compared with the control rats(n=8), hyperthyroid rats(n=8) showed a reduction in the fifth lumbar vertebral BMD as well as in the entire femoral BMD (p=0.033 and 0.026, respectively). Histomorphometric analysis of the proximal tibial metaphysis showed that the percentage of the trabecular area, trabecular number, and percentage of the cortical bone area in the hyperthyroid rats significantly decreased compared with those of the control rats. Conversely, bone formation rate (per unit of bone surface and bone volume), percentage of the osteoclast perimeter, trabecular separation, and endosteal mineral apposition rate in the hyperthyroid rats significantly increased compared with the control rats (all p<0.05). Micro-CT three-dimensional structural changes in the proximal tibial metaphysis: compared with CON group, the connective density, volumetric bone density, bone volume fraction, number of trabecular bones and trabecularthickness were decreased in hyperthyroid group, but structural model index increased(all P<0.05). Except for stiffness, all bone biomechanical properties of the femur showed a significant decreasing trend in the hyperthyroid rats versus the control rats (all p<0.05). Serum levels of osteocalcin, alkaline phosphatase, terminal telopeptides of type β collagen, and tartrate-resistant acid phosphatase were higher in the hyperthyroid rats than in the control rats (all p< 0.05). Using iTRAQ, the expression levels of 1,310 proteins in left femurs were found to be significantly different between the hyperthyroid and control rats (711 proteins were upregulated and 599 were downregulated in hyperthyroid rats). Gene Ontology and Kyoto Encyclopedia of Genes and Genomes pathway enrichment analyses showed that most of the enzymes in the glycolysis–tricarboxylic acid (TCA) cycle–oxidative phosphorylation signalling pathway were upregulated in hyperthyroid rats, and seven differentially expressed proteins were selected to verify the iTRAQ results using western blotting.Energy metabolism via the glycolysis–TCA cycle–oxidative phosphorylation pathway is positively associated with T4-induced bone histomorphometric changes in rats.

Deficiency of Long Non-Coding RNA ADPC Impairs Bone and Adipose Tissue Metabolism Yao Liu*[1,2], En Luo [2], Junxiang Lian[1,2], Qisheng Tu[1], Zoe(Xiaofang) Zhu[1,3], Jake(Jinkun) Chen[1,4]. [1]Division of Oral Biology Tufts University School of Dental Medicine, Boston, MA, United States, [2]State Key Laboratory of Oral Diseases, National Clinical Research Center for Oral Diseases, West China Hospital of Stomatology, Sichuan University, Chengdu, China, [3]Shanghai Jiaotong University, China, [4]Department of Developmental, Molecular and Chemical Biology Sackler School of Graduate Biomedical Sciences Tufts University School of Medicine, Boston, MA, United States

Objectives. The long non-coding (lnc) RNA ANRIL is a 58-kilobase (kb) interval on human chromosome 9p21 and associated with coronary artery disease, periodontitis, diabetes mellitus and cancers. In mouse genome there is an orthologous lncRNA of ANRIL on the chromosome 4 known as AK148321, temporarily termed lncRNA ADPC. We hypothesized that ADPC has the similar biological functions as ANRIL playing important regulatory roles in bone and adipose tissue metabolism. We planned to use AK148321 knockout mice to study the roles and mechanism of ADPC in vitro and in vivo. Materials and Methods. Mice were genotypedly separated into 3 groups as AK148321-KO (homozygous, hm), heterozygous (ht) and wild type (WT). Bone marrow stem cells (BMSCs) were isolated and cultured with osteo-/adipo- genesis-inducing medium, respectively. In vitro studies included CCK8 cell proliferation assay, scratch migration assay, quantitative RT-PCR, Alizarin Red staining (ARS), ALP staining and oil red O staining. Bone and adipose tissues were analyzed by Micro CT scanning and histological examination. Osteo-/adipo- genetic markers (osteogesis: Runx2, OCN, BMP-2, ALP; adipogenesis: FAS, aP2, C/EBPα), and metabolic and

inflammatory markers (PPARγ, CXCR4, APN, IL-6 and TGFβ) were also tested.Results. The expression of AK148321 in BMSCs increased during the early stage of osteogenesis, while decreasing in adipogenesis. The enhancement of migration and proliferation in hm group were observed comparing with ht and WT groups in vitro. The expression of SDF-1 and MMP9 were upregulated in hm group. The reducing of osteogenesis and mild enhancing of adipogenesis were found by qPCR and staining analysis, while the expression of inflammation markers mildly increasing in hm group. The obvious phenotyping differences of bone and white adipose tissue (WAT) appeared until 8 weeks with the osteogenetic markers downregulated and reduced bone mineralization in hm. Upregulation of adipogenetic markers appeared in hm comparing with ht and WT groups. There was a slight increasing of inflammation markers in hm group.Conclusions. Deletion of lncRNA ADPC in mice impaired bone formation and enhanced inflammation. At the meantime ADPC deficiency promoted adipogenesis. ADPC represents an important regulatory element in bone and fat tissue metabolism. Currently we are further studying the epigenetic mechanism and molecular signaling pathway of how ADPC exerts its effects in metabolism of a variety of tissues.

Differentiation of Japanese Black Bears' Adipose-Derived Stem Cells to Osteoblasts Alireza Nasoori*[1], Yuko Okamatsu-Ogura[2], Woongchul Shin[2], Michito Shimozuru[1], Mohamed Abdallah Mohamed Moustafa[1], Toshio Tsubota[1]. [1]Laboratory of Wildlife Biology and Medicine, Department of Environmental Veterinary Science, Graduate School of Veterinary Medicine, Hokkaido University, Japan, [2]Department of Biomedical Sciences, Graduate School of Veterinary Medicine, Hokkaido University, Japan

Background: Bears are resistant to disuse bone loss in 5 months of hibernation. Therefore, understanding bears' bone cell response would enable bone biologists to develop therapeutic measures for osteoporosis. Accordingly, here we report our methodology by which we recruited bears' adipose derived stem cells (ADSCs) to be differentiated to osteoblats. Methods: Adipose tissue was obtained from 4 mature male Japanese black bears in active season (September). The animals – based on our institutional rules for handling wild animals – were anesthetized by medetomidin and tiletamine/zolazepam. The samples, which were obtained from the inguinal and intrascapular areas, were delivered to lab within 72 hours at room temperature. The tissues were digested by collagenase with BSA and DMEM for 90 min at 37ºC. After twice filtrations (200 and 20 μm) and centrifugations (1000 rpm/5min), the ADSCs were isolated, and then preserved at -80°C. After 4 months, the ADSCs were cultured on dish with DMEM with 10% FCS. After 2 subcultures, the cells were treated with 50 mM ascorbic acid, 10 mM beta glycerophosphate, 100 nM dexamethasone in α-MEM for 21 days. The cells were supplemented by 10% FCS, or 10% active bear plasma (ABP) or hibernating bear plasma (HBP), and were incubated at 37°C with 5% CO2. The cells were assessed by observation and Alizarin Red S staining.Results: After 4 months of preservation, bears' ADSCs proliferated well. The cells supplemented by FCS and ABP both could differentiate well. Whereas, HBP-supplemented cells showed poor differentiation. Differentiated cells were trigonal or polygonal after 21 days. Cell size by FCS and ABP supplementations were rather similar, and appeared larger than HBP-supplemented cells. Alizarin Red S showed mineralization in all groups. However, FCS and ABP-cultured cells had more calcium accumulation than HBP. Conclusions: We observed that Japanese black bears' ADSCs differentiated to osteoblasts. The differentiation was affected by cell supplementations; the use of active bear plasma in cell culture resulted in more differentiation and mineralization than the use of hibernating bear plasma. The use of bear plasma in this study showed its effectiveness for bear ADSCs differentiation. Further investigations are required to check gene expression for bears' osteoblasts proliferation and differentiation when cells are treated with different supplementations.

Uc-dpMGP is associated with body composition and BMD in type 2 diabetes mellitus Natascha Schweighofer*[1], Christoph Haudum[1], Michaela Goschnik[2], Ewald Kolesnik[3], Ines Mursic[1], Albrecht Schmidt[3], Thomas R Pieber[1], Barbara Obermayer-Pietsch[1]. [1]Div. Endocrinology and Diabetology, Medical University Graz, Austria, [2]Endocrinology Lab Platform, Medical University Graz, Austria, [3]Div. Cardiology, Medical University Graz, Austria

Body composition significantly influences the development of type 2 diabetes mellitus (T2DM) which affects bone metabolism and strength. Matrix gla protein (MGP) has been associated with bone parameters, but also with cardiovascular risk in patients with and without T2DM. We investigated whether uncarboxylated, dephosphorylated MGP (uc-dpMGP) is associated with parameters of body composition, bone density and clinical parameters, and whether these associations change during diabetes progression in lean and obese subjects.We analysed data from the BioPersMed cohort (n=966, 531 females and 435 males, mean age 58 +/- 9 years), a prospective cohort study of asymptomatic patients at cardiovascular risk with broad clinical and lab phenotyping. T2DM, prediabetic and non T2DM patients were defined according to ADA criteria. Uc-dpMGP was measured with IDS-iSYS InaKtif MGP Kit. Body composition and bone mineral density were determined by Lunar iDXA.Uc-dpMGP correlated in T2DM with tissue and overall mass negatively in lean (both r=-0.78; p=-0.039) and positively in obese patients (both r=0.27; p=0.047 and p=0.044, respectively) and with lean and fat free mass in obese pre-diabetes patients (both -0.30; p=0.007). A correlation of regional fat distribution with uc-dpMGP was seen in non-diabetic (both lean and obese) and obese prediabetic patients. Furthermore, uc-dpMGP and total fat mass correlated positively in both lean (r=0.26; p=0.004) and obese (r=0.18; p=0.046) non-diabetic patients, but only in obese prediabetic (r=0.43; p<0.0001) and obese diabetic (r=0.30; p=0.025) patients.Total bone mass and uc-dpMGP correlated differentially in obese prediabetic patients and T2DM. As MGP is expressed in fat tissue, uc-dp MGP might have a potential role as a modulator of body composition and fat distribution which changes during diabetes progression. Our data implicate an association of uc-dp MGP depending on differentially carboxylated and phosphorylated forms of MGP.

AdipoRon Alleviates Diabetic Bone Disorders via Suppressing Inflammation Wei Qiu*[1], Jake Chen[2], Qisheng Tu[2], Xingwen Wu[2], Xuedong Zhou[1], Junxiang Lian[2]. [1]West China School of Stomatology, Sichuan University, China, [2]Tufts Univ.School of Dental Medicine, United States

Objectives: Diabetic bone disorders including osteoporosis, arthritis and periodontitis cause an increase in bone fractures, delay healing of fractures, and affect the quality of life of patients. AdipoRon, a recently found orally active small molecule, binds and activates both adiponectin receptors (AdipoR1, R2), with potent effects of anti-diabetes and prolonging shortened life of diabetic mice. However, its effects and underlie mechanisms of anti-inflammation on diabetic bone disorders are unknown. In this study, we investigated whether AdipoRon could suppress inflammation in diet-induced obesity (DIO) mice and explored the molecular mechanisms of signal transduction in the process. Our findings suggest a promising approach for the treatment of bone diseases via suppressing inflammation particularly in diabetes patients.Materials, Methods and Results: DIO mice with AdipoRon gavage showed an decreased number of multinucleated giant cells in spleen by histomorphometry analysis (Fig. A). Real-time PCR analysis exhibited that the increased mRNA expressions of inflammation-associated cytokines (IL-6, IL-1β, TNF-α and IL-10) were reversed in DIO mice with AdipoRon treatment in spleen (Fig. B), bone marrow and white adipose tissues (data not shown). In vitro experiments, bone marrow-derived macrophages (BMMs) (data not shown) and RAW264.7 cells were stimulated by AdipoRon and Lipopolysaccharides (LPS)separately or synergistically. Results of Real-time PCR and Western blot analysis showed that AdipoRon suppressed LPS-stimulated inflammatory environment (Figs. C, F). Functional inhibition experiments (Pharmacological inhibitor TBB and siRNA knockdown) demonstrated the involvement of AdipoR1, APPL1/2 and CK2 axis in signal pathway (Figs. D, E, G). Co-immunoprecipitation assays indicated that the interaction of AdipoR1-APPL1 and MyD88 blocked the signal transduction in macrophages stimulated by LPS (Fig. H).Conclusions: AdipoRon suppresses diabetes-induced systemic inflammation in DIO mice and reverses LPS-stimulated inflammatory environment in the early phase of differentiation of BMMs and RAW264.7 cells via the interaction with AdipoR1-APPL1 and MyD88. In summary, AdipoRon represents a potential molecule for the treatment of diabetic bone disorders via strongly suppressing inflammation.

A-H: AdipoRon suppresses inflammation in DIO mice. H&E stain of spleen (A) and real-time PCR analysis of spleen (B) in WT and DIO mice with and without adipoRon gavage. Values are presented as mean ± SEM (n=3). *P< 0.05 compared to the WT Vehicle, #P< 0.05 compared to the DIO Vehicle.

C-E: AdipoRon suppresses inflammation in mRNA level in vitro. Raw264.7 cells were pretreated with different concentrations of adipoRon (C), TBB (D) or transfected with siRNAs (E) followed by stimulation of adipoRon levels by qRT-PCR. Values are presented as mean ± SEM (n=3). *P< 0.05, **P<0.01, ***P<0.001, ****P<0.0001.

F-G: AdipoRon suppresses inflammation in protein level in vitro. Raw264.7 cells were pretreated with adipoRon and/or LPS (F) for the measurement of proteins levels by WB. Raw264.7 cells were transfected with siRNAs (G) for the measurement of proteins levels by WB.

H: interaction of APPL1 and MyD88. Raw264.7 cells were pretreated with adipoRon and/or LPS for the measurement of interaction of protein and protein by Co-immunoprecipitation. Protein immunoprecipitated by the anti-APPL1 antibody was subjected to IB analysis to detect levels of MyD88 and AdipoR1.

Lipid Droplets Contribute to the Bioenergetic Capacity of Osteoblasts by Supplying Endogenous Fatty Acids for Mitochondrial Respiration Elizabeth Rendina-Ruedy*[1], Ron Helderman[1], Michael Czech[2], Clifford Rosen[1]. [1]Maine Medical Center Research Institute, United States, [2]Program in Molecular Medicine, University of Massachusetts Medical School, United States

Bone formation by the osteoblast has been described as an energy-demanding process which requires various substrates to generate cellular energy or adenosine triphosphate (ATP). As such, much of the interest surrounding osteoblast substrate utilization has been focused on these cells unique ability to metabolize glucose via aerobic glycolysis. In addition to glucose osteoblasts also require fatty acids (FAs) which can undergo β-oxidation and subsequent oxidative phosphorylation for energy generation. Until recently the source of these fatty acids had remained somewhat illusive and presumed to primarily be supplied from exogenous sources, however, we now know that FAs can also be mobilized from endogenous, lipid droplets. Therefore, we aimed to further characterize lipid droplet function in osteoblasts throughout their differentiation by determining their contribution to overall bioenergetic capacity. The dependency of primary bone marrow stromal cells (Day 0 osteogenic differentiation), osteoprogenitor (Day 2 osteogenic differentiation), or mature osteoblasts (Day 7 osteogenic differentiation) on endogenous FAs for mitochondrial respiration was determined by first inhibiting FA (etomoxir) utilization and measuring the change in oxygen consumption rate (OCAR). Afterwards, glutamine (BPTES) and glucose/ pyruvate (UK5099) utilization was inhibited and dependency was calculated based on any further change in OCAR. Alternatively, the capacity of the cells to utilize endogenous FAs was measured by directing the cells to utilize FAs by inhibiting glutamine and glucose/ pyruvate while measuring OCAR, and then subsequently blocking FAs. Interestingly, our results demonstrate bone marrow stromal cells depend more on endogenous FAs vs. glucose or glutamine, while maintaining a similar capacity to use FAs and glucose when exogenous substrates are limited. Osteoprogenitor cells and mature osteoblasts were equally dependent on endogenous glucose and FAs and have a similar capacity to use these substrates. Cells throughout osteoblast differentiation demonstrated a lower capacity to use endogenous glutamine, and the cells did not rely on this substrate for mitochondrial respiration. While studies are ongoing to further delineative the role of lipid droplets in osteoblasts, these results suggest that lipid droplets supply a considerable amount of FAs for mitochondrial respiration during osteoblast differentiation.

Complex Role for PPARγ in Bone, Inflammation and Immune function in Aging Animals Raysa Rosario*, Ashwin Ajith, Ke-Hong Ding, Ranya Elsayed, Yun Su, Anatolij Horuzsko, Mohammed Elsalanty, Meghan Mcgee Lawrence, Carlos Isales, Xing-Ming Shi. Medical College of Georgia, United States

Aging is a state of chronic low-grade inflammation, and is accompanied by bone loss, marrow fat accumulation, and decline of immune function. Peroxisome proliferator-activated receptor gamma (PPARg) is a key transcription factor regulating adipocyte differentiation and function. The adipose tissues produce many factors including adipokines, inflammatory cytokines and chemokines that may contribute significantly to the aging process. In the present study, we hypothesized that inhibition of PPARg would reduce fat-generated inflammatory responses, improve immune function, and decrease age related bone loss. To test this hypothesis, we treated young (6mo) and old (23mo) female C57BL/6 mice with a PPARg antagonist GW9662 (1mg/kg body weight, daily IP injection for 6 weeks) and examined the effects on bone mass, lymphoid to myeloid cell lineage skewing, and the expression profiles

of inflammation related genes. micro-CT analysis showed that GW treatment significantly increased Tb.Th, but also the Tb.Sp in old mice. GW treatment increased BV/TV and Tb. N in young mice, although these increases were not statistically significant. These results suggested that inhibition of PPARg has limited beneficial effect on bone mass in old mice. FACS analysis data showed that in the bone marrow, GW treatment significantly increased lymphoid and decreased myeloid lineage cells in young mice, as indicated by large increases in CD3/CD11b and CD4/CD8 ratios, and decreased the Ly6C/Ly6G ratio. GW treatment increased CD4/CD8 ratio significantly only in the old mice. In the spleen, GW significantly increased the CD3/CD11b ratio in young, and CD4/CD8 ratio in old mice. GW treatment significantly decreased Ly6C/Ly6G ratio in both young and old mice. Similar to that seen in bone marrow and spleen, in peripheral blood, GW treatment increased CD4/CD8 ratio in the old, but only decreased Ly6C/Ly6G ratio in the young mice. These data indicate that inhibition of PPARg can significantly improve immune functions of the old mice by increasing the numbers of CD4+CD8+ T cells in blood, spleen, and bone marrow. Interestingly, NanoString profiling of inflammation related genes in bone cells revealed opposite effects of GW treatment in young vs. old mice; i.e., genes whose expression are downregulated by GW in bone cells of the young mice are upregulated in the old mice. Taken together, these data demonstrate that while inhibiting PPARg can improve immune function in older animals, it may actually exacerbate the inflamm-aging. Thus, tissue or site-specific approaches should be considered when PPARg is targeted for therapeutic interventions.

Mouse Model of Severe Osteogenesis Imperfecta is Protected Against High-Fat Diet Induced Obesity but not against High-Fat Diet Induced Insulin Resistance Josephine T. Tauer*, Iris Boraschi-Diaz, Svetlana Komarova. Shriners Hospital for Children and Faculty of Dentistry, McGill University, Canada

Objective: Osteogenesis imperfecta (OI) is a genetic disorder mainly caused by mutations in collagen type I, and characterised by high bone turnover leading to low bone mass and high fracture rates. Recently, we have shown that young Col1a1Jrt/+ mice - mouse model of severe OI - exhibit beside high bone turnover, altered glucose/insulin metabolism, and energy expenditure, due to elevated levels of undercarboxylated osteocalcin, a novel bone-derived hormone that affects insulin production and sensitivity. Here we examined the effect of long-term high-fat diet on weight gain, glucose metabolism, and bone properties in Col1a1Jrt/+ mice. Methods: Starting at an age of 4 weeks, male and female wild-type (WT) and OI mice were fed with either high-fat diet (60%, HFD) or a matched low-fat diet (10%, LFD) for 26 weeks. Body weight was measured weekly and glucose metabolism by glucose tolerance test every 4 weeks. Long bone properties were examined by MicroCT and 3-point-bending test at the end of the study. Results: At 4-weeks of age, male and female OI mice had 20% lower body mass than WT littermates. WT male and female mice on LFD gained 0.65±0.03 g/week and 0.39±0.02 g/week, respectively, while on HFD males gained 1.00±0.05 g/week and females 1.10±0.06 g/week. Compared to WT mice, male and female OI mice showed significantly lower increase in body mass. Female OI mice gained about 0.28±0.02 g/week on LFD and 0.62±0.04 g/week on HFD. Male OI mice were protected from HFD-induced weight gain and showed a gain in body mass of 0.44±0.02 g/week on LFD and 0.46±0.02 g/week on HFD. In WT mice, HFD-induced gain of body mass coincided with an increase in white adipose tissue and liver weight, whereas in OI white adipose tissue and liver weight was not affected. No diet-induced changes in brown adipose tissue, heart, spleen, or pancreas weight was observed in WT or OI mice. Glucose tolerance test demonstrated HFD-induced diabetic changes in glucose metabolism in both WT and OI mice. Trabecular structure as well as mechanical properties of long bones were significantly different between WT and OI but were not affected by LFD or HFD.Conclusion: Here we show for the first time that mice with a severe form of OI, in particular males, are protected against HFD-induced weight gain, but not from HFD-induced insulin resistance disclosing an altered fat and energy metabolism in OI.

Kado[9], Gudny Eiriksdottir[3], Tamara Harris[8], Xiaojuan Li[6], Clifford J Rosen[5], Ann V. Schwartz[4]. [1]Academic Medical Center dept of Endocrinology and Center for Clinical and Translational Research, Maine Medical Center Research Institute, Netherlands, [2]Dept. Medicine, University of California San Diego and VA San Diego Healthcare System, United States, [3]Icelandic Heart Association, Iceland, [4]Department of Epidemiology and Biostatistics, University of California San Francisco, United States, [5]Center for Clinical and Translational Research, Maine Medical Center Research Institute, United States, [6]Program of Advanced Musculoskeletal Imaging (PAMI), Cleveland Clinic, United States, [7]Icelandic Heart Association Faculty of Medicine, University of Iceland, Iceland, [8]National Institute on Aging, National Institutes of Health (NIA, NIH), United States, [9]Dept of Medicine and Department of Family Medicine and Public Health, University of California, United States

Purpose Bone marrow adiposity increases with age, particularly in women around menopause when estradiol levels decrease and follicle stimulating hormone (FSH) levels increase. Increased bone marrow adiposity is associated with osteoporosis and vertebral fractures. Understanding the factors that regulate bone marrow adiposity in older adults may lead to novel mechanisms for combatting age-related bone loss. Postmenopausal hormonal replacement therapy, increasing estradiol and decreasing FSH levels, decreases bone marrow adiposity. A recent study in mice showed that blocking FSH signaling with an antibody also decreases bone marrow adiposity following ovariectomy. The association between FSH and bone marrow adiposity in humans has not been previously reported. Methods We hypothesized that in humans higher FSH levels are associated with greater bone marrow adiposity. To test this hypothesis, we performed a cross-sectional, observational study in the AGES-Reykjavik cohort. In 237 women and 245 men, we measured vertebral (L1-L4) bone marrow adipose tissue (BMAT, %) by magnetic resonance spectroscopy and serum FSH concentration by ELISA. Results In older women (mean age 80.6 years) with a mean FSH of 71.5 IU/L and a mean vertebral BMAT of 55%, mean vertebral BMAT was 0.65% greater for each 10 IU/L increment of FSH (95% CI: 0.19, 1.10, p=0.006) in linear regression models adjusted for age, BMI and estradiol. In older men (mean age 82.4 years) with a mean FSH of 19.0 IU/L and a mean vertebral BMAT of 54%, there was no evidence of an association between vertebral BMAT and FSH in unadjusted (beta 0.23, 95% CI: -0.42, 0.87, p=0.49) or adjusted (beta -0.25, 95% CI: -0.94, 0.45, p=0.48) models. Conclusion Higher FSH is associated with greater vertebral bone marrow adiposity in older women but not in men. Longitudinal studies are needed to determine whether higher FSH levels predict increases in bone marrow adiposity in older adults.

Network analysis of skeletal muscle during spaceflight in male mice David Waning*[1], Paul Childress[2], Raina Kumar[3], George Dimitrov[3], Bintu Sowe[4], Aarti Gautam[5], Nabarun Chakraborty[6], Rasha Hammamieh[5], Melissa Kacena[2]. [1]Penn State College of Medicine, United States, [2]Indiana University School of Medicine, United States, [3]Advanced Biomedical Computing Center, NCI, United States, [4]ORISE, US Army Center for Environmental Health Research, United States, [5]Integrative Systems Biology, US Army Center for Environmental Health Research, United States, [6]Geneva Foundation, US Army Center for Environmental Health Research, United States

The unloading associated with spaceflight results in the rapid loss of bone and muscle tissue thereby affecting functionality. These are two of the most concerning physiologic changes that occur in space and could limit long-term occupation in space. Thus, a better understanding of the mechanisms of changes to bone and muscle could lead to development of improved therapies to counteract both spaceflight and terrestrial-based bone and muscle dysfunction. Here we used a non-biased, stringent, deep sequencing (96 million paired end reads targeting 100 bp read length) assay to examine genomic networks altered by spaceflight in the quadriceps (n=4/group). Specifically, 9-week-old C57BL/6 male mice were housed on the International Space Station or at Kennedy Space Center for approximately four weeks (n=10/group). 14,228 genes (70% of whole mouse genome) met the cut-off criteria and the data sets were mapped to an average of ~76% of the whole mouse genome. Of these, 840 genes met the t-test criteria, p < 0.05. Canonical networks linked to EIF2 signaling, mTOR signaling, calcium ion signaling, and oxidative stress response were significantly enriched by the differentially expressed genes. A comprehensive energy deprivation was indicated as functions related to protein synthesis and degradation, lipid synthesis and oxidation, and ATP hydrolysis were inhibited, and mitochondrial dysfunction was activated. This is the first time that skeletal muscle changes have been studied in male mice during spaceflight, and these mice were euthanized in space to avoid rehabituation to earth's gravity. These data add important new findings to changes that occur to the musculoskeletal system in male mice during spaceflight.Disclaimer: Research was conducted in compliance with the Animal Wel-

fare Act, and all other Federal requirements. The views expressed are those of the authors and do not constitute endorsement by the U.S. Army.

SUN-0305

High Fidelity of Mouse Models Mimicking Human Genetic Skeletal Disorders Resulting from Mutations in 316 Genes (Skeletal Dysplasia Society 2015 Nosology Update) Robert Brommage*, Claes Ohlsson. Centre for Bone and Arthritis Research, Sahlgrenska Academy, University of Gothenburg, Sweden

The 2015 Human Genetic Skeletal Disorders Nosology update (Bonafe L, Am J Med Genet A 167A:2869-2892; 2015) summarizes knowledge of human skeletal disorders with Mendelian inheritance. The 316 genes identified code for enzymes (33%), signal transduction proteins (17%), transcription factors (16%), scaffolding proteins (15%), cilia proteins (7%), extracellular matrix proteins (6%) and membrane transporters (5%).The goal of this analysis was to determine the extent to which mutant mouse models (spontaneous and chemical-inducted mutants, global and conditional gene knockout mice, and transgenic mice with gene overexpression or specific base-pair substitutions) show skeletal phenotypes similar to those observed in homologous human gene disordersThe human X-linked gene ARSE (Arylsulfatase E) and small nuclear RNA U4ATAC, a component of the minor spliceosome, do not have mouse homologues. Mutations in seven (3%) mouse genes (Fgf10, Flna, Hlxb9, Lmd3, Nsd1, Smarcal1, Wisp3) do not result in similar skeletal phenotypes observed with mutations of the homologous human genes. These discrepancies can result from failure of mouse models to mimic the exact human gene mutations.Skeletal phenotypes resulting from mutations in 200 mouse genes (63%) are similar to those observed in homologous human skeletal disorders. Mutant mice are not presently available for 56 (17%) of genes. For 52 mouse mutants (16%) possible bone phenotypes have not been investigated. Global gene knockouts of several of these genes result in early embryonic lethality, precluding skeletal analyses.Since many human disorders involve gain-of-function or dominant-negative mutations, future studies will undoubtedly utilize CRISPR/Cas9 technology to examine transgenic mice having genes modified to exactly mimic variant human sequences.These comparisons indicate that homologous mutations in 97% of mouse genes examined (200 of 207) result in skeletal phenotypes mimicking human skeletal disorders. Mutant mice provide excellent models for drug development, with examples including Acvr1 (Fibrodysplasia Ossificans Progressive), Casr (Familial Hypocalcemic Hypercalcemia), Notch2 (Hajdu-Cheney Osteolysis Syndrome) and Phex (Hypophosphatemic Rickets).The International Skeletal Dysplasia Society met during September 2017 and an updated Nosology summary is anticipated during 2018.

SUN-0306

Spontaneous Knee Osteoarthritis Caused by 1,25(OH)2D Deficiency Is Corrected by Overexpression of Sirt1 in Mesenchymal Stem Cells Jie Chen*[1], Na Lu[1], Lulu Chen[1], David Goltzman[2], Dengshun Miao[1]. [1]Nanjing Medical University, China, [2]McGill University, Canada

Vitamin D deficiency is associated with an increased risk of developing osteoarthritis (OA), however, the mechanisms are unclear. We compared the knee phenotypes of 6-month-old 1α(OH)ase-/- mice fed a high calcium/phosphate diet after weaning with age- and diet-matched wild-type mice. We found that serum calcium, phosphorus and PTH were normalized by the diet but serum 1,25(OH)2D3 was undetectable. In these mice, safranin O staining and type II collagen immunostaining of the articular cartilage of the medial femoral condyle and the tibial plateau were reduced compared to WT mice. In contrast, the summed tibial and femoral OARSI (Osteoarthritis Research Society International) score, the percentages of chondrocytes positive for type X collagen, MMP-3/13, β-galactosidase and p16, and inflammatory factors, including TNFα, IL-1α/β and IL-6 gene expression levels were all increased significantly in 1α(OH)ase-/- mice compared to WT mice. Furthermore, these OA phenotypes in 1α(OH)ase-/- mice became more severe with anterior cruciate ligament transection and with age, however, they were rescued by supplementation with exogenous 1,25(OH)2D3 or with antioxidant N-acetyl-L-cysteine. We then examined the expression of the NAD-dependent deacetylase, Sirt1 (Sirtuin1), which has previously been reported to exert a preventive role against the development of OA. The expression levels of Sirt1 were down-regulated significantly in 1α(OH)ase-/- chondrocytes compared to WT chondrocytes. By using a chromatin immunoprecipitation approach and luciferase assays, we then demonstrated that 1,25(OH)2D3 directly regulates Sirt1 expression at a transcriptional level, mediated via VDR. Since disruption of Sirt1 in chondrocytes can accelerate development of osteoarthritis, we crossed Prx1-Sirt1 transgenic mice with 1α(OH)ase-/- mice to generate 1α(OH)ase-/- mice with Sirt1 overexpression in mesenchymal stem cells (MSCs). Overexpression of Sirt1 in 1α(OH)ase-/- mouse MSCs rescued all OA phenotypes observed in 6- and 12-month-old 1α(OH)ase-/- mice. These studies therefore indicate that 1,25(OH)2D deficiency can induce the development of spontaneous knee OA by transcriptional down-regulation of Sirt1, inducing chondrocyte senescence and production of inflammatory factors, whereas overexpression of Sirt1 in MSCs can prevent the development of OA caused by 1,25(OH)2D deficiency.

SUN-0307

Effects of Alzheimer's Disease and high-fat diet on bone quality and quantity in mice Ryanne Chitjian*[1], Anthony Capellino[2], Lisa S Robison[3], Olivia J Gannon[3], Abigail E Salinero[3], Kristen L Zuloaga[3], David E Komatsu[2]. [1]Stony Brook University, Department of Biomedical Engineering, United States, [2]Stony Brook University, Department of Orthopaedics, United States, [3]Albany Medical College, Department of Neuroscience & Experimental Therapeutics, United States

Clinical observations have noted that patients with Alzheimer's Disease (AD) have a concomitantly higher incidence of osteoporosis and the data suggest that the two diseases share common antecedents. In addition, high-fat diets are know to exacerbate both AD and osteoporosis. Therefore, we sought to evaluate the interplay of AD and dietary fat intake on bone quality and quantity. 3xTg-AD mice containing three human mutant genes that result in familial AD, Psen1tm1Mpm, APPSwe, and tauP301L, on a mixed background and wild-type controls were utilized. At 2.5 months of age, the mice were randomized into groups and fed either a high-fat diet or a low-fat diet for the next 4.5 months and they were then euthanized at 7 months of age. Left femurs were subjected to μCT evaluation (μCT40, Scanco) at 10μm resolution to assess morphometric properties. Among female mice fed a low-fat diet, μCT analysis of the distal femoral metaphysis revealed significant increases in BV/TV (315%), trabecular thickness (141%), trabecular number (224%), and BMD (134%), as well as a decreases in BS/BV (61%) and SMI (85%) and for the 3xTg-AD mice compared to wild-type controls (p < 0.05). Similarly, analysis of the femoral mid-diaphysis in female mice fed a low-fat diet identified significant increases in bone volume (125%) and cortical thickness (129%) for the 3xTg-AD compared to wild-type controls (p < 0.05), as well as a trend toward decreased BMD. These morphometric data suggest that 3xTg-AD mice may have increased bone quantity compared to wild-type mice both in trabecular and cortical. However, as the wild-type controls were not littermates it is to early to determine if these findings are fully attributable to the genotype. Regardless, these data suggest that the interplay between AD, osteoporosis, and dietary fat is more complex than expected. We are currently performing additional morphometric and biomechanical analysis in these mice, as well as female mice subjected to high-fat diets and male mice subjected to low- and high-fat diets. As this study did not identify the concomitant development of AD and osteoporosis in this strain of mice, it suggests that we have only begun to elucidate the interactions between these two devastating and widespread diseases.

Investigating Zbtb40 as a Determinant of Osteoblast Function and Commitment Madison Doolittle*[1], Robert Maynard[1], Gina Calabrese[2], Charles Farber[2], Cheryl Ackert-Bicknell[1]. [1]University of Rochester, United States, [2]University of Virginia, United States

Osteoporosis is a polygenic disorder that occurs due to an imbalance between bone formation and resorption rates. Focusing our genetic studies on bone formation, we previously identified a genomic locus on Chromosome 4 associated with mouse osteoblast mineralization, which lies upstream of the uncharacterized gene Zinc Finger and BTB Domain-Containing 40 (Zbtb40). A locus for bone mineral density (BMD) at the homologous region in humans has been identified in multiple previous genome wide association studies. This gene has no known function; however, proteins from the same family are transcription factors that regulate cell differentiation and maturational commitment. Our studies indicate that Zbtb40 has its highest expression in the initial days of in vitro differentiation of both MC3T3-E1 preosteoblasts and primary calvarial osteoblasts, with expression tapering as these cells mature. Using siRNA-mediated gene silencing, we found that knocking down Zbtb40 expression in differentiating MC3T3-E1 cells drastically decreased alkaline phosphatase activity (a marker of osteoblast differentiation) and inhibited mineralization by mature osteoblast-like cells. Furthermore, silencing of Zbtb40 decreased expression of early osteoblast markers Col1a1, Runx2, and Sp7. Zbtb40 knockdown also inhibited expression of Msx2, a transcription factor that stimulates commitment of mesenchymal progenitors to the osteoblast over adipocyte lineage. Moreover, we found that expression of Pparg, an adipocyte marker, was markedly increased in these cells, suggesting Zbtb40 loss-of-function down-regulates osteoblast commitment and up-regulates adipogenesis. We constructed a CRISPR mutant mouse line with a germline mutation causing systemic production of a truncated form of the ZBTB40 protein to study loss-of-function in vivo. Female mice from this line exhibit decreased BMD (WT=0.052 g/cm2 Zbtb40mut=0.049g/cm2 p=0.035) and bone mineral content (WT=0.43 g Zbtb40mut=0.39 g p=0.024) at 16 weeks of age. In summary, we demonstrate that Zbtb40 has a role in bone metabolism whereby reduced expression leads to decreased osteoblast differentiation and mineralization in vitro, and decreased bone mass in vivo. These data strongly support the hypothesis that Zbtb40 is the gene underlying these mouse and human genetic loci and that this gene represents a novel regulator of bone mass, possibly through regulation of mesenchymal cell fate commitment down the osteoblast lineage.

Short Truncation of the C-terminus Tail of Connexin43 in Mice Causes Metaphyseal Dysplasia, Stunted Growth and Low Bone Mass Francesca Fontana*, Marcus Watkns, Roberto Civitelli. Washington University School of Medicine, United States

Connexin43 (Cx43) forms trans-cellular channels that allow direct gap junctional intercellular communication (GJIC) between apposing cells. Recent data indicate that the C-terminus tail of Cx43 also serves as a scaffold for components of signaling pathways important for osteogenic cells, independent of channel function. We have previously reported that mice with either conditional deletion of Gja1 or with one Gja1G138R mutant allele, found in patients with oculodentodigital dysplasia (ODDD), develop abnormally expanded long bones with thinner cortices, secondary to increased osteoclastogenic support by mutant osteoblastic cells. As the G138R Cx43 mutant abrogates gap junction channel function, these data corroborate the notion that GJIC is important for Cx43 action on bone remodeling. To further define the role of Cx43 signaling scaffold function in vivo, we generated mice carrying one Gja1 allele truncated of the last 5 aminoacids at the C-terminus, Gja1D378STOP/+;Tw2-cre (cDel5CTw2), thus removing the ZO1 binding site. In the heart, such mutation causes fatal arrhythmias, despite conserved gap junction channel function. Strikingly, young cDel5C mice exhibit stunted growth and 40% lower body weight at 4 weeks of age relative to WT littermates. They also have 20% lower whole-body bone mass by DXA at 6 weeks of age compared to control littermates, in both genders. Plane radiography reveals misshapen diaphysis and a flaring of the metaphyses of long bones remindful of the Erlenmeyer flask deformity typical of metaphyseal dysplasia. Consistently, Gja1D378STOP/+;Osx-cre (c5CdelOsx) mice exhibit similar delays in skeletal growth and juvenile phenotype, with low bone mass and Erlenmeyer flask deformity at 6 weeks of age. In cDel5CTw2 mice, the modeling defects slowly improve with aging, but the diaphyses become tubular, taking a shape observed in mice lacking Cx43 in osteolineage cells. Mechanistically, bone marrow stromal cells from cDel5C mice retain GJIC capacity but induce higher osteoclast numbers when co-cultured with bone marrow monocytes. Intriguingly, a mutation in the C-terminus tail of Cx43 has been recently identified in families with a rare recessive form of craniometaphyseal dysplasia (rCMD). Thus, both the gap junction and scaffolding/signaling functions are important for Cx43 modulation of bone modeling and osteoclastogenesis, offering pathogenetic mechanisms for the spectrum of Cx43 diseases, including ODDD and rCMD.

Aberrant Endo-lysosomal-mitochondrial System in Skeletal Progenitors Causes Inordinate Bone Growth Xianpeng Ge*[1], Lizhi He[2], Haibo Liu[3], Guangchuang Yu[4], Bradford Tremblay[3], Ben Zhang[5], Cole Haynes[3], Jaehyuck Shim[1]. [1]Department of Medicine, Division of Rheumatology, University of Massachusetts Medical School, United States, [2]Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, United States, [3]Department of Molecular, Cell and Cancer Biology, University of Massachusetts Medical School, United States, [4]State Key Laboratory of Emerging Infectious Diseases, School of Public Health, The University of Hong Kong, China, [5]Department of Orthopedics, University of Massachusetts Medical School, United States

The intracellular endo-lysosomal pathway is critical in keeping protein and metabolic homeostasis. A broad interaction between this pathway and mitochondria is being increasingly appreciated, thereby constituting an integrated endo-lysosomal-mitochondrial system. Dysfunction of this system can cause complex human diseases like lysosomal storage diseases which may manifest severe musculoskeletal abnormalities. Previously we discovered that the ESCRT protein CHMP5 is essential for lysosomal degradation in embryonic fibroblasts during development. To explore the role of CHMP5 in skeletal biology, we deleted this gene in periosteal/periarticular progenitors and endosteal/bone marrow DMP1-expressing bone lineage cells by generating Chmp5Ctsk and Chmp5Dmp1 mouse strains. Ablation of Chmp5 in these skeletal progenitors caused significant bone overgrowth including extended cortical bone, ectopic bone formation at entheses, progressive joint stiffness and craniofacial suture patency. Fate mapping using the Chmp5Ctsk;Rosa26-mTmGfl/+mouse line showed that both Chmp5 knockout and wild type cells were involved in the abnormal bone growth. Chmp5 knockout cells displayed decreased proliferation and enhanced mineralization when induced toward osteogenesis in vitro, while wild type GFP- cells showed both enhanced proliferation and osteogenesis. Mechanistic analyses revealed that Chmp5 depletion induced cellular senescence and elevated the secretory activity of skeletal progenitors. As observed in Chmp5 knockout mouse embryonic fibroblasts, the endo-lysosomal pathway was disrupted in Chmp5 depleted skeletal progenitors. Moreover, these progenitors demonstrated accumulation of mitochondria and elevated levels of extracellular acidification rate, mitochondrial respiration and reactive oxidative species. The increased oxidative stress may contribute to cellular senescence of Chmp5 knockout cells. Overall, our data revealed that CHMP5 is essential for normal function of the endo-lysosomal-mitochondrial system in skeletal progenitors. Mutation or loss of function of this gene can disrupt this intracellular quality control system, activate the aging process of skeletal progenitors and ultimately lead to multiple skeletal abnormalities. The Chmp5Ctsk and Chmp5Dmp1 mouse models recapitulate musculoskeletal pathologies in multiple human complex diseases and thus may

represent valuable animal models to explore the underlying mechanism and develop potential novel therapeutics.

Identification of putative variants underlying human hip bone geometry using murine functional epigenomics data Terence D. Capellini*[1], Yi-Hsiang Hsu[2], Mariel Young[1], Douglas P. Kiel[2], David Karasik[2]. [1]Human Evolutionary Biology, Harvard University, United States, [2]Institute for Aging Research Hebrew SeniorLife, United States

Hip geometry (HG) is an important predictor of bone fracture. We performed a meta-analysis of GWAS studies to identify genetic variants associated with proximal femur geometry. The Discovery stage included 18,719 adult men and women; in-silico replication included 8,334 men and women. We analyzed four geometry phenotypes measured from DXA scans: 1) Femoral neck length (FNL); 2) Neck-shaft angle (NSA); 3) Femoral neck width, and 4) Femoral neck section modulus (NNZ). In the top 13 genome-wide significant loci (p≤5x10-8), for the lead (index) SNP in each locus we identified all hg19 variants in LD with the conditionally independent lead SNP (r2 ≥ 0.4, 1000G build hg19). This yielded 880 SNPs in LD with HG variants. To whittle this variant list down to putative functional variants , the Assay for Transposase-Accessible Chromatin followed by sequencing (ATAC-seq) was performed genome wide using E15.5 embryonic mouse proximal femora to derive two datasets consisting of: (A) 24,804 proximal head+neck+femur growth plate ATAC-seq peaks; and (B) 22,727 femoral head-specific peaks. After mapping the peaks in mice to the human genome, we used BED intersection tools and the UCSC Genome Browser to detect and visualize overlaps between a HG variant and an ATAC-seq (open chromatin) peak. Strikingly, our intersections with the complete proximal femur dataset (A) revealed 9 HG variants from 4 loci that overlapped an ATAC-seq peak. At the HHIP locus (Chr. 4) associated with NNZ, rs13106087 (r2 = 0.9 with the lead variant) resided within an ATAC-seq peak marking the promoter region (Figure1). At the IRX1/ADAMTS16 locus (Chr. 5) associated with FNL, four variants fell within the same cis-acting ATAC-seq peak, whereas at the GDF5/UQCC1 locus (Chr. 20) three variants associated with NNZ fell in separate ATAC-seq peaks. Intersections with the femoral head-specific dataset (B) yielded two variants in an intronic peak in the C8orf34 locus (Chr. 8) associated with NSA. The remaining loci did not yield intersections with either dataset. In conclusion, we found associations between HG measures and several genes belonging to biological pathways relevant to body size. Associated HG proxy SNPs were identified through intersections with epigenomic datasets relevant to proximal femoral morphology. Integration of GWAS with molecular data from bone development underscores the significance of non-coding variants and aids in understanding the biology underlying normal human bone geometry.

SUN-0312

Distinct subsets of non-coding RNAs, including miRNAs, are associated with BMD in stressed and unstressed bone Kaare M. Gautvik*[1], Clara-Cecilie Günther[2], Mazyar Yazdani[3], Einar Lindalen[1], Haldor Valland[4], Vigdis T. Gautvik[1], Ole K. Olstad[3], Marit Holden[2], Tor P. Utheim[3], Sjur Reppe[1]. [1]Lovisenberg Diakonale Hospital, Norway, [2]Norwegian Computing Center, Norway, [3]Oslo University Hospital, Norway, [4]Diakonhjemmet Hospital, Norway

The causes and molecular pathogenesis of postmenopausal osteoporosis (PMO) are far from understood even though osteoporotic fractures affect almost 50% of women above 50 years of age, resulting in e.g. femoral neck fractures imposing high risk to normal life. We addressed this issue by characterizing the global non-coding RNA (ncRNA) transcriptomes in non-weight bearing (unstressed) iliac and weight bearing (stressed) femoral postmenopausal bone across BMDs varying from normal (T-score >-1.0) to osteoporotic (T-score ≤ -2.5). The analyses were performed on transiliacal (84) and femoral trochanter (18) bone biopsies. Nearly 700 iliac bone ncRNAs were determined by a PCR based method and more than 6600 femoral ncRNAs were accessed by Affymetrix microchip analysis. BMD associations were calculated by linear regression and validated by Lasso analysis. DIANA TOOLS – mirPath v.3 software was used to identify overrepresented signaling pathways among the BMD associated transcripts at the two different sites.In iliac bone 36 or 75 ncRNAs were associated with age and body mass index (BMI) adjusted total hip BMD at 1% or 10% FDR, respectively. Lasso analysis involving cross validations identified nine iliac bone ncRNAs explaining 41% of the BMD variation. In trochanter, we identified 89 ncRNAs correlated to total hip, age and BMI adjusted BMD at 0.1% FDR. Several miRNAs, including hsa-miR-484, hsa-miR-378a-5p, and hsa-miR-409-3p, correlated positively to BMD in femoral

bone, but inversely to BMD in iliac bone. Furthermore, several ncRNAs correlating to BMD in iliac bone were not correlated in femoral bone, and vice versa. Several small ncRNAs were correlated to BMD in both stressed and unstressed bone. Using mirPath v.3 with conservative statistics, the "Extracellular matrix-receptor interaction" pathway came out as the topmost, involving KEGG pathway in both stressed and unstressed bone with same p=1E-325. "Fatty acid biosynthesis" and "Fatty acid metabolism" were significant only in unstressed bone (p=1E-325 and p=8E-8, respectively).In conclusion, we have performed a comprehensive mapping of ncRNAs in stressed and unstressed bone from postmenopausal women with greatly varying BMDs and identified striking differences in the expression pattern between the two tissues. The differences may reflect a requirement for higher turnover in stressed bone, e.g. due to repair of microfractures and demonstrate a remarkable functional adaptability of bone tissue.

SUN-0313

An evolving classification system for the range of skeletal phenotypes encountered in IMPC mice. David Rowe*[1], Douglas Adams[2], Hong Seung-Hyun[3], Caibin Zhang[4], Shin Dong-Guk[3], Sundberg John[5], Cheryl Ackert-Bicknell[6]. [1]School of Dental Medicine, University of Connecticut, United States, [2]School of Medicine, University of Connecticut Health, United States, [3]School of Engineering, University of Connecticut, United States, [4]School of Dental Medicine, University of Connecticut Health, United States, [5]The Jackson Laboratory, United States, [6]University of Rochester School of Medicine, United States

The International Mouse Phenotyping Consortium (IMPC) lists >10,000 gene-inactivated mouse lines. We have examined 220 unselected KO lines by μCT and bone cryohistolomophometry and find that about 12.5% have significant variation in bone mass (trabecular or cortical) that is exceptionally dimorphic for both sex and site (appendicular vs axial). Our data and that of others indicate the ~2,500 homozygous viable KO genes contribute to variance in bone mass. The number will be even greater when mice heterozygous for a perinatal lethal homozygous mutation are examined. Thus the magnitude of the genetic influence on skeletal health is overwhelming. We are exploring how to present this broad array of KO mice that is reliable, informative and organized in a manner that recognizes similar patterns of bone architecture, body size and osteoclast (Oc) number and osteoblast (Ob) activity as interpreted by bone cryohistomorphometry. Two well-characterized KO lines, Irf8 and Spp1, were encountered that provide a comparison of data produced by individual research laboratories and our screening program. Based on this experience, two levels of classification have been developed. (1) Bone architecture and body weight: Low and high trabecular bone volume can be subdivided by the presence of a corresponding normal, low or high bone size and body weight. The latter two groups have an overall phenotype of frailty and fitness. Bone size can also vary without a change in trabecular bone volume. (2) Dynamic cellular activity of bone: KO lines with a low bone mass (low trabecular volume and/or bone size) can be classified as having high turnover or remodeling (high Oc number and Ob activity), adynamic bone or low remodeling (low Oc number and Ob activity), Oc/Ob uncoupling or low modeling (normal Oc number and low Ob activity) and ineffective Ob function (low Oc number and high Ob activity). KO lines with a high bone mass (high trabecular volume and/or bone size) can be classified as low remodeling (low Oc number with normal Ob activity), ineffective remodeling (high Oc number without an increase Ob activity) and continued modeling activity (low Oc number and high Ob activity). These classification patterns are likely to be expanded as more KO lines are encountered and additional phenotyping criteria are developed. As this basic fund of knowledge grows, it will contribute to the interpretation of genomic sequencing of human subjects with disorders of the bony skeleton.

SUN-0314

Male specific low bone mass phenotype in Down Syndrome humans and mouse models Diarra Williams*[1], Alexis Mitchell[1], Alyssa Falck[1], Shannon Huggins[1], Kent Mckelvey[2], Dana Gaddy[1], Larry Suva[1]. [1]Texas A&M University, United States, [2]University of Arkansas for Medical Sciences, United States

Low BMD in people with Down syndrome (DS) is associated with impairments in skeletal maturation and bone-mass accrual that predispose patients to fracture. We previously identified that low BMD and low bone turnover was common in healthy, euthyroid, calcium-replete, community dwelling adults with DS. Indeed, serum bone turnover markers were significantly decreased in the face of profound hypogonadism, a situation that is usually associated with high bone turnover. Moreover, the low bone mass condition was more pronounced in DS men and osteopenia appeared earlier in males than females; although bone deficits progressed with age in each group. In order to investigate this apparent sex difference, we have characterized the skeletal phenotypes of 3 of the most commonly used murine DS models, Ts65Dn, Tc-1, and DP16(Yey1). Human chromosome 21 (Hsa21) contains ~300 genes of which 166 orthologs are present in mice and carried on three murine chromosomes (Mmu10, 16, 17). Ts65Dn mice are trisomic for 152 genes of Mmu16, Tc-1 are transchromosomic for Hsa21 (trisomic for 152 genes) and Dp(16)1Yey are trisomic for the entire syntenic region of Mmu16 and contain 110 genes orthologous to Hsa21. These murine models manifest as DS and recapitulate many, but not, all of the phenotypic characteristics

of human DS and have been used extensively to investigate the pathology of DS behavioral, cardiac and metabolic phenotypes. We previously reported that Ts65Dn male mice phenocopy the low bone mass phenotype of human DS. However, in comparison with Ts65Dn mice, Tc-1 mice that model many of the behavioral aspects of DS lack any discernible bone phenotype. Female Ts65Dn mice are unavailable for study. However, we have analyzed the bone phenotype of both male and female 3 month old Dp(16)1Yey mice, and identified that just as in humans, the low bone mass phenotype in DP16(Yey1) is also more pronounced in males. Male Dp(16)1Yey mice display low total body BMD, tibial trabecular BV/TV and number, decreased total cross-sectional area, periosteal and endosteal perimeters, with significantly diminished mineral apposition rates. These data demonstrate that both Ts65Dn and Dp(16)1Yey DS have low bone mass more consistently in males than females that appears to be the result of decreased bone accrual. In sum, these animals have the potential to provide a more detailed understanding of the genetic and cellular basis for the altered bone development of people with DS.

Metabolomic signatures of high fruit and vegetable intake and reduced prevalence of osteoporosis: The Boston Puerto Rican Osteoporosis Study
Kelsey Mangano*[1], Sabrina Noel[1], Chao Qiang Lai[2], Laurence Parnell[2], Jose Ordovas[2], Katherine Tucker[1]. [1]University of Massachusetts, Lowell, United States, [2]Nutrition and Genomics Laboratory, Jean Mayer U.S. Department of Agriculture Human Nutrition Research Center on Aging, Tufts University, Boston, MA, United States

There is evidence that fruit and vegetable [FV] intake is important for bone health, but the mechanisms underpinning this link remain unclear. The purpose of the current study was to examine associations between FV intake and metabolomic profiles in 586 older adults, aged 47-77y, from the Boston Puerto Rican Osteoporosis Study (BPROS), an ancillary study to the Boston Puerto Rican Health Study (BPRHS). Bone mineral density was measured using dual-energy X-ray absorptiometry and osteoporosis (OS) at the femoral neck or the lumbar spine was defined as T-score, ≤ 2.5 (2.5 SD or more below peak bone mass of a 30 y/o reference group). Usual dietary intakes were assessed with a food frequency questionnaire, adapted and validated for use in this population. The association between total FV intake and odds of OS was assessed by logistic regression. Metabolomic analyses were conducted to determine associations between FV intake, metabolites and OS. Enriched metabolic pathways related to FV-associated metabolites were examined for enzyme inhibition among participants with and without OS. Covariates included age (y), sex, education, menopause, smoking status, alcohol status, physical activity score, total energy intake, height and body mass index. Greater FV intake was associated with lower prevalence of OS (P=0.031). Among participants without OS, 66 metabolites were associated with high FV intake. In men without OS, FV intake was related to 38 metabolites, vs. 66 metabolites in women without OS. In both men and women, 30 metabolites were associated with OS, without correction for multiple testing. Of these metabolites, 10 were overrepresented in the branched chain amino acid (BCAA) metabolic pathway (P≤5.65x10-15) in men; and 10 were overrepresented in the steroid hormone pathway (P≤8.49x10-21) in postmenopausal women not taking estrogen. Hence, these results suggest that sex-specific metabolic pathways are linked to OS with FV-associated metabolite enrichment. Of the 66 identified metabolites associated with FV intake, five were observed as inhibitors of enzymes in the steroid hormone pathway in women and one inhibitor of L-amino-acid oxidase, encoded by the IL4I1 gene, in the BCAA pathway in men. We hypothesize that high FV consumption is associated with reduced risk of OS through regulation of the steroid hormone pathway in women; data in men are less clear. Future research should elucidate downstream effects of modulated metabolic pathways by FV metabolites.

Exercise preconditioning promotes bone anabolism in hind-limb suspended mice via miR-152-3p-TFAM signaling dependent mitochondrial DNA replication Jyotirmaya Behera*, Suresh C Tyagi, Kimberly E Kelly, Neetu Tyagi, Nicholas Theilen. University of Louisville, United States

Aims: Exercise exerts a wide range of biological actions in the body, especially in the promotion of bone mass. However, critical process of mitochondrial DNA (mtDNA) replication that regulates mitochondrial biogenesis and bone formation during exercise is largely unknown. Therefore, we aimed to investigate whether exercise affects mtDNA replication to promote bone anabolism in a hind-limb suspension (HLS) induced bone loss model. We hypothesize that exercise enhances mtDNA copy number via inhibition of DNA methyltransferase 1 (Dnmt1) transcription and TFAM promoter demethylation. Methods: To test this hypothesis, 12-week-old female mice were underwent preconditioning treadmill exercise (5 day/week@7-11 m/min) for 4 weeks followed by HLS for another 3 weeks. Results: Here, we demonstrated that trabecular bone phenotype (BV/TV; 34% in the femur) was significantly increased upon exercise treadmill test in comparison with HLS group, as assessed by In vivo, μCT measurements. In vitro study also confirmed BMMSC derived osteoblast mineralization was increased upon exercise administration. MicroRNA analysis using qRT2-PCR array demonstrated a significant reduction in the transcript expression of

microRNA-152-3p (miR-152-3p) in the BMMSCs of HLS mice as compared to wild-type controls. The sequence matching tools also validated miR-152 targets the Dnmt1 transcriptional activity by binding to its 3′UTR of Dnmt1 mRNA. It was demonstrated that hyperhomocysteinemia (HHcy) phenotype was observed in HLS mice group. The mechanistic study revealed that HHcy reduced miR-152 transcriptionally upregulates the Dnmt1 expression. Bisulfite sequencing PCR (BSP) and methylation-specific PCR (MSP) confirmed that HLS enhanced TFAM promoter hyper-methylation leads to reduced mtDNA copy number and oxidative phosphorylation. Administration of miRNA mimics (agomiR) or Dnmt1 knockdown diminished the HLS obliterated mtDNA replication, and BMMSCs mediated osteogenesis. In addition, TFAM knockdown diminished exercise-enhanced in vivo bone formation. We further found that exercise was able to reverse the plasma level of Hcy which caused to upregulate the transcript level of microRNA-152-3p and decreases the Dnmt1 transcription. Conclusion: Our data provide the evidence that exercise administration contributes to mtDNA replication and bone formation via epigenetic mechanism miRNA-TFAM signaling and provides a novel therapeutic avenue against osteoporosis.

Transcriptional Profiling of Two Mechanisms of Bone Fracture Repair
Brandon Coates*, Jennifer Mckenzie, Evan Buettmann, Matthew Silva. Washington University in St. Louis, United States

Bone fracture is a debilitating orthopedic injury. Depending on the severity of the injury, fractures heal through either endochondral ossification, which has a cartilaginous intermediate state, or intramembranous ossification, which is direct bone formation. While these bone repair types have been well studied separately, the specific molecular cues that govern their similarities and differences have not been documented. Twelve-week old C57BL/6J female mice underwent either a full femur fracture (Fx) to induce endochondral bone repair, or an ulnar stress fracture (Sfx) to induce intramembranous bone repair. Post fracture time points were selected to coincide with periods of inflammation, angiogenesis, and osteogenesis which are characteristic for endochondral (4 hrs, 1, 3, 7, & 14 days) and intramembranous (4 hrs, 1, 3, 5, & 7 days) repair. RNA-seq analysis (n=5 mice/group; N=50 total) was performed on bilateral bone segments including bone and callus tissue. Segments were pulverized, RNA was extracted, and RINs were measured to assure quality (RIN > 6). All samples were processed by using Illumina HiSeq, 50 bp single end reads and mapped to mouse genome mm10. Injured samples in each time point were compared to pooled non-fractured controls (n=10/fracture type) for differential expressed genes (DEGs) (FDR<0.05 and fold-change >2). Fx resulted in immediate and robust differential expression that continued through all time points and peaked at 7 days post-fracture. Sfx had little change in expression at 4 hrs and 1 day with more robust differential expression for the remaining time points and a peak at day 5 post-fracture. Tracking the fold change of genes with annotations of inflammation, angiogenesis, cartilage development, and ossification revealed some differences between fracture types (Fig 1). Fx induced a higher upregulation of inflammatory and angiogenic genes, especially at early time points. Contrastingly, Sfx repair displayed an earlier and more prolonged upregulation of ossification related genes. This works represents a valuable source of data that can illuminate many unanswered questions about endochondral and intramembranous fracture healing. With these data we can probe the expression of single genes, gene families, and signaling pathways in two distinct types of bone formation across several time points, providing useful insight into the complex biological process of fracture repair.
Figure 1. Heat maps of the Log2 fold change (over contralateral controls) for each time point of fracture repair for gene lists with annotations of "Inflammatory Response" and "Ossification" generated using AmiGO2. Fx has a strong upregulation of inflammatory genes at early time points, while Sfx has a much more subdued reaction to injury. Both injuries show robust upregulation of ossification related genes, especially at later time points, with Sfx turning on these genes earlier than Fx.

Using Co-expression Network Analysis to Inform GWAS for Bone Mineral Density Olivia Sabik*[1], Gina Calabrese[1], Cheryl Ackert-Bicknell[2], Charles Farber[1]. [1]University of Virginia, United States, [2]University of Rochester Medical Center, United States

Genome-wide association studies (GWASs) have identified over 200 genomic loci associated with bone mineral density (BMD); however, the causal genes are unknown for the majority of loci. Here, we hypothesized that causal genes underlying a subset of BMD GWAS loci could be identified by integrating GWAS data with an osteoblast specific co-expression network. Our approach was based on the idea that a subgroup of causal genes are likely to influence BMD via osteoblast-mediated bone formation and genes involved in specific biological processes are often co-expressed. To test this hypothesis, we applied weighted gene co-expression network analysis (WGCNA) to genome-wide gene expression profiles of mineralizing calvarial osteoblasts from a population of genetically diverse mice and identified 65 modules of co-expressed genes. Of these, one module was significantly enriched for genes located within BMD GWAS loci (odds ratio (OR) = 3.4, P = 4x10-9) and its expression was significantly correlated with in vitro levels of mineralization (r = 0.49; FDR = 0.012). This module was also enriched for skeletal development genes (OR = 8.58; P <2.2x10-16), and for genes that result in a bone phenotype when knocked-out (OR = 4.06; P = 2.14x10-9). Genes in this module were expressed in two distinct patterns, either early or late in osteoblast differentiation, and the enrichments listed above were increased in the late differentiation group. Additionally, we observed that the mean connectivity of GWAS-implicated genes was significantly higher than non-GWAS genes, leading us to prioritize genes based on their degree of connectivity within the module. Of the 30 most highly connected genes in the late differentiation subset, 13 had not been previously linked to bone formation, and three (Beta-1,4-N-Acetyl-Galactosaminyltransferase 3 (B4galnt3), Cell Adhesion Molecule 1 (Cadm1), and Solute Carrier Family 8 Member A3 (Slc8a3)) were located within BMD GWAS loci. For all three genes, their expression in humans was regulated by local expression quantitative trait loci (eQTL) that colocalized with the BMD GWAS associations. Furthermore, B4galnt3 and Cadm1 knockout mice had decreased whole-body BMD and Slc8a3 knockout mice exhibited increased vertebral trabecular bone volume fraction. Through the integration of mouse co-expression network analysis and GWAS data, we have identified the genes responsible for three BMD GWAS associations and improved our understanding of the genetics of BMD.

Genetic Variants Associated with Circulating Parathyroid Hormone among Patients with Chronic Kidney Disease Cassianne Robinson-Cohen*[1], Farzana Perwad[2], Myles S. Wolf[3], Ian H. De Boer[4], Bryan Kestenbaum[4], Loren Lipworth[1], Adriana Hung[1], T. Alp Ikizler[1]. [1]Vanderbilt University Medical Center, United States, [2]University of California San Francisco, United States, [3]Duke University, United States, [4]University of Washington, United States

Recent genome-wide association studies (GWAS) identified loci associated with differences in parathyroid hormone (PTH) concentrations, near genes involved in vitamin D metabolism and calcium and renal phosphate transport. These studies were conducted among individuals with preserved kidney function. It is possible that genetic contributions to circulating PTH may differ among individuals with mineral metabolism disturbances, such as those with chronic kidney disease (CKD), in whom the biologic implications and potential treatment options are most relevant. We examined 5 SNPs previously identified in GWAS of PTH (index SNPs) and 53 putatively functional SNPs in the surrounding regions (±250kb) among unrelated individuals of European ancestry (n=1,666) who participated in the Chronic Renal Insufficiency Cohort (CRIC) Study. We additionally tested for interactions of eGFR on the SNP-PTH association.Two index SNPs were associated with PTH, after adjustment for age, sex, eGFR and BMI: rs6127099 at 20q13.2/CYP24A1 (beta coefficient for the T allele: 4.5% higher PTH, 95% CI: 0.28,8.83, p=0.036) and rs4074995 at 5q35.3/RGS14 (beta for the G allele: 5.7% higher PTH, 95% CI: 1.19,10.42, p=0.013). All 5 SNPs were directionality-consistent with the previously published results. When we expanded to surrounding functional variants, 21 SNPs were associated with PTH (false discovery rate ≤ 0.05), all within the 5q35.3 region. The strongest association was for rs3812035 in SLC34A1 (NaPi-IIa) (beta for the A allele: 7.8% lower PTH, 95% CI: -11.6,-3.9, p=1x10-4). Statistically significant interaction by eGFR was noted for the association of rs1801725 at 3q13.33/CASR (p<0.05).Our findings provide evidence that some genetic variants associated with PTH under normal conditions are also associated with PTH in the setting of CKD. Larger, more comprehensive studies are needed to fully assess the generalizability of published GWAS findings and to identify potential novel associations in CKD. Both replication and lack of replication of published GWAS findings in CKD provides important information on the genetic etiology and the importance of pathways influencing mineral metabolism disorders.

PTEN REGULATION ALLEVIATES THE ALCOHOL-INDUCED OSTEOPENIA IN RAT VIA AKT/GSK-3B/B-CATENIN PATHWAY IN BMSCS Yi-Xuan Chen*, You-Shui Gao, Chang-Qing Zhang. Shanghai Sixth People hospital, China

Background: Alcohol is regarded as a leading risk factor of osteopenia. Our previous works indicated Akt/GSK-3β/β-catenin pathway plays crucial role in the ethanol-induced anti-osteogenic effect in bone mesenchymal stem cells (BMSCs). It was acknowledged that PI3K/Akt is negatively regulated by the phosphatase and tensin homologue (PTEN) phosphatase. PTEN expression was reported to be upregualted in ethanol-administrated animals. Objectives: In this study, we explored the molecular mechanisms underlying alcohol-induced osteopenia and investigated the role of PTEN and Akt/GSK-3β/β-catenin axis in this pathological process.Methods: In vitro, Western blotting, separation of nucleus and cytosolic extracts, confocal scanning, RT-PCR were used to investigate the inhibition of ethanol on Akt/GSK3β/β-catenin signaling pathway via upregulation of PTEN in hBMSCs. In vivo, micro-computerized tomography, hematoxylin & eosin (H&E) staining, Van Gieson staining, Masson's trichrome and fluorochrome labeling were employed to reveal that PTEN inhibition provided protective effects against ethanol on bone tissue.Results: We found that ethanol increased PTEN expression both in BMSCs and in bone tissue of ethanol-administrated rats. PTEN upregulation impaired the recruitment of Akt to the plasma membrane, and suppressed Akt phosphorylation at Ser473, there by inhibiting the Akt/GSK3β/β-catenin signaling pathway in BMSCs and inhibited the expression of osteogenic genes COL1 and OCN both in vitro and in vivo. To counteract the inhibitory effect of ethanol, two selective PTEN inhibitors were introduced. The result of micro-computerized tomography, hematoxylin & eosin (H&E) staining, Van Gieson staining, Masson's trichrome and fluorochrome labeling indicated PTEN inhibition provided protective effects against ethanol on bone tissue. Interestingly, our data revealed that the mRNA of PETN, paralleled with PTENP1, was increased in a time-dependent manner upon ethanol stimulation, which resulted in increasing PTEN protein level. In addition, ethanol increased PTEN expression while decreased p-PTEN expression in a time-dependent manner, which indicated the generation of more functional PTEN.

Megalin-Mediated 25-hydroxyvitamin D Actions in Human Mesenchymal Stem Cells Yuan Gao*, Simon Luu, Shuanhu Zhou, Julie Glowacki. Brigham and Women's Hospital, United States

Between 85-90% of circulating 25-hydroxyvitamin D [25(OH)D] is bound to D-binding protein (DBP), but implications of free and bound 25(OH)D are not known. Megalin is a cellular receptor for DBP in renal tubular epithelial cells, but nothing is reported about

megalin in human Mesenchymal Stem Cells (hMSCs). We tested the hypotheses that (i) megalin is expressed in hMSCs, (ii) megalin is required for 25(OH)D but not 1α,25-dihy-droxyvitamin D(1,25)-induced osteoblastogenesis, and (iii) megalin is required for DBP-dependent 25(OH)D action. hMSCs from surgically discarded marrow were used for gene expression by RT-PCR and alkaline phosphatase (ALP) enzyme activity for osteoblasto-genesis. Transient transfection of siRNA for megalin (si-Meg) and control (si-Ctr) was performed with the Human MSC Nucleofector Kit (Lonza). Because constitutive megalin was variably expressed in 15 specimens, hMSCs with high (hi-Meg) or low (lo-Meg) megalin were studied first. Both 1,25 (10nM) and 25(OH)D3 (100nM) induced osteoblast signature genes Runx2 and ALP (3d), and stimulated ALP activity (Panel A, 7d in osteogenic medium, p<0.05) in hi-Meg hMSCs, but only 1,25 did so in lo-Meg hMSCs. The amount of extra-re-nal 1,25 biosynthesized from 25(OH)D3 by si-Meg hMSCs was only 26% of that for si-Ctr cells (p<0.05). Both 1,25 and 25(OH)D3 increased expression of Runx2, ALP, and BSP, and stimulated ALP activity (Panel B, p<0.05) in si-Ctr cells, but only 25(OH)D failed to do so in si-Meg cells. In 10% fetal bovine serum (FBS), 25(OH)D3 induced target gene CYP24A1 in hi-Meg and si-Ctr cells, but was blocked in lo-Meg and si-Meg cells. In contrast, 1,25 induction of CYP24A1 was equivalent in MSCs between hi-Meg and lo-Meg or between si-Meg and si-Ctr. In serum-free medium however, 25(OH)D3 stimulated CYP24A1 in all hi-Meg, lo-Meg, si-Meg, and si-Ctr hMSCs. Addition of 0.02 g/L rhDBP to serum-free me-dium blocked 25(OH)D3's induction of CYP24A1 in lo-Meg and si-Meg hMSCs, but not in hi-Meg and si-Ctr hMSCs; thus megalin was required for CYP24A1 activation by the DBP-dependent 25(OH)D3, but not for free 25(OH)D. In conclusion, to our knowledge, this is the first study showing that megalin is expressed in hMSCs and is required for extra-renal hydroxylation of 25(OH)D and production of 1,25 and for the 25(OH)D/DBP complex to stimulate VDR targets and osteoblastogenesis in hMSC.

Phosphorylation of S122 in ERα is Dispensable for the Physiological Regulation of the Skeleton in Female Mice Karin Gustafsson*[1], Helen Farman[1], Petra Henning[1], Vikte Lionikaite[1], Sofia Movérare-Skrtic[1], Klara Sjögren[1], Pierre Chambon[2], Claes Ohlsson[1], Marie Lagerquist[1]. [1]Centre for Bone and Arthritis Research at the Institute of Medicine, Sahlgrenska Academy at University of Gothenburg, Sweden, [2]Institut de Génétique et de Biologie Moléculaire et CellulaireCentre National de la Recherche Scientifique, National de la Sante et de la Recherche Medicale, ULP, Collège de France, Illkirch-Strasbourg, France

Estrogen signaling leads to cellular responses, not only in reproductive tissues, but also in several other tissues, including the skeleton. Loss of estrogen leads to increased risk of postmenopausal osteoporosis and fracture. It is therefore important to increase our knowl-edge regarding estrogen signaling in the skeleton. ERα, the main mediator of estrogen effects in the skeleton, is widely subjected to posttranslational modifications (PTMs). PTMs can affect cellular responses to estrogen in a tissue specific manner by influencing the function of ERα and its interactions with other proteins. Phosphorylation of S122 has been shown, in vitro, to affect the transcriptional activity of ERα, but the role in vivo is still unknown. Our aim was to investigate if phosphorylation of S122 in ERα is involved in the physiological regulation of the skeleton in vivo. Female mice with a point mutation in S122 (S122A) were compared to wild-type (WT) littermates and analyzed using DXA at 3, 6, 9, 12 and 15 months of age, and high resolution micro CT at 3 and 15 months of age. S122A mice had normal levels of estradiol and testosterone compared to WT mice, as measured using GC-MS/MS, demonstrating a normal sex steroid feedback. DXA analysis showed no difference in total body bone mineral density between S122A and WT mice at any time point. Further-more, analysis using micro CT demonstrated that the trabecular bone fraction (BV/TV) in long bones and vertebrae, as well as cortical thickness in long bones were similar between S122A and WT mice at both 3 and 15 months of age. Interestingly, S122A mice displayed significantly increased fat content, as analyzed by DXA, at 6, 9, 12 and 15 months of age. In conclusion, we demonstrate that phosphorylation of S122 in ERα might have a role in the regulation of fat mass in older mice, but that it is dispensable for the physiological regulation of the skeleton in female mice.

SUN-0364

Glucocorticoid receptor dimerization is deleterious in trauma-induced compromised fracture healing Yasmine Hachemi*[1], Anna E. Rapp[2], Ann-Kristin Picke[1], Anita Ignatus[3], Jan Tuckermann[1]. [1]Institute of Comparative Molecular Endocrinology, Ulm University., Germany, [2]German Rheumatism Research Centre, Germany, [3]Instiue of Orthopedic Research and Biomechanics, Center for trauma research, Ulm University Medical Center., Germany

After severe trauma, fracture healing is impaired. Glucocorticoids (GCs), acting via the glucocorticoid receptor (GR) influence fracture healing by modulating the trauma-induced local and systemic inflammation. Our previous study revealed an important role of the GR in endochondral ossification by promoting cartilage to bone transition. GR dimerization depen-dent gene regulation is essential for the anti-inflammatory effects of GC. In a murine model of trauma, combining femur osteotomy and blunt thorax trauma, resembling human trauma situations such as a car accident, we aim to investigate how GR dimerization affects trauma response towards fracture. Therefore we used male BALB/C mice with a point mutation im-pairing GR dimerization capacity (GRdim) and wildtype littermate control mice (WT). We performed a femur osteotomy stabilized by an external fixator and challenged the mice with an additional thorax trauma. Subsequently, healing phase was analysed by histomorphom-etry, μCT, and biomechanics.As expected, in WT mice the thoracic trauma compromised fracture healing. Bone formation in the fracture callus was strongly reduced in comparison to WT mice with fracture only (-47%, p=0.003), resulting in poor mechanical properties of the healed bone and reduced bending stiffness (-68%, p=0.001). In contrast, fracture healing was not impaired in GRdim mice after additional trauma. Furthermore, 23 days after osteot-omy, residual cartilage was increased in calli of WT compared to GRdim mice after thorax trauma (+167%, p=0.0009).Collectively, our data show that intact GR dimerization critically contributes to trauma-induced compromised bone repair.

SUN-0365

Relaxin Accelerates Rat Midpalatal Suture Expansion and Subsequent Bone Formation Hiroyuki Kamimoto*, Yukiho Kobayashi, Keiji Moriyama. Department of Maxillofacial Orthognathics, Division of Maxillofacial and Neck Reconstruction, Graduate School of Medical and Dental Sciences, Tokyo Medical and Dental University, Japan

Objectives: Relaxin (RLN) is an insulin-like peptide hormone that enables softening and lengthening of the pubic symphysis and uterine cervix. This study analyzed the effect of RLN2 on the expansion of rat midpalatal suture (MPS) using a magnetically controlled liposome-based drug delivery system. Materials and Methods: Thirty-six male SD rats were divided into three groups: the control (MPS was not expanded), lipo (MPS expanded for 1 week, treated with liposome only), and RLN-lipo groups (MPS expanded for 1 week, treated with liposomes encapsulating RLN2 [100 ng/kg], ferric oxide, and fluorescent Cy5.5 dye). Each group was subdivided into two groups: the expansion group, sacrificed after the 1-week expansion, and the retention group, sacrificed after a 2-week retention period following ex-pansion. MPS expansion was performed using a helical spring of 0.014-inch orthodontic stainless-steel wire. To accumulate RLN2-liposome, a magnetic sheet was fixed to the pala-tal mucosa, just above the MPS. Either liposomes or RLN2-liposome mixture were injected into the MPS every 48 h. Bone histomorphometric analysis was performed by bone dou-ble-labeling method with calcein and tetracycline. Accumulation of liposomes was tracked in vivo using IVIS imaging system. Morphological analysis of skeletal tissue was performed by micro-CT, HE, and alkaline phosphatase (ALP) staining. Expressions of RLN2, Rln re-ceptor (Rxfp) 1 and 2, periostin (Postn), inducible NO synthase (iNos), and matrix metallo-proteinase-1 (Mmp-1) in the MPS were analyzed by immunohistochemical (IHC) staining. Results: In vivo imaging showed magnetically controlled accumulation of liposomes in the MPS area for 72 h. IHC staining revealed the existence of applied RLN2 in the MPS after the expansion, and Rxfp2 expression at the osteogenic front (OF) in the RLN-lipo group alone, while all groups expressed Rxfp1 in the MPS. Micro-CT, bone double-labeling, and ALP staining showed significantly accelerated MPS expansion and bone formation at the OF in RLN-lipo group as compared to other groups. In the RLN-lipo group, HE staining revealing sinuous bone deposition at the OF, while IHC staining showed increased expression of iNos and Mmp-1 in the MPS and Postn at the OF. Discussion and Conclusions: These results suggested that RLN promoted MPS expansion through secretion of iNos and Mmp-1 by fibroblasts in the MPS, and it could enhance subsequent bone formation by Postn at the OF during the MPS expansion via Rxfp2.

Skeletal Effects of Non-Genomic Thyroid Hormone Receptor (TR) β1 Signaling in Mice Richard Lindsey*[1,2], Catrina Godwin[1], Subburaman Mohan[1,2]. [1]Musculoskeletal Disease Center, VA Loma Linda Healthcare System, United States, [2]Department of Medicine, Loma Linda University, United States

Thyroid hormone (TH) levels increase rapidly during the prepubertal growth period in mice, and studies have shown that this change is necessary for endochondral ossification of

the epiphyses. Recent studies have suggested that the effect of TH on epiphyseal chondrocyte hypertrophy involves TRβ1-mediated activation of Indian hedgehog (IHH) signaling. In addition to its traditional genomic signaling role as a transcription factor, TRβ1 can also exert non-genomic effects by interacting with other signaling molecules such as PI3K. To investigate the role of non-genomic TRβ1 signaling in endochondral ossification, we evaluated the skeletal phenotype of TRβ147F mutant mice in which a tyrosine residue which is essential for interaction with PI3K is replaced with phenylalanine. These TRβ147F mice exhibit a normal genomic response of TRβ1 to TH, but the non-genomic response through the PI3K pathway is impaired. Using microCT, we found that 13-week-old TRβ147F mice had significantly less trabecular bone mass in the distal femoral secondary spongiosa compared with littermate control mice, and trabecular BV/TV at the tibial epiphyses was also decreased. The mutants' reduced trabecular bone mass was primarily due to decreased trabecular thickness. Histomorphometric analyses of distal femoral secondary spongiosa revealed that labeled surface to bone surface and BFR/BS were reduced in the mutant mice. To explore the mechanisms of these TRβ1 effects in osteoblasts, we measured changes in mRNA expression caused by TRβ-specific agonist GC-1 in calvarial osteoblasts of mutant and control mice. We found that GC-1 increased Alp expression in control osteoblasts (1.55-fold, P = 0.01) but not TRβ147F mutant osteoblasts. Since canonical β-catenin signaling has been implicated in mediating PI3K non-genomic signaling in other cell types, we evaluated the GC-1 effect on β-catenin protein levels in MC3T3-E1 pre-osteoblasts. GC-1 treatment, however, did not significantly alter β-catenin levels, suggesting that PI3K non-genomic TRβ1 pathway modulation of β-catenin signaling is not likely involved in mediating GC-1 effects on osteoblast differentiation. Together, these results suggest that TH acting through TRβ1 regulates endochondral ossification in part via non-genomic signaling in mice. Further investigation of this non-genomic mechanism of TRβ1 signaling could lead to novel therapeutic targets for promoting endochondral ossification.

Parathyroid Hormone is Anabolic for Bone due to Progenitor Recruitment and Adipogenic Lipolysis David Maridas*[1], Elizabeth Rendina-Ruedy[2], Ron Helderman[2], Victoria Demambro[2], Daniel Brooks[3], Anyonya Guntur[2], Vicki Rosen[1], Beate Lanske[1], Mary Bouxsein[3], Clifford Rosen[2]. [1]Harvard School of Dental Medicine, United States, [2]Maine Medical Center Research Institute, United States, [3]Center for Advanced Orthopaedic Studies, Beth Israel Deaconess Medical Center, United States

Parathyroid hormone (PTH) prevents adipogenesis of bone marrow stromal cells in vitro, and in vivo, suppresses bone marrow adipose volume in both mice and humans. Furthermore, genetic deletion of the PTH receptor in mice results in an excess of bone marrow adipose tissue (BMAT). Thus, we postulated that PTH could prevent the increase of BMAT in calorie-restricted mice that recapitulates the marrow phenotype in anorexia nervosa. 8-week-old female C57BL/6J mice were fed the AIN93M control diet (CTRL) or calorie restricted at 30% (CR). At 12 weeks of age, CR and CTRL mice were injected daily with PTH (CR/PTH or CTRL/PTH) or vehicle (CR/Veh or CTRL/Veh) for 4 weeks. 2 other cohorts of 8-week-old mice were calorie-restricted and simultaneously injected (CR+PTH or CR+Veh) for 4 weeks. CR mice had markedly reduced bone mass and histological sections revealed an accumulation of BMAT in the proximal tibias. Intermittent PTH injections significantly increased aBMD and aBMC in both CR/PTH and CTRL/PTH mice as well as in CR+PTH mice when compared with their respective controls. Intermittent PTH significantly increased femoral and vertebral BV/TV in all cohorts despite calorie reduction in the experimental group. Cortical bone fraction was considerably decreased with calorie restriction but PTH injections only increased it in the CR+PTH but not in the CR/PTH cohort. Adipocyte density and size were markedly increased with calorie restriction. PTH significantly reduced adipocyte numbers in CR+PTH mice while adipocyte size was reduced in CR/PTH mice. Bone marrow stromal cells cultures differentiated into adipocytes and treated with PTH showed increased concentration of glycerol, a byproduct of lipolysis, in their conditioned media. In summary, our results suggest that when PTH injections start simultaneously with CR, PTH affects the number of adipocytes indicating an inhibition of adipogenesis. However, when PTH treatment occurs after CR has started, a lipolytic effect is observed with a significant reduction in adipocyte size. Thus, PTH can partially rescue both bone loss and MAT expansion in CR mice by affecting progenitor recruitment and lipolysis of marrow adipocytes. PTH induction of lipolysis in BMAT may provide a synergistic mechanism to provide fuel for osteoblasts during anabolic therapy.

SUN-0368

Propranolol treatment reduced sympathetic tone and prevented PTH-induced resorption in C57BL/6J mice Annika Treyball*[1], Hina Hashmi[1], Daniel Brooks[2], Kenichi Nagano[3], Deborah Barlow[4], Karen Houseknecht[4], Roland Baron[3], Mary Bouxsein[2], Anyonya Guntur[1], Katherine Motyl[1]. [1]Maine Medical Center Research Institute, United States, [2]Beth Israel Deaconess Medical Center, United States, [3]Harvard School of Dental Medicine, United States, [4]University of New England, United States

Previous studies have demonstrated that the β2-adrenergic receptor (β2AR) is required for the anabolic effect of intermittent parathyroid hormone (PTH). Conversely, the non-selective βAR blocker, propranolol (PRO) improves bone parameters with PTH in ovariectomized (OVX) mice. This suggests that there are differences in the mechanisms of action of the β2AR deletion and the βAR blocker. In order to better understand this phenomenon, we wanted to determine whether the positive effects of combined treatment could also be observed in intact mice. We treated 16-wk-old C57BL/6J female, intact mice with vehicle (VEH), PTH (80 μg/kg, 5 days/wk), PRO (5 mg/mL), or a combination of PTH and PRO for 4 wks. We hypothesized that PRO would enhance the anabolic effect of PTH. Interestingly, PTH and PRO had additive effects on trabecular bone volume fraction in the vertebrae (p<0.001), but PTH improved trabecular and cortical parameters to the same extent with or without PRO in the femur. PTH+PRO mice had higher serum P1NP (p=0.012) and lower CTX (p<0.001) levels than those treated with PTH alone, suggesting PRO improved bone formation and reduced PTH-induced resorption. While PTH alone caused a significant increase in osteoclast number/total area in the vertebrae (p=0.001), this was completely blocked in the PTH-PRO group. In contrast, PRO did not improve static or dynamic osteoblast parameters beyond that of PTH in vertebrae. However, the combination significantly reduced cortical porosity in both the tibia (p=0.019) and femur (p=0.007) while neither PTH nor PRO had a significant impact on porosity alone. We found no differences in femur cortical bone PTH-induced Rankl or Opg expression when PRO was present, but extracellular matrix genes Osteomodulin (p=0.003) and Dmp1 (p<0.001) were increased by PTH+PRO, suggesting osteocytes may play a role in the improved cortical porosity distinctive to combination treatment. Finally, we determined that PTH+PRO also reduced serum norepinephrine (as measured by mass spectrometry) by 38% (p=0.014), suggesting that combined treatment uniquely reduced sympathetic tone. In light of the current literature, our data suggest that suppression, but not complete loss, of βAR signaling improves bone parameters from PTH treatment, and we hypothesize that the site- and compartment- specificity may be related to localized differences in sympathetic nervous system activity.

A Novel Long-Acting PTH(1-34) Analog Containing a Palmitoylated C-Terminal Tag Hiroshi Noda*, Ashok Khatri, Thomas J Gardella. Massachusetts General Hospital and Harvard Medical School, United States

PTH analogs with prolonged actions have potential therapeutic applications, particularly for hypoparathyroidism. Unmodified PTH(1-34) clears rapidly from the circulation (t1/2~30'), in part via renal filtration, and thus has a limited duration of action. Addition of bulky polyethylene glycol (PEG) chains to the peptide's C-terminus can impede renal filtration and result in a prolong circulation half-time, but such PEGylated peptides are difficult to produce in pure form, in part due to the non-mono-dispersed nature of the PEG precursors. Zorzi et al. (Nat Comm. 2017) developed a palimitoylated heptapeptide tag sequence [EYEK(palmitoyl)EYE] that is optimized for binding albumin, which has a half-life in the serum of ~20 days, and thus can be used to extend the pharmacokinetic (PK) profile of a target peptide in vivo. We explored this approach for PTH by synthesizing a PTH(1-34) analog containing the [EYEK(palmitoyl)EYE] tag at the C-terminal position and assessing the peptide, called palm-PTH(1-34) in cells and in mice. In human osteoblast-derived SaOS-2 cells, palm-PTH(1-34) stimulated cAMP formation with the same potency as PTH(1-34) (pEC50= 9.65±0.1 vs. 9.60±0.1, respectively). After injection into mice, palm-PTH(1-34) (10 nmol/kg, s.c.) increased blood Ca++levels for at least 24 hours, whereas an equal dose of PTH(1-34) increased blood Ca++for no longer than 7 hours. Palm-PTH(1-34) also induced more prolonged hypophosphatemia. Consistent with these prolonged pharmacodynamic (PD) actions, palm-PTH(1-34) exhibited a markedly prolonged PK profile, as it persisted in the plasma following a single injection (10 nmol/kg, s.c.) for longer times, and attained a significantly greater maximum concentration than did PTH(1-34) (t1/2= 1.9 h vs. 0.2 h; Cmax = 28.1 vs. 0.65 nM; detection by PTH(1-34) ELISA, Quidel Inc.). Evaluation of renal filtration using TMR-labeled derivative peptides and tracking TMR fluorescence in the urine at times after injection, revealed that TMR-palm-PTH(1-34) was excreted into the urine at a greatly reduced rate, as compared to TMR-PTH(1-34). The findings overall show that palm-PTH(1-34) mediates prolonged PK/PD actions in vivo via a mechanism that involves reduced renal filtration, as presumably mediated by binding to serum albumin. The tagged peptide maintains adequate affinity for the PTH receptor and effectively activates down-stream signaling responses in bone and kidney target cells. Further study of such PTH

analogs may lead to new treatment options for hypoparathyroidism and potentially other PTH-related disorders.

Standardizing 25-Hydroxyvitamin D Concentrations Does Not Change the Number of Infants Classified as Vitamin D Deficient Sharina Patel*[1], Sherry Agellon[1], Paula Lavery[1], Catherine A. Vanstone[1], Nora Shero[1], Nathalie Gharibeh[1], Maryam Razaghi[1], Shuqin Wei[2], Hope A. Weiler[1]. [1]School of Human Nutrition, McGill University, Canada, [2]Department of Obstetrics and Gynecology, Sainte Justine Hospital, University of Montreal, Canada

Immunoassays are commonly used to measure total 25-hydroxyvitamin D (25(OH)D) concentrations in research and clinical settings due to their low cost and high-throughput. Large assay variability in measuring serum 25(OH)D impedes the ability of researchers to effectively make comparisons across studies and draw conclusions about potential deficiencies. Even within a laboratory, assay drift can occur over time despite the use of external quality control programs. The Vitamin D Standardization Program (VDSP) was organized to address these issues and has developed protocols to standardize laboratory 25(OH)D measurements to gold-standard reference measurement procedures (RMPs). Our objective was to standardize total serum 25(OH)D values of infants from a newborn vitamin D screening program to RMPs. Capillary blood samples taken from 849 neonates 24-36 h after birth (March 2016 through March 2018) were analyzed for total serum 25(OH)D using a chemiluminescent immunoassay (Liaison, Diasorin). Across this period, 142 quality control samples with 25(OH)D values assigned by the National Institute for Standards and Technology (NIST) were measured using the same immunoassay: 50 NIST 972a Level 1-4 samples and 92 Vitamin D External Quality Assessment Scheme (DEQAS) samples. The NIST and Liaison 25(OH)D concentrations of quality control samples were used to establish a weighted Deming regression equation to standardize infant serum 25(OH)D concentrations to RMPs. Fisher's exact test was used to compare proportions before and after standardization. The inter-assay coefficient of variation for NIST and DEQAS samples was 6% at 47.3 nmol/L and 7% at 116.2 nmol/L 25(OH)D, with a mean accuracy of 92%. The weighted Deming regression equation was: $y = 1.002x - 2.449$. After standardization, mean infant serum 25(OH)D increased from 43.0 ± 18.8 to 45.3 ± 18.8 nmol/L (mean ± SD). The median and interquartile range increased from 41.9 (29.7, 54.0) to 44.3 nmol/L (32.1, 56.3). Proportions of infants with serum 25(OH)D < 30, 30-49.9 and ≥ 50 nmol/L were originally 25%, 42% and 33%, and were 23%, 40% and 37% after standardization ($p > 0.05$; Figure 1). Standardizing original measurements to RMPs led to small increases in 25(OH)D concentrations yet no difference in rates of deficiency (< 30 nmol/L), inadequacy (30-49.9 nmol/L) or sufficiency (≥ 50 nmol/L). Standardization of infant serum 25(OH)D concentrations will enable comparisons of this data to other studies as well as national data.

Hypocalcemia from Hypoparathyroidism after Harvoni treatment for Hepatitis C Puspalatha Sajja*, Catherine Anastasopoulou, Nissa Blocher. Einstein Medical Center, United States

Background: Harvoni (Ledipasvir and Sofosbuvir) is one of the treatment options for Hepatitis C infection. We report a case of hypocalcemia from hypoparathyroidism precipitated by Harvoni therapy. Case Presentation: A 64-year old African American man with Hepatitis C was treated with 12 weeks course of Harvoni. He had no previous history of hypocalcemia prior to the therapy. Patient was first noted to have corrected calcium of 8.4 mg/dl during the last week of Harvoni treatment with repeat calcium level of 8.2 mg/dl two months later. Another two months later he presented to Emergency Department with numbness, palpitations, and muscle cramping. His blood work showed calcium 6.6 mg/dl, albumin 4.3 mg/dl, PTH 18 pg/ml, 25-hydroxy vitamin D 11 ng/ml, magnesium 2.2 mg/dl, phosphorus 3.8 mg/dl and 24-hour urine calcium was less than 2. Oral calcitriol, ergocalciferol and calcium carbonate were initiated at that point and his calcium normalized on treatment within four weeks. Five months later repeat labs showed 25(OH)vit D 37.2 ng/ml and PTH 18 pg/ml. His calcium remained normal on calcitriol and calcium carbonate, but because of the persistently low PTH intact levels, patient was considered for parathyroid hormone injections. Discussion: Harvoni is a combination medication of Ledipasvir and Sofosbuvir which are hepatitis C virus NS5A protein and NS5B RNA polymerase inhibitors blocking viral replication. There have been no case reports of hypoparathyroidism in the literature from Harvoni treatment. In our patient, the absence of other potential causes of hypoparathyroidism, including lack of autoimmune background, or any history of neck surgery or radiation exposure, as well as the sudden onset of hypocalcemia right at the end of Harvoni treatment,

Sunday Posters

makes Harvoni the most likely cause of his hypoparathyroidism. More long term data on this drug is needed to find out if hypoparathyroidism is one of the potential complications of Harvoni therapy.Conclusion: Hypoparathyroidism leading to hypocalcemia could be a potential complication of Harvoni treatment. Monitoring calcium and parathyroid hormone levels prior to initiation and periodically after completion of Harvoni treatment should be recommended for all patients.

FGF Receptor 1c Works as a Phosphate-Sensor to Regulate FGF23 Production Yuichi Takashi*[1], Yuka Kinoshita[2], Nobuaki Ito[2], Shun Sawatsubashi[1], Hidetaka Kosako[1], Masahiro Abe[1], Munehide Matsuhisa[1], Toshio Matsumoto[1], Seiji Fukumoto[1]. [1]Tokushima University, Japan, [2]The University of Tokyo Hospital, Japan

Phosphate is essential for proper functions of all cells. Serum phosphate level is maintained within a narrow range indicating that there is a machinery to monitor changes of this mineral concentration. Fibroblast growth factor (FGF) 23 produced by bone especially osteocytes is a hormone that decreases serum phosphate level. However, it has been unclear how changes of phosphate level modify serum FGF23 concentration. FGF23 level can be regulated by both its expression in osteocytes and posttranslational cleavage into inactive fragments. Galnt3 gene product initiates the attachment of mucin-type O-glycan to FGF23 and prevents this cleavage. High phosphate diet increased serum phosphate and FGF23, and enhanced the expression of Galnt3 in bone without changing that of Fgf23 in mice. These results suggest that posttranslational modification via Galnt3 gene product is the main mechanism to regulate serum FGF23 level at least in this model. Then, transcriptomic analysis was employed to identify regulatory factors of Galnt3 expression using UMR106 cells. High extracellular phosphate upregulated expression of several transcription factors and signaling components of ERK pathway. Subsequent functional analysis identified early growth response 1 (EGR1) and ETS variant 5 (ETV5) are required to enhance transcription of Galnt3 by phosphate. We further explored how UMR106 cells sense extracellular phosphate to activate ERK. We focused on receptor tyrosine kinases (RTKs) which can activate the ERK pathway. LC-MS/MS analysis of immunoprecipitated cell extract using anti-phosphotyrosine antibody identified Tyr583 and Tyr 653 of FGF receptor (FGFR) 1c as phosphorylated residues by high extracellular phosphate. Western blotting indicated that high extracellular phosphate induced phosphorylation of FGFR substrate 2α (FRS2α) and ERK. Inhibitors of FGFR and ERK pathway abolished the stimulatory effect of phosphate on Galnt3 expression. In addition, an inhibitor of FGFR also abolished the effect of high phosphate diet on Galnt3 expression in mice. Together, we have shown that phosphate activates FGFR1c to phosphorylate FRS2α, leading to activation of the ERK pathway that induces Galnt3 expression via two transcription activators. These findings uncover an unrecognized facet of FGFR1c function and provide a molecular basis of phosphate-sensing in regulated FGF23 production.

Effects of Biliopancreatic Diversion on Bone Turnover Markers and Association with Hormonal Factors in Patients with Severe Obesity Anne-Frederique Turcotte*[1], Thomas Grenier-Larouche[2], Roth-Visal Ung[1], David Simonyan[3], Anne-Marie Carreau[2], André Carpentier[2], Fabrice Mac-Way[1], Claudia Gagnon[1]. [1]Laval University, Canada, [2]Sherbrooke University, Canada, [3]Chu de Quebec, Canada

Context:No study has assessed the early impact of biliopancreatic diversion with duodenal switch (BPD-DS) on bone remodeling and whether it is influenced by hormonal factors.Objectives: To evaluate the early, mid- and longer-term changes in serum bone turnover markers and its regulators as well as their associations with hormonal factors after BPD-DS in patients with severe obesity. Methods: Ancillary study using fasting frozen plasma from 16 individuals with severe obesity (11F/5M, 69% with type 2 diabetes, mean BMI 49.4 kg/m2) assessed before (T0), 3 days (T1), 3 months (T2) and 12 months (T3) after BPD-DS. Serum bone turnover markers (C-terminal telopeptide (CTX), intact osteocalcin (OC)), regulators of bone turnover (sclerostin, osteoprotegerin (OPG)) and hormonal factors (GLP-1, GIP, insulin, glucagon, leptin, high molecular weight adiponectin, PTH and 25-hydroxyvitamin D) were analyzed at each visit. Changes between baseline and each timepoint in bone turnover markers and its regulators were correlated with changes in hormonal factors using Pearson partial correlations adjusted for weight loss.Results: Weight did not change at T1 but decreased by 33±27 kg at T2 and 59±12 kg at T3. CTX increased significantly at T1 (+66%), T2 (+219%) and T3 (+295%). OC decreased significantly at T1 (-19%) then increased at T2 (+69%) and T3 (+164%) (Figure 1). Change in sclerostin was modest overall and only significant between T1-T2 (+13%) while change in OPG was only significant between T0-T1 (+48%) and T0-T3 (+45%). All changes were similar between participants with or without diabetes. The increase in CTX correlated with weight loss at T2 (r=-0.63, p=0.009) and T3 (r=-0.58, p=0.039). Changes in sclerostin correlated with changes in insulin at T3 (r=-0.60, p=0.040) and adiponectin at T2 (r=-0.62, p=0.013). Changes in adiponectin also correlated with changes in OC at T1 (r=0.54, p=0.039) and OPG at T1 (r=-0.61, p=0.017). No other hormonal factor correlated significantly with bone turnover markers or its regulators. Conclusions: BPD-DS causes an earlier and greater increase in bone resorption over bone formation, potentially favouring bone loss. Sclerostin did not increase as expected following massive weight loss, suggesting an altered osteocyte response to mechanical unloading. Changes in adiponectin and insulin seem to play a role independent of weight loss in bone remodeling after BPD-DS.

SUN-0375

The Kruppel-like transcription factor 6 (KLF6/CPBP) plays a critical role in Colony Stimulating Factor 1-dependent transcriptional activation of the SPHK1 gene Gang Qing Yao*, Karl Insogna. Yale university, United States

Intermittent activation of the PTH receptor stimulates bone formation. CSF1 is the principal colony stimulating activity released by osteoblasts constitutively and in response to PTH treatment and its receptor, c-fms, is more highly expressed on osteoclasts than any other cell in bone. We have found that deleting c-fms in osteoclasts attenuates the anabolic response to PTH, suggesting that PTH-induced CSF1 from osteoblasts may stimulate the release of anabolic clastokines from osteoclasts. Sphingosine kinase 1 (SPHK1) is the rate-limiting enzyme required for the synthesis of sphingosine-1-phosphate (S-1-P), a phospholipid with known anabolic effects in bone and we have previously reported that CSF1 increases SPHK1 expression by transcriptional activation of the SPHK1 gene.To study the mechanism of CSF1-induced SPHK1 gene expression, we cloned a 2,608 bp fragment of the murine SPHK1 gene (-2497 to +111 bp relative to the transcription start site) into the pGL3-basic vector and transfected it into P-zen cells (murine fibroblasts engineered to express c-fms). SPHK1 promoter activity was assessed using the Dual-Luciferase reporter assay system, which employs the pGL4.73 vector (Promega®). By analyzing a series of 5'-deletions, we identified a CSF1-responsive region located in the region -1250 to -1016 bp.To define putative DNA binding site(s) in this fragment, we generated two biotin-labeled fragments, one 163 bp in length (-1302 to -1139) and one 169 bp in length (-1158 to -989) that completely overlap this region. EMSAs revealed the 163 bp fragment as the target for protein binding. Using EMSAs, we further narrowed the binding region to an 83 bp fragment, (-1222 to -1139). By querying the TRANSFAC database, we identified a cis element consensus sequence for the transcription factor CPBP/KLF6 in this region. Cold competitor fragments for use in an EMSA were engineered based on this sequence, a wild type sequence and a CPBP-mutated sequence. We found that a shifted band, which was induced by CSF1, was completely competed using the wild type oligo but not the mutated oligo. Full-length wild type and CPBP/KLF6-mutated promoters were introduced into the pGL3 expression vector and transfected into P-zen cells. Mutating the CBPB site nearly completely abrogated the ability of CSF1 to activate the promoter. We conclude that the CPBP/KLF6 cis-element plays an important role in mediating CSF1-dependent transcriptional activation of the SPHK1 gene.

Specific modulation of vertebral marrow adipose tissue by physical activity Daniel Belavy*[1], Matthew Quittner[1], Nicola Ridgers[1], Adnan Shiekh[2], Timo Rantalainen[3], Guy Trudel[2]. [1]Deakin University, Australia, [2]University of Ottawa, Canada, [3]University of Jyväskylä, Finland

BACKGROUND: Marrow adipose tissue (MAT) accumulation with normal aging impacts the bone, hemopoiesis and metabolic pathways. Hormonal and nutritional factors have been reported to accelerate the process. There is also evidence that reduced physical activity (spinal cord injury, experimental bed-rest) leads to accelerated MAT accumulation. It is unknown whether increased physical activity, or specific types of physical activity, may reduce MAT. We investigated whether exercise was associated with lower MAT, as measured by vertebral marrow fat fraction (VFF) on magnetic resonance imaging.METHODS: 101 healthy individuals (54 females) aged 25-35 yrs without spine or bone disease but with distinct exercise histories were studied. We examined 25 long-distance runners, 30 habitual joggers, 22 high-volume road cyclists and 24 non-sporting referents. VFF was quantified in

lower thoracic (T10, T11, T12) and lumbar (L1 to L5) vertebrae via mDIXON sequence on magnetic resonance imaging. All participants wore a 3D accelerometer (ActiGraph) at their hip for 8d after scanning. In 10 additional individuals, accelerometry data were collected in to associate acceleration profiles with specific physical activities.RESULTS: Long-distance runners exhibited lower mean lumbar VFF (27.9[8.6]% vs. 33.5[6.0]%; p=0.0048) than non-sporting referents. In habitual joggers, mean lumbar VFF was 31.3(9.0)% (p=0.22 versus referents) and 6.0 percentage points lower than referents at vertebrae T10, T11 and T12 (p≤0.023). Regression analysis showed a 0.7 percentage point reduction in mean lumbar VFF with every 9.4km/week run (p=0.002). Mean VFF of high-volume road cyclists was comparable to non-sporting referents. 3D accelerations corresponding to faster walking, slow jogging and high-impact activities correlated with lower VFF while low-impact activities and sedentary time correlated with higher mean lumbar VFF (all p≤0.05).CONCLUSIONS: This study presents the first evidence in humans or animals that specific volumes and types of exercise may influence the age-determined adipose marrow conversion and result in low MAT. There is an estimated adipose bone marrow conversion of 7% per decade of life. In comparison to this, long distance runners, with 5.6 percentage points lower VFF, showed an estimated 8-year younger vertebral marrow adipose tissue phenotype. Running, but not high volume road cycling, may impact MAT.

SUN-0402

The role of acetylcholine receptor signaling in bone mechanotransduction Karl J Lewis*, Alexander G Robling. Indiana University School of Medicine, United States

Decades ago, Rubin and Lanyon showed that disuse-induced bone loss could be mitigated by short bouts of daily loading[1]. Cytokine signaling changes among bone cells related to mechanical loading are well studied, however the role of neurotransmitters is not well understood. Our group recently found that transcripts for the nicotinic acetylcholine (Ach) receptor subunit CHRNA1 are significantly down regulated in cortical bone after mechanical loading, suggesting ACh signaling may be important for osteocyte mechanotransduction. The present studies interrogate the role of Ach signaling in bone mechanotransduction.Botulinum toxin (BTX), a potent inhibitor of Ach release, has been used as a model for limb disuse in rodents previously[2,3]. Here we use this method as both a model of disuse and means of exposing bone to BTX locally. We injected BTX into the major muscle groups surrounding the tibia and femur of 15wk old female B6 mice (n=10), followed by 3 tibial loading bouts per week for 2 weeks(2700µ?, 120 cycles, 2Hz). Saline injected (n=6), non-injected (n=6), and BTX injected/non-loaded (n=10) groups were included as controls. DEXA scans were collected at 15 (experiment start) and 18 wks (experiment termination) wks of age, and µCT analysis was performed after sacrifice at 18 weeks. Additionally, a CHRNA1 floxed loss-of-function mouse was generated, crossed to the Dmp1-Cre driver, and characterized with µCT following 2wks of tibial loading. Statistical analyses by Student's t-test, p<0.05. Loading resulted in a significant increase in DEXA properties among the saline-injected mice. BTX treatment resulted in bone loss in the treated limb, whether the limb was loaded or not, though more severe bone loss was found in the mice that were not loaded. µCT data taken from the tibial midshaft, however, showed cortical BV/TV and BMC decreased in only the non-loaded BTX group. CHRNA1 mutants showed no statistically significant differences from wild-type B6 controls. The lack of response to loading in BTX-treated limbs suggests that either Ach signaling is required for osteocytes but was prevented by local BTX injection around the nearby bone, that in order for bone to respond to mechanical stimuli a tonic myokine originating from nonparalyzed muscle is required, or some combination of the two. These data suggest that either CHRNA1 can be compensated for by some other subunit, or that the effect of Ach signaling in bone is mediated through some other receptor. [1] C.T. Rubin, L.E. Lanyon, J Bone Joint Surg Am. 66 (1984) 397–402.[2] S.E. Warner et al, Bone. 38 (2006) 257–264.[3] S.L. Manske et al, Calcif Tissue Int. 87 (2010) 541–549.

Expression pattern of the mechanoresponsive piezo2 ion channel during skeletal development and growth Jerahme Martinez*, Ashutosh Parajuli, Sucharitha Parthasarathy, Padma Srinivasan, Catherine Kirn-Safran, Liyun Wang. University of Delaware, United States

Piezo2, a recently discovered stretch-activated cation channel, plays an important role in mediating mechanosensation and proprioceptive. Mutations in the piezo2 gene have been associated with the human musculoskeletal disorder Gordon syndrome (GS; MIM #1143000), characterized by impaired mobility, congenital contractures of the limbs, and shortened statue. The ability of piezo2 to sense mechanical stimuli and its role in musculoskeletal development prompted us to explore its role in bone. The widespread expression of piezo2 in mechanosensitive tissues suggests a distinct physiological role for mechanotransduction. We hypothesize piezo2 acts a mechanosensor in bone and plays an important role in maintaining overall skeletal health and bone adaptation. To gain insight into its function within the skeletal system we examined piezo2 transcript levels in murine bone under in vivo mechanical loading, and characterized protein spatial and temporal expression patterns bone tissue, via quantitative real-time PCR (qPCR) and immunohistochemistry (IHC), respectively. Peizo2 mRNA levels were elevated in murine bone when subjected to 7 days of axial tibia loading relative to the non-loaded control limbs, whereas no change was overserved follow-

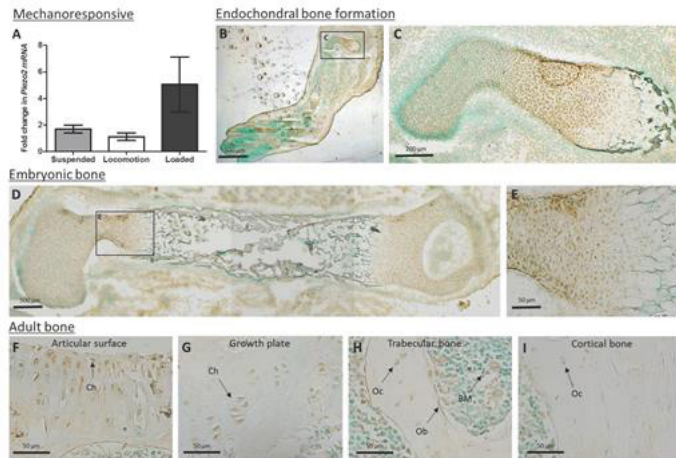
ing one bout of loading. We demonstrated piezo2 is present during the early stages of murine embryonic development, particularly in mesenchyme tissue undergoing endochondral bone formation, and was found to be expressed by bone cells (e.g. osteoblasts and osteocytes), bone marrow cells, and chondrocytes of adult bone. These studies implicate the piezo2 gene in the adaptive response of bone when subjected to dynamic loading and unloading. At the protein level, piezo2 is present within bone tissue throughout all stages of development and growth. Additionally, we found piezo2 is expressed by key cells involved in the bone remodeling process, and is present in regions that are subjected to high levels of mechanical load. It is possible that piezo2 serves as a key contributor of bone adaptation process and may function as a viable target to orchestrate bone formation.


Figure 1. Piezo2 transcript levels in response to mechanical stimulation and protein expression during skeletal growth. (A) Piezo2 transcript levels were elevated in bone under both unloaded and loaded conditions, using the hind limb suspension unloading and axial tibia loading models respectively. Piezo2 levels were determined by qPCR analysis. (B-I) Immunohistochemistry analysis of piezo2 protein accumulation in embryonic and adult tissue. (B-C) Piezo2 is expressed in E14.5 in mesenchymal/precartilage tissue undergoing endochondral ossification. (D-E) As bone continues to develop piezo2 expression is found along the proximal and distal ends of the femur, particularly at the growth plate region. (F-I) In adult bone (16 weeks), piezo2 is expressed by chondrocytes of articular cartilage (F) and the growth plate (G), bone marrow cells (H), osteoblasts (H), and osteocytes (H-I).

Substantial Repair of Diffuse Damage in Bone In-Vitro Can Occur Through Physicochemical Mechanisms. Leila Mehraban Alvandi*, Donna Chen, Samuel Stephen, Zeynep Seref-Ferlengez, Robert J Majeska, Mitchell B. Schaffler. Department of Biomedical Engineering, City College of New York, United States

Linear microcracks (50-100 µm long) and diffuse damage (Dif-Dx) (sub-micron size cracks) are the major microdamage types resulting from wear and tear in bone. Recently, we discovered that Dif-Dx repairs without remodeling, pointing to a direct healing mechanism for these cracks (1). Here we tested the hypothesis that repair of Dif-Dx regions in bone, as assessed functionally by recovery of mechanical properties, can occur in vitro in the absence of viable osteocytes. Methods: Diffuse damage was selectively introduced into the ulnar diaphysis of rats (SD, Female, 19w, n=8) in vivo. The loading used for these studies (~15% stiffness loss in creep) selectively creates a discrete Dif-Dx region in the mid diaphysis (1, 2).Ulnae were harvested after loading and frozen in PBS at −20°C until tissue testing. One mm thick cross sections from diaphyseal damage zones were mounted on small plastic slides and incubated in saline buffer either with or without supplemental Ca2+ at plasma concentration (2mmol/L) for 5 days at 37ºC. This solution has been shown to remineralize small enamel defects. Samples from acutely damaged and non-damaged control bones as well as baseline bone slices were tested using microindentation to determine tissue level Elastic modulus (E) and Dif-Dx area was measured by histomorphometry. Comparisons: Nonparametric ANOVA with post-hoc Mann-Whitney U-test. Results: Elastic modulus in Dif-Dx zones (acute loaded ulnae, time=0) was reduced significantly (15%) compared to non-damaged control bone. Modulus of Dif-Dx region was recovered to 95% of control level after 5 days incubation in saline+Ca2+. In addition, Dif-Dx area was reduced by 55% after 5 days incubation in saline+Ca2+ vs acute diffuse damage levels (Fig 1). Discussion: In the current study Dif-Dx in compact bone repaired through purely physicochemical processes and without live osteocytes, as evidenced by recovery of tissue mechanical properties and reduction in damage content. Dif-Dx occurs entirely within cortical bone. The principal exchange surface within cortex is the osteocyte lacunar-canalicular space (LCS).We posit that the Ca2+ source responsible for healing Dif-Dx in vivo is the fluid contained within the LCS. How this repair occurs is not yet known but may include growth of existing mineral crystals and/or infilling of crack spaces with new mineral deposition analogous to enamel repair (3). Bone Properties and the Endocannabinoid System Observed with Neurectomy and Hibernation in Marmots (Marmota flaviventris) Emily Mulawa*, Rebecca Packer, Jay Kirkwood, Lisa Wolfe, Samantha Wojda, Jessica Prenni, Gregory Florant, Seth Donahue. Colorado State University, United States

Hibernators have adapted a physiological mechanism allowing them to undergo long periods of inactivity without experiencing bone loss from disuse. A previous study of the bone proteome in marmots found monoacylglycerol lipase to be 98-fold higher during hibernation. Monoacylglycerol lipase is responsible for degrading the endocannabinoid ligand 2-arachidonoyl glycerol and endocannabinoid-like ligands N-palmitoylethanolamide (PEA) and N-oleoylethanolamide (OEA). The primary cannabinoid receptors (CB) have divergent localization in bone. CB1 is predominately found on sympathetic nerve terminals, while CB2 is found on bone cells and their progenitors. This study determined the contribution of neural innervation on endocannabinoid regulation of bone remodeling. Neurectomy for forced disuse was performed on the right leg sciatic nerve perineal branch, with the left leg serving as a control, in both hibernating and active groups of marmots. Endocannabinoid and endocannabinoid-like ligand concentrations were measured from the fourth metatarsals using microflow chromatography coupled with tandem quadrupole mass spectrometry (LC-QQQ-MS). In addition, trabecular bone properties of the fifth metatarsals were evaluated using micro-computed tomography to quantify bone loss. The endocannabinoid anandamide, as well as PEA and OEA, significantly increased with neurectomy in bone marrow in active, but not hibernating, marmots. Ligand concentrations in bone did not change significantly with neurectomy regardless of state. There were no significant changes with neurectomy in trabecular bone properties of active and hibernating marmots, indicating that bone loss did not occur. Elucidating the mechanism hibernators use to maintain bone architecture and density could help guide development of novel bone loss prevention therapies in humans.

The Role of Panx1 and P2X7R in Inflammation-induced Diabetic Bone Dysfunction Zeynep Seref-Ferlengez*[1], Marcia Urban-Maldonado[1], Herb Sun[1], Mitchell Schaffler[2], Sylvia Suadicani[1], Mia Thi[1]. [1]Albert Einstein College of Medicine, United States, [2]City College of New York, United States

Bone loss is a complication in diabetes that is often overlooked. Despite growing clinical and epidemiological evidence that supports the association of Type 1 diabetes (T1D) with low bone mass and fractures, the mechanisms underlying diabetic osteopenia are still not completely understood. We propose that diabetic bone becomes insensitive to mechanical loading due to dysregulation of the osteocyte Panx1-P2X7R mechanosignaling complex that not only disrupts proper load-induced bone adaptation but also triggers local load-induced inflammation, which in combination ultimately lead to bone loss in T1D. To test this hypothesis we used the Akita (C57BL/6J-Ins2Akita) mouse model of T1D and age-matched wildtype (WT) mice (8 wk old, male, n=7/group) that were submitted to mechanical loading by treadmill running (2 or 4 wks; 5 days/wk, 300 m/day) or to normal cage control activity. All animals were euthanized immediately after the last running bout. Right hindlimbs were used for histomorphometry, lefts were used for Western blotting and forelimbs were used for qPCR analysis. All experiments were performed under IACUC approval. We found that the anabolic response to mechanical loading is impaired in Akita mice when compared to

age-matched WT mice. We also observed that mechanical loading regulates both Panx1 and P2X7R expression in the bone (Fig.1). In WT mice, Panx1 and P2X7R expression changed in response and adapted to different loading durations; expression peaked at 2 wks loading time and returned to basal levels at 4 wks loading time when compared to non-loaded WT bones (blue traces). This adaptive response was not lost in diabetic bone, but was dysregulated (red and green traces; Panx1 and P2X7R remain at higher levels at 4 wks loading time), indicating that diabetic mice are unable to properly adapt to mechanical loading. Remarkably, this dysregulation of Panx1-P2X7R was accompanied by a significant inflammatory response in diabetic bone, as evidenced by upregulation of the NLRP3 inflammasome and IL-1β (Fig. 2). Because Panx1 and P2X7R can mediate NLRP3 inflammasome activation, it is likely that Panx1-P2X7R dysregulation is the major driver of this load-induced inflammatory response. Such dysregulation of Panx1-P2X7R signaling, fueling the inflammasome activation in response to mechanical loading, may thus be a key factor in the events leading to the lack of load-induced anabolic response and increased bone loss observed in T1D mice.
Figure 1. Panx1-P2X7R mechanosignaling complex responds differently to mechanical loading in wildtype and T1D Akita mice. Panx1 and P2X7R in loaded wildtype (WT) and Akita mice compared to their age-matched non-loaded WT before (0 week) and after 2 or 4 weeks of loading (treadmill running). Protein levels normalized by β-actin then by age-matched non-loaded WT levels or non-loaded Akita levels. *P<0.05, ***P<0.001, non-loaded Wt vs. age-matched loaded Akita and wildtype (blue and red traces). **P<0.01, ****P<0.001, non-loaded Akita vs. age-matched loaded Akita (green trace), one-way ANOVA followed by Tukey's multiple comparison test. Loading group: n = 4-6 (0 week), n= 7-9 (2 weeks), n = 9 (4 weeks). Data presented as means ± SEM.
Figure 2. Mechanical loading upregulates IL-1β and NLRP3 in Akita bones. IL-1β and NLRP3 mRNA levels in non-loaded and in 2-week loaded WT and Akita bones compared to non-loaded age-matched WT controls. Note already higher IL-1β and NLRP3 in non-loaded Akita that are further increased by loading. *P<0.05, **P<0.01, ***P<0.001, non-loaded WT vs. loaded WT and Akita, one-way ANOVA followed by Tukey's multiple comparison test. Exercise in Calorie Restricted Mice fails to Increase Bone Quantity, despite suppression of Marrow Adipose Tissue (MAT) Cody Mcgrath*[1], Jeyantt Sankaran[1], Negin Misaghian-Xanthos[1], Buer Sen[1], Zhihui Xie[1], Martin A Styner[2], Xiaopeng Zong[3], Maya Styner[1]. [1]Division of Endocrinology and Metabolism, Department of Medicine, UNC-Chapel Hill, United States, [2]Departments of Computer Science and Psychiatry, UNC, United States, [3]Biomedical Research Imaging Center, UNC, United States

Marrow adipose tissue (MAT) and its physiologic relevance to skeletal health in the setting of anorexia or calorie restriction (CR) is unknown. We hypothesized that MAT of CR differs from the calorie-replete state. Ten-week-old female B6 mice fed a regular (RD) or 30% CR-diet were allocated to sedentary (RD n=10, CR n=10) and running exercise groups (RD-E n=7, CR-E n=7). After 6 weeks, CR mice weighed 20% less than RD, p<0.001; exercise did not affect weight. Femoral bone volume (BV) quantified by 3D-MRI/9.4T scanner was 20% lower in CR and CR-E compared to RD and RD-E (p<0.0001). CR associated with decreased bone by μCT: Tb.Th was 15% less in CR vs RD p<0.03, and cortical bone fraction was 4% less, p<0.01. Similarly, in CR-E, trabecular bone was 27% less than RD-E, p<0.0001. Exercise associated with increased trabecular bone quantity (+18% RD-E vs RD p<0.0001) but failed to in CR. Furthermore, cortical porosity, which was similar between RD and RD-E- increased in CR-E vs CR (+33%, p=0.04), suggesting the combination of CR and exercise is deleterious to bone, particularly the cortex. Metaphyseal MAT/ BV quantified by 3D-MRI/9.4T scanner increased by 159% in CR vs RD, p=0.003. As expected, exercise lessened MAT/ BV by 52% in RD, p<0.05, Fig 1. Notably, exercise also suppressed CR MAT by 47%, p<0.05. Histologic analysis of marrow adipocytes correlated with MRI findings, Fig 2. Tibial mRNA demonstrated an increase in PLIN1 in CR (+100% CR vs RD, p=0.065), confirming an increase in adipocytes.Unexpectedly, SOST mRNA negatively associated with MAT in CR (r2=0.49, p =0.06), indicating that increased SOST was not responsible for increase in MAT in CR; as well, a significant decrease in osteoclasts (Fig 2) in CR was consistent with decreased SOST. Intriguingly, the repressed SOST in CR rose with exercise, and may underlie the failure of CR-bone to increase due to exercise. In sum, our study shows that CR is associated with a robust increase in MAT. While CR-MAT decreases with exercise, exercise fails to increase bone in CR, perhaps due to impaired bone formation.
Figure 1. MAT quantified by 3D-MRI/9.4T reduced by exercise in CR.
Figure 2. Representative sections of mouse femurs (n=2 per group), stained with TRAP.

Mechanical signals activate YAP and TAZ in part via Piezo 1 Xuehua Li*[1], Charles O'Brien, Jinhu Xiong. University of Arkansas for Medical Sciences, United States

YAP (Yes associated protein) and TAZ (transcriptional co-activator with PDZ-binding motif) are related transcription cofactors that are thought to mediate cellular responses to mechanical signals. Specifically, in vitro studies show that mechanical signals emanating from extracellular matrix or fluid flow enhance YAP/TAZ activity by promoting their nuclear translocation, suggesting that YAP/TAZ are mediators of transcriptional changes induced by mechanical signals. Previous studies have examined the role of YAP/TAZ in mature osteoblasts and osteocytes by deleting them from mice using the Dmp1-Cre transgene. These mice exhibited decreased bone mass associated with decreased bone formation and increased bone resorption, consistent with loss of mechanical signals in bone. However, the underlying molecular mechanisms remain unknown. To determine whether YAP/TAZ are regulated by mechanical signals in osteoblast-lineage cells, the MLO-Y4 cell line or primary calvaria cells were cultured under either static or fluid shear stress and gene expression was examined by Taqman assay. Fluid flow significantly increased the activity of YAP/TAZ as measured by the expression of their target gene Ctgf. Moreover, deletion of YAP/TAZ in calvaria cells significantly blunted the effect of fluid flow as measured by expression of Cox-2, a gene well-known to be responsive to fluid flow. To examine the mechanisms by which YAP/TAZ are activated by mechanical signals in osteoblast-lineage cells, we focused on Piezo1, a mechanical activated ion channel that has been reported to be critical for fluid shear stress induced calcium signaling and nitric oxide synthase expression. Besides fluid shear stress, matrix stiffness also regulates Piezo1 activity, as it does YAP/TAZ. Therefore, we determined whether Pieoz1 regulates YAP/TAZ activity in osteoblastic cells by responding to mechanical signals. Piezo1 expression increased significantly with fluid flow in osteoblastic cells, and this is associated with increased expression of Cox-2 and Ctgf. More importantly, deletion of Piezo1 in osteoblastic cells blunted the increase of Cox-2 and Ctgf expression induced by fluid flow. Taken together, these results indicate that YAP/TAZ are mediators of mechanotransduction in bone cells and that Piezo1 activates YAP/TAZ by responding to fluid shear stress. Thus, loss of YAP/TAZ mediated mechanical response may contribute to the skeletal phenotype of mice lacking YAP/TAZ in osteocytes.

Disruption of Nucleo-Cytoskeletal Connectivity Impairs Mechanical Competence of MDA-MB-231 Cells and Regulates Responses to Low Magnitude Mechanical Forces Xin Yi*[1], Laura Wright[1], Gabriel Pagnotti[1], Gunes Uzer[2], Clinton Rubin[3], Uma Sankar[1], Katherine Powell[1], Joseph Wallace[1], Khalid Mohammad[1], Theresa Guise[1], William Thompson[1]. [1]Indiana University, United States, [2]Boise State University, United States, [3]Stony Brook University, United States

Low intensity vibrational (LIV) forces are capable of stimulating bone formation. Additionally, LIV restricts bone loss and tumor progression in models of ovarian cancer and myeloma. The mechanisms by which mechanical forces influence cancer are unknown. Transmission of LIV requires connection between the actin cytoskeleton and the nucleus via the Linker of Nucleoskeleton and Cytoskeleton (LINC) complex. This study examined the mechanisms by which the LINC complex regulates LIV effects on MDA-MB-231 cells. Human MDA-MB-231 breast cancer cells, which induce osteolysis in mice, were exposed to LIV (90Hz, 0.3g) in twenty-minute bouts, twice a day. LIV had no direct effect on cell death; however, LIV upregulated expression of the death receptor Fas (3-fold, p<0.05), suggesting that MDA-MB-231 cells may be more susceptible to Fas-ligand (FasL)-mediated death after LIV. Compared to static controls, treatment with recombinant FasL, after LIV, resulted in a 2-fold increase (p<0.05) in apoptosis. Using trans-well assays, a 4-fold (p<0.05) decrease in cell invasion was observed following LIV. Reductions in Mmp1 (4-fold, p<0.01) and Mmp3 (3-fold, p<0.05) mRNA were seen with LIV. To determine if exposure of MDA-MB-231 cells to LIV influences osteoclast formation, conditioned media from MDA-MB-231 cells, exposed to LIV, was added to RAW 264.7 macrophages. Conditioned media from LIV treated cells reduced osteoclast formation by 3-fold (p<0.0001). Disruption of nucleo-cy-

Sunday Posters

toskeletal connectivity, by siRNA knock-down of LINC genes Sun1 and Sun2 blocked the beneficial effects of LIV on cell invasion and osteoclastogenesis. Furthermore, as assessed by atomic force microscopy, LIV treatment increased cell stiffness by 1.2-fold (p<0.05) and enhanced actin stress fiber formation. siRNA knockdown of Sun1 and Sun2 negated the increases in actin formation and cellular stiffness. Expression of LINC genes Syne1 (2-fold, p<0.001), Syne2 (3-fold, p<0.05), Sun1 (2-fold, p<0.001), and Sun2 (4-fold, p<0.05) were increased with LIV treatment. These data demonstrate that the beneficial effects of LIV in human breast cancer cells requires nucleo-cytoskeletal connectivity. As a decline in cell stiffness is associated with increased metastatic potential and expression of LINC genes are suppressed in breast tumors, LIV may serve as a non-invasive intervention to suppress breast cancer metastasis and osteolysis by increasing physical connections between the nucleus and actin cytoskeleton.

Defining the Role of BMP Signaling in the Development of Degenerative Disc Disease Avionna Baldwin*[1], Roman Eliseev[1], Addisu Mesfin[1], Noriaki Yokogawa[2], Alex Hollenberg[1]. [1]University of Rochester School of Medicine and Dentistry, United States, [2]Kanazawa University, Japan

Purpose: Degenerative disc disease (DDD) has become an increasing burden on society as the population ages with 80% of the population complaining of back and neck pain at a certain point. The intervertebral disc is composed of two cartilage endplates, nucleus pulposus cells, and annulus fibrosis. Pain associated with DDD can be secondary to dysfunction of all of these parts of the intervertebral disc. This current study sought to determine if upregulation of the BMP-SMAD pathway leads to the development of DDD.Methods: Human DDD and control intervertebral disc samples were collected and analyzed by immunohistochemistry for expression phosphorylated (active) SMAD1/5/8 (p-SMAD), BMP-2, and Alk3(BMP-2 receptor). Slides were photographed and analyzed for positive and total cell count using OsteoMeasure software. In vitro, chondrocyte-like ATDC5 cells were transfected with SMAD1. After 24 hrs media was changed, and 24 or 48 hrs later cells were analyzed for SMAD activity using a luciferase promoter reporter and collected for RNA and protein. RT-PCR was used to assess expression of inflammatory markers (IL6 and TNFα). Western blot was used to assess expression of SMAD, p-SMAD, and Bax (apoptosis).Results: BMP-2 and p-SMAD expression was significantly higher in patient samples with DDD while Alk3 did not change. In vitro we observed that after transfection of ATDC5 cells with SMAD1, SMAD activity significantly increased, protein levels of SMAD, p-SMAD and Bax were elevated, and RNA levels of inflammatory cytokines IL6 and TNFα were upregulatedConclusion: These results suggest that BMP-SMAD pathway plays a role in DDD pathogenesis by upregulating inflammatory cytokines and apoptotic factor Bax. Future studies will focus on a mouse model of DDD using Alk3 gain of function mice. Currently there are no targeted treatment options for patients with DDD as there is a limited role for spine fusion for back or neck symptoms only. Therefore, understanding which pathway results in DDD can help in the development of future targeted treatment. Importantly this study challenges the current dogma about the role of BMP-2 in treatment for DDD.

Age-related changes in bone strength of male radii depend on outer bone size Erin M.R. Bigelow*[1], Daniella M. Patton[1], Gurjit Mandair[1], Ferrous S. Ward[1], Stephen H. Schlecht[1], Michael D. Morris[1], David Kohn[1], Todd L. Bredbenner[2], Karl J. Jepsin[1]. [1]University of Michigan, United States, [2]University of Colorado Colorado Springs, United States

Intracortical remodeling was shown to be greater in wide compared to narrow bones. As remodeling is central to age-related declines in bone mass and strength, we hypothesized whole bone strength would decline faster with age in wide compared to narrow bones. Cadaveric male radii (n=36, 18-89 years) were imaged with pQCT to measure mid-shaft cross-sectional morphology and loaded to failure in 4-point bending to assess strength. Porosity, ash content, mineral/matrix ratio (MMR), and tissue-level mechanical properties were assessed using contralateral radii. Bones were sorted into narrow and wide subgroups using height-adjusted robustness (total area/bone length).When using all the data, bone strength did not decline with age (R2=0.025, p=0.36). However, when split by subgroup, bone strength declined significantly with age for wide (R2=0.56, p=0.0012) but not narrow radii (R2=0.0004, p=0.94)(Fig 1). Significant positive correlations between age and robustness (R2=0.27, p=0.05), cortical area (CtAr)(R2=0.36, p=0.02), ash content (R2=0.37, p=0.02), and MMR (R2=0.32, p=0.03) were seen for narrow but not wide radii (robustness, R2=0.02, p=0.65; CtAr: R2=0.1, p=0.25; Ash: R2=0.03, p=0.54; MMR (R2=0.06, p=0.35)). A new porosity measure called Cortical Pore Score (CPS) was quantified as CPS = S Ap d2 by summing over all pores in nanoCT cross-sections (Ap=pore area, d=distance from the geometric centroid). Porosity increased with age for narrow (R2=0.42, p=0.01) and wide (R2=0.22, p=0.06) radii, but a significantly greater elevation in the CPS-porosity regression for wide compared to narrow radii (p=0.003, ANCOVA) showed that pores had a more deleterious effect on strength for wide radii. The data together provided insight into novel biomechanical mechanisms that explain the different strength-decline trajectories. Narrow radii had a lower baseline strength, which was maintained with aging by increases in outer bone size, CtAr, and ash content that mechanically offset an increase in porosity. Wide radii had a greater

baseline strength, much of which was lost with aging as the effects of porosity and pore location were not offset by changes in morphology or ash content. Subgroup analysis provided evidence of different strength-decline trajectories among individuals that arise through different biomechanical mechanisms. Consideration of inter-individual strength declines could greatly advance our understanding of the biomechanical pathways underlying fracture risk.

Figure 1. Linear regression between whole bone strength and age when A) using all the data and B) when samples were segregated into narrow and wide subgroups.

Adult vs. Middle-Aged Bone Responses to Hindlimb Unloading in Males and Females Rihana Bokhari*[1], Corinne Metzger[1], Alexandra Marich[1], Emily Sturgell[1], Matthew Allen[2], Alyssa Flack[1], Larry Suva[1], Susan Bloomfield[1]. [1]Texas A&M University, United States, [2]Indiana University of Medicine, United States

Pre-clinically, skeletally mature rodents are used to model the adult human skeleton. In C57Bl6/J mice 16 weeks of age is considered skeletally mature. A recent study suggested that both male and female C57Bl/6J mice experience age-related declines in bone volume throughout life, starting at 6-8 wks of age (Glatt 2009). Indeed, the greatest decline in BV/TV occurred after 20 months, but a steady decline was observed between 4 and 20 months. To this end, the response of male and female C57Bl6/J mice to 28 days of hindlimb unloading (HU) was examined in both adult skeletally mature mice (ASM; 16 wks) and older skeletally mature mice (OSM; 44 wks). HU is a well-accepted model of disuse that has been used to measure the impact of disuse primarily in adult or aged animals. Age matched controls (n=10/group) were compared, by t-test, to HU mice at each age (n=10/group/sex). Dual x-ray absorptiometry revealed ASM female total body bone mineral density (BMD) was 7%, lean mass was 5% lower and fat mass was 30% lower with HU. In ASM males, there were no differences in BMD, but lean mass was 7% and fat mass was 39% lower with HU. In ASM females, HU resulted in 26% lower bone volume (BV/TV), 10% lower trabecular thickness (Tb. Th) and 17% lower trabecular number at the distal femur with similar significant declines in cancellous bone microarchitecture in ASM males. OSM females had no differences in BMD or in distal femur cancellous bone microarchitecture; however, lean mass was 7% and fat mass was 71% lower with HU. OSM males were lower with HU by 10% in BMD, 11% in lean mass, 70% in fat mass, 25% in BV/TV and 15% in Tb. Th.Together these results suggest that the impact of disuse on the appendicular skeleton is not uniform in all skeletally mature rodents. Additionally, these data highlight an interesting age- and sex-dependent response to disuse where OSM females are largely resistant to the effects of HU whereas OSM male remain sensitive and have significant decreases in bone architecture. Since the majority of studies assessing disuse effects on bone have been conducted in either young (< 5 mo) rodents or old (>20 mo) rodents, these data demonstrate that disuse-induced bone loss varies by both sex and age. Importantly, the spectrum of what constitutes so-called "skeletally mature rodents" should be challenged and the idea that ASM rodents are representative of middle-aged humans, such as those embarking on spaceflight missions, should be carefully considered.

SUN-0429

Tomographic and biomechanical differences in trabecular bone in the early stage of male osteoporosis Ruei-Ming Chen*, Wei-Hua Chang. Taipei Medical University, Taiwan

Osteoporosis, also called a silent disease, is an age-related continuous process of bone demineralization. Compared to women, osteoporotic fracture in men is associated with greater morbidity and mortality. This study was aimed to elucidate tomographic and mechanistic differences in trabecular and cortical bone in the early stage of male osteoporosis. Male Wistar rats were divided into sham-operated and orchiectomy groups. After surgery for 4 weeks, the animals were sacrificed and their femurs and tibias were collected. Scanning the distal femurs with micro-computed tomography revealed that orchiectomy decreased the trabecular bone number and the trabecular separation, but increased the trabecular pattern factor. Separately, mechanistic analyses of trabecular bone using a reduced-platen-compression test further showed that orchiectomy diminished the maximum loading force, the displacement at maximum load, the energy at maximum force, and the ultimate stress. In contrast, orchiectomy did not influence tomographic structures and mechanistic strength of

cortical bone in the early stage of male osteoporosis. Moreover, statistical analyses demonstrated that the alterations in the maximum loading force measure in osteoporotic trabecular bone meaningfully correlated with the changes in the trabecular bone number, the trabecular separation, and the trabecular pattern factor. Taken together, this study shows the significant trabecular demineralization in the early stage of male osteoporosis.

The Decline of Osteoprogenitor Number and Loss of Bone Mass with Old Age in Mice is Attenuated by Repleting NAD+ with Nicotinamide Riboside Administration Ha-Neui Kim*[1,2], Li Han[1,2], Srividhya Iyer[1], Jianhui Chang[1], Aaron Warren[1,2], Julie Crawford[1,2], Daohong Zhou[1], Stavros Manolagas[1,2], Maria Almeida[1,2]. [1]University of Arkansas for Medical Sciences, United States, [2]Central Arkansas Veterans Healthcare System, United States

The forkhead box O (FoxO) transcription factors attenuate Wnt signaling and the proliferation of osteoprogenitors, and thereby decrease bone formation. The NAD+ dependent Sirtuin1 (Sirt1) deacetylates FoxOs and inhibits their binding to β-catenin; and it also deacetylates β-catenin. Via these mechanisms Sirt1 in osteoblast progenitors increases bone mass. A decline in NAD+ levels with age occurs in many species, from yeast to humans. NAD+ repletion with precursors such as nicotinamide riboside (NR) attenuates the loss of muscle function with old age and prolongs lifespan in mice. Here, we examined whether the NAD+/Sirt1/FoxO signaling pathway plays a role in the age-related bone loss. The levels of NAD+ were decreased in bone marrow stromal cell cultures from 22 month-old as compared to 6 month-old C57BL/6 mice. Acetylation of FoxO1 was also increased in cells from old mice, while the levels of Sirt1 were unaltered. Addition of NR to the cultures increased NAD+ levels in cells from both young and old mice. NR also decreased the acetylation of both FoxO1 and β-catenin and increased the total levels β-catenin in cells from old mice. In addition, NR decreased several marker of senescence including p21, GATA4 and the senescence associated secretory phenotype. Consistent with these effects, NR increased the osteoblastogenic capacity of cells from old mice, but had no effect in cells from young mice, as determined by Alizarin Red staining. We next administered NR (via the drinking water) to 12 month-old C57BL/6 female mice or TdRFP;Osx1-Cre mice, to achieve a dose of 400 mg/kg of body weight/day, for 8 months. NR administration increased the levels of NAD+ in liver and fat, and in cultured bone marrow-derived stromal cells. The number of TdRFP;Osx1 osteoprogenitors, present in the bone marrow, was also increased as determined by flow cytometry. Furthermore, NR attenuated the loss of both cortical and cancellous bone as determined by micro-CT in femur and vertebra. The bone mass phenotype was associated with increased osteoblast differentiation in bone marrow cultures. These findings suggest that the decrease in bone formation with old age is due to a decrease in NAD+ and inhibition of Sirt1 activity in osteoblast progenitors. NAD+ repletion, therefore, represents a rational therapeutic approach to skeletal involution, in addition to other aging associated pathologies.

SUN-0431

Microstructural analysis of human whole spine vertebrae by using HR-pQCT Narihiro Okazaki*[1], Shuta Yamada[1], Ko Chiba[1], Toshiyuki Tsurumoto[2], Makoto Osaki[1]. [1]Department of Orthopaedic Surgery, Nagasaki University Hospital, Japan, [2]Department of Macroscopic Anatomy, Nagasaki University Graduate School of Biomedical Sciences, Japan

Introduction: Vertebral fracture is the most frequent osteoporotic fracture, and various factors are involved in its occurrence. Although bone microstructure is an important factor contributing to the bone strength, there are no studies that have analyzed the microstructure of human whole spine vertebrae. In this study, we analyzed the microstructure of human spine vertebrae by using high-resolution peripheral quantitative computed tomography (HR-pQCT), and investigated the differences between their vertebral levels.Methods: Three formalin-fixed cadavers were investigated (average age: 80.3 years, women). A total of 63 vertebrae (21 vertebrae of C3-L4, each cadaver) were scanned using HR-pQCT (XtremeCT II; Scanco Medical, Switzerland) with a voxel size of 60.7 μm. After excluding the upper and lower endplates and posterior elements, the trabecular and cortical bone microstructure were analyzed for each vertebra: trabecular volumetric bone mineral density (Tb.vBMD), bone volume fraction (BV/TV), trabecular number (Tb.N), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), structure model index (SMI), connectivity density (Conn.D), and degree of anisotropy (DA), cortical thickness (Ct.Th), and cortical porosity (Ct.Po). We divided the spine into 4 regions: cervical region (C3-7), thoracic region (T1-12), thoracolumbar junction (T12-L1) and lumbar region (L2-4), and analyzed the differences of the microstructure parameters between 4 regions.Results: Tb.vBMD, BV/TV, Tb.N, and Conn.D of cervical region were significantly higher, and Tb.Sp, SMI, DA, and Ct.Po of cervical region were significantly lower compared with the other regions. In addition, Ct.Th of cervical region was significantly higher than that of the thoracic region. Meanwhile, there were no statistical differences between thoracic region, thoracolumbar junction, and lumbar region. Conclusions: The cervical spine had higher Tb.vBMD, well-connected plate-like trabecular bone, thickened cortical bone with lower cortical porosity, compared with the other sites.

In addition to the lower mechanical loads, it might be one of the reasons that osteoporotic vertebral fracture is uncommon in the cervical spine.

SUN-0448

Role of Discoidin Domain Receptor 2 in Bone Regeneration Abdulaziz Binrayes*, Renny Franceschi. University of Michigan, United States

Study Goals:Bone is a dynamic tissue with self-healing capabilities that allow the repair of defects and fractures with restoration of original architecture. Bone regeneration requires differentiation of mesenchymal stem cells to osteoblasts and remodeling of the bone extracellular matrix (ECM). Discoidin domain receptor 2 (DDR2) is a bone-associated collagen-activated receptor tyrosine kinase that is required for normal bone development and homeostasis. The purpose of this study is to investigate the role of DDR2 in bone regeneration using a Ddr2-null mouse model (Ddr2slie/slie mice, which contain a spontaneous 150 kb deletion in the Ddr2 locus to create an effective null). Methods: Two bone sites were evaluated for bone regeneration, calvaria and tibia. For calvarial bone regeneration, a 0.5 mm subcritical size defect (SSD) was created in 8 week wild-type (WT), Ddr2slie/slie, and Ddr2+/lacZ mice (contain a LacZ knock-in in one Ddr2 allele) in the parietal lobe of the calvaria. Four weeks post-surgery, bone regeneration of the SSD was compared between WT and Ddr2slie/slie mice.For the tibial fracture model, a tibial fracture was generated in WT, Ddr2slie/slie, Ddr2+/lacZ mice. Three weeks post-surgery, bone healing was compared between WT and Ddr2-/- mice. Results: For calvarial bone regeneration, Ddr2slie/slie mice showed delayed bone regeneration of the SSD with significant lower BV/TV compared to the WT mice. Furthermore, Ddr2slie/slie female mice exhibited lower BV/TV of the SSD than Ddr2slie/slie male mice. In addition, immunohistochemistry showed less Gli1 positive cells in the sagittal suture of Ddr2slie/slie mice when compared with WT. The Ddr2+/lacZ mice showed that Ddr2 is highly expressed in the defect area. For the tibial fracture model, Ddr2slie/slie mice had a lower Radiographic Union Score Tibia (mRUST) than WT. In addition Ddr2slie/slie mice had a larger callus volume compared with the WT. Conclusion: These results indicate that Ddr2 is required for normal intramembranous and endochondral bone regeneration.

Cartilage-like microfiber/hydrogel composite scaffold for articular cartilage therapy and regeneration Young Hun Jeong*, Cheol Woo Park, Gyu Man Kim, Moon Kyu Kwak. Kyungpook National University, Republic of Korea

Cartilage, an important tissue related to the stability of joint motion in human body, has limited life and repair capability. Therefore, the damaged cartilage is difficult to heal or regenerate and it leads to swelling, function impairment, and instable motion with severe pains. There are various surgical and medicinal therapeutic methods that help to postpone the total replacement of joint. Recently, tissue engineering to regenerate new cartilage is being developed using scaffold and stem cells. Particularly, hydrogel receives a lot of attention because of its advantages as tissue engineering scaffold. However, it has low mechanical strength and toughness, which are troublesome limitations in cartilage tissue engineering. Here, we present a cell-laden microfibers/hydrogel construct for cartilage regeneration. The construct is composed of melt-electrospun microfibers, cell-laden hydrogel, and solution-electrospun thin nanofibers. Microfibers provide a higher pore size for cell/hydrogel infiltration and higher mechanical properties. Thin nanofibers were deposited on the microfibers, which could help to prevent washing-out cells and hydrogels by synovial fluid flow. The hydrogel can encapsulate the cells and provide cartilage ECM-like environment to the cells. We used two types of hydrogels; alginate and hyaluronic acid. The cells for this study were human bone marrow-derived mesenchymal stem cells. The transforming growth factor (TGF)-β was loaded into the each type of hydrogel to accelerate cartilage differentiation and maturation. After the fabrication, we investigated morphological properties of nano- and microfibers using scanning electron microscopy. Also, the mechanical properties of the constructs with different hydrogels were identified using compression tests. We carried out the in-vitro cell tests to evaluate cell proliferation, differentiation, and maturation. Consequently, we demonstrated that the mechanical properties of constructs could be controlled and close to real cartilage. Furthermore, the cells in the construct exhibited excellent differentiation into a cartilage phenotype and secretion of cartilage-related ECM as well as high cell viability and proliferation. This work was supported by the NRF funded by the Korea government (MSIT) (No. 2018R1A2B2009540, 2016R1A2B4007858, 2017R1A2B2005515) and "Project of Advanced Technology Center (10077414, 2017)" funded by the Korean Government (MOTIE).

Pin1 suppression rescued impaired endochondral ossification in Fgfr2 S252W/+ Apert mouse model Bong-Soo Kim*, Hye-Rim Shin, Han-Sol Bae, Woo-Jin Kim, Hee-In Yoon, Won-Jun Yoon, Hyun-Mo Ryoo. Seoul National University, Republic of Korea

Apert syndrome is a genetic disease showing craniosynostosis and midface hypoplasia, which is caused mainly by activating mutations on FGFR2. Compare to premature fusion of cranial sutures, impaired endochondral ossification has been poorly understood. In this study, we observed abnormal growth of cranial base and long bone development in Apert syndrome mouse. Furthermore, to rescue Apert phenotypes, we modulated peptidyl-prolyl cis/trans isomerase (Pin1) that is a modifying enzyme of FGF signal transduction by genetic or pharmacological way.Newborn and three-week old mice were analyzed by microCT and histological examination. RNA isolated from cartilage, primary cultured cells and chondrogenic cell line, ATDC5 were assessed for gene expression profiles. For the genetic modulation of Pin1, mice carrying the Fgfr2 S252W/+; Pin1 +/- were generated. To test the effect of Pin1 inhibition on cartilage development, isolated cranial base and tibia from P0 mice were cultured for three weeks with or without Pin1 inhibitor, juglone.Apert syndrome mouse showed early fusion of cranial sutures and midface hypoplasia with high neonatal lethality. Synchondrosis of cranial base was significantly shortened and cranial base was bent in a 10° angle in Apert mouse compare to normal. Severer phenotypes were showed in three-week old mouse including absence of matrix ossification, hypoplasia of cranial base and shortened cranial length. The similar phenotype was observed on tibia. Osteogenic and chondrogenic marker expression was reduced, while proliferation and apoptosis were increased. Interestingly, these abnormal cranial phenotypes were partially rescued in Pin1-deficient Apert mice at P0 stage. Likewise, upon Pin1 inhibitor treatment during organ culture, reduced chondrocyte maturation and cartilage development were restored. Increased chondrogenesis by Pin1 inhibition was also confirmed in vitro.We closely investigated abnormal endochondral ossification in Apert mouse model. Especially, decreased maturation and hypertrophy of chondrocyte caused by activating mutation of Fgfr2 led to under-development of cranial base and long bone. Inhibition of FGF signal by modulating Pin1 resulted rescue of chondrocyte hypertrophy and relieved abnormal craniofacial phenotype in Fgfr2 S252W/+ mice. So far, we briefly showed the possibility of Pin1 inhibition as a therapeutic method on impaired chondrocyte and cartilage development, further studies need to be performed.

Adult Ece1 Ablation in Mice Causes Pulmonary Dysfunction and Pectus Excavatum Jasmin Kristianto*[1], Michael Johnson[2], Abigail Radcliff[2], Robert D Blank[1]. [1]Medical College of Wisconsin, United States, [2]University of Wisconsin Madison, United States

Endothelin (ET) signaling has been shown to mediate the development of osteoblastic lesions in cancer. Endothelin converting enzyme-1 (Ece1) catalyzes the production of mature ET peptides. Previous gene targeting studies in mice showed that homozygous Ece1 deletion had an embryonic lethal phenotype arising from failure of multiple neural crest-derived lineages, characterized by craniofacial malformations, cardiovascular system defects, and colonic aganglionosis. To study the role of Ece1 in post-natal physiology, our lab generated an inducible Ece1 knockout (KO) mouse model using tamoxifen-Cre-ERT2 recombinase. We crossed Ece1flox/flox and Cre-ERT2 Ece1Δ/+ mice and studied male and female offspring of all resulting genotypes. We treated the Cre-ERT2 Ece1Δ/flox mice with either tamoxifen or vehicle, and treated all other genotypes with tamoxifen at 8-9 weeks of age. The adult Ece1 KO mice started to develop respiratory distress about ~4 weeks after tamoxifen injection, accompanied by kyphosis and reduction of activity. They also lost weight (p<0.001) and reached endpoint criteria by 16-20 weeks of age. Pulse oximetry prior to euthanasia showed 10%-20% reduction in SpO2 (Males, p=0.003; Females, p=0.005), and isolated right heart failure (Ejection fraction, p=0.001). At necropsy, pectus excavatum, which is typically seen in restrictive lung disease, was found in all the Ece1 KO mice and none was observed in the control groups. Histology of the lungs showed mild emphysematous changes in the Ece1 KO mice, but not of sufficient severity to account for the degree of respiratory disease. There was no evidence of pulmonary fibrosis or other restrictive lung disease, as determined by picrosirius red histology or collagen quantification (p=0.46) of lung tissue. This combination of findings indicates that impaired pulmonary function in the Ece1 KO mice is primarily musculoskeletal in origin, and demonstrates that Ece1 function is essential in normal physiology as well as in development. Severe cases of pectus excavatum and kyphosis are known to reduce pulmonary function. It is also worth noting that severe forms of osteogenesis imperfecta and hypophosphatasia also cause lethality because of the skeleton inability to support breathing.

A Survey of Skeletal Adaptations in Young Male Mice after Four Weeks of Microgravity Aboard the International Space Station Kevin Maupin*[1], Paul Childress[1], Riley Gorden[1], Alexander Brinker[1], Elliott Beckner[1], Rachel Mannfeld[1], Faisal Khan[1], Matthew Allen[1,2], Nabarun Chakraborty[3], Aarti Gautam[4], Rasha Hammamieh[4], Melissa Kacena[1,2]. [1]Indiana University School of Medicine, United States, [2]Richard L. Roudebush VA Medical Center, United States, [3]Geneva Foundation, US Army Center for Environmental Health Research, United States, [4]US Army Center for Environmental Health Research, United States

Rapid loss of both bone mass and strength is a serious complication experienced by extended exposure to microgravity. Without the skeletal loading that bone is subjected to by Earth's gravity, bone has less stress placed on it, and consequently, bone mass significantly decreases. Astronauts lose a staggering ~1-3% of their bone mass per month while in space, compared to osteoporosis patients who lose ~1% of their bone mass per year. The loss of bone mass in space is not equally distributed across the skeleton and tends to be worse in load bearing bones such as the femur. Characterizing how multiple skeletal compartments change in response to microgravity will lead to better countermeasures to preserve skeletal health for successful long-term spaceflight.To better understand the effects of microgravity on skeletal health, we characterized the skeletal phenotype of young male C57BL/6J mice after four weeks aboard the International Space Station and compared them to identically housed ground controls. Ten-week-old cohabitated male mice (n = 10; 5 mice per cage) were flown on SpaceX-10, launched February 19, 2017. From these mice we analyzed the calvarial parietal bone, mandible, incisor, humerus, tibia, rib, sternum, and L5 vertebra via microcomputed tomography. We observed several significant differences (p < 0.05) between flight and ground mice. There was a decrease in the bone volume fraction (BV/TV) of the incisor, driven by increased expansion of the dental pulp. BV/TV was also decreased in the L5 vertebra due to a reduction in bone volume. There was an overall reduction in rib size including tissue area (T.Ar), bone area (B.Ar), and marrow area (M.Ar). Although there was a trend toward increased calvarial BV/TV (p = 0.1), this was not due to increased bone volume, but reduced tissue volume. Surprisingly, no significant differences were observed in the humerus, which is a weight-bearing bone in mice. Unique to our study was the use of young-adult males and increased mouse density per cage. The colonization of space may require the migration of individuals of healthy reproductive age. Our study increases our knowledge of detrimental effects of unloading/microgravity on the skeleton, and brings mankind one paw closer to Mars…and beyond.Disclaimer: Research was conducted in compliance with the Animal Welfare Act, and all other Federal requirements. SUN-0453

Beginning Maternal Vitamin D Supplementation Before Pregnancy is Associated with Higher Serum Vitamin D Status in Neonates Maryam Razaghi*[1], Sharina Patel[1], Nathalie Gharibeh[1], Nora Shero[1], Sherry Agellon[1], Catherine Vanstone[1], Shugin Wei[2], Hope Weiler [1]. [1]McGill University, Canada, [2]Hôpital Sainte-Justine (Montréal), Canada

Adequate vitamin D intake during pregnancy may improve pregnancy and neonatal health outcomes. Approximately 24% of neonates in Quebec City are born with inadequate serum 25-hydroxyvitamin D (25(OH)D) concentrations. This preliminary analysis aimed to

explore the association of maternal vitamin D supplementation before and/or during pregnancy with neonatal serum 25(OH)D concentrations.Healthy mother-infant pairs (n=849) were recruited at the Lakeshore General Hospital, Montreal, from March 2016 through March 2018. Within 36 h of delivery, maternal demographic and lifestyle factors were surveyed and newborn capillary blood samples were taken to assess vitamin D status using total serum 25(OH)D (Liaison, Diasorin). Data were analyzed descriptively (mean±SD or n (%)) and using mixed model ANOVA with Tukey post hoc tests accounting for effects of neonatal sex, season of delivery, maternal prepregnancy body mass index, family income and maternal race. Mothers were classified into 3 groups according to supplement intake, those taking supplements: during the 3 mo before and during pregnancy (group 1), only during pregnancy (group 2) and not at all (group 3). Differences among groups were tested using ANOVA with Tukey's post hoc tests. Proportions were tested using Chi square analyses.As many as 329 (39%) mothers reported taking a vitamin D supplement before and during pregnancy, while 459 (54%) took it only during pregnancy. Overall, 310 (37%) mothers before pregnancy and 724 (85%) mothers during pregnancy took a supplement at least 4 days per week. Infants born to mothers in group 1 (45.7±18.9 nmol/L) had a higher serum 25(OH)D than those in group 2 (42.1±18.4 nmol/L; p=0.0290) and group 3 (34.0±18.8 nmol/L; p=0.0001); group 2 was higher than group 3 (p=0.0114). More neonates had healthy serum 25(OH)D ($\geq$ 50 nmol/L) in group 1 (37%) than in group 2 (30%) or group 3 (18%; Table 1).Beginning vitamin D supplementation 3 months prior to gestation is associated with higher neonatal vitamin D status than beginning during pregnancy. Considering that low vitamin D status is common among pregnant women, prenatal vitamin D supplementation may be important to establish vitamin D stores in the developing fetus and subsequently improve neonatal status. Public health policy and healthcare professionals should consider recommendations to encourage vitamin D supplementation prior to pregnancy and to reinforce the importance of supplementation during pregnancy.

Table 1. Frequency of infant serum 25(OH)D concentrations by group*

	Group 1	Group 2	Group 3
Overall	329 (39%)	459 (54%)	60 (7%)
≤ 29.9 nmol/L	59 (18%)	127 (28%)	29 (48%)
30.0 – 49.9 nmol/L	143 (43%)	190 (41%)	20 (33%)
≥ 50.0 nmol/L	127 (37%)	142 (30%)	11 (18%)

Effect of extracellular high phosphate on myogenesis of C2C12 myoblasts
Eisuke Tomatsu*[1], Hidehito Inagaki[2], Tsukasa Kawakami[1], Yohei Asada[1], Shogo Nakayama[1], Izumi Hiratsuka[1], Yasumasa Yoshino[1], Sahoko Sekiguchi-Ueda[1], Megumi Shibata[1], Takeshi Takayanagi[1], Yoshihisa Sugimura[1], Hiroki Kurahashi[2], Atsushi Suzuki[1]. [1]Department of Endocrinology and Metabolism, Fujita Health University, Japan, [2]Division of Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Japan

Background: Our previous study shows that the vascular smooth muscle cells survive by changing osteoblast-like cells and promoting extracellular matrix calcification in mild high phosphate (Pi) medium. However, the higher Pi concentration lead apoptosis in the vascular smooth muscle cells. On the contrary, osteoblasts and chondrocytes can survive at higher Pi concentration. Therefore, the impact of hyperphosphatemia seems to depend on cellular phenotype. The purpose of our study is identifying how the skeletal muscle cell lineage behaves under high Pi milieu.Methods: We cultured the C2C12 myoblasts, skeletal muscle cell lines of mouse derived muscle satellite cells, for 7 days in 1 to 10 mM Pi concentration. The cell number was counted with Cell Counter, and their myotube formation was observed with light microscopy. RNA expression levels of Runx2, MyoD1, Myogenin, ACTA2 at each Pi concentration were quantified by RT-PCR on day = 1, 4 and 7.Result: The C2C12 myoblasts survived for 7 days under higher Pi concentration up to 5 mM Pi. However, 10 mM Pi induced cell apoptosis in these cells. The gene expression of Runx2 temporarily increased in high Pi medium (x 2.27 in 2 mM, x 3.03 in 3 mM, x 1.48 in 5 mM, x 2.50 in 10 mM at 8 h incubation), and then decreased for 24 hours. When the cells were cultured in high Pi medium for 7 days, high Pi milieu up to 5 mM did not affect the Runx2 expression but suppressed the MyoD1 expression. On the other hand, the gene expression of Myogenin and ACTA2 was not affected by high Pi milieu. C2C12 cells in high Pi milieu up to 5 mM showed myotube differentiation as well as in normal Pi concentration.Conclusion: High Pi milieu temporally enhances osteoblastgenesis and reduces myogenesis in C2C12 myoblast, but does not affect final differentiation to myotubes.

Delayed tooth eruption in Runx2+/- mice is rescued by HDAC inhibitors.
Heein Yoon*, Han-Sol Bae, Hye-Rim Shin, Bong-Soo Kim, Jeong-Hwa Baek, Yun-Sil Lee, Kyung-Mi Woo, Hyun-Mo Ryoo. Seoul National University, Republic of Korea

Cleidocranial dysplasia (CCD) is an autosomal dominant skeletal dysplasia caused by loss-of-function mutations in RUNX2. The distinct symptoms of CCD include premature closure of cranial sutures, poorly developed clavicles and dental anomalies. The latter include retention of deciduous teeth, delayed or unerupted permanent teeth and supernumerary teeth and the treatment at present would be very painful surgical and expensive orthodontic intervention. The objective of this study is to elucidate the mechanism of th tooth eruption problems in CCD patients and to develop easier and cheaper therapeutic avenues. We found that Runx2+/- mice have delayed tooth eruption by micro CT and histological analysis. Runx2+/- mice have shown decreased TRAP-positive multinucleated osteoclasts in histological analysis. The combinations of co-cultures of bone marrow-derived macrophage / osteoblast from WT and Runx2+/-, respectively, indicated that Runx2+/- primary osteoblast is responsible for the decreased osteoclast differentiation. RNA sequencing analysis of mRNAs from Runx2+/- calvarial tissue and primary oseoblasts indicated that the mRNA expression of Csf-1 in primary osteoblast was signficantly and consistently lower in Runx2+/- than in WT. As our previous reports indicated several histone deacetylase (HDAC) inhibitors can recover genetic Runx2 deficiency through both epigenetic regulation of Runx2 expression and posttranslational modification of Runx2 activity. HDAC inhibitors treated group recovered decreased Runx2 mRNA level in Runx2+/- primary osteoblasts. Previous papers suggested that decreased osteoclast differentiation in Runx2+/- mice is caused by decreased Rankl/Opg. Interestingly, the Rankl/Opg ratio was neither changed significantly nor increased by HDAC inhibitors treatment in Runx2+/- primary osteoblasts culture system. Importantly, administration of a HDAC inhibitor, accelerated delayed tooth eruption of Runx2+/- mice significantly. These results indicated that attenuated expression of Csf-1 in Runx2+/- osteoblast could be the major target for recovery of down-regulated osteoclast differentiation and consequently of delayed tooth eruption in Runx2+/- mice. Taken together, our work establishes a suggestion that a HDAC inhibitor could be a potential therapeutic reagent of dental anomalies in CCD patients.

Toll-like Receptors 3 and 4 are Critical Regulators of Bone Formation even in the Absence of Infection Alan Davis*. Baylor College of Medicine, United States

Toll-like Receptors 3 and 4 are Critical Regulators of Bone Formation even in the Absence of InfectionToll-like receptor pathways TLR3 and 4 play a critical role in innate immunity because they are upstream regulators of the NFκB pathway. These receptors are present on macrophages and activated by binding of dsRNA (TLR3) or LPS (TLR4) as a rapid defense mechanism that leads to both Cox2 formation as well as interferon release. Surprisingly, both receptors have been recently linked to cancer because of the production of myeloid-derived suppressor cells that prevent adaptive immunity and support tissue growth, which in the case of TLR4 includes the production of osteoclasts. We recently noted that cells within peripheral nerves begin to express TLR3, which is normally absent, after induction of heterotopic ossification (HO). Since nerves are normally protected by a blood-nerve barrier, its presence inside such nerves led us to hypothesize that it plays an additional function in HO beyond immune surveillance. In support of this finding, studies of HO in mice lacking TLR3, show a four-fold reduction in bone volume as assessed by microCT compared to their wild type counterparts (p less than 0.001), whereas mice lacking TLR4 show an increase in bone volume. Further, while our studies show that TLR3 is expressed, after HO induction ,in the endoneurium of peripheral nerves , both TLR3 and 4 are also expressed in a key regulatory population of cells, which are also present in humans during HO, that we have termed transient brown fat (tBAT). Finally, mice lacking TLR3 have an altered vasculature and during induction of HO undergo substantial hemorrhaging at the site of new bone formation. Since we have previously shown that cells within the endoneurium respond to BMP2 signaling and rapidly exit the nerve to contribute directly to bone formation, we hypothesize that TLR3 may play a key role in this process. Since we observe the presence of osterix expression in cells present in the endoneurium, we hypothesize that activation of TLR3 in the presence of BMP2 signaling may be capable of driving trans-differentiation of nonmyelinating Schwann cells, to a cell type with the characteristics of neural crest. Since the TLR3 pathway has been shown to be essential for the formation of induced pluripotent stem cells (IPS cells), we hypothesize that this is a key component in this process. To further confirm this, we are analyzing TLR3 KO mice for the presence of the neural-derived osteogenic cells. We are also characterizing the additional early molecular and cellular stages of HO in both the TLR 3 and TLR4 KO mice and highlighting differences between HO in these mice and their wild type counterparts

Discoidin Domain Receptor 2 Controls Skeletal Stem Cell Lineage Chunxi Ge*[1], Fatma Mohamed[2], Yi Tang[3], Stephan Weiss[3], Renny Franceschi[1]. [1]Dept of Periodontics & Oral Medicine, University of Michigan School of Dentistry, United States, [2]Dept of Periodontics & Oral Medicine, Univ. of Michigan School of Dentistry, United States, [3]Life Sciences Institute, University of Michigan, United States

Discoidin domain receptor 2 (DDR2), a receptor tyrosine kinase activated by fibrillar collagens, is essential for skeletal development. In humans, mutations in DDR2 cause spondylo-meta-epiphyseal dysplasia (SMED), an autosomal recessive disorder characterized by abnormal skeletal development, short stature, craniofacial and dental anomalies. Ddr2-deficient mice phenocopy SMED and have defects in bone formation and osteoblast differentiation accompanied by increased marrow adipogenesis (Ge et al. JBMR 31:2391, 2016). This study examines whether these changes are explained by a possible requirement for DDR2 in skeletal stem cell (SSC) function. Ddr2 expression, measured using Ddr2+/lacZ mice, localized Ddr2 to most skeletal structures including regions known to harbor SSCs (cranial sutures, resting zone cartilage and marrow). In addition, FACS-purified LacZ+ marrow cells were enriched in SSC marker mRNAs (Sca1 and LepR). Likewise, purified SCCs (PDGFRa+CD51+) were enriched in Ddr2 mRNA when compared with unsorted nucleated cells. To determine if Ddr2 is necessary for SCC lineage allocation, PDGFRa+CD51+ SSCs were purified from Ddr2loxp/loxp mice and treated with control (AdLacZ) or Cre-expressing adenovirus (AdCre). Ddr2 knockout reduced CFU-OB and osteoblast differentiation while increasing CFU-Adipo and adipocyte differentiation without altering CFU-F. The basis for Ddr2-dependent changes in SSC lineage is currently being explored, but may be related to possible functions of Ddr2 in ECM remodeling in that Ddr2 deficient mice have low bone levels of MT1-MMP (MMP14), a matrix metalloproteinase with known effects on SSC osteoblast/adipocyte lineage commitment (Tang et al Dev Cell 2013;25:402-16). Indeed, MT1-MMP induction during osteoblast differentiation is decreased in BMSCs from Ddr2-deficient mice. Together, these studies identify an important function of Ddr2 in SSCs that is likely related to its ability to remodel the SSC ECM niche.

Sost KO mice cannot rescue the conditional knockout of the Bmp2 gene Using the Osterix-CreERt2 or aSMA-CreERt2 model Stephen E Harris*[1], Jelica Gluhak-Heinrich[1], Marie A Harris[1], Jian Feng[2], Yong Cui[1], Ivo Kalajzic[3]. [1]uthscsa, United States, [2]texas a and m Dental School, United States, [3]Uconn Health, United States

We have deleted the Bmp2 gene in stem/progenitor cells in the bone marrow and periodontium, using the aSMA-CreERt2 and Osterix-CreERt2 models starting at 6 day and assayed up to 3 months. As in previous studies, the major defects in the spine, long bones, and periodontium is on the periosteum progenitors and vascular associated mesenchymal stem/progenitor cells in the bone marrow and periodontium, as assayed in vivo with CD146, aSMA, and CD31 immunocytochemistry. Using EdU labeling, we have found that one of the functions of Bmp2 is to allow expansion and growth of the stem cells, as well as drive their differentiation to osteoblast, -cytes, alveolar bone and cementums of the mandible. In vivo and in vitro studies have demonstrated that one of the major enhancers of the Bmp2 regulator region contains, an estrogen receptor response element, and is stimulate by estradiol 17beta. This same region of the Bmp2 gene enhancer, also contains a TCF/b-catenin response region and has been shown to respond to Wnt3a in vitro. In vivo the Bmp2 gene expression is increased in the Axin2 deletion model, where Axin2 normally acts to inhibit or restrain Wnt activity. Our hypothesis is that Bmp2 gene is a critical downstream component of Wnt activity on long bones/spine and bones of the craniofacial region. To test this hypothesis, we crossed the Bmp2cKO mouse models, in which the Bmp2 gene is removed in stem/progenitor cells in the bone marrow or periodontium (aSMA+ or Osterix+), with the global SostKO. SostKO has been established to increase both alveolar bone in the mandible and increase bone mass in the long bones and spine, due to the increased canonical Wnt signaling in the absence of the Sost gene. We found that deletion of the Sost gene increases bone mass, as expected. However, the bone and mandible bone defects are not rescued in Bmp2 cKO with deletion of the Sost gene. Thus, the Bmp2 gene is a critical downstream component and node of canonical Wnt activity on both, long bones, spine and mandibular alveolar bone.

Exposure of Nutrient-stressed Bone-derived Mesenchymal Stem Cells to the Tryptophan Metabolite Kynurenine Inhibits Autophagy and Promotes Cell Death Robert Bragg*[1], Thomas Barrett[2], Ahmed Elmansi[2], Khaled Hussein[2], Tanner Mobley[1], Wendy Bollag[3], Sadanand Fulzele[4], Xingming Shi[5], Meghan Mcgee-Lawrence[2], Mark Hamrick[2], Carlos Isales[6], William Hill[2,7]. [1]Medical College of Georgia, Augusta University, United States, [2]Dept Cellular Biology & Anatomy, Medical College of Georgia, Augusta University, United States, [3]Department of Physiology and Endocrinology, Medical College of Georgia, Augusta University, United States, [4]Department of Orthopedic Surgery, Medical College of Georgia, Augusta University, United States, [5]Dept of Neuroscience and Regenerative Medicine, Medical College of Georgia, Augusta University, United States, [6]Dept of Medicine Endocrinology, Medical College of Georgia, Augusta University, United States, [7]Charlie Norwood VAMC, United States

Autophagy is increasingly understood to be critical in promoting cell survival in response to stressors. Bone-derived mesenchymal stem cells (BMSCs) differentiate into osteoblasts and osteocytes driving formation of new bone. BMSC survival and capacity to differentiate declines with age, correlating with impaired autophagy in aged BMSCs. A proposed reason for such deterioration is chronic exposure to a hostile microenvironment brought on by age-associated changes within the bone marrow niche, such as an increase in free radicals and reactive oxygen species (ROS).A recently identified change in bone and bone marrow is a relative increase in the metabolism of the essential amino acid tryptophan (TRP) to kynurenine (KYN), catalyzed by indoleamine_2,3-dioxygenase (IDO) or free-radical oxidation of TRP to KYN. IDO activity increases with age, and could be a promising therapeutic target for age-related osteopenia and osteoporosis. To further investigate this link, our group has shown that serum levels of KYN are elevated with age and correlate with bone loss in vivo. Furthermore, direct administration of KYN in the diet decreases bone mass in vivo and in vitro murine BMSCs treated with KYN show decreased osteogenesis. Here we determined the effects of KYN on autophagy as a modulator of both BMSC survival and function. BMSCs were treated with KYN (200uM) in the presence or absence of 100uM chloroquine (CQ) to assess autophagic flux under serum starvation. LC3-II, a prominent marker of autophagy, showed disruption of autophagic flux by 12 through 24 hours post KYN treatment relative to controls under normoxic (21% oxygen) culture conditions. Further, under more physiologically representative long-term 3% oxygen culturing conditions found in the bone marrow BMSC niche microenvironment LC3-II was markedly lower across all time points (4, 12, and 24 hours) following kynurenine treatment. Again showing disruption of autophagic flux as well as overall reduction in LC3-II levels. Additionally, markers for apoptosis (e.g. cleaved PARP) were also lost with kynurenine treatment suggesting a more rapid rate of cell death and switching of the cell death mechanism to necrosis. Overall, these data indicate that kynurenine enhances cell death in BMSCs during prolonged stress, in part by blocking autophagy

The role of the RhoGTPase cdc42 in the differentiation of mesenchymal stromal cells to osteoblasts and adipocytes Katrin Huck*[1], Carla Sens-Albert[2], Inaam Nakchbandi[1]. [1]Max-Planck Institute for Medical Research, Germany, [2]University of Heidelberg, Germany

Mesenchymal stromal cells (MSCs) in the bone marrow either differentiate to osteoblasts or adipocytes. Despite major advances in understanding how cell fate decisions are made much remains to be understood. Integrins are receptors on cell surfaces that transmit cues from the microenvironment and control vital functions such as cell differentiation. Integrins and Rho family GTPases interact to affect cell behavior. Our aim was to evaluate the role of integrins and integrin signaling in determining whether mesenchymal stromal cells differentiate to osteoblasts or adipocytes.As MSCs differentiate to osteoblasts integrin expression changes with a decrease in β3, suggesting that integrins play a role in differentiation. Inhibiting FAK, an early mediator of integrin signaling decreased PPARγ mRNA expression, the master regulator of adipogenesis in MSCs. Either culturing on or adding tenascin C decreased PPARγ mRNA expression (30% and 50% of CT respectively). Since tenascin C engages, among others, β3 integrins, we deleted β3 integrin genetically. This increased PPARγ expression in MSCs in line with a possible inhibitory effect on adipogenesis mediated by a β3 integrin. Calvarial osteoblasts from knockout mice also showed decreased nodule formation and stimulation of β3 integrin mediated signaling increased nodule formation. Thus, stimulating β3 integrin increases osteogenic differentiation in parallel to inhibiting adipogenesis.We then evaluated two key RhoGTPases cdc42 and rac1, because of their role in mediating integrin signaling. Chemically inhibiting either molecules diminished osteoblast differentiation and increased mainly the number of preadipocytes in newborn calvarial osteoblast cultures. The inhibition of cdc42 or rac1 increased PPARγ mRNA expression in MSCs (3-fold increase; p<0.05). While cdc42 affected PPARγ by stimulating MAP kinase (ERK and p38) signaling, rac1 effects were modest. In line with this, deletion of cdc42 in stromal cells led to an increase in adipocytes in the bone marrow (Osx-cre_cdc42fl/fl vs. Osx-cre: 2-fold increase, p<0.05), while deletion of rac1 failed to show an effect.Taken together, our data suggest that integrin signaling in mesenchymal stromal cells, at least partially through β3 integrin, enhances osteoblast differentiation while inhibiting adipocyte

differentiation molecules in the bone marrow. Furthermore, the RhoGTPase cdc42 in MSCs mediates the crosstalk between osteogenic and adipogenic differentiation pathways.

Cartilage tissue engineering using poly(PCL/PTHF urethane)/collagen nanofibers via blocking NF–kappa B signaling pathway Tongmeng Jiang*, Xianyuan Huang, Shujun Heng, Li Zheng, Jinmin Zhao. Guangxi Engineering Center in Biomedical Materials for Tissue and Organ Regeneration & Guangxi Collaborative Innovation Center for Biomedicine, The First Affiliated Hospital of Guangxi Medical University, China

Cartilage tissue engineering is one of the most promising methods for cartilage repair. We carried out nanofibers made of poly(ε-caprolactone)/polytetrahydrofuran (PCL/PTHF) and collagen I from calf skin using electrospinning technology, and further effects of chondrogenesis of mesenchymal stem cells (MSCs) and the cartilage regeneration in vivo were evaluated. PCL/PTHF nanofibers had a modulus of 4.3 Mpa and PCL/PTHF/collagen nanofibers had a modulus of 6.8 Mpa are within the range of the modulus of natural cartilage (1 to 10 MPa). Intriguingly, the softer PCL/PTHF/collagen nanofibers induced the chondrogenesis in vitro and cartilage regeneration in vivo more efficiently than the stiffer PCL/PTHF nanofibers without additional chondrogenesis inducers. Transcriptional profiles showed that the PCL/PTHF/collagen nanofibers prior to PCL/PTHF/collagen nanofibers in inducing chondrogenesis by suppressing inflammation via specifically blocking the NF–kappa B signaling pathway. This study indicates that the PCL/PTHF/collagen nanofibers can serve as building blocks of new scaffolds and provides new insights on the effect of the mechanical properties of the nanofibers on the cartilage tissue engineering.

A Long Intergenic Noncoding RNA in Macrophages and Mesenchymal Stem Cells Regulates in vivo Trabecular Bone Formation Coralee E. Tye*[1], Jonathan A.R. Gordon[1], Kristiaan Finstad[1], Roland Elling[2], Kate A. Fitzgerald[2], Janet L. Stein[1], Gary S. Stein[1], Jane B. Lian[1]. [1]Department of Biochemistry, University of Vermont Larner College of Medicine, United States, [2]Department of, Medicine, University of Massachusetts Medical School, United States

Long non-coding RNAs(lncRNAs) are critical for organ development, sex determination and lineage commitment through multiple mechanisms. Among their functional activities are regulating RNA splicing, forming interactomes with transcription factors, acting as sponges to inhibit miRNAs and mediating chromatin interactions – all contributing to a cell's phenotype. Thousands of lncRNAs are found within any genome; however, in vivo functional characterization of lncRNAs for all tissues and disease states is limited. We have identified lncRNAs associated with specific stages of osteoblastogenesis by global RNA-Seq using human and mouse primary mesenchymal stromal cells (hMSC; mMSC) during osteoblast differentiation (days 0-proliferation, 7-commitment,14- ECM deposition, 21-mineralization). In contrast to expressed genes and miRNAs, only 22% of mouse lncRNA genes had conserved expression with human. Focusing on these common lncRNAs,, subsets of lncRNAs were expressed at distinct stages. Guilt-by association analyses correlated the expression patterns of lncRNAs with mRNAs, and mRNA clusters were associated with differ-

ent functional activities (GO terms). Biological categories were related to skeletal development, ossification, mineralization, proteins located at the cell periphery, G-protein receptor signaling and metabolism. We have characterized a lncRNA expressed during proliferation to identify the presence of a bone phenotype in an available KO mouse of the lncRNA, lincRNA-Cox2(ptgs2os2). This lncRNA is responsible for NF-kB signaling in macrophages and is a broad–acting regulator of the inflammatory response. The lincRNA-Cox2 is located proximal to the prostaglandin synthase gene, Pgts. Crosstalk between osteoblasts and macrophages has been well documented in the literature. We found that female KO mice exhibit a 2.5-3.7 fold increase in trabecular bone (TB) formation by 2 month and was sustained at 4 and 6 month compared to WT bone (Scanco CT analyses, n=12 KO and WT, 4 HET/ group) with no effect on cortical bone. However male mice exhibited 1.6-2.1 fold increase at 2 month in TB which was not sustained at 4 months. This sexual dimorphism is currently being addressed in vitro. These findings open novel dimensions for exploring this linc-COX2 in contributing to skeletal disorders, resulting from inflammation and for many other lncRNAs with potential and critical roles in bone formation.

SUN-0484

Autograft ligament-tendon tissues formed a "new knee" in the damaged knee surface Chi Ma*[1], Chuanju Liu[2], Lei Zhang[1], Hu Zhao[3], Xiaohua Liu[3], Yan Jing[3], Jian Q. Feng[2]. [1]Postdoctoral Fellow, United States, [2]Professor, United States, [3]Assistant Professor, United States

Although a great progress has been made in last decades in improving skeletal trauma repairing, cartilage trauma or diseases cannot be repaired by their own cells, and common procedures for restoration of joint function are the replacement with metal prostheses. The aim of this study is to develop a new strategy for cartilage and bone repairing by the detached ligament/tendon. To achieve this goal we firstly carried out the surgery at the mandible of a young adult mice in the line of Gli1-CreERT2 and 3.2 Col 1-CreERT2 , where a bone trauma was created at the mandible, and the tendon from lateral masseter was cut and fixed on the defective bone surface. The mice were given injection of tamoxifen to activate the tdTomato signal simultaneously. These mice were separately collected at weeks-1, -2 and -3. There were ectopic bones formed on the bone surface by m-CT (Fig.1a). Histological analyses showed the newly formed tissue with the typical articular structure (cartilage & subchondral bone) (Fig.1b). The cell lineage tracing studies showed that 1) there were a gradual increase in the Gli1+ bone & cartilage cells in neo-tissue during 3 weeks (Fig 2); 2) the new formed " subchondral bone " strongly expressed markers of tendon, cartilage and bone (vimentin, periostin, aggrecan, Col X and DMP1) compared to the existed bone. Importantly, in the 3.2 Col 1 tracing line, there were much more tdTomato+ bone cells in the early repairing (Fig 3), supporting the notion that the terminate tendon cells react to trauma first and the Gli1+ progenitor-derived cells add new tenocytes, which take much long time. Next, we created a trauma sites in the knee joint of mice (including removal of the articular cartilage) under the background of the the Gli1-CreERT2 mice. Following the same strategy as described above, the results showed the great increase of the ectopic calcified mass. By 3-weeks, there were astonishing amount of new bone formed on the bone surface and a "new knee" on the articular cartilage surface (Fig 4a). Histology data revealed an articular-subchondral bone-like structure on the articular trauma area (Fig 4b), and a clear view of the tendon-derived bone cells in the damaged bone surface (Fig 4c). These finding suggest that 1) the cells from ligament and tendon can directly transdifferentiate into either cartilage or bone cells based on the local factors released from trauma sites; and 2) the newly formed "knee" or bone are robust in speed and quantity.

Characterizing Osteogenic Deficiency in Neurofibromatosis Type 1 at Single-Cell Resolution Nandina Paria*[1], Jinyan Chan[2], Jingua Gu[2], Carol Wise[1], Jonathan Rios[1]. [1]Texas Scottish Rite Hospital for Children, United States, [2]Baylor Research Institute, United States

Neurofibromatosis Type 1 (NF1) is a cancer-predisposing syndrome caused by haploinsufficiency of the NF1gene. Some children with NF1 present at birth with significant tibia deformity that has a high risk of fracture and subsequent persistent healing defects (pseudoarthrosis, PA) often requiring amputation. The goal of this study is to characterize the molecular mechanisms leading to fracture healing defects in children with NF1. Studies in multiple mouse models suggest that loss of Nf1in mesenchymal progenitors leads to a failure in osteogenic differentiation, and thus skeletal defects. We previously demonstrated that tibia PA is associated with NF1-deficiency caused by somatic mutation of the remaining NF1allele. However, mechanistic studies of osteogenic differentiation defects have been limited by the mosaic nature of somatically-mutated PA cells in culture. We recently established that upregulation of EREG, encoding Epiregulin, is a biomarker for NF1-deficient patient-derived stromal cells from the PA site that, for the first time, allows study of NF1-deficient cells from a mixed population in culture. Here we report a new study in which single-cell mRNA-sequencing (sc-mRNAseq) was performed on patient-derived stromal cells from the affected PA and unaffected iliac crest bones cultured through a time-course of osteogenic differentiation. Single-cell expression results were used to organize cells along an "osteogenic trajectory" that proceeds from undifferentiated cell to osteoblast cell populations. For the first time, we show that osteogenic differentiation is a dynamic process during which cells progress through multiple transition states. As expected, patient-derived EREGLOW haploinsufficient cells from PA bone display an osteogenic trajectory consistent with proper differentiation, similar to iliac crest cells. Surprisingly, EREGHIGHNF1-deficient PA cells upregulate ALPL(encoding Alkaline Phosphatase), a marker of osteogenic differentiation, independent of differentiation state, a phenomenon not observed in mouse stromal cells. Furthermore, EREGHIGHNF1-deficient cells show a scattered osteogenic trajectory suggestive of cell-autonomous defects throughout differentiation. Coupling sc-mRNAseq with a novel biomarker, our approach allows for a mechanistic investigation of the osteogenic defects associated with NF1-deficiency leading, at least in part, to persistent fracture healing defects in children with NF1.

βcatenin preserves stem state of MSC through activation of EZH2 Buer Sen*[1], Zhihui Xie[1], Jeyantt S Sankaran[1], Amel Dudakovic[2], Gunes Uzer[3], Maya Styner[1], Mark B Meyer[4], Andre J Van Wijnen[2], Janet Rubin[1]. [1]University of North Carolina, United States, [2]Mayo Clinic, United States, [3]Boise State University, United States, [4]University of Wisconsin, United States

The contribution of βcatenin to Wnt's downstream osteogenic effect is a significant but poorly understood area. While bcatenin promotes expansion of the osteoprogenitor clone, it does not, alone, cause osteoblast differentiation. While βcatenin directly inhibits MSC adipogenesis through inhibition of PPARγ activity, it also inhibits PPARγ expression via unknown mechanisms. We postulated that βcatenin might regulate the switch between osteoblast and adipocyte differentiation through co-modulation of cytoskeletal cues known to affect lineage selection. We thus set out to find if βcatenin inhibition of adipogenesis was dependent on cytoskeletal context, overexpressing βcatenin resistant to proteolysis ("mutβcat") in marrow derived mouse MSC. The anti-adipogenic effect of mutβcat (↓>50%) persisted when the actin cytoskeleton was either enhanced (LPA) or depleted (ROCK inhibition). siRNA silencing of βcatenin promoted adipogenesis (↑>50%) was also cytoskeleton independent. We next asked if βcatenin's anti-adipogenic effect was at the expense of enhanced osteogenesis. Mutβcat overexpression did not promote osteogenesis, but rather significantly inhibited osteoblast gene expression by >50% (Sp7, Bglap, Alpl). siRNA against βcatenin significantly enhanced osteogenesis; all effects were independent of cytoskeletal context. A clue to the mechanism by which βcatenin prevented both adipogenesis and osteogenesis was found in ChIPseq of LiCl-treated MSC: βcatenin associated with the Ezh2 promoter. Ezh2, a key component of the PRC2 complex, is inhibits osteogenesis by promoting stemness and proliferation through genome methylation. This led us to hypothesize that βcatenin might alter Ezh2 activity. Indeed, overexpression of mutβcat increased Ezh2 expression and H3K27 methylation, and silencing βcatenin decreased Ezh2 expression and activity. Critically, inhibition of Ezh2 genome methylation with GSK126 blocked βcatenin's inhibition of both osteogenic and adipogenic differentiation. Taken together, our results suggest that βcatenin is not a primary effector of Wnt-induced osteogenesis. Instead, βcatenin serves to preserve MSC stemness and prevent differentiation, independent of but additive to cytoskeletal context. Most importantly, this fundamental effect of βcatenin requires direct control of Ezh2 activity, indicating that βcatenin regulation of MSC fate involves alterations in chromatin state.

The avascular nature of cartilage makes it a unique tissue in the human body, but whether and how the absence of blood vessels regulates chondrogenesis remains unknown. In this study, we show that obstruction of vascular invasion during bone healing favors chondrogenic over osteogenic differentiation of skeletal progenitor cells. Unexpectedly, we found that this process was linked to a decreased availability of extracellular lipids. When lipids are scarce, skeletal progenitors increase intracellular lipid droplet turnover to temporarily maintain fatty acid oxidation (FAO). At the same time, lipid deprivation increases the levels of the master chondrogenic transcription factor SOX9, which acts as a regulator of cellular metabolism by suppressing FAO. In accordance, mature chondrocytes exhibit low rates of FAO compared to skeletal progenitors and mature osteoblasts. Together, our results define lipid scarcity as an important determinant of chondrogenic commitment, and identify SOX9 as a critical metabolic mediator.

Nestin+ Mesenchymal Stem/Progenitor Cells essential for Type H Vessels Formation in Coupling Osteogenesis Liang Xie*[1], Xiao Wang[2], Manman Gao[2], Changjun Li[2], Hui Xie[3], Lingling Xian[4], Mei Wan[5], Qianming Chen[1], Xu Cao[2]. [1]State Key Laboratory of Oral Diseases, West China Hospital of Stomatology, Sichuan University, China, [2]Department of Orthopedic Surgery, School of Medicine, Johns Hopkins University, United States, [3]Department of Sports Medicine, Xiangya Hospital, Central South University, China, [4]Division of Hematology, Department of Medicine, The Johns Hopkins University School of Medicine, United States, [5]Department of Orthopaedic Surgery, Johns Hopkins University School of Medicine, United States

Bone remodeling is a lifelong process depending on two dynamic and balanced activities. Specifically, mature bone is removed by osteoclasts, which are phagocytic cells generated by the fusion of monocytes, and new bone is formed by osteoblasts, which are differentiated by bone marrow mesenchymal stem/progenitor cells (MSPCs). Nestin was recognized as an MSPCs' marker, while recent studies suggested nestin+ cells are heterozygous populations providing the precursors to both mesenchymal and endothelial lineages. Clarification of the nestin+ cell fate is necessary for the understand the mechanism of bone remodeling. The coupling of bone resorption by osteoclasts and bone formation by osteoblasts during bone remodeling may be regulated by the vascular system. Cumulative evidence demonstrated that angiogenesis not only establishes local circulation in the newly formed bone, but also directly promotes osteogenesis. Particularly, a subset of smallest vessels highly expressed CD31 and endomucin (Emcn), termed CD31hiEmcnhi type H vessel, has recently been shown to promote bone formation, presumably by optimizing efficiency of blood flow and nutrient exchange. However, the cellular origin of type H vessel is unknown. In this study, we sought to characterize cell origin of type H vessels, particularly during bone pathophysiological changes such as in PDGF-BB signaling deficient mice or after PTH stimulation. We found that bone marrow nestin+ cells located in metaphysis gave rise to type H vessel formation and subsequent osteogenesis during bone remodeling in different animal models. A subset of nestin+ MSCs enriched in metaphysis are essential for type H vessels formation during bone remodeling. Deletion of nestin+ cells caused less vessels formation. PDGF-BB could bind to its receptor PDGF-β on nestin+ cells, thereby affect type H vessels angiogenesis. PTH accelerated bone remodeling through induced type H vessels formation by increasing nestin+ cells. Our finding fully characterizes this sub-population of MSCs and help to understand the physiological function of nestin+ cells in angiogenesis during bone remodeling.

RNA-Seq Based Comparative Transcriptome Profiling To Decipher The Role Of Glycogen Synthase Kinase 3 Signaling In Cartilage Biology Supinder Kour Bali*[1], Lauren Solomon[2], Dawn Bryce[1], Frank Beier[1]. [1]Department of Physiology and Pharmacology, The University of Western Ontario, Canada, [2]Department of Pathology and Laboratory Medicine, The University of Western Ontario, Canada

Osteoarthritis is the most common degenerative disease of diarthrodial joints, which is classically characterized by the breakdown of articular cartilage. However, increasing scientific evidence support involvement of other tissues in the affected joint, contributing to disease pathophysiology and progression. It is, therefore, crucial to identify molecular pathways that regulate regenerative potential of cartilage and other joint tissues, with the long-term goal to design strategies to regenerate damaged joint tissues and to prevent or reverse disease progression. Studies have shown glycogen synthase kinase (GSK) 3 alpha and beta to be key regulators of cartilage development, but their roles in cartilage homeostasis and disease are not well understood. In this study, we aim to investigate key GSK-3 dependent processes and functions by comparative differential transcriptome profiling of normal mouse articular chondrocytes and those treated with a pharmacological inhibitor of GSK-3. Immature murine articular chondrocytes were treated with GSK3 inhibitor SB216763 for 24 hours, followed by RNA-Seq. GTF 'mm10' was used to map alignment of query sequence reads on mouse genome. Two publically available databases – UCSC and Ensembl - were used to analyze RNA-Seq data; and only included the transcripts represented and annotated in both the databases for enrichment analyses. RNA-Seq results were further validated by gene expression studies using real-time PCR.Bioinformatics analyses for comparative differential gene expression profiling between the two experimental groups highlighted 324 genes involved in various biological, cellular and molecular processes, as well as skeletal abnormalities associated with reported human phenotypes. For further validation of results, we performed gene expression analysis by real-time PCR using a subset of these 324 genes, which are involved in important biological processes as well as in musculoskeletal health and disease. Gene expression of molecules important in maintenance of cartilage such as Acan, Comp, Matn1, Col2a1, Col10a1 and Frzb were significantly downregulated upon pharmacological or genetic inhibition of GSK-3 in immature mouse articular chondrocytes, supporting our RNA-Seq results.These results suggest significant involvement of GSK-3 signaling in cartilage health and disease, and highlight potential molecular targets involved in various developmental skeletal defects as well as in maintenance of cartilage health.

The Rare Disease, Alkaptonuria, Reveals New Mechanisms of Joint Destruction, Subchondral Cracking and HDMP Formation, that may be Prevalent in Osteoarthritis J A Gallagher*[1], N P Thomas[1], N Jeffery[1], L R Ranganath[1], A Boyde[2]. [1]University of Liverpool, United Kingdom, [2]Queen Mary University of London, United Kingdom

Osteoarthritis (OA) is a major cause of disability, yet, despite major research efforts, the pathogenesis has not been elucidated and there are no therapies. Studying extreme phenotypes of Mendelian disorders can reveal pathological mechanisms present in more common diseases. The purpose of our research was to investigate the early onset, severe arthropathy in the ultra-rare disorder, alkaptonuria (AKU), to better understand the pathogenesis of OA.We investigated joints obtained at surgery from AKU patients, by correlated ex vivo MRI, microCT, BSE-SEM and LM. Subsequently we extended the investigation to OA joints obtained at surgery or from donated cadavers. We also analysed clinical DESS MRI knee scans from patients in the Osteoarthritis Initiative Progression Cohort from five annual visits. Finally we surveyed MR, microCT and histological images from public data bases and publications. In AKU joint samples studied ex vivo using microCT and BS-SEM, we identified cracks in the subchondral plate which ran though bone and articular calcified cartilage. In some cases cracks had healed by intercalation of a highly mineralised infill material. This material also extruded into hyaline articular cartilage as High Density Mineralised Protrusions (HDMPs), which could by detected by microCT, DESS MRI, BSE-SEM and LM. Subsequently we identified HDMPS in ex vivo OA joints from surgery and cadavers by DESS MR, corroborated by microCT. We identified homologous features in >80% of images acquired from the Osteoarthritis Initiative. Our search of online CT and MR databases revealed that putative HDMPs were widely identifiable in joints including vertebral joints. We also detected evidence of previously unrecognised HDMPs in histological images of joints from OA mice in published papers, despite their destruction by decalcification during processing.Our results from these parallel studies reveal a high incidence of HDMPs in joints and suggest that they constitute a major but previously unrecognised cause of joint destruction, not only in rare diseases, such as AKU, but also in common OA. HDMPS are hard and may fragment to produce an abrasive cutting and grinding agent, damaging HAC from within. They appear to form prior to the detection of symptomatic OA and could provide a useful imaging biomarker to monitor disease progression. The identification of widespread prevalence of this mechanism of joint destruction provides a new paradigm for joint destruction in OA.

Porous Tantalum Rods Implantation for Osteonecrosis of Femoral Head: Longitudinal Follow-up of 40 hips Mincong He*[1], Qiushi Wei[2], Wei He[2], Yi-Xian Qin[3]. [1]First School of Clinical Medicine, Guangzhou University of Chinese Medicine, China, [2]Department of Orthopaedics Surgery, The First Affiliated Hospital of Guangzhou University of Chinese Medicine, China, [3]Department of Biomedical Engineering,Stony Brook University, United States

The objective of this study was aimed to evaluate the clinical and radiographic outcomes, and the hip survivorship of osteonecrosis of femoral head (ONFH) patients accepting a surgery implantation for femoral head fixation with a porous tantalum rods surgery(PTRS). Total of 38 subjects (40 hips) were included in this retrospective study, surgeries performed between January 2008 and December 2011. All the subjects were evaluated prior to the surgery using the Association Research Circulation Osseous (ARCO) classification, the Japanese Institute Committee (JIC) classification and Harris hip Score (HHS). The end point of hip survivorship analysis was set as the time of failure of the hip preservation with the total hip arthroplasty (THA) revision surgery. The mean time for following up was up to 75.5 months; and the overall survival rate reached to 70% after 72 months (ARCO stage 2: 81.5%; stage 3: 46.2%; JIC type B: 100%; C1: 78.3%; C2: 30%. The average HHS in the preoperation of PTRS was 75.8±8.0, contrast to 93.0±4.8 of the postoperative on (P<0.05). Twelve hips required for secondary THA were followed for 65.3±18.2 months; and the control group underwent primary THA were followed for 55.6±15.7 months. HHS in revision group was at a mean of 90.1±6.4, and primary THA was 93.0±5.2(P>0.05). Secondary THA had poorer clinical outcome when compared to the primary THA patients, but the difference was not significant. The results suggested the outcome of porous tantalum implant in the mid-term follow-up showed an encouraging survival rate in symptomatic patients with ONFH in early stages or limited necrotic lesion. Patients with necrotic area involving large area or in late stage THA are not suitable for the tantalum rods implantaion but THA can be a considerable remedy once the tantalum rods are failed.

TGF-β Signaling Plays an Important Role in Chondrocyte Senescence after Oxidative Stress Jie Jiang*, Tieshi Li, Alessandra Esposito, Lai Wang, Xin Jin, Joseph Temple, Arnavaz Hakimiyan, Susan Chubinskaya, Anna Spagnoli. Department of Pediatrics, Rush University medical Center, United States

Senescence is associated with much different age-related pathology. A recent study has shown new evidence for the causative role of senescent cells (SnCs) in the development of osteoarthritis (OA). A key characteristic of SnCs is their senescence-associated secretory phenotype (SAPS) that includes many different inflammatory cytokines. Our previous study of Tgfbr2 conditional knockout mice resulted in undeveloped joints and a change in the expression of inflammatory cytokines. Additionally, TGF-β signaling has been shown to accelerate senescence in many different cell types including mesenchymal stem cells. The overall goal of this study was to examine the role of TGF-β signaling in chondrocyte senescence during both development and osteoarthritis. This abstract presents data on the effect

of up- and down-regulation of TGF-β signaling in vitro after oxidative stress. Oxidative stress is a contributing factor to various diseases, and more recently in OA. Human articular cartilage plugs (4mm diameter) were cored out from cadavers with healthy articular cartilage (Collins grade 0 or 1). Cartilage explants were cultured in vitro and then stimulated with $H2O2$ (200μM) for 3 hours in ITS media. After induction of oxidative stress, the cartilage explants were then treated with recombinant TGF-β1 (10ng/mL) to activate TGF-β signaling or with TGF-β inhibitor SB505124 (10μM) and ITD1 (5μM) to block TGF-β signaling for up to 48 hours. Cartilage explants was harvested and whole-mount senescence associated β-galactosidase staining was performed. We found that oxidative stress with H2O2 resulted in an increase in senescence associated β-galactosidase (SA-β-gal) staining. TGF-β treatment resulted in further increase in staining intensity while blocking TGF-β signaling with SB505124 and ITD1 resulted in reduced staining. These data indicate that articular cartilage chondrocytes are susceptible to oxidative stress and that TGF-β signaling can further exacerbate cellular senescence. To examine the role of TGF-β signaling and senescence during the development of musculoskeletal system, we examined the conditional knockout mice where Tgfbr2 was knocked-out with Prx1Cre. In these mice, the joint cavity between the phalanges fails to form. The formation of the joint cavity requires the clearance of cells that reside in the cavity either through apoptosis or senescence. When the SA-β-gal staining was compared, a marked decrease in Tgfbr2 knockout mice was found. Taken together, we found that TGF-β signaling may play a significant role in modulating senescence during both development of joint cavity and disease progression in articular cartilage. Future studies will focus on the mechanism by which TGF-β signaling modulate cellular senescence and using in vivo OA model to further confirm the role of TGF-β signaling in cellular senescence during the progression of OA.
Senescence associated β-galactosidase staining after 48hours of treatment in human articular cartilage explant. A) no-treatment; B) H2O2 treatment; C) H2O2 with TGF-β1 treatment; D) H2O2 with SB505124 treatment; E) H2O2 with ITD1 treatment. Oxidative stress cause by H2O2 treatment resulted in increased senescence in cartilage explant and TGF-β inhibitor reduced senescence in the cartilage explant after oxidative stress.

Clinical symptoms, quality of life (QOL), function and gait in community dwelling Seniors: Comparing those with and without osteoarthritic (OA) knee pain. Angela Juby*[1], Christopher Davis[1], Justin Lewicke[2]. [1]University of Alberta, Canada, [2]Glenrose Rehabilitation Hospital, Canada

BackgroundKnee pain is a common symptom in Seniors. The Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) is the most widely used validated tool for assessing knee and hip osteoarthritis. It assesses pain, stiffness and function. The EuroQol 5D (EQ-5D) is a validated self administered QOL scale. The functional assessments in this study are validated tests recommended by the OA Research Society International (OARSI) as objective performance-based tests for knee OA evaluation. PurposeTo assess whether knee pain will measurably affect symptoms, quality of life, functional performance and gait. MethodsCommunity dwelling Seniors were invited to participate. Evaluations included demographics, medical history, clinical knee examination, Romberg test, peripheral

neuropathy evaluation, symptom questionnaires (WOMAC, KOOS), Quality of Life (EQ-5D), 30s chair stand, 40m walk test, stair climb, Timed up and go (TUG), 6 minute walk test, pedobarographic assessment, and motion capture gait analysis. Here we present the clinical and functional results. Results30 participants completed the study, 11 men and 19 women, with an average age of 77 years (69-89). 9 reported no pain, and 21 reported knee pain. Most with knee pain had some knee X-ray abnormalities, but 2 with no knee pain had osteoarthritic X-ray changes. The average WOMAC score was not significantly different between those with pain versus those without (27.9 vs 32.3), in fact it was higher in the no knee pain group because 3 of the subjects had other pathologies affecting lower limb function (peripheral neuropathy, chronic Achilles tendonitis, plantar fasciitis). QOL using EQ 5D was not statistically significant between the two groups, however the KOOS QOL subscale did discriminate between those with and without pain. Similarly, timed functional evaluations were no different. There was a clinical difference in distance walked in the 6 minute walk test (pain vs no pain: 388m vs 500m), but this was not statistically significant. ConclusionsThe results were not what was hypothesised. This study did not show any significant symptomatic, overall QOL or functional differences between these community dwelling Seniors with and without knee pain. All reported high QOL. The WOMAC was not discriminatory, and was also elevated in those with other causes of lower limb dysfunction. The KOOS scale, being highly specific for knee symptoms, better discriminated between those with and without knee pain.

Biochemical Profiling of MRI-detected Bone Marrow Lesions in Knee Osteoarthritis Patients: Altered Mineralization of the Subchondral Bone Matrix Julia Kuliwaba*, Yea-Rin Lee, Dzenita Muratovic, David Findlay. Adelaide Medical School, The University of Adelaide, Australia

Purpose: The osteochondral degenerative changes in human osteoarthritis (OA) are most prominent in MRI-detected subchondral bone marrow lesion (BML) zones [Muratovic et al. 2016]. Given that BMLs associate with pain and structural progression, emerging treatment approaches for OA (eg. anti-resorptives) are now targeting BMLs. However, the molecular basis for the distinctive pathology of BMLs remains unclear. Thus, the study aim was to examine the biochemical composition of BMLs for human knee OA.Methods: Tibial plateaus (TP) collected from 24 knee OA arthroplasty patients (11 men, 13 women; aged 52-77 years) and from 8 non-OA control cadavers (5 men, 3 women; aged 44-80 years) were MRI scanned (PDFS and T1) to identify BMLs. Four groups, each n=8, were assessed: OA-noBML, OA-BML1 (PDFS detected in medial-TP), OA-BML2 (PDFS+T1 detected in medial-TP), control. For each TP, subchondral trabecular bone was sampled from the medial (BML zone/noBML) and lateral compartment for Raman spectroscopy analysis and quantitative backscattered electron imaging (qBEI).Results: The mineral-organic matrix ratios of phosphate/amide I, phosphate/proline and phosphate/amide III, were similar between OA-noBML and control subchondral bone (for medial and lateral). In contrast, phosphate/amide I was reduced in the medial BML zones, for both OA-BML1 (p=0.02) and OA-BML2 (p=0.004), compared to control. Also, phosphate/proline was lower for OA-BML1, compared to control (p=0.02). Within the OA-BML1 and OA-BML2 groups, phosphate/amide I (BML1:p<0.0001; BML2:p=0.009) and phosphate/amide III (BML1:p=0.006; BML2:p=0.0005) were lower in medial vs lateral. The qBEI bone mineralization density distribution (BMDD) for both OA-BML1 and OA-BML2 was shifted to low mineralization density (p<0.03) combined with an increased peak width (p<0.04), compared to control. There were no differences for mineral crystallinity, type-B carbonation, relative proteoglycan content, or hydroxyproline/proline.Conclusions: Raman spectra of subchondral bone from knee OA patients without tibial BMLs and non-OA controls demonstrated a similar mineral-organic bone matrix composition. However, medial-tibial BML tissue from knee OA patients showed an altered Raman spectral bone signature, characterized by reduced mineralization with increased heterogeneity. These data support the concept of BMLs representing localized areas of active bone remodeling in response to microdamage accumulation [Muratovic et al. 2018].

SUN-0519

Subchondral tibial bone texture is related with knee replacement surgery Thomas Janvier*[1], Guillaume Odri[2], Rachid Jennane[1], Hechmi Toumi[1], Eric Lespessailles[3]. [1]University of Orléans, I3MTO Laboratory, France, [2]Hospital Lariboisière, Orthopedics, France, [3]Hospital of Orléans, Rhumatology, France

Purpose: Examine the association between subchondral bone changes reflected by trabecular bone texture (TBT) analyses on computed radiograph, and knee replacement surgery (KRS). Methods: Data were obtained from the osteoarthritis initiative (OAI) public use data set. In this preliminary study 1304 patients were included based on: at least one symptomatic knee, 48 months radiographic follow-up and baseline digital radiographs. These patients correspond to the pooling of two previous studies focused on the prediction of knee osteoarthritis incidence and progression [1,2]. Cases were defined as patient-reported KRS and adjudicated confirmed status on subsequent radiograph between baseline and the 108 month follow-up visit.Baseline radiographs were semi-automatically segmented into a patchwork of 16-squared region of interest (ROI) covering the whole proximal tibial epiphysis (Figure). Each ROI was characterized using fractal descriptors (FD) computed along the vertical and horizontal axis for two observation scales (short range: [100µm, 400µm], long range:

[600µm, 2mm]).Non-parametric Mann-Whitney test was used to compare patients with and without KRS for both WOMAC, BMI, age and TBT markers. Odds ratio (OR) were computed for lower and upper quartiles with each ROI and TBT markers.Results: From the 2497 analyzed knees, 39 underwent KRS within 108 months. No differences in the age, BMI nor gender were found between the groups whereas WOMAC scores for pain (P <0.001) and stiffness (P = 0.006) were significantly higher in the KRS group.TBT analysis along the vertical axis for short range (blue arrows in Figure) showed significantly higher FD for the KRS group in the distal and lateral ROIs (P < 0.05). Such differences were confirmed by the higher prevalence of KRS for patients with FD in the lower quartile (OR > 2).In the medial compartment, horizontal and vertical FD at long range (red arrows in Figure) was lower in the KRS group (P < 0.05).Conclusions: These results suggest that the TBT of the subchondral proximal tibia assessed at baseline on computed radiographs is related to KRS as well as WOMAC pain and stiffness score. This preliminary study provides a proof of concept for a future comprehensive study of the full longitudinal OAI cohort.[1] Janvier T, Jennane R, Valery A, et al. Subchondral tibial bone texture analysis predicts knee osteoarthritis progression: data from the Osteoarthritis Initiative. Osteoarthr Cartil. 2017[2] Janvier T, Jennane R, Toumi H, Lespessailles E. Older adults with greater severity of lumbar disc height narrowing and facet joint osteoarthritis have higher lumbar volumetric BMD, independently of body weight: Framingham QCT Study Elizabeth Samelson*[1], Mohamed Jarraya[2], Michelle Yau[3], Elise Morgan[4], Brett Allaire[5], Mary Bouxsein[5], Marian Hannan[3], Douglas Kiel[3], Thomas Travison[3], Pradeep Suri[6], Ali Guermazi[7]. [1]Institute for Aging Research, Hebrew SeniorLife, Harvard Medical School, United States, [2]Mercy Catholic Medical Center, United States, [3]Institute for Aging Research, Hebrew SeniorLife, United States, [4]Boston University, United States, [5]Beth Israel Deaconess Medical Center, United States, [6]University of Washington, United States, [7]Boston Medical Center, United States

Spinal degeneration is a major public health problem, causing pain, disability, and high health care costs. Despite its importance, the etiology of spinal degeneration is not well-established. Individuals with osteoarthritis (OA) are observed to have elevated BMD, however, it is unknown whether this is due to alterations in mechanical loading and bone remodeling, increased body weight, or an artifact of DXA measures of areal BMD. Therefore, we conducted a cross-sectional study of spinal degeneration and BMD, based on QCT imaging measures, in the community-based Framingham Study. Further, in order to tightly control for weight, which is associated with OA and high BMD, we stratified our analysis by BMI and additionally adjusted for weight. We used QCT scans to evaluate L3 trabecular volumetric BMD (Tb vBMD) and disc height narrowing (DHN) and facet joint OA (FOA) from L1/L2-L4/L5. DHN and FOA were scored at each level as 0=normal, 1=mild, 2=moderate, or 3=severe, based on standardized criteria. Briefly, DHN for a selected level was compared (>, =, <) to the height of the disc immediately superior. FOA was scored based on the presence and severity of joint space narrowing, osteophytes, hypertrophy of articular process, subarticular bone erosions, subchondral cysts, and vacuum phenomenon in the joints. We created summary indexes for DHN and FOA by summing scores across the 4 levels (bilaterally for FOA) and categorized each into quartiles. Participants included 1,130 individuals: 616 women, 514 men, mean age 60 ± 8 years. Mean summary index was 2.4 ± 2.3 for DHN (range, 0-12) and 7.1 ± 5.0 for FOA (range, 0-24). Mean L3 Tb vBMD increased with increasing quartile of DHN and FOA, adjusted for age, sex, height, and weight, and a positive trend was observed in those with low and high BMI (TABLE). Results were similar when additionally

adjusted for vertebral fracture and when women and men were analyzed separately. We found individuals with more severe spinal degeneration had higher trabecular volumetric BMD, independent of weight. These results suggest that alterations in bone remodeling and biomechanical factors from FOA may increase bone density, or conversely, increased BMD may accelerate FOA. Longitudinal assessments will allow us in the future to more clearly determine the pathway between spinal degeneration and increased BMD, and this knowledge may have important implications for prevention.

Association between severity of lumbar spine disc height narrowing (DHN) and facet joint osteoarthritis (FOA) and L3 trabecular volumetric bone mineral density (vBMD), stratified by body mass index (BMI)

Postmenopausal Women Have Increased Risk of Periprosthetic Fracture After Total Knee Arthroplasty Blossom Samuels*[1], Josue Santana[2], Alexander Dash[1], Yi Liu[1], Alana Serota[1], David Mayman[1], Kaitlin Carroll[1], Michael Pitta[1], Timothy Wright[1], Emily Stein[1]. [1]Hospital for Special Surgery, United States, [2]Cornell University, United States

The number of total knee arthroplasty (TKA) procedures is burgeoning due to the increasing population of older adults. As a result, the number of complications after TKA is also rising. Periprosthetic fractures (PPFXs), while relatively rare, are a devastating and costly complication that necessitate revision surgery. Whether these fractures relate to poor bone quality is not known. In this study, we investigated risk factors for periprosthetic knee fracture using a large prospective registry at a single institution. We hypothesized that patients with PPFXs would have similar characteristics to patients with classic osteoporotic fractures, namely postmenopausal status, older age, and low BMI. Our registry captured a total of 18,065 primary total knee arthroplasties (TKA), performed in 16,083 patients over 5 years (2007-2012). In follow-up (2007-2016), 405 primary TKAs in 400 patients failed, resulting in revision surgery. The vast majority (93%) of patients had primary surgery for osteoarthritis. A retrospective review of patient medical records and radiographic data was performed to determine a cause of failure (Pitta et al., J Arthroplasty). As menopausal status was not easily ascertained from the medical records, a classification of >60 years was used as a conservative definition. DXA data were available on only a few patients. Of 400 patients with failed TKAs, the most common reasons for revision were infection (26%) and instability (24%). Fourteen (3.5%) patients required revision because of PPFX. Baseline factors were compared in patients with PPFXs and those with revisions for other reasons (Table). Patients with PPFXs were older and were more likely to be postmenopausal women. No differences in BMI, or time to failure were found. In summary, the availability of a large, well classified cohort with close follow-up enabled us to investigate risk factors for PPFX, a rare but devastating complication of TKA. In this study, in the absence of DXA data, we used postmenopausal status as a surrogate for skeletal fragility. Our finding that older patients and in particular postmenopausal women were at greatest risk for PPFX suggests that poor bone quality may be a risk factor for this complication. Future studies are needed to confirm these findings. Further evidence linking PPFXs with poor bone quality would support development of strategies for early identification and therapeutic intervention for patients at greatest risk.

Characteristics of Patients Requiring Revision After TKA (mean ± SD)

Characteristic	PPFX (n=14)	Other revision (n=391)	p-value
Mean Age (years)	68±10	62±10	<0.03
Postmenopausal Female (%)	64%	36%	<0.04
BMI (kg/m²)	32±9	31±7	0.54
Unilateral TKA (%)	86%	21%	0.12
Time of implantation (months)	29±27	25±21	0.55
Early failure, <1 yr (%)	43%	28%	0.47
Intermediate failure, 1-3 yr (%)	35%	48%	
Late failure >3 yr (%)	23%	24%

CaMKK2-AMPK-p38MAPK Axis Regulates the Onset of Post-Traumatic Osteoarthritis Uma Sankar*[1], Elsa Mevel [1], Yong Li[1], Ushashi Dadwal[1], William Thompson[1], Diane Wagner[2], Stephen Trippel[1], Matthew Allen[2], David Burr[1]. [1]Indiana University School of Medicine, United States, [2]Indiana University Purdue University of Indianapolis, United States

Osteoarthritis (OA) is a severely debilitating degenerative joint disease that is the leading cause of adult disability worldwide. The disease is characterized by the progressive loss of articular cartilage, remodeling and sclerosis of the subchondral bone and inflammation of the synovial tissue. Patients experience debilitating pain, stiffness of joints and lack of mobility. Unfortunately, no curative treatments exist in the clinic, leaving pain management and/or joint replacement as the only therapeutic options. Calcium/calmodulin-dependent kinase kinase 2 (CaMKK2) is a multifunctional serine/threonine protein kinase activated by Ca2+-bound calmodulin (CaM). In addition to its substrates within the CaMK cascade, CaMKK2 phosphorylates adenosine mono phosphate-dependent protein kinase (AMPK) to regulate cell-metabolic responses to stress. We previously reported roles for CaMKK2 in bone remodeling and inflammation, two key mechanisms in OA. In this study, we investigated the role of CaMKK2 in the onset of post-traumatic OA (PTOA) surgically induced by destabilizing the medial meniscus (DMM). CaMKK2 is expressed by murine articular chondrocytes and its levels in chondrocytes within the superficial zone significantly increase following OA induction at 8 weeks post-surgery. These data informed our hypothesis that targeting CaMKK2 will protect against PTOA. We observed that the genetic deletion or pharmacological inhibition of CaMKK2 in 10-week old male C57BL6 mice prevents the occurrence of the three major joint pathologies associated with PTOA viz., cartilage destruction, subchondral bone alteration and synovial inflammation. When challenged with interleukin-1β (IL-1β), primary chondrocytes lacking CaMKK2 display attenuated inflammatory and cartilage catabolic responses. Moreover, Camkk2-/- chondrocytes expressed enhanced levels of type II collagen (Col2) and glycosaminoglycan (GAG) in response to IL-1β, indicating an anabolic response when challenged with the inflammatory cytokine. Mechanistic investigations reveal that CaMKK2 acts as a "molecular hub" coordinating catabolic and inflammatory responses in chondrocytes through its regulation of the AMPK-p38 mitogen activated protein kinase (p38MAPK) and extracellular receptor kinase (ERK) signaling cascades. Our findings reveal a novel function for CaMKK2 in chondrocytes and identify this kinase as an attractive therapeutic target in the prevention of OA.

Targeting the IGF-1 Signaling Pathway for the Prevention of Post-Traumatic Osteoarthritis (PTOA) Yongmei Wang*[1], Long Le[2], Tianlu Wang[1], Tejal Desai[2], Daniel Bikle[1]. [1]Endocrine Unit, University of California, San Francisco and San Francisco VA Health Care System, United States, [2]Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, United States

Our previous studies showed that ablation of the insulin-like growth factor-1 receptor (IGF1R) in chondrocytes prevented the development of PTOA suggesting a potential means for its prevention. Here, we investigated the therapeutic role of the IGF1R inhibitor (NVP-AEW541) in PTOA development. NVP-AEW541 (IGF1Ri) was incorporated into the poly-ethylene glycol dimethacrylate (PEG-DMA) hydrogel carriers (microrods) for prolonged local delivery in the joint space following ACL rupture (ACLR). ACLR was achieved with a single bout of tibial compression overload (TCO) at 12 N of the right knee in12 wks old C57BL6 mice. The left knee served as the control (CON). 1 day after the TCO, vehicle (Veh) or microrods loaded with inhibitor (IGF1Ri/rod) was injected into the injured knee. The CON and ACLR knees were analyzed 2wks later. Immunohistochemistry (IHC) demonstrated that ACLR induced phosphorylation of Erk in the Veh-treated injured knee, but the effect was blocked in the IGF1Ri-treated injured knee, verifying inhibition of IGF1 signaling. As determined by μCT, compared with the CON knee, ACLR decreased BV/TV (24%) in the subchondral bone, while the IGF1Ri/rod treatment (Tx) prevented the bone loss. Safranin O /Fast Green staining revealed erosion of the articular cartilage and formation of osteophytes in the Veh-treated injured knee, but these effects were not observed in the CON or IGF1Ri-treated injured knee. As indicated by IHC, ACLR increased the number of PCNA positive articular chondrocytes and MMP-13 production in the Veh-treated injured knee, but these effects were blunted in the IGF1Ri-treated knee. Moreover, ACLR increased the production of VEGF, resulting in vessel formation within articular cartilage (as indicated by CD31) in the Veh -treated knee, but these effects were blocked in the IGF1Ri-treated knee. To test the effects of IGF1Ri/microrods in chondrocytes in vitro, ATDC5 cells were treated by DMSO or IGF1Ri/microrod (4,000 microrods/ 0.5 ml), then further treated with PBS or IGF1. QPCR showed that delivery of the inhibitor blocked IGF1 stimulated expression of MMP-13 (65%) in chondrocytes. Our data indicate that IGF1 signaling plays deleterious roles in the development of PTOA by promoting abnormal articular chondrocyte proliferation and vascular invasion, while increasing matrix metallopeptidase production to damage articular cartilage and subchondral bone. Inhibition of this pathway may lead to therapy that can prevent and/or treat PTOA.

A Standardized Approach to Quantifying Pathological Parameters of Osteoarthritis in a Preclinical Model Gregory Young*, Fadia Kamal, Vengadesh Karrupagounder, William Pinamont, Reyad Elbarbary. Department of Orthopedics and Rehabilitation, Penn State University, College of Medicine, Hershey PA., United States

Gregory M. Young, Vengadesh Karrupagounder, William Pinamont, Reyad Elbarbary, Fadia Kamal. Department of Orthopedics and Rehabilitation, Penn State University, College of Medicine, Hershey PA.Objective: Measuring OA severity is essential to exploring potential disease pathways and novel therapies. Currently, OA is measured largely using OARSI scoring system, which limits statistical rigor and introduces observer bias. So far, cartilage area has been the most commonly reported quantitative measure of OA severity, however, pathological changes observed in OA also include other joint compartments. The purpose of this study was to discern critical parameters which can be measured quantitatively using an established system to define OA progression and severity. Method: Safranin-O Fast green stained knee sections were obtained from naïve mice and mice with surgically induced OA (12 weeks following DMM, Destabilization of the medial meniscus). OA induced histopathological changes were examined quantitatively using the OsteoMeasureTM system. After these changes were well defined, measurements were performed by several observers independently following a short training session.Results: Nine parameters proved to be statistically significant in determining OA severity. These factors include changes in articular cartilage (Fig. 1 A&B: reduced uncalcified cartilage area, increased cartilage surface fibrillation, reduced normal chondrocyte number and increased number of chondrocytes with pathological phenotype in OA vs naive), changes in subchondral bone (Fig. 1 C&D: increased osteophyte formation and reduced marrow area in OA vs naive), and changes in the synovium (increased thickness, inflammation and fibrosis in OA vs naive).Conclusion: Measuring parameters which change during OA can clearly quantify OA development and progression. By measuring these parameters quantitatively, we can determine the reach and scale of potential novel signaling pathways and drug therapies, which may exert a selective effect on some or all of these pathological changes in OA. In conclusion, we are able to establish a system that allows us to quantify pathological changes in OA in a sensitive, highly reproducible and unbiased manner.

SUN-0557

Pro-Osteoporotic mir-320a Induces Oxidative Stress and Impairs Osteoblast Function Natalia Garcia-Giralt*[1], Laura De-Ugarte[2], Susana Balcells[3], Xavier Nogues[1], Daniel Grinberg[3], Adolfo Diez-Perez[1]. [1]IMIM (Hospital del Mar Medical Research Institute), CIBERFES, Spain, [2]IMIM (Hospital del Mar Medical Research Institute), Spain, [3]Universitat de Barcelona, CIBERER, Spain

MicroRNAs (miRNAs) are important regulators of many cellular processes, including the differentiation and activity of osteoblasts. Hence, their alteration may provoke an impaired functioning of these cells that lastly might affect bone turnover. In this regard, miR-320a was previously found overexpressed in osteoporotic bone tissue but it role in osteoblasts is still unknown. In the present study, functional assays were performed with the aim to elucidate the mechanism of action of miR-320a in osteoblastic cells. For this purpose miR-320a was either overexpressed or inhibited in human primary osteoblasts (hOB) and gene expression changes were evaluated through microarray analysis. In addition, the effect of miR-320a on cell proliferation, viability and oxidative stress of hOB and osteosarcoma cell lines (MG-63 and U2OS) was evaluated. Finally, osteoblast functionality was also evaluated by assessing matrix mineralization and alkaline phosphatase activity.Microarray results showed a number of key osteoblast genes, together with genes involved in oxidative stress, which were regulated by miR-320a. Regulation of osteoblast differentiation and ossification appeared as best significant biological processes (PANTHER P value=3.74E-05; and P value=3.06E-04, respectively). The other enriched pathway was that of the cellular response to cadmium and zinc ions, mostly by the overexpression of metallothioneins. In hOBs, overexpression of miR-320a increased proliferation and oxidative stress levels whereas mineralization capacity was reduced. In osteosarcoma cells, miRNA-320a also in-

Sunday Posters

duced oxidative stress leading to reduced cell viability and mineralization capacity.In conclusion, overexpression of miR-320a produces an increase in stress oxidation levels and a reduced osteoblastic functionality that could trigger an osteoporotic phenotype.

Role of Methylsufonylmethane (MSM) as an osteoinductive material in the osteogenesis of stem cells from human exfoliated deciduous teeth (SHED) Hanan Aljohani*, Meenakshi A. Chellaiah. University of Maryland- Dental School, United States

In the field of dentistry, there is always a necessity for new advancement in bone restoration therapy. Methylsulfinylmethame (MSM) showed the ability to induce osteogenic differentiation of stem cells from human exfoliated deciduous teeth (SHED). It serves as a cost-effective adjunct to available bone augmentation techniques.Objectives:1. To show the ability of SHED cells to differentiate into osteoblast.2. To determine a dose and time dependent effect of MSM on SHED cells to induce osteogenic differentiation as an alternative to the commonly used osteogenic medium3. To demonstrate the combination effect of MSM and bone particles on osteogenesis of SHED cells Methods: MSM was used to induce osteoblast differentiation in stem cells from human exfoliated deciduous teeth (SHED). The expression of osteogenic markers in SHED cells was examined using immunoblotting and real-time PCR analysis for protein and mRNA expression, respectively. Alizarin red and Calcein blue mineralization assays were used to asses osteogenic differentiation.Results: Our findings revealed the following:1) SHED cells express osteogenic markers: Ostrix, OPN, Runx2, and OCN at protein and mRNA, respectively.2) SHED cells have the ability to express alkaline phosphates and produce mineralization nodules under osteogenic medium.3) MSM induces osteogenesis of SHED cells by expressing osteogenic markers: Ostrix, OPN, Runx2, and OCN at protein and mRNA, respectively4) MSM induces osteogenesis of SHED cells by increasing ALP activity and mineralization nodules.5) Combination of MSM and bone particles induce osteogenesis and mineralization of SHED cells.Conclusion: Methylsulfinylmethame (MSM) is a potential cost-effective osteoinductive material. It has the capability to induce dental stem cells to differentiate into osteoblast by enhancing the expression of mineralization markers, resulting in bone formation.

FGF23 Counters Osteoblast Differentiation in Human Mesenchymal Stem Cells by Inhibiting Vitamin D Signaling and Metabolism Christopher Bertucci*, Fangang Meng, Shuanhu Zhou, Julie Glowacki. Brigham and Women's Hospital, United States

Chronic kidney disease (CKD) is associated with vitamin D deficiency, decreased BMD, and increased risk of hip fractures. Circulating FGF23 is elevated in CKD and reduces renal biosynthesis of $1\alpha,25$-dihydroxyvitamin D3 (1,25) by inhibiting renal 1α-hydroxylase/CYP27B1 gene expression and activity. With human mesenchymal stem cells (hMSCs), we tested the hypotheses that 1) rhFGF23 inhibits 1,25-stimulated osteoblast differentiation and 2) rhFGF23 inhibition occurs through specific signaling pathways; 3) because hMSCs express CYP27B1 and 1α-hydroxylate 25(OH)D, we also tested the effects of rhFGF23 on 25(OH)D actions and metabolism. Human MSCs were isolated from discarded orthopedic surgical tissue. Upon confluence, hMSCs (passage 2-5) were cultured ± treatments ± pathway inhibitors for 1 day (RT-PCR) or 7 days (ALP activity, osteogenic medium, n=4). Group data were analyzed non-parametrically and are presented as mean ± SEM. rhFGF23 (0.1-1 ng/mL) dose-dependently inhibited osteoblastogenesis (ALP activity) stimulated by 1,25 (10 nM) (Panel A). The mechanism by which rhFGF23 inhibited MSCs was investigated. First, 1,25 induced BMP-7 and IGF-I expression; rhBMP-7 (50-100 ng/mL) dose-dependently stimulated osteoblastogenesis. BMPR inhibitor (10 µM LDN214117) blocked 1,25 stimulation of ALP activity. rhFGF23 (1 ng/mL) or VDR siRNA blocked 1,25 upregulation of BMP-7; IGF-IR inhibitor (3 µM AG1024) blocked rhFGF23 inhibition of 1,25's stimulation of ALP activity (Panel B) and of BMP-7 gene expression (Panel C). rhFGF23 also reduced constitutive expression of VDR and CYP27B1; FGFR1 inhibitor (0.5 µM BGJ398) blocked this action. Similar experiments with 25(OH)D (100 nM) showed rhFGF23 inhibited stimulation of ALP activity and reduced BMP-7, VDR, and CYP27B1 gene expression. These data indicate that FGF23 inhibits 1,25 stimulation of osteoblastogenesis through VDR, IGF-IR, and BMP-7 signaling pathways. FGF23's downregulation of CYP27B1 expression in hMSCs is evidence of similarity to the effects of CKD on vitamin D metabolism in renal cells. These findings highlight the importance of exogenous and endogenous 1,25 in osteoblast differentiation and how elevated serum FGF23 levels in CKD could contribute to poor skeletal status. Studies with hMSCs can provide better understanding of extra-renal D metabolism in hMSCs and mechanisms of FGF23 impairment of osteoblastogenesis; they may indicate new approaches to improve bone quality in CKD.

Effects of rhFGF23 on $1\alpha,25(OH)2D$ action and signaling in hMSCs.
(A) Osteoblastogenesis (ALP activity) stimulated by $1\alpha,25(OH)2D$ (10nM) was dose-dependently inhibited by rhFGF23. (B) rhFGF23 (1 ng/mL) inhibition of $1\alpha,25(OH)2D$-stimulated ALP activity was blocked by IGF-IR inhibitor (3 µM AG1024). (C) IGF-IRi blocked rhFGF23 inhibition of $1\alpha,25(OH)2D$-stimulated BMP-7 expression. (*p<0.05, ***p<0.001, n=4, ANOVA)

Developmental contribution of growth plate-derived hedgehog signal-responsive cells in growing bone Ryuma Haraguchi*[1], Riko Kitazawa[2], Yuuki Imai[3], Sohei Kitazawa[1]. [1]Department of Molecular Pathology, Ehime University Graduate School of Medicine, Japan, [2]Department of Diagnostic Pathology, Ehime University Hospital, Japan, [3]Proteo-Science Center, Ehime University, Japan

Background: Longitudinal bone growth progresses by continuous bone replacement of epiphyseal cartilaginous tissue, known as "growth plate", produced by columnar proliferated- and differentiated-epiphyseal chondrocytes. The endochondral ossification process at the growth plate is governed by paracrine signals secreted from terminally differentiated chondrocytes (hypertrophic chondrocytes), and hedgehog signaling is one of the best known regulatory signaling pathways in this process. Here, to investigate the developmental relationship between longitudinal endochondral bone formation and osteogenic progenitors under the influence of hedgehog signaling at the growth plate, genetic lineage tracing was carried out with the use of Gli1CreERT2 mice line in order to follow the fate of hedgehog signal-responsive cells during endochondral bone formation. Finding: Gli1CreERT2 genetically labeled cells are detected in hypertrophic chondrocytes and osteo-progenitors at the chondro-osseous junction (COJ); these progeny then commit to the osteogenic lineage in periosteum, trabecular and cortical bone along the developing longitudinal axis. Furthermore, in ageing bone, where longitudinal bone growth ceases, hedgehog signal responsiveness and its implication in osteogenic lineage commitment is significantly weakened. Conclusion: Our results show, for the first time, evidence of the developmental contribution of endochondral progenitors under the influence of epiphyseal chondrocyte-derived secretory signals in longitudinally growing bone. This study provides a pBrecise outline for assessing the skeletal lineage commitment of osteo-progenitors in response to growth plate-derived regulatory signals during endochondral bone formation. We are currently conducting a mouse genetically conditional gene mutation analysis with the use of the Gli1CreERT2 line for understanding growth plate-derived regulatory signals during endochondral bone formation within hedgehog signal-responsive cell lineages.

The role of Fam20C on the bone and tooth formation Katsutoshi Hirose*[1], Yu Usami[1], Kaori Oya[1], Sunao Sato[1], Toshihisa Komori[2], Satoru Toyosawa[1]. [1]Osaka University Graduate School of Dentistry, Japan, [2]Nagasaki University Graduate School of Biomedical Sciences, Japan

[Background] Family with sequence similarity 20-C (Fam20C) is Golgi-localized protein kinase, which phosphorylates secretory proteins with S-X-E/pS motifs, including SIBLINGs family proteins. Fam20C is highly expressed in the bone and tooth. In vitro studies demonstrated that recombinant Fam20C can phosphorylate Dmp1 and osteopontin, which are important for mineralized tissue formation. However, the role of Fam20C on these mineralized tissues is still unclear. In this study, we investigated the role of Fam20C on the min-

eralized tissue using osteoblast-specific Fam20C overexpressing mice (Fam20C-Tg).[Materials and methods] We generated the transgenic mice that Fam20C is driven by a 2.3-kb pro-α1(I) collagen promoter, leading to osteoblast-specific Fam20C overexpression. Skeletal samples were analyzed in vivo and in vitro.[Results and Discussion] In Fam20C-Tg, exogenous Fam20C produced by osteoblasts actually had a kinase activity. Phosphoproteomic analysis of the cortical bone revealed that various proteins including SIBLINGs, were highly phosphorylated. Fam20C-Tg had significantly higher cortical MAR and BFR/BS than wild type mice (WT), which may lead to an increased cortical bone volume of Fam20C-Tg (Fig. A). Moreover, porosity had increased in the cortical bone of Fam20C-Tg compare to that of WT, indicating an increase in bone resorption (Fig. A, arrows). The number of osteocyte in the Fam20C-Tg cortical bone was also increased (Fig. A, arrowheads). Gene expression analyses of cortical bone revealed that there was no significant difference in type I collagen (osteoblast marker) mRNA expression between Fam20C-Tg and WT. However, osteocalcin (mature osteoblast marker) and Dmp1 (osteocyte marker) mRNA expression in Fam20C-Tg mice were significantly increased compared to those in WT. These findings were consistent with the increased osteocyte number in cortical bone of Fam20C-Tg. On the other hand, Fam20C-Tg had significantly lesser trabecular bone volume than those of WT, which may be caused by an increased number of osteoclasts in trabecular bone of Fam20C-Tg.Fam20C protein was also overexpressed in the odontoblast, cementoblast and periodontal ligament cell. Fam20C-Tg had porous jawbone and decreased dentin and cementum formation of the dental root whereas there was no significant change in the dental crown (Fig. B). We have in vivo findings that Fam20C is associated with regulation of bone and tooth formation by phosphorylating secretory proteins.
SUN-0562

Adenosine Receptors A2A and A3 are crucial in Pulsed-Electromagnetic-Field Induced Pre-Osteoblast Cell Differentiation Niladri S. Kar*[1], Daniel Ferguson[2], Nianli Zhang[3], Erik I. Waldorff[3], James T. Ryaby[3], Joseph A. Didonato[1]. [1]Cleveland Clinic, United States, [2]Washington University in St. Louis, United States, [3]Orthofix, United States

Though for years Pulsed Electromagnetic Field (PEMF) is known to effectively augment the healing process of non-union fracture, the upstream biochemical and signaling processes leading to such effects have not been studied extensively, and thus deserve further attention. PEMF treatment has been shown to enhance migration of Adenosine class A Receptors A2A and A3 (Adora2A and Adora3) to the plasma membrane, and to modulate cAMP levels leading to anti-inflammatory responses in various cell types. Here we report that a four-hour daily PEMF stimulation enhances cellular differentiation of the mouse preosteoblast, MC3T3-E1, to osteoblast as a model response for the fracture healing observed with PhysioStim™ (Orthofix, Inc., Lewisville, TX). AlpI, cFos, Pthr1 and Runx2 are the primary genes that are found to be overexpressed in the PEMF-mediated osteoblast differentiation process in the wildtype preosteoblast cells. The two Adenosine Receptors, A2A and A3 were functionally impaired by biochemical inhibitors or CRISPR-Cas9-mediated gene disruption, and the effects were studied in the context of the PEMF-mediated osteoblast differentiation as measured by alkaline phosphatase enzymatic activity and cell alkaline phosphatase staining, collagen staining, mineralization staining, and quantitative RT-PCR for expression of the differentiation-associated genes. We observed that, while the disruption of Adora2A resulted in a delayed AlpI mRNA expression, but alkaline phosphatase activity and cell staining were nearly equal to the wild type; Adora3 disruption as well as simultaneous disruption of both receptors resulted in significantly reduced responses at both the mRNA and protein levels for the alkaline phosphatase activity throughout the PEMF stimulation period.

Moreover, in the cells with Adora2A disruption, gene expression profile showed a blunted response of cFos and Pthr1 to PEMF treatment, where as in the cells with Adora3 disruption, the responses of those genes were mostly unaltered. To demonstrate specificity for A3 function to PEMF, further experiments are being performed to rescue PEMF responsiveness in Adora3 disrupted cells by a CRISPR-Cas9 based inducible knock-in of Adora3 into the ROSA26 locus. Thus, in the PEMF-enhanced osteoblastic differentiation in bone healing, we propose complementary positive roles for Adenosine Receptor A2A and A3 in regulating cFos and Pthr1 PEMF-mediated gene overexpression and alkaline phosphatase-mediated signaling pathways, respectively.

The epigenetic regulator and H3K9me2 demethylase encoded by the Hairless (Hr) gene controls osteoblast differentiation Farzaneh Khani*, Roman Thaler, Christopher Paradise, Amel Dudakovic, Andre Vanwijnen. Department of Orthopedic Surgery, Mayo Clinic, United States

The Hairless gene (Hr) has key functions in skin and hair development and genetic mutations in the Hr gene lead to a bald mouse phenotype. Specific mutations in the human HR gene have been associated with delayed bone development during childhood. Furthermore, Hr has been recently shown to act as a histone H3 lysine 9 demethylase (H3K9me2). Because epigenetic modifications at the histone level and chromatin organization control osteogenic lineage commitment and progression, we addressed the role of Hr during osteoblast maturation. Using RNA-seq analysis and our RT-qPCR platform for epigenetic regulators, we show that Hr is expressed at a low basal level in bone marrow derived mouse and human mesenchymal stem cells (BMSCs), mouse MC3T3 osteoblasts and MLO-A5 osteocytes, as well as human bone outgrowth cells. However, Hr expression steadily increases during differentiation of MC3T3-E1 osteoblasts, as well as primary mouse BMSCs and human bone outgrowth cells. In contrast, Hr is only transiently expressed during differentiation of MLO-A5 osteocytes where it is initially increased during the initial stages of differentiation but declines at later stages of differentiation. Loss of function analysis by depletion of Hr through shRNA mediated stable knock down in MC3T3-E1 osteoblasts and MLO-A5 osteocytes compromises differentiation, as reflected by decreased extra cellular matrix (ECM) deposition and mineralization, reduced ALPL activity and suppressed expression of several primary osteoblastic genes like Sp7, Sparc (osteonectin), Phex, Ibsp (bone sialoprotein), Ifitm5 and several members of the Wnt family. Strikingly, CRISPR-dCas9 mediated inducible overexpression of Hr in MC3T3-E1 cells also inhibits osteoblast differentiation by suppressing Alpl activity, ECM deposition and mineralization. This suppression of osteoblastogenesis is associated with decreased expression of primary osteoblastic factors like Runx2, Bglap, Phospho1 and others. The inhibition of osteoblastogenesis by either loss or gain of function of Hr indicates that its balanced and carefully regulated expression is critical for its normal function as H3K9me2 demethylase during bone cell differentiation. Because H3K9me2 demethylase activity removes H3K9me3 marks necessary for heterochromatin formation, it appears that fidelity of heterochromatinization is important for late stages of osteoblast maturation.

SUN-0564

Salt-inducible kinase 1 regulates bone metabolism by affecting proliferation of osteoblast precursors and differentiation of osteoblasts Min Kyung Kim*, Hong-Hee Kim. Department of Cell and Developmental Biology, Seoul National University, Republic of Korea

A good understanding of the molecular mechanisms that regulate the various stages in bone metabolism is crucial to the development of therapeutic agents to prevention and treatment of bone diseases. In present study, we demonstrate the potential of Salt-inducible kinase 1 (SIK1) as a candidate for therapeutic agents. SIK1 previously known to be important for various reactions including myogenesis, hepatogenesis. However, the role of SIK1 in bone metabolism has not been known. Especially, SIK1 expression was sharply downregulated among SIK isoforms during osteogenesis. Knockdown an overexpression of SIK1 affected osteogenic process including expansion of osteoblast precursors and differentiation of osteoblast. And, its kinase activity modulated osteogenesis through CREB/Id1 axis by phosphorylating Transducer of regulated CREB activity 1 (TORC1). Calvariae transfected SIK1siRNA showed a phenotype of increased osteoblast number and ALP activity. In addition, enhanced bone mass and bone parameters were revealed in SIK1 knockout mice. Osteoblast differentiation and mineralization were increased in calvarial osteoblasts of SIK1 KO mice, but osteoclast formation and marker genes were not altered in SIK1 KO BMMs compared with WT. Taken together, our results demonstrate that SIK1 is a novel role in osteoblast precursors proliferation and differentiation stage via CREB/Id1 axis during osteogenesis and is a possible therapeutic drug target in bone disease.

Osteoblast-Specific Cell-Surface Antigen Regulating Osteoclastogenesis and Calcification: A Possible Unique Modulator of Bone Remodeling Tamer Badawy*[1], Yukari Kyumoto-Nakamura[1], Norihisa Uehara[1], Akiko Kukita[2], Toshio Kukita[1]. [1]Molecular Cell Biology & Oral Anatomy, Faculty of Dental Science, Kyushu University, Japan, [2]Microbiology, Faculty of Medicine, Saga University, Japan

(Background & Purpose) Bone remodeling is a continuous process characterized by highly coordinated cell-cell interaction in distinct multi-cellular units. Osteoclasts play a central role in bone remodeling. Although RANKL/RANK axis is considered to determine the gross number of osteoclasts present in bone tissues, detailed molecular events regulating frequency and efficiency of bone remodeling are still ambiguous. We hypothesized that osteoblast-specific cell-surface molecules could contribute to the fine regulation of bone remodeling. Therefore, we searched for cell-surface regulatory molecules expressed in osteoblasts. In the course of such survey, we found a unique cell-surface antigen (A7 antigen) highly specific to cells in the osteoblast-lineage. Here we report on the expression pattern and possible unique function of A7 antigen in bone remodeling.(Methods) Osteoblastic cell line ROS17/2.8 cell clone was utilized for BALB/c mice immunization. Splenocytes were fused with murine myeloma cell line. A panel of monoclonal antibodies was established according to the standard protocol. Antibody screening was performed by staining rat bone marrow cultures, mesenchymal stem cells, and osteoblastic cell lines. Bioassay was performed using calvaria-derived primary osteoblasts to form calcified matrices and osteoclastogenesis using bone marrow cultures. (Results and Discussion) In vitro, A7 antigen was expressed on cell-surface of osteoblasts and bone marrow stromal cells. In vivo, A7 antigen was detected in a subset of bone surface osteoblasts and in osteocytes, with a typical membrane expression pattern. Tissue array analysis showed only a limited expression of A7 antigen in osteocytes just close to the bone surface. Immunoblotting and immunoprecipitation analysis showed that A7 antigen is a lineage-specific cell-surface protein with approximate molecular weight of 45 KDa. Cross-linking of cell-surface A7 antigen in cultures of osteoclastogenesis showed limited stimulation of osteoclast formation. Marked suppression of calcification was observed when A7 antigen was cross-linked by A7 MAb in cultures of primary osteoblasts. These data suggest that A7 antigen is a key cell-surface molecule involved in the fine regulation of osteoclast recruitment as well as in the critical regulation of osteoblast maturation especially in calcification. A7 antigen could be a therapeutic molecular target in pathological bone diseases.

Osteoblast-specific overexpression of Gαs or Gα11 leads to differential fracture healing responses. Kathy Kyungeun Lee*[1], Jane Mitchell[1], Marc Grynpas[2]. [1]University of Toronto, Canada, [2]Lunenfeld-Tanenbaum Research Institute, Canada

Bone exhibits a remarkable ability for self-repair; however, the normal process of healing is sometimes compromised resulting in non-union that requires additional interventions that are costly and have long-term adverse impact on quality of life and productivity. Thus, advances in our understanding of the regulatory pathways underlying bone repair, which may be therapeutically targetable, have clinical and economical potential. G protein-coupled receptor signaling in osteoblasts has a regulatory role in skeletal development and homeostasis. Aberrant expression of Gαs and Gαq/11 leads to profound changes in bone mass,

quality, and rate of bone turnover. Here we have examined the effects of Gαs and Gα11 overexpression in osteoblasts on bone healing from stabilized transverse osteotomy of tibiae using wild-type and two transgenic mouse models previously developed in our lab, Gs-Tg that has increased bone and G11-Tg that has osteopenia. The progression of fracture healing was evaluated by Micro-CT analysis and histomorphometry at 2 and 3 weeks post-fracture. Our Micro-CT analyses revealed that increased Gαs signaling in osteoblasts leads to rapid fracture healing with enhanced callus mineralization at 2 weeks and new bone formation at 3 weeks in Gs-Tg mice. On the contrary, increased Gα11 signaling in osteoblasts leads to delayed fracture healing with reduced bone formation but early transition into the remodeling phase at 3 weeks. Histologically, Safranin-O/Fast Green staining demonstrated a large amount of newly formed woven bone containing residual cartilage matrix at 2 weeks and persistence of irregular morphology of woven bone at 3 weeks in Gs-Tg mice. Interestingly, despite high basal osteoclast activity in G11-Tg mice, residual cartilage islands were still evident at the fracture site at 2 weeks similar to WT mice. However, no obvious difference in the remodeling of woven bone into a lamellar bone structure was observed between WT and G11-Tg mice at 3 weeks. Altogether, our results indicate that osteoblast-specific overexpression of Gαs and Gα11 lead to different fracture healing responses.

Analysis of osteoblast-specific histone-modifying enzymes Mof reveals novel epigenetic basis of osteoblast differentiation Xiangzhi Li*[1], Jianmei Chen[1], Di Liu[2], Minqi Li[3], Yang Yang[1], Shuang Gao[1], Meng Wang[1], Shiguo Yan[4]. [1]Department of Cell Biology, Shandong University School of Basic Medical Sciences, China, [2]Department of Prosthodontics, Shandong Provincial Key Laboratory of Oral Tissue Regeneration, School of Stomatology Shandong University, China, [3]Department of Bone Metabolism, School of Stomatology Shandong University, China, [4]Department of Periodontology, School of Stomatology Shandong University, China

Translational histone modification and accompanying histone-modifying enzymes form the largest and most complex regulatory entity, which is an important epigenetic modification that contributes to specific functions of different cell types. However, available information is lacking regarding the changes in the specific epigenetic program that may directly interfere with the differentiation process. To study the function of histone H4K16 acetyltransferase Mof in osteoblast differentiation for 3, 7 and 14 days, protein expression of Mof and the H4K16 acetylation level were gradually elevated according to time course of induction measured by Western blot, quantitative reverse transcription-polymerase chain reaction (RT-qPCR), alkaline phosphatase (ALP) and Alizarin Red strain assays. Small interfering RNA targeting Mof and Flag-Mof plasmid were constructed and transfected into ST2 and MC3T3-E1 cells to silent and overexpress Mof in both of cell types were determined by measuring expression changes of key markers of osteoblast differentiation; these markers include runt-related transcription growth factor 2 (Runx2), Osterix (Osx), Bone Morphogenetic Protein-2 (BMP-2), B-catenin, transforming growth facor (Tgf) B1, and BMP9 by using Western blot, Rt-qPCR, ALP strain and co-immunoprecipitation technique. Results showed that Runx2 and Osx expression declining dramatically at mRNA and protein levels during Mof knock-down. No significant changes were observed in BMP2, B-catenin, TgfB1, and BMP9. Altogether, these results strongly indicate that Mof plays an important role in proper osteoblast differentiation.

Plasticizer Di(2-ethylhexyl)phthalate Interferes with Osteoblastogenesis and Adipogenesis in vitro and in vivo Rong-Sen Yang*, Chen-Yuan Chiu, Ding-Cheng Chan, Shing-Hwa Liu. National Taiwan University, Taiwan

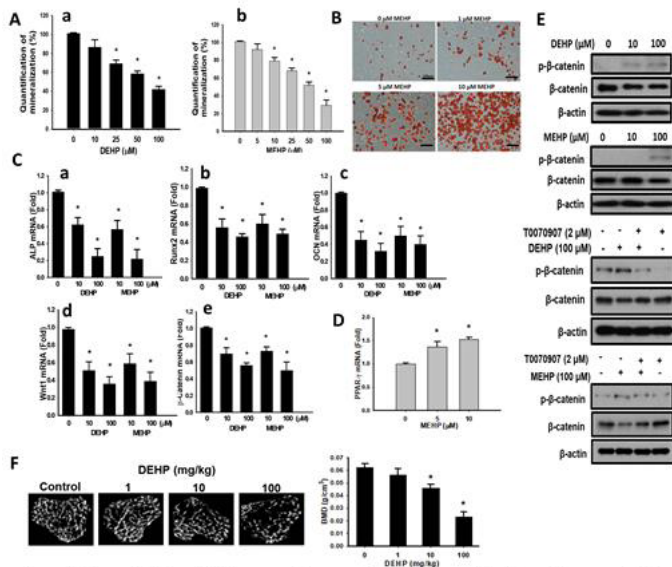
Introduction: Plasticizer di(2-ethylhexyl)phthalate (DEHP) can leach from medical devices. Epidemiological studies showed that phthalate metabolites levels in the urine are associated with low bone mineral density (BMD) in older women. The effect and mechanism of DEHP on bone loss remain to be clarified. Here, we investigated the effect and mechanism of DEHP and its active metabolite mono(2-ethylhexyl)phthalate (MEHP) on osteoblastogenesis and adipogenesis from bone marrow stromal cells (BMSCs) in vitro and BMD and microstructure in mice.Methods: The primary BMSCs were isolated from mice for osteoblastogenesis or adipogenesis. Both alkaline phosphatase (ALP) activity and mineralized nodule formation stained by Alizarin red S were determined for osteoblastogenesis. Adipocyte staining by Oil Red O was determined for adipogenesis. The protein expressions were determined by Western blotting. Moreover, mice were randomly divided into four groups (12 animals/group): 0 (corn oil), 1, 10, and 100 mg/kg DEHP (oral administration for 8 weeks). Bone mass and microarchitecture analysis in mice were determined by a micro-computed tomography (μCT).Results: The osteoblast differentiation of BMSCs was significantly and dose-dependently decreased by DEHP and MEHP (10-100 μM) without cytotoxicity to BMSCs (Figure 1-A; n=5, p<0.05). The mRNA expressions of alkaline phosphatase, Runx2, osteocalcin, Wnt1, and β-catenin were significantly decreased in DEHP- and MEHP-treated BMSCs during differentiation (Figure 1-C; n=3, p<0.05). MEHP significantly increased the adipocyte differentiation of BMSCs and PPARγ mRNA expression (Figure 1-B and D; n=5, p<0.05). DEHP did not promote the adipogenesis (n=5, p<0.05). Both DEHP and MEHP significantly increased the ratios of phosphorylated β-catenin/β-catenin and inhibited osteoblastogenesis, which could be reversed by Wnt activator lithium chloride (n=3, p<0.05) and PPARγ inhibitor T0070907 (Figure 1-E; n=3, p<0.05). Moreover, exposure of mice to DEHP (1, 10, and 100 mg/kg) for 8 weeks altered BMD and microstructure (Figure 1-F; n=12, p<0.05). In BMSCs isolated from DEHP-treated mice, osteoblastogenesis and Runx2, Wnt1, and β-catenin expression were decreased, but adipogenesis and PPARγ expression were increased (n=3, p<0.05).Conclusion: DEHP and its metabolite MEHP exposure may inhibit osteoblastogenesis and promote adipogenesis of BMSCs through the Wnt/β-catenin-regulated signals and thus triggering bone loss.


Figure 1. Effects of DEHP and MEHP on osteoblastogenesis and adipogenesis *in vitro* and bone mass *in vivo*. BMSCs were cultured in osteogenic differentiation medium (A, C, E) or adipogenic differentiation medium (B, D) with or without DEHP (10-100 μM) and MEHP (1-100 μM) for 7 or 16 days, respectively. In *in vivo* experiments, mice were orally administered with corn oil (vehicle control) or DEHP (1, 10, and 100 mg/kg) daily for 8 weeks (F). The excised tibia specimens were used for μCT analysis. Data are presented as mean ± SEM of at least three independent experiments performed in triplicates. * P < 0.05 compared to the control.

TRAPPC9 Regulates BMP2-mediated Osteoblast Differentiation and Bone Regeneration through Down-Regulation of NF-kB Activation Thomas Mbimba*[1], Gregory Sondag [1], Fouad Moussa[1], Fayez Safadi[2]. [1]Musculoskeletal Research Group, NEOMED, United States, [2]Musculoskeletal Research Group, NEOMED, Akron Children Hospital, United States

Intellectual disability (ID) is a serious disorder of the central nervous system with a prevalence of 1-3% in the general population. Recent studies identified different nonsense mutations in the trafficking protein particle complex (TRAPPC9) gene in consanguineous and nonconsanguineous families with autosomal-recessive non syndromic mental retarda-

tion. These patients exhibit severe skeletal phenotypes such as short stature, polydactily, craniofacial deformity and microcephaly. TRAPPC9 is known to bind NFkB inducing kinase (NIK) and IkB kinas-beta (IKKbeta) and enhances cytokine-induced NFkB activation by increasing the kinase activities of IKK2 (IKKbeta) and NIK. It thus plays a role in the canonical and non-canonical NFkB signaling. Recent studies have identified NF-kB as a major negative regulator of osteoblast (OB) proliferation and differentiation that binds and suppresses Runx2 activation in response to BMP2. Here we hypothesize that TRAPPC9 regulates BMP2-mediated activation of NF-kB through Samd/p38/MAPK activation. We first examined TRAPPC9 expression and localization in bone by qPCR, Western blot and immunoprecipitation, which confirmed its expression in both OC and OB. Co-immunoprecipitation studies confirmed TRAPPC9 binding to both NIK and IKK2 in OB. To examine TRAPPC9 role during OB differentiation, we performed loss- and gain-of-function studies in both MC3T3 and Bone marrow-derived MSCs using shRNA viral system. TRAPPC9 down-regulation showed a marked increase in all osteogenic markers such Runx2, Osx, Ocn, ALP, ColA1A. TRAPPC9 down-regulation increases matrix maturation and mineralization shown by an increase in ALP staining and activity, Von Kossa and Alizarin red staining. Next, we showed that TRAPPC9 down-regulation mediates an increase in Smad1,5,8 and p38 MAPK activation associated with NF-kB down-regulation. Next, we assessed the effects of TRAPPC9 downregulation on bone regeneration in vivo using calvarial defect model and found that MSC engineered with shRNA for TRAPPC9 incudes bone regeneration compared to control cells. Taken together, these data suggest that inhibition of TRAPPC9 enhances OB differentiation through Smad1,5,8 and P38 activation and bone regeneration, at least in part, by suppressing of NF-kB signaling.

SUN-0570

Role of Hp1 family proteins Cbx1, Cbx3, and Cbx5 during osteoblastic differentiation Christopher R. Paradise*[1], Pengfei Zan[1], Roman Thaler[1], Farzaneh Khani[1], Merel O. Mol[2], Esther Liu[1], Guodong Li[3], Peter Kloen[2], Marianna Kruithof-De Julio[4], Simon M. Cool[5], David R. Deyle[1], Amel Dudakovic[1], Andre J. Van Wijnen[1]. [1]Mayo Clinic, United States, [2]University of Amsterdam, Netherlands, [3]Tongji University, China, [4]University of Bern, Switzerland, [5]Agency for Science, Technology and Research, A(*)STAR, Singapore

Bone development and homeostasis are tightly regulated by several cellular mechanisms, including epigenetic control of gene expression. Post-translational modifications of histone tails are critical in this process as they induce chromatin compaction and/or relaxation to control access to regulatory sequences and genes packaged into nucleosomes. Heterochromatin-associated Chromobox (Cbx) proteins play a crucial role in chromatin compaction by binding the repressive marks tri-methylated histone 3 lysine 9 (H3K9Me3) and tri-methylated histone 3 lysine 27 (H3K27Me3). Analysis of our comprehensive musculoskeletal RNA-seq dataset revealed that among the family of 8 Cbx genes, all three isotypes of the heterochromatin protein 1 (HP1) subfamily (Cbx1, Cbx3, and Cbx5) which bind and compact H3K9Me3 are highly expressed in bone and osteoblastic cells. Loss of function analysis of these CBX proteins was carried out by siRNA mediated knockdown. Depletion of Cbx1 and Cbx3 promotes osteogenic differentiation of pre-osteoblasts as shown by the enhanced expression of key osteogenic transcription factors Runx2 and Sp7 (Osx) and ECM-maturation associated genes Alpl, Ibsp, Bglap, and Col1a1. Furthermore, knockdown of these genes increases extracellular matrix mineralization during an osteogenic differentiation time course. In contrast, knockdown of Cbx5 reduces matrix mineralization and does not affect expression levels of osteoblast-specific gene. We also note a compensatory effect within the Hp1 family members as knockdown of one member induces expression of the remaining two. Simultaneous siRNA mediated knockdown of two or three Hp1 family members no longer enhanced osteoblastic differentiation as observed previously with the single knockdown of Cbx1 or Cbx3. We also noted an increase in nuclear size after knockdown of the Hp1 proteins, suggesting relaxation of chromatin condensation. Interestingly, we observe a major reduction in global H3K9Me3 levels upon knockdown of all three Hp1 related Cbx proteins but not with single or double knockdown. Taken together, our results indicate that Cbx1, Cbx3 and Cbx5 collectively protect H3K9me3 heterochromatin marks and that these HP1 family proteins have novel roles in regulating osteoblast differentiation.

SUN-0571

Role of Pre-proenkephalin 1 in the response of bone to mechanical unloading and in osteoblast differentiation Nadia Rucci*, Antonio Maurizi, Isabella Baldini, Mattia Capulli, Anna Teti. University of L'Aquila, Italy

Pre-proenkephalin 1 (Penk1) belongs to the family of the typical opioid peptides. The Penk1 gene encodes for a pro-peptide that is proteolytically processed to generate 4 copies of Met-enkephalin, 2 copies of Met-enkephalin extended sequence and 1 copy of Leu-enkephalin. These pentapeptide opioids modulate the response to stimuli such as the perception of pain. Interestingly, we found Penk1 to be the most down-regulated gene in a microarray analysis performed in osteoblasts subjected to microgravity (0.008 g) as a model of in-vitro mechanical unloading. Penk1 mRNA downregulation was confirmed in the bones of two in-vivo models of mechanical unloading: tail suspended mice (-30%, p=0.023) and mice

injected with botulin toxin A (-40%, p=0.057). Consistently, in human sera from healthy volunteers subjected to bed rest, we observed an inverse correlation between PENK1 levels and duration of bed rest (p=0.0006, R=0.6). These results prompted us to investigate a role for PENK1 in bone metabolism. We found Penk1 to be highly expressed in the marrow flushed-out bone, and its expression progressively increased during in vitro osteoblast differentiation in osteogenic medium. Accordingly, the stimulation of osteoblast differentiation by the c-Src inhibitor PP1 increased Penk1 mRNA (1.8-fold, p=0.03). Silencing osteoblast Penk1 by siRNAs decreased Alp (-37%, p=0.018) and Runx2 (-40%, p=0.019), while it increased Sclerostin (7.5-fold, p=0.035) compared to osteoblasts treated with scrambled siRNA. Consistently, overexpression of Penk1 by Amaxa nucleofection increased osteocalcin expression (6-fold p=0.02). Moreover, primary osteoblasts isolated from Penk1 KO mice showed lower formation of mineralization nodules (-60%) and ALP activity (-70%) compared to the WT mice. Interestingly, mouse primary osteoblasts expressed all the known opioid receptors, thus suggesting that osteoblasts could respond to the enkephalin treatment. Indeed, osteoblast cultures treated with Met- and Leu- enkephalins showed an increased osteocalcin expression (4-fold, p=0.03), together with an increased mineralization (1.5-fold). Accordingly, the type I collagen release in the medium was higher in both Met- and Leu-enkephalin treated osteoblasts compared to control. Taken together, these results highlight a role for PENK1 in osteoblast differentiation and in the regulation of the response of the bone to mechanical unloading.

Iron Involves in the Regulatory Effect of High Static Magnetic Field on Osteoblasts and Osteoclasts Jiancheng Yang*[1,2], Jian Zhang[1,2], Dandan Dong[1,2], Shenghang Wang[1,2], Peng Shang[2,3]. [1]School of Life Sciences, Northwestern Polytechnical University, China, [2]Key Laboratory for Space Bioscience and Biotechnology, Institute of Special Environment Biophysics, Northwestern Polytechnical University, China, [3]Research & Development Institute in Shenzhen, China

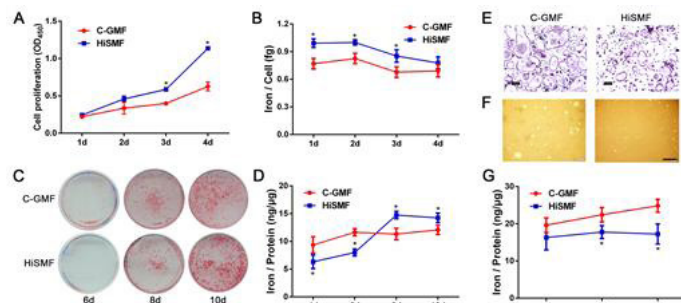
High static magnetic fields (HiSMF) are usually defined as those static fields with intensities ≥1T. Although many studies have indicated that static magnetic fields have positive effects on bone tissue, there were limited studies investigate the effects of HiSMF on bone system. Evaluating the effects of HiSMF on osteoblasts and osteoclasts, which is critical for understanding the possible risks or benefits from HiSMF to the balance of bone remodeling. Iron and magnetic fields have the natural relationship, and iron is an essential element for normal bone remodeling. Iron overload or deficiency can cause severe bone disorders including osteoporosis. In this study, HiSMF of 16T were used to investigate how osteoblasts (MC3T3-E1 cells) and osteoclasts (Raw264.7 cells) response to HiSMF and the changes of intracellular iron levels under HiSMF.The results showed that HiSMF promoted osteoblast proliferation with an increased iron content. One possible explanation for this finding is that elemental iron is essential for cell growth and crucial to many fundamental cellular processes, including DNA synthesis, respiration, cell cycle regulation and the function of proteins. During osteoblast differentiation, HiSMF reduced the initial stage of osteogenic differentiation and cellular iron, but accelerated matrix maturation, ultimately enhancing osteogenic mineralization and iron levels in osteoblasts. Osteoblast mineralization is a process that mineral crystals of hydroxyapatite were embedded into type I collagen fibers. And iron is a cofactor for the prolyl- and lysyl-hydroxylases in collagen synthesis and plays a crucial role in collagen maturation. As for osteoclasts, osteoclast differentiation and bone resorption activity was inhibited by HiSMF and was accompanied by a decrease of iron content in osteoclasts. Mature osteoclasts highly express tartrate-resistant acid phosphatase (TRAP) that they release upon active bone resorption. It is important that TRAP contains 2 iron atoms/molecule, and its activity is rapidly inhibited by the iron chelators.In conclusion, our results showed that HiSMF have positive effects on osteoblasticgenesis with altered iron levels, meanwhile, osteoclastogenesis was suppressed with decreased iron content under HiSMF. These results will improve our further understandings of the exact mechanisms of HiSMF on bone remodeling and have potential application value in treating or preventing human bone metabolism disorders.


Figure 1. Iron involves in the regulatory effect of HiSMF on osteoblasts and osteoclasts. A, The proliferation of MC3T3-E1 cells were examined by CCK8 assay; B, Iron levels of osteoblasts during proliferation was detected by graphite furnace AAS; C, Osteogenic differentiation was confirmed by alizarin red S staining; D, Iron content of osteoblasts during differentiation; E, TRAP staining of osteoclasts generated by RAW264.7 cells; F, Bone resorption ability in osteoclast was determined by pit formation assay; G, Iron content of osteoclasts during differentiation. All HiSMF groups were compared with the geomagnetic field (GMF). Data shown are mean ± SD. * p < 0.05.

The sulforaphane-sensitive Tet2 enzyme controls osteoblast differentiation and bone homeostasis by regulating active DNA demethylation Roman Thaler*, Farzaneh Khani, Chris Paradise, Oksana Pichurin, Amel Dudakovic, Andre J Van Wijnen. Mayo Clinic, United States

Proper osteoblastic differentiation is essential for normal bone development and homeostasis. We have previously shown that small molecules like Sulforaphane (SFN) or DMSO strongly promote osteoblastic differentiation by active DNA demethylation via Tet enzymes (Ten-eleven translocation methylcytosine dioxygenases). Specifically, because sulforaphane induces Tet1/Tet2-mediated active DNA demethylation, we addressed the molecular and physiological contribution of Tet enzymes to osteoblast differentiation in culture and bone in vivo. Using in vitro shRNA-mediated gene knock-down and CRISPR-dCas9 mediated gene activation paired with a conditional knock-out mouse model, we investigated the biological roles of the Tet1 and Tet2 enzymes in osteoblast differentiation and bone physiology.In mesenchymal stem cells, in osteoblasts as well as in primary bone tissue, Tet1 is expressed at low levels, but Tet2 expression is about 4-6 fold higher and appears to control active DNA demethylation during osteoblastic differentiation. We find that Tet2 but not Tet1 is required for global active DNA demethylation as measured by cytosine hydroxymethylation levels in MC3T3-E1 and MLO-A5 cells. However, both enzymes are necessary for osteoblast maturation as measured by ALPL activity, extra cellular matrix (ECM) deposition, ECM mineralization as well as expression of several osteoblastic genes. Conversely, forced expression of Tet1 and Tet2 reveals that a global increase of active DNA demethylation is achieved by Tet2, but not Tet1. Moreover, only Tet2 overexpression results in enhanced osteoblast function. We further confirmed the role of Tet2 in bone homeostasis using conditional Tet2 knock-out mice driven by an osteoblast specific Osx-Cre recombinase. Although these mice do not show apparent effects on general bone morphology, the overall bone quality and strength may be compromised as compared to their littermate controls. Collectively, our results establish Tet2 as a central epigenetic driver of osteoblast differentiation in vitro and in vivo and that active hydroxymethylation is causally linked to normal bone development and maintenance of bone health.

Notch activation augments bone morphogenetic protein mediated human osteoblast differentiation Yadav Wagley*[1], Matthew Johnson[2], Sumei Lu[2], Andrew Wells[2,3], Alessandra Chesi[2], Struan F.A. Grant[2,4], Kurt Hankenson[1]. [1]Department of Orthopaedic Surgery, University of Michigan Medical School, United States, [2]Center for Spatial and Functional Genetics and Division of Human Genetics, The Children's Hospital of Philadelphia, United States, [3]Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, United States, [4]Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, United States

Bone morphogenetic proteins (BMP) play a well-established role in osteoblastogenesis, while the role of canonical Notch signaling in osteoblastogenesis is less-understood. To determine common regulatory mechanisms between Notch-mediated and BMP-mediated human osteoblast differentiation, three independent primary human donor mesenchymal progenitor cell isolates were stimulated in parallel with either the Notch ligand Jagged-1 or BMP2. Both treatments similarly increased terminal osteoblast differentiation as determined by alkaline phosphatase (ALPL) activity and Alizarin red S staining. RNA was harvested three days post-treatment and subjected to RNA-seq on the Illumina NovaSeq platform. Data was analyzed with the PORT pipeline and differential expression analysis was performed with the R-package limma. At FDR<10%, 4477 and 370 genes were differentially expressed in the BMP2 and the Jagged-1 treated cells, respectively. Genes associated with osteoblast differentiation, such as SPP1, SOST, DKK1, Osterix (SP7) and DMP1 were induced in BMP2-treated cells, but not in Jagged-1-treated cells. 45 genes were commonly upregulated, and 69 genes were commonly downregulated (FC>1.5). ALPL and genes involved in extracellular matrix synthesis (eg. ACAN, ADAMTS10, ADAMTS2, HAPLN3, and HAS3) were upregulated with both treatments. Ingenuity pathway analysis of commonly upregulated genes showed increases in Notch signaling; Regulation of the Epithelial-Mesenchymal Transition Pathway; Osteoarthritis Pathway; RhoA signaling; and Epithelial Adherens Junction Signaling. Common downregulated pathways were NF-kB signaling; Hepatic Fibrosis/ Hepatic Stellate Cell Activation; LXR/RXR Activation; Uracil Reduction II (Reductive); and Thymine Degradation. Notably, two of the top 5 commonly upregulated genes belonged to the Notch signaling pathway (Hey2 and Hes4), and additionally both induction protocols induced Jagged-1 and Notch 3. Interestingly, inhibiting Notch signaling with the gamma-secretase inhibitor DAPT during BMP-mediated human osteoblast differentiation abolished terminal osteoblastogenesis. Taken together, these data advance our current understanding of the basic mechanisms regulating bone formation, and suggest that Notch signaling is required for BMP-mediated osteoblastogenesis. These findings highlight the role of aberrant Notch signaling associated with human skeletal disorders, such as those seen in Alagille syndrome.

Gi signaling regulates the fate of murine bone marrow mesenchymal progenitor cells Liping Wang*, Linh Ho, Theresa Roth, Robert Nissenson. Endocrine Research Unit, San Francisco VA Medical Center, and Departments of Medicine and Physiology, University of California, United States

Signaling through Gs-G protein coupled receptors (GPCRs) is known to regulate the fate of bone marrow mesenchymal progenitor cells (MPCs). Stimulating Gs activity in MPCs enhances osteoblast differentiation and suppresses adipocyte differentiation. In contrast, little is known about the role of inhibitory Gα protein (Gi) signaling in determining the fate of MPCs. We have previously shown that constitutive activation of Gi signaling in committed osteoblasts restrains bone formation and leads to osteopenia. We hypothesized that enhancing Gi signaling in MPCs would suppress osteoblast differentiation and promote bone marrow adipogenesis, thereby reducing bone mass. To test this hypothesis, we generated a mouse line (Ro1 mice) in which an engineered, constitutively active Gi-activating receptor (Ro1) is expressed in MPCs, driven by an osterix promoter. The tet-off system was used to delay the expression of Ro1 in MPCs until approximately the time of birth. Firstly, μCT assessment of distal femurs of 10-week-old Ro1 mice demonstrated that constitutive Gi activation in MPCs decreased bone fractional volume by almost 50% (p<0.05) in female (F) mice and by about 21% (p>0.05) in male (M) mice, compared to age and sex matched littermate control mice. The decreased bone volume in Ro1 mice was mainly associated with decreased trabecular number (M vs. F: 38% vs. 46%) and increased trabecular separation (M vs. F: 66% vs. 75%). Secondly, bone marrow stromal cells (BMSCs) from Ro1 mice were cultured. Under osteogenic conditions, activating Gi signaling by expression of Ro1 decreased mRNA levels of alkaline phosphatase (1.6 fold, p<0.05), osteocalcin (3 fold, p<0.01), and type 1 collagen (1.5 fold, p<0.01). By contrast, under adipogenic conditions, expression of Ro1 led to a 1.6 fold increase in adipogenesis, assessed by Oil Red O staining (p<0.01). Thirdly, 6-week-old Ro1 mice were fed a high fat diet (HFD, 60% of kcal from fat) for 4 weeks. Activation of Gi signaling by expression of Ro1 in mice on a control diet significantly increased (by 2.4-fold, p<0.05) the number of adipocytes in the bone marrow, compared to littermate controls. HFD led to a 2.3-fold (p<0.05) increase in marrow adipocytes in Ro1 mice vs. the HFD-fed littermate control mice. The MPCs from Ro1 mice fed with HFD were harvested. HFD significantly increased the expression of oxidative stress response genes in MPCs, including Hif-1α (2.5 fold, p<0.01) and SOD1 (1.7 fold, p<0.01). Strikingly, the expression of the gene encoding, Gαi2 was increased by 10 fold. In conclusion, endogenous Gi signaling regulates the fate of MPCs. Excessive Gi activity in MPCs drives adipocyte differentiation at the expense of osteoblast differentiation. Metabolic stress such as HFD enhances the expression of oxidative stress genes in MPCs and this together with upregulation of Gi signaling may serve to increase marrow adipogenesis at the expense of osteogenesis.

Calmodulin dependent protein kinase kinase-2 (CamKK2) activates AMPK at an early stage which is required for osteoblast differentiation Susan D'Costa*, Gang Xi, David Clemmons. University of North Carolina at Chapel Hill, United States

Our previous studies showed that activation of AMPK at an early stage (day 1-9) is required for osteoblast differentiation. However, that study did not determine the upstream kinase which is directly responsible for AMPK activation during osteoblast differentiation. LKB1 is the traditional upstream kinase that activates AMPK but an LKB1 inhibitor had no effect thereby excluding it as a candidate kinase in this context. Previous studies have shown that calmodulin dependent protein kinase kinase-2 (CamKK2) is an alternative upstream kinase for AMPK activation. Our in vitro data clearly showed that addition of STO609, a CamKK2 inhibitor, at the early stage of differentiation inhibited AMPK activation in a dose dependent manner. Alizarin red staining and osteocalcin immunoblotting results showed that STO609 treatment early in the differentiation cycle attenuated osteoblast differentiation but

it was without effect if added at the later stages of differentiation, such as after day 11. This time frame was similar to the timeframe of AMPK activation during osteoblast differentiation. In vitro kinase assays showed that commercially available pure CamKK2 or CamKK2 immunoprecipitated from lysates obtained from cells that had been exposed to differentiation medium phosphorylated a substrate peptide AMPK homologue containing the T172 site activation site and STO609 inhibited this phosphorylation. This supports the hypothesis that CamKK2 is active during differentiation and phosphorylates AMPK T172. Furthermore, immunoprecipitation studies demonstrated that AMPK bound to CamKK2 during the early phase of differentiation. In addition, knock down of CamKK2 using a siRNA suppressed both basal and IGF-I-stimulated AMPK activation. Consistent with the inhibitor data, silencing CamKK2 was also able to inhibit osteoblast differentiation but only if the siRNA was added early in the differentiation cycle and no inhibition was detected if it was added after day 11. We conclude CamKK2 is activated early in the differentiation cycle, it directly phosphorylates AMPK and that CamKK2-mediated AMPK activation at an early stage is required for osteoblast differentiation.

Snx10 and PIKfyve are Required for Lysosome Formation in Osteoclasts Weimin Liu*[1], Gabriela Picotto[2], Leslie Morse[3], Megan Summers[3], Ricardo Battaglino[1]. [1]UC Denver, United States, [2]U de Cordoba, Argentina, [3]Craig Hospital, United States

Osteoclasts rely on intracellular trafficking and organelle homeostasis for normal function. Snx10 is a PI3P-binding protein which localizes to osteoclastic early endosomes. Snx10-deficient osteoclasts show impaired endocytosis, extracellular acidification, ruffled border formation and bone resorption, suggesting that Snx10 regulates vesicular trafficking in endosome/lysosome formation. In order to elucidate the cellular mechanisms by which Snx10 regulates vesicular transport to control osteoclastic resorption we studied PIKfyve, another PI3P-binding kinase, which phosphorylates PI3P to PI(3,5)P2. PI(3,5)P2 is required for the biogenesis of lysosomes. Genetic or pharmacological inhibition of PIKfyve (and diminished PI(3,5)P2 synthesis) causes endosome enlargement and cytoplasmic vacuolation. Overexpression of SNX10 also induces accumulation of early endosomes. These changes in the number and size of endosomes and lysosomes suggests that both Snx10 and PIKfyve are involved in membrane traffic between these organelles. Apilimod, a small molecule with cytotoxic activity used for the treatment of inflammatory diseases, inhibits PIKfyve with nanomolar specificity. Intriguingly, expression of CLCN7, OSTM1, and SNX10 is essential for sensitivity to apilimod which suggests that endosome/lysosome dysfunction mediates apilimod's cytotoxic effect. Snx10 and PIKfyve co-localize to early endosomes in osteoclasts, as determined by subcellular fractionation studies and immunofluorescent staining. Treatment with 10nM Apilimod results in accumulation of early endosomes, inhibition of RANKL-induced osteoclast formation, inhibition of lysosome formation and secretion of TRAP from differentiated osteoclasts. Apilimod, on the other hand, does not inhibit lysosome biogenesis in Snx10-deficient osteoclasts. Taken together, these results suggest that Snx10 and PIKfyve are involved in the regulation of endosome/lysosome homeostasis via the synthesis of PI(3,5)P2. These findings may suggest novel therapeutic approaches targeting the secretory pathway in osteoclasts.

Biodegradable Polymeric Nanoparticles Encapsulated with Small Molecular Weight L-Plastin Peptides Reduces Resorption Activity of Osteoclasts Sunipa Majumdar*[1], Aniket Wadajkar [2], Anthony Kim[2], Meenakshi Chellaiah[1]. [1]Department of Oncology and Diagnostics, University of Maryland, School of Dentistry, United States, [2]Departments of Neurosurgery and Pharmacology, University of Maryland School of Medicine, United States

Background: Tumor necrosis factor alpha (TNF-α) was shown to stimulate the resorptive activity of osteoclasts (OCs) independent of integrin αvβ3. The actual target of TNF-α signaling is unclear. We have shown the vital role of an actin-bundling protein L-plastin (LPL) previously, in the assembly of nascent sealing zones (NSZs) at the early phase of sealing ring formation. TNF-α signaling regulates the phosphorylation of LPL at Ser-5 and -7 residues and the assembly of NSZs. These studies prompted us to gain more insight into

the role of LPL phosphorylation on OC bone resorption.Materials: To test the hypothesis that reducing the phosphorylation of LPL will attenuate the formation of NSZs and resorption, we used TAT-fused small molecular weight LPL peptides (P1 and P2) containing unmutated (P1-TAT-MARGSVSDEF) and mutated (P2- TAT-MARGAVADEF) serine residues. Polylactic-co-glycolic acid (PLGA) is an FDA approved polymer and a commonly used delivery system in bone tissue engineering. To deliver the peptides in a controlled and sustained fashion in vivo in mice, we formulated P1 or P2-loaded PLGA nanoparticles. Prior to injecting into mice, we characterized the P1 or P2-loaded PLGA nanoparticles (~150 nm) and analyzed their effects on OCs in vitro.Results: Transduction of TAT-fused P1 into OCs reduces the formation of both NSZs and bone resorption which is due to the selective inhibition of cellular LPL phosphorylation. Characterization of the peptide (P1 and P2) loaded nanoparticles demonstrated the following: a) Transmission electron microscopy (TEM) images showed well-dispersed spherical shaped nanoparticles. b) The release of peptides over three weeks period due to slow hydrolysis of biodegradable polymer over time. c) both P1 and P2 nanoparticles had nearly neutral surface charge of -3.6 mV and -3.1 mV, respectively. d) Incubation of OCs with peptide-loaded PLGA nanoparticles for 4h substantiates the significance of the inhibitory effect of the P1 peptide on LPL phosphorylation and NSZs formation.Discussion and conclusion: Attenuation of NSZs formation and bone resorption in OCstransduced with TAT-fused P1 and not with P2 peptide documents the importance of phosphorylation of LPL in OC function. Small molecular weight peptide-based manipulations of OC bone resorption have the potential for pharmacological manipulations. Inhibition of endogenous LPL phosphorylation and NSZs formation by P1 -loaded PLGA nanoparticles suggests the entry of these particles into OCs in vitro. These observations provide a 'stepping stone' to evaluating the effects of loaded nanoparticles in mouse models in vivo. (Patent pending for peptides; Equal contribution by 1st and 2nd authors; Work is supported by funding from NIH-NIAMS R01-AR46292 and R01AR066044 to MAC)

HDAC4-ERK Crosstalk Regulates Osteoclast Function Bora Faulkner*, Nicholas Blixt, Rajaram Gopalakrishnan, Eric Jensen, Kim Mansky. University of Minnesota, United States

Bone-resorbing osteoclasts are important for physiological bone remodeling process; however, their dysregulation contributes to development of skeletal diseases such as osteoporosis and cancer-induced bone disease. Histone deacetylases (HDACs) are well known repressors of gene transcription and have been shown to induce specific changes in gene transcription. Studies have shown that HDACs can influence skeletal development by affecting bone formation and resorption. These observations imply roles of HDACs in skeletal diseases such as osteoporosis and suggest these molecules could represent unique therapeutic targets. Here, we examined the consequence of genetic disruption of HDAC4, a class IIA deacetylase, in osteoclastogenesis using both in vitro cellular and molecular analyses associated to in vivo characterization of conditional HDAC4-knockout (HDAC4cKO). Thus, we mated Hdac4fl/fl mice with those expressing c-Fms-Cre to target osteoclast lineage cells. We found that male HDAC4cKO mice at 3 months of age exhibit increased bone volume by micro-CT and decreased bone resorption. This result was unexpected given previous work on other class IIA deacetylases by our lab and others that had demonstrated that loss of HDAC7 or HDAC9 expression in osteoclasts resulted in mice with osteopenia. Analysis of the in vitro phenotype of osteoclasts from the HDAC4cKO mice demonstrate osteoclasts from the HDAC4cKO were larger than wild-type during early stages of osteoclast differentiation but had less demineralizing activity. Mechanistically, we show that in the absence of HDAC4, ERK1/2 activation is reduced independent of changes in MEK1/2 phosphorylation status. This data suggests that HDAC4 might target a MAP kinase phosphatase (MKP) to regulate ERK1/2 phosphorylation. ERK1/2 signaling has been shown to promote osteoclast survival, so this may represent a mechanism to explain the osteopetrotic phenotype of the HDAC-4cKO mice. Moreover, these data support the hypothesis that HDAC4 could be involved in bone disease, and provide a rationale for the development of novel HDAC4-specific inhibitors as potential therapies for excessive osteoclast activity.

MEF2C positively regulates osteoclastogenesis by controlling c-Fos expression Takayuki Fujii*, Lionel Ivashkiv, Kyung Parkmin, Ye Ji Lee, Seyon Bae, Sehwan Mun, Kaichi Kaneko, Carmen Chai, Eric Sohn. Arthritis and Tissue Degeneration Program, David Z. Rosensweig Genomics Research Center, Hospital for Special Surgery, United States

Hypoxia augments osteoclastogenesis and can contribute to bone resorption at hypoxic sites such as bone marrow and the synovium of rheumatoid arthritis (RA) patients. We previously identified that hypoxia enhances osteoclast formation by suppressing COMMD1, a negative regulator of osteoclastogenesis. However, the mechanism which hypoxia increases osteoclastogenesis is complicated and remains unclear. In this study, we used transcriptomic and bioinformatics approaches to discover a positive regulator important for osteoclastogenesis under hypoxia conditions. We treated human osteoclast precursors (OCPs) with RANKL in either normaxia or hypoxia (2% of O2) conditions. RNA sequencing analysis identified that MEF2 family members are significantly enriched in the RANKL-inducible and hypoxia-enhanced genes, in addition to HIF family proteins. In human CD14+ cells,

MEF2C gene silencing using siRNA dramatically suppressed osteoclast formation in hypoxia conditions and inhibited osteoclast marker genes such as NFATC1, CTSK and ITGB3. Consistently, the gain-of function approach using adenovirus encoding human MEF2C enhances osteoclastogenesis in normaxia and phenocopied hypoxia mediated enhancement of osteoclastogenesis. We found that c-FOS is a downstream mediator of MEF2C and c-FOS target genes are significantly enriched in MEF2C-regulated genes. RANKL-induced c-FOS expression is correlated with MEF2C expression in human osteoclasts. To further investigate the function of MEF2C in vivo, we deleted Mef2c in mice using Mx-cre inducible system and evaluated the bone phenotype. MEF2c deficient mice revealed increased bone mass. Mef2c-deleted bone marrow-derived macrophages showed inhibition of osteoclast formation with low expression of c-FOS. These findings identify MEF2C as a positive regulator of osteoclastogenesis in physiological and pathological conditions. Taken together, MEF2C positively regulates osteoclastogenesis and works by enhancing c-FOS expression that is important for osteoclastogenesis. Our results provide insight into mechanisms by which hypoxia promotes osteoclastogenesis by enhancing a positive regulator MEF2C as well as suppressing a negative regulator COMMD1.

Osteoporosis and dementia common pathways and targets: Investigating the effect of acetylcholine esterase inhibitors on bone. A Mouse Model. Charles Inderjeeth*[1], Dian Teguh[2], Warren Raymond[1], Jennifer Tickner[2], Jiake Xu[2]. [1]Sir Charles Gairdner Hospital and University of WA, Australia, [2]University of WA, Australia

Purpose: Previous research has shown that low bone mass density (BMD) appears to be related to increased risk of Alzheimer's disease. A recent study by Tamimi and colleagues in 2012 suggests cholinesterase inhibitors to treat dementia may reduce fracture risk. We previously reported that in vitro cholinesterase inhibitor Donepezil reduces osteoclast activity. We aimed to establish the therapeutic effects of Donepezil, on bone loss in ovariectomised (OVX) mouse model.Methods: In healthy mice we compared sham OVX (4) and OVX (4) against low (4) and high dose (5) Donepezil. MicroCT scanning was utilised to assess femur and Tibia bone quality parameters including BV/TV, TbSp, TbTh, TbN, cortical bone area, cortical thickness and marrow area.Results: At both femur and tibia as expected OVX mice showed deterioration in most parameters compared to sham. Donepezil treated mice showed trend to maintenance or improvement in these parameters. This was not dose dependent. As an example BV/TV changes are illustrated in Figure 1.Conclusions: Osteoporosis and dementia may share some common pathogenesis and potential therapeutic targetsAcknowledgements: Dr Shangfu Li;Grant: RAC Grant #2015-16_047

Ion-doped hydroxyapatite nanoparticles designed for bone regeneration affect osteoclastogenesis in vitro Carina Kampleitner*[1], Montserrat Espanol[2], Maria-Pau Ginebra[2], Michelle Epstein[3], Oskar Hoffmann[1]. [1]Dept. Pharmacology and Toxicology, University of Vienna, Austria, [2]Universitat Politècnica de Catalunya, Spain, [3]Dept. Dermatology, Medical University of Vienna, Austria

Nanosized hydroxyapatite (HA), chemically similar to the mineral phase of hard tissue, is a promising biomaterial for the treatment of large bone lesions. A novel strategy to enhance its osteoconductive and osteoinductive properties is ionic substitution (doping) into the HA nanocrystal structure. Locally applied, HA nanoparticles (NPs) can interact with bone cells and modulate cell behavior. However, HA-NP features as size, composition, morphology, surface charge and dose can differently affect bone cell responses and finally treatment outcomes. We sought to investigate the effect of non-doped and ion-doped HA-NPs for

bone tissue engineering on bone cell viability and osteoclast (OC) development and activity in vitro. Four recently developed HA-NPs formulations were evaluated: 1) non-doped HA (HA), 2) carbonate-doped HA (10 wt%, cHA), 3) strontium-doped HA (6 wt%, srHA) and 4) silicon-doped HA (2 wt%, siHA). To determine the cytocompatibility of HA-, cHA-, srHA-, and siHA-NPs, primary mouse osteoblasts (OBs) and OBs co-cultured with mouse bone marrow-derived OC precursors were incubated with NPs (250 µg/ml) for 24 hours and tested in WST-1 cell viability assays. We observed that non-doped and ion-doped HA-NPs were well tolerated at the concentrations tested without evidence of adverse or cytotoxic effects due to ionic substitution. To assess OC development and activity, we used a mouse OB-OC co-culture and added NPs at 50, 100 and 250 µg/ml. After 6 days, multinucleated OCs were stained for tartrate-resistant acid phosphatase, quantified by counting, and cathepsin K, a marker for OC activity, was measured. We found that non-doped and ion-doped NPs dose-dependently (250 > 100 > 50 µg/ml) reduced OC differentiation and activity in a similar manner. The different HA-NPs decreased RANKL levels in cell lysates, whereas RANKL added to NPs-treated co-cultures was able to stimulate OC development suggesting that OB-mediated OC development might be impaired. In summary, these data show that NPs can modulate OC differentiation and behavior, which might affect bone metabolism, and indicate more in-depth investigations on the mechanisms involved. Although HA-NPs are potential candidates for bone regeneration, pre-clinical in vitro evaluation of novel NPs elucidating effects on cells within the bone microenvironment should be considered before their clinical use.

Estrogen-Related Receptor Gamma Negatively Regulates Osteoclastogenesis and Protects Against Inflammatory Bone Loss Hyun-Ju Kim*, Hye-Jin Yoon, Woo Youl Kang, Sook Jin Seong, Young-Ran Yoon. Kyungpook National University, Republic of Korea

Estrogen-related receptor gamma (ERR-gamma) is an orphan nuclear receptor that plays an important role in various metabolic processes under physiological and pathophysiological conditions. Here, we report that ERR-gamma functions as a negative regulator in RANKL-induced osteoclast differentiation. We observed that ERR-gamma was strongly expressed in osteoclast precursors, bone marrow-derived macrophages (BMMs) while its expression was significantly reduced by RANKL during osteoclastogenesis. Overexpression of ERR-gamma in BMMs suppressed the formation of multinucleated osteoclasts and attenuated the induction of c-Fos and NFATc1, which are critical modulators in osteoclastogenesis. Similarly, the treatment of ERR-gamma agonists, DY131 or GSK4716, also inhibited osteoclast generation and the expression of these key modulators. On the other hand, shRNA-mediated knockdown of ERR-gamma accelerated the formation of bone resorbing cells and the expression of osteoclastogenic markers. Forced expression of ERR-gamma blocked RANKL-stimulated phosphorylation of the NF-κB inhibitor IκBa and suppressed NF-κB transcriptional activity induced by RANKL or the NF-κB subunit p65. Furthermore, by employing a pharmacological approach, we showed that the ERR-gamma agonist DY131 protected against inflammatory bone loss induced by lipopolysaccharide in vivo. Together, our findings reveal that ERR-gamma is a pivotal regulator in RANKL-mediated osteoclastogenesis and suggest that ERR-gamma may have potential as a therapeutic target for pathological bone loss.

G Protein-Coupled Receptor 120 Signaling Inhibited Osteoclast Formation and Bone Resorption Akiko Kishikawa*[1], Keisuke Kimura[1], Masahiko Ishida[1], Kazuhiro Shima[1], Saika Ogawa[1], Jiawei Qi[1], Wei-Ren Shen[2], Fumitoshi Ohori[1], Takahiro Noguchi[1], Aseel Marahleh[1], Hideki Kitaura[1]. [1]Division of Orthodontics and Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan, [2]Division of Orthodontics and Dentofacial Orthopedics, Tohoku University Graduate School of Dentistry, 4-1 Seiryo-machi, Aoba-ku, Sendai 980-8575, Japan

In recent years, obesity has been regarded as one of lifestyle-related diseases. Recent studies have shown that when a high fat diet is given to mice deficient in G-protein coupled receptor 120 (GPR 120), obesity was occurred. GPR120 can be activated by free fatty acids. Therefore, GPR120 was found to be related to obesity. Also, it was newly discovered that osteoclast formation is suppressed by signaling from GPR120. In this study, we investigated the effects of docosahexaenoic acid (DHA), which is one of the free fatty acids and agonist of GPR120, on LPS-induced osteoclast formation and bone resorption. LPS with or without DHA was administered to mouse calvariae by daily subcutaneous injection for 5 days. After sacrifice, the number of osteoclasts, the area of bone resorption, and the level of C-terminal telopeptide fragments of type I collagen cross-links (CTX) were significantly decreased in LPS and DHA co-administrated mice compared to LPS alone administrated mice. Furthermore, the effect was eliminated by administering of AH7614 which is inhibitor of GPR120. In vitro experiment, bone marrow macrophages were cultured in a medium containing M-CSF and RANKL or TNF-α with or without DHA. The results showed direct inhibitory effects of DHA on RANKL-induced osteoclast formation and TNF-α-induced osteoclast formation. Expression levels of both RANKL and TNF-α mRNA were also reduced

in the DHA and LPS co-administrated group than LPS administrated group in vivo. These results suggest that DHA inhibits LPS-induced osteoclast formation and bone resorption in vivo by decreased LPS-induced osteoclast related cytokines TNF-α and RANKL production and directly inhibits osteoclast formation via GPR120 stimulation.

SUN-0624

Local Regulator Del1 Inhibits Bone-resorption via Suppression of Wnt5a-Ror2 Signaling Axis Tomoki Maekawa*[1], Yasuhiro Kobayashi[2], Hisanori Domon[1], Hikaru Tamura[1], Takumi Hiyoshi[1], Takeyasu Maeda[1], Yutaka Terao[1], George Hajishengallis[3]. [1]Niigata University, Japan, [2]Matsumoto Dental University, Japan, [3]University of Pennsylvania, United States

Objectives: The endothelial cell-secreted protein Del1 works homeostatically to regulate neutrophil transmigration and local inflammation. Our preliminary studies suggest that Del1 also regulates osteoclasts via Wnt5a-Ror2 axis. Therefore, the multifunctional Del1 can potentially act as a gatekeeper of inflammation and may be a candidate therapeutic target. The overall objective is to investigate how Del1 expression is regulated at the molecular signaling level, define novel Del1 functions, and identify key functional sites within the Wnt5a-Ror2 signaling that could be exploited as anti-inflammatory drugs. Methods: The expression of osteoclast-related molecules was examined in bone marrow cell cultures from Del1-KO and Ror2-KO mice using immunoblotting and qPCR. To determine interactions between Del1 and Wnt5a-Ror2 axis, all recombinant (r) proteins were subjected to pull-down assay. Binding kinetics and affinity of rDel-1, rWnt5a and rRor2 was calculated by Surface Plasmon Resonance. To evaluate Del1 and Ror2 function, intervention study was performed in periodontitis model in mice. To understand the mechanisms whereby Del1 regulates osteoclastogenesis and test its capacity to block inflammatory bone loss, three adult cynomolgus monkeys were used for local (intragingival) administration of Del1–Fc or Fc control. Therapeutic treatments were performed two times per week, starting 3 days after study initiation. Effect of daily injection of srRor2, Del1 or DHEA in arthritis were evaluated in collagen antibody induced arthritis (CAIA)-Del-1 WT or CAIA-Del-1 KO mice on arthritis scores and microcomputed tomography analysis. Results: Del1 suppressed Wnt5a-Ror2 axis in osteoclast precursors, which, in turn, decreased osteoclast formation and their bone-resorbing activity. Moreover, Del1 competitively antagonize Wnt5a to Ror2. Administration of Del1 in mice inhibits inflammation and bone loss by CAIA mice and periodontitis, suggesting that Del-1 suppresses bone destruction through the inhibition of Wnt5a-Ror2 axis. Conclusions: In the present study, Del1 is suggested to be a functionally versatile molecule which homeostatically regulates critical upstream (inflammatory cell recruitment) and downstream (osteoclastogenesis – suppression of Wnt5a-Ror2 axis) events during inflammatory bone loss.

Fine tuning of calcium oscillations by ITAM receptors regulates RANKL-induced osteoclast differentiation Hiroyuki Okada*[1], Hiroshi Kajiya[2], Jun Hirose[1], Takumi Matsumoto[1], Koji Okabe[2], Takeshi Miyamoto[3], Sakae Tanaka[1]. [1]Department of Orthopaedic Surgery, The University of Tokyo, Japan, [2]Department of Physiological Science and Molecular Biology, Fukuoka Dental College, Japan, [3]Department of Orthopaedic Surgery, Keio University School of Medicine, Japan

[Introduction]Costimulatory signals mediated by ITAM (immunoreceptor tyrosine-based activation motif) receptors play critical roles in RANKL-induced osteoclastogenesis. Although Ca oscillations are considered essential for RANKL-induced osteoclastogenesis downstream of ITAM receptors, accurate monitoring of Ca oscillations in osteoclast precursor cells (OCPs) has been challenging because of the difficulty in detecting oscillation waves in OCPs. Previous studies demonstrated that at least 24 hours of RANKL treatment was necessary to detect oscillation waves in osteoclasts. In the present study, we developed a novel method to analyze the frequency of oscillations in OCPs, and demonstrated that each ITAM receptor regulates different types of Ca oscillations.[Methods]OCPs obtained from mice with four different phenotypes were subjected to experiments: wild type, FcRgamma KO, DAP12 KO, and FcRgamma & DAP12 double KO (ITAMs DKO). To obtain OCPs, adherent bone marrow macrophages cultured on glass cover slips were incubated with M-CSF and RANKL for 24 or 48 hours. Prepared coverslips stained with a fluorescent calcium indicator fura-2 were placed in a chamber of a fluorescent microscope, and ratio of fluorescence emission was measured at an interval of approximately two seconds. Software R version 3.4.3 was used for statistical analysis.[Results]We detected two distinguished types of Ca oscillations, oscillations in high frequency range (HFR) and low frequency range (LFR), at early stages of osteoclast differentiation. In wild type and FcRgamma KO-derived OCPs, HFR oscillations appeared after 48 hours of RANKL stimulation, while HFR oscillations were detected by 24 hours with RANKL stimulation, and disappeared after 48 hours in DAP12 KO-derived cells. Interestingly, HFR oscillations were observed in OCPs from ITAMs DKO mice even before RANKL stimulation, and the HFR oscillations continued after RANKL stimulation. In contrast, LFR oscillations were detected in DAP12 KO and ITAMs DKO OCPs but not in wild type or FcRgamma KO OCPs.[Discussion]Previous studies have demonstrated the critical role of ITAM receptor-mediated Ca oscillations in

osteoclast differentiation although the exact role remains elusive. In the present study, we found that 2 different types of Ca oscillations, HFR and LFR oscillations, were induced by RANKL in OCPs. Using ITAM receptor-deficient cells, we found that the induction of HFR and LFR oscillations was different depending on the types of ITAM receptor deficiency. These results, in combination with the observation that osteoclast differentiation was defective in DAP12 KO and ITAMs DKO OCPs, indicate a distinguished and crucial role of two types of RANKL-induced Ca oscillations in osteoclast differentiation, and the fine tuning of Ca oscillations is necessary for RANKL-induced osteoclast differentiation.

Molecular and cellular analyses of BMP-dependent coupling signals between osteoclasts and osteoblasts during bone remodeling Maiko Omi*[1], Ce Shi[2], Yuji Mishina[1]. [1]Department of Biologic and Materials Sciences, University of Michigan, School of Dentistry, United States, [2]Department of Oral Pathology, School and Hospital of Stomatology, Jilin University, China

The balance between bone formation and bone resorption is regulated by a cellular mechanism called coupling that includes communication from osteoclasts (OCs) to osteoblasts (OBs) in a direct or an indirect manner. We previously reported that osteoclast (OC)-specific disruption of Bmpr1a using a cathepsin K-Cre mouse line (Ctsk-Cre/+; Bmpr1a flox/flox) results in an increase of OB-mediated bone formation. These findings allow us to generate a novel hypothesis that BMPs regulate OB function through altering OC function. We hypothesize that BMP signaling mediated by BMPR1A in OCs regulates OB function through paracrine or direct cell contact mechanisms. To address this hypothesis, we applied conditioned media (CM) from mature OCs into OB cultures to examine if OC-secreting factors affect OB activity. To further elucidate the direct cell-cell contact mechanism, we focus on a new route of cell-cell communication called tunneling nanotubes (TNTs). TNT is a recently recognized distinct type of intercellular communication devise. OC precursors form TNTs in prior to cell–cell fusion, which is an essential process during osteoclastogenesis. We hypothesize that OCs communicate with OBs through TNTs that regulate OB function.We found that (1) OC-secreting factors increased OB mineralization in vitro, and (2) secreted factors from Bmpr1a mutant OCs further increased OB mineralization. These results suggest that BMP signaling mediated by BMPR1A in OCs regulates OB differentiation by paracrine mechanisms. In contrast, (3) OCs inhibited OB differentiation in the direct OC-OB culture system, suggesting that other means of cell-cell communication occur when cells are in physical contact with each other. We found that (4) OCs communicated with OBs via TNTs. Furthermore, (5) Bmpr1a mutant OCs had less ability to form TNTs than controls and (6) the communication from Bmpr1a mutant OCs to OBs was less than that from control OCs. This result suggests that the communication via TNTs is critical for OC-OB coupling and this communication is one of the downstream events of BMP signaling.Overall, our data strongly suggest that secreted factors from OCs enhance OB activity and the direct communication between OCs and OBs negatively regulates OB function. Our data also suggest that loss of BMPR1A-mediated BMP signaling in OCs promotes enhancing activity in secreted fractions and reduces TNT formation that results in reduction of suppressive activity toward OB differentiation.

The Effect of Retention Period and an Anti-c-Fms Antibody On Orthodontic Relapse In a Mouse Model Jiawei Qi*, Keisuke Kimura, Masahiko Ishida , Akiko Kishikawa, Kazuhiro Shima, Saika Ogawa, Wei-Ren Shen, Fumitoshi Ohori, Takahiro Noguchi, Aseel Marahleh, Hideki Kitaura. Division of Orthodontics and Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan

Orthodontic relapse has been a major clinical issue troubled orthodontic dentist and patient. Therefore, it is important to prevent orthodontic relapse. However, the mechanism of relapse is still unknown because there are few reports about relapse in mouse model. Orthodontic force induces osteoclastogenesis in vivo. Macrophage-colony-stimulating factor (M-CSF) is essential factor for osteoclast formation. It has recently been reported that administration of an antibody against the macrophage-colony-stimulating factor (M-CSF) receptor c-Fms inhibited mechanical loading-induced osteoclastogenesis and osteolysis in an orthodontic tooth movement model in mice. This study aimed to establish orthodontic relapse mouse model and examine the effect of an anti-c-Fms antibody on orthodontic relapse in mouse model. The Ni-Ti closed-coil spring was fixed between the upper incisors and the upper-left first molar to move first molar to mesial direction in 10-week-old wild type mice. After 12 days the tension appliance was removed. Mice were randomly divided into without-retention group (R0), retention for keeping space 2-weeks group (R2) and retention for keeping space 4-weeks group (R4). In R2 and R4, light-cured resin was put into the space between first and second molar and solidified through LED light to keep the moved space for 2 or 4 weeks. After 2 or 4 weeks the resin was removed, then the relapse check was started in R2 and R4 for 15 days. R4 group showed the smallest relapse distance in all groups. Only R4 group showed bone resorption by osteoclast. Therefore, we decided R4 group is a suitable model for our experiment. We injected anti-c-Fms antibody into a local site during relapse after 4 weeks retention. The anti-c-Fms antibody inhibited orthodontic relapse. The

findings suggested that M-CSF and/or its receptor are potential therapeutic targets in orthodontic relapse, and that injection of an anti-c-Fms antibody might be useful for inhibition of orthodontic relapse.

DPP-4 Inhibitor Inhibits LPS-induced Osteoclast Formation and Bone Resorption In Vivo Through Downregulating TNF-α Expression of Macrophages Wei-Ren Shen*, Masahiko Ishida, Keisuke Kimura, Akiko Kishikawa, Kazuhiro Shima, Saika Ogawa, Jiawei Qi, Fumitoshi Ohori, Takahiro Noguchi, Aseel Marahleh, Hideki Kitaura. Division of Orthodontics and Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan

Recently, patients with metabolic syndrome have increased as a result of the global trends in population aging. Diabetes is one of the major diseases developed from metabolic syndrome. Dipeptidyl peptidase 4 (DPP-4) inhibition is a new therapeutic strategy for type 2 diabetic patients. DPP-4 has been reported to enhance inflammation. However, the effect of DPP-4 inhibition on inflammation remains unknown. Lipopolysaccharide (LPS) is a strong inducer of inflammation and osteoclast formation. To investigate in vivo effects of DPP-4 inhibition on LPS-induced osteoclast formation and bone resorption, LPS with or without a DPP-4 inhibitor was subcutaneously injected into mouse calvaria for 5 days. Osteoclast number and bone resorption were significantly lower in mice underwent LPS and DPP-4 inhibitor co-administration than that of LPS administration alone. Moreover, RANKL and TNF-α expression also reduced in the LPS and DPP-4 inhibitor co-administration group. In vitro, there were no direct effects of DPP-4 inhibitor or DPP-4 on RANKL- and TNF-α-induced osteoclast formation, or LPS-induced RANKL expression in stromal cells. Nevertheless, macrophages from LPS and DPP-4 inhibitor co-administrated mice exhibited lower TNF-α mRNA expression than macrophages from LPS-only mice. However, TNF-α mRNA expression was not reduced in LPS and DPP-4 inhibitor co-treated macrophages in vitro, compared with macrophages treated with LPS alone. These results indicate that DPP-4 inhibition may inhibit LPS-induced osteoclast formation and bone resorption in vivo by down-regulating LPS-induced TNF-α production by macrophages.

Deletion of the gene encoding Nupr1/p8, a regulator of autophagy, attenuates osteoclastogenesis but increases trabecular bone mass by enhancing osteoblast differentiation Makoto Shiraki*[1], Hirohito Hirata[2], Asana Kamohara[2], Juan Iovanna[3], Toshio Kukita[4], Masaaki Mawatari[1], Akiko Kukita[2]. [1]Department of Orthopaedic Surgery, Faculty of Medicine, Saga University, Japan, [2]Department of Pathology and Microbiology, Faculty of Medicine, Saga University, Japan, [3]Centerb de Recherche en Cancérologie de Marseille, INSERM U1068, France, [4]Department of Molecular Cell Biology & Oral Anatomy, Faculty of Dentistry, Kyushu University, Japan

Backgrounds: Nuclear protein1 (Nupr1)/p8 is a nuclear protein induced by multiple stress stimuli, that is involved in tumor progression and pathological conditions by regulating cell growth, apoptosis and autophagy. However, its normal function remains poorly understood. We have shown that Nupr1 regulate autophagy and apoptosis of osteoclast (OC) under serum-starved condition. Recent reports show that autophagy has an important role in long-lived cells such as osteoblasts (OB) and osteocytes in bone. Herein, we analyzed role of Nupr1 in bone homeostasis using Nupr1 KO mice.Methods and Results: MicroCT analysis revealed that trabecular bone volume and trabecular number were significantly increased in the femur of Nupr1 KO mice compared to wild-type (WT). Bone histomorphometry of trabecular bone indicated that the number of OC and preosteoclasts (pOC), and eroded surface were decreased in Nupr1 KO mice. In contrast, the number of OB and mineral apposition rate were increased to about 2-fold in Nupr1 KO mice. Using calvarial primary OB, expression of OB-related genes and bone formation were assessed. Alizalin red staining of primary OB showed calcification was enhanced in Nupr1 KO mice. The mRNA levels of osteocalcin, type I collagen, Runx2 and Osterix were also upregulated in specifically early phase of OB differentiation in Nupr1 KO. Interestingly, SOST mRNA expression was significantly reduced in Nupr1 KO. Expression analysis of autophagy-related genes, Foxo3 and Bnip3 which are targets of Nupr1 and Western analysis of LC3, p62 and ATG5 indicated that autophagy is upregulated in OB of Nupr1 KO. Defect of autophagy in osteoblasts is known to cause bone loss and increase the number of empty lacunae which is an indicator of osteocyte death. Analysis of osteocytes showed the number of empty lacunae was reduced in Nupr1 KO mice. We analyzed OC differentiation from bone marrow macrophages in more detail. The data showed that expression of OC-specific genes were reduced in Nupr1 KO mice. In addition, FACS analysis showed surface expression of RANK was decreased in bone marrow macrophage of Nupr1 KO mice, suggesting Nupr1 KO has defect in pOC.Conclusion: In summary, our data show inhibition of Nupr1 increase bone mass by enhancing differentiation and autophagy of OB but attenuating early OC differentiation. Nupr1 could be a new drug target to increase bone mass.

Carbon Monoxide Releasing Molecule 3 Inhibits Osteoclastogenic Differentiation of RAW264.7 Cells by Heme Oxygenase 1 Hui Song*, Fenghe Zhang. School of Dentistry Shandong University, China

Increased osteoclastogenic differentiation may disrupt the balance of bone resorption and formation, giving rise to bone defective disease. The study aimed to investigate the influence of carbon monoxide releasing molecule 3 on osteoclastogenic differentiation of RAW264.7 cells, and explore the possible mechanism underlying the regulatory effect.Influence of CORM-3 on the proliferation of RAW264.7 cells was determined by CCK-8 assay. RAW264.7 cells were divided into four groups: Control group; Osteoclastogenic differentiation group, in which cells were induced osteoclastogenic differentiation in medium supplemented with 100μg/L RANKL and 50μg/L M-CSF; Degassed CORM-3-osteoclastogenic differentiation group, in which cells were pretreated with 200μmol/L degassed CORM-3 for 6hrs, and then induced osteoclastogenic differentiation; CORM-3-osteoclastogenic differentiation group, in which cells were pretreated with 200μmol/L CORM-3, and then induced osteoclastogenic differentiation. The mRNA and protein expression of RANK, TRAP, MMP-9, Cathepsin K and HO-1 of the cells during the osteoclastogenic differentiation was checked by RT-qPCR and Western blot. The induced osteoclasts were identified by TRAP staining. The HO-1 expression of the RAW264.7 cells was silenced by lentivirus transfection, and the expression of RANK, TRAP, MMP-9 and Cathepsin K was examined by RT-qPCR and Western blot.CORM-3 promoted the proliferation of RAW264.7 cells at the concentration of 200μmol/L. Pretreatment with CORM-3, but not degassed CORM-3, significantly decreased the mRNA and protein expression of osteoclast-specific marker TRAP, RANK, MMP-9 and Cathepsin K induced by RANKL and M-CSF on day 5, 7 and 9 during the osteoclastogenic differentiation (P<0.05). After HO-1 was silenced by lentivirus transfection, the mRNA and protein expression of TRAP, RANK, MMP-9 and Cathepsin K in group with CORM-3 pretreatment maintained the same level as in osteoclastogenic differentiation group.CORM-3 inhibits osteoclastogenic differentiation of RAW264.7 cells via releasing CO. The inhibitory effect is mediated partially by HO-1 pathway. The results suggest the potential application of CORM-3 on some bone defective diseases.

The Role of G alpha 12 In Osteoclast Min-Kyoung Song*, Hong-Hee Kim. Department of Cell and Developmental Biology, BK21 Program and Dental Research Institute, Seoul National University, Republic of Korea

The G12 family of G protein alpha subunits has been shown to participate in the regulation of various physiological processes. However, the role of Gα12 in bone physiology has not been well described. Here, by micro-CT analysis, we discovered that Gα12-knockout mice have an osteopetrotic phenotype. Histological examination showed lower osteoclast number in femoral tissue of Gα12-knockout mice compared to wild-type mice. Additionally, in vitro osteoclastic differentiation of precursor cells with receptor activator of nuclear factor-κB ligand (RANKL) showed that Gα12 deficiency decreased the number of osteoclast generated and the bone resorption activity. The induction of nuclear factor of activated T-cell c1 (NFATc1), the key transcription factor of osteoclastogenesis, and the activation of RhoA by RANKL was also significantly suppressed by Gα12 deficiency. We further found that the RANKL induction of NFATc1 was not dependent on RhoA signaling, while osteoclast precursor migration and bone resorption required RhoA in the Gα12-mediated regulation of osteoclasts. Therefore, Gα12 plays a role in differentiation through NFATc1 and in cell migration and resorption activity through RhoA during osteoclastogenesis

Fusion and Hemagglutinin Proteins of Canine Distemper Virus Support Osteoclast Formation Through NF-κB Dependent and Independent Mechanisms in Paget's disease Wei Wang*, Dongfang Li, Minqi Li. Department of Bone Metabolism, School of Stomatology Shandong University, Shandong Provincial Key Laboratory of Oral Tissue Regeneration, Jinan, China

Paget's disease (PD) features abnormal osteoclasts which sharply increase in number and size and then intensely induce bone resorption. The purpose of this study was to determine the direct effects of canine distemper virus (CDV) and its fusion and hemagglutinin proteins (FH) on receptor activator of nuclear factor kappa-B ligand (RANKL) induced osteoclast formation in vitro. Here, CDV promoted osteoclast formation in RAW 264.7 mouse monocyte cell line and human peripheral blood mononuclear cells, and the effect of FH have been detected on the former by lentiviral vectors. We applied immunofluorescence assay to prove the infectious effects of CDV and FH lentiviral vectors; tartrate-resistant acid phosphatase (TRAP) staining and bone resorption pit formation assay to detect the function of osteoclast; western blot analysis to observe the alteration of osteoclastic transcription factors and the phosphorylation of intracellular signaling pathway transduction proteins; RT-PCR analysis to test the alteration of osteoclastic marker genes and inflammatory cytokine marker genes. As results, immunofluorescence assay provided the first conclusive proof that CDV can infect and replicate in primary human osteoclast precursor cells. Both of CDV and FH significantly promoted osteoclast formation and bone resorption induced by RANKL. Mean-

while high level expression of osteoclastic marker genes and transcription factors confirmed differential regulation of RANKL-induced osteoclastogenesis by CDV and FH stimulation. TRAP, Cathepsin K and matrix metalloproteinase 9 levels mainly depended on nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) activation and interleukin-6 levels principally depended on p38 mitogen-activated protein kinase (MAPK) activation after the same stimulation. Intracellular signaling transduction analysis revealed CDV and FH specifically upregulated the phosphorylation of NF-κB and MAPKs induced by RANKL, respectively. Moreover, without RANKL stimulation, both of CDV and FH slightly induced osteoclast-like cells formation in RAW 264.7 cell line even in the presence of NF-κB inhibitor. Taken together, our findings demonstrated that FH regulate osteoclast differentiation and activity through modulation of NF-κB signaling pathway and induce osteoclast precursor cells merging dependent on the function of protein themselves. These results meant that FH play a pivotal role in CDV supporting osteoclast formation during PD happening.

Mutual restriction between p38/NFATc1 and p38/Pax6 axis during osteoclastogenesis Ziang Xie*, Shunwu Fan. Sir Run Run Shaw Hospital, School of Medicine, Zhejiang University, China

Balance of osteoclast formation is regulated by receptor activator of NF-κB ligand (RANKL) and extracellular negative regulator such as interferon-γ (IFN-γ) and interferon-β (IFN-β) , which can suppress excessive bone destruction. However, poor knowledge is known about intrinsic negative regulatory factors in RANKL-mediated osteoclast differentiation. Recently, paired-box homeodomain transcription factor Pax6 is shown to act as a negative regulator of RANKL-mediated osteoclast differentiation, but the crosstalk related to the other signaling pathway is still unclear. Here, we show a novel p38 inhibitor (VX-745) upregulates the expression of Pax6 during osteoclastogenesis. Subsequently, we found that β-catenin was binded to the proximal region of Pax6 promoter and promotes the transcription of Pax6, which was impaired by VX-745 through enhancing the ubiquitination degradation of β-catenin. These results suggest that Pax6 is positively regulated by p38/β-catenin signaling pathway, which maintains the balance of osteoclast formation with the classical p38/c-Fos/NFATc1 signaling pathway. Our study demonstrates that the p38/β-catenin/Pax6 signaling pathway contributes a new aspect of the negative regulatroy in osteoclastogenesis and the novel p38 inhibitor VX-745 and the blocking of Pax6 might provide additional approaches to treat osteoclast-related diseases.

LRP1 suppresses bone resorption in mice by inhibiting the RANKL-stimulated NFκB and p38 pathways during osteoclastogenesis Di Lu*, Jianshuang Li, Huadie Liu, Gabrielle Foxa, Bart Williams, Tao Yang. Van Andel Research Institute, United States

Single nucleotide polymorphisms in the LRP1 gene coding sequence are associated with low bone mass, and cell culture studies suggest that LRP1 plays a role in osteoblast proliferation and osteoblast-mediated osteoclastogenesis. However, the in vivo function of LRP1 in bone homeostasis has not been explored. In this work, we studied the osteoclast-specific role of LRP1 in bone homeostasis using a Ctsk-Cre;Lrp1f/f mouse model on the C57BL/6J background. These mice had a dramatically decreased trabecular bone mass with markedly more osteoclasts, while the osteoblast activity was unaffected or slightly increased. The cortical bone parameters were largely unaltered. Upon RANKL treatment, Lrp1-deficient bone marrow monocytes more efficiently differentiated into osteoclasts and showed elevated p65 NFkB and p38 signaling. Consistently, Lrp1-overexpressing Raw264.7 cells were desensitized to RANKL-induced p38 and p65 activation and osteoclastogenesis. Moreover, RANKL treatment led to a sharp decrease of LRP1 protein and RNA in BMMs. Overall, our data suggest that osteoclast-expressed LRP1 is a crucial regulator of bone mass. It inhibits the NFkB and p38 pathways and lessens the efficiency of RANKL-induced osteoclastogenesis.

Nuclear Factor of Activated T Cells 2 Is Required for Osteoclast Differentiation and Function in vitro Jungeun Yu*, Stefano Zanotti, Lauren Schilling, Ernesto Canalis. UConn Health, United States

Nuclear factor of activated T cells (NFATc) 2 is important for the immune response and its activation in the osteoclast lineage can compensate for the downregulation of NFATc1 and promote osteoclastogenesis. However, the role of NFATc2 in the osteoclast lineage is uncertain because studies interrogating its function in the skeleton have used mouse models of global Nfatc2 gene inactivation. Nfatc2 null mice have a generalized inflammatory phenotype, limiting their usefulness. To study the direct effect of NFATc2 in osteoclasts, Nfatc2loxP/loxP mice, where the Nfatc2 exon2 is flanked by loxP sequences, were created and mated with mice expressing Cre under the control of the Lyz2 promoter. Nfatc2 mRNA was downregulated by 50-80% in bone marrow-derived macrophages (BMMs) and in in-

tact bones and NFATc2 protein was not detectable in BMMs from Lyz2Cre/WT;Nfatc2Δ/Δ mice by immunoblotting, documenting downregulation of Nfatc2. Cultured BMMs from Lyz2Cre/WT;Nfatc2Δ/Δ mice exhibited a 30% decrease in osteoclast number in comparison to cells from littermate controls. Lyz2Cre/WT;Nfatc2Δ/Δ osteoclasts exhibited a 50% decrease in total bone resorption area. When corrected for osteoclast number, bone resorption area was 30% lower in Lyz2Cre/WT;Nfatc2Δ/Δ than controls, indicating decreased osteoclast resorptive activity. Actin staining of osteoclasts from Lyz2Cre/WT;Nfatc2Δ/Δ mice cultured on bovine bone slices revealed smaller cells with smaller sealing zones than littermate controls. These findings demonstrate that NFATc2 is necessary for optimal osteoclast maturation and function in vitro. Lyz2Cre/WT;Nfatc2Δ/Δ mice did not exhibit an obvious skeletal phenotype in vivo by microcomputed tomography (μCT) at either 1 or 4 months of age when compared to Nfatc2loxP/loxP littermates. Bone histomorphometry confirmed the μCT results, and conditional Lyz2Cre/WT;Nfatc2Δ/Δ mice did not exhibit changes in parameters of bone formation or resorption compared to controls. The absence of an in vivo phenotype is likely because of compensation by NFATc1. In conclusion, NFATc2 is necessary for optimal osteoclast differentiation and function in vitro, but its downregulation in osteoclast precursors does not alter skeletal remodeling in vivo.

Osteocytes Are the Major Source of Circulating FGF23 During Acute Inflammation Guillaume Courbon*[1], Claire Gerber[1], Samantha Neuburg[1], Maralee Capella[1], Xueyan Wang[1], Corey Dussold[1], Lixin Qi[1], Wenhan Chang[2], Myles Wolf[3], Aline Martin[1], Valentin David[1]. [1]Division of Nephrology and Hypertension, Department of Medicine, and Center for Translational Metabolism and Health, Institute for Public Health and Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL, United States, [2]Division of Endocrinology and Metabolism, UCSF, San Francisco, CA, United States, [3]Division of Nephrology and Hypertension, Duke University, Durham, NC, United States

Background: Inflammation is a novel mechanism that stimulates fibroblast growth factor (FGF) 23 production in bone cells and extraosseous tissues, however the contribution of osteocytes to circulating FGF23 levels during acute inflammation is unknown.Methods: To investigate the effects of inflammation on FGF23 production, wild-type (WT) mice and mice with a conditional deletion (cKO) of Fgf23 in osteocytes (Fgf23fl/fl;DMP1-Cre+) received a single injection of interleukin-1β (IL-1β) or saline (Ctr). We measured FGF23 mRNA and circulating intact and total protein (cFGF23 which includes intact and cleaved proteins) up to 6 hours post injection.Results: In WT mice,injection of IL-1β increased circulating levels of intact and total FGF23 (12-fold and 62-fold, respectively, p<0.001 vs Ctr). IL-1β increased Fgf23 mRNA expression by 60 fold in bone, 7 fold in spleen and 300 fold in kidney (p<0.05 vs. Ctr), suggesting that extraosseous production of FGF23 may contribute to circulating FGF23 levels. In line with these findings, cKO-Ctr mice did not show a significant reduction in circulating FGF23 compared to WT-Ctr mice, suggesting that extraosseous FGF23 production is sufficient to maintain relatively normal circulating FGF23 levels. However, cKO mice showed a markedly reduced FGF23 secretion in response to IL-1β injection compared to WT- IL-1β mice for both intact (-80%) and total FGF23 (-92%, p<0.001). Consistent with these data, bone Fgf23 mRNA and protein expression levels were also dramatically reduced by 80% (p<0.01) in cKO- IL-1β mice compared to WT- IL-1β. Finally, IL-1β treatment of primary osteocytes cultures from WT and cKO animals increased Fgf23 mRNA expression and protein secretion by 10 fold in WT mice (p<0.05 vs. Ctr) but failed to increase FGF23 in cKO cultures.Conclusions: These results suggest thatFgf23 expression is increased in bone and extraskeletal tissues during acute inflammation, however osteocytes are the major secretory source for the circulating FGF23 protein.

Sclerostin regulates adipocyte fate and mediates paracrine and endocrine signaling between osteocytes and fat. Jessica H. Nelson*[1], Hannah M. Davis[2], Kevin Mcandrews[2], Meloney D. Cregor[2], William R. Thompson[3], Lilian I. Pltokin[2], Alexander G. Robling[2], Teresita Bellido[2], Jesus Delgado-Calle[1]. [1]Indiana University School of Medicine, Dept. of Medicine, Hematology/Oncology, United States, [2]Indiana University School of Medicine, Dept. of Anatomy and Cell Biology, United States, [3]School of Health and Rehabilitation Sciences, Dept. of Physical Therapy, United States

Osteocyte (Ot)-derived sclerostin (Scl) acts on osteoblastic cells by binding to its chaperone LDL receptor related protein (LRP) 4 and to the Wnt co-receptors LRP5/6 to antagonize Wnt/β-catenin signaling, inhibiting bone formation and stimulating bone resorption. Emerging evidence suggests that Scl also regulates adipose tissue (AT), however conflicting results have been reported. We examined the effects of Scl on AT of the bone marrow (BMAT) and peripheral fat depots using mice with activated β-catenin in Ots (daβcatOt), a mouse model characterized by high bone remodeling with bone gain and elevated Scl expression in bone. daβcatOt mice display a marked increase in BMAT volume, a 3-4 fold increase in BM adipocyte number, and elevated mRNA expression of the adipocyte marker

Fabp4 in bone/BM. In addition, daβcatOt mice exhibit a 3-fold increase in mRNA expression of the brown adipocyte markers Ucp1, Pgc1α, and Zic1, without changes in the white adipocyte markers Cidec, HoxC9, or Tbx1, in bone/BM. daβcatOt mice also show a 3-fold increase in serum Scl, which is accompanied by increased body fat mass, elevated peripheral inguinal white AT (iWAT; 50%), and increased interscapular brown AT mass (BAT; 15%). Similar to the findings in BMAT, mRNA expression of the brown adipocyte markers Pgc1α and Zic1 is also increased by 2-3-fold in iWAT from daβcatOt mice. Remarkably, mice with LRP4 deletion in Ots, another high bone mass model exhibiting high serum Scl, also display increased body-fat mass and elevated BAT mass compared to control mice; although, iWAT mass is decreased. Further, treatment of mesenchymal stem cells (MSCs) with recombinant (r)Scl or conditioned media from daβcatOt bones increased by 15-20% their differentiation into adipocytes, an effect that was fully blocked by an anti-Scl antibody. Moreover, rScl increased the expression of Fapb4 and adiponectin and the brown adipocyte marker Ucp1 in MSCs undergoing adipogenic differentiation; and also increased Ucp1 expression when added to MSCs fully differentiated into mature adipocytes. Thus, Scl stimulates adipogenesis in the BM and in both white/brown peripheral fat depots, regulates MSC differentiation, and alters adipocyte fate favoring brown versus white adipocyte identity. These findings demonstrate paracrine and endocrine signaling between Ot-derived Scl and adipocytes, and reveal a novel paradigm of high adipocyte number together with high osteoblast number and elevated bone formation.

Connexin 43 Hemichannels Protect Bone Loss during Estrogen Deficiency Rui Hua*[1], Liang Ma[1], Hongyun Cheng[1], Roberto Fajardo[2], Joseph Pearson[3], Teja Guda[3], Daniel Shropshire[1], Sumin Gu[1], Jean X. Jiang[1]. [1]Department of Biochemistry, UT Health San Antonio, United States, [2]Department of Orthopaedics, UT Health San Antonio, United States, [3]Department of Biomechanical Engineering, University of Texas at San Antonio, United States

Estrogen deficiency in post-menopausal women is a major cause of bone loss resulting in osteopenia, osteoporosis and a high risk for bone fracture. Connexin 43 (Cx43) forms gap junctions that mediate osteocyte coupling and are critical for maintaining proper bone physiology. Hemichannels (HCs), unpaired gap junction channels, are extensively involved in the communication between osteocytes and their extracellular environment, and play important roles in osteocyte viability and bone remodeling. Here we show that estrogen deficiency reduced Cx43 expression and Cx43 hemichannel activity in vitro. To determine if functional HCs protect osteocytes and bone loss during estrogen deficiency in vivo, we adopted an ovariectomy (OVX) model in wild type (WT) and two transgenic Cx43 mice: R76W (dominant-negative mutant affecting only gap junction channels) and Cx43 Δ130-136 (dominant-negative mutant compromising both gap junction channels and HCs). The bone mineral density (BMD), bone structure and histomorphometric changes of cortical and trabecular bones after OVX were investigated. Our results showed that the extent of bone loss in trabecular and cortical bones in R76W was similar to those in WT control mice. However, the Δ130-136 transgenic cohort had a greater decrease in trabecular bone than WT and R76W mice, associated with a significant increase in numbers of apoptotic osteocyte and empty lacunae. Interestingly, osteoclast surfaces in trabecular and cortical bones were increased after OVX in the WT and R76W but not in Δ130-136 mice. Furthermore, biomechanical properties were analyzed using three-point bending flexural evaluation of the femurs. OVX significantly reduced bone stiffness in Δ130-136 mice while no significant changes were observed in WT and R76W groups, and there was a significant decrease shown in the percentage of yield force change between the Δ130-136 and R76W groups. Additionally, ablation of HCs may render osteocytes more vulnerable to oxidative stress, indicated by the increased 4-hydroxynoneanal (4-HNE) positive osteocytes, which is a biomarker for lipid peroxidation. Taken together, given the functional differences of R76W and Δ130-136 on gap junctions and gap junctions/HCs, respectively, these data demonstrate that impairment of Cx43 HCs in osteocytes accelerates bone loss and increases osteocyte apoptosis after OVX, and further suggest that Cx43 HCs in osteocytes protect bone fragility against catabolic effects due to estrogen deficiency.

Mechanical Regulation of Breast Cancer Bone Metastasis via Osteocytes' Signaling to Endothelial Cells Yu-Heng Vivian Ma*, Liangchen Xu, Xueting Mei, Lidan You. University of Toronto, Canada

Introduction: Bone metastases occur in 65-75% of patients with advanced breast cancer and significantly increase their morbidity and mortality. Bone mechanical loading during exercise, commonly suggested for patients, stimulate osteocytes, the major cell population in the bone. We previously showed that mechanically stimulated osteocytes affect breast cancer cell apoptosis and migration both directly and indirectly through osteoclasts and endothelial cells. Since endothelial cells respond to osteocyte signaling and exist in large number and close proximity to metastasizing cells in blood vessels, we hypothesize that their response to mechanically stimulated osteocytes affect breast cancer cell activity during bone metastasis.Methods: To simulate the mechanical stimulation osteocytes experience physiologically, MLO-Y4 osteocyte-like cells (gift of Dr. Bonewald, Indiana University) were placed in flow chambers and subjected to oscillatory fluid flow (OFF; 1Pa; 1Hz; 2 hours).

Controls were MLO-Y4 cells not placed in flow chambers. Human umbilical vein endothelial cells (HUVECs; gift of Dr. Young, University of Toronto) were conditioned in medium extracted (conditioned medium; CM) from MLO-Y4 cells. The strength of MDA-MB-231 breast cancer cells' adhesion to HUVECs was tested by applying 30 minutes of OFF (1Pa; 1Hz) after 30 minutes of adhesion. Gene expression of MDA-MB-231/1833 bone-metastatic breast cancer cells (gift of Dr. Seth, University of Toronto) conditioned in HUVEC CM was determined with qPCR.Results: CM from OFF-stimulated MLO-Y4 cells reduces the adhesion of MDA-MB-231 cells (by 18%) to HUVECs by lowering HUVECs' expression of ICAM-1 (intercellular adhesion molecule 1) (Fig. A). This aligns with our previous result demonstrating MDA-MB-231 cells' lower extravasation towards CM from OFF-stimulated MLO-Y4 cells. Furthermore, CM from HUVECs conditioned in CM form OFF-stimulated MLO-Y4 cells lowered the expression of MMP-9 (matrix metallopeptidase 9; important for cancer cells to degrade matrix during invasion into the bone) by MDA-MB-231/1833 cells (by 54%) (Fig. B).Conclusion: We demonstrated that endothelial-mediated signaling from mechanically stimulated osteocytes reduced the ability of breast cancer cells to adhere to endothelial cells and degrade the bone (Fig. C). This provides insights into the impact of exercise on bone metastases, and will assist in designing exercise or bone loading regimens that lower the risk for bone metastases.

Stretch-stimulus activates the mechano-signaling via opening of the mechano-sensitive channel, Piezo1 and the subsequent calcium influx in osteocyte-like cells. Takuya Notomi*[1], Akiko Hiyama[1], Tadashige Nozaki[1], Masaki Noda[2]. [1]Osaka Dental University, Japan, [2]Yokohama City Minato Red Cross Hospital, Japan

The bone mechano-signaling is related to membrane-bound molecules and the subsequent intracellular signaling. We have focused on one of membrane proteins, Piezo channels (Piezo) and investigated their role on mechano-signaling in bone cells. The Piezo are mechano-sensitive cation channel and two subtypes (Piezo1, Piezo2) are reported. The expression of mRNA levels of Piezo1 was abundant and Piezo2 was background levels in osteocyte-like cells (MLO-Y4) and calvariae primary osteoblasts. The phosphorylated ERK/total ERK (ERK ratio) was quantified as the indicator for activation of mechano-signaling. The ERK ratio was increased at 10min after application of stretch-stimulus but this increment was decreased by the addition of Piezo inhibitor. Addition of Piezo agonist increased the ERK ratio without stretch-stimulus. Next, we generated Piezo1-deficient MLO-Y4 (Piezo1-KO) by CSIPR/CAS9. The stretch-stimulus increased the ERK ratio in Piezo1-wild type (Piezo1-WT) but not in Piezo1-KO cells. To investigate intracellular mechano-signaling, intracellular Ca2+ levels were measured. The cells which exhibit Ca2+ oscillation in response to stretch-stimulus were identified as Ca2+ oscillation-positive cells. The stretch-stimulus occurred the Ca2+ oscillation in Piezo1-WT cells, but the number of Ca2+ oscillation-positive cells were decreased with Piezo channel inhibitor. In Piezo1-KO cells, the number of Ca2+ oscillation-positive cells were decreased in comparison to Piezo1-WT cells. The generation of Ca2+ oscillation was diminished by exclusion of extracellular Ca2+. These results suggested that the stretch-stimulus induced Ca2+ oscillation via activation of Piezo1 and the subsequent Ca2+ inflow. Then the relationships between voltage-gated Ca2+ channel (VGCC) and Piezo were investigated. We focused on L-type VGCC which is highly expressed in osteocyte and osteoblasts. Addition of inhibitors for L-type VGCC decreased the number of Ca2+ oscillation-positive cells while inhibition of both L-type VGCC and Piezo further decreased the number of Ca2+ oscillation-positive cells. In addition, the Piezo agonists-induced Ca2+ oscillation was decreased by addition of L-type VGCC inhibitors. These

results indicate that Piezo1 channel activates mechano-signaling via intracellular Ca2+ pathway. Our findings suggest that the mechano-channels and the related membrane molecules might give the cue for elucidating bone mechano-signaling.

Nfat Transcription Factors are Key Regulators of Osteocyte Function Independent of c-fos Matt Prideaux*, Lynda Bonewald. Indiana University, United States

We have previously shown that during lactation, osteocytes remove mineral from their perilacunar matrix. This is mediated through the receptor PTH1R in response to PTHrP, which is elevated during lactation. Genes normally associated with osteoclasts, such as At-p6v0d2, Ctsk, Acp5/Trap and Mmp13 were also increased in osteocytes with lactation. As Nfatc1 is a transcription factor known to regulate the differentiation and activity of osteoclasts, we sought to determine if it plays a role in osteocyte perilacunar remodeling. We utilized the MLO-Y4 osteocyte-like and the IDG-SW3 mature osteocyte-like cell lines. MLO-Y4 cells were treated with 40μM INCA6, an inhibitor of Nfat/calcineurin activity, for 72 hrs and the expression of key osteocyte genes examined by qRT-PCR. INCA6 decreased the expression of Atp6v0d2 by 53% (p<0.01), Rankl by 50% (p<0.001) and Acp5/Trap by 30% (p<0.05). Treatment of differentiated, mature IDG-SW3 cells with INCA6 downregulated Sost (44%, p<0.05), Rankl (57%, p<0.001) and Mepe (57%, p<0.01) and upregulated the mineralization-associated genes Dmp1 (95%, p<0.001) and Ocn (58%, p<0.01). To determine whether Nfats play a role in PTHrP signaling, mature IDG-SW3 cells were treated with 100nM PTHrP in the presence or absence of INCA6 for 72 hrs. The expression of Nfatc1 was increased by PTHrP treatment (3-fold, p<0.001). Atp6v0d2 mRNA expression was increased by PTHrP (15-fold, p<0.001), which was attenuated 46% (p<0.01) by co-incubation with INCA6. Rankl was strongly induced by PTHrP (35-fold, p<0.001) and attenuated 55% (p<0.01) by INCA6. INCA6 also decreased Mmp13 (30%, p<0.001) and Car2 (46%, p<0.01) mRNA expression. As Nfatc1 activity in osteoclasts is downstream of c-fos, we next investigated the effects of blocking c-fos in osteocytes using the inhibitor T-5224. T-5224 did not block the PTHrP-induced increase in Atp6v0d2 and Rankl in IDG-SW3 cells. Furthermore, T-5224 failed to decrease Sost expression, suggesting that in osteocytes Nfat activity is independent of c-fos. Together, these results suggest that Nfats may be essential regulators of bone remodeling by targeting genes such as Sost and Rankl in osteocytes. Furthermore, Nfats may function in a similar manner in osteocytes as in osteoclasts, by inducing factors that promote resorption such as Atp6v0d2. Ongoing studies targeting deletion of Nfatc1 in osteocytes in vivo, will further elucidate the role of Nfat activity in osteocyte perilacunar remodeling and bone homeostasis.

PINCH regulates bone homeostasis through its expression in osteocytes Yishu Wang*[1], Qinnan Yan[1], Yiran Zhao[1], Yiming Lei[1], Liting Ma[1], Simin Lin[1], Yumei Lai[2], Huiling Cao[1], Chuanyue Wu[1], Guozhi Xiao[1]. [1]Department of Biology and Guangdong Provincial Key Laboratory of Cell Microenvironment and Disease Research, Southern University of Science and Technology, China, [2]Department of Orthopedic Surgery, Rush University Medical Center, United States

Pinch is a LIM-domain-only adaptor that plays an important role in integrin activation and extracellular matrix adhesion and migration. Mammalian cells have two functional Pinch proteins, Pinch1 and Pinch2. To investigate the role of Pinch in bone, we deleted Pinch1 expression selectively in osteocytes by the Dmp1-Cre transgene and Pinch2 globally in mice (Pinch1f/f; Dmp1-Cre; Pinch2-/- mice, referred to as P1D1/P2KO hereafter). P1D1/P2KO mice displayed a severe osteopenic phenotype. Both trabecular and cortical bone parameters such as the bone volume fraction (BV/TV), trabecular number (Tb.N), cortical thickness (Cort.Th) and bone mineral density (BMD) were dramatically reduced and trabecular separation (Tb.Sp) was increased in P1D1/P2KO mice compared to age- and sex-matched control littermates. Results from calcein double labelling experiments revealed significant reductions in mineralization apposition rate (MAR), mineralizing surface per bone surface (MS/BS), and bone formation rate (BFR) in the femoral metaphyseal cancellous bones in P1D1/P2KO mice compared control littermates. In contrast, osteoclast formation and bone resorption were not altered in P1D1/P2KO relative to control littermates. Interestingly, neither osteocyte-specific Pinch1 knockout nor global Pinch2 knockout mice displayed any marked bone phenotypes, suggesting a functional redundancy between the two Pinch proteins in control of bone mass. In vitro studies revealed that the osteoblast differentiation was severely impaired in primary bone marrow stromal cultures from P1D1/P2KO mice. These results demonstrate a critical new role for Pinch proteins through its expression in osteocytes in regulation of bone homeostasis.

Validated analyses of osteocyte-mediated bone remodeling using in vivo and in vitro methods Cristal S. Yee*, Tamara Alliston. UCSF, United States

Perilacunar/canalicular remodeling (PLR) is a dynamic process by which osteocytes resorb and replace local bone extracellular matrix (ECM). During PLR, osteocytes secrete matrix metalloproteases (MMPs) and enzymes like cathepsin K and carbonic anhydrases to resorb organic and mineral components of the perilacunar ECM. PLR maintains systemic mineral homeostasis, lacunocanalicular networks (LCN), and bone quality. As with osteoblasts and osteoclasts, deregulation of osteocyte PLR can be a product or a driver of skeletal disease. Therefore, there is a need to elucidate the regulation and role of PLR in skeletal health. However, the methods to study PLR are rapidly evolving and are not yet used or interpreted consistently. For example, quantification of lacunar size by 3D radiographic detection of perilacunar mineral may yield different outcomes from 2D histomorphometric analysis of demineralized sections. Therefore, standardization and validation of methods to evaluate PLR would improve efforts to understand this cellular process. Ideally, a robust analysis would include qualitative and quantitative in vivo and in vitro outcomes for PLR that are validated, reproducible, simple, and cost-effective. We have streamlined the analysis of PLR by developing and validating in vivo and in vitro outcome measures to investigate the effect of physiologic, pathologic, or pharmacologic interventions on PLR. As MMP13 is a key PLR enzyme, we used an osteocyte specific MMP13 knockout mice (MMP13ocy-/-) that had PLR deficiency and validated in vivo PLR outcomes using a 'gold standard' model of lactation-induced PLR. In vitro PLR outcomes were tested in MLOY4 or OCY454 osteocyte-like cell lines. We prioritized outcomes with the sensitivity and reproducibility to consistently reveal qualitative and quantitative significant differences in PLR between virgin and lactating cohorts of WT and MMP13ocy-/- mice. Based on this process, we developed a protocol for quantifying LCN integrity, as well as a PLR gene profile to gain molecular insight. For in vitro outcomes apart from the PLR gene profile, we monitored PLR function by measuring osteocyte intracellular acidification. These in vitro outcomes efficiently corroborate our in vivo findings. By presenting the validation and methodologic details for these protocols, our work will support the efforts of this research community to investigate and better understand the role of PLR in skeletal health and diseases.

In Vivo Analysis of Fracture Healing by HR-pQCT: The Effect of Osteosynthesis Plate on Image Quality Ko Chiba*, Makoto Era, Yuichiro Nishino, Takashi Miyamoto, Narihiro Okazaki, Makoto Osaki. Department of Orthopedic Surgery, Nagasaki University Graduate School of Biomedical Sciences, Japan

Introduction: It has been difficult to study fracture healing in living patients at the micro level. HR-pQCT is a high-resolution clinical CT for human peripheral sites, which enables us to analyze the bone microstructure of living humans non-invasively.In this study, we validate the accuracy and reproducibility of HR-pQCT analysis of distal radius with metal plate in order to establish in vivo analysis of fracture healing treated by osteosynthesis plate. Methods: (Study-1 SNR) Four metal plates for distal radius fracture (VA-LCP, Synthes, Switzerland / DVR, Biomet inc., USA / Acu-Loc2, Acumed, USA / Stellar, HOYA, Japan) were put on a rubber bag filled with water. The middle region of the metal plate was scanned by HR-pQCT at the voxel size of 61 μm (XtremeCT II, Scanco Medical, Switzerland). Signal to noise ratio (SNR) was calculated in the water region under the metal plate.(Study-2 Accuracy) 12 cadaveric radiuses (age: 72 years, 60-80 years) were scanned by HR-pQCT under conditions with and without the metal plates. Cortical bone mineral density (Ct.BMD) and cortical thickness (Ct.Th) were measured at the whole circumference and dorsal 1/3 cortical regions (TRI/3D-BON, Ratoc System Engineering). Percentage changes in the conditions with and without metal plates were analyzed. (Study-3 Reproducibility) 10 patients with distal radius fractures (54 years, 21-74 years) were treated with VA-LCP plates. Two scans were performed using HR-pQCT, Ct.BMD and Ct.Th were measured at the dorsal 1/3 cortical region, and the root mean square percent coefficient of variance (RMS%CV) was analyzed. Results: (Study-1 SNR) There was no great difference in the SNR of the control (49.9), VA-LCP (45.6), DVR (47.6), Acu-Loc2 (43.6), and Stellar (47.7).(Study-2 Accuracy) When the whole circumference of the cortical region was measured, percentage changes with and without a metal plate were 1.4-3.2% in Ct.BMD and 7.2-9.8% in Ct.Th. When the dorsal 1/3 region was measured, percentage changes with and without metal plate were 0.4-1.7% in Ct.BMD and 1.7-2.7% in Ct.Th.(Study-3 Reproducibility) RMS%CV were 1.1% in Ct.BMD and 4.2% in Ct.Th.Conclusion: The accuracy and reproducibility of HR-pQCT analysis of distal radius with osteosynthesis plate are acceptable when the dorsal 1/3 region is analyzed. This method would be useful for the research of fracture healing.

Opportunistic screening for osteoporosis using abdominopelvic CT: Direct comparison of asynchronous QCT with DXA and TBS in older healthy Chinese Wing P. Chan*[1], Yi-Chien Lu[1], Ying Chin Lin[2]. [1]Department of Radiology, Wan Fang Hospital, Taipei Medical University, Taiwan, [2]Shuang Ho Hospital, Taipei Medical University, Taiwan

Background: It has recently been reported that abdominopelvic CT scans obtained for other indications can be used to assess bone mineral density (BMD) in the spine for opportunistic screening for osteoporosis. Asynchronous calibration quantitative computed tomography (QCT) is a new tool that allows quantification of BMD without the use of a calibration phantom during routine CT scanning. Use of the trabecular bone score (TBS) has been suggested to improve the diagnostic performance of DXA of the lumbar spine for patients with low bone mass (LBM). This study aimed to compare BMDs obtained using asynchronous QCT during abdominopelvic CT for health screening with DXA and TBS in older Chinese adults. Methods: Consecutive patients who underwent a CT examination of the abdominopelvic region and who also received a DXA during health examinations were retrospectively included. This cohort included 494 adults (men aged at least 50 years and postmenopausal women) who underwent standard non-contrast CT assessments at 120 kVp as well as DXAs for BMD assessment within 3 months. The 3D spine function QCT pro software (Mindways Software Inc., TX) was used to perform L1–L4 BMD analysis using the asynchronous calibration module, and TBS was analyzed using iNsight software (Med-Imaps, Pessac, France).Lumbar spine BMD was measured by DXA. Diagnosis of osteoporosis was based on T-score according to WHO classification. Vertebral fractures were identified on sagittal-reformed standard CT images of the lumbar spine using Genant's semi-quantitative method. Results: In this sample, 48 individuals (9.7%) had osteoporosis according to DXA, and 7 (1.4%) had vertebral fractures. The correlation between DXA and QCT was good (R2 = 0.611, p < 0.001); it was fair between DXA and TBS (R2 = 0.470, p < 0.001) and between QCT and TBS (R2 = 0.405, p < 0.001). In 17.3% of the sample, QCT found a more degraded BMD to be LBM, whereas DXA reflected normal BMD for these individuals. On the other hand, in 9.4%, DXA identified a more degraded BMD to be LBM compared to QCT. Likewise, TBS classified the highest percentage in this way compared to QCT (32.7%) and to DXA (24.5%). Conclusion: For spine BMD screening during routine abdominopelvic CT, asynchronous QCT performs as well as DXA. Also, TBS provides information that is independent of spinal BMD. Spinal TBS reclassifies LMB as osteoporosis less often than DXA but yields similar results compared to QCT

Trabecular Bone Score in aged postmenopausal women with type 2 diabetes without fragility fracture history Dong Jin Chung*, Jin Ook Chung, Dong Hyeok Cho, Min Young Chung. Chonnam National University Medical School, Republic of Korea

Type 2 diabetic patients are at increased risk for osteoporotic fracture regardless of BMD status.In addition to many falling risks factors, deterioration of bone quality such as bone microstructure may be one of the important underlying mechanism. Trabecular bone score (TBS) is a novel texture index that evaluates the pixel gray-level variations in lumbar spine dual-energy X-ray absorptiometry images and is related to bone microarchitecture independent of bone mineral density (BMD). We investigated lumbar spine TBS as an indicator for skeletal microarchitectural deterioration in type 2 diabetes. We included 52 type 2 diabetic (71.6±6.5 years) and 77 non-diabetic (71.1±4.2 years) aged postmenopausal Korean women without fragility fracture history who visited the outpatient clinic of Chonnam National University Hospital. Serum 25OHD, CTX, osteocalcin and other laboratory data were aquired after overnight fasting. BMD was measured at the lumbar spine using dual energy X-ray absorptiometry (Hologic Discovery-Wi). All TBS measurements were performed retrospectively using the TBS iNsight Software, ver. 3.0.2.0 (Med-Imaps) using spine DXA files from the database. Lumbar spine BMD was higher in type 2 diabetic women (0.834 ± 0.129 vs 0.771 ± 0.095 g/cm2, P<0.05) than in nondiabetic women, whereas lumbar spine TBS was not significantly different between two groups (1.341 ± 0.086 vs 1.332 ± 0.074). Serum 25OHD level was lower in diabetic women than in nondiabetic women (21.0 ± 10.4 vs 25.1 ± 11.4, P<0.05). Serum CTX and osteocalcin levels were not significantly different between two groups. Unlike from previous studies which showing lower TBS in diabetic patients, lumbar TBS was not lower in aged diabetic women in this study. It may still suggest deterioration of bone microstructure in diabetic women when considering higher BMD status. Otherwise, it may be due to small sample size of participants. Larger studies considering many confounding factors such as onset, duration of diabetes, glycemic control status, diabetic complications, or the use of antidiabetic drugs which are known to be affect on bone metabolism are needed.

SUN-0703

TBS VALUE IN POSTMENOPAUSAL WOMEN WITH AND WITHOUT FRACTURES Edward Czerwinski*[1], Maja Warzecha[2], Malgorzata Berwecka[2], Anna Kumorek[3], Jaroslaw Amarowicz[2], Didier Hans[4]. [1]Krakow Medical Centre, Poland, [2]Department of Bone and Joint Diseases Jagiellonian University Medical College, Poland, [3]Healthy Statistic, Poland, [4]Center of Bone Diseases Bone and Joint Department, Switzerland

Determining the risk of fracture is a key problem in osteoporosis. The threshold of -2.5 BMD T-score has been used as a criterion for diagnosing osteoporosis (OP), majority of fractures are sustained by patients above this threshold. However, bone structure quality is more important in assessing fracture risk than bone density alone. A major advance in osteoporosis diagnostics is Trabecular Bone Score (TBS), a method to indirectly assess bone structure based on lumbar spine DXA in clinical routine.TBS was assessed from lumbar spine DXA image in Lausanne, blinded from clinical outcome in a group 1045 postmenopausal women (mean age 65 ± 7 SD), patients of Krakow Medical Centre. All statistics were performed in Krakow.Low-energy fractures were diagnosed in a group of 244 women, while the group without fractures was 761 women. In non-fractured group (mean age 64 ± 7.2 SD) the mean TBS was 1.238± 0.09 SD (partly degraded). In the group with prevalent low energy fractures of spinal and non-spinal (mean age 67± 7,6 SD), TBS equaled 1.202± 0.09 SD (p<0.0001 after age and BMI adjustment). The mean TBS in the group with prevalent non-spinal fractures only was 1.213± 0.09 SD and in the group of women with spinal fractures 1.166± 0.08 SD (fully degraded) (p<0.01 after age and BMI adjustment).Conclusions: The mean TBS in non-fractured women showed a partial bone structure degradation, whereas in patients with prevalent fractures of any kind the mean was within the scope of degraded structure.

Trabecular Bone Score (TBS) ex-vivo performance study for the GE Healthcare ARIA system Franck Michelet*, François De Guio, Christophe Lelong. Medimaps, France

Aim: Trabecular Bone Score (TBS) is compatible with multiple DXA systems from different manufacturers. Technical requirements, like image resolution and noise level, are a prerequisite for TBS compatibility with a given DXA system. Then, pre-clinical and clinical performance can be evaluated to further assess compatibility with TBS. The goal of this study is to assess the TBS ex-vivo performance of General Electrics Healthcare (GE) Aria DXA system. Results from the GE Aria device are compared to those of GE Prodigy devices. Material and methods: We used 15 dry ex-vivo human vertebrae, set in AP position. Soft tissues were simulated by a mix of homogeneous layers of HDPE and PVC, achieving an equivalent thickness of 16.7cm with 29.4% fat content. We scanned these vertebrae 3 times each without repositioning on a GE Aria device and on 3 different GE Prodigy devices. For each device model, we computed the ex-vivo reproducibility of TBS as the root mean square

standard deviation (rms-SD). We also computed the coefficient of determination (r²) between the 15 TBS values obtained on GE Aria and the 15 average TBS values obtained on the 3 GE Prodigy devices.Results: TBS ex-vivo reproducibility was measured at rms-SD = 0.025 for GE Aria and rms-SD = 0.019 for GE Prodigy. The coefficient of determination between GE Aria and the average of GE Prodigy devices was r² = 98.8%. By comparison, the average coefficient of determination between GE Prodigy devices, was r² = 99.4%.Conclusion: The strong correlation between TBS values on GE Aria and GE Prodigy devices validates the first step for having TBS compatibility with GE Aria devices. As expected, TBS ex-vivo reproducibility appears to be better on GE Prodigy than on GE Aria, but this trend will have to be confirmed with an in-vivo reproducibility study.

Trabecular microstructure is influenced by race and sex in young adults Julie Hughes*[1], Kristin Popp[2], Chun Xu[3], Amy Yuan[2], Ginu Unnikrishnan[3], Jaques Reifman[3], Mary Bouxsein[2]. [1]USARIEM, United States, [2]MGH, United States, [3]BHSAI, United States

Lower rates of fracture in Black men and women compared to their White counterparts, may, in part, be explained by enhanced cortical bone microstructure. Using individual trabecular segmentation (ITS) analysis of high-resolution peripheral quantitative computed tomography (HR-pQCT) may allow better understanding of the contribution of the trabecular bone compartment to bone strength and fracture risk. A prior study using ITS technology suggests that among older Black and White women, Black women had more plate-like trabecular morphology and higher axial alignment of the trabeculae compared to White women. However, it is not known whether these racial differences are established in young adulthood or developed during aging, nor whether they exist among men. Therefore, the purpose of this study was to determined differences in trabecular bone microarchitecture, connectivity and alignment according to race and sex. We analyzed HR-pQCT scans of 184 young adult (24.2±3.4 yrs) women (n=51 Black, n=50 White) and men (n= 34 Black, n=49 White) from a prior cross-sectional study. We used two-way ANOVA to compare bone outcomes, adjusted for age, height, and weight. Overall, the effect of race on bone outcomes did not differ by sex, and the effect of sex on bone outcomes did not differ by race. After adjusting for covariates, Blacks and men had significantly greater trabecular plate volume fraction, plate thickness, plate number density, and plate surface area in addition to greater axial alignment of trabeculae compared to Whites and women (Table 1, p<0.05 for all). These findings demonstrate that more favorable bone microarchitecture in Blacks compared to Whites and in men compared to women is not unique to the cortical bone compartment. Enhanced plate-like morphology and greater axial alignment of trabeculae, established as early as young adulthood, may contribute to the improve bone strength and lower lifetime fracture risk among Blacks and men compared to their White and female counterparts.

Table 1. Individual trabecular segmentation analyses at the distal tibia (4%) among Black and White men and women adjusted for height, weight, and age.

A Novel Dual-Mode Ultrasonic Method for Assessing Tibial Cortical Bone Quality Jonathan Kaufman*[1,2], Gangming Luo[1]. [1]CyberLogic, Inc., United States, [2]The Mount Sinai School of Medicine, United States

Osteoporotic fractures are a major public health problem; diagnosis is based on x-ray densitometry (DXA). However DXA is not able to accurately predict who will and will not suffer a fracture. An alternative to DXA is ultrasound, which is viewed as having the potential to better characterize fracture risk. Our approach is based on "dual-mode" ultrasound in which two distinct modes of propagation are used together. In particular, measurements are made at the mid-shaft tibia in both axial-transmission and pulse-echo modes. Axial transit time (τA) and pulse-echo transit time (τP/E) are obtained at the same tibial site. The potential for the dual-mode's approach to assess bone quality is rooted in the facts that (i) the pulse-echo mode measurement is dependent on cortical bone quality (as reflected in radial ultrasound velocity (UV) as well as on cortical thickness; and (ii) the axial transit time measurement is dependent on cortical bone quality (as reflected in axial UV) and on cortical thickness as well. Therefore, the measurement of both ultrasonic parameters (that is, the pulse-echo and axial transmission times) allows for identification of both bone quality (as reflected in ultrasound velocity) and cortical thickness (a structural parameter), both of

which are related to bone strength and fracture risk. These 2 transit times can be used in a classification scheme to identify individuals at greatest risk of fragility fracture. The two transit times can also be converted to axial UV (UVa=d/τA, where d is the separation of two ultrasound receivers), and nominal cortical thickness (CTN = VR · τP/E/2, where VR is the radial UV). A pilot set of measurements on 11 individuals has been carried out to demonstrate the feasibility of the proposed technology. For the 11 subjects, each subject data point was found to be located in a distinct region (i.e., a hypothesized distinct bone quality-bone structural state) of the quadrant associated with axial UV and nominal CT. Because the 2 parameters are each affected in distinct fashions by a variety of bone quality factors (such as degree of mineralization, porosity, cortical thickness, biomechanical stiffness), the bivariate feature has the potential to more accurately identify those individuals at increased risk of fracture. The figure shows the data for the 11 subjects ("Fx" indicates two subjects with fragility fractures). Future studies will elucidate the capabilities of the new dual-mode ultrasound technology.

3D Modelling of hip DXA indicates cortical vBMD superior efficacy of denosumab versus alendronate Mohammed Almohaya*[1], Naveen Sami[2], Renaud Winzenrieth[3], David Kendler[4]. [1]King Fahad Medical City, , Saudi Arabia, [2]Prohealth Clinical Research, Canada, [3]Galgo Medical, Spain, [4]University of British Columbia, Canada

Evaluation of the cortical compartment of bone may be valuable in determining risk of nonvertebral fracture and treatment effects of therapies which may benefit cortical bone. Clinical evaluation of cortical bone at the hip has been restricted to high-resolution CT techniques requiring high dose radiation and high cost. More recently, modelling algorithms have been developed to estimate cortical bone parameters from hip DXA scans.We retrospectively reviewed 252 consecutive male and female patients referred for osteoporosis consultation at a specialist clinic in Vancouver Canada. All patients had baseline and follow-up hip DXA scans on the same equipment, which were subjected to DXA-based 3D modeling (3D-SHAPER v2.7, Galgo Medical, Spain) for cortical bone parameters. Patients' average age was 71±9 years; there were 225 females and 27 males. Patients were divided into groups according to their treatment prior to and subsequent to baseline: treatment naïve to bisphosphonate (tnBP, N = 56), treatment naïve to denosumab (tnDmab, N = 92), or prior bisphosphonate to denosumab (switch, N = 104). Using 3D-SHAPER, volumetric trabecular and volumetric cortical BMD as well as average cortical thickness (CTh) were evaluated (Figure 1).Cortical vBMD increased in both tnDmab (+13.8 mg/cm3, +1.9%, p=0.0002) and Switch groups (+11.1 mg/cm3, +1.53%, p=0.0005); in the tnBP group, cortical vBMD was stable (+3.17 mg/cm3, +0.44%, p=0.34). Cortical vBMD increased significantly more in the tnDmab (p=0.026) and the Switch group (p=0.036) compared to the tnBP group. CTh increased significantly more after denosumab, either tnDmab (1.02%, p=0.02) or Switch (1.35%, p=0.0009) as compared to tnBP (0.47%, p=0.68). There were positive correlations between cortical vBMD and femoral neck DXA aBMD (r=0.64) and trochanter DXA aBMD (r=0.79).These data provide the first observational evidence of hip cortical volumetric bone density improvements after denosumab and differentiation from bisphosphonate therapy. This may be supportive of observations of long-term progressive increases in BMD on denosumab with greater non-vertebral fracture prevention associated with longer duration of denosumab therapy. This information may aid clinicians with treatment decisions where non-vertebral fracture prevention is important.

Structural analysis at the female femoral neck for a clinically useful predictor of future hip fracture risk Ling Wang*[1], Benjamin Cc Khoo[2], Joshua Lewis[3], Keenan Brown[4], Xiaoguang Cheng[1], Richard Prince[5]. [1]Beijing Jishuitan Hospital, China, [2]Medical Technology & Physics, Australia, [3]Edith Cowan University, Australia, [4]Mindways Software, United States, [5]University of Western Australia, Australia

Age, gender and two dimensional (2D) DXA imaging of proximal femur areal bone mineral density (aBMD), are the established and commonly used predictors of hip fracture risk. To improve prediction we have been exploring the use of structural information present in the DXA image in addition to aBMD, these are bone width (BW), standard deviation of a normalised mineral-mass projection profile distribution (σ) and displacement between centre-of-mineral-mass and geometric centre-of-mineral-mass of projection profile (δ) [1]. We report the differences in these measurements in hip fracture cases and controls in a large Chinese data set. Participants were 447 Chinese females who sustained trochanter or femoral neck fractures and 528 community controls. The four femoral neck (FN) structural variables were calculated from DXA equivalent 2D images obtained from QCT scans of non-fractured hips analysed using BIT QCT software (Mindways Software, Texas, USA) [1]. Comparison of the mean (SD) of age, and the structural data in the fracture and control participants are shown in the Table. Compared to controls fracture participants were older, had lower values for aBMD, similar FNBW but higher values for the other structural variables previously associated with increased fracture propensity [2].Stepwise logistic regression modelling was used to select the most parsimonious model from these 6 variables, the final model included FNaBMD, FNs and FNd. To assess hip fracture prediction the area under the ROC for the final model was found to be significantly larger than for the base model ROC of age and THaBMD (0.876 and 0.834 respectively, P<0.001).A risk model including FNaBMD together with FNs and FNd suggest that extra information from the DXA equivalent image provided a substantially better hip fracture risk prediction than the gold standard of THaBMD and age, and thus may be a useful additional analysis in older women. Resorbed and Formed Bone Mass in Osteoporosis Treatment Were Correlated with the Values of the DXA and Bone Turnover Markers Measurements: by Bone Morphometry Using Multiple Detector Computed Tomography (MDCT) Images Nobuhito Nango*[1], Shogo Kubota[1], Kazutaka Nomura[1], Yusuke Horiguchi[1], Ko Chiba[2], Masafumi Machida[3]. [1]Ratoc System Engineering Co., LTD., Japan, [2]Department of Orthopedic Surgery, Nagasaki University Graduate School of Biomedical Sciences, Japan, [3]Department of Spine and Spinal Cord Surgery, Yokohama Brain and Spine Center, Japan

1. IntroductionBone metabolism markers can be used to evaluate the state of bone turnover and are applied in the treatment of osteoporosis. However, how the values for these markers correlate with increases or decreases in bone remains unclear.Measuring the resorbed bone mass and formed bone mass to controlling the medication efficacy are thought to be important in enhancing the therapeutic effects.In this study, using the computed to-

mography (CT) images, we investigated bone volume fractions and resorbed bone mass are correlated with DXA bone density and bone resorption markers in each other.2. CasesThe subjects were (A) using MDCT images, 12 women (mean age: 71 years) undergoing osteoporosis treatment with denosumab and teriparatide and (B) using HR-pQCT images, 10 volunteers (mean age: 65 years; 9 women and 1 man) undergoing osteoporosis treatment with denosumab, teriparatide and other protocols.3. Methods (1) The MDCT images of lumbar vertebrae were measured.For bone extraction, we set the TMD value to ≥80 mg/cm3. When bone with a TMD value of ≥80 mg/cm3 decreased to <60 mg/cm3 after 6 months, the bone was determined to be resorbed. Conversely, after 6 months, when the tissues of <60 mg/cm3 reached a bone density of ≥80 mg/cm3, bone was determined to be formed. (2) Using HR-pQCT, the distal tibia and the distal radius were scanned.The TMD value for bone extraction was 300 mg/cm3. Used software was TRI/3D-BON-FCS V.10.0 (RATOC, Tokyo, Japan). Also, the DXA bone density (mg/cm2) in patients were measured.(3) Serum marker measurementThe bone resorption marker TRACP-5b and bone formation marker P1NP were measured.4. Results (1) The tibial bone mass BV/TV measured by HR-pQCT correlated with the femoral areal BMD evaluated by DXA (r2 > 0.7; p < 0.00). (2) A correlation was noted between bone resorption mass and resorption markers. In the lumbar vertebrae assessed by MDCT, the resorbed bone mass and value for the pre-administration resorption marker (TRACP-5b) after 6 months of osteoporosis drug administration were correlated (r2 = 0.8; p < 0.00). In contrast, in the case of distal tibia evaluated by HR-pQCT, we observed a correlation (r2 = 0.41; p < 0.00). (3) The correlation between the formed bone mass and formation markers was weak.In the lumbar vertebrae assessed by MDCT, the formed bone mass 6 months after was correlated with the bone formation marker P1NP after starting medication, r2 = 0.46. Correlation was r2 = 0.11 in the tibia as measured by HR-pQCT.5. Discussion (1) These results suggested that a period close to 6 months is required to determine the efficacy of the resorption marker values. (2) The weak correlation of formation markers with the new bone suggested that bone could be resorbed without becoming hypercalcified.6. Conclusions (1) From CT images, it is possible to know the detailed mechanism of calcified bone modification as a result of drug treatment. (2) Although the voxel resolution of MDCT is 0.5 mm, it will be feasible to measure the trends in bone metabolism by reconfiguring the resolution to 0.2 mm.

Trabecular Bone Score in Thais with or without Type 2 Diabetes. Hataikarn Nimitphong*[1], Sasima Srisukh[1], Jintanan Jangsiripornpakorn[1], Nantaporn Siwarasanond[1], Sirimon Reutrakul [1,2], Sunee Saetung[1], Suchawadee Musikarat[3], Chanika Sritara[3], Piyamitr Sritara[1], Boonsong Ongphiphadhanakul[1]. [1]Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand, [2]Division of Diabetes, Endocrinology and Metabolism, University of Illinois College of Medicine at Chicago, Chicago, Illinois, United States, [3]Department of Diagnostic and Therapeutic Radiology, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand

Background When compared with non-diabetic subjects, patients with type 2 diabetes mellitus (T2DM) have an increase in fracture risk at most skeletal sites despite having higher bone mineral density (BMD). Lumbar spine trabecular bone score (TBS) provides skeletal microarchitecture information not captured by BMD measurement and is associated with fracture risk in Caucasians. Previous studies, mostly in Caucasians, demonstrated that TBS is lower in T2DM subjects than non-diabetic subjects and associated with poor glycemic control. The utility of TBS as a fracture risk assessment tool in Asians with T2DM is currently unclear. We compared lumbar spine BMD and TBS in Thai subjects with or without T2DM. The correlation between TBS and glycemic control in subjects with T2DM was also investigated.Methods This is a cross-sectional study of 104 T2DM subjects and 342 non-diabetic controls. Lumbar spine (L1-L4) BMD was measured by dual-emission x-ray absorptiometry (DXA) and TBS was calculated using TBS iNsight software.Results Subjects with T2DM were older and had higher body mass index (BMI) than non-diabetic subjects. When compared with non-diabetic subject, higher BMD was demonstrated in T2DM subjects in both unadjusted model (p=0.001) and adjusted model for age, gender and BMI (p<0.001). Lumbar spine TBS was significantly lower in T2DM (p<0.001) in both unadjusted model and adjusted model for age and gender. However, after further adjustment for BMI, there were no differences among the two groups (p=0.808). There was no correlation between TBS and hemoglobin A1c (HbA1c; p=0.863).Conclusion Subjects with T2DM have higher lumbar BMD than those without. Contrary from the previous report in Caucasians, lumbar spine TBS in Thai T2DM was not different from non-diabetic subjects after controlling for BMI. There was no association between TBS and glycemic control in this study.

Optimal Bone Mineral Density Testing Intervals in Korean Women Seung Shin Park*[1], Jung Hee Kim[1], Hyung Jin Choi[2], Eu Jeong Ku[3], Seo Young Lee[1], A Ram Hong[1], Nam H. Cho[4], Chan Soo Shin[1]. [1]Department of Internal Medicine, Seoul National University College of Medicine, Republic of Korea, [2]Department of Anatomy, Seoul National University College of Medicine, Republic of Korea, [3]Department of Internal Medicine, Chungbuk National University College of Medicine, Republic of Korea, [4]Department of Preventive Medicine, Ajou University School of Medicine, Suwon, Republic of Korea

Background: Low bone mineral density (BMD) is a major predictor of fragility fracture. BMD testing is recommended for screening for osteoporosis, but there were a few studies regarding the appropriate BMD testing intervals in normal or osteopenic subjects. Therefore, we aimed to elucidate the optimal BMD testing intervals according to baseline BMD and clinical risk factors in Korean postmenopausal women.Methods: In a Korean prospective cohort study, we included 938 postmenopausal women who underwent repeated BMD testing during a median follow-up period of 7.2 years. We classified study subjects into four groups according to baseline BMD T-score. The duration of transition to osteoporosis was assessed using the parametric estimation of cumulative incidence functions for interval-censored competing risk data. After adjusted for age and body mass index (BMI), the estimated time for 10% of subjects to transit to osteoporosis were calculated for each group. Fracture events were treated as a competing risk.Results: The prevalence of normal BMD (T score ≥ -1.00), mild (T score, -1.01 to -1.49), moderate (T score, -1.50 to -1.99), and severe osteopenia (T score, -2.00 to -2.49) based on baseline BMD T-score were 48.5%, 17.7%, 20.5%, and 13.3%. The mean age and BMI of study subjects were 62.9 (±7.6) years and 25.0 (±3.3) kg/m2. Women with lower BMD T-score tended to be older and had lower BMI (all p for trend <0.001). During a median follow-up duration of 7.2 years, 10.3% (97/938) of subjects made transition to osteoporosis. The rate of transition to osteoporosis in women increased with lower BMD T-score (2.6%, 3.6%, 12.0%, 44.8% respectively, p<0.001). The time for 10% of subjects to make the transition to osteoporosis was 10.6 years (95% confidence interval [CI], 7.6 to 14.8) for subjects with mild osteopenia, 8.3 years (95% CI, 6.7 to 10.2) for subjects with moderate osteopenia, and 3.8 years (95% CI, 2.9 to 5) for subjects with severe osteopenia. In subjects with normal BMD, the time for 10% of subjects to transit to osteoporosis was not estimated due to the low incidence of osteoporosis.Conclusions: Approximately 10 years, 8 years, and 3 years may be an appropriate interval of BMD screening for subjects with mild osteopenia, moderate osteopenia, and severe osteopenia respectively. There is very low likelihood of a transition to osteoporosis in subjects with normal BMD.

Active Young Women with Current Tibial Stress Fracture have Reduced Cortical and Total Bone Area Kristin Popp*[1], Sara Rudolph[1], Amy Yuan[1], Julie Hughes[2], Chun Xu[3], Ginu Unnikrishnan[3], Jaques Reifman[3], Mary Bouxsein[4]. [1]Massachusetts General Hospital, United States, [2]United States Army Research Institute of Environmental Medicine, United States, [3]Department of Defense Biotechnology High Performance Computing Software Applications Institute, United States, [4]Massachusetts General Hospital and Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, United States

Stress fractures are common overuse injuries, particularly among young women participating in repetitive physical activity. These partial or complete bone fractures occur most often in the tibia and require significant healing time that can hinder or terminate sports and military training. While numerous risk factors for stress fracture have been identified, few studies have quantified measures of bone microarchitecture and strength that discriminate women with a current stress fracture from healthy active women. Purpose: We aimed to determine differences in bone density, microarchitecture and strength among active young women with a current tibial stress fracture compared to those without. Methods: We enrolled 30 women within 3 weeks of an MRI diagnosed tibial stress fracture and 47 healthy controls. All participants were 18-35 years old and reported ³ 4 hours of weight-bearing exercise weekly. We used dual-energy X-ray absorptiometry (DXA) to assess areal bone mineral density (aBMD) of the hip and spine, and high-resolution pQCT (HR-pQCT; 82 mm3 voxel size) to assess cortical and trabecular bone density, microarchitecture and strength by microfinite element analysis (mFEA) at the distal tibia (4% of tibia length). We compared the uninjured tibia in those with a current stress fracture to the non-dominant tibia among controls. We used ANCOVA to compare bone outcomes, adjusting for age, height, weight, menstrual status and age of menarche. Results: Mean age was 25.0±4.0 and BMI 22.7±2.7 kg/m2. Groups were comparable for age, height, weight, menstrual status, age of menarche, aBMD, and most bone parameters. However, women with a current stress fracture had smaller total area (-5.6%, p<0.05) by Hr-pQCT compared to healthy controls. Total volumetric bone mineral density (vBMD; +7.4%), trabecular thickness (+8.7%) and trabecular vBMD (+10.56%) were higher among women with a stress fracture compared to controls (p<0.05 for all), though there were no differences in cortical microstructure or estimated strength and stiffness between groups. Conclusion: These data indicate that while microarchitecture is largely similar between groups, women with a current stress fracture have higher bone density and trabecular thickness compared to controls but smaller bone size. Smaller, more consolidated

bones may be at greater risk for stress fracture compared to larger, less dense bones, although this remains to be verified.

Postmenopausal Women with Isolated Osteoporosis at the 1/3 Radius Have Generalized Abnormalities in Microarchitecture and Stiffness Emily Stein*[1], Alexander Dash[1], Mariana Bucovsky[2], Sanchita Agarwal[2], X. Edward Guo[2], Elizabeth Shane[2]. [1]Hospital for Special Surgery, United States, [2]Columbia University Medical Center, United States

Postmenopausal women with osteoporosis only at the 1/3 radius (1/3RO), but not the spine or hip, present a therapeutic dilemma because little is known about whether they have focal cortical bone deficits or generalized skeletal fragility. It is therefore often unclear whether to initiate treatment in these patients, particularly as most available medications do not significantly improve BMD at this site. In this study, we used high resolution peripheral QCT (HRpQCT) to measure volumetric BMD (vBMD), microarchitecture, and stiffness in women with 1/3RO. We hypothesized that compared to controls, women with 1/3RO have smaller bone size and cortical deficits at the radius that contribute to low areal BMD by DXA, but preserved trabecular bone, and few abnormalities at the tibia. We enrolled 285 postmenopausal women; all had BMD of lumbar spine (LS), total hip (TH), femoral neck (FN) and1/3 radius (1/3R) measured by DXA, trabecular (Tb) and cortical (Ct) vBMD and microarchitecture measured by HRpQCT (voxel size ~82 µm) of the distal radius (RAD) and tibia (TIB) and whole bone stiffness estimated by finite element analysis. Women were grouped by their densitometric pattern: isolated osteoporosis (T<-2.5) at the 1/3 radius (1/3RO, n=30), classical osteoporosis at the spine or hip (PMO, n=85) and controls without osteoporosis at any site (C, n=170). Mean age of subjects was 70±8, 75% were Caucasian. 1/3RO tended to be older than C (p=0.06) but similar in age to PMO. BMI did not differ among groups. Mean DXA T-scores were, in 1/3RO: -1.2±0.7 at LS, -1.5±0.5 at TH, -1.9±0.4 at FN, -3.0±0.5 at 1/3R, in PMO: -2.6±1.0 at LS, -2.1±0.6 at TH, -2.4±0.6 at FN, -2.3±1.2 at 1/3R. While bone size did not differ, 1/3RO had lower total, Ct and Tb density at RAD and TIB than C (Table). At RAD, 1/3RO also had lower Ct thickness and Tb number, higher Tb separation and heterogeneity. Whole bone stiffness was lower at both sites. There were no significant differences in vBMD, microarchitecture and stiffness between 1/3RO and PMO. In summary, women with isolated osteoporosis at the 1/3 radius by DXA have abnormal Ct and Tb microarchitecture and low stiffness by HRpQCT at both radius and tibia. Our results suggest that although aBMD appears relatively preserved at the spine and hip by DXA, postmenopausal women with osteoporosis only at the 1/3R site have comparable deficits in vBMD, microarchitecture and stiffness to postmenopausal women with osteoporosis at the spine and hip.

Peripheral Artery Calcification on HR-pQCT Scans and Cardiovascular Risk in Men Pawel Szulc*, Catherine Plankaert, Roland Chapurlat. INSERM UMR 1033, University of Lyon, Hôpital Edouard Herriot, France

Data on the link between severity of peripheral artery calcification and cardiovascular risk are limited and focused on patients with chronic kidney disease and peripheral artery disease. Our aim was to study the association between severity of peripheral artery calcification found on the scans of distal forearm and distal leg obtained by high resolution peripheral quantitative computed tomography (HR-pQCT) and the prospectively assessed cardiovascular risk in community-dwelling older men. In a cohort of 819 men aged 60-87, calcification was assessed at baseline on HR-pQCT scans at the level of the arteries of distal leg (ante-

rior and posterior tibial artery [a.], intraosseous aa.) and distal forearm (ulnar a., radial a., intraosseous aa.). For each artery calcification was scored 0 to 2 yielding a global score of 0 to 12. During the prospective 8-year follow-up, 164 men died (55 cardiovascular deaths) and 53 men had acute coronary syndrome confirmed by troponin assay, electrocardiogram or coronarography. Peripheral artery calcification score increased with age. After adjustment for age, the score was higher in men with obesity, diabetes mellitus, ischemic heart disease or hypertension and in men taking vitamin K antagonists (p<0.005). In 43 men with severe calcification (score >5), all-cause mortality was higher compared to men with lower calcification score (0-5): HR=1.68, 95%CI: 1.01 – 2.82, p<0.05 after adjustment for age, BMI, lifestyle, co-morbidities, treatments, biological measures and abdominal aortic calcification. In this group, cardiovascular mortality was significantly increased: HR=2.60 vs. men with the score 0-5, 95%CI: 1.19 – 5.66, p<0.05 after adjustment for confounders. Finally, severe peripheral artery calcification was associated with higher risk of acute coronary syndrome: HR=5.58 vs. men with the score 0-5, 95%CI: 2.49 – 12.54, p<0.001 after adjustment for relevant confounders. In conclusion, in older community-dwelling men followed up prospectively, severe peripheral artery calcification observed on the HR-pQCT scans is associated with a significantly higher risk of cardiovascular death and acute coronary syndrome. Severe peripheral artery calcification found fortuitously on a medical imaging scan performed for other reasons can provide clinically relevant information on the cardiovascular risk.

The Correction of Quantitative Computed Tomography Measurements of Vertebral Bone Mineral Density for Marrow Fat using Magnetic Resonance Imaging Ling Wang*[1], Xiaoguang Cheng[1], Glen Blake[2], Keenan Brown[3], Li Xu[1], Zhe Guo[1]. [1]Department of Radiology, Beijing Jishuitan Hospital, China, [2]King's College London Osteoporosis Research Unit, United Kingdom, [3]Mindways Software Inc., United States

Purpose: Single-energy quantitative computed tomography (SEQCT) measurements of volumetric bone mineral density (vBMD) are subject to errors due to variations in bone marrow composition. We describe a method of using chemical shift-encoded magnetic resonance imaging (CSE-MRI) measurements of marrow fat to correct these errors, together with a validation study in which CSE-MRI corrections to SEQCT vBMD measurements of L1 trabecular bone were compared with the same corrections derived from dual-energy QCT (DEQCT) scans. Methods: We describe a method based on the H2O and K2HPO4 equivalent densities of bone, red and yellow bone marrow to correct SEQCT vBMD measurements for marrow fat using CSE-MRI measurements of proton density fat fraction (PDFF). Using data from earlier studies, we show that PDFF measurements provide a reliable estimate of the yellow marrow content of bone marrow. The resulting corrections to spine SEQCT vBMD measurements were compared with similar corrections obtained by performing DEQCT scans in 18 subjects enrolled as healthy controls in the China Action on Spine and Hip Status study. Results: Plots of the MRI vBMD corrections against the DEQCT corrections showed statistically significant correlations for 80 kVp (r2 = 0.541; P < 0.001) and 120 kVp vBMD data (r2 = 0.620; P < 0.001). Bland-Altman plots showed a bias of 1.1 (95% LOA: -7.7 to 10.0) mg/cm3 at 80 kVp and 1.5 (95% LOA: -10.3 to 13.3) mg/cm3 at 120 kVp. Conclusions: We have validated a method of using CSE-MRI measurements of PDFF to correct the accuracy errors in SEQCT vBMD measurements.

Cortical and trabecular bone of patients with prevalent major osteoporotic fracture: a case-control study using DXA-based 3D modelling Renaud Winzenrieth*[1], Ludovic Humbert[1], Edward Leib[2]. [1]Galgo Medical SL, Spain, [2]Dept. of Medicine, University of Vermont College of Medicine, United States

Purpose: The aim of this study was to assess the differences at the cortical and trabecular bone between subjects with and without prevalent osteoporotic fractures in a large cohort of non-Hispanic white women from USA, using DXA-based 3D modelling.Method: This retrospective case-control study involved 1746 women aged 50 and older. Eligibility was determined through a thorough review of records of patients having had a DXA scan between 2002 and 2008. Individuals suffering from illness or taking medications known to affect bone metabolism were excluded. Individuals in the fracture group (n=105) had at least one low-energy major osteoporotic fracture (MOF). Areal BMD (aBMD) was measured at lumbar spine (aBMDLS) and total femur (aBMDTot). A software algorithm was used to derive 3D models from the hip DXA scans and compute the following measurements: trabecular volumetric BMD (TrabvBMD) and cortical surface BMD (CortsBMD). Descriptive statistics and inferential tests for difference between groups were used. Univariate and multivariate logistic regression models were used to investigate possible association between independent variables and the presence of fracture. Odds ratios per standard deviation decrease (OR) and areas under the ROC curve (AUC) were evaluated.Results: Mean age, aBMDTot, TrabvBMD, smoking (all p<0.001), as well as CortsBMD (p=0.02) and aBMDLS (p=0.03) were significantly different between control and fracture groups, whereas no difference was noted for BMI, weight, height, menopause status, family history of osteoporosis (FHOp) and parental history of hip fracture (ParFx). After adjustment for age and smoking, aBMDTot (p=0.037) and TrabvBMD (p=0.021) remained significantly lower in individuals with MOF while aBMDLS and CortsBMD were not. AUC of aBMDTot and TrabvBMD were 0.60 [0.54-0.65] and 0.61 [0.55-0.66] respectively. Using multivariate analysis, TrabvBMD, age and smoking were the three co-factors included in the model to explain presence of MOF, while aBMDLS, aBMDTot, CortsBMD, FHOp, and ParFx were excluded from the model (p>0.1). Trabecular vBMD remained associated with the presence of prevalent fracture after adjustment for age and smoking with an OR of 1.28 [1.03-1.60] (1.52 [1.22-1.89] before adjustment).Conclusion: This study demonstrates the potential of DXA-based 3D measurements to discriminate between subjects with and without MOF. TrabvBMD was the measurement exhibiting the strongest association with the presence of fragility fracture, which is consistent with results in the literature obtained in similar studies using quantitative computed tomography.

The Design and Validation of a New Algorithm to Identify Initial Incident and Recurrent Incident Fragility Fractures in Administrative Claims Data Nicole Wright*[1], Shanette Daigle[2], Mary Melton[2], Elizabeth Delzell[1], Akhila Balasubramanian[3], Jeffrey Curtis[2]. [1]Department of Epidemiology, University of Alabama at Birmingham, United States, [2]Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, United States, [3]Center for Observational Research, Amgen Inc, United States

Purpose: Administrative databases offer an avenue for clinical research on osteoporotic fractures. The procedure codes of the Ray et. al fracture identification algorithms have been updated, potentially affecting algorithm validity. We validated new claims-based algorithms to identify incident and recurrent fractures in administrative claims data.Methods: We used 2005-2014 Medicare claims linked to the Reasons for Geographic and Racial Differences in Stroke (REGARDS) study, a prospective cohort of Black and White adults ≥45 years. "Case qualifying (CQ)" incident fractures (defined in Table footnote) were identified among participants (≥65 years) having ≥12 months of traditional fee-for-service coverage prior to first fracture claim, and ≥6 months after. A recurrent fracture was defined as the first CQ event to occur after a clean period (≥90 days) before the preceding incident fracture episode. We used medical record content (discharge summary, imaging and/or surgical report) to adjudicate fractures, and ensured the claim event was correctly matched to the fracture site. We calculated positive predictive values (PPV) as the number of confirmed fractures divided by the total number of claims-identified fractures.Results: We identified 2,049 potential incident fractures in claims among 1,650 participants, and attempted record retrieval for 728 (35.5 %) suspected incident fracture events (prioritizing recent CQ fractures associated with osteoporosis). Our final sample included 520 claims-identified CQ incident fractures having medical records; 502 (96.5%) were confirmed. The PPVs of the hip, radius/ulna, humerus, and clinical vertebral all exceeded 95% (Table). We identified 117 beneficiaries with 292 ≥2 CQ fracture episodes at the same skeletal site, and attempted retrieval for 105 (36.0%) episodes. Our analytic sample included 72 (68.5%) CQ episodes from 33 participants. The PPVs for identifying recurrent clinical vertebral, hip/femur, and non-vertebral fractures with a clean period ≥90 days exceeded 95%.Conclusions: Our fracture identification algorithms had high validity, even for clinical vertebral fractures and recurrent fractures of the same site (not previously evaluated by Ray et al). While medical record review and clinical adjudication remains a gold standard, our claims-based algorithms provide valid fracture outcome ascertainment, particularly for research questions focusing on high specificity such as comparative effectiveness and safety.

Table. Validation of Case-Qualifying Claims-based Algorithm to Identify Initial Incident and Recurrent Incident Fragility Fractures

	Episodes Identified by Claims	Medical Record Confirmed	PPV (95% CI)
Incident Fractures			
All Clinical CQ Fractures*	520	502	96.5 (94.6, 97.8)
Hip	107	102	95.3 (89.5, 98.0)
Radius/Ulna	90	87	96.7 (90.7, 98.9)
Humerus or Scapula	54	53	98.1 (90.2, 99.7)
Clinical Vertebral	148	146	98.6 (95.2, 99.6)
Recurrent Fractures⁺			
All clinical fractures*⁺	72	70	97.2 (90.4, 99.2)
Clinical Vertebral	40	39	97.5 (87.1, 99.6)
Hip/Femur	22	21	95.5 (78.2, 99.2)
All Non-Vertebral**	32	31	96.9 (84.3, 99.4)

PPV = Positive Predictive Value; CI = Confidence Interval; CQ = Case Qualifying
Case qualifying fractures were identified on the basis of meeting any of the following criteria:
(1) fracture diagnosis code was in the primary position on an hospitalized claim, or
(2) fracture diagnosis code was in secondary (i.e. non-primary) position on an hospitalized claim, or
(3) fracture diagnosis code was on an outpatient claim and paired with surgical fracture repair procedure, or
(4) for clinical vertebral fractures, fracture diagnosis code was on a physician claim and paired with spine imaging code (±10 days)

*All clinical fractures include hip, pelvis, femur, tibia/fibula or ankle, radius/ulna, humerus or scapula, clavicle, and clinical vertebral fractures
**All non-vertebral fractures include hip, pelvis, femur, tibia/fibula or ankle, radius/ulna, humerus or scapula, and clavicle fractures
⁺90 day clean-period in which no fracture claims were observed during the 90-days

Serum Circulating MicroRNAs as a Novel Biomarker for Osteoporotic Vertebral Fractures Patryk Zarecki*[1], Matthias Hackl[2], Johannes Grillari[3], Miguel Debono[1], Richard Eastell[1]. [1]University of Sheffield, United Kingdom, [2]TAmiRNA GmbH, Austria, [3]TAmiRNA GmbH, Christian Doppler Laboratory on Biotechnology of Skin Aging, Austria

Vertebral fractures are the hallmark of osteoporosis. Some microRNAs (miRNAs) can affect bone homeostasis, including bone remodelling and fracture healing by altering the gene expression in osteoblasts, osteoclasts and osteocytes. We hypothesise that miRNAs affect bone metabolism and their levels should differ between osteoporotic patients and healthy controls.We compared the levels of circulating miRNAs in older women with osteoporotic vertebral fractures, women with low bone mineral density (BMD) and healthy controls. We correlated miRNAs expression levels with currently-used bone turnover markers (BTMs) and osteoporosis-related hormones.The set of 20 circulating miRNAs was selected based on the literature and our previous studies. The serum levels of selected miRNAs were measured by a RT-qPCR in 4 groups of older women: healthy controls (n=40, group 1); low BMD and no fractures (n=35, group 2); vertebral fractures and low BMD without a treatment (n=24, group 3); or receiving a treatment against osteoporosis (n=17, group 4). The data quality was monitored using spike-in and hemolysis controls and was normalized to the RNA spike-in control. Statistical analysis was performed by a two-way ANOVA with Tukey post hoc test with statistical significance of P-value < 0.05. The correlation between miRNAs and BTMs was performed in SPSS Statistics software by regression analysis.We found 7 miRNAs (miR-375, miR-532-3p, miR-19b-3p, miR-152-3p, miR-23a-3p, miR-335-5p, miR-21-5p) which were upregulated (P<0.05) in patients with vertebral fractures/low BMD against patients with low BMD/no fractures (2-fold) and against healthy controls (1.5-fold), regardless of osteoporosis treatment. There were no significant differences in any miRNA level between low BMD/no fracture group and healthy controls. We found 39 significant correlations (P<0.05) of measured miRNAs with: CTX, PTH, PINP, OC, Bone ALP, cortisol, estrone and 25-OH vit D. There was no correlation between any of measured miRNAs with: IGF-1 and estradiol.These data suggest that some miRNA levels reflect the presence of osteoporotic vertebral fractures. They are unlikely to reflect low BMD, and more likely changes in bone quality or fracture healing. Bisphosphonate treatments do not appear to have a large influence on miRNA levels in this cohort. The correlation between miRNAs and BTMs suggest that miRNAs may be involved in bone turnover or fracture healing.

Multiple missed opportunities to reduce key fragility fractures: can we afford to continue to ignore the facts? Emese Toth*[1], Jonas Banefelt[2], Kristina Akesson[3], Anna Spangeus[4], Gustaf Ortsater[2], Cesar Libanati[1]. [1]UCB Pharma, Belgium, [2]Quantify Research, Sweden, [3]Lund University, Skåne University Hospital, Department of Orthopaedics, Sweden, [4]Department of Endocrinology/Department of Medical and Health Sciences, Linköping University Hospital, Sweden

The ageing population in most countries will precipitate a healthcare crisis if the increasing burden of fragility fractures (Fxs) is not addressed. Despite the well-recognized increase in imminent Fx risk after a first fragility Fx, worldwide, most patients remain undiagnosed and untreated. While we must continue to prevent first Fx, this requires the identification of patients who are very often asymptomatic. In contrast, identifying patients at risk

Sunday Posters

of secondary Fx requires less effort, as they become known to healthcare systems during their Fx episode. Here, we report on missed opportunities to reduce secondary hip, clinical vertebral (clin vert), and humerus fragility Fxs in postmenopausal women in Sweden. Women aged 55–90 years with a hip, clin vert, or humerus fragility Fx in 2013 (index Fx) were identified from Swedish national registries. For each woman, we calculated the number of previous Fx from their medical history (earliest available date 2001) as well as exposure to osteoporosis therapies (OP Tx). The cumulative incidences of hip, clin vert and humerus Fx within 24 months following index Fx were also assessed in order to evaluate the association between index Fx type and subsequent Fx incidence. The analysis included 14,971 women (index Fx type: 7,180 hip; 2,831 clin vert; 4,960 humerus). Mean age at index date was 77 years (range, 55–90 years). The percentage of patients with a prior Fx, by their index-Fx type were: 38% hip; 37% clin vert; 28% humerus. The proportion of women with a history of Fx prior to the index Fx increased with age (Table 1A). Cumulative incidences of new Fx over 24 months are shown by index-Fx type in Table 1B. The Fx event (index Fx) had little effect on the initiation of OP Tx. At the time of index Fx, only 23% of women had any prior OP Tx; during the 2 years following the index Fx this proportion increased slightly to 27%. In conclusion, more than a third of women with an index hip, humerus, or clin vert Fx were found to have ≥1 previous Fx, suggesting an association between Fx, in particular clin vert Fxs, and subsequent Fx. Of note, most women were not receiving OP Tx and most had no OP Tx during the 2-year follow up. Specific treatment pathways and guidelines, with clear metrics and performance assessments, are needed to ensure timely identification and intervention in patients at risk of Fx. These findings indicate that opportunities are being missed to improve a current and future healthcare problem.

Table 1.

A: Prevalence (%) of prior Fx by index-Fx type and age (years)

Index Fx type	55–59	60–69	70–79	80–89	90
All	14.7	27.1	32.3	40.2	44.4
Hip	24.2	35.2	34.9	39.5	44.2
Clin vert	15.2	30.3	33.5	43.6	46.3
Humerus	12.0	22.5	28.5	38.9	43.4

B: Incidence (%) of subsequent fractures after the index Fx by index-Fx type

Index Fx type	Subsequent fracture type within 24 months			
	Hip	Humerus	Clin vert	Any
Hip	4.0	2.6	1.7	13.7
Humerus	4.0	0.6	1.5	11.4
Clin vert	5.9	2.0	4.6	17.6
Any	4.4	1.8	2.2	8.0

'Any' Fx refers to either hip, humerus or clin vert Fx for both index and subsequent Fx.

SUN-0761

Women and Men with Diabetic Complications have a Greater Risk for Hip Fracture Shreyasee Amin*, Elizabeth Atkinson, Sundeep Khosla. Mayo Clinic, United States

Impaired bone quality contributes to increased fracture risk in diabetics, which may be related to poor blood glucose control. Complications related to diabetes mellitus, which reflects poor long-term disease control, may be a relevant clinical marker of bone fragility and increased fracture risk. We examined the association between diabetes, with and without complications, and hip fractures, in both women and men. Using administrative claims data from a large US commercial insurance database (OptumLabs Data Warehouse), we identified women and men aged ≥50 yrs who had a hip fracture between Jan 1, 2006-Dec 31, 2016, and who had at least 1 yr health plan coverage pre-fracture. Control subjects without known hip fracture were matched to cases exactly on sex, age, race, year, US region, and insurance; they were also required to have at least 1 yr of health plan coverage pre- index date. Diagnostic codes related to diabetes with or without complication and medications were captured for the year prior to fracture/index date. We categorized subjects into 3 groups (no diabetes, diabetes without complications, and diabetes with complications) and used conditional logistic regression to examine the association with hip fracture. Women and men were analyzed separately and also by race, focusing on those identified as white, black or Asian. We studied 50,136 white/5,770 black/1,130 Asian women (median age [IQR], yrs: 79 [72, 83]/ 78 [71, 83]/ 79 [71, 83], respectively) and 22,329 white/2,419 black/451 Asian men (median age [IQR], yrs: 77 [66, 82]/ 75 [66, 81]/ 78 [67, 83], respectively) who had hip fractures and an equal number of matched controls. Compared to the referent group (no diabetes), we found that both women and men with diabetic complications had an increased risk for hip fracture, while diabetics without complications had no association with hip fractures (Table). Findings were similar in women and men across races studied (Table) and when subset to diabetics not on insulin (data not shown). Diabetics who have no complications may not be at imminent risk for hip fracture. On the other hand, diabetics who do have complications should have further evaluation of their bone health and be considered for preventive therapy. Further work is indicated on determining whether poor glucose control, generally, or specific complications have a greater impact on hip fracture risk among diabetics.

Temporal Trends in Prevalence and Incidence of Diagnosed Osteoporosis in Quebec, Canada Claudia Beaudoin*[1], Philippe Gamache[1], Suzanne N. Morin[3], Jacques P. Brown[4], Louis Bessette[4], Sonia Jean[1]. [1]Institut national de santé publique du Québec, Canada, [3]McGill University, Canada, [4]CHU de Québec Research Center, Canada

Background: Osteoporosis (OP) and related fractures are associated with increased mortality, morbidity and medical costs. Given the major consequences of OP, its monitoring is an important part of a chronic disease surveillance system. Objective: The objective of this study is to describe temporal trends in the prevalence and incidence rate of diagnosed OP in individuals aged ≥45 years from the province of Quebec, Canada. Method: This study was performed using four linked provincial administrative databases (health insurance, hospitalizations, physician claims, and pharmaceutical services). Individuals were considered to have OP diagnosis if they had one or more: (i) physician claims with an OP diagnosis code (ICD-9-CM: 733.0, 733.9), (ii) hospital discharges with an OP diagnosis code (ICD-9-CM: 733.0, 733.9; ICD-10-CA: M80, M81), or (iii) prescription claims for an OP medication. The sensitivity of this case-definition was 0.65 and the positive predictive value was 0.73 in a previous validation study. To identify incident cases, a "run-in" period of 5 years (from 1996-97 to 2000-01) was used to exclude prevalent cases. Crude prevalence and incidence rates were calculated annually between 2001-02 and 2015-16. Prevalence and incidence rates standardized to the 2001 age structure of the Quebec population were also calculated. Negative binomial regression was used to test for linear change in standardized incidence rates. Results: In 2015-16, the crude prevalence of diagnosed OP was 15.7%. The prevalence was higher in women (25.0%) than in men (5.6%) and increased with age (45-54y: 2.1%, 55-64y: 9.2%, 65-74y: 23.7%, 75-84y: 38.1%, ≥85y: 50.6%). The age-standardized prevalence increased slightly from 13.8% in 2001-02 to 14.4% in 2011-12, and remained stable afterwards. The age-standardized incidence rate decreased significantly from 19.3 cases per 1,000 adults in 2001-02 to 10.7 cases per 1,000 adults in 2015-16 (p<0.001, Figure 1). Average annual percent changes were -4.8 (95% CI -5.2, -4.4) and -1.9 (95% CI -2.3, -1.5) in women and men, respectively. Conclusion: In Quebec, the age-standardized prevalence of diagnosed OP remains around 14% since 2011-12. A significant decrease in the rate of individuals newly diagnosed with OP has been observed between 2001-02 and 2015-16. This may be attributable to a decrease in the management of OP, fracture rate, use of OP diagnosis codes, prescriptions for an OP medication, or OP risk factors over time.

AAPC: Average annual percent change

AAPC (95% CI) = -4.8 (-5.2; -4.4)

AAPC (95% CI) = -1.9 (-2.3; -1.5)

SUN-0763

Social deprivation is associated with poor health outcomes following hospital admission for hip fracture in England Arti Gauvri Bhimjiyani*[1], Jenny Neuburger[2], Yoav Ben-Shlomo[3], Celia L Gregson[1]. [1]Translational Health Sciences, Bristol Medical School, University of Bristol, United Kingdom, [2]Department of Health Services Research and Policy, London School of Hygiene and Tropical Medicine, United Kingdom, [3]Population Health Sciences, Bristol Medical School, University of Bristol, United Kingdom

Social deprivation predicts a range of adverse health outcomes; however, its impact post hip fracture is not established. We examined the effect of area-level social deprivation on outcomes after hospital admissions for hip fracture in England.We used English Hospital Episodes Statistics linked to the National Hip Fracture Database (04/2011-03/2015) and National Statistics mortality data to identify patients admitted with hip fracture aged 60+ years. Deprivation was measured by quintiles of the Index of Multiple Deprivation; Q1-least deprived; Q5-most deprived. Charlson score quantified comorbidities. Associations with 30-day mortality and emergency readmissions were assessed by logistic regression, adjusted for age and gender. Mean length of stay (LOS) in acute plus rehabilitation hospitals ('superspell') and total bed occupancy within 1-year post-fracture were calculated; their associations with deprivation were estimated using linear regression.We identified 218,907 hospital admissions with an index hip fracture over 4 years. Mean [SD] age 82.8 [8.4] years; 72.6% female, 75.9% had ≥1 comorbidity. Overall 30-day mortality was 7.8% (n=17,072/218,907). Among survivors, mean superspell was 23.6 [21.6] days; 15.6% were re-admitted within 30 days (n=31,072/199,564), mean 1-year bed occupancy 33.4 [32.7] days.Greater deprivation was associated with higher 30-day mortality (Q5: 8.4% [n=3,229/38,434] vs. Q1: 7.2% [n=3,143/43,866]), age/gender-adjusted OR 1.32 (95% CI [1.25,1.39], p<0.001); partly explained by further comorbidity adjustment (OR 1.18 [1.12,1.25], p<0.001).Among survivors, age/gender-adjusted mean superspell was longer in those most deprived (Q5: 18.5 95% CI [17.6,19.4] days, Q1: 16.7 [16.1,17.2], p<0.001). 30-day readmissions were higher in those most deprived 17.5% (Q5: n=6,062/34,693) vs. those least deprived 14.2% (Q1: n=5,744/40,377), age/gender-adjusted OR 1.32 [1.27,1.38], p<0.001; this was not explained by comorbidity (OR 1.24 [1.20,1.29], p<0.001). A similar trend was seen for mean 1-year hospital bed occupancy (Q5: 28.1 [26.8,29.4] days; Q1: 24.8 [24.0,25.6], p<0.001).Greater deprivation predicts reduced 30-day survival and, among survivors, longer hospital stays and a greater need to be re-admitted once discharged. Whilst deprivation-related comorbidity explains part of these apparent health inequalities, the role of other patient factors and the configuration of hospital services remains to be determined.

SUN-0764

Performance of FRAX and FRAX-Based Treatment Thresholds in Women aged 40 and Older: The Manitoba BMD Registry Carolyn Crandall*[1], John Schousboe[2], Suzanne Morin[3], Lisa Lix[4], William Leslie[4]. [1]University of California, Los Angeles, United States, [2]Park Nicollet Institute, United States, [3]McGill University, Canada, [4]University of Manitoba, Canada

Objective. To examine among women aged ≥40 years the performance of the Fracture Risk Assessment Tool (FRAX) and FRAX-based osteoporosis treatment thresholds under

the U.S. National Osteoporosis Foundation (NOF) and U.K. National Osteoporosis Guideline Group (NOGG) guidelines.Methods. We used registry data for all women aged ≥40 years in Manitoba, Canada with baseline bone mineral density (BMD) testing (n = 54,459). The Canadian FRAX was used to calculate 10-year risk of hip or major osteoporotic fracture (MOF). Incident MOF, hip fracture, and any fracture (excluding head, neck, hand, foot, and ankle) were assessed from population-based health services data (mean follow-up 10.5 years). Age-stratified hazard ratios (HR) were estimated from Cox regression models, with interaction terms for age decade. We assessed the sensitivity, specificity, positive predictive value (PPV), and number needed to treat (NNT) to prevent a fracture (assuming 40% relative risk reduction on Rx) for osteoporosis treatment thresholds under the NOF and NOGG guidelines.Results. Femoral neck T-score and FRAX (with and without BMD) predicted all fracture outcomes at all ages. Age interactions, where detected, were modest. There was good calibration in FRAX-predicted vs observed 10-year MOF and hip fracture probability. The sensitivity (PPV) for incident MOF was: 25.7% (24.0%) for femoral neck T-score ≤ -2.5, 20.3% (26.3%) for FRAX-predicted 10-year MOF risk ≥ 20% (NOF threshold), 27.3% (22.0%) for FRAX-predicted 10-year MOF risk ≥ age-dependent cutoff (NOGG threshold), 59.4% (19.0%) for the full NOF algorithm, and 28.5% (18.4%) for the full NOGG algorithm. The sensitivity of the strategies for incident MOF varied markedly by age, often being lowest in women 40-49 years-old (range 0.0%- 26.3%). The strategies with the lowest NNT for MOF were femoral neck BMD T-score ≤-2.5 and FRAX-predicted risk of MOF ≥20% (NNT = 10 overall, maximum NNT = 15 age 40-49 years-old, minimum NNT = 9 age 80+ years-old). NNTs were similar for the full NOF (=13 overall) and full NOGG (=14 overall) guidelines.Conclusion. The gradient of risk for fracture prediction from femoral neck T-score and FRAX (with and without BMD) as continuous measures was strong across the age spectrum. The sensitivity and PPV of the strategies examined based upon dichotomous cutoffs were low, especially among women aged 40-49 years where the incidence rates are the lowest, but the NNT is reasonable at all ages.

Table. Association of Fracture Risk Assessment Tool (FRAX)*-Predicted Risk with Incident Fracture, Stratified by Age Group[†]

Incident Major Osteoporotic Fracture (MOF)	FRAX MOF risk ≥ 20%								
	Incidence	HR per SD (CI)	Sens.	Spec.	PPV	NPV	Acc	NNS	NNT (PPV, 40% RRR)
Age 40-49 (N=5324)	5.4%	1.67 (1.44-1.95)	0.0%	99.9%	0.0%	94.4%	94.2%	761	Calculation not possible
Age 50-59 (N=15,466)	7.1%	2.06 (1.89-2.23)	1.5%	99.4%	17.5%	92.9%	92.4%	159	14

Increased mortality risk, but no increased subsequent fracture risk following hip fracture in elderly patients with chronic kidney disease Irma Ja De Bruin*[1], Caroline E Wyers[1], Patrick C Souverein[2], Tjeerd P Van Staa[2,3,4], Piet Pm Geusens[5,6], Joop Pw Van Den Bergh[1,6], Frank De Vries[2,5], Johanna H Driessen[2,5]. [1]VieCuri Medical Center, Department of Internal Medicine; Maastricht UMC+, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Internal Medicine, Netherlands, [2]Utrecht University, Utrecht Institute of Pharmaceutical Sciences, Division of Pharmacoepidemiology and Clinical Pharmacology, Netherlands, [3]London School of Hygiene & Tropical Medicine, [4]University of Manchester, Farr Institute for Health Informatics Research, [5]Maastricht UMC+, CAPHRI Care and Public Health Research Institute, Department of Internal Medicine subdivision of Rheumatology, Netherlands, [6]Hasselt University, Netherlands

Purpose: To evaluate the association between chronic kidney disease (CKD, stages G3-G5 versus G1-G2) and the risk of a subsequent non-hip major fragility fracture (humerus, distal forearm and vertebral fracture) following a hip fracture.Methods: A retrospective cohort study using data from the UK Clinical Practice Research Datalink (CPRD) (2004-2016) was conducted. All patients with a first hip fracture, aged 50 years or older were included. Kidney function (eGFR) was assessed time-dependently and the eGFR was used to determine the KDIGO CKD stage. Cox proportional hazard analyses adjusted for lifestyle variables, comorbidities and concomitant drug use, were used to estimate cause specific (cs)-hazard ratio (HR) of the association between kidney function (CKD G3-5 vs CKD G1-2) and subsequent non-hip major fragility fracture risk. CKD G3-5 was further stratified by CKD 3, 4 and 5 stages. To explore the potential competing risk of mortality, a cause-specific HR for

mortality was estimated. In addition, the cumulative incidence of different outcomes after the initial hip fracture was calculated.Results: We included 37,820 patients with a first hip fracture during the study period. Patients with CKD stage G1-G2 were younger than patients with CKD stage G3-G5 (79.2 vs. 84.2 years). CKD G3-G5 was not associated with risk of subsequent major fragility fractures (adjusted cs-HR: 0.89, 95%CI 0.79-1.00). Stratification of kidney function by CKD resulted in a cs-HR of 0.89 (95%CI 0.79-1.01) for CKD G3, 0.88 (95%CI 0.64-1.20) for CKD G4 and 0.56 (95%CI 0.20-1.56) for CKD G5. CKD G3-G5 was associated with a small increased risk of mortality (cs-HR 1.05 (95%CI 1.01-1.09)). Stratification by CKD stage resulted in a 1.5 and 3-fold increased mortality risk for CKD G4 and CKD G5, respectively (cs-HR CKD G4 1.50, 95%CI 1.38-1.62; CKD G5 2.93, 95% CI 2.48-3.46). The cumulative incidence of fracture and mortality outcomes after the initial hip fracture is shown in figure 1.Conclusion: This study did not demonstrate an increased risk of subsequent fractures following a hip fracture in patients with CKD G3-G5 compared to CKD G1-2. However, mortality risk was increased in patients with CKD G4 and G5 as compared to CKD G1-2. The higher mortality risk may, as competing risk, explain our main finding of no increased subsequent fracture risk with CKD stage 3-5.

Long-term impact of body mass index in childhood on adult bone mineral density Hongbo Dong*, Yinkun Yan, Junting Liu, Dongqing Hou, Jie Mi. Capital Institute of Pediatrics, China

OBJECTIVES This study aimed to examine the association of long-term burden and trajectory patterns of childhood body mass index (BMI) with adult bone mineral density (BMD) and the mediation effet of adult BMI on these assoication.METHODS The longitudinal study consisited of 397 adults (54.4% males), who had been examined for BMI 4-8 times during childhood (6-19 years) and BMD in adulthood (29-37 years). Adult BMD was assessed via dual-energy x-ray absorptiometry. Childhood BMI growth cruves were constructed using a random-effects mixed model. The area under the curve (AUC) was calculated to represent the long-term burden of childhood BMI.RESULTS From age around 10-years onwards, men with normal BMD had significantly higher BMI than those with low BMD at femoral neck, and similar trend was observed for spine BMD in females. In both sexes, childhood BMI measures (BMI at the first exam and total AUC) were all significantly and positively associated with adult BMD of whole body, spine, and femoral neck. Mediation effects of adult BMI were significant for the association of childhood BMI measures with adult femoral neck BMD (63.4% to 87.0%) in both sexes and childhood BMI at the last exam with adult spine BMD (74.6%) in males, but not significant for childhood BMI measures and whole body BMD in either sex.CONCLUSIONS These findings suggest that the impact of body weight on adult BMD originated partly from childhood, which differs by sex and skeletal sites. Maintaining an adequate weight from childhood is important for achievement of higher subsequent bone density.KEYWORDS child, bone density, body mass index, longitudinal study

The distribution of prevalent and short-term incident vertebral fractures on chest CT scans according to fracture severity in smokers with and without COPD Johanna Driessen*[1], Mayke Van Dort[2], Piet Geusens[3], Frank De Vries[4,5], Emiel Wouters[6], Joop Van Den Bergh[7,8]. [1]CAPHRI Care and Public Health Research Institute, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Clinical Pharmacy and Toxicology, Maastricht University Medical Centre+ (MUMC+), Netherlands, [2]NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), Netherlands, [3]Department of Internal Medicine, Rheumatology, Maastricht University Medical Centre+ (MUMC+), the Netherlands, Netherlands, [4]Department of Clinical Pharmacy and Toxicology, Maastricht University Medical Centre+ (MUMC+), Netherlands, [5]CAPHRI Care and Public Health Research Institute, Netherlands, [6]Department of Respiratory Diseases, Maastricht University Medical Centre+ (MUMC+), the Netherlands, Netherlands, [7]Department of Internal Medicine, VieCuri Medical Centre, Venlo, Netherlands, [8]Department of Internal Medicine, NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), Netherlands

Background: Biomechanical analyses indicate that compressive load is heterogeneous throughout the thoraco-lumbar spine, with maximal loads during daily activities in T7-T8 and T11-L1 (Bruno, 2017). At population level, studies have shown a bimodal spinal distribution of prevalent and incident VFs. However, prevalence and short-term incidence of individual VFs according to both their location and severity has not been reported. Therefore, the aim of this study was to analyse the distribution of prevalent and 3-year incident VFs according to severity on chest CT scans.Methods: The ECLIPSE study included current and former heavy smokers without (n=240) and with chronic obstructive pulmonary disease (COPD) (n=998), mean age 61.3 years, 61% men.VFs were scored according to Genant (grade (Gr) 0, 1, 2 or 3). Vertebrae with Schmörlse nodules, Scheuerman's disease and platyspondyly were excluded. All vertebrae which were evaluable at baseline and at 3 years were included (n=14,974). Incident VFs were defined as a new or a worsening VF. The proportion of VFs at preferential locations versus other locations were compared by McNemer`s test for dependent proportions.Results: Clinical chest CT scans were available at baseline and 3 years for 1238 patients. At patient level, VF prevalence was 20.4% and the 3-year VF incidence was 24.0%. According to the individual vertebrae analysis, we identified 461 (3.1%) prevalent VFs and 473 (3.2%) incident VFs within 3 years. Prevalent VFs (n=239 Gr1, 179 Gr2 and 43 Gr3) showed bimodal distributions over the spine region T1-L1, for each of the VF grades 1-3. Prevalent VFs were preferentially located at T7-T8 and T11-T12. The proportion of prevalent VF fractures located at T7, T8, T11 or T12 was 5.7%, as compared to 1.8% for all other locations (p<0.01).A similar bimodal distribution at T7-8 and T11-12 was found for incident VFs (n=250 Gr1, 179 Gr2 and 44 Gr3) (Figure). The proportion of incident VF fractures located at T7, T8, T11 or T12 was 5.4%, as compared to 2.1% for all other locations (p<0.01).Conclusion: These results indicate that the prevalence and short term incidence of VFs is high in current and former heavy smokers with and without COPD. Prevalent VFs as well as incident VFs, regardless of VF severity, are preferentially located at T7-T8 and T11-T12 on chest CT scans. These regions have been documented to be at highest compressive load during daily activities.

Lower limb muscle force is negatively associated with hip fracture risk in community-dwelling older women April Hartley*[1], Yunhua Luo[2], Andrew Goertzen[3], Kimberly Hannam[1], Ahmed Elhakeem[1], Emma M Clark[1], William D Leslie[4], Jon H Tobias[1]. [1]Bristol Medical School, University of Bristol, United Kingdom, [2]Faculty of Engineering, University of Manitoba, Canada, [3]Department of Radiology, University of Manitoba, Canada, [4]Rady Faculty of Health Sciences, University of Manitoba, Canada

Background: Reduced muscle mass, a hallmark of sarcopenia, is associated with increased hip fracture risk. However, it is less clear whether directly measured lower limb muscle function also relates to hip fracture risk. Dual X-ray Absorptiometry (DXA)-based finite element analysis (FEA) is a novel method designed to determine fracture risk from 2D hip DXA images.Aims: (i) determine whether peak lower limb muscle force and/or power, assessed by Jumping Mechanography (JM), are related to hip bone mineral density (BMD) in older women; (2) establish whether equivalent relationships are seen for risk of hip fracture as determined by FEA.Methods: Community-dwelling women aged 71-88 attended an assessment clinic where total hip BMD, fat and lean mass were assessed by DXA. Fracture risk indices (FRI) at the femoral neck, intertrochanteric and subtrochanteric sites were calculated using FEA of hip DXA images. A two-footed jump was performed to assess lower limb peak muscle power and a one-legged hop used to assess peak muscle force. We analysed cross-sectional associations between total body lean mass (TBLM), peak force and power as exposures, and hip BMD and FRI as outcomes, using multivariable linear regression. Results are shown adjusted for age, height, weight (fat mass for models including TBLM) and comorbidities (self-reported by questionnaire).Results: 266 women had complete JM, hip DXA and covariate data, mean age 76.4 [SD 2.6] years. TBLM was strongly associated with total hip BMD (β=0.31 [0.14, 0.47] p=4x10-4) (β represents an SD change in outcome per SD change in exposure). TBLM was also inversely associated with fracture risk, estimated by FRI, at the femoral neck and intertrochanteric regions (-0.19 [-0.37, -0.01] and -0.13 [-0.23, -0.04] respectively, both p<0.05). Peak muscle force was strongly associated with total hip BMD (0.28 [0.14, 0.41] p=8x10-5). Peak force was also inversely related to FRI estimated at the femoral neck, intertrochanteric and subtrochanteric hip regions (-0.17 [-0.31, -0.03], -0.07 [-0.12, -0.01] and -0.18 [-0.32, -0.04] respectively, all p<0.05). There was some evidence for an inverse association between peak power and intertrochanteric and subtrochanteric FRI, but confidence intervals were wide.Conclusions: Lower limb peak muscle force is inversely related to hip fracture risk, estimated by FEA in older women, supporting the use of leg muscle strengthening exercises to reduce hip fracture risk in this population.

Contribution of Multimorbidity to Post-Fracture Mortality: Result of a Long Term Population Based Study Thao P. Ho-Le*[1], Thach S. Tran[2], Jacqueline R. Center[2,3], John A. Eisman[2,3,4], Tuan V. Nguyen[1,4,5,6]. [1]School of Biomedical Engineering, University of Technology, Sydney, Australia, [2]Bone Biology Division, Garvan Institute of Medical Research, Australia, [3]St Vincent Clinical School, UNSW Australia, Australia, [4]School of Medicine, Notre Dame University, Australia, [5]Bone Biology Division, lia, Australia, [6]School of Public Health and Community Medicine, UNSW Australia, Australia

Aims: Osteoporosis frequently coexists with other chronic diseases. Multimorbidity is defined as the co-occurrence of two or more chronic diseases. The present study sought to define the pattern of multimorbidity and its impact on the risk of post-fracture mortality. Methods: This is a prospective, population-based study that involved 890 women and 244 men with a fracture. Health status of the individuals had been monitored for over 20 years. Osteoporosis was defined as femoral neck bone mineral density T-score ≤ -2.5. Seven broad diseases were considered: osteoarthritis, cardiovascular disease, type II diabetes, cancer, rheumatoid arthritis, neurological illnesses, and mental illnesses. The diseases were self-report ascertained at baseline. A latent class analysis (LCA) was used to define the pattern of co-occurrence of diseases within an individual. The relationship between the LCA-derived clusters of diseases and post-fracture mortality was assessed by the Cox's proportional hazard model.Results: During the follow-up period (1989 to 2009), the mortality rate for men was 54%, approximately two-fold higher than that for women (30%). The prevalence of multimorbidity was 38% in women and 35% in men. Multimorbidity was associated with increased risk of post-fracture mortality (HR 2.4, 95%CI: 1.68-3.38). The LCA identified 3 clusters of patients: low multimorbidity group (68%), moderate multimorbidity group (20%), and high multimorbidity group (12%). The 5-year risk of post-fracture mortality among the high multimorbidity group was 45%, which was 1.64-fold higher than the moderate multimorbidity group, and 2.3-fold higher than the low multimorbidity group. The increased risk of death was mainly seen among individuals with cardiovascular disease (HR 1.6, 95%CI: 1.2-2.3), type II diabetes (HR 1.8, 95%CI: 1.0-3.2), rheumatoid arthritis (HR 1.8, 95%CI: 1.1-2.9) and neurological illnesses (HR 2.74, 95%CI: 1.2-6.3). The proportion of post-fracture mortality attributable to multimorbidity in women and men was 33% and 28%, respectively.Conclusions: These prospective data suggest that more than one-third of men and women with a fracture have multimorbidity, and that the coexistence of morbidities account for one-third of post-fracture mortality. The data emphasize the need for a wholistic management of patients with a fracture.

Decreased Physical Health-Related Quality of Life – a Persisting State for Older Women Living with Clinical Vertebral Fracture Lisa Johansson*[1], Daniel Sundh[1], Hilda Svensson[2], Jon Karlsson[3], Lars-Eric Olsson[2], Dan Mellstrom[1], Mattias Lorentzon[1]. [1]Geriatric Medicine, Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, University of Gothenburg, Gothenburg, Sweden, [2]Institute of Health and Care Sciences/ Centre for Person-Centred Care (GPCC) Sahlgrenska academy Gothenburg university, Sweden, [3]Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden

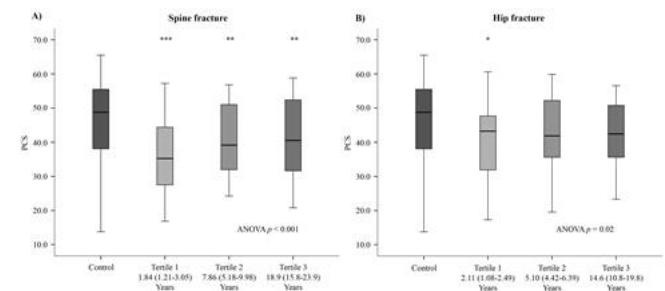
IntroductionVertebral fractures are often associated with back pain and reduced physical function, which might result in isolation and depression. As a result, women with vertebral fractures often have lower health-related quality of life (HRQoL), but during what time frame the decrease lingers is unclear. Therefore, the aim of this study was to investigate if clinical vertebral fracture was associated with lower HRQoL and to determine whether the association remained over time.MethodsVertebral fracture assessment (VFA) was performed using dual-energy X-ray absorptiometry. Data regarding prior fractures, medications, medical history, and physical activity was collected using a questionnaire. Self-rated physical HRQoL was assessed using the 12-Item Short-Form Health Survey (SF-12). Women with clinical vertebral fractures were divided into tertiles according to time since fracture and their HRQoL was compared with non-fractured women.ResultsIn a population-based study of 3028 women aged 77.8±1.63 (mean±SD), a total of 130 (4.3%) women reported at least one clinical vertebral fracture. Women with a clinical vertebral fracture, divided into tertiles (T1-T3) depending on time since the fracture occurred, had lower physical HRQoL (T1: 36.3±10.8; T2: 41.0±9.94; and T3:41.6±11.4) than women without fracture (46.2±10.6; p<0.001) (Figure 1A), whereas no differences were seen for mental HRQoL. Physical HRQoL in women with hip fracture showed a similar pattern (T1: 40.7±11.8; T2: 42.7±11.6; T3:42.4±10.6) compared to women without fracture (46.2±10.6; p=0.02) (Figure 1B). Using linear regression analysis, clinical vertebral fracture was associated with reduced physical HRQoL for up to 18.9 years, independently of covariates (age, height, weight, smoking, prior stroke, mental HRQoL, and grip strength).ConclusionClinical vertebral fracture was associated with lower self-rated physical HRQoL, for up to 18.9 years after time of fracture independently of covariates. Our results indicate that clinical vertebral fracture affects physical HRQoL, with a persisting decline which resembles the reduction following hip fracture, indicating that vertebral fracture patients deserve the same attention and rehabilitation as hip fracture patients.


Figure 1 Physical component summary (PCS), obtained from the SF12 questionnaire. Comparison between controls (without any fracture) and women with a clinical vertebral fracture (A) and hip fracture (B) according to tertiles of time since fracture. Differences were compared with ANOVA and following post hoc analyses were performed with least significant difference (LSD) and significant levels are presented as: *p<0.05, **p<0.01, ***p<0.001

SUN-0771

Effect of hemoglobin A1c and treatment regimen on fracture risk among older men with diabetes mellitus Richard Lee*[1], Richard Sloane[1], Carl Pieper[1], Cathleen Colon-Emeric[2]. [1]Duke University, United States, [2]Durham VAMC, United States

Introduction: Type 2 diabetes mellitus among older men has been associated with increased bone mineral density, but paradoxically increased fracture risk. Prior studies have not examined the relative contribution of and interaction between treatment regimen and glycemic control.Methods: Retrospective study of male Veterans age ≥65 years who received primary care in the Veterans Health Administration (VHA) from 2000 to 2010, using administrative data from all 146 VHA medical centers, linked to Medicare fee-for-service data. Sample was limited to those with diagnosis of diabetes and baseline Hemoglobin A1c (HbA1c) value. Prescription data for diabetes medications were obtained from pharmacy database 1 year prior to baseline HbA1c value. Hazard ratios were calculated, using competing risk hazards models, adjusted for fracture risk factors including age, race/ethnicity, BMI, and medical comorbidities including alcohol and tobacco use, rheumatoid arthritis, corticosteroid use, cardiovascular disease, chronic kidney disease, and peripheral neuropathy. Results: During the study period, there were 900,402 males with a diagnosis of diabetes, of whom 652,901 (72.5%) had a baseline HbA1c value. After adjusting for fracture risk factors, the risk of any clinical fracture associated with HbA1c < 6.5% was 1.08 (95%CI: 1.06–1.11), compared to those with HbA1c of 7.5-8.5%. Fracture risk was not increased among those with A1c ≥ 8.5%, nor among those with A1c 6.5-7.5%. Independent of HbA1c level, use of insulin was associated with greater risk of fracture (HR 1.10, 95% CI: 1.07–1.12). There was significant interaction between insulin use and HbA1c level, (P < 0.001), such that those using insulin with HbA1c < 6.5% had HR 1.23 and those with HbA1c 6.5-7.5% had HR 1.15. Metformin use was associated with decreased fracture risk (HR 0.88, 95% CI: 0.87–0.90). Conclusions: Among older men with diabetes, those with HbA1c lower than 6.5% are at increased risk for clinical fracture. Insulin use is associated with higher fracture risk, especially among those with tight glycemic control. Our findings demonstrate the importance of the treatment regimen and avoiding hypoglycemia for fracture prevention in older men with diabetes.

Non-trauma rib fracture in the elderly: risk factors and mortality consequence Ha Mai*, Thach Tran, Thuy Pham, Jacqueline Center, John Eisman, Tuan Nguyen. Garvan institute of medical research, Australia

Objectives: To define the epidemiology of rib fractures and the association between rib fracture and mortality in men and women aged 60 years and older. Methods: The study was part of the Dubbo Osteoporosis Epidemiology Study (DOES) which was designed as a population-based prospective study. The study consisted of 2.041 participants (1.132 women and 909 men) whose average age was ~70 years at baseline. The incidence of minimal trauma rib fractures was ascertained from X-ray reports and clinical details during the follow-up (1989–2016). Femoral neck bone mineral density (FNBMD) was measured by dual-energy X-ray absorptiometry (GE-LUNAR Prodigy). Data on anthropometry, clinical history and lifestyle were ascertained by a structured questionnaire at baseline and subsequent visits. The association between risk factor and rib fracture was analyzed by Cox's proportional hazards model, and population attributable risk was assessed to determine the contribution of risk factors to fracture. The time-dependent Cox's model was used to access the relationship between rib fracture and mortality.Results: Fifty nine men and 78 women sustained a rib fracture, making the cumulative incidence ~7%. Each 5-year advancing age was associated with a 37% and 47% (P<0.001) increase in the hazard of fracture in men and women, respectively. In addition, lower FNBMD was associated with increased risk of fracture in

men (HR 1.9; 95% CI, 1.4 to 2.6) and women (HR 2.1; 95% CI, 1.6 to 2.8). A prior fracture increased the risk of fracture by 8.5-fold (95%CI, 3.6 to 20.1) in men and 3.8-fold (95%CI, 1.5 to 9.6) in women. Approximately 45% and 50% of rib fractures in men and women, respectively, were attributable to advancing age and osteoporosis. Rib fracture was associated with an increased risk of death in the first 2.5 years post-fracture, after adjusting for age and co-morbidities. The risk of death was highest within the first 12 months (HR 7.75; 95%CI 2.7 to 22.5 in men and HR 4.9; 95%CI 2.0 to 11.8 in women).Conclusions: Advancing age, reduced bone mineral density, prior fall (in men) and prior fracture were risk factors for rib fracture, and rib fracture signaled an increased mortality risk.
Figure 1: Hazard ratio of mortality associated with rib fracture by time, adjusted for age and co-morbidity in men (left panel) and women (right panel)

SUN-0773

Is Type II Diabetes a Clinical Risk Factor for Atypical Femur Fractures? (The View from South Texas) Kenneth Mensch*[1], Roberto Fajardo[2], Todd Bredbenner[3], Khang Dang[1], Rose Huynh[1], Sean Catlett[1], Mtchell Hymowitz[1], Patrick Ryan[1], Ventrice Shillingford-Cole[1], Sara Spreicher[1]. [1]UT Health San Antonio, United States, [2]Univeristy of Incarnate Word School of Osteopathic Medicine, United States, [3]University of Colorado -Colorado Springs, United States

Although clinical guidelines report that bisphosphonate (BP) use and type 2 diabetes (T2D) are independent risk factors for atypical femur fractures (AFFs), there has been little evidence to support a relationship between T2D and atypical fractures. The objective of this study is to determine the relationship between T2D, as well as use of BPs, and AFFs in a clinical sample of femur fracture patients from South Texas, where the T2D prevalence is over 25% among elderly residents.Methods: We performed a retrospective analyses of University Hospital patients (aged 50-89) presenting with a closed femur fracture during 2007 - 2017. Trauma cases were excluded. Demographic data, fracture dates, bisphosphonate and glucocorticoid use, menopausal and diabetic status were recorded. Fracture type, cortical thickness, and AFF status were determined by two physicians using the ASBMR Task Force Case Definition. Matched case-control conditional logistic regressions were used to calculate odds ratios and 95% confidence intervals of risk factors for Subtrochanteric/ Femoral Shaft (ST/FS) fractures matched to intertrochanteric fracture controls. A binary logistic regression was used to identify risk factors for typical and atypical ST/FS fractures. Results: The sample size equaled 236 subjects, 19.5% of the cases were ST/FS and 36.9% intertrochanteric fractures. In this sample, 43% of the subjects were diabetic and 10% had a history of bisphosphonate use. Seven AFFs were identified among the ST/FS cases; all cases were female. The prevalence of AFFs in the entire sample was 3.0% and 15.2% among all ST/FS fractures. Results indicate minor differences between ST/FS and matched intertrochanteric fractures. Diabetes trended strongly in the AFF group (71.4%) compared to the typical ST/FS fracture group (40.5%, p=0.220). BP use also trended higher among the AFF cases (42.9%) compared to typical ST/FS cases (8.1%, p=0.146). Cortical thickness trended higher in the ST/FS group (p=0.064) compared to the IT group but was similar in all ST/FS cases (p=0.928).Discussion: The prevalence of AFFs (3%) in our study was over two-fold greater than previously reported by Guisti et al. We also found strong trends in our results: all AFFs were female, and bisphosphonates and diabetes were independently associated with AFFs, although significant differences have not been observed yet. It is still unclear whether AFFs are associated with BP use or diabetes and merit further study.

Evidence of a Causal Effect of Estradiol on Fracture Risk in Men Maria
Nethander*[1,2], Liesbeth Vandenput[1], Anna Eriksson[1], Sara Windahl[1], Thomas
Funck-Brentano[1], Claes Ohlsson[1]. [1]Centre for Bone and Arthritis Research,
Department of Internal Medicine and Clinical Nutrition, Institute of Medicine,
Sahlgrenska Academy, University of Gothenburg, Sweden, [2]Bioinformatics Core
Facility, Sahlgrenska Academy, University of Gothenburg, Sweden

Observational association studies indicate that serum estradiol (E2) is more strongly
associated with bone mineral density (BMD) than serum testosterone (T) while both E2 and
T associate with fracture risk in men. The possible causal effect of E2 and/or T levels on
fracture risk in men is unknown. It is possible that endocrine therapies for prostate cancer
may have differential skeletal side-effects depending on whether they affect both E2 and T
levels or only androgen receptor action.To evaluate the causal effect of E2 and T primarily on
fracture risk but also on estimated BMD (eBMD) of the heel using ultrasound, a Mendelian
Randomization (MR) approach was undertaken using individual-level data of genotypes,
eBMD, fractures (n=17,650), and relevant covariates from 175,583 unrelated men (mean age
57 ± 7 years) of European origin. This research has been conducted using the UK Biobank
Resource. The genetic instruments for serum E2 and T were taken from the most recent large
scale GWAS meta-analyses on these hormones in men. MR analyses demonstrated a causal
effect of serum E2 on eBMD and fracture risk. A 1 SD (or 9.6 pg/ml) genetically instrument-
ed decrease in serum E2 was associated with a 0.38 SD decrease in eBMD (p-value 9.7 x
10-74) and an increased risk of any fracture (OR 1.35, 95% CI, 1.18-1.55), non-vertebral
major osteoporosis fractures (OR 1.75, 95% CI, 1.35-2.27) and wrist fractures (OR 2.27,
95% CI, 1.62-3.16) (see figure). These causal effects of serum E2 on fracture risk were
robust in sensitivity analyses and remained unchanged in stratified analyses for age (divid-
ed by median age), BMI (overweight yes/no), eBMD (divided by median), smoking status
(current smoking yes/no), and physical activity (vigorous activity yes/no). MR analyses re-
vealed no evidence of a causal effect of T levels on fracture risk.In this study, we provide the
first evidence of a robust causal effect of serum E2, but not T, on fracture risk in men. Our
findings may have direct clinical implications for prostate cancer patients when comparing
the possible skeletal side-effects of endocrine treatments affecting both E2 and T levels with
those only modulating androgen receptor action.

Estimated causal effect of estradiol on fracture risk. Odds ratios for fracture risk are given
per SD decrease in estradiol (95% confidence intervals). Total numbers of subjects/fracture
cases are given within brackets.

**Mechanisms of Injury Associated with Non-Traumatic Vertebral Fractures
in Older Adults** Sara E. Rudolph*[1], Signe Caksa[1], Dennis E. Anderson[2,3], Mary
L. Bouxsein[1,2,3]. [1]Endocrine Unit, Massachusetts General Hospital, United States,
[2]Harvard Medical School, Boston, MA, United States, [3]Center for Advanced
Orthopedic Studies, Beth Israel Deaconess Medical Center, United States

Vertebral fractures (VF) contribute to morbidity and decreased quality of life in older
adults. Few studies have examined the precipitating events leading to VF. To address this
knowledge gap, we determined the mechanism of injury associated with clinical VF by sex
and spinal region. We reviewed medical records of 65 men and 65 women aged ≥60 years
diagnosed with a VF via radiology report in 2013-2017 at Partners HealthCare hospitals.
VF involving pathologic vertebrae, transverse or posterior elements, spinal cord injury, or
a history of spinal surgery with hardware were excluded. Data were extracted regarding
mechanism of injury, medical/lifestyle history and region of VF: upper thoracic (T1-T5),
mid-thoracic (T6-T10), thoracolumbar (T11-L1), or lumbar (L2-L5). Here we report on 159
events involving 228 VF by sex and region of VF. Fractures occurred most commonly in
the thoracolumbar region (42.1%), followed by lumbar (27.0%), and upper and mid-tho-
racic (6.3% each). Men with VF were more likely to have a history of smoking (50.0% vs.
24.7%, p=0.005) and Parkinson's disease (6.8% vs. 0.0%) than women with VF, but lower
prevalence of osteoporosis (14.9% vs 63.5%), chronic back pain (5.4% vs. 31.8%), and hy-

pothyroidism (6.8% vs. 20.0%) (p<0.05 for all). Multiple VF occurred in 28.9% of events,
and concomitant injury in 20.1% of events. The mechanisms of injury were fall from stand-
ing height or less (34.6%), falls on steps or from greater than standing height (8.8%), other
minimal trauma (4.4%), other severe trauma (5.0%), or unknown (47.2%). More men re-
ported falls than women (52.7% vs. 35.3% of events, trending towards significance, p=0.08).
Among reported falls, the direction of the fall was backwards (36.2%), sideways (7.2%),
forwards (7.2%) or unknown (49.3%), and the site of fall impact was buttocks (24.6%), back
(11.6%), head (8.7%), extremity (4.4%) or unknown (50.7%).Thoracolumbar VF were more
likely to have occurred with a backwards fall (42.5%) and with impact on the back or but-
tocks (52.5%) compared to other regions. Consistent with prior reports, our results indicate
that falls contribute to many VF. Falling backwards and impacting the buttocks may be an
important mechanism of injury. However, the mechanisms of injury associated with VF re-
main unknown in about half of cases, warranting further investigation in prospective studies.

**A Preliminary Study of the Association Between Bone Material Properties
and Clinical Risk Factors for Fracture** Pamela Rufus*[1], Kara L Holloway-
Kew[1], Adolfo Diez-Perez[2], Mark A Kotowicz[1], Julie A Pasco[1]. [1]Deakin
University, Australia, [2]Department of Internal Medicine, Hospital del Mar-
IMIM, Autonomous University of Barcelona and CIBERFES, Instituto Carlos
III., Spain

PurposeImpact microindentation is an emerging technique which measures bone ma-
terial strength index (BMSi) in vivo. However, it is unclear how well the technique predicts
bone fragility. The aim of this study was to evaluate the association between BMSi and
clinical risk factors for fracture.MethodsBMSi was measured using the OsteoProbe for the
first 266 men (ages 33-92yr) assessed in the current phase of the Geelong Osteoporosis
Study, a population-based cohort study in Australia. Associations between BMSi values and
clinical risk factors from the FRAX were identified using Pearson's correlation for continu-
ous variables and 2-sample t-tests for categorical variables. Risk factors included: BMD at
the femoral neck, age, height, weight, prior fracture, parental hip fracture, smoking, alcohol
consumption, glucocorticoid use, rheumatoid arthritis and secondary osteoporosis. Multiple
regression models were used to determine whether identified differences in BMSi were in-
dependent of other factors.ResultsThere were 26(9.9%) men with prior fracture, 31(11.7%)
with parental hip fracture, 20(7.6%) smokers, 4(1.5%) glucocorticoids users, 7(2.7%) with
rheumatoid arthritis, 3(1.1%) with secondary osteoporosis and 133(50%) alcohol consum-
ers. Mean (±SD) for BMD, age, weight and height were 0.967±0.122g/cm2, 63.7±12.5yr,
81.3±10.9kg and 174.3±6.8cm respectively. No correlations were detected between BMSi
and BMD (r=0.001, p=0.99), age (r=-0.082, p=0.18), weight (r=-0.051, p=0.18) and height
(r=0.083, p=0.18). Mean BMSi for men with and without risk factors were: prior fracture
(80.5±5.5 vs 83.1±5.6, p=0.02); parental hip fracture (81.8±5.1 vs 83.0±5.7, p=0.25); smok-
ing (83.7±5.5 vs 82.8±5.7, p=0.41); alcohol consumption (82.8±5.7 vs 82.9±5.7, p=0.95).
The lower BMSi for men with prior fracture persisted after adjustment for BMD, age, weight
and height (p=0.02). The numbers of glucocorticoid users, and those with rheumatoid arthri-
tis or secondary osteoporosis were too small for further analyses.ConclusionsWith the ex-
ception of smoking, mean BMSi values were lower in the presence of risk factors; however,
this difference was significant only for prior fracture. We acknowledge that small numbers
may have limited our ability to detect differences in BMSi and further work is in progress.
Taken together, these data support the notion that impact microindentation may be a useful
technique for identifying men with bone fragility.

Urban-Rural Differences In Hip Fracture Mortality. A NOREPOS Study

Siri Marie Solbakken*[1], Jeanette H. Magnus[2], Haakon E. Meyer[1,3], Anne Johanne Søgaard[4], Grethe S. Tell[5,6], Nina Emaus[7], Kristin Holvik[4], Siri Forsmo[8], Clara G. Gjesdal[9], Berit Schei[10,11], Peter Vestergaard[12], Tone K. Omsland[1]. Purpose: To study urban-rural differences in mortality 30 days and 1 year post hip fracture, and to explore whether possible differences were associated with level of education. Methods: The study was based on the NOREPOS hip fracture database (NORHip) using hip fractures sustained during 2002-2013. The first registered hip fracture was included in the study. Dates on death and emigration were obtained from the National Registry. Information on education and municipality of residence was obtained from the 2001 Population and Housing Census, Statistics Norway. The degree of urbanization was based on the proportion of inhabitants living in densely populated areas (rural: <1/3, semi-rural: 1/3-2/3 and urban: >2/3). Mortality in hip fracture patients living in urban and semi-rural municipalities was compared to mortality in patients living in rural municipalities using a negative binomial model. Analyses on 30-day mortality and 1-year mortality were adjusted for age, and analyses of 1-year mortality were additionally adjusted for education. In the current abstract we have chosen to focus on differences between rural and urban areas only.Results: In 27 748 male and 65 527 female hip fracture patients aged 50-100 years there was no statistically significant urban-rural difference in 30-day hip fracture mortality (incidence rate ratio (IRR) 1.00 (95% CI 0.84, 1.18) in men and 1.03 (95% CI 0.88, 1.22) in women). Among women, 1-year mortality was higher in hip fracture patients living in urban compared to rural municipalities (IRR 1.16 (95% CI 1.01, 1.32)), with similar results in men (IRR 1.15, (95% CI 0.98, 1.35)). Differences in 1-year mortality were even more pronounced when adjusting for education (IRR 1.24, (95% CI 1.05, 1.45) in men and 1.21 (95% CI 1.06, 1.37) in women). Conclusions: One-year post hip fracture mortality was 16% higher in women in urban compared to rural municipalities, and similar estimates were found in men. There were no significant differences in 30-day mortality, suggesting that the immediate post-fracture quality of healthcare does not differ substantially between urban and rural areas. On the other hand, the differences in 1-year mortality could possibly be explained by inequalities in follow-up health care services or by differences in general health status between urban and rural hip fracture patients, but this requires further investigations.

SUN-0779

Factors associated with delayed wound healing longer than 8 weeks after tooth extraction in Japanese patients >60 years of age Akira Taguchi*[1], Mikio Kamimura[2], Shigeharu Uchiyama[3], Hiroyuki Kato[4]. [1]Department of Oral and Maxillofacial Radiology, School of Dentistry, Matsumoto Dental University, Japan, [2]Center for Osteoporosis and Spinal Disorders, Kamimura Orthopedic Clinic, Japan, [3]Department of Orthopedic Surgery, Okaya City Hospital, Japan, [4]Department of Orthopedic Surgery, Shinshu University School of Medicine, Japan

Little is known about whether osteoporosis, use of antiresorptive medication, or duration before tooth extraction is a main risk factor for osteonecrosis of the jaw. We evaluated whether use of bisphosphonate (BP) and/or denosumab (Dmab), self-reported kyphosis, or duration before tooth extraction were associated with an incidence in delayed wound healing beyond 8 weeks after tooth extraction during the past year in Japanese men and women 60 years of age and older. Among the 586 patients who responded to the structured questionnaire survey, 426 patients (151 men and 275 women) aged 60-96 years participated in this study. Subjects who had waited >2 months for tooth extraction had a significantly higher risk of delayed wound healing compared with those whose tooth was extracted within 1 month (Odds ratio [OR] 7.23; 95% confidence interval [CI] 2.19–23.85). The presence of self-reported kyphosis was significantly associated with an increased risk of delayed wound healing (OR 5.08; 95%CI 1.11–23.32). BP and/or Dmab use was not significantly associated with delayed wound healing (p=0.17). A long waiting time before tooth extraction

and self-reported kyphosis but not use of antiresorptive medication may be risk factors for delayed wound healing beyond 8 weeks after extraction.

Prevalence of Morphometric Vertebral Fractures Does Not Differ in Patients With and Without Clinical Fractures in a Fracture Liaison Service Open Model Francisco Torres-Naranjo*[1], Alejandro Gaytán-González [1], Roberto González-Mendoza[3], Noé Albino González-Gallegos[4], Pilar De La Peña-Rodríguez[5], Hugo Gutiérrez-Hermosillo[6], Pedro García-Hernández[7], Claudia Flores-Moreno[7], Jorge Alberto Morales-Torres[8], Juan López-Taylor[9]. [1]Centro de Investigación Ósea, Universidad de Guadalajara., Mexico, [3]Instituto de Ciencias Aplicadas a la Actividad Física y del Deporte, Universidad de Guadalajara, Mexico, [4]Departamento de Bienestar y Desarrollo Sustentable, Centro Universitario del Norte, Universidad de Guadalajara, Colotlán, Mexico, [5]Servicios Médicos De la Peña, Mexico, [6]Universidad de Guanajuato Hospital Aranda de la Parra, Mexico, [7]Endocrinología/Centro de Osteoporosis, Hospital Universitario de Monterrey, Mexico, [8]Hospital Aranda de la Parra y CIMOVA, Mexico, [9]Instituto de Ciencias Aplicadas a la Actividad Física y del Deporte, Mexico

Vertebral fractures are associated with a high risk of new vertebral and non-vertebral fractures and with increased morbidity and mortality. Fracture Liaison Service (FLS), as proposed by the International Osteoporosis Foundation (IOF), focuses in clinical vertebral and non-vertebral fractures as trigger for the search of radiographic vertebral fractures. Since vertebral fractures are generally asymptomatic and occur early in the course of the disease, the lack of a systematic approach for the early detection of morphometric vertebral fractures (MVF) in patients without clinical fractures can lead to a large number of patients with vertebral fractures being undiagnosed.Purpose:To compare the prevalence of MVF in patients with and without clinical fractures at a center with a FLS open model.Methods:From August to December of 2017, 126 Mexican patients aged 50 to 80 years visited our osteoporosis center, 35 patients with clinical fracture where evaluated according to the IOF Capture the Fracture Program Best Practice Framework, and 91 patients with low bone mineral density (BMD) and without clinical fracture were evaluated at primary prevention unit (PPU). For detection of vertebral fractures, a vertebral morphometry was performed in all patients utilizing the High Definition Instant Vertebral Assessment (Hologic) on images obtained from DXA scans. MVF were defined according the Genant's semiquantitative method. For analysis, sample was stratified in decenniums. We compared the prevalence of MVF and BMD at three sites between groups using X2 and ANCOVA, respectively, both with a significant level of p<0.05.Results:The overall prevalence of MVF was of 46.8% (IC95% 38.0 − 55.6). For the FLS group we observed a prevalence of 51.4% (IC95% 34.0 – 68.9), and 45.1% (IC95% 34.7 – 55.5) for the PPU group. The prevalence per decennium was extended from 18.4% to 66.7% in both groups. No significant differences were observed in prevalence between groups (Table 1). There were significant differences in BMD between the patients with and without MVF. We observed significantly lower BMD at lumbar spine, total hip and femoral neck in patients with MVF.Conclusions:Prevalence of MVF were similar independently of presence or absence of clinical fracture at the moment of initial evaluation. Our findings suggest that evaluating for vertebral fracture is necessary in patients with low BMD with or without clinical fractures at the moment of initial evaluation.

Age		FLS		PPU		p
		n	%	n	%	
50-60	(n = 45)	7	28.6	38	18.4	0.28
60-70	(n = 53)	16	50.0	37	64.9	0.16
>70	(n = 28)	12	66.7	16	62.5	0.8
Total	(n = 126)	35	51.4	91	45.1	0.26

FLS= Fracture Liaison Service (patient with clinical fracture)
PPU= Primary Prevention Unit (patients without clinical fracture)

Increase in Bone Mineral Density in Transwomen and Transmen During the First Ten Years of Gender-affirming Hormonal Treatment Chantal Wiepjes*, Christel De Blok, Mariska Vlot, Paul Lips, Renate De Jongh, Martin Den Heijer. VU University Medical Center, Netherlands

Purpose: Concerns about the effects of gender-affirming hormonal treatment (HT) on BMD exist, particularly regarding the decrease in estrogen concentrations in transmen. HT in transgender people affects BMD on short term, but long-term follow-up studies are lacking. Therefore this study aimed to investigate the change in BMD during the first 10 years of HT in transwomen and transmen, in order to determine whether it is necessary to assess BMD during HT.Methods: A retrospective cohort study was performed in adult transgender

people receiving HT at the VU University Medical Center Amsterdam between 1998 and 2015. People were included for analyses if they were HT naïve and had a DXA scan at the start of HT. Follow-up DXA scans performed after 2, 5, or 10 years of HT were used for analyses. The change in Z-scores of the lumbar spine during the first 10 years of HT were analyzed using multilevel analyses. Furthermore, the influence of serum sex hormone concentrations during HT were analyzed.Results: 711 transwomen (median age 35 years, IQR 26-46 years) and 543 transmen (median age 25 years, IQR 21-34) were included for analyses. Prior to the start of HT, 22% of transwomen and 4% of transmen had a low BMD, defined as a Z-score below -2.0. In transwomen, mean baseline Z-score was -0.93 (SD±1.32), which increased with +0.22 (95%CI 0.12–0.32) after 10 years of HT. Transmen had a mean baseline Z-score of +0.01 (SD±1.14), which increased with +0.34 (95%CI 0.23–0.45) after 10 years of HT. In transwomen, higher estradiol concentrations were associated with a larger increase in Z-score, but LH and testosterone concentrations were not associated with a change in Z-score. In transmen, estradiol and testosterone concentrations were not associated with a change in Z-score, but lower LH concentrations were associated with a larger increase in Z-score.Conclusion: This study showed that HT does not have negative effects on BMD in transgender people, which indicates that regularly assessing BMD during HT does not seem necessary. However, as even prior to start of HT a high percentage of low BMD is found, especially in transwomen, evaluation of bone health prior to start of HT may be considered. Higher estradiol concentrations in transwomen and lower LH concentrations in transmen were associated with a larger increase in Z-score, which indicates that adequate hormone substitution and therapy compliance should be stimulated, particularly in those with low baseline Z-scores.

More Frequent and More Sustain Osteoporosis Treatment After Fragility Vertebral Fractures When Introduced Early in Inpatients Than Delayed in Outpatients: A Controlled Study Thierry Chevalley*[1], Herve Spechbach[2], Isabelle Fabreguet[1], Emilie Saule[1], Magaly Hars[1], Jerome Stirnemann[3], Serge Ferrari[1], Rene Rizzoli[1]. [1]Division of Bone Diseases, University Hospitals and Faculty of Medicine, Switzerland, [2]Division of General Internal Medicine, University Hospitals and Faculty of Medicine, Switzerland, [3]Division of General Internal Medicine, University Hospitals of Geneva and Faculty of Medicine, Switzerland

Objective: After a fragility fracture, fracture liaison service (FLS) allow the identification of patients at risk and secondary prevention of fragility fracture. In general, osteoporosis treatment appears more frequent and more adequate when introduced in the hospital phase of FLS than upon recommendation to primary care physician (PCP). Whether this is true regarding prevalent vertebral fractures detected on routine X-rays during hospitalization in general internal medicine for other causes however remains unknown. We tested whether in-hospital management of patients with newly identified vertebral fractures leads to a higher percentage of patients with osteoporosis medication at 3 and 6 months than delayed management by PCP in outpatients.Methods: In-hospital patients over 60 years systematically searched for vertebral fractures by semi-quantitative visual grading on lateral chest and/or spinal radiographs were included either in phase 1 (outpatients care - recommendations to PCP on assessments and osteoporosis medications to be prescribed) or phase 2 (inpatients care - assessments and osteoporosis medication initiated in hospital). The percentage of patients under specific osteoporosis treatment was evaluated by telephone-interview at 3 and 6 months. Results: Patients included as outpatients (84 with fracture out of 407 assessed, 21%; 75.7±7.7 years) and as inpatients (100/524, 19%; 77.8±9.4 years) were similar for gender, mean age, prevalence of vertebral fractures of grade 1 or grade 2 and more, prevalence of prior fractures as well as for FRAX scores and Charlson comorbidity index. A specific osteoporosis medication was more often prescribed in inpatients than in outpatients at 3 (67 vs 19%, p<0.001) and 6 months (69 vs 27%, p<0.001). Percentage of patients still under treatment was higher in inpatients than in outpatients at 3 (52 vs 19%, p<0.001) and 6 months (54 vs 22%, p<0.001). Similar results were observed in patients with grade ≥ 2 vertebral fracture only. Length of stay and destination after discharge were not different between both groups.Conclusion: This controlled study highlights that, in a FLS, early patient assessment and osteoporosis treatment initiation during hospital stay rather than delayed management in outpatients, is a more efficacious strategy of secondary fracture prevention for oldest olds with newly detected vertebral fragility fractures, and that without difference in length of stay.

Self-reported fracture history compared to fracture codes from an electronic health record dataset Maria I. Danila*[1], Amy Mudano[1], Elizabeth Rahn[1], Andrea Lacroix[2], Jeffrey Curtis[1], Kenneth Saag[1]. [1]University of Alabama at Birmingham, United States, [2]University of California, San Diego, United States

Purpose: Self-reported fracture (fx) history data is frequently used in epidemiological studies of osteoporosis. Self-reported fx data may differ from fx history coded in electronic health records (EHR) due to imperfect patient recall, incomplete communication with clinicians, or lack of a universal EHR. Because both self-reported fx history and EHR data can define phenotypes for clinical research studies, it is important to understand how these 2 data

sources compare. Our objective was to compare self-reported fx history using survey data with fx codes from an available EHR dataset.Methods: Self-reported fx data was derived from the Activating Patients at Risk for OsteoPOroSis (APROPOS) trial, which recruited participants from the Global Longitudinal study of Osteoporosis in Women (GLOW) cohort. Prior fx data was collected using a survey deployed June - August 2015. Women were asked if they ever had a fx and for each fx type the date of the most recent one. Data on fx recorded in the EHR September 2011 - June 2015 was obtained from Kaiser Permanente Washington Health Research Institute. We excluded skull, toes and fingers fxs. We defined concordance between the EHR and self-reported data if the location of fx was reported to be the same and if the reported dates were within 1 year of each other. Kappa (κ) statistic described the concordance between the 2 sources of fx history. Descriptive statistics evaluated potential factors associated with discordance between the self-reported and EHR-coded fx history. Results: A total of 133 fxs from 360 women (91% white, mean[SD] age 74.5(7.5) years, 82% had some college education) were included. There were 35 fxs reported on the survey but not in the EHR and 39 fxs coded in the EHR but not in the survey. Agreement between self-reported and EHR fxs was κ=0.48. Of the discordant fxs, we were more likely to find claims for fxs in EHR referent to self-report among whites (OR=5.5, 95%CI 1.1-27.9), for major osteoporotic fxs (OR=2.8, 95%CI 1.1-7.1), and for fragility fxs that typically require hospitalization (vertebral, hip, femur, pelvis) (OR=3.8, 95%CI 1.3-10.7). Discordance between EHR codes and self-reported fxs did not vary by age, formal education, or health literacy. Conclusion: There was only modest correlation between self-reported fx history and EHR fx codes. This discrepancy may have implications for clinical and epidemiological studies of fxs suggesting that combining both types of data may be optimal.

Radiological Validation of Fracture Definitions from Administrative Data: The Manitoba Bone Mineral Density Database Riley Epp*, Mashael Alhrbi, Linda Ward, William Leslie. University of Manitoba, Canada

BACKGROUND: Health care services / administrative data used for studying the epidemiology of osteoporosis-related fractures typically rely on fracture ascertainment from hospitalization and medical claims diagnoses. Fracture definitions used for national surveillance by the Public Health Agency of Canada (PHAC) show sex- and age-specific fracture rates in Manitoba comparable to radiologically confirmed fractures in a national population-based cohort but have not been directly validated against x-rays.PURPOSE: To determine the level of agreement between fractures ascertained from administrative data and radiological imaging.METHODS: We selected all patients in the Manitoba Bone Mineral Density Database (MBMDD) with a Winnipeg postal code who underwent bone mineral density (BMD) testing March 1- 31, 2016. This population was enriched with fractures by including patients undergoing BMD testing January 1- February 28, 2016, who were coded as having a prior fracture in the BMD report. For each patient we reviewed all relevant imaging and reports on province-wide Picture Archiving and Communication System (PACS) for the presence and date of fractures affecting the hip, vertebrae, forearm or humerus preceding the BMD test. We restricted analysis to fractures that occurred since 2011, the year PACS was expanded to include images and reports for all imaging modalities. We excluded fractures that were not reported, and where x-ray review and the BMD report for fracture were inconsistent. These radiologically confirmed fractures were then compared with fractures in the prior 5 years as determined from administrative data using the PHAC case definitions. Negative predictive values (NPV) and positive predictive values (PPV) were calculated overall and for each fracture site.RESULTS: The final study population included 480 patients, 148 with a radiologically confirmed fracture in the last 5 years. For any fracture, administrative case definitions gave PPV of 94.6% and NPV of 88.9% (see TABLE). PPV and NPV were high for non-vertebral fractures (range 88.2 to 100.0%, 98.5 to 100.0%, respectively), but were slightly lower for vertebral fracture (81.8% and 96.4%, respectively).CONCLUSIONS: Administrative case definitions from fracture ascertainment show acceptably high PPV and NPV for identifying radiologically-confirmed fracture of the hip, forearm, humerus and vertebrae supporting their role in epidemiological research and surveillance.

TABLE: Positive and negative predictive values (PPV and NPV) for radiological confirmation of fracture from administrative data.

	Number of fractures	PPV*	NPV**
Hip fracture	23	100.0%	100.0%
Vertebral fracture	42	81.8%	99.4%
Forearm fracture	74	90.0%	99.4%
Humerus fracture	22	88.2%	99.2%
Any of the above	148	94.6%	95.6%

Defining Alendronate Drug Holidays and Re-initiation in US Medicare Data Ayesha Jaleel*[1], Jeffrey Curtis[2], Rui Chen[2], Huifeng Yun[2], Tarun Arora[2], Suzanne Cadarette[3], Nicole Wright[2], Amy Mudano[2], Phillip Foster[2], Kenneth Saag[2]. [1]Brookwood Baptist Hospital, United States, [2]University of Alabama at Birmingham, United States, [3]University of Toronto, Canada

Introduction: Given alendronate's (ALN) prolonged skeletal retention and emerging safety concerns, the ASBMR task force recommended consideration of a "drug holiday" after 5 years of use. Distinguishing a prolonged gap in intended treatment vs. an intentional drug holiday is often unclear. We sought to estimate the prevalence of potential ALN holidays using two definitions of drug discontinuation, and to evaluate the characteristics of those who restart osteoporosis (OP) therapy after an ALN treatment gap.Methods: We included only women ALN users (n = 81,287) with a treatment gap in the 2006-2015 US Medicare data, with medical and pharmacy coverage (Medicare parts A, B, and D), and who were at least 80% adherent (MPR) with ALN for ≥3 years prior to the gap. We excluded patients with history of cancer, Pagets, Osteogenesis Imperfecta, or systemic hormone therapy. We evaluated the proportion of women with a treatment gap (no prescription claims) for ≥ 6 months and/or ≥ 1 year at which time follow-up began (day 184 and day 366) (index date) until restarting of any OP medication (study end). We used descriptive statistics to characterize women restarting vs. not restarting therapy after a gap of >1 year. Result: Using the 6-month gap definition, we identified 35,239 women (43.3% of previously adherent long-term ALN users) who discontinued ALN, of which 6172 (17.5%) restarted on any OP therapy. The median time to restart was 162 days (58, 413.5; 25th and 75th percentile). Half (50%) of the women restarted therapy within a year of stopping, suggesting that a 6-month gap may not truly represent an intended drug holiday. Using a ≥1 year gap definition, we identified 27,436 (33.8%) women with a possible drug holiday, of which 2978 (10.9%) restarted OP therapy. The median time to restart was 259 days (92, 512; 25th and 75th percentile). Using the ≥1 year definition, restarters and non-restarters differed significantly (p < 0.001) by fracture history (6.9% vs 5.1%), history of previous DXA (21.6% vs. 15.0%), and ≥1 rheumatologist or endocrinologist visit (13.8% vs. 8.6%).Conclusion: Given the large proportion of rapid restarters, a drug holiday gap of only 6-months may not accurately reflect a true drug holiday; a minimum of a 1-year gap appeared more appropriate for defining a likely drug holiday. Increased OP care and history of fractures were associated with OP therapy restart.

TREATMENT GAP AFTER FRACTURE IN OSTEOPOROSIS PATIENTS – RESULTS OF THE AUSTRIAN ARM OF THE INTERNATIONAL COSTS AND UTILITIES RELATED TO OSTEOPOROTIC FRACTURES STUDY (ICUROS) Oliver Malle*, Hans Peter Dimai. Medical University of Graz, Dpt. of Internal Medicine, Div. of Endocrinology and Diabetology, Austria

Objective Despite availability of effective treatment options proven to prevent osteoporotic fractures, a huge gap in osteoporosis treatment exists. Reasons for this gap include underdiagnosis of osteoporosis, lack of adequate patient management, and concerns of adverse events. The aim of the present study was to evaluate the treatment rate after osteoporotic fracture in Austria, one of the 25 wealthiest countries worldwide by measure of gross domestic product at purchasing power parity (PPP) per capita. Material and Methods The ICUROS is a prospective observational study aimed to describe costs and Quality of Life (QoL) consequences of osteoporotic fractures. An amendment to the protocol of the Austrian arm of the ICUROS aimed at assessing the treatment rate after fracture without a concomitant awareness program, thus providing data from the "real world". Patients who had sustained a major osteoporotic fracture were interviewed at the time of the index fracture, and 4, 12, and 18 months thereafter. Results A total of 915 patients with a recent fracture were recruited at 8 different trauma centers throughout Austria. 78.3% of these patients were female. Mean age at the time of fracture was 75.5 + 10.2 yrs. Female and male patients were stratified into 2 groups, depending on whether she or he received an osteoporosis treatment at the time of fracture or not (Fig.). At the time of fracture, some 20% of the patients were receiving anti-osteoporotic treatment. In this group, follow-up analysis after 4, 12 and 18 months revealed a treatment rate of 65%, 54% and 60%, respectively, in female patients. Comparable results were detected in male patients. The treatment rate in the female group without osteoporosis medication at the time of the fracture was 18%, 16%, and 15%, after 4, 12, and 18 months, respectively, and the treatment rate in the respective male group was 8%, 12%, and 10%. Among the different fracture types, no significant differences were found in the treatment rate. Conclusion Only 1 in 10 men, and less than 2 in 10 women who do not receive an osteoporosis treatment at the time of fracture is prescribed an adequate osteoporosis treatment in Austria. Even worse, roughly every second patient who receives an osteoporosis treatment at the time of fracture will be deprived of his/her treatment after the fracture.

Time of fracture	Sex	Months after fracture		
		4	12	18
Without osteoporosis treatment (n = 731; ♀ = 546, ♂ = 185)	Female	17.6%	16%	15.4%
	Male	8%	12.2%	10.3%
With osteoporosis treatment (n = 184; ♀ = 170, ♂ = 14)	Female	65.4%	54.2%	60.4%
	Male	66.7%	55.6%	55.6%

Treatment rate

SUN-0816

The category of non-osteoporotic bone mineral density in proximal hip fragility fracture cases: Preliminary data from a tertiary care hospital Hyun Uk Moon*[1], Yong Jun Choi[1], Jung-Taek Kim[2], Ye-Yeon Won[2], Yoon-Sok Chung[1]. [1]Department of Endocrinology and Metabolism, Ajou University School of Medicine, Suwon, South Korea, Republic of Korea, [2]Department of Orthopedic Surgery, Ajou University School of Medicine, Suwon, South Korea, Republic of Korea

There is a discrepancy between low bone mineral density (BMD) and fracture risk, as many fractures are observed in elderly people who are not in the osteoporotic range. We investigated the proportion of the non-osteoporotic patients among the patients with proximal femur fracture aged over 50 and their risk factors for fragility fracture.A total of 81 fragility hip-fracture (neck or trochanter) patients (mean age of 75.3) were included (72.8% female) in this prospective real-world setting study. Consultations and BMD measurements (GE Lunar DXA) were performed with collaboration among responsible departments including Endocrinology and Orthopedics in a tertiary care academic hospital (Ajou University Hospital) in South Korea, from April 27th, 2017 to March 14th, 2018.From all the fracture cases, the percentages of osteoporosis and normal or osteopenia were 70.4% (n=57) and 29.6% (n=24), respectively. Analyzing the normal or osteopenia group, 54.2% (n=13) had no specific risk factors. Some of them had been exposed to only chronic heavy alcohol intake. Specific risk factors involved in non-osteoporotic group were suspected in 11 subjects as bone metastasis (n=3), previous osteoporotic fracture (n=4), chronic renal failure (n=3), liver cirrhosis (n=1), glucocorticoids exposure (n=1), rheumatoid arthritis (n=1). Two subjects had two risk factors concomitantly. Subsequently, we assessed the ten-year fracture risk for each normal or osteopenia subject using FRAX scoring system. The mean (range) risk of ten-year major osteoporotic fracture was 6.4% (2.9%~18%), and that of ten-year hip fracture was 2.6% (0.3 %~6.3%). These FRAX scores were below the general guideline of intervention threshold. Although osteoporosis was still the dominant category in hip fracture patients, normal or osteopenia in BMD also accounted for considerable proportion of hip fractures in this study. In addition, even osteopenia patients without known risk factors were not free from hip fracture risk. The study emphasizes that we need more attention to patients with normal or osteopenic BMD but no osteoporosis to prevent fractures.

The category of bone mineral density in proximal hip fragility fractures

- Osteoporosis
- Osteopenia or normal bone density
- Secondary fracture with risk factor
- Primary fracture without risk factor

70.4% 29.6% 13.6% 16.0%

Improving Access to Osteoporosis Specialists through Electronic Consultations Christopher Tran*, Krista Rostom, Clare Liddy, Erin Keely. University of Ottawa, Canada

Purpose: Ensuring timely access to specialist care in Canada remains challenging. Electronic consultations (eConsults) can help address long wait times by allowing primary care providers (PCPs) to access specialist advice in lieu of face-to-face office visits. The purpose of this study is to describe the impact of eConsult advice provided by osteoporosis specialists.Methods: We performed a cross-sectional study of osteoporosis-related eConsults submitted to endocrinologists and rheumatologists between April 2011 and January 2015. Each eConsult was coded according to clinical topic and question type through consensus between two authors. eConsult usage data and PCP survey responses were analyzed to determine response times, PCP practice behavior, and referral outcomes.Results: A total of 74 PCPs submitted 119 osteoporosis-related eConsults during the study period. Osteoporosis cases comprised of 22% and 15% of all eConsults submitted to rheumatology and endocrinology, respectively. Patients were mainly female (86%). Median age was 70.4 years. Fragility fractures were present in 38 (32%) of cases; 20 of these were vertebral fractures. Median response time was 0.8 days, with 75% of responses occurring within 3 days. More than half of PCPs received a new or additional course of action as a result of an eConsult. A face-to-face referral was avoided in 67% of cases where the PCP initially contemplated requesting a referral .Among the 85 eConsults pertaining to pharmacotherapy, common questions included when to start therapy (24%), how to coordinate a drug holiday (14%), drug of choice (14%) and side effects (13%). Other eConsults included 9 cases on how to define a fragility fracture and 8 cases on how to interpret a bone mineral density report. Conclusion: The clinical content of osteoporosis-related eConsults is comparable to face-to-face referrals. By providing timely, practice-changing advice while avoiding unnecessary face-to-face office visits, eConsults can improve access to osteoporosis specialists.

Three months of vitamin D3 supplementation, 2,800 IU/d, improves trabecular bone microarchitecture and bone strength in vitamin D insufficient, hyperparathyroid women – a randomized placebo controlled trial Lise Sofie Bislev*[1], Lene Langagergaard Roedbro[1], Lars Rolighed[2], Tanja Sikjaer[1], Lars Rejnmark[1]. [1]Department of Endocrinology and Internal Medicine, Denmark, [2]Department of Surgery, Denmark

IntroductionVitamin D supplementation has historically been associated with improved bone health, but lately, the role of vitamin D without calcium supplementation has been questioned. MethodsIn a double-blinded placebo controlled randomized trial, we aimed to investigate the effect of vitamin D3 supplementation (2800 IU/d vs. placebo) for three months during wintertime in 81 healthy postmenopausal women with low 25(OH)D (<20 ng/mL) and high PTH levels. We assessed bone health by bone turnover markers, DXA- (spine L1-L4, hip, forearm, and total body), HRpQCT- (tibia and radius) and QCT (spine L1-L2 and hip) scans. ResultsMedian age was 65 (range 60-76) years. Baseline levels of p-25(OH)D was 13±3.7 ng/mL and p-PTH 58.4±13.5 ng/mL. None used daily supplements with calcium and/or vitamin D. The median estimated dietary calcium intake was 800 mg and 22% have had fractured during adulthood. Compared with placebo, vitamin D3 supplementation increased levels of 25(OH)D and 1,25(OH)2D by 230% (95% CI: 189% to 272%, p<0.0001) and 58% (95% CI: 190% to 271%, p<0.0001)) respectively. PTH was reduced by 17% (-23% to -11%, p<0.0001).Vitamin D3 supplementation had no effect on bone turnover markers, except from borderline (p=0.07) increased osteocalcin levels. Nor were there any effect on aBMD at any site measured by DXA. HRpQCT showed no changes in radius, but in tibia, vitamin D3 increased trabecular number (1.2% vs -0.2%, p=0.04), trabecular thickness (1.8% vs -3.2%, p<0.01) and reduced trabecular separation (0.0% vs -0.1%, p=0.05) compared with placebo. Finite element analysis revealed a highly significant improvement in bone strength in the vitamin D3 group compared with placebo, assessed by failure load (1.0% vs -1.4%, p=0.001) and stiffness (1.3 vs -1.7%, p=0.002).Trabecular vBMD measured by QCT increased in the trochanter region (0.4% vs -0.6%, p=0.02) and tended to increase vBMD at the total hip (p=0.10) and femoral neck (p=0.07).Changes in 25(OH)D correlated with failure load (r=0.33, p=0.01), stiffness (r=0.20, p=0.07) and tended to correlate with trabecular thickness (r=0.30, p=07) in tibia, whereas changes in PTH did not correlate with any of the stated measurements. ConclusionCompared with placebo, three months of treatment with vitamin D3, 2,800 IU/d improved trabecular microarchitecture and bone strength without affecting BMD. Our data suggest beneficial bone effects of improving vitamin D status in postmenopausal women with low 25(OH)D levels.

Trunk Muscle Endurance in Women with Osteoporotic Vertebral Fractures: an Exploratory Analysis from a Pilot Randomized Controlled Trial Caitlin Mcarthur*[1,2], Jenna C. Gibbs[3], Jonathan Adachi[1], Maureen C. Ashe[4], Robert Bleakney[5], Angela M. Cheung[5], Keith D. Hill[6], David L. Kendler[4], Aliyah Khan[1], Sandra Kim[7], Judi Laprade[5], Nicole Mittman[5], Alexandra Papaioannou[1,2], Sadhana Prasad[8], Samuel C. Scherer[9], Lehana Thabane[1], John D. Wark[10], Lora Giangregorio[3]. [1]McMaster University, Canada, [2]GERAS Centre for Aging Research, Canada, [3]University of Waterloo, Canada, [4]University of British Columbia, Canada, [5]University of Toronto, Canada, [6]Curtin University, Australia, [7]Women's College Hospital, Canada, [8]Centre for Bone Health, Canada, [9]Northern Health, Australia, [10]University of Melbourne, Australia

Purpose: To explore (1) the relationships between trunk muscle endurance, balance, and falls self-efficacy for woman with vertebral fractures, and (2) the effect of a 1-year home exercise program on trunk muscle endurance. Methods:This is an exploratory, secondary analysis of a pilot randomized controlled trial of a 1-year home exercise program including strength, balance, aerobic and postural exercises compared with equal attention control. Trunk muscle endurance was assessed with the Timed Loaded Standing (TLS) test, standing balance with the Balance Outcome Measure for Elder Rehabilitation (BOOMER), and falls self-efficacy with the Falls Efficacy Scale International (FES-I). The associations between TLS, balance and falls self-efficacy were tested via linear regression models adjusted for age, pain with movement, and occiput to wall distance. The models for the BOOMER were also adjusted for the FES-I total score, and the models for the FES-I were adjusted for the BOOMER total score. Linear models were constructed for the total score of the BOOMER and FES-I, and for each of the components of both tests. Associations with p < 0.05 were considered statistically significant. Differences in mean change of TLS from baseline were compared between groups using general linear models adjusted for baseline measures (analysis of covariance). Results:Thirty-one women, with a mean age of 75.5 years (standard deviation (SD) 6.9), an average of 3.0 (SD 2.1) vertebral fractures, and a mean history of 0.6 falls (SD 1.3) in the previous year were included in the analyses. The mean baseline TLS holding time was 85.6 seconds (SD 39.8) for the intervention group (n=17), and 84.3 (SD 41.2) for the control group (n=14). Trunk muscle endurance was associated with better balance performance, specifically static standing with eyes closed (parameter=0.005, standard error (SE)=0.003, p=0.02), and with reported self-efficacy of the ability to get out of a chair without falling (parameter=0.005, SE 0.002, p=0.04). There was no improvement in trunk muscle endurance at 12 months for women who participated in the home exercise program as compared with the control group (mean between group difference -0.5, 95% CI -24.3 to 23.3, p=0.96). Conclusions:Our study contributes to the growing literature surrounding trunk muscle endurance for people with osteoporosis, and suggests a positive relationship between standing balance, falls self-efficacy, and trunk muscle endurance.

Different Association of Dietary Fat Intake with Femoral Neck Strength According to Gender in Korean Population (KNHANES 2008-2010) Hyeonmok Kim*, Sun Hee Beom, Tae Ho Kim. Seoul Medical Center, Republic of Korea

Introduction: Despite the general belief that higher fat intake may be harmful for bone homeostasis, its associations with human bone health, mainly focused on bone mass, have been inconsistent. Furthermore, the role of dietary fat intake in bone strength, which can predict fracture risk independently of bone mineral density (BMD), has not been thoroughly studied. We here investigated the association between dietary fat intake and composite indices of femoral neck (FN) strength reflecting the risk of hip fracture.Methods: This population-based cross-sectional study examined data from Korea National Health and Nutrition Examination Surveys. After serial selection of subjects according to the exclusion criteria, 2595 subjects were included in our analysis. Usual dietary intake and bone mineral density (BMD) was assessed, and composite indices of FN strength, such as compression strength index (CSI), bending strength index (BSI), and impact strength index (ISI) were calculated. Results: After adjustment for confounders, daily fat intake (%) meaning fat energy intake divided by total energy intake negatively correlated with CSI and ISI in men (P = 0.010 and 0.046, respectively), but not in women. For further analysis, we categorized our participants into quintiles according to daily fat intake (%). In men, compared with subjects in the lowest fat intake quintile, those in the third, fourth and highest quintiles had significantly lower FN BMD, CSI and ISI values (P = 0.003 – 0.026), except for CSI in the highest quintile. In contrast to men, CSI and ISI values were significantly lower in women in lowest and highest quintile both than in those in the third quintile group (P = 0.005 – 0.044). We additionally divided our participants into three groups [<15% (low), 15% to 25% (appropriate), <25% (high)] according to recommended dietary reference intake of fat for Korean population. After adjustment for confounding variables, men with low fat intake group had higher ISI, and women with appropriate fat intake group was associated with higher all composite indices of FN strength.Conclusion: These results demonstrate that the effect of dietary fat intake on FN strength may be different according to gender, therefore appropriate amount of fat intake may be assessed based on gender, at least in bone health.

Prevalence of Vitamin D Deficiency in Postmenopausal Fracture Patient Ji Wan Kim*[1], Jun Sung Lee[2], Kwang Hwan Jung[3], Jai Hyung Park[4], Hyun Chul Shon[5], Jae Suk Chang[1]. [1]Asan Medical Center, Republic of Korea, [2]Haeundae Paik Hospital, Republic of Korea, [3]Ulsan University Hospital, Republic of Korea, [4]Kangbuk Samsung Hospital, Republic of Korea, [5]Chungbuk National University Hospital, Republic of Korea

Objective : The goal of this study was to investigate prevalence of vitamin D deficiency in post-menopausal women with fracture and to determine if there is any association between injury mechanism and serum vitamin D level. Methods : This study is a retrospective cohort study. The medical records of patients who presented with a fracture from March 2010 to October 2017 were retrospectively obtained. Inclusion criteria were following; 1) long bone fracture or pelvis fracture, 2) post-menopausal women aged 50years or older, 3) patients who had data of serum vitamin D level. Exclusion criteria were 1) pathologic fracture, 2) metabolic bone disease like Paget's disease, hyperparathyroidism, 3) isolated hand and foot fracture. One hundred and thirty-six patients were enrolled, and divided two groups according to injury mechanism; low-energy (107 patients) and high energy (29 patients). Serum vitamin D levels, bone turnover markers including serum osteocalcin, PTH, C-telopeptide and calcium, phosphorus, alkaline phosphatase, albumin, body mass index, bone mineral density, history of previous osteoporosis medications, vitamin D supplement and postoperative prescription rate were compared between two groups. Results: The rate of Vitamin D deficiency was 62%, and the rate of insufficiency was 14%, while only 24% of patient showed normal. The average level of Vitamin D level was 24.1ng/ml in low-energy group, and 21.1ng/mL in high energy group, respectively (p=0.889). The rate of Vitamin D deficiency rate was 61% and 66% in low-energy and high energy group (p=0.673). There was no difference in age between low and high energy groups. No seasonal variation of Vitamin D deficiency rate was observed. BMI, serum Ca, P, PTH, Osteocalcin, C-telopeptide, ALP, albumin were similar between two groups. BMD was evaluated in 85% of low energy group, and 77% of high energy group (p=0.441). The rate of osteoporosis (≤ -2.5 of T-score) was higher in low energy group (62.6% vs 37.5%, p=0.024). BMD in spine and femoral neck were similar between two groups (p=0.368, p=0.067), but BMD in total femur was lower in low-energy group (p=0.005). Postoperative Ca and Vitamin D supplement was taken in 91% of low energy injury and 59% of high energy injury (p = 0.003). Osteoporosis medication was prescribed more frequently in low energy group (74% vs 48%, p=0.009). In both groups, the prescription rate of calcium & Vitamin D supplement and osteoporosis medication was increased after fracture. Conclusion: Post-menopausal women with fracture have high incidence of Vitamin D deficiency in both high and low-energy injury group. Therefore physician should pay attention to Vitamin D deficiency in high energy injury group, as well as low energy group.

Prevalence of Hypovitaminosis D in Patients from a Private Hospital in Leon, Mexico Jorge L A Morales Torres*[1,2], Hugo Gutierrez-Hermosillo[3], Gilberto Aguilar-Orozco[1], Jaime Romero-Ibarra[2], Enrique Diaz De Leon-Gonzalez[4], Francisco Torres-Naranjo[5]. [1]Hospital Aranda de la Parra, Mexico, [2]Morales Vargas Centro de Investigacion, Mexico, [3]Medicina y Nutricion, Universidad de Guanajuato, Mexico, [4]Instituto Mexicano del Seguro Social, Mexico, [5]Centro de Investigacion Osea, U. de Guadalajara, Mexico

Hypovitaminosis D is extremely common worldwide. There is limited information in Latin America, but existing reports suggest a high prevalence linked to important health impacts. Attempts to improve our knowledge on hypovitaminosis D may come from many sources.Objective: To stablish the frequency of Vitamin D deficiency and insufficiency in patients studied in a private hospital in Leon, Mexico.Methods: This observational, descriptive study included all the 25-OH-Vitamin D measurements performed at the laboratory of Hospital Aranda de la Parra from June 19, 2012 to September 19, 2017 by chemiluminescent microparticle immunoassay (Abbott Diagnostics, USA). We considered Vitamin D insufficiency in those below 30 ng/ml and deficiency below 20 ng/ml.Results: We identified 2165 measurements (1795 in women,370 in men), of whom 1538 (71%) were Vitamin D insufficient and 559 (25.8%) were deficient. Mean age according to the levels of Vitamin D are: <10 ng 62±23 years; 10-30 ng/ml, 56±18 and >30 ng, 57±17 (p=0.658). Table 1 shows the distribution of values across decades of age.Conclusions: Hypovitaminosis D is highly prevalent in all age groups in this sample of population. This prevalence tends to be higher in the extremes of age Table 1. Levels of Hypovitaminosis D across decades of ageAge (years) n (%) <20 ng/ml (%) <30 ng/ml (%)0-10 59 (2.7) 14 (23.7) 44 (74.5)11-20 48 (2.2) 9 (18.7) 37 (77)21-30 87 (4) 29 (33.3) 66 (75.8)31-40 170 (7.8) 40 (23.5) 123 (72.3)41-50 271 (12.5) 70 (26.1) 203 (74.9)51-60 581 (26.8) 132 (22.7) 404 (69.5)61-70 495 (22.8) 107 (21.6) 328 (66.2)71-80 342 (15.9) 106 (30.9) 245 (71.6)81-90 100 (4.6) 44 (44) 76 (76)91-100 12 (0.5) 7 (58.3) 12 (100)TOTAL 2165 (100) 559 (25.8) 1538 (71)

Effects of Vitamin D Intake and Status on Changes in Distal Tibia Strength in Marine Recruits Undergoing Training Anna Nakayama*[1], Katelyn Guerriere[2], Laura Lutz[2], Leila Walker[2], Jonathan Scott[3], Heath Gasier[3], James Mcclung[2], Erin Gaffney-Stomberg[2]. [1]Oak Ridge Institute for Science and Education, United States, [2]US Army Research Institute of Environmental Medicine, United States, [3]Uniformed Services University of Health Sciences, United States

Bone health is a concern during initial military training (IMT) due to a high incidence of stress fracture, particularly in the lower extremities. Studies in Army recruits demonstrated that supplemental Ca and vitamin D above reference intakes throughout 8 weeks of IMT increased tibia vBMD and maintained parathyroid hormone (PTH) compared to placebo. The objective of this study was to assess the effects of the same dose of Ca (2000 mg/day) and vitamin D (1000 IU/day), provided as a twice daily fortified food product, on bone changes after 12 weeks of IMT. Marine recruits were enrolled during two seasons (summer and winter) and block randomized by sex (male=69, female=77) and race (69% white, 24% black, 7% other) to receive either two Ca and vitamin D fortified (Ca+D) or placebo food bars (130 kcal/each) daily throughout IMT. Serum bone turnover markers, nutritional status indicators, and pQCT scans of the tibia at the 4%, 14%, and 66% sites were collected at the start and end of IMT. Data were analyzed using linear mixed modeling evaluating time, group, and the time-by-group interaction, with race, sex, and BMI as covariates (SPSS v21). There were no differences in dietary Ca (1201 ± 620 mg, 1157 ± 678 mg) nor vitamin D (288 ± 194 IU, 264 ± 190 IU) when comparing supplemented and placebo groups, respectively at baseline. Mean bar consumption was >96% in both groups. IMT resulted in significant changes in BMC and strength at all 3 sites (Figure, p<0.05, all such), as well as vBMD at the 4% site. Those receiving the food product, Ca+D, compared to placebo, demonstrated greater increases in some pQCT measures, but none reached significance. When volunteers were divided into tertiles according to percent change in 4% BSI, change in 25OHD was greater in tertile 3 (+3.9 ± 25.7 ng/ml) as compared to tertile 1 (-9.9 ± 31.3 ng/ml, p<0.05) and this change exhibited a linear trend (r=0.21, p<0.05). Greater body fat loss and lower baseline 25OHD were also observed in those who exhibited the greatest change in BSI and change in body fat was negatively correlated with change in 25OHD (r=-0.21, p<0.01). In addition, a greater proportion of volunteers in tertile 3 entered training in the winter months (62%) as compared to volunteers in tertile 1 (42%). In conclusion, baseline 25OHD, as well as change in 25OHD due to shifts in body composition and season, may be important regulators of the skeletal responses to IMT.

Figure. Percent change of bone indices at the 4%, 14%,and 66% sites of the tibia
* indicates variable significantly increased after IMT (p<0.05); analyzed using linear mixed modeling evaluating time, group, and the time-by-group interaction; covariates include race, sex, and BMI.

Meal Phosphate Bioavailability Alters Hormonal Response in Healthy Humans Kathryn Neville*, Mandy Turner, Cynthia Pruss, Laura Couture, Michael Adams, Rachel Holden. Queen's University, Canada

Background: Chronic kidney disease (CKD) patients have impaired phosphate (PO4) excretion, leading to chronically elevated parathyroid hormone (PTH) and eventually hyperphosphatemia. Elevated PO4 and PTH contribute to mineral-bone disorders and cardiovascular disease. Dietary PO4 contributes to the elevation of these markers, therefore CKD patients are often prescribed phosphate-restricted diets. Current kidney disease guidelines stress reducing PO4 intake, however, there is little emphasis on the composition of the source. PO4 sources vary greatly in their bioavailability, with plant-derived sources being less bioavailable, and inorganic PO4 additives being ~100% bioavailable. PO4 salts are add-

ed to a large number of processed foods, which are consumed in excess in North America, particularly in lower socioeconomic status groups.Methods: Healthy individuals (N=18) were recruited to participate. Two meals with identical PO4 amounts, but different compositions were selected; one healthy meal that contained organic sources of PO4, such as fruits and whole grains, and a second convenience-style meal with inorganic PO4 sources, such as additives. Fasted participants were randomized to one of the two meals. Baseline urine and blood samples were taken, and participants consumed the meal in 15 minutes. Post-prandial blood and urine samples were taken over three hours. Participants returned to consume the second meal, with at least a week separating visits.Results: The two meals resulted in vastly different circulating mineral and hormonal responses and resultant altered urinary appearance of phosphate. Compared to the convenience meal, the healthy meal displayed significantly lower serum PO4 after 30 minutes (-0.053mM, $p<0.05$), had significantly less urinary PO4 appearance after 120 minutes (-22.6%, $p<0.001$), significantly increased serum Ca after 60 minutes (-0.07mM, $p<0.001$), and significantly decreased serum PTH after 90 minutes (-0.073mM, $p<0.05$). No significant difference was seen between the meals in respect to urinary Ca. Preliminary results in CKD patients (N=2) show a similar trend.Conclusions: Differences in the mineral and hormonal responses between meals can likely be attributed to the meal bioavailaibilites, although insulin response could also have a role. We expect the distinction between meals to be exacerbated in CKD. These data suggest that dietary restrictions should emphasize PO4 composition, in addition to amount.

Systematic Screening For Environmental And Behavioral Determinants Identifies Factors Detrimental to Skeletal Health Ling Oei*[1], Joy Wu[2], Edwin Oei[3], Fernando Rivadeneira[1], Andre Uitterlinden[1], John Ioannidis[4], Michael Snyder[2], Chirag Patel[5]. [1]Erasmus MC, Dept. Internal Medicine, Netherlands, [2]Stanford School of Medicine, United States, [3]Erasmus MC Dept. Radiology, Netherlands, [4]Stanford School of Medicine, Netherlands, [5]Harvard Medical School, United States

Objective: An increasing amount of biomedical data is becoming available, and methods are needed to tackle these "big data". We performed a systematic evaluation of 138 environmental and behavioral factors in relation to bone mineral density (BMD) in the National Health and Nutrition Examination Survey (NHANES).Methods: Dual energy X-ray absorptiometry (DXA) scans were available for total body, head, pelvis and lumbar spine for 27,259 participants from NHANES surveys 1999-2000 (A), 2001-2002 (B), 2003-2004 (C) and 2005-2006 (D). After the Bonferroni correction for multiple testing (P< 0.00036) in the discovery random effects meta-analysis of surveys B and D, there were seven unique environmental factors that replicated in the joint analysis of surveys A and C.Results: Higher serum levels of a-tocopherol and of g-tocopherol, forms of vitamin E, were associated with decreased BMD (per SD β=-369% and β=-150% for lumbar spine). In contrast, retinol serum levels were related to higher BMD (per SD β=+11.6% for total body). Serum lead levels had a negative relationship to BMD of the lumbar spine (per SD β=-1.2%) and head (per SD β=-2.2%). Higher levels of physical activity were associated with higher BMD (total body: per MET +1.2%). Being a current or past smoker was associated with decreased BMD of the total body, pelvis and head. Summary and Conclusions: In conclusion, our study demonstrates consistently that several behavioral traits and fat-soluble vitamins may have detrimental effects on BMD, while reinforcing the benefit of physical activity for skeletal health.

Association Between Fermented Milk Product Intake and Bone Health In Postmenopausal Women: A Systematic Review Angel Ong*[1], Hope Weiler[1], Suzanne Morin[2], Kai Kang[1]. [1]School of Human Nutrition, McGill University, Canada, [2]McGill University, Canada

Purpose: Emerging evidence suggests that fermented milk products (FMPs) may have more favorable effects on bone health than non-fermented milk. The present systematic review aimed to summarize the evidence on the association of FMP intake with bone health indicators including bone mineral density (BMD), incident fractures, and bone turnover markers in postmenopausal women. Methods: This review followed the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) guidelines. The protocol was registered at PROSPERO (CRD42018085232). We searched CENTRAL (Cochrane), EMBASE, MEDLINE, PubMed, and CINAHL up to January 2018 without language restrictions. Randomized controlled trials (RCTs), cohort studies and case-control studies examining the association between FMP intake, including cheese and yogurt, and bone health outcomes were included. Two reviewers independently screened articles for inclusion, performed data extraction, and assessed risk of bias of included studies. Results: Of the 468 retrieved citations, 11 articles met the inclusion criteria (3 RCTs, 5 prospective cohort studies, 3 case-control studies). Association between bone health outcomes and cheese intake was examined in 9 studies, whereas the association with yogurt intake was evaluated in 7 studies. One short-term yogurt-based RCT reported a reduction in bone resorption and 1 cohort study suggested an inverse association between yogurt/sour milk intake and hip fracture rates; 4 other cohort studies and 1 case-control study reported no association between yogurt intake and bone health outcomes. A trial of cheese fortified with vitamin D and calcium reported a reduction

in bone resorption, but no effect on bone formation was observed in an RCT of non-fortified cheese. Two case-control studies suggested that regular cheese consumption is a protective factor for osteoporosis, whereas evidence from cohort studies examining cheese intake is less clear. No association was found between hip fractures and cheese intake. Some concerns for bias from the randomization process were identified in 2 RCTs. The methodological quality of all observational studies was high, except for 2 case-control studies with moderate quality. Conclusion: It remains unclear whether FMP intake is a protective factor for bone health in postmenopausal women, owing to the paucity of literature examining its effect. Larger and higher quality RCTs are required to further examine the role of FMP in skeletal health.

SUN-0845

Milk and Alternatives Intervention Improves Total Hip and Whole Body Bone Mineral Accretion in 14- to 18-year Postmenarcheal Females: Results at 12 Months From a 2-year Randomized Controlled Trial May Slim*, Catherine Vanstone, Suzanne Morin, Elham Rahme, Hope Weiler. McGill University, Canada

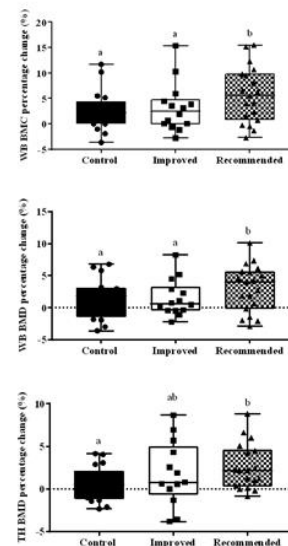
Purpose: The role of milk and alternatives intake (MILK) in optimizing peak bone mass during skeletal growth has been widely recognized. However, average intakes for Canadians 9 y and older fall below Canada's Food Guide (CFG) recommendations for MILK. The objective was to examine bone mineral accretion from baseline to 12 months (mo) in postmenarcheal females with usual intake of < 2 servings of MILK per day who are participating in a 2-year trial (NCT02236871, August 2014-December 2018).Methods: Healthy girls 14- to 18-y (n=64) from Montreal, Canada were randomized to control [no intervention], improved [3 MILK servings/d] or recommended [4 or more MILK/d] intervention groups. Bone mineral content (BMC, g), bone mineral density (BMD, g/cm2) and BMD z-scores (BMDZ) of the whole body (WB), lumbar spine 1-4 (LS), 33% radius (R), femoral neck (FN) and total hip (TH) were measured at baseline and at 12 mo using DXA (Hologic Discovery APEX version 13.3:3). Differences among trial groups were tested using mixed model ANOVA with post-hoc Tukey adjustment; data are mean ± SD.Results: At baseline, mean age was 16.3 ± 1.4 y and BMI was 22.3 ± 3.5 kg/m2. BMC, BMD and BMDZ were not different among groups at R, TH and FN, but were higher in the recommended group compared to the improved group at LS and WB ($p<0.005$). Compared to baseline, all groups showed no change over time in any of the bone parameters at LS, R, and FN, whereas only the recommended group increased BMC, BMD and BMDZ at WB and TH at 12 months ($p<0.02$). At 12 mo, all WB bone parameters were significantly higher in the recommended group compared with the other 2 groups ($p< 0.02$). Furthermore, BMD and BMDZ were higher in the recommended group compared with the control at the TH ($p<0.05$). Compared with the improved and control groups, the recommended group had greater increases of WB BMC (5.6%) vs the improved group (3.2%, p=0.03) and control group (2.6%, p=0.03), and greater increases in WB BMD (3.0%) vs the improved group (1.5%, p=0.01) and the control group (1.4%, p=0.03). Moreover, TH BMD increased significantly in the recommended compared with the control group only (2.6% vs 0.7%, p=0.01) (Figure).Conclusions: These results suggest that increasing MILK intake to meet CFG's recommendation for this age group favors bone mineral acquisition in postmenarcheal females particularly at the whole body and total hip.


Figure: Percent change in whole body BMC and BMD, and total hip BMD over 12 mo in adolescent females 14 to 18 y participating in a trial to improve milk and alternatives intakes.
[a, b] Groups with different superscripts are significantly different from each other using a mixed model ANOVA, adjusted for height, weight and skin color (p<0.05). Data are represented in a box and whisker plot format showing median and interquartile range along with the actual values of a sample of 64 participants.
WB: Whole body; TH: total hip; BMD: bone mineral density; BMC: bone mineral content.

Bone formation is suppressed and resorption increased during 72 hours of sleep restriction Jeffery Staab*, Tracey Smith, Marques Wilson, Scott Montain, Erin Gaffney-Stomberg. US Army Research Institute of Environmental Medicine, United States

Chronic sleep deprivation (<6.5 hr sleep per night) in adulthood is associated with reduced bone density and strength compared to adequate sleep (6.5-10 hr per night). Acutely, markers of bone resorption and urinary calcium (UCa) excretion are increased after 72 hr of sleep deprivation in male military service members; and, markers of bone formation have been found to be reduced in military personnel following 8 weeks of multi-stressor training that included sleep deprivation. The objective of the current study was to evaluate how controlled, short-term sleep restriction (SR; 72 hr) alters markers of both bone formation and resorption, and UCa, as well as examine the temporal relationship of these changes. Ten healthy, sleep-adequate, males ([mean ± SD] 21.5 ± 4.9 yrs, 1.75 ± 0.9 m, and 80.9 ± 9.3 kg body weight, respectively) were admitted and housed in the research facility one day prior to and for the duration of the SR period. Diet was controlled to provide adequate energy balance and macronutrient distribution and to meet the recommended dietary allowance (RDA) for Ca (1000 mg/d). During SR, participants were continuously monitored by study staff and engaged in activities (light exercise, video and board games, movies) to maintain wakefulness and were allowed 2 hr of sleep per night (0430-0630). Fasting blood samples were collected each morning at 0 hr (baseline) and 24, 48, and 72 hr of SR. Serum was assayed for parathyroid hormone (PTH), bone alkaline phosphatase (BAP), tartrate-resistant acid phosphatase (TRAP) and C-terminal telopeptide of type I collagen (CTX). Urine was collected in 24 hr increments during SR for measurement of Ca and creatinine (Cr). BAP was suppressed after 48 and 72 hr of SR (p=0.01) whereas the resorption markers TRAP and CTX were increased after 48 and 72 hr of SR compared to baseline (p<0.05). The ratio of BAP:TRAP was calculated as an index of bone turnover and was significantly suppressed (p=0.01) at 48 and 72 hr of SR. In contrast, total 24 hr UCa excretion and Ca/Cr were unchanged during the study period. These results indicate that markers of bone formation and resorption are uncoupled in response to as little as 48 hr of SR even when Ca intake is at the RDA. Sleep deprivation may be a risk factor for reduced bone health due to perturbations in both formation and resorption.

Physical Activity Across Adulthood and Bone Health in Later Life: the 1946 Birth Cohort Stella Muthuri*[1], Kate Ward[2], Diana Kuh[1], Ahmed Elhakeem[3], Judith Adams[4], Rachel Cooper[1]. [1]MRC Lifelong Health and Ageing at University College London, United Kingdom, [2]MRC Lifecourse Epidemiology, University of Southampton, United Kingdom, [3]MRC Integrative Epidemiology at University of Bristol, United Kingdom, [4]University of Manchester, United Kingdom

Leisure time physical activity (LTPA) is widely recommended for the prevention of osteoporosis, falls and fractures in older populations. However, whether the beneficial effects of LTPA on bone accumulate across life and are maintained even after reduction or cessation of regular PA in later life remains to be established. The aim of this study was therefore to investigate whether LTPA across adulthood was cumulatively associated with volumetric and areal BMD (vBMD, aBMD) at age 60-64; and the extent to which any associations were mediated by lean mass. Data were from up to 1498 participants (700 men) in the Medical Research Council National Survey of Health and Development. LTPA was self-reported at ages 36, 43, 53 and 60-64, and responses (inactive, moderately or most active) at each age were summed to generate a cumulative score (range:0 inactive at all 4 ages to 8 most active at all 4 ages). Total and trabecular vBMD were measured at the distal radius using pQCT and aBMD at the total hip and lumbar spine (L1-L4) were measured using DXA. Linear regression was used to test associations of the cumulative LTPA score with each bone outcome. Path analysis was used to quantify the mediating effects of lean mass. In men, after adjustment for current height and weight, a 1-unit increase in the cumulative LTPA score was associated with mean % differences [95% CI] of: 1.55% [0.78%, 2.31%] in radial trabecular vBMD; 0.83% [0.41%, 1.25%] in total hip aBMD; and 0.97% [0.44%, 1.49%] in spine aBMD. These associations were maintained after adjustment for a range of covariates. Among women, associations were weaker and less consistent but positive associations were seen for radial

trabecular vBMD and total hip aBMD among those of greater weight (LTPA x weight interaction p≤ 0.01). Lean mass index partly mediated these associations, except for radial trabecular vBMD in women.There is evidence of cumulative benefits of LTPA across adulthood on BMD in early old age. These benefits are partly mediated by lean mass, especially among men. That associations were weaker among women suggests that the promotion of specific types of LTPA may need to be promoted for the benefit of bone health in women.

Validated and in-depth characterized sandwich ELISA for the quantification of mouse periostin Elisabeth Gadermaier*, Jacqueline Wallwitz, Gabriela Berg, Gottfried Himmler. The Antibody Lab GmbH, Austria

Purpose: Periostin (osteoblast-specific factor OSF-2) is an extracellular matrix protein which belongs to the FAS1 superfamily. It consists of a conserved N-terminus and a C-terminal region which is affected by alternative splicing leading to different isoforms. In bone, periostin is mainly expressed in the periosteum of long bones and in osteocytes. It has a general function in bone homeostasis and is regulated by factors like mechanical stimulation, PTH, growth factors and cytokines. It is upregulated during bone development and remodeling, and it acts on bone formation by increasing osteoblast function. To further study periostin in preclinical mouse models, there is the need for a high-quality assay for periostin quantification. Methods: We developed a sandwich ELISA using polyclonal and monoclonal anti-periostin antibodies. Linear epitopes of the antibodies were resolved with microarray technology. Assay parameters like specificity, accuracy, dilution linearity, and precision were determined, and different sample matrices were tested (serum, plasma, urine). The binding pattern of periostin isoforms was analyzed.Results: Linear epitopes of the employed antibodies are located in the fourth FAS1 domain for the monoclonal coating antibody, or distributed over the whole periostin sequence for the polyclonal detection antibody. The assay is calibrated with mouse periostin isoform 1. It covers a resorbable triphasic calcium range of 0.5 – 16 nmol/L, and has a quantification limit of 0.125 nmol/L. The assay uses only minimal amounts of sample (0.5 µl/well) and detects periostin in mouse serum and plasma, but not in mouse urine. The assay is highly specific for mouse periostin. Assay characteristics like accuracy (mean spike recovery: serum 97%; plasma 88%), dilution linearity (mean recovery 1+1 dilution: serum 116%; plasma 128%), and precision (intra-mediate: mean 5%, inter-mediate: mean 11%) meet the standards of acceptance. From five currently known mouse periostin isoforms, four are recognized in the assay (binding to isoform 4 is not known yet).Conclusion: The novel mouse periostin ELISA provides a reliable and accurate tool for the quantification of mouse periostin in minute amounts of serum and plasma samples.

SUN-0866

Local Osteoporotic Enhancement Procedure Demonstrates Analogous Implant Resorption and Bone Formation Across Three Species With or Without Antiresorptive Treatment James Howe*[1], Jonathan Shaul[1], David Burr[2], Deborah Hall[3], Thomas Turner[3], Robert Urban[3], Bryan Huber[4], Ronald Hill[1], Klaus Engelke[5], Harry Genant[6]. [1]AgNovos Healthcare, United States, [2]Indiana University School of Medicine, United States, [3]Rush University Medical Center, United States, [4]Copley Hospital, United States, [5]Bioclinica-Synarc, Germany, [6]Synarc-Bioclinica & University of California San Francisco, United States

Fragility hip fractures significantly impact quality of life and are associated with high mortality rates. These fractures often occur due to failure of trabecular bone in the proximal femur. Antiresorptives, the most commonly used pharmaceuticals to treat osteoporosis, reduce fracture risk by inhibiting osteoclast activity and decreasing bone turnover to stabilize BMD and bone strength. A new investigational treatment uses a minimally-invasive local osteo-enhancement procedure (LOEP) to inject a resorbable triphasic calcium sulfate/calcium phosphate implant (AGN1) into the proximal femur to replace lost trabecular bone and increase strength. This study examined AGN1 resorption and bone formation with or without antiresorptive treatment in three species: distal femoral defects in ovariectomized rats (n=6/group, IACUC approved); critical size humeral defects in normal dogs (N=10/group, IACUC approved); and proximal femurs of post-menopausal osteoporotic women (N=6/group, IRB approved). More than 95% of AGN1 resorbed within 26 weeks post-treatment in all 3 species. Antiresorptives had a non-significant impact on AGN1 resorption (Figure 1). AGN1 was replaced by normal bone in rats as assessed by histology and µCT and also in normal dogs by histology, µCT and biomechanical testing. In patients, bone formation was established by aBMD changes (0.530±0.045 to 0.917±0.140 g/cm3, 0 to 25 wks) and evolution in CT appearance. Alendronate (15µg/kg 2x wk) increased rat BV/TV (histopathology): 26.4±14.0% vs 13.4±6.0%, 18 wks, p=0.012. In dogs, alendronate (0.2mg/kg/day) impact on BV/TV (histomorphometry) was minimal: 22.0±7.0% vs 19.0±3.4%, 26 wks, p=0.147. aBMD was not significantly affected in patients prescribed alendronate or ibandronate compared to those not taking antiresorptives (0.938±0.152 vs 0.897±0.139 g/cm3, p=0.636 at 25 wks). This study supports the conclusion that AGN1 resorption and bone formation is analogous across species and that antiresorptives had a minimal impact on AGN1 resorption and only significantly increased bone volume in rat. Although µCT and histopathology analyses

were not possible clinically, the analogous results across species suggest that bone formed in patients would also be healthy, normal bone.

Figure A: Ovariectomized Rat; B: Normal Dog; C: Osteoporotic Patients

SUN-0867

Central Acetylcholine Signaling Contributes to Age-related Bone Loss Yun Ma*, Florent Elefteriou. Baylor College of Medicine, United States

Bone loss begins in the third decade of life and continues after menopause/andropause, thus mechanisms additional to gonadal deficiency contribute to age-related bone loss. Studies in both humans and rodents have shown that parasympathetic cholinergic tone decreases, while sympathetic outflow increases with aging. Although reports have illustrated effects of cholinergic receptors global embryonic genetic ablation on bone, mechanisms whereby cholinergic signaling impacts bone homeostasis in adults and during aging remain unknown. To address this question, we chronically raised acetylcholine (ACh) levels in WT mice at time of peak bone mass and before bone loss associated with aging (14 weeks of age), by using blood brain barrier (BBB) permeable and non-permeable acetylcholinesterase inhibitors (AChEIs). Mice were sacrificed 6 weeks later and were analyzed by microcomputed tomographic and histomorphometric analyses. These analyses revealed that only AChEIs able to pass blood brain barrier (BBB), thereby elevating central ACh level, increased bone mass. The bone anabolic effect of centrally-acting AChEIs was associated with an increase in both osteoblast and osteoclast number/surface. Unexpectedly, the bone anabolic effect of AChEIs was observed only in females. Bone marrow stromal cells (BMSCs) isolated from long bones of vehicle or AChEIs-treated females and differentiated in osteogenic conditions formed a similar number of colony-forming unit (cfu)-AP/-Ob. AChEIs treatment of WT BMSCs at 3 different doses (0.1, 1 and 10uM) during 5 days did not have any stimulatory effect on BMSC number, and upon growth in osteogenic medium did not increase differentiation, as measured by alkaline phosphatase (ALP) staining. No major effect of treatments was detected either on osteoclast differentiation, measured by tartrate-resistant acid phosphatase (TRAP) staining of spleen monocytes in the presence of MCSF and RANKL. These results thus are in line with a mechanism of action whereby ACh signaling in the central nervous system prevents bone loss after peak bone acquisition, consistent with previously published data related to the bone phenotype of M3r-deficient mice. They also suggest that the beneficial effect of centrally-acting AChEIs on cognition in patients with Alzheimer disease (AD) may be associated with positive effects on bone health, which is supported by the recent observation of reduced fracture risk in AD patients taking AChEIs.

SUN-0868

The Chemotherapeutic Trabectedin Negatively Impacts Osteal Macrophages and Bone Healing Benjamin Sinder*[1], Justin Do[2], Amy Koh[2], Hernan Roca[2], Laurie Mccauley[2]. [1]UConn Health, United States, [2]University of Michigan, United States

Osteal macrophages have emerged as vital regulators of bone mass and inhibition of macrophages compromises bone formation. A key function of macrophages is to efferocytose apoptotic cells, a normal process which is ramped up during wound healing. Trabectedin is an FDA approved chemotherapeutic that induces apoptosis in macrophages and certain types of cancer cells and reduces macrophage efferocytosis. The purpose of this study was to investigate the role of macrophages and trabectedin on bone healing. A stress fracture (sFx) was created in the ulna of 16 wk old C57BL/6 male mice using 2Hz cyclic fatigue loading at 80% of ultimate force until a total displacement of 0.55mm was achieved. After stress fracture, mice were immediately treated with trabectedin or vehicle (0.15mg/kg i.v, n=8-10/gp). Stress fractures were allowed to heal for 3 days (n=20) or 1wk (n=16) followed by flow cytometric analyses, histology for macrophage immunostaining, and microCT outcomes. After 3 days of healing, trabectedin significantly reduced F4/80+ (-35%) and CD11b+ (-33%) macrophages and monocytes in non-sFx (unloaded) bone marrow as assessed by flow cytometry. Correspondingly, spleen weight was also reduced (-28%), suggesting systemic disruption of the myeloid system. Histologic analysis of total callus sFx area at the 3day time point revealed trabectedin significantly reduced (-45%) early callus size. Total callus F4/80+ macrophages were significantly reduced (-55%) with trabectedin and F4/80+ macrophages per sFx callus area trended towards a decrease (-25%, p=0.16). After 1wk of healing, the early impact of trabectedin persisted and microCT analysis revealed significantly reduced total callus size (-52%) as well as callus bone volume (-57%) with trabectedin treatment (p<0.01). Histologic immunostaining for macrophages with the F4/80+ marker showed a significant reduction in the total number of callus macrophages after 1wk (-60%), but no significant reduction in F4/80+ cells in the callus normalized to sFx callus area. In conclusion, trabectedin significantly compromises osteal macrophages and has a negative impact

on bone healing. Results of this study highlight the regenerative role that macrophages play in osseous wound healing and may have immediate clinical relevance for patients receiving trabectedin treatment.

SUN-0869

Evidence of Mitochondrial Fusion and Biogenesis Altering in Diabetic Bones Xiaoxuan Wang*[1,2], Zhekai Hu[1], Xingwen Wu[1], Qisheng Tu[1], Jinkun Chen[1,3]. [1]Division of Oral Biology Tufts University School of Dental Medicine., United States, [2]Department of Periodontology, Peking University School and Hospital of Stomatology, Beijing, China, [3]Department of Developmental, Molecular and Chemical Biology Sackler School of Graduate Biomedical Sciences Tufts University School of Medicine, United States

Objective: Diabetes mellitus (DM) is one of the most common metabolic diseases worldwide. Diabetes has been reported to disrupt the dynamics and biogenesis of mitochondria. Mitofusin 2 (Mfn2), plays critical roles in mitochondrial fusion. PGC-1β and Nrf2 are related to mitochondrial biogenesis. Expression of Mfn2, PGC-1β and Nrf2 changed in brains, heart, muscles of diabetic rodents while not clear in bone of diabetic rodents. This study is to investigate the expression of Mfn2, PGC-1β and Nrf2 genes in bone of type 2 diabetes mellitus (T2DM) mouse model.Materials and methods: Twenty-week-old diet-induced obesity (DIO) mice model of T2DM and wild type mice were used for the animal experiments. Femur and tibia of mice were isolated and RNA was extracted. Bone marrow derived stem cells (BMSCs) were isolated from femur and tibia of mice. Mice bone marrow-derived macrophages (BMMs) were isolated and cultured in medium supplemented with soluble receptor activator of NF-κB ligand and macrophage colony-stimulating factor. Cells were treated respectively with low glucose (5mM glucose, glucose control), high glucose (25 mM glucose). Expression of Mfn2, PGC-1β and Nrf2 genes were detected by real time PCR assays in mouse bone, BMMs and BMSCs.Results: Expression of Mfn2, PGC-1β were increased in the bone of DIO mice compared to the WT mice while expression of Nrf2 was decreased (p<0.05). Expression levels of all the three genes were higher in the BMMs isolated from DIO mice than that from WT mice when treated with high glucose or not. Interestingly, expression levels of Mfn2 and PGC-1β were decreased while the expression of Nrf2 increased in BMSCs when treated with high glucose or not. Furthermore, in the DIO mice group, the alterations of genes expression were opposite in the BMSCs and BMMs when the cells were treated with high glucose. Expression of Mfn2 was upregulated and PGC-1β downregulated in BMMs. In contrary, expression of Mfn2 was downregulated and PGC-1β upregulated in BMSCs. In the WT mice group, the alterations of genes expression in BMMs and BMSCs were similar with the DIO mice group when treated with high glucose.Conclusion: This study represents the first report exploring the gene expression profiles in diabetic bone tissues, BMMs and BMSCs. These data suggest that Mfn2, PGC-1β and Nrf2 may participate in the bone metabolism in T2DM mouse model and the alteration of these genes expression may contribute to the T2DM osteoporosis.
SUN-0870

Microbiota Regulates Bone Loss in Sickle Cell Disease Male Mice Liping Xiao*, Kavita Rana, Kimberly Pantoja. UConn Health, United States

Bone loss is a common complication in sickle cell disease (SCD) subjects. The mechanism(s) of bone loss in SCD patients has not been fully investigated. Studies showed increased circulating aged neutrophils that are regulated by the intestinal microbiota and depletion of gut microbiota significantly reduced the number of aged neutrophil and dramatically improved the inflammation-related organ damages in SCD mice. Since neutrophils

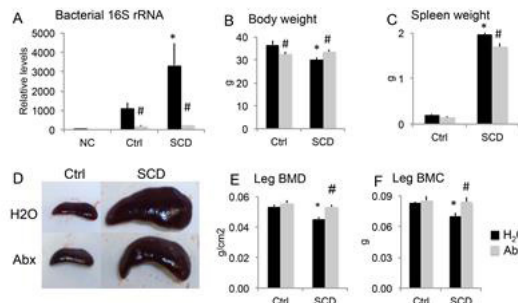
are abundantly present in bone marrow (BM) and regulate bone cells, we examined whether bone loss in SCD mice is due to microbiota-regulated accumulation of aged neutrophils in BM. We treated control and SCD male mice with a broad-spectrum antibiotic to deplete gut microbiota. Antibiotic treatment significantly improved splenomegaly and improved decreased body weight, leg bone mineral density, leg bone mineral content, bone formation parameters of the femur, and Runx2 and Igf1 mRNA in tibia from SCD mice. Antibiotic treatment rescued accumulation of BM aged neutrophils. Decreased osteoblast functions co-cultured with BM neutrophils from SCD mice were rescued when co-cultured with BM neutrophils from antibiotic treated mice. We conclude that increased gut bacteria load may contribute to bone loss in SCD male mice. Furthermore gut microbiota-regulated BM neutrophil ageing may contribute to impaired osteoblast function in SCD mice.


Figure 1. Microbiota depletion improved splenomegaly and leg BMD and BMC in SCD male mice. Mice were housed by genotype after weaning. Ctrl and SCD male mice were singly housed to avoid cage effects on microbiota at 4 months of age and randomly assigned to H$_2$O or Abx treatment groups. After 7 weeks of age, feces were collected, body weight was measured, and in vivo DEXA was performed. Then mice were euthanized for sample collection. (A) Increased gut bacteria load in SCD mice and bacterial depletion after Abx treatment in both Ctrl and SCD mice. Genomic DNA was isolated from equal amounts of fecal material of Ctrl and SCD mice with and without Abx treatment. Relative quantification of 16S rRNA gene copies of total bacteria was determined by real time PCR using universal 16S rRNA primers. NC: negative control, every step is same as real samples except no feces were collected in the collecting tube. n=4 mice/group. (B) Body weight. n=4 mice/group. (C) Spleen weight. n=4 mice/group. (D) Representative images of spleen. (E) Leg BMD and (F) BMC were significantly decreased in SCD-H$_2$O mice compared with Ctrl-H$_2$O mice and Abx treatment significantly increased leg BMD and BMC in SCD mice. n=4 mice/group. Data are mean±SE. *: Compared with Ctrl-H$_2$O p<0.05; #: compared with corresponding H$_2$O group p<0.05 by two-way ANOVA.

SUN-0886

Cross sectional study of severity of bone disease in liver transplant from pre-transplant to one year post transplant and potential factors associated with bone loss Ejigayehu Abate*. Mayo Clinic Florida, United States

Background: The liver plays an important role in bone and mineral metabolism. The rate of bone loss is highest in the first 6-12 months after transplant. We evaluated rate of bone loss in 1st year of transplant and potential factors contributing to bone loss.Methods: This is a retrospective study of 296 patients with liver transplant at Mayo Clinic Florida in 2009 to 2013 and 19 patients had combined kidney/liver transplant analyzed separately.Results: An unadjusted annual rate of bone loss from pre-transplant to 1 year post transplant was an increase of 0.78% in the spine (0.78%,95% CI 0.07% to 1.49%), a decrease of 5.67% in the total hip (-5.67%, 95% CI -7.79% to -3.5%), decrease of 3.67% in femoral neck (-3.67%, 95% CI -4.23% to -3.11%). Worsening BMD at all site (spine, hip and femoral neck) was associated with a lower MELD score at the time of transplant (P<0.001). In addition, worsening BMD of the total hip and femoral neck were associated with lower body mass index prior to transplant (P=0.003) and the number of days between pre-transplant BMD test and transplant (P=0.035). There was no association of prednisone dose after transplant and the annual percent change in BMD at the spine, hip, or femoral neck. Among those with fracture within the first year of transplant, history of fracture before transplant and annual total hip BMD change of -3.5% or higher was associated with higher rate of fracture after transplant. Although not statistically significant, we noticed that 26% those who had a combined liver and kidney transplant had a fracture within the 1st year vs. 14% of the liver transplant alone (P=0.14). Prednisone dose of >1.2grams was associated with increased risk of fracture (P=0.24). Among those who had prednisone prior to transplant, 25.0% had a fracture within 1 year post transplant compared to 14.2% of those who did not have any prednisone before transplant (P=0.24).Conclusion: This study shows a significant bone loss in the hip and femoral neck within 1 year of transplant. Higher MELD scores and low BMI at the time of transplant are the main risk factor to bone loss. We did not find a significant correlation between prednisone dosage and rate of bone loss although higher dose was associated with increased risk of fracture. Prior fracture regardless of bone density changes was a main predictor of fracture risk within the first year of transplant. Findings signify the importance of utilizing other modalities for assessment of fracture in these patients rather than relying on bone mineral density testing alone.

Prevalence and Risk factors for Low Bone Mineral Density in Transfusion Dependent Anemia Rahul Agarwal*[1], Farzana Sayani[2], Mohammad El Sibai[1], Mona Al Mukaddam[1]. [1]Perelman School of Medicine at the University of Pennsylvania, Division of Endocrinology, Diabetes and Metabolism, United States, [2]Perelman School of Medicine at the University of Pennsylvania, Division of Hematology and Oncology, United States

Purpose: Osteoporosis and fractures are increasingly reported complications in transfusion dependent anemia (TDA). This retrospective study reports on the prevalence of low bone mineral density (BMD; defined as Z-Score ≤ -2.0) and its association to risk factors in adult patients with TDA.Methods: We performed a retrospective review of the electronic medical record for adult patients (age 18 or above) with confirmed TDA seen at the Penn Comprehensive Adult Thalassemia Program between July 2012 and June 2017. Only patients who underwent at least one dual-energy x-ray absorptiometry (DXA) scan were included in the analysis.Results: A total of 38 patient charts were reviewed and 33 patients who had a DXA measurement (28 with Beta Thalassemia, 5 with Diamond Blackfan Anemia) were included in the final analysis. 17 patients were males, 20 Caucasians, 10 Asians, and 3 African Americans with average age of 37 years at time of DXA measurement (Table 1). 23 patients (69.7%) had low BMD and 11 patients (33%) had a fracture. The most commonly associated endocrinopathy was hypogonadism in 22 (67%) patients. Patients with low BMD were more likely be males, had prior history of steroid use, osteoporosis treatment, delayed puberty, hypogonadism, hypothyroidism, and diabetes. There was no difference in ferritin level and liver and cardiac iron deposition between the two groups. Only 13 patients had a 24-hour urine collection for calcium and creatinine and 12 (92%) of these patients had hypercalciuria as defined by >4mg/kg/24 hours. 5 of the 12 hypercalciuric patients (42%) had kidney stones and all 12 patients were taking the iron chelating drug deferasirox. Patients who were followed by endocrinology were more likely to have serial DXA measurements (18/21(86%) vs. 8/12(67%)) and 24-hour urine calcium measurement (13/21(62%) vs. none) compared to patients not followed by endocrinology.Conclusions: This study on racially diverse adults with TDA living in the US demonstrates a high prevalence of low bone mineral density, fractures, endocrinopathies and hypercalciuria. Routine endocrinology referral is recommended and further research in the pathogenesis and treatment of low bone mineral density in this patient population is required.

The Effects of Cortisol and Adrenal Androgen on Bone Mass in Asian Patients with and without Subclinical Hypercortisolism Seong Hee Ahn*[1], Jae Hyeon Kim[2], Mihye Jung[1], Yoon Young Cho[3], Sunghwan Suh[4], Beom-Jun Kim[5], Seongbin Hong[1], Seung Hun Lee[5], Jung-Min Koh[5], Kee-Ho Song[6]. [1]Department of Endocrinology and Metabolism, Inha University Hospital, Inha University School of Medicine, Republic of Korea, [2]Division of Endocrinology and Metabolism, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Republic of Korea, [3]Division of Endocrinology and Metabolism, Department of Medicine, Gyeongsang National University Hospital, Gyeongsang National University School of Medicine, Republic of Korea, [4]Division of Endocrinology and Metabolism, Department of Medicine, Dong-A University Medical Center, Dong-A University College of Medicine, Republic of Korea, [5]Division of Endocrinology and Metabolism, Asan Medical Center, University of Ulsan College of Medicine, Republic of Korea, [6]Division of Endocrinology and Metabolism, Department of Medicine, Konkuk University Medical Center, Konkuk University School of Medicine, Republic of Korea

Purpose: Despite ethnic differences in cortisol sensitivity between Caucasians and Asians, scanty reports evaluated bone metabolism in Asian patients with subclinical hypercortisolism (SH). We investigated associations of both cortisol and dehydroepiandrosterone-sulfate (DHEA-S), an adrenal androgen, with bone mineral density (BMD) and bone turnover makers (BTMs) in Asian adrenal incidentaloma (AI) patients with and without SH. Methods: We measured BMD, BTMs, cortisol levels after 1 mg-dexamethasone suppression test (1 mg-DST), and cortisol to DHEA-S ratio (cort/DHEA-S) in 109 AI patients with SH (56 women and 53 men) and 686 with non-functional AI (NFAI) from a large Korean cohort. Results: Women but not men with SH had lower BMDs at lumbar spine (LS), femoral neck, and total femur than patients with NFAI (P <0.001 to 0.015). After adjusting for confounders, higher 1 mg-DST was associated with lower BMDs at all skeletal sites in women (β = -0.021 to - 0.032, P = 0.010 to 0.023), but not in men. Higher cort/DHEA-S was associated with lower LS BMD in both women (β = -0.035, P <0.001) and men (β = -0.029, P = 0.011). The inverse association of cort/DHEA-S with LS BMD remained significant even after adjusting for 1 mg-DST (β = -0.031, P <0.004 for women; β = -0.026, P <0.029 for men). In women, the odd ratio for lower BMD by cort/DHEA-S was 1.54 (95% confidence interval, 1.02–2.31). Conclusion: Subtle cortisol excess in women and reduced DHEA-S in both genders may contribute to BMD reduction in Asian patients with SH.

Severe asthma and high doses of corticosteroid impair trabecular bone score more than bone mineral density Yong Jun Choi*[1], Hyun-Young Lee[2], Sihoon Lee[3], Yoon-Sok Chung[1], Young-Min Ye[4]. [1]Department of Endocrinology and Metabolism, Ajou University School of Medicine, Republic of Korea, [2]Clinical Trial Center, Ajou University Medical Center, Republic of Korea, [3]Gachon University School of Medicine, Republic of Korea, [4]Department of Allergy and Clinical Immunology, Ajou University School of Medicine, Republic of Korea

BACKGROUND: In asthmatic patients, treatment with corticosteroids, in addition to conventional risk factors for osteoporosis, may lead to bone loss. Trabecular bone score (TBS) is a new, indirect parameter of bone quality. Studies have yet to evaluate TBS in asthmatic patients in relation to disease severity and corticosteroid use.OBJECTIVE: This study aimed to evaluate TBS in asthmatics in comparison to propensity score-matched controls and to investigate correlations between TBS and cumulative systemic and inhaled corticosteroid doses 1 year prior to bone mineral density measurement in patients with asthma.METHODS: In total, 627 patients with asthma and the same number of non-asthmatic controls matched for sex and age were included in this retrospective cohort study. TBS was calculated in the lumbar region, based on two dimensional projections of dual-energy X-ray absorptiometry. RESULTS: Patients with severe asthma exhibited lower vertebral TBS values (1.33±0.11) than those with non-severe asthma (1.37±0.10, P=.004), with non-active asthma (1.38±0.10, P<0.001), and without asthma (1.39±0.10, P<.001). No significant differences in BMD were noted among the study groups (0.96±0.18 vs 0.98±0.25 vs 0.97±0.17 vs 0.97±0.18, all P-values>.05). A TBS of 1.42 was determined as a cut-off for osteoporosis. TBS was significantly associated with cumulative systemic and inhaled corticosteroid doses, as well as lung function and airway hyper-responsiveness.Conclusion: TBS can be used as an early indicator of altered bone quality stemming from glucocorticoid therapy or, possibly, more severe asthma.

The effects TSH suppressive therapy of on changes of TBS and BMD in menopausal women with for differentiated thyroid cancer Yun Kyung Jeon *[1], Keunyoung Kim[2], In Joo Kim[1], Kyoung Min Kim[3], Kyoungjune Pak[2], Seong-Jang Kim[4]. [1]Endocrinology and metabolism, Pusan National University Hospital, Republic of Korea, [2]Department of Nuclear Medicine and Biomedical Research Institute, Pusan National University Hospital, Republic of Korea, [3]Seoul National University College of Medicine and Seoul National University Bundang Hospital, Republic of Korea, [4]Department of Nuclear Medicine and Biomedical Research Institute, Yang San Pusan National University Hospital, Republic of Korea

This study aimed to examine the changes of trabecular bone score (TBS), areal bone mineral density (aBMD) and diagnosis in postmenopausal women who were undergoing thyrotropin (TSH) suppressive therapy for treatment of papillary thyroid cancer (PTC) after total thyroidectomy.Methods: We enrolled a total of 36 postmenopausal patients (mean age: 60.5 ±5.5 years) undergoing TSH suppressive therapy with levothyroxine after receiving total thyroidectomy for papillary thyroid cancer. Ninety-four postmenopausal women (mean age: 60.8 ±5.3 years) matched for age and body mass index were recruited as healthy control group. Dual-energy X-ray absorptiometry (DXA) was performed for the evaluation of BMD status. The BMD and TBS of the lumbar spine were generated from DXA at the baseline and after mean 4.92 year.Results: The proportion of both osteopenia and osteoporosis was not significantly different between TSH suppression group and control group at the first DXA evaluation, (11.2% vs. 21.2%, p=0.350), however, progression rate of normal to osteopenia or osteopenia to osteoporosis was more common in a group of TSH suppression (77.8% vs 38.5%, p<0.001). The incidence of osteoporosis is more common at the time of followed DXA evaluation (27.8% vs. 10.6%, p<0.001). The TBS was not significantly different between initial DXA and follow up DXA images. There was slightly decreasing trend in TBS and BMD among the patients and control groups, however, there was no statistical significance. The median degradation ratio of TBS was significantly higher in PTC group (median 0.054; IQR: 1.18–1.47) than in control group (median: 0.020; IQR: 1.18–1.47, p=0.039), however, BMD did not show significant median changing ratio (p=0.215). The number of patients who showed TBS < 1.3 was significantly higher in the group of PTC than in the group of normal control group at the time of the first DXA evaluation (28.5% vs. 12.8%, p=0.027).In total 132 patients, if the initial TBS was higher than 1.3, more participants stay at the same BMD status, whereas, if the initial TBS was lower than 1.3, more patients have trend of deteriorating BMD status without statistical significance. Even TBS of the participant was higher than 1.3, the patients who were under TSH suppression were more tend to progress to osteopenia or osteoporosis (85.2% vs. 52.4%, p=0.003).Conclusions: BMD and TBS were not significantly changed during short-term follow up period in both groups of PTC and control. The degradation ratio of TBS was minimal but significantly decreased and the incidence of progression to deteriorating BMD was higher in PTC group despite of normal TBS value. Therefore, dedicated management and evaluation including TBS should be considered in the postmenopausal patients undergoing long-term TSH suppressive therapy.

Bone Mineral Density and Trabecular Bone Score Associations with Hypertension and Diabetes in the VITamin D and OmegA-3 TriaL (VITAL): Effects on Bone Structure and Architecture Study Meryl Leboff*[1,2], Catherine Donlon[1], Nancy Cook[2,3,4], Julie Buring[2,3,4], Joann Manson[2,3,4]. [1]Division of Endocrinology, Diabetes and Hypertension, Brigham and Women's Hospital, United States, [2]Harvard Medical School, United States, [3]Division of Preventive Medicine, Brigham and Women's Hospital, United States, [4]Department of Epidemiology, Harvard T.H. Chan School of Public Health, United States

Previous studies have shown associations between hypertension and low bone mineral density (BMD) and increased fracture risk. Both cardiovascular disease (CVD) and osteoporosis share similar risk factors, including older age, diabetes, smoking, and low physical activity levels. In this study, we investigated whether Trabecular Bone Score (TBS) and BMD at the spine, femoral neck, total hip, and whole body were associated with a history of hypertension, diabetes, and/or use of anti-hypertensive, anti-diabetic, or cholesterol-lowering medications in VITamin D and OmegA-3 TriaL (VITAL).The parent VITAL study is a 2x2 factorial randomized controlled trial (RCT) investigating effects of supplemental cholecalciferol (2000 IU/d) and/or omega (ω)-3 fatty acids (1 g/d) for the primary prevention of cancer and CVD. The study had a median of 5-yrs of treatment in 25,874 US men ≥50 yrs and women ≥55 yrs. In our ancillary study, VITAL: Effects on Bone Structure and Architecture,1,2 in-person assessments were completed in a subcohort of 771 participants (46.8% women, 53.2% men). Medical histories were obtained by annual questionnaires, and BMD was determined by dual-energy X-ray absorptiometry (Discovery W; APEX Software Version 4.2, Hologic, Bedford, MA). TBS, a measure of bone structure, was derived from the spine DXA images (Medimaps Version 2.1, Geneva, Switzerland). All analyses were adjusted for age, race, sex, and BMI.Overall, higher BMD at the spine was associated with ever use of anti-hypertensive medications (p=0.049) and history of diabetes (p=0.031). When anti-hypertensive medications were broken down by type (ie. beta-blockers, calcium-blockers, diuretics, ACE-inhibitors, angiotensin-receptor blockers, or alpha-blockers), there were no associations with spine BMD, possibly due to smaller sample sizes. TBS was not significantly associated with hypertension or anti-hypertensive medications but was lower in participants with a history of diabetes (p=0.003) and those currently using anti-diabetic medication (p<0.001). There were no associations between total hip, femoral neck, or whole body BMD and hypertension, diabetes, or anti-hypertensive, anti-diabetic, or cholesterol-lowering medications. In future analyses in the VITAL RCT, we will assess whether hypertension and diabetes are associated with incident fractures and changes in bone structure and whether these co-morbidities modify effects of supplemental vitamin D and/or ω-3 fatty acids on bone health.References: 1. LeBoff MS, et al. Contemp Clin Trials. 2015 Mar;41:259-682. Donlon CM, et al. Contemp Clin Trials. 2018 Apr;67:56-67

Accuracy of FRAX® in People with Multiple Sclerosis: A Manitoba BMD Registry-Based Cohort Study Etienne J. Bisson*[1], Marcia Finlayson[1], Okechukwu Ekuma[2], Ruth Ann Marrie[2], William D Leslie[2]. [1]Faculty of Health Sciences, Queen's University, Canada, [2]Rady Faculty of Health Sciences, University of Manitoba, Canada

People with multiple sclerosis (MS) have a higher risk of low bone mineral density (BMD) and osteoporotic fractures as compared to healthy adults. The fracture risk assessment tool (FRAX®) has been reported to underestimate fracture risk in people with MS when BMD is unknown.AIM: To test the performance of FRAX BMD for people with MS, and determine if MS is a risk factor for fracture independent of FRAX score.METHODS: Using population-based data for Manitoba Canada, we identified MS cases with BMD screening after diagnosis (n=744) and controls matched on age, sex and BMD screening date (n=3721). We calculated FRAX 10-year probabilities and ascertained subsequent major osteoporotic fractures (MOF). Cox proportional hazards models were used to assess the effect of MS on the risk of MOF, after accounting for baseline risk. Calibration (predicted vs observed 10-year MOF probability with competing mortality) was compared in people

with MS with/without use of secondary osteoporosis (2ary OP) as an input to FRAX without BMD, and with/without use of rheumatoid arthritis (RA) as a proxy for MS in FRAX with BMD.RESULTS: MS cases had higher mean FRAX MOF probability calculated with BMD than controls (8.32% vs 6.98%; p<0.01) and lower femoral neck T-score (1.42 vs 1.07; p<0.01). MS cases had a higher cumulative incidence of MOF (n=77; 10.4%) compared to controls (n=238; 6.4%; p<0.001). FRAX stratified risk for incident MOF in people with MS (HR=2.08, 95% CI 1.67-2.61 without BMD; HR=1.99, 95% CI 1.60-2.47 with BMD) similar to those without MS (HR=1.62, 95% CI 1.42-1.85 without BMD; HR=1.77, 95% CI 1.56-2.01 with BMD). MS was a predictor of MOF after controlling for FRAX without BMD (HR=1.67, 95%CI 1.29-2.16), FRAX with BMD (HR=1.48, 95%CI 1.14-1.92), and individual risk factors including BMD (HR=1.45, 95% CI 1.12-1.89). FRAX was well-calibrated in the controls but underestimated observed MOF risk in MS cases (by 4.4% without BMD, by 3.1% with BMD; both p<0.01). Calibration improved when 2ary OP was used to calculate FRAX without BMD, and was best when RA was used to calculate FRAX probability with BMD.CONCLUSION: MS is a FRAX-independent risk factor for MOF but FRAX still stratifies fracture risk in people with MS. Using secondary osteoporosis or RA as proxies for MS improves performance of FRAX and accurately predicts MOF outcomes in those with MS. This provides clinicians with a readily available approach to improve the accuracy of fracture prediction in MS.

Smaller but Denser Bones in Older Women with Type 2 Diabetes Anna Nilsson*[1,2], Daniel Sundh[1], Mattias Lorentzon[1,3]. [1]Geriatric unit, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [2]Dept Endocrinology, Internal Medicine, Sahlgrenska University Hospital, Sweden, [3]Geriatric Medicine Clinic, Sahlgrenska University Hospital, Sweden

Background: Type 2 diabetes mellitus (T2DM) is associated with an increased risk of fractures, despite higher bone mineral density (BMD) compared to controls, which may be due to higher body mass index (BMI). There are conflicting results in the literature regarding bone microstructure. Objective: The objective of the present study was to evaluate bone microstructure and bone geometry in older women with T2DM.Methods: 293 women with T2DM were identified in a population-based study on 3,028 women between 75-80 years, performed in Gothenburg 2013-2016. After exclusion of 20 women with T1DM, propensity score matching for age, BMI, family history of fractures, smoking, alcohol habits, rheumatoid arthritis, and glucocorticoid usage, was performed to select 3 controls per subject with T2DM. Volumetric BMD (vBMD) and bone microarchitectural indices were assessed at two sites in radius and tibia (standard site and at 14% of bone length) with high-resolution peripheral quantitative computed tomography. Physical function (Timed Up and Go (TUG), one-leg standing (OLS), number of chair-stands, grip strength, and walking velocity), was tested in all women by physiotherapists.Results: After matching, mean (±SD) age was 77.7±1.6 years in both groups, and BMI was 29.0±5.1 kg/m2in women with T2DM and 28.9±4.8 kg/m2in controls (n=879). Despite highly similar BMI, women with T2DM had generally better values with higher total vBMD (e.g.,standard site tibia 248±52 vs. 232±45 mg/cm3, p<0.001), cortical vBMD (e.g.,14% site tibia 930±41 vs. 914±40 mg/cm3, p<0.001) and trabecular bone volume fraction (e.g.,standard site tibia 13.3±2.9 vs. 12.5±2.7%) than controls. However, the total area of the bone sections was significantly smaller (e.g.,14% tibia 429±57 vs 442±59 mm2, p=0.001) despite a clearly greater cortical area (e.g.,14% tibia 156±24 vs 152±24 mm2, p=0.007) in T2DM (Fig.1). Cortical porosity was lower at 14% tibia (4.8±2.4 vs 5.3±2.4%, p=0.001) in T2DM. All tests showed a significantly worse physical function (TUG +10%, OLS -8.6%, chair-stands -6.4%, grip strength -7.3%, walk speed -4.9%) in women with T2DM compared to controls.Conclusion: Elderly women with T2DM had smaller but denser bones and performed worse in physical function tests than controls matched for BMI. Whether reduced bone size and poorer physical function explain an increased fracture risk in T2DM, despite higher bone density, remains to be elucidated.
Figure 1. Total (A) and cortical (B) area and trabecular bone volume fraction (C) at the 14 % tibia site in women with type 2 diabetes (n=293) and in BMI-matched controls (n=879). ** p<0.01, *** p=0.001

Bone Biomarkers Do Not Differ in Older Men With and Without Severe Nocturnal Hypoxemia Christine Swanson*[1], Steven Shea[2], Sheila Markwardt[3], Orfeu Buxton[4], Katie Stone[5], Thuy-Tien Dam[6], Nancy Lane[7], Susan Redline[8], Jane Cauley[9], Douglas Bauer[10], Eric Orwoll[11]. [1]University of Colorado, Division of Endocrinology, Metabolism and Diabetes, United States, [2]Oregon Institute of Occupational Health Sciences, Oregon Health and Science University, United States, [3]OHSU-PSU School of Public Health, United States, [4]Department of Biobehavioral Health, Pennsylvania State University, United States, [5]California Pacific Medical Center Research Institute and San Francisco Coordinating Center, United States, [6]Columbia University, United States, [7]Center for Musculoskeletal Health, University of California, Davis Medical Center, United States, [8]Department of Medicine, Brigham and Women's Hospital and Beth Israel Deaconess Medical Center, Harvard Medical School, United States, [9]Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, United States, [10]University of California Medical Center, United States, [11]Division of Endocrinology Bone and Mineral Unit, Oregon Health and Science University, United States

Obstructive sleep apnea (OSA) is a risk factor for many endocrine disorders but has been variably linked with alterations in bone metabolism. The inconsistent associations between OSA and bone health may be due to the complex OSA phenotype and spectrum of sleep disruption seen in OSA sufferers (e.g., nocturnal hypoxemia, sleep fragmentation, sleep loss, etc.). We used the Osteoporotic Fractures in Men (MrOS) study to investigate the association between nocturnal hypoxemia and biomarkers of bone metabolism. Biomarkers of bone formation (P1NP), resorption (CTX), and osteocyte function (sclerostin, FGF-23) were obtained in older men with polysomnography recordings from the MrOS ancillary sleep study. Men were excluded if they had other sleep disorders, were on treatment for OSA or osteoporosis, had daytime hypoxemia at rest (SaO2 < 90%), were current smokers, had excess alcohol use, a fracture within three months of their blood draw, were using glucocorticoids, or had a condition known to affect bone metabolism (hyper/hypothyroid, diabetes mellitus, or eGFR < 30 mL/min/1.73 m2). Polysomnography was used to determine the severity of nocturnal hypoxemia based on percent (%) sleep time with oxygen saturation (SaO2) less than 90% and the apnea hypopnea index (AHI) which was defined as all events with a ≥ 4% desaturation. Bone biomarker levels were compared between a subgroup of men with severe nocturnal hypoxemia (defined as ≥ 10% sleep time with SaO2 < 90% and AHI ≥ 15) and age/BMI/race-matched men with normal nocturnal oxygenation (defined as < 1% sleep time with SaO2 < 90% and AHI < 5) using a paired t-test. In total, 36 pairs of men met inclusion/exclusion criteria and had sufficient serum available for this analysis. On average, men were 78 ± 4.6 years old, had a BMI of 28.4 ± 3.0 kg/m2, and all were Caucasian. Levels of 25OHD, testosterone, and eGFR were similar between the two groups. CTX tended to be lower in men with severe nocturnal hypoxemia compared to age/BMI/race-matched men with normal nocturnal oxygenation but this was not statistically significant (Table 1). Levels of P1NP, FGF-23, and sclerostin were not significantly different in men with severe nocturnal hypoxemia compared to those with normal nocturnal oxygenation (Table 1). In conclusion, severe nocturnal hypoxemia is not associated with bone biomarkers in older men. This should be confirmed in larger studies.

Table 1: Bone biomarker levels in men with and without severe nocturnal hypoxemia

	Severe Nocturnal Hypoxemia (Mean ± SE)	Normal Nocturnal Oxygenation (Mean ± SE)	Difference (95% CI)	p-value
CTX (ng/mL)	0.38 ± 0.03	0.44 ± 0.03	-0.06 (-0.13, 0.01)	0.12
P1NP (mcg/L)	39.87 ± 2.67	43.05 ± 2.67	-3.18 (-10.60, 4.24)	0.39
FGF-23 (pg/mL)	54.71 ± 2.66	52.35 ± 2.66	2.36 (-4.89, 9.61)	0.51
Sclerostin (pmol/L)	71.33 ± 4.06	72.07 ± 4.06	-0.74 (-12.20, 10.72)	0.90

Effects of Teriparatide on Bone Microarchitecture and Stiffness Assessed by High Resolution Peripheral Computed Tomography (HR-pQCT) in Premenopausal Idiopathic Osteoporosis (IOP) Sanchita Agarwal*[1], Adi Cohen[1], Stephanie Shiau[2], Mafo Kamanda-Kosseh[1], Mariana Bucovsky[1], X Edward Guo[3], Elizabeth Shane[1]. [1]Division of Endocrinology, Department of Medicine, Columbia University, United States, [2]Gertrude H. Sergievsky Center, Columbia University Medical Center, United States, [3]Bone Bioengineering Laboratory, Department of Biomedical Engineering, Columbia University, United States

Premenopausal women with IOP (PreMenIOP) have marked deficits in bone mass, microarchitecture and stiffness. In a pilot study of teriparatide (TPTD) in 21 PreMenIOP, we observed increases in BMD by DXA at the spine and hip and no change at the 1/3 radius. After 18M of TPTD, HR-pQCT revealed significant 2.5% increases in trabecular (Tb) density and estimated stiffness, at both radius (RAD) and tibia (TIB), and in cortical (Ct) porosity at RAD only.In a double-blind, placebo-controlled, single-switchover study of TPTD (20mcg SC QD), 41 PreMenIOP were randomized to ActiveTPTD or Placebo pens. At 6M, those randomized to ActiveTPTD continued for 18M and those randomized to Placebo began ActiveTPTD and continued for 24M. A subset (n=34; age=37±8 yrs) had HR-pQCT performed at baseline and after 6M on ActiveTPTD (n=25) or Placebo (n=9) injections. All 34 subjects were scanned after 12M of ActiveTPTD. 22 of 34 had baseline scans on the first-generation HR-pQCT scanner (XCT1) and follow-up scans on the second-generation HR-pQCT (XCT2). To compare subjects with scans on different scanners, XCT2 data were calibrated to XCT1 with regression equations developed in our lab. After excluding 3 radius scans with motion score >3, 6 subjects in the Placebo group had paired 6M scans. Data were analyzed as percent change from baseline. Independent and paired t-tests were performed with p<0.05 considered significant.At baseline, there were no between-groups differences at the RAD. TIB Tb thickness was 7 microns lower in the Placebo group (p=0.034). There were no significant between- or within-group differences in Total, Ct or Tb volumetric density, Ct porosity or estimated stiffness after 6M of ActiveTPTD or Placebo at the RAD or TIB. After 12M of ActiveTPTD, TIB Ct porosity increased significantly (+16%, p=0.04), with a trend towards an increase at the RAD (+14%, p=0.06). There were no significant increases in Total, Ct or Tb volumetric density, or estimated stiffness at either site.In summary, we did not detect significant between- or within-groups differences in volumetric density, Ct porosity or stiffness after 6M of ActiveTPTD or Placebo, although the small number of Placebo subjects renders this analysis unreliable. After 12M of ActiveTPTD, we did not detect significant changes in volumetric density or microstructure at either RAD or TIB. We conclude that the increase in Ct porosity with TPTD does not adversely affect Ct volumetric BMD and stiffness in PreMenIOP.

Figure: Median percentage changes and interquartile range (box) for measurements at distal radius (blue) and tibia (green) at 12M on Active Teriparatide, *p<0.05.

Effects Of Two Years Of Teriparatide Treatment Followed By Two Years Of Bisphosphonates In Reduction In Fracture Rate And Back Pain At Patients With Multiple Pre-Existing Vertebral Fractures. Corina Galesanu*[1], Iulian Pascariu[2], Veronica Mocanu[3], Mihail Romeo Galesanu[4]. [1]University of Medicine and Pharmacy "Grigore T.Popa", Romania, [2]Sf.SpiridonEmergency Clinical Hospital, Romania, [3]Grigore T. Popa University of Medicine and Pharmacy, Romania, [4]Romanian Academy of Medical Sciences, Iasi, Romania

Background: Teriparatide (TPTD) is a therapeutic agent that increases the formation of new bone tissue and provide some remediation of the architectural defects in the osteoporotic skeleton. It is unclear which treatment should be given after stopping teriparatide therapy for severe osteoporosis. Bisphosphonate therapy can maintain bone mineral density (BMD) gains after medication cessation. Objectives: To evaluate the effect of prior teriparatide exposure and after that the bisphosphonate response, and to compared BMD effects of follow-up treatments. Methods : Ten osteoporotic naïve-patients (7 postmenopausal women and 3 men) are treated with teriparatide 20 μg/day for 24 months, followed by risedronate 75 mg/mo for other 24 months. All patients received calcium and vitamin D supplementation. Changes in BMD from baseline to 24 mo, 48 mo were analyzed . Fasting serum was collected for baseline PTH , 25 hydroxyvitamin D, and baseline and treatment 24,48 mo, P1NP, CTX , bone ALP, osteocalcin ,serum calcium. Results: Daily teriparatide treatment for 2 yr significantly increased spine BMD by 16.6%, total hip and femoral neck, 7.5% and 11,9% respectively. Under the risedronate the year 2 nd have had an increase of BMD at the lumbar by 6.7% , and 4.0% at the total hip and -1.6% at femoral neck. Markers of bone formation (PINP, bone ALP, osteocalcin) increased early during teriparatide therapy . Under the risedronate markers in bone resorption (CTX) decreased. Conclusions:, BMD increases progressively over 2 yr of teriparatide therapy in patients with severe osteoporosis. After discontinuation of teriparatide, risedronate 75 mg increases spine and total hip BMD . This confirms the need an antiresorptive treatment to prevent bone loss after teriparatide.

Effect of Buffered Solution of Alendronate 70mg on Bone Mineral Density and Bone ALP: Prospective Observational Study Andrea Giusti*[1], Dennis M Black[2], Antonella Barone[3], Josef Hruska[4], Gerolamo Bianchi[1]. [1]La Colletta Hospital, Italy, [2]University of California San Francisco, United States, [3]Galliera Hospital, Italy, [4]EffRx Pharmaceuticals, Switzerland

Keywords: osteoporosis, bone mineral density, buffered alendronate Introduction: Alendronate 70mg effervescent (ALN-EX) is administered as buffered solution of fully dissolved ALN1. While registration studies have demonstrated bioequivalence of ALN-EX to ALN tablets (ALN-T)1, BMD and BTM data are lacking. Objective: To evaluate the effect of ALN-EX on BMD and bone-ALP (b-ALP), and to compare the outcomes with a historical cohort of patients on ALN-T. Materials and Methods: A standardized Clinical Database has been used for the study. 42 postmenopausal women (PMW), presenting with BMD T-score <-2.5, or between -2 and -2.5 and at least one vertebral fracture, starting ALN-EX between July 2015 and June 2016 were enrolled. BMD at femoral neck (FN-BMD), total hip (TH-BMD), and b-ALP were measured at baseline and after 12-month. 54 PMW on ALN-T were randomly selected for the historical cohort. Mean % changes (±SD) of FN-BMD, TH-BMD and b-ALP from baseline to 12-month were compared between the two groups (ALN-EX and ALN-T). Results: The two groups were comparable at baseline, including previous history of vertebral/femoral fractures, and baseline BMD. The two groups had comparable mean % increases in FN-BMD and TH-BMD after 12-month of treatment: in ALN-EX group by 1.5%±2.8% (FN-BMD) and 2.1%±2.6% (TH-BMD), in ALN-T group by by 1.4%±3.3% (FN-BMD) and 2.2%±3.5% (TH-BMD). Also the absolute decrease (mean U/L±SD) of b-ALP was comparable between ALN-EX group (-6.0±2.8 U/L) and the ALN-T group (-6.9±4.4 U/L). There was no significant difference in BMD or BTM change between ALN-EX and ALN-T. Conclusion: To the best of our knowledge, this is the first report comparing BMD and a marker of bone turnover between PMW treated with ALN-EX and PMW treated with ALN-T. Given the limits of the trial design (e.g., lack of randomization), the results of our study demonstrated that ALN-EX is as effective as traditional ALN-T on surrogate anti-fracture efficacy outcomes.

Variable		ALN-EX	P	ALN-T	P

Patient Characteristics and Fracture Outcomes in Patients Previously Treated With Bisphosphonates or Treatment-naïve in the Teriparatide versus Risedronate VERO Clinical Trial Peyman Hadji*[1], Fernando Marin[2], David Kendler[3], Piet Geusens[4], Luis Russo[5], Jorge Malouf[6], Peter Lakatos[7], Salvatore Minisola[8], Pedro López-Romero[2], Astrid Fahrleitner-Pammer[9]. [1]Krankenhaus Nordwest GHMB, Germany, [2]Lilly Research Center Europe, Spain, [3]University of British Columbia, Canada, [4]Maastricht University Medical Center, Netherlands, [5]Centro de Analises e Pesquisas Clínicas LTDA, Brazil, [6]Hospital Sant Pau, Spain, [7]Semmelweis University Medical School, Hungary, [8]Sapienza Rome University, Italy, [9]Division of Endocrinology, Medical University of Graz, Austria

Background: The fracture results after switching osteoporosis drugs have not been adequately addressed in randomized clinical trials. We previously reported a significant reduction in the risk of new vertebral (VFx) and clinical fractures in patients treated with teriparatide (TPTD) compared to risedronate (RIS), similar in both prior bisphosphonate (BP) users, and in osteoporosis treatment naïve patients1. Incident fracture rates were also similar regardless of prior BP treatment1. Here, we report a post-hoc analysis comparing the baseline patient characteristics by prior BP therapy.Patients & Methods: 1360 postmenopausal women with at least 2 moderate or 1 severe VFx and low bone mass (BMD T-score ≤-1.5) were randomized and treated with SC daily TPTD 20 μg or oral weekly RIS (35 mg) in a double-blind, double-dummy 2-year trial. Patients were considered prior BP users if they had received ≥3 months of any oral, im or iv BPs (ibandronate or pamidronate), or ≥1 dose of iv zoledronic acid. The osteoporosis treatment-naïve group included patients who received none or <3 months of any osteoporosis drugs. Calcium and vitamin D supplements were not considered osteoporosis medications. Data from 57 (4.2%) patients who had received non-BP drugs are not shown.Results: 728 (53.5%) patients were prior BP users and 575 (42.3%) were treatment-naïve (full analysis set). Prior BP users were older, had a lower body mass index, more frequently reported a history of a non-vertebral fracture, and were more frequently enrolled in Europe and North America (Table). Fewer prior BP users had a history of a recent clinical vertebral fracture (32.0% vs 43.0%; p<0.0001). Baseline mean serum 25OH-vit D levels were higher in BP users (33.3 vs 29.7 ng/mL; p<0.01). The number and severity of prevalent vertebral fractures and baseline BMD T-scores were similar in the two groups (Table).Conclusion: The baseline characteristics of postmenopausal women enrolled in the VERO trial are relatively similar with regard to fracture risk in both women with prior BP use or treatment-naïve. The lower frequency of prior recent spine fracture in the prior BP users was balanced with a higher frequency of prevalent non-vertebral fractures in this group. Differences in baseline characteristics between prior BP users and treatment naïve women are unlikely to have impacted on the fracture risk reduction observed in women randomized to TPTD or RIS.1Geusens P et al. JBMR (2018);DOI:10.1002/jbmr.3384

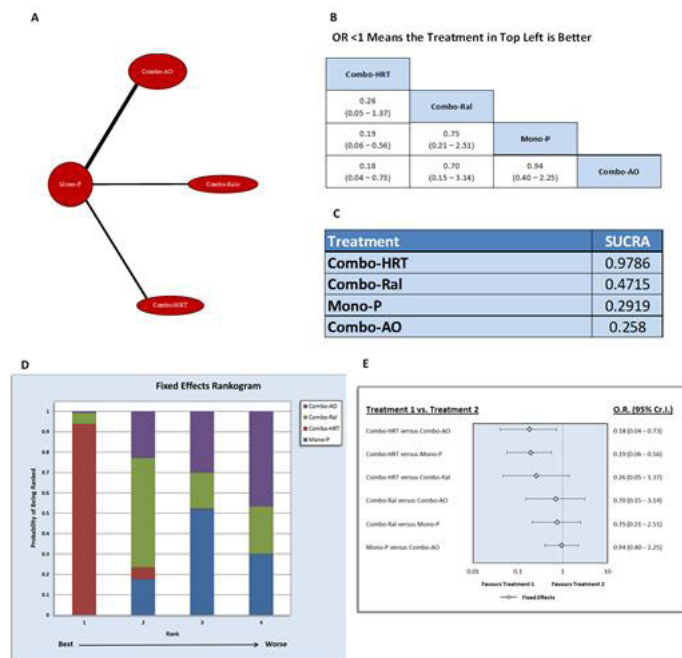
SUN-0927

Combination therapies for the treatment of osteoporotic fractures are not created equal: A network meta-analysis study Osama Haji Ahmed*[1], Paula Karabelas[2], Abdulhafez Selim[3]. [1]Mouwasat Hospitals, Saudi Arabia, [2]Independent Investigator, United States, [3]PCOM, United States

Background: According to the mechanisms of action, combination therapy may produce more effect for the treatment of osteoporosis. This study aims to assess the effect of 4 interventions: (1) anabolic monotherapy of parathyroid hormone (PTH); (2) combination therapies of anabolic (PTH) and other treatment modalities including anti-osteoclast (AO) agents (Bisphosphonates or Denosumab); (3) hormone replacement therapy (HRT); or (4) Raloxifene (Ral) in adults with osteoporosis.Methods: We searched Medline, EMBASE, and The Cochrane Library from January 1, 1980 to March 1, 2018 for randomized controlled trials of adults with osteoporosis treated in combination therapy compared with monotherapy. The outcome was the incidence of osteoporotic fractures. A total of 11 trials were analyzed with a total of 1,130 patients. The analysis included 4 interventions: monotherapy of PTH (Mono-P), PTH with HRT (Combo-HRT), PTH with Raloxifene (Combo-Ral), and PTH with anti-osteoclast agents (Combo-AO). The meta-analysis was performed using a fixed-effects model. The data were expressed as odds ratio (OR) and 95% CI.Results: Combo-HRT was the only combination that demonstrated a statistically significant reduction of fracture risk compared to Mono-P (OR of 0.18, CI: 0.04-0.73). A significant difference in risk reduction was also observed in the Combo-HRT group when compared to the Combo-AO group (OR of 0.19, CI: 0.06-0.56). Overall ranking demonstrated that Combo-HRT is the most effective treatment (SUCRA score of 94.0%), followed by Combo-Ral (SUCRA score of 47.0%). The Mono-P and Combo-AO groups had low SUCRA scores of 29.0% and 26.0% respectively. Additional data are presented in Figure 1.Conclusion: This is the first network meta-analysis study to evaluate various modalities of the combination therapies. Moderate-quality evidence shows that the combination therapy of PTH and HRT, followed by the combination of PTH and Raloxifene are superior to PTH monotherapy. These differences may be clinically meaningful, particularly for patients at highest risk for hip fractures, including those who have had a recent hip fracture, multiple prevalent fractures, or extremely low hip BMD. Significant differences in effectiveness may be attributed to the variability among mechanisms of action. Further, properly designed, high methodological quality studies are needed to determine the anti-fracture efficacy, cost-effectiveness, and safety of this strategy of combination therapy.


A: Network diagram. B: League table. C: SUCRA scores. D: Rankogram. E: Forest Plot. Combo-HRT: Combination of PTH and HRT. Combo-Ral: combination of PTH, and Raloxifene. Mono-P: PTH only. Combo-AO: combination of PTH, and anti-osteoclast agents (bisphosphonates or Denosumab). SUCRA is a numeric presentation of the overall ranking and presents a single number associated with each treatment. SUCRA values range from 0 to 100%. The higher the SUCRA value, and the closer to 100%, the higher the likelihood that a therapy is in the top rank or one of the top ranks.

Goal-Directed Treatment of Osteoporosis in Patients with Rheumatoid Arthritis Using Daily Teriparatide for Two Years Followed by Antiresorptive Drugs for Three Years (Results in Five Years in Total) Yuji Hirano*, Daisuke Kihira. Department of Rheumatology, Toyohashi Municipal Hospital, Japan

Background: Osteoporosis (OP) is frequently concomitant with rheumatoid arthritis (RA). Effective treatment have to be performed in RA patients with OP (RAOP). We reported results of treatment with 2-year daily teriparatide (dTP) followed by either denosumab (DMB) or minodronate (MIN: a bisphosphonate developed in Japan) with eldecalcitol (ELD: activated vitamin D developed in Japan) in RAOP at ASBMR 2015, 2016 and 2017. It was shown that both treatment strategy has similar efficacy in RAOP. Recently treatment goal of OP was reported from ASBMR-NOF working group (Goal-Directed Treatment, JBMR2017). This progress report advocated that the goal of treatment is a T-score>-2.5 at femoral neck (FN), total hip (TH) or lumbar spine (LS) by DXA if the primary reason for starting treatment was T-score?-2.5 at that skeletal site. The aim of this retrospective study is to evaluate whether 2-year dTP followed by "DMB" or "MIN with ELD" for 3 years can achieve treatment goal of OP reported recently.Methods: This study used 24 female RAOP patients from Toyohashi RA database (TRAD). All patients completed 2-year dTP treatment followed by 3-year either antiresorptive drug treatment shown in background part (DMB: n=10, MIN+ELD: n=14). Treatment goal was set as T-score>-2.5 at five years in patients whose T-score is below -2.5 at the same skeletal site at the initiation of OP treatment in this study. Bone mineral density (BMD) was measured by DXA. As was in clinical setting in Japan, dTP was prescribe as daily self-injection agent. 60mg DMB was administered every 6 months with native vitamin D3 agent. 50mg MIN was administered every 4 weeks and 0.75 μg ELD was administered every day. Results: Baseline characteristics of 24 patients: Mean age was 70 years. RA duration was 18 years. Prednisolone usea was 67%. Number of patients with T-score<-2.5 in LS, TH and FN at baseline was 14, 18 and 16, respectively. Proportion of patients with T-score>-2.5 at 5 years was 57.1% in LS-BMD, 22.2% in TH-BMD and 25.0% in FN-BMD (Fig1). Cut-off values at baseline for achievement of treatment goal calculated using receiver operating characteristic (ROC) analysis was -3.4 in LS-BMD, -3.0 in THBMD and -2.9 in FN-BMD.Conclusions: This study suggested that achievement of treatment goal in RAOP is possible in LS-BMD but difficult in TH-BMD and FN-BMD when 2-year dTP followed by antiresorptive drugs for 3 years was used as treatment for RAOP. ROC analysis revealed that early intervention is necessary when treating RAOP aiming treatment goal especially in treating THBMD and FNBMD.
Fig1. Change of percentage of patients with T-score>2.5

Daily teriparatide treatment was performed from baseline to 2 years. Either denosumab treatment or monodronate with eldecalcitol was performed from 2 years to 5 years.

Determinants of Oral Bisphosphonate Therapy Beyond Five Years Monika Izano*[1], Bonnie Li[2], Fang Niu[3], Romain Neugebauer[1], Bruce Ettinger[1], Susan Ott[4], Joan Lo[1], Annette Adams[2]. [1]Division of Research, Kaiser Permanente Northern California, United States, [2]Department of Research & Evaluation, Kaiser Permanente Southern California, United States, [3]Pharmacy Outcomes Research Group, Kaiser Permanente California, United States, [4]Department of Medicine, University of Washington, United States

Purpose: In this cohort study of women receiving osteoporosis treatment with oral bisphosphonate (BP) within Kaiser Permanente Southern California, we investigated factors that were associated with BP continuation.Methods: Women who received 5 consecutive years of BP treatment entered the cohort during 2002-2010 and were followed for up to 5 additional years. A woman was considered on treatment in each 90-day interval of follow-up if she received BP for more than a 0.6 proportion of days covered based on pharmacy days' supply. We used multivariable logistic regression with robust standard errors (Generalized Estimating Equations) to evaluate the possible association of (1) demographic factors, (2) period of cohort entry, (3) predictors of fracture risk, and (4) elements of medical history with continuation of BP treatment.Results: The study cohort included 19481 women, median age 72 years (interquartile range: 65–79 years); 58% were white, 5% black, 16% Hispanic, and 17% Asian; 25% entered the study between 2002-2007, and 75% entered between 2008-

2010; 43% were overweight/obese, 40% had a Charlson Comorbidity Index (CCI) ≥1, and 10% had diabetes mellitus. Of the 13302 women with available bone mineral density (BMD) measured in the 2 years prior to BP initiation, 55% had a BMD t-score ≤-2.5 (lowest of hip, femur, spine).Factors significantly associated with increased odds of BP continuation were: (a) cohort entry on or before 2007 (Odds Ratio (OR)=1.38, 95% Confidence Interval 1.32–1.44), (b) most recent BMD t-score (referent t-score >-2; OR=1.50, 1.42-1.58 for -2.5<t<-2; OR=1.49, 1.38-1.61 for -2.5≤t<-3; OR=1.70, 1.57-1.85 for t≤-3.0), and (c) longer BP use (OR ranging 1.2-1.3 from 1-5 years, compared to <6 months). In contrast, factors significantly associated with decreased odds of continued BP use were: (a) a recent hip (OR=0.64, 0.55-0.75) or non-major osteoporotic fracture (OR=0.86, 0.80-0.93), (b) CCI >2 (OR=0.92, 0.85–0.99), (c) Hispanic (OR=0.91, 0.86–0.96) or Asian (OR=0.94, 0.89–0.99) race, (d) proton-pump inhibitor (OR=0.59, 0.38–0.91), glucocorticoid (OR=0.82, 0.72–0.95), and aromatase-inhibitor (OR=0.44, 0.39–0.50) use. Age, smoking, estimated low income/education, body mass index, chronic kidney disease, and fracture prior to BP initiation were not associated with BP continuation.Conclusions: Factors that predict continued BP treatment beyond 5 years include recent fracture, low BMD t-score, medication exposure and era of treatment.

Increased iliac crest bone hardness under Denosumab treatment is accompanied by a low number of viable osteocytes Katharina Jähn*[1], Björn Jobke[2], Eva Maria Wölfel[1], Tobias Barth[1], Christoph Riedel[1], Maya Hellmich[3], Mathias Werner[4], Björn Busse[1]. [1]University Medical Center Hamburg-Eppendorf, Germany, [2]Telemedicine Clinic, Spain, [3]Immanuel Krankenhaus Berlin, Germany, [4]Helios Klinikum Emil von Behring, Germany

Antiresorptives are among the first treatment options for osteoporosis. Denosumab is the latest approved potent osteoclast inhibitor.Recent data identified the risk of vertebral fractures during drug-holiday from Denosumab osteoporosis therapy. In bone health, the spatiotemporal activation of bone remodeling is guided by the mechanosensitive osteocyte network. One hallmark of osteoporosis progression is the death of osteocytes with weakening of their network connectivity and regulatory functionality.We have identified iliac crest biopsies (n=25 during Denosumab - duration: 26±13 months, n=10 on drug-holiday from Denosumab – holiday duration: 15±12 months, n=11 age-matched osteoporotic controls; 67±14yrs) that underwent previous clinical histopathological assessment. We performed structural and cellular histomorphometry according to ASBMR guidelines. Histological sections were stained with toluidine blue and von Kossa van Gieson and analyzed with Osteomeasure. Biomechanical properties of the bone tissue were tested with nano-indentation. The local degree of tissue mineralization was assessed by backscattered electron microscopy. Statistics were performed by ANOVA and Turkey post-hoc test.Bone tissue exposed to Denosumab treatment had a higher tissue hardness compared to osteoporotic controls (0.62±0.05 to 0.52±0.09 GPa; p=0.0042). The tissue mineralization, expressed by calcium weight percentages, was not significantly higher in the Denosumab group compared to untreated (22.2±1.3 to 21.2±2.0 wt%; p=0.074). However, the percentage of micropetrotic, mineralized lacunae was higher in the Denosumab group (8.1±4.1, compared to control: 3.3±1.6 %; p=0.0067). Trabecular BV/TV was lowest during drug-holiday compared to Denosumab (10.48±3.41 vs. 15.93±6.45; p=0.036). As expected, osteoclast numbers were significantly lower with treatment in comparison to untreated individuals (0.12±0.23 vs. 0.72±0.8 /mm; p=0.003). Interestingly, the number of empty osteocyte lacunae in trabecular bone was higher with Denosumab treatment compared to osteoporotic controls (35.1±10.5 vs. 23.3±5.7 %; p=0.011) and remained elevated (35.8±13.4) during drug-holiday (p=0.039 to control).Our results imply that Denosumab treatment results in harder bone tissue accompanied by a lower number of viable osteocytes at the iliac crest.

Influence of glucocorticoids on effect of denosumab on osteoporosis in patients with Japanese rheumatoid arthritis; 36 months of follow-up ~a Multicenter Registry Study~ Yasuhide Kanayama*[1], Yuji Hirano[2], Nobunori Takahashi[3], Naoki Ishiguro[3], Toshihisa Kojima[3]. [1]Toyota Kosei Hospital, Japan, [2]Toyohashi Municipal Hospital, Japan, [3]Nagoya University Graduate school of Medicine, Japan

[Objectives]To investigate the efficacy of DMB for 36 months on glucocorticoid- induced OP in Japanese RA patients.[Methods] Patients with a diagnosis of RA according to the 2010 ACR/EULAR criteria who had been prescribed DMB from Tsurumai Biologics Communication Registry (TBCR)-BONE between October 2013 and February 2015 were enrolled. The final study cohort of 65 patients received continuous DMB therapy more than 36 months. The DMB dose was 60mg at once every 6 months. In all cases native or activated vitamin D has been used.We reviewed the results for 36 months about the increase and decrease of bone mineral density(BMD) of lumbar spine(LS) and total hip(TH) by DEXA and bone turnover markers, intact n-terminal propeptide type I procollagen(PINP) and tartrate-resistant acid phopshatate form 5b(TRACP-5b).[Results] In the patients receiving oral prednisolone group(n=24, GC+) and not receiving group(n=41, GC-), the number of female was each 22(92%) and 39(95%) cases(p=0.576). The mean age was 69.9 ± 6.8 and 70.8 ± 7.2 years old (p=0.749); disease duration was 15.4 ± 9.1 and 15.5 ± 12.6 years (p=0.859);

the body mass index was 20.8 ± 3.5 and 19.7 ± 3.0 (p=0.226) and the FRAX was 34.3 ± 18.7 and 23.6 ± 13.4 (p=0.013). Clinical findings related to RA and OP at baseline were as follows; CRP 1.2 ± 1.4 and 0.4 ± 1.0 mg/dl(p=0.006); DAS-CRP 3.09 ± 1.20 and 2.48 ± 1.23(p=0.032); HAQ-DI 1.19 ± 0.91 and 0.80 ± 0.81(p=0.098); PINP 60.8 ± 37.9 and 55.3 ± 31.8 μg/l(p=0.471); TRACP-5b 521 ± 255 and 504 ± 201 mU/dL (p=0.870) ; LS-BMD 0.87 ± 0.18 and 0.80 ± 0.14 g/cm2(p=0.091) and TH-BMD 0.60 ± 0.11 and 0.60 ± 0.08 g/cm2 (p=0.674). The rate of decreased PINP from baseline to 6, 12, 24 and 36 months were each -27.8% vs -39.8% (p=0.237) at 6 month, -11.1% vs -44.1% (p=0.047) at 12 month, -16.8% vs -35.8% (p=0.172) at 24 month and -15.0% vs -33.4% (p=0.298) at 36 month and TRAC-5b were -28.6% vs -35.6% (p=0.994) at 6 month, -24.5% vs -36.7% (p=0.273) at 12 month, -23.0% vs -30.7% (p=0.613) at 24 month and -23.0% vs -30.7% (p=0.613) at 36 month in the GC+ group vs GC- group. The rate of increased LS-BMD from baseline to 6, 12, 24 and 36 months were each 4.1% vs 4.6% (p=0.682) at 6 month, 5.2% vs 7.1% (p=0.221) at 12 month, 9.9% vs 7.9% (p=0.119) at 24 month and 11.1% vs 9.9% (p=0.151) at 36 month and TH-BMD were 3.5% vs 2.4% (p=0.408) at 6 month, 1.6% vs 3.8% (p=0.842) at 12 month, 5.9% vs 4.8% (p=0.954) at 24 month and 7.8% vs 4.7% (p=0.873) at 36 month in the GC+ group vs GC- group (Fig.1). [Conclusion]DMB was effective in OP of RA patients. Glucocorticoids use did not influence the efficacy of DMB for 36 months.

Spontaneous Fusion after Vertebroplasty and Kyphoplasty in Painful Osteoporotic Compression Fracture Jin Hwan Kim*[1], Jae Hyup Lee[2], Young Kyu Kim[1]. [1]Inje University, Ilsanpaik Hospital, Republic of Korea, [2]Seoul National University, College of Medicine, Republic of Korea

Purpose : We found a spontaneous fusion at adjacent vertebrae after percutaneous vertebroplasty (PVP) or kyphoplasty in painful osteoporotic compression fractures and analyze the radiologic & clinical characteristics. Materials & Methods : Between January 2002 and December 2015, 555 patients were treated with PVP or kyphoplasty for osteoporotic compression fracture in our department. We classified the spontaneous fusion as two groups. One is solid spontaneous fusion group with at least three cortical continuity to adjacent vertebrae, the other is partially fusion group which progressed fusion compared to previous radiologic finding. We reviewed the plain film and analyzed the radiologic characteristics of those patients with duration of fusion, location and extent of fused segments. A clinical characteristic by visual analogue score (VAS) compared to our previous report was checked. Results : Among them, 54 patients (9.7%) had an solid spontaneous fusion and 43 patients (7.7%) had partially fused on plane image. In solid fusion group, the average duration of fusion was 19 months ranged of 3 to 48 months. Forty six cases (85%) of solid fusion patients had occurred with proximal adjacent vertebrae and 7 cases (13%) had proximal with distal adjacent vertebrae. Forty one cases (76%) of spontaneous fusion occurred within 1 segment and 13 cases within multiple segments. The most cases of solid fusion group were occurred at thoracolumbar junction (40 patients, 74%). Mean VAS score of solid fusion group was 2.0 at final follow-up and were analyzed relatively low score compared to mean VAS of our previous report (2.0, 2.8 respectively). Conclusion : After percutaneous vertebroplasty or kyphoplasty in painful osteoporotic compression fracture, unpredictable spontaneous fusion could develop more than 10% rate, especially with proximal vertebra within 1 segment at thoracolumbar junction in radiologic aspect. Clinically, patients with spontaneous fusion had a tendency of more reduced pain than others.

Is early bisphosphonate treatment safe or effective for pyogenic vertebral osteomyelitis with osteoporosis? Jihye Kim*[1], Tae-Hwan Kim[2]. [1]Kangdong Sacred Heart Hospital, Hallym University College of Medicine, Republic of Korea, [2]Hallym University Sacred Heart Hospital, Hallym University College of Medicine, Republic of Korea

Background. Patients with pyogenic vertebral osteomyelitis (PVO) have greatly increased risk of bone loss because of rapid destruction of vertebral structure by the causative organism, delay in diagnosis, bed rest and immobilization by rigid brace for three to four months, and limited sunlight exposure by long hospitalization for long-term intravenous antibiotic administration. Such bone loss could be fatal on bone health of elderly PVO patients with several medical comorbidities. In this respect, early bisphosphonate therapy would be clinically effective for PVO patients with osteoporosis.Methods. A retrospective case review was performed on PVO patients who received bisphosphonate treatment for osteoporosis. PVO patients were divided into three groups: 1) group A (initiation of bisphosphonate within 6 weeks after PVO diagnosis); 2) group B (initiation of bisphosphonate between 6 weeks and 3 months after PVO diagnosis), and group C (initiation of bisphosphonate between 3 and 6 months after PVO diagnosis). Long-term effectiveness and safety of bisphosphonate on bone loss after PVO was analyzed by Cox proportional hazard model.Results. A total of 405 PVO patients with osteoporosis were evaluated for following four endpoints. Group A PVO patients had significantly lower hazard ratio for undergoing late surgery than either group B or C PVO patients (p=0.020). There was no difference in the rate of recurrence among the three groups (p=0.602). Significant difference was observed in the occurrence of subsequent fractures at adjacent vertebral bodies among the three groups (p=0.020), and group A PVO patients had significantly lower hazard ratio for subsequent fracture than either group B (p=0.032) or group C (p=0.004) PVO patients. Hazard ratios were not significantly different among the three groups for either overall death (p=0.133) or later death (p=0.127) Conclusions. Early bisphosphonate treatment in PVO patients with osteoporosis was associated with lower occurrence of subsequent vertebral fracture at adjacent vertebral bodies, and lower occurrence of late surgery.

Effect of Medications on Secondary Prevention of Osteoporotic Vertebral Compression Fracture: a Meta-analysis of Randomized Controlled Trials Yuan-Zhe Jin*[1], Jae Hyup Lee[1], Jin-Hwan Kim[2]. [1]Seoul National University, College of Medicine, Republic of Korea, [2]Inje University, College of Medicine, Republic of Korea

Bone loss with aging and menopause increases the risk of fragile vertebral fracture, osteoporotic vertebral compression fracture (OVCF). The fracture causes severe pain, impedes respiratory function, lower the quality of life, and increases the risk of new fractures and deaths. Various medications have been prescribed to prevent a secondary fracture, but few study summurized their effects. Therefore, we investigated the effects of medications on preventing subsequent OVCF via meta-analyses of randomized controlled trials. Elec-

tronic databases, including MEDLINE, EMBASE, CENTRAL, and Web of Science were searched for published randomized controlled trials until December 2017. The trials that recruited participants with at least one OVCF were included. We assessed the risk of bias of every study, estimated relative risk ratio of secondary OVCF, non-vertebral fracture, gastrointestinal complaints and discontinuation due to adverse events. Finally, we evaluated the quality of evidence. Thirty-nine articles were included. Moderate to high quality evidence proved the effectiveness of alendronate (Relative Risk, RR: 0.54), risedronate (RR: 0.52), ibandronate (RR: 0.52), parathyroid hormone (RR: 0.30), and selective estrogen receptor modulators (Raloxifene, RR: 0.58; Bazedoxifene, RR: 0.66) in preventing secondary fractures. Moderate quality evidence proved romosozumab had better effect than alendronate (Romosozumab vs. alendronate, RR: 0.64) and high quality evidence proved that teriparatide had better effect than risedronate (risedronate vs. teriparatided, RR: 1.67). Zoledronic acid, alendronate, risedronate, etidronate, ibandronate, parathyroid hormone, denosumab and selective estrogen receptor modulators had significant secondary prevention effects on OVCF. Moderate quality evidence proved romosozumab had better effect than alendronate. High quality evidence proved parathyroid hormone had better effect than risedronate, but with higher risk of adverse events.

Incidence of Complete Atypical Femur Fracture among Women with Oral Bisphosphonate Exposure in an Integrated Healthcare System Joan Lo*[1], Christopher Grimsrud[2], Susan Ott[3], Malini Chandra[1], Rita Hui[4], Monika Izano[1], Annette Adams[5], Bruce Ettinger[1]. [1]Division of Research, Kaiser Permanente Northern California, United States, [2]Department of Orthopedic Surgery, Kaiser Permanente Oakland Medical Center, United States, [3]Department of Medicine, University of Washington, United States, [4]Pharmacy Outcomes Research Group, Kaiser Permanente California, United States, [5]Research and Evaluation, Kaiser Permanente Southern California, United States

PURPOSE: This study provides annual estimates of the incidence of atypical femur fracture (AFF) among older women with a history of oral bisphosphonate (BP) exposure, a measure for which few recent population-level estimates are currently available.METHODS: The study population included 94,553 Kaiser Permanente Northern California (KPNC) female members age 45-89 years who initiated oral BP between 2002-2014 and had at least 2 years prior health plan membership. We excluded women who received intravenous BP, teriparatide, or denosumab or who had metastatic cancer, skeletal disorders, or advanced chronic kidney disease prior to the start of follow-up. Among this group ("ever-users"), follow-up started at BP initiation and ended at disenrollment, death, age 90 years, or development of an aforementioned exclusion indication. We searched for ICD-9 codes for hospitalized diaphyseal femur fractures and reviewed radiographs to identify complete AFF using the 2013 ASBMR criteria, ascertaining the first AFF per person. The annual incidence of AFF (2002-2015) was calculated as the ratio of AFF events that year to the number of women with BP exposure; this number included women initiating BP in that year or in prior years (BP exposure could have varied from <1 and up to 14 years). We additionally estimated AFF incidence (2005-2015) among women who received at least 3 consecutive years of treatment (adherence 60%) after BP initiation.RESULTS: The cumulative number women with AFF in the KPNC cohort increased dramatically over the years 2002-2015; there were <10 women with AFF in the first 6 years of observation and >100 women with AFF by the end of the 14-year period. The number of BP ever-users increased more than 3-fold during this same observation period; in 2007, there were >40,000 women, and by 2015, there were >60,000 women. The number of women who had adherent BP treatment for at least 3 years after BP initiation increased more than 2-fold during 2005-2015; in 2007, there were >9,000 women, and by 2015, there were >14,000. AFF incidence for ever-users averaged 21.3 per 100,000 during 2007-2015. In marked contrast, AFF incidence for those with at least 3 years of BP use was more than double that of ever-users in the same time period, averaging 56.9 per 100,000 during 2007-2015.CONCLUSION: The duration of BP exposure is important when examining the incidence of AFF.

AFF Incidence by Year among Women with a History of BP Exposure

Compliance, Adverse Effects, Bone-related Mineral and Vitamin D Status, and Literature Review of Denosumab Therapy for Osteoporosis in Japan
Yukio Nakamura*, Takako Suzuki, Hiroyuki Kato. Shinshu University School of Medicine, Japan

Background: Denosumab is a first-line drug both for primary and secondary osteoporosis. In our clinical setting, denosumab use on patients ranging from 2 to 110 years of age have reached over 2500 osteoporosis cases to date for analysis of bone turnover markers, bone mineral density of the lumbar 1-4 vertebrae and bilateral total hips, calcium, and vitamin D metabolism (ClinicalTrials: #NCT02156960). Over the last few years, more than 15 English reports have been published regarding the usefulness and efficacy of denosumab (generally 60 mg subcutaneously every 6 months with adjustment according to body weight for children) for osteoporosis related to such conditions as congenital skeletal diseases (TJEM. 2017; MR. in press), glucocorticoid-induced osteoporosis with collagen diseases (JCM. 2018; MR. 2018; Ther Clin Risk Manag. 2018), early pregnancy (JNDT. 2017), and others including atypical femoral fracture caused by long-term bisphosphonate (BP) therapy (MR. 2017; MR. 2018). Of particular note was the rarity of serious adverse effects, such as hypocalcaemia or osteonecrosis of the jaw. However, real-world data on denosumab use remain insufficient.Methods: We present novel findings concerning: 1) the compliance, discontinuation rate, and fracture incidence of 143 primary osteoporotic postmenopausal Japanese women (average age: 76.4 ± 0.9 years) and 96 osteoporotic women with RA (average age: 70.0 ± 0.8 years) after 2 years of denosumab treatment, and 2) serum bone-related minerals (zinc, iron, and magnesium) and 25-hydroxyvitamin D (25OHD) status in female osteoporosis with RA of low-to-moderate disease activity in 26 cases with BP pre-treatment (mean age: 69.8 ± 1.3 years) and 26 cases without (mean age: 70.6 ± 1.9 years) after 3 years of denosumab treatment.Results and Conclusions: We observed that: 1) discontinuation rate was low over 2 years of treatment in primary osteoporotic patients, with high persistence at 24 months (65.0%) and no occurrence of fracture. In RA patients, discontinuation was found to increase due to economic reasons from 1 to 2 years of therapy, but overall persistence remained high at 24 months (70.8%), with 2 reports of fracture, and 2) among bone-related minerals, serum zinc and iron levels were significantly improved at 12 months and serum 25OHD remained high after denosumab therapy. Taken together, denosumab treatment was successful, thus validating its use as a first-line drug for primary and secondary osteoporosis.

SUN-0937

Subgroup Analysis of the Effect of Denosumab Compared With Risedronate on Percentage Change in Lumbar Spine Bone Mineral Density at 24 Months in Glucocorticoid-treated Individuals Ken Saag*[1], Nico Pannacciulli[2], Piet Geusens[3], Jonathan Adachi[4], Eric Lespessailles[5], Jorge Malouf-Sierra[6], Bente Langdahl[7], Peter W. Butler[2], Xiang Yin[2], Willem F. Lems[8]. [1]University of Alabama, Birmingham, United States, [2]Amgen Inc., United States, [3]Maastricht University Medical Center, Netherlands, [4]McMaster University, Canada, [5]University Hospital Orleans, France, [6]Hospital San Pablo, Spain, [7]Aarhus University Hospital, Denmark, [8]VU University Medical Centre, Netherlands

Purpose: We previously demonstrated that denosumab (DMAb) increased lumbar spine (LS) and total hip (TH) BMD significantly more than risedronate (RIS) at 12 and 24 months (mos) in glucocorticoid (GC)-treated individuals (Saag ACR 2016; Saag ECTS 2018). Prespecified subgroup analyses of LS BMD at 12 mos indicated that DMAb was superior to RIS across 7 subgroups of GC-treated individuals (Saag ASBMR 2017). This analysis explored the effects of DMAb and RIS on LS BMD in the same subgroups of GC-treated

individuals at 24 mos.Methods: The phase 3, randomized, double-blind, double-dummy, active-controlled study enrolled women and men age ≥18 years receiving ≥7.5 mg prednisone or equivalent daily for <3 mos (GC-initiating [GC-I]) or ≥3 mos (GC-continuing [GC-C]) before screening. All subjects age <50 years were required to have a history of osteoporotic fracture. GC-C subjects age ≥50 years were required to have LS, TH, or femoral neck BMD T-score ≤?2.0; or ≤?1.0 with a history of osteoporotic fracture. Subjects were randomized 1:1 to DMAb 60 mg SC every 6 mos or RIS 5 mg PO daily for 24 mos. All subjects were to receive daily calcium (≥1000 mg) and vitamin D (≥800 IU). The treatment difference (DMAb – RIS) for percentage change from baseline in LS BMD at 24 mos was estimated in the GC-I and GC-C subpopulations, both overall and in 7 prespecified subgroups where treatment effect might differ (sex, race, age, baseline BMD T-score, geographic region, menopausal status, and baseline GC daily dose).Results: The study enrolled 795 subjects (290 GC-I, 505 GC-C). Baseline characteristics were balanced between treatment groups within each subpopulation. DMAb was superior to RIS for gains in LS BMD at 24 mos in both the GC-I and GC-C subpopulations. Within each subgroup (Table), DMAb was consistently associated with a greater increase in LS BMD at 24 mos compared with RIS. Significant quantitative interactions were observed only in the sex and race subgroups in the GC-I subpopulation. However, qualitative tests indicated the direction of the DMAb effect did not differ significantly by sex or race in this subpopulation.Conclusion: DMAb consistently increased LS BMD more than RIS at 24 mos in both GC-I and GC-C subpopulations, with no evidence of directional heterogeneity in treatment effect across 7 prespecified subgroups of GC-treated individuals. DMAb may be a useful addition to the osteoporosis armamentarium in the common clinical setting of GC use.

Table. Treatment Difference (DMAb − RIS) in Lumbar Spine BMD Percentage Change From Baseline at Month 24

Teriparatide re-activates bone metabolism of the patients with bisphosphonates treatment failures. Shinya Tanaka*[1], Katsuya Kanesaki[2], Yoichi Kishikawa[3], Sathoshi Ikeda[4], Masato Nagashima[5], Tsuyoshi Miyajima[1], Hiromi Oda[1]. [1]Saitama medical university, Japan, [2]Nagat orthopedic hospital, Japan, [3]Kishikawa orthopedic surgery, Japan, [4]Ken-ai memorial hospital, Japan, [5]Katsuki brain and orthopedic surgery, Japan

In the practice of the goal-directed treatment of osteoporosis, physicians must change treatments when treatment failures, no increase in bone mineral density (BMD) or occurrences of vulnerable fracture, happen. Once treatment failure occurs during osteoporosis treatment with bisphosphonate, it is reasonable to re-activate bone metabolism. In this retrospective cohort study, we tested whether teriparatide can re-activate the bone metabolism of the patients with bisphosphonates treatment failures.Patients and Methods; Menopausal osteoporosis patients whose BMD had not increased or who had had vulnerable fractures during bisphosphonate treatment were included this study. Daily teriparatide was used for 28 patients for 2 years (dTPD group) and weekly teriparatide was used for 34 patients for 1.5 years (wTPD group). After teriparatide therapy, patients were treated by anti-bone resorption drugs, bisphosphonates or anti-RANKL-antibody, and were measured BMD periodically by 1 year after the end of teriparatide therapy. We investigated changes of BMD during those therapies.Results; There were 11.9% increase in lumbar vertebral BMD and 2.7% increase

in femoral neck BMD of dTPD group during theriparatide therapy. Anti-bone resorption therapy after teriparatide brought 2.0% increase in the vertebral BMD. There was 3.2% increase in lumbar vertebral BMD of wTPD group. Anti-bone resorption therapy after weekly teriparatide brought 5.6% increase in the vertebral BMD and 3.1% increase in femoral neck BMD.Discussion; In spite of after bisphosphonate therapy, teriparatide therapy and following anti-resorption therapy partially brought increase in BMD. Teriparatide causes re-activation of metabolism and increase in bone mass to the metabolism suppressed bone and following anti-resorption therapy accelerated the calcification of the bone mass, and BMD increased.Conclusion; Teriparatide re-activates bone metabolism of the patients with bisphosphonates treatment failures.

Two-year persistence with Teriparatide improves significantly after extension of an educational and motivational support program Maud Van Maren*[1], Caroline E Wyers[1,2], Johanna Hm Driessen[3], Jonathan V Visser[4], Frank De Vries[5], Katrien Van De Wijdeven[4], Sonja Gevers[4], Willem F Lems[6], Marielle H Emmelot-Vonk[7], Joop Pw Van Den Bergh[1,2,8]. [1]VieCuri Medical Center, Department of Internal Medicine, Netherlands, [2]Maastricht University Medical Center (Maastricht UMC+), NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Internal Medicine, Netherlands, [3]Maastricht UMC+, CAPHRI Care and Public Health Research Institute, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Clinical Pharmacy and Toxicology, Netherlands, [4]ApotheekZorg (Pharmacy), Netherlands, [5]Maastricht UMC+, Department of Clinical Pharmacy and Toxicology, Netherlands, [6]VU Medical Centre, Amsterdam Rheumatology and Immunology Center, Netherlands, [7]University Medical Center Utrecht, Department of Geriatric Medicine, Netherlands, [8]Hasselt University, Netherlands

Purpose:To determine whether an educational and motivational support program increases treatment persistence with teriparatide (TPTD) in the Netherlands.Methods: In the Netherlands, one central pharmacy provides TPTD, enabling us to study persistence in all patients who were prescribed TPTD from January 2013 - January 2018. TPTD was dispensed as a pre-filled pen containing 750mcg TPTD intended to be used as daily subcutaneous injection of 20mcg TPTD for 28 consecutive days. A max. of 26 pens was dispensed during the 24-month treatment period. From January 2013 - April 2015, all patients were instructed and followed according to a basic care program (BCP) consisting of an intake, educational home visit by a nurse, TPTD home delivery, phone calls at 1 week, 2.5 weeks and 8 weeks after treatment initiation. Since May 2015, the BCP was extended with an educational and motivational support program (EMP) including the Morisky scoring system (MSS) during phone calls, an extra phone call at 12 months and motivational letters at 9 and 14 months. The MMS was aimed at identifying potential non-persistent patients and providing them an additional phone call or home visit to enhance the awareness of the importance of treatment completion. Persistence was defined as the act of continuing the treatment for the prescribed duration,without exceeding the permissible gap (discontinuation up to 28 days). Patients were classified as persistent if 24-26 pens were delivered. The potential 24-month treatment period was evaluated using age and sex adjusted Cox proportional hazard analyses.Results: TPTD treatment was initiated in 1162 patients: 766 received BCP (88% women, mean age 72yrs), and 396 received EMP (84% women, mean age 72yrs). In the BCP group, 2-year persistence was 59% vs. 73% in the EMP group (p<0.001). Reasons for treatment discontinuation were comparable between both groups, except for discontinuation due to side effects, which was lower in the EMP group (18% vs 8% respectively, p<0.001). Adjusted analyses showed a reduction of 40% for being non-persistent with the EMP compared to the BCP (HR:0.58 95%CI:0.46-0.72)(Fig.1).Conclusion:Persistence with TPTD significantly improved by the EMP including the MSS. The MSS was able to identify patients who were at risk of treatment discontinuation mainly due to side effects and allowed targeted interventions by a trained nurse resulting in a significant reduction of non-persistence during the 24-month treatment course.

Treatment Patterns in the Management of Osteoporotic Fractures in Older Adults Lagari Violet*[1], Levis Silvina[1], Naomi Leonore[1], Berger Hara[2], Rodriguez Gracielena[1]. [1]Miami VA Healthcare System, United States, [2]Reproductive Health Physicians, United States

After the first fracture, the risk of subsequent fractures is significantly increased, with the highest risk following hip (RR, 9.97) and vertebral (RR, 15.12) fractures. Independence, mobility and quality of life decrease with recurrent fractures, while morbidity and mortality increase. Although medical treatment can reduce the risk of a second fracture by about 50%, many older adults do not receive osteoporosis medication following their first fracture.This observational study aimed to understand treatment patterns in the initiation of anti-osteoporosis therapy in older adults who sustain osteoporotic fractures at the Miami Veterans Affairs (VA) Healthcare System.Over a 12-month period, reports from VA's electronic medical records identified patients with a new ICD-10 fracture code in the prior month. After excluding traumatic fractures and fractures in nursing homes residents, a total of 148 cases who had an indication for osteoporosis treatment were identified; 89% men, 67 ± 9 years, 57% non-Hispanic white, 22% non-Hispanic black, 18% Hispanic white, and 3% unknown. The Figure describes our findings. Chart review indicated that 34 (23%) had had a bone density (BMD) or medical treatment prior to the fracture. After the fracture, most patients, 72/114 (63%), did not have a BMD or medical treatment. Only 25/114 (20%) patients were started on an osteoporosis medication by their primary care physician.While a clinical diagnosis of osteoporosis may be made based on a low trauma fracture, this study demonstrates that physicians may not equate low trauma fractures with a diagnosis of osteoporosis. Along with our previous findings, this study suggests that physicians are more likely to prescribe osteoporosis therapy based on a BMD T-score diagnosis of osteoporosis, rather than a clinical diagnosis of osteoporosis based on a low trauma fracture. There was no correlation between treatment initiation and gender or type of fracture. Continuous education in the primary care setting is necessary to improve the medical treatment of osteoporotic fractures.

Forearm Bone Mineral Density and Fracture Incidence in Postmenopausal Women with Osteoporosis: Results from the ACTIVExtend Phase 3 Trial Nelson B. Watts*[1], Robin K. Dore[2], Sanford Baim[3], Gary Hattersley[4], Greg Williams[4], Yamei Wang[4], Tamara D. Rozental[5], Meryl S. Leboff[6]. [1]Mercy Health Osteoporosis and Bone Health Services, United States, [2]Robin K Dore M.D., Inc., United States, [3]Rush University Medical Center, United States, [4]Radius Health, Inc., United States, [5]Beth Israel Deaconess Medical Center, United States, [6]Brigham and Women's Hospital, United States

Wrist fractures are the most common fracture of the upper extremity and are associated with increased subsequent fracture risk in women with postmenopausal osteoporosis. Most wrist fractures occur at the ultradistal (UD) radius. Abaloparatide (ABL) is a selective activator of the PTH1 receptor signaling pathway that stimulates bone formation. In the ACTIVE phase 3 study, 18 months of ABL significantly increased bone mineral density (BMD) at the UD radius and maintained BMD at the 1/3 distal radius vs placebo (PBO) and teriparatide (TPTD). BMD effects were associated with a trend for numerically lower wrist fracture incidence for ABL vs TPTD (P=0.052). Women receiving ABL or PBO in ACTIVE were offered enrollment in the ACTIVExtend extension study in which both groups received 24 months of open-label alendronate (ALN) 70 mg/wk for a total of 43 months (18 months ABL or PBO, 1 month for reconsent, 24 months ALN). Our objective was to determine the efficacy of ABL followed by ALN (ABL/ALN) vs PBO/ALN on BMD at the UD radius over 43 months.Forearm BMD data (ACTIVE baseline and month 43) were measured for 213 and 233 women in ABL/ALN and PBO/ALN groups, respectively. BMD was centrally analyzed and adjusted for machine differences. DXA scanner and baseline BMD were included as covariates. Wrist fracture event rates were estimated for the ACTIVExtend ITT population (558 ABL/ALN; 581 PBO/ALN) by KM method.Over the 18 months of the ACTIVE trial, BMD of the UD radius decreased in the placebo group but increased with ABL; these increases were maintained over the ALN extension (Figure). There were 15 women with wrist fractures in the ABL/ALN group (KM estimate: 2.8%) and 20 in the PBO/ALN group (3.6%). Although the number of wrist fractures was low, these fractures were numerically lower with ABL/ALN vs PBO/ALN (HR=0.77, 95% CI [0.39, 1.50], P=NS).In conclusion, the BMD gains at the UD radius following treatment with ABL were maintained over the subsequent 24 months of treatment with ALN. Wrist fracture risk was numerically lower with ABL/ALN vs PBO/ALN. These results, together with previous ACTIVE analyses, suggest that BMD of the UD radius, which is rich in trabecular bone, may be a better predictor of wrist fracture than the 1/3 distal radius.

Figure. Mean (± SE) Percent Change in Ultradistal Radius BMD from Baseline Through Month 43

Missing BMD data imputed using the method of last observation carried forward. ABL, abaloparatide; ALN, alendronate; SE, standard error.

Eldecalcitol Increases BMD More Than Alfacalcidol in Chinese Osteoporotic Patients without Vitamin D or Calcium Supplementation Yan Jiang*[1], Hai Tang[2], Xinlong Ma[3], Qun Cheng[4], Hua Lin[5], Xiaolan Jin[6], Zhenlin Zhang[7], Wei Yu[1], Tsuyoshi Kobayashi[8], Satomi Uehara[8], Toshio Matsumoto[9], Weibo Xia[1]. [1]Beijing Union Medical College Hospital, China, [2]Beijing Friendship Hospital, Capital Medical University, China, [3]Tianjin Hospital, China, [4]Huadong Hospital affiliated to Fudan University, China, [5]Nanjing Drum Tower Hospital Affiliated of Nanjing University Medical School, China, [6]Chengdu Military Central Hospital, China, [7]Shanghai Sixth People Hospital, China, [8]Chugai Pharmaceutical Co., Ltd., Japan, [9]okushima University, Fujii Memorial Institute of Medical Sciences, Japan

Eldecalcitol was shown to prevent vertebral fractures and increase bone mineral density (BMD) who received vitamin D supplementation to keep serum 25(OH)D over 20 ng/mL. In the current study, 265 Chinese patients with osteoporosis were randomly assigned to receive 1.0 µg/day alfacalcidol or 0.75 µg/day eldecalcitol for 12 months without vitamin D or calcium supplementation. Lumbar BMD increased by 2.51% with eldecalcitol treatment for 12 months, while the increase was 0.46% in the alfacalcidol group (LS mean difference, 2.05%; 95% confidence interval, 0.96-3.15; p<0.001). Total hip and femoral neck BMD

also increased with eldecalcitol, by 1.50% and 1.95% respectively, but were not increased with alfacalcidol. Baseline serum 25(OH)D levels were 15.6 ± 6.3 ng/mL (mean ± SD) in the eldecalcitol-treated group and 17.0 ± 8.3 ng/mL in the alfacalcidol treated group, and remained almost constant throughout the study in both groups. Baseline calcium intake was 500 ± 268 mg/day (mean ± SD) in the eldecalcitol group and 549 ± 271 mg/day in the alfacalcidol group. The eldecalcitol group was further analyzed by stratifying into subgroups by baseline serum 25(OH)D and calcium intake. Lumbar spine BMD increased by 2.60% from baseline in the subgroup with baseline serum 25(OH)D < 20 ng/mL and by 2.17% in the subgroup with serum 25(OH)D ≥ 20 ng/mL. Lumbar spine BMD increased by 2.81% in the subgroup with calcium intake <400 mg/day and 2.28% in the subgroup with calcium intake ≥400 mg/day. Serum calcium exceeded 10.4 mg/dL in 8 of 136 patients (5.9%) in the eldecalcitol group and 11 of 127 patients (8.7%) in the alfacalcidol group. Urinary Ca/creatinine ratio exceeded 0.4 in 5 patients (3.7%) in the eldecalcitol group and 3 (2.4%) in the alfacalcidol group. These results demonstrate that eldecalcitol increases both lumbar and hip BMD in Chinese osteoporotic patients more than alfacalcidol without sustained hypercalcemia or hypercalciuria, and that eldecalcitol increases BMD in osteoporotic patients regardless of serum 25(OH)D level or calcium intake.

Gender Differences in Tibial Fracture Healing in Normal and Muscular Dystrophic Mouse Models Zhenhan Deng*, Xueqin Gao, Xuying Sun, Yan Cui, Sara Amara, Walter R. Lowe, Johnny Huard. University of Texas Health Science Center at Houston, United States

Introduction:Duchenne muscular dystrophy (DMD) patients have high fracture risk and poor fracture healing. The mdx mice is a mouse model for study of human DMD and exhibits delayed bone fracture healing due to chronic inflammation. Previous work in our lab has shown that male muscle-derived stem cells (MDSCs) are more osteogenic and chondrogenic in vitro and regenerate more bone and cartilage in vivo. However, whether there are gender differences in fracture healing in normal and mdx mice is not known. The objective of this study was to explore gender differences in fracture healing, and their mechanistic basis, in normal and mdx mice.Methods:Two-month-old wild-type C57BL/10J (WT) and mdx mice underwent tibial fracture surgery. MicroCT live scanning was performed at the fracture site at 2, 4, and 6 weeks after surgery. The callus was manually segmented from the host bone, and bone histomorphometric parameters were measured. The mice were sacrificed at 6 weeks and 10 days post-surgery for the purpose of characterization and mechanistic studies, respectively. The callus was collected for histology. RNA was extracted from the 10-day callus, and several osteogenesis-related gene markers were detected with RT-qPCR. Gene expression was expressed as fold change versus the male control or mdx groups.Results:1. The fracture site was healed in both groups at the 6 weeks after surgery. The callus size was larger in both male normal and male mdx mice, but showed less remodeling, than in the female groups. The callus bone density was higher in females. More osteoclasts (OCs) were detected in the female callus, but no gender differences were observed in osteoblast (OB) number.2. At 10 days after surgery, males formed larger calli composed of more mesenchyme, whereas females formed well-remodeled calli with greater bone percentage. More OBs were detected in the male groups. There were no gender differences in the number of pSMAD1/5-positive cells in both groups. Higher IGF-1 expression was seen in male mdx mice, whereas female mdx and WT mice showed a trend toward higher osterix (OSX) expression.Conclusions:Male mice form larger bone calli during tibial fracture healing in both groups; this may be attributed to higher IGF-1 expression and greater OB number during callus formation. Female mice achieve better morphology in the healed fractured bone with higher bone quality, due to the greater number of OCs and higher OSX levels in the female callus.

IGF1 Signaling Regulation of Bone Lining Cells Osteogenic Differentiation Through CXCL12 Expression is Critical in Fracture Repair and Bone Homeostasis Alessandra Esposito*, Jie Jiang, Lai Wang, Tieshi Li, Xin Jin, Anna Spagnoli. Rush University Medical Center, United States

IGF signaling through IGF1/IGF1r plays a key anabolic role in postnatal skeletal development. We previously reported that C-X-C-motif-chemokine-ligand-12 (CXCL12) plays a critical role in fracture repair. Here we test the hypothesis that IGF1 signaling regulates CXCL12's expression to maintain bone homeostasis and to promote fracture repair. To this purpose, we generated conditional IGF1rCKO mice by crossing Prx1Cre+ with IGF1r-floxed mice. In IGF1rCKO mice, we found impaired bone formation and abnormal cortical bone neo-angiogenesis, associated with an increase of bone lining CXCL12+/CXCR4+ cells surrounding endothelial CD31+ cells. To evaluate the role of IGF1/CXCL12 interplay in fracture repair, we generated inducible IGF1rICKO mice. To this purpose, adult mice received 4OHTam 3 days before and 2 days post fracture (PFD). Calluses from IGF1rICKO and controls were collected and analyzed at different PFDs. µCT analyses at PDF14 showed that IGF1rICKO mice have reduced total callus, soft tissue and new bone volumes compared to controls (Fig). mRNA expression analyses of IGF1rICKO PDF14 calluses showed an increase of CXCL12, CXCR4, CD31 and pericytes markers, as well as a decrease of osteo-chondrogenic markers, compared to controls (Fig). To further evaluate the IGF1r-CX-

CL12 axis, we isolated endosteal cells from the hind-limb long bones of IGF1rICKO mice and controls. IGF1rICKO endosteal cells showed an increase in pericyte markers, and a decrease in osteogenic markers and Alizarin-Red (AR) staining (Fig). Furthermore, in IGF1rICKO endosteal cells CXCL12, CXCR4 and CD31 mRNA expressions were respectively 5-, 2- and 4-fold higher than controls (Fig). Next, we treated IGF1rICKO endosteal cells with AMD3100, an inhibitor of CXCL12 signaling. AMD3100 rescued the osteogenic differentiation defect of IGF1rICKO endosteal cells, as shown by an increase in osteogenic marker and AR-staining (Fig). We then evaluated the effect of AMD3100 in vivo. IGF1rICKO mice and controls were treated with AMD3100 (2.5 μg/g by intraperitoneal injection given twice a day from PFD2 through PFD7). Analyses of calluses obtained respectively at PDF7 and PDF14, showed that in IGF1rICKO, AMD3100 treatment normalized mRNA levels of CXCL12, CXCR4, CD31, pericyte and osteochondrogenic markers. μCT and histological analyses are in progress. Findings unveil a novel role of IGF1 signaling in regulating CXCL12 expression in bone lining cells that is critical to promote fracture healing.

IGF1 signaling in bone lining cells plays a key role in osteogenic differentiation through CXCL12 expression. A) Saf-O/Orange-G stained section of callus at PFD10 of IGF1rIcKO and their littermates control. B) Decreased volume of tibia callus, both volume of soft tissue and new bone in IGF1rIcKO and their TAM-treated controls at 10 and 14 days after fracture. Data represent mean ± SD of 3-6 samples. *, p<0.05; **, p<0.01; compared to control. C-I) AMD3100 reduces CXCL12 expression in EC of IGF1rcKO and rescues osteogenic bone defect. qRT-PCR, *p=0.05, **p=0.01, vs day 0 =1. N=3 each time. N=2 each group. I) AMD3100 reduces CXCL12 expression in callus of IGF1rIcKO and rescues osteogenic bone defect. qRT-PCR, *p=0.05, **p=0.01, vs day 0 =1. N=3 each time. N=2 each group.

SUN-0968

The C-terminal domain of PTHrP limits PTH receptor-mediated changes in gene expression in osteocytes Yao Sun*[1], Patricia W M Ho[1], Rachelle W Johnson[2], T John Martin[1], Natalie A Sims[1]. [1]St. Vincent's Institute of Medical Research, Australia, [2]Vanderbilt University, United States

Parathyroid hormone-related protein (PTHrP) promotes skeletal development and maintains bone mass. PTHrP and PTH share a common receptor (PTHR1) and both promote bone formation, as indicated by the anabolic effects of their N-terminal domains. However, PTHrP contains additional protein domains, with intracellular and nuclear activities, that are independent of the PTHR1; these could be exploited to improve anabolic activity.To determine the effects of PTHrP's unique domains in osteocytes, Ocy454 cells expressing the following PTHrP isoforms were generated: PTHrP-FL = full length PTHrP(1-139); PTHrP-ΔNLS = PTHrP lacking the nuclear localization sequence (NLS); and PTHrP-67 = PTHrP(1-67) lacking both the NLS and C-terminal regions. Stable expression of each isoform was validated by qPCR, RIA and bioassay. Gene expression changes induced by each PTHrP isoform compared to vector control were analysed by RNA-Seq.When compared to vector control, cells expressing PTHrP-67 regulated a greater number of genes (4463, FDR<0.05) than cells expressing either full length, or NLS-deficient constructs (1413 and 1741 genes, respectively). This suggests that the PTHrP C-terminal domain has intracellular functions that suppress gene responses to PTHrP. To test whether the C-terminus suppresses the extent of gene responses to endogenous full length PTHrP in osteocytes, we compared genes regulated by both PTHrP-67 and PTHrP-FL (n=1154). The magnitude of change (increased and decreased) in these genes was significantly greater in cells expressing PTHrP-67 than those expressing PTHrP-FL (p=0.0008). In contrast, a similar comparison of common genes regulated by both PTHrP-FL and PTHrP-ΔNLS (n=515) found no difference in the magnitude of response (P=0.5592). This indicates that the PTHrP C-terminus, but not the NLS, restricts the amplitude of gene responses to PTHrP in osteocytes. To determine wheth-

er this action suppresses PTHR1-mediated action, we assessed a panel of 32 known CREB responsive genes in each cell line, since PTHR1 signals through cAMP/CREB. PTHrP-67 regulated more than double the number of CREB responsive genes than PTHrP-FL (21/32 compared to 8/32), indicating that absence of the C-terminal domain increases PTHR1-CREB signalling.Deciphering these suppressive activities of C-terminal PTHrP may lead to ways to improve the bone formation response to PTHR1 activation and thereby optimize anabolic effects of PTHrP-based therapies in bone.

Myeloid Wnts control cortical and trabecular bone formation through paracrine and autocrine production of recruitment and differentiation factors Megan Weivoda*[1], Ming Ruan[1], Glenda Evans[1], Christine Hachfeld[1], Jean Vacher[2], Bart Williams[3], Sundeep Khosla[1], Jennifer Westendorf[1], Merry Jo Oursler[1]. [1]Mayo Clinic, United States, [2]McGill University, Canada, [3]Van Andel Institute, United States

Eighty percent of age-related fractures involve cortical bone, yet current therapies are not highly effective at preventing cortical fractures. Because of this, there is a need to understand the mechanisms that support cortical, as well as trabecular, bone formation. CD11b+ myeloid cells are located in cortical and trabecular regions and express the canonical Wnt co-receptors Lrp5/6, suggesting that myeloid cells are Wnt responsive. While the positive influences of Wnts on bone formation are well known, whether there are influences of myeloid Wnt responses on bone metabolism remains unexplored. We employed CD11b-Cre mice to delete Lrp5/6 in myeloid cells (Lrp cKO mice) and observed trabecular osteopenia and decreased cortical thickness. There were significant reductions in osteoblasts and bone formation in Lrp cKO bones, supporting myeloid cell production of osteogenic factors in response to canonical Wnt signaling. We examined monocytes isolated from control and Lrp cKO mice without intervening culture to provide a "snapshot" of cell responses to altered myeloid canonical Wnt signaling in the in vivo microenvironment. Loss of canonical Wnt signaling reduced expression of several osteogenic genes including BMPs and Wnts as well as numerous chemokines. These data indicate that myeloid cells are likely pro-osteogenic mediators of the positive influences of Wnts on bone metabolism.We next sought to determine possible sources of Wnts that could influence myeloid cells. Wnt hydrophobicity reduces diffusion, thus Wnt sources within bone are local. Our studies revealed that myeloid cells expressed several canonical and noncanonical Wnts and we therefore conjectured that myeloid Wnts could act in an autocrine manner. To examine this, we conditionally deleted Wntless (Wls) using the CD11b-Cre mice (Wls cKO mice). Consistent with Lrp cKO mice, femurs from the Wls cKO mice exhibit trabecular osteopenia, decreased cortical thickness, and reduced osteoblast numbers. There was a striking 78% reduction in periosteal mineral apposition rate in the cortical bone.Our data support that myeloid canonical Wnts directly promote bone formation and act in an autocrine manner to stimulate production of chemotactic and osteogenic factors. These studies have elucidated an important Wnt source in bone and revealed potential mechanisms by which myeloid cell Wnt responses influence cortical and trabecular bone metabolism.

Phytic acid, a phosphate store in plants, inhibits osteogenic differentiation in ectopic calcifications but not in bone. Faisal Ahmed*, Tomoko Minamizaki, Masaaki Toshishige, Yuji Yoshiko. Department of Calcified Tissue Biology, Hiroshima University Graduate School of Biomedical and Health Sciences, Japan

Ectopic calcification is defined as abnormal biomineralization occurring in soft tissues including arteries, skins and joints age- and disease-dependently (for example, arteriosclerosis, diabetes, and chronic kidney disease). An active process is implicated in ectopic calcifications via a variety of the mechanisms underlying impairments in the production of pyrophosphate, an endogenous inhibitor of mineralization, BMP2 signaling, inorganic phosphate transport. Plants store phosphate as phytic acid (myo-inositol-1,2,3,4,5,6- hexaphosphate, IP6). In humans, dietary intake of grains increases serum IP6 levels. IP6 is known to act as an antioxidant via metal ion chelation and suppression of hydroxyl radical formation and used as pharmaceutical and food ingredients. We hypothesized the clinical benefits of IP6 for ectopic calcification. First, we found that IP6 inhibited matrix mineralization but not osteogenic cell proliferation and development in fetal rat calvaria and mouse MC3T3-E1 cell cultures. The anti-mineralization effect of IP6 appears to be involved in its calcium chelating activity. We also tested mouse aorta organ cultures under conditions at high phosphate levels; IP6 inhibited not only matrix mineralization but also expression of osteoblast marker genes and proteins. Using osmotic pumps, we injected IP6 intravenously into three different rodent ectopic calcification models: mice intramuscularly implanted with collagen sponges including BMP2 and TGFb (Fibrodysplasia Ossificans Progressiva), rats treated with warfarin (aortic calcification induced by dysfunction of MGP), and the Enpp1 mutant mice as models of generalized arterial calcification of infancy. In all three independent rodent models, IP6 significantly suppressed ectopic calcification with inhibition of osteogenic differentiation, while it showed no obvious effects on bone parameters and serum Ca and Pi levels. Given the finding of unique gene clusters in the mouse aorta organ culture model as

Sunday Posters

above, these data suggest that IP6 may act on osteogenic fate conversion in ectopic calcification processes. Our results indicate that IP6 may strongly suppress ectopic calcification by inhibiting heterotopic osteogenesis. Thus, IP6 may represent a new class of anti-ectopic calcification agents.

Doses of 1,25-Dihydroxyvitamin D Supplementation in CKD Rats Influence Bone Mineralisation and Vascular Calcification Sarah-Kim Bisson*, Roth-Visal Ung, Sylvain Picard, Mohsen Agharazii, Richard Larivière, Fabrice Mac-Way. Centre de recherche de l'Hôtel-Dieu de Québec, Canada

Background: Active vitamin D is widely used for the treatment of secondary hyperparathyroidism in CKD. Recent animal studies in CKD suggest that high doses of active vitamin D (calcitriol) also induce bone mineralisation defects. The objective of this study was to assess the effects of high vs low doses of calcitriol on hemodynamic, biochemical, bone parameters and vascular calcification in CKD rats. Methods: CKD was induced in rats by a 5/6 nephrectomy. Animals were then fed with an enriched calcium (1.2%) and phosphate (1.2 %) diet (Ca/P), and were given either 0.1 µg/kg or 0.5 µg/kg of calcitriol 3 times/week and compared to controls for a month. Hemodynamic parameters were measured prior to sacrifices where tibias, femur and aortas were harvested for bone histomorphometry, micro-CT analysis and quantification of vascular calcification. Results: Rats treated with Ca/P + 0.1 µg/kg or 0.5 µg/kg calcitriol had similar systolic, diastolic and mean arterial pressure. However, animals treated with 0.5 µg/kg calcitriol had higher pulse pressure and pulse wave velocity while vascular calcification occurred only in rats treated with the high dose of calcitriol. Serum biochemical parameters also revealed lower creatinine clearance and higher renal excretion of Ca and P in these animals. While micro-CT analysis did not reveal notable differences in the tibia bone volume and size between the two groups, bone mineral density was decreased in the high calcitriol group only, suggesting decreased mineralisation. Finally, histomorphometry analysis confirmed a bone mineralisation defect in the high but not in the low calcitriol treated group of animals. Conclusion: In CKD rats fed with enriched Ca/P diet, a higher dose of calcitriol induces vascular calcification, further deterioration of kidney function and bone mineralisation anomalies. Further studies regarding the safe dose of calcitriol should be conducted in CKD patients.

A cysteine peptidase inhibitor from the Orange tree (Citrus sinensis) inhibits periodontitis-induced bone loss by retaining osteoclasts at the macrophage stage. Natalia Da Ponte Leguizamon*[1], Glaucia Coletto-Nunes [2], Daniela Morilha Néo-Justino[3], Vanessa Karine Schneider[3], Andressa Vilas Boas Nogueira[4], Rafael Scaf Molon[4], Flavio Henrique Da Silva[3], Andrea Soares Da Costa Fuentes[3], Ulf Holger Lerner[5], Joni Augusto Cirelli[4], Pedro Paulo Chaves Souza[2]. [1]Department of Diagnosis and Surgery, School of Dentistry at Araraquara, Sao Paulo State University, Brazil, [2]Department of Physiology and Pathology, School of Dentistry at Araraquara, Sao Paulo State University-UNESP, Brazil, [3]Department of Genetics and Evolution, Federal University of São Carlos, Brazil, [4]Department of Diagnosis and Surgery, School of Dentistry at Araraquara, Sao Paulo State University-UNESP, Brazil, [5]Centre for Bone and Arthritis Research at the Sahlgrenska Academy, University of Gothenburg, Sweden

During the course of periodontitis, bone resorption by osteoclasts causes loss of alveolar bone and loosened teeth. Thus, targeting osteoclastogenesis and osteoclast activity is a strategy to block the progression of this bone destructive disease. In humans, cystatins or cysteine peptidase inhibitors are responsible for regulation of physiological processes, which are limited by overexpression of cysteine peptidases. The lack of regulation of cathepsins-like activity can result in bone loss process. The cDNA from a cysteine peptidase inhibitor (Csin-CPI-2) from Citrus sinensis was cloned and expressed in Escherichia coli. This protein was purified by affinity chromatography and its ability to inhibit human cathepsins was tested. The activity of human cathepsins was efficiently inhibited by CsinCPI-2, with Ki in nanomolar order. CsinCPI-2 was capable to inhibit RANKL-induced TRAP+ multinucleated osteoclast formation in mouse bone marrow macrophage (BMM) cultures in a concentration-dependent manner, with maximal effect at 20 µM and with IC50 at approximately 2.7 µM. This effect was not due to cytotoxicity, as demonstrated by MTT assay in BMMs and osteoclasts cultured for 4 days. CsinCPI-2 was capable to inhibit RANKL-induced mRNA expression of the osteoclast phenotypical markers Acp5, Ctr and Ctsk, but not mRNA expression for the receptor RANK, encoded by the Tnfrsf11a gene. Down-regulation of the mRNA expression for the macrophage marker Irf8 by RANKL was partially prevented by CsinCPI-2. The RANKL-induced up-regulation of Nfatc1 mRNA and protein, a crucial transcription factor for RANKL-induced osteoclast differentiation downstream to RANK, was also inhibited by CsinCPI-2. In vivo, using the ligature-induced periodontitis model, we demonstrated, using microCT analyses, that treatment with CsinCPI-2 (0.82Ug/Kg) prevented the loss of alveolar bone mass (BV/TV) and the decrease of bone height (assessed by measuring the distance between the cementum-enamel junction and alveolar bone crest), caused by periodontal dis-

ease. In conclusion, CsinCPI-2 has the potential to prevent bone loss induced by periodontal disease, by retaining osteoclast precursors at the macrophage stage.

Compositional Heterogeneity in Lumbar Vertebral Trabecular Bone as a Function of Disease and Treatment Isabel Colon-Bernal*[1], Phillip Yang[2], Taeyong Ahn[3], Le Duong[4], Brenda Pennypacker[5], Meagan Cauble[6], Sriram Vaidyanathan[7], Kenneth Kozloff[8], Bradford Orr[9], Mark Banaszak Holl[10]. [1]Chemistry Department, University of Michigan, United States, [2]Biomedical Engineering, University of Michigan, United States, [3]Macromolecular Science and Engineering, University of Michigan, United States, [4]Merck & Co, Inc (Retired), United States, [5]Merck & Co, Inc, United States, [6]Department of Orthopaedic Surgery, University of Connecticut Health Center, United States, [7]Department of Pediatrics, Stanford University, United States, [8]Department of Orthopaedic Surgery and Biomedical Engineering, University of Michigan, United States, [9]Physics Department, University of Michigan, United States, [10]Department of Chemical Engineering, Monash University, Australia

Osteoporosis is a degenerative bone disease characterized by a loss of bone density and quality. Recent studies have demonstrated that compositional heterogeneity plays an important role in fracture prevention for osteoporotic bone. In this study, we seek to understand compositional changes linked to disease and treatment in lumbar vertebral trabecular bone using a treatment animal model. A group of cynomolgus monkeys were either ovariectomized (OVX) or submitted to sham surgery. Two years post-surgery, OVX animals were treated in rescue mode with vehicle (VEH), ALN (0.03 mg/kg weekly), or CatKi MK-0674 (0.6 mg/kg daily) for two years and compared to a control Sham surgery group. Baseline BMD values taken prior to drug treatment show a significant decrease in BMD for all OVX animals (10-15% decrease in BMD) indicating the animals became osteoporotic. To understand compositional changes, atomic force microscopy with infrared spectroscopy (AFM-IR) was used to obtain topographical information coupled to chemical composition for cross-section of lumbar vertebrae 4 (LV4). A total of 16 locations were imaged per sample, a 10 by 10 µm and two 3.5 by 3.5 µm images were obtained as well as a localized IR spectrum per 3.5 by 3.5 µm image. The average organic matrix and mineral content for each group was evaluated. Average mineral (1200-900 cm-1) to matrix (1800-1500 cm-1) ratios obtained for Sham, ALN, and CatKi groups were 0.31, 0.34 and 0.38 respectively (p < 0.05), which all differ from the 0.22 value for the OVX group. These results indicate an average bone composition recovery for both the ALN and CatKi treatments. Our presentation will link these average compositional changes to previous micro-CT and mechanical measurements as well as the full distribution of composition results from across the entire LV4 cross-section.

Comparison of Calcitonin Receptor Fragment Peptide to Teriparatide for the Prevention of Ovariectomy-Induced Bone Loss David E Komatsu*[1], Anthony Cappellino[1], Ryanne Chitjian[2], Anne Savitt[3], Sardar Mz Uddin[1], Suresh Anaganti[3], Srinivas Pentyala[4]. [1]Stony Brook University, Department of Orthopaedics, United States, [2]Stony Brook University, Department of Biomedical Engineering, United States, [3]AJES Lifesciences, United States, [4]Stony Brook University, Department of Anesthesiology, United States

Osteoporosis is the most widespread musculoskeletal disorders in the US with a prevalence of >10 million. Moreover, ~2 million osteoporotic fractures occur annually, which result in pain, immobility, and loss of independent living, as well as increased morbidity and mortality. While there is widespread clinical availability of several classes of antiresorptive drugs, such drugs merely reduce disease progression and do not induce new bone formation. One anabolic agent, teriparatide, is available, but it has not garnered widespread utilization. As such, there is a clear need for new skeletally anabolic treatments. We previously reported on the development and characterization of Calcitonin Receptor Fragment Peptide (CRFP), a short peptide with homology to the C-terminus of the calcitonin receptor. In this study, we directly compared the efficacy of CRFP to teriparatide in improving rat bone quality and quantity following ovariectomy (OVX). Twenty-four Sprague Dawley rats underwent OVX surgery at 6 months of age and were randomly assigned to 4 groups (N=6/group) by body weight. The first group was immediately sacrificed to serve as baseline controls. The remaining rats were treated with vehicle, teriparatide (10ug/kg), or CRFP (150ug/kg) 5 days/week for 5 weeks via subcutaneous injections. They were then euthanized, and femora were collected for analyses. In addition, serum was collected weekly and at the time of euthanasia. The femora were analyzed by microCT at the midshaft and distal metaphysis followed by 3-point bending tests. Serum samples were used for antibody analyses. MicroCT analyses revealed a trend towards increased bone mineral density (BMD) in the mid-diaphysis in both the teriparatide and CRFP treated rats as compared to baseline and vehicle. In the distal metaphysis, trabecular bone volume fraction (BV/TV) and BMD in CRFP treated rats trended higher in comparison to all other groups. Subsequent mechanical testing identified trends toward increased yield force and ultimate force for both teriparatide and CRFP treated rats as compared to baseline and vehicle controls. Serum analysis of CRFP treated rats showed

no production of CRFP binding antibodies. Serum biomarker analyses, as well as dynamic histomorphometry and vertebral analyses are ongoing. The relative efficacy of CRFP compared to teriparatide in the treatment of ovariectomy-induced bone loss cannot be conclusively determined given the limited sample size for this study. Future longitudinal in vivo bone morphometry studies with a larger number of animals are being planned to validate the osteogenic potential of CRFP. In summary, the data from this study demonstrates that CRFP administration to OVX rats is safe and results in changes in bone density, structure, and mechanical characteristics similar to teriparatide.

Biological Effects of Abaloparatide on Bone Mass and Bone Turnover in Mice, a Comparison with Teriparatide. Akito Makino*[1], Tomoka Hasegawa[2], Norio Amizuka[2]. [1]Pharmacology Research Department, Teijin Pharma Limited, Japan, [2]Developmental Biology of Hard Tissue, Graduate School of Dental Medicine, Hokkaido University, Japan

Background: Abaloparatide (ABL), an analog of parathyroid hormone-related protein, has been recently approved by Food and Drug Administration as a drug for severe osteoporosis. In the phase 3 ACTIVE clinical trial, daily administration of ABL induced a robust increase in BMD and reduction of fracture rate. It also increased total hip and femoral neck BMD to a greater extent than daily administration of teriparatide (TPTD, PTH[1-34]). In this study, therefore, we have examined the bone mass and bone turnover between ABL- or TPTD-treated mice.Methods: Six-week-old male C57BL6/J mice received subcutaneous injection of ABL or TPTD for 28 days. The dosage of these peptides was fixed to 30 mcg/kg daily. Taking the different activation frequency (rate of bone turnover) between human and rodents into account, the dosing frequency was once daily (30 mcg/kg every 24 hrs), twice daily (15 mcg/kg every 12 hrs) or three times a day (10 mcg/kg every 8 hrs). BMD of femurs and lumbar was measured under anesthesia on the day before the last injection. Next day of the last injection of the drug, blood and femurs were collected after euthanasia. The femurs were then analyzed with micro-CT, or embedded in paraffin for histological analysis. Results and Discussion: Both ABL and TPTD administration increased the BMD of femurs and lumbar depending on the dosing frequency. There was no significant difference in BMD between the two peptides when administrated once daily. However, when the dosing frequency was twice daily or more, a significant increase in BMD was found in ABL group when compared with TPTD group. Micro-CT analysis showed a significant increase in trabecular and cortical bone when administered with ABL rather than TPTD. The index of serum PINP was significantly higher in ABL-treated group compared with TPTD group in the regimens of two or three times a day administration. However, regardless of the administration frequency, there seems no significant difference in the indices of serum CTx and urine DPD/Cr between the two peptides. Histological analysis demonstrated abundant alkaline phosphatase-positive osteoblasts and trabecular bone in femoral metaphysis with injections of ABL three times a day. Taken together, it seems likely that ABL potently stimulates anabolic activities in bone with limited elevation of catabolic activity that consequently brings robust BMD increase in mice.

Analgesic Effects of Morphine on Knee Osteoarthritis Induced by Intra-Articular Monosodium Iodoacetate in Rats Jukka Morko*, Jukka Vaaraniemi, Jaakko Lehtimaki, Zhiqi Peng, Jussi M Halleen. Pharmatest Services Ltd, Finland

Several experimental animal models have been developed for human osteoarthritis (OA) and used to study the preclinical efficacy of symptom and disease modifying OA drug candidates. One of these models is induced chemically by an intra-articular injection of monosodium iodoacetate (MIA) into rat knee. Intra-articular MIA disrupts chondrocyte glycolysis through the inhibition of glyceraldehyde-3-phosphate dehydrogenase leading to chondrocyte death, joint damage, and OA symptoms. In this study, we characterized the effects of intra-articular MIA injection on knee joint discomfort and pain and evaluated the analgesic effects of opioid morphine both at rest and during movement in young rats. Unilateral OA was induced by the injection of MIA at 2 mg into the knee joint of male Sprague-Dawley rats at 6 weeks of age. The effects of MIA and the analgesic effects of morphine (3 mg/kg s.c.) were analyzed at 2 days and at 1, 2, 3 and 4 weeks after the MIA injection. Knee joint discomfort was determined as static weight bearing and measured as hind paw weight distribution (HPWD) using Incapacitance Tester. Knee joint pain was determined as static mechanical allodynia and analyzed as paw withdrawal threshold (PWT) using von Frey monofilaments. Changes in gait were used as an index of knee joint discomfort and pain during movement. The gait was analyzed using CatWalk XT computer-assisted method of locomotor analysis. The analgesic effects of morphine were studied by von Frey monofilaments at 1 hour, by CatWalk at 1.5 hours and by Incapacitance Tester at 2 hours after treatment. Intra-articular MIA injection decreased static HPWD and PWT during the entire study period indicating knee joint discomfort, static mechanical allodynia and neuropathic pain in MIA-injected hind limb. The MIA injection decreased dynamic weight bearing and slowed down and impaired movement during the entire study period as well. This was demonstrated by changes in various gait parameters including decreased paw weight distribution, stride length and swing speed. Treatment with morphine reversed the reduction in PWT completely and improved gait during the entire study period as well as reversed the reduction in HPWD

partly during the first 3 weeks. This rat MIA model of OA-related joint pain and these assessments of static weight bearing, static mechanical allodynia and gait can be used to study the preclinical efficacy of symptom modifying OA drug candidates at rest and during movement.

Targeted Delivery of Peptide Therapeutics to Bone Fractures Jeffery Nielsen*, Philip Low, Stewart Low. Purdue University, United States

Background: We sought to develop a drug delivery system that can safely and effectively be used to deliver therapeutics to the site of a bone fracture. Bone homing oligopeptide drug conjugates are one of the most promising strategies to increase the efficacy and safety of drugs used to treat bone-related diseases. Targeting also opens the door for new methods of administering drugs. Traditionally, use of bone anabolic agents to treat bone fractures has relied entirely on local surgical application. However, because these methods are so invasive, their use and development has been limited. By conjugating bone anabolic agents to bone homing molecules, bone fracture treatment can by performed through minimally invasive subcutaneous administration. The exposure of raw hydroxyapatite that occurs at the bone fracture site allows hydroxyapatite-binding molecules to concentrate on the fracture surface and stimulate bone deposition at the fracture site. Many bone-homing molecules (such as bisphosphonates and tetracycline targeting) have been developed to treat osteoporosis. However, several of these have toxicity associated with them.Methods/ Results: We have found that certain short oligopeptides can localize to bone fractures with high selectivity and have very low toxicity compared to bisphosphonates and tetracyclines. We have also demonstrated the ability of these oligopeptides to target bone with numerous payloads of small molecules linked via liable linkers with high selectivity. We have also established that the same targeting peptides can be used to deliver drugs of all chemical classes: hydrophobic, neutral, cationic, anionic, large, and small. This is particularly useful as many bone anabolics are peptidic in nature and have better persistence at the site of the fracture than bisphosphonate-targeted therapeutics. We have also seen that the increased size of the targeting ligand has increased the selectivity for the fracture site over that of the healthy bone in comparison with bisphosphonate targeting. This method allows for a systemic administration of bone anabolics to treat bone fractures, which it achieves by accumulating the bone anabolic agent at the fracture site. This method opens the door for a new way of treating the prevalent afflictions of broken bones and associated deaths.

In Vitro and In Vivo Assessment of Poloxamers as a Drug Delivery System for Bone Regeneration Young-Eun Park*[1], Kaushik Chandramouli[2], Maureen Watson[3], Karen Callon[3], Mark Zhu[4], Donna Tuari[3], Dorit Naot[4], David Musson[4], Darren Svirskis[4], Manisha Sharma[4], Jillian Cornish[5]. [1]Miss, New Zealand, [2]Mr, New Zealand, [3]Ms, New Zealand, [4]Dr, New Zealand, [5]Professor, New Zealand

Numerous hydrogels have been tested for delivery of growth factors or cells into areas of bone injury. Although the general approach is promising, there is a need for better hydrogel formulations and a great scope for the development of novel drug delivery systems for bone repair. Poloxamers are copolymer hydrogels used for a wide range of applications, including drug delivery in cancer treatment. The aim of this study was to determine the potential of poloxamers as a delivery system for the bone anabolic factor lactoferrin (LF).The release profile of LF from poloxamers was measured by HPLC over a 72 hour period. To assess poloxamers' cytocompatibility, LF-loaded poloxamers (LF/poloxamers) were placed in tissue culture inserts suspended above cultures of primary rat osteoblasts, and viability assessed after 72 hours using alamarBlue® assay. Immune response was assessed in THP-1 human macrophage-like cells. Cells were collected after 24 and 48 hours with LF/poloxamers and gene expression of proinflammatory cytokines evaluated by real-time PCR. To study bone regeneration in vivo, 5 mm critical-size defects were created over the parietal bone in

43 Sprague–Dawley rats. The rats were randomized into three groups of: Control (n=20); Defects grafted with LF/poloxamers (40 ug/gel, n=20); and Sham surgeries (n=3). The rats were sacrificed at 4 or 12 weeks post-operation, calvariae were dissected and bone regeneration determined by microCT (Skyscan1172).The study of the release profile found that 50% of the LF was released from the poloxamers during the first 8 hours, with the remaining released over 72 hours. Cell viability assays demonstrated that poloxamers, with and without LF, increased alamarBlue reading at 72 hours (p<0.001). LF/poloxamers had no effects on the levels of expression of IL1b and IL8 genes in THP-1 cells, whereas TNF gene expression was higher than the controls group at 24 hours, but was back to control levels at 48 hours. MicroCT analysis of bone regeneration showed that the LF/poloxamers had no effect on bone volume (BV) and tissue mineral density (TMD) at the defect site at 4 weeks post-operation, however at 12 weeks the LF/poloxamers group had lower BV than the controls. TMD was similar in the two groups.LF/poloxamers are cytocompatible and support cell viability in vitro, and are not likely to induce an unfavourable immune response. However, the current formulation of LF/poloxamers did not improve bone regeneration in vivo.

Distinct mechanisms regulate the response of female and male skeletons to sex steroid deficiency and to the bone protective effects of blueberry containing diets. Amy Y Sato*[1], Gretel G Pellegrini[2], Meloney Cregor[1], Kevin Mcandrews[1], Emily Atkinson[1], Roy B Choi[1], Maria Maiz[3], Lilian I Plotkin[1], Linda D Mccabe[4], George P Mccabe[4], Munro Peacock[5], Connie Weaver[3], David Burr[6], Teresita Bellido[7]. [1]Department of Anatomy & Cell Biology, Indiana University School of Medicine, United States, [2]CONICET-Universidad de Buenos Aires. Instituto de Inmunología, Genética y Metabolismo (INIGEM). Facultad de Farmacia y Bioquímica-Hospital de Clínicas, Universidad de Buenos Aires, Facultad de Odontología. Cátedra de Bioquímica Gral y Bucal, Argentina, [3]Department of Nutrition Science, Purdue University, United States, [4]Department of Statistics, Purdue University, United States, [5]Department of Medicine, Division of Endocrinology, Indiana University School of Medicine, United States, [6]Department of Anatomy & Cell Biology, Department of Biomedical Engineering, Indiana University School of Medicine, United States, [7]Department of Anatomy & Cell Biology, Department of Medicine, Division of Endocrinology, Indiana University School of Medicine, Roudebush Veterans Administration Medical Center, United States

There is an unmet need for non-sex steroid interventions that prevent bone loss induced by sex steroid deficiency with better compliance and lower side effects than current approaches. Loss of sex steroids causes accumulation of reactive oxygen species (ROS) in bone. ROS, in turn, activate the transcription factor Nrf2 and increase the endogenous antioxidant response (EAR), in an attempt to mitigate damaging oxidative effects. We investigated the ability to prevent bone loss due to sex steroid deficiency of diets containing 10% of 3 types of blueberries rich in antioxidant metabolites fed to 4 mo-old female (F) or male (M) WT and Nrf2 KO littermate mice (N=19-26). In mice fed control diet, ovariectomy (OVX) or orchidectomy (ORX) induced the expected bone loss, which was similar in WT and KO mice, as quantified by % change BMD/month or final BMD. Only the diet with Montgomery berries decreased the rate of bone loss, either fully in F or partially in M. Whereas the berry diet prevented bone loss in both WT and KO F, it only prevented bone loss in WT M. OVX decreased expression of the estrogen response element (ERE)-containing gene C3 and ORX decreased expression of the androgen ARE-containing gene Rhox5 in bone, in WT and KO mice fed control diet. And, C3 or Rhox5 expression remained low in OVX or ORX mice fed the berry diet, indicating that bone protection is not due to estrogenic/androgenic actions of the diet. OVX increased the EAR in bone, but ORX did not. Moreover, the berry diet prevented the increase in EAR induced by OVX in both WT and KO mice, but it did not alter EAR in ORX mice. In summary, (1) bone loss induced by estrogen/androgen deficiency is independent of Nrf2; (2) only Montgomery berry diet decreased bone loss rate; (3) berry diet-induced skeletal protection depends on sex (full in F vs partial in M) and is exerted by a mechanism independent of canonical ERE or ARE signaling; and (4) bone EAR in sex steroid deficiency (OVX-increased vs ORX-not altered) or in response to the berry diet (prevention of OVX-induced increases vs not altered-ORX) also depends on sex. We conclude that distinct mechanisms underly the response of the F and M skeletons to (a) sex steroid deficiency, as bone EAR is increased in F but not M, or to (b) bone protection by the berry diet, as Nrf2 is required in M but not in F. Thus, optimal skeletal benefits might be achieved by tailoring antioxidant-rich diets to patients of either sex.

SUN-0999

Pasteurized Akkermansia muciniphila reduces fat mass accumulation after ovariectomy but induces bone-loss in the femur of gonadal intact mice Lina Lawenius*[1], Julia Scheffler[1], Petra Henning[1], Karin Gustafsson[1], Karin Nilsson[1], Hannah Colldén[1], Ulrika Islander[1], Willem M De Vos[2], Patrice Cani[3], Hubert Plovier[3], Claes Ohlsson[1], Klara Sjögren[1]. [1]Centre for Bone and Arthritis Research, Institute of Medicine, Sahlgrenska Academy at University of Gothenburg, Sweden, [2]Laboratory of Microbiology, Wageningen University, Netherlands, [3]Université catholique de Louvain, Louvain Drug Research Institute, WELBIO (Walloon Excellence in Life sciences and BIOtechnology), Metabolism and Nutrition Research Group, Belgium

The gut microbiota effects the metabolism and immune system of its host. Ovariectomy (ovx) leads to bone loss, altered immune status and intestinal permeability. Different strains of Lactobacillus protect from ovx-induced osteoporosis associated with effects on gut permeability. Pasteurized Akkermansia muciniphila increases the mucus layer in the intestine and contributes to the gut barrier. The aim of the study was to determine if treatment with A. muciniphila protects from ovx-induced bone loss. Mice were treated with pasteurized A. muciniphila or vehicle (veh) by oral gavage for 28 days, starting 3 days before sham or ovx surgery.The percentage of retroperitoneal fat was reduced when treating both gonadal intact mice (-36%, p<0.05) and ovx-mice (-34%; p<0.05) with pasteurized A. muciniphila compared to veh treated ovx mice. Pasteurized A. muciniphila treatment decreased bone mineral density (BMD) measured by DXA in femur in gonadal intact mice (-9%, p<0.01). As expected, ovx decreased BMD in femur in veh treated mice (-9%, p<0.01). However, ovx did not further decrease the already low femur BMD in pasteurized A. muciniphila treated mice. Pasteurized A. muciniphila treatment did not significantly affect BMD in vertebra (L5) in gonadal intact mice. Ovx reduced vertebrae BMD in both veh treated (-15%, p<0.01) and pasteurized A. muciniphila treated mice (-10%, p<0.05), indicating no protective effect of pasteurized A. muciniphila on ovx-induced bone loss in vertebra.Regulatory T cells (Tregs) can be protective of bone and the frequency of Tregs in bone marrow was measured by flow cytometry to evaluate the effect of pasteurized A. muciniphila. The frequency of Tregs was decreased in veh treated ovx-mice compared to veh treated gonadal intact mice (-29%, p<0.01). Tregs was also decreased for pasteurized A. muciniphila treated gonadal intact mice compared to veh treated gonadal intact mice (-29%, p<0.01). Tregs was further decreased for pasteurized A. muciniphila treated ovx-mice compared to pasteurized A. muciniphila treated gonadal intact mice (-21%, p<0.01).In conclusion, pasteurized A. muciniphila reduced BMD in femur but not in vertebrae in gonadal intact mice. In addition, pasteurized A. muciniphila reduced the frequency of Tregs in bone marrow. This study does not support a beneficial effect of pasteurized A. muciniphila in ovx-induced osteoporosis.

Assessing the effects of a ketogenic diet on the development of osteoarthritis in obese mice Thomas Solé*[1], Thierry Thomas[2], Laurence Vico[1], Maura Strigini[1]. [1]INSERM, U1059 and University of Lyon, UJM Saint-Etienne, France, [2]INSERM, U1059 and University of Lyon, University Hospital Saint-Etienne, France

Osteoarthritis (OA) is a disease of joints defined by multi-tissue degradation including cartilage, subchondral bone and synovial membrane. OA is particularly prevalent in the obese population, where weight-related joint overload is accompanied by a chronic, low-grade metabolic inflammation and a damaging adipokine-related profile.beta-hydroxy-butyrate (BHB) is a ketone body whose plasma levels increase during fasting or following a ketogenic diet (KD) - a low carb/high fat regime inducing a metabolic state known as ketosis. BHB affects histone modifications and gene expression in vitro and in vivo possibly also by interfering with the activity of histone deacetylases (HDAC). HDAC inhibitors downregulate the expression of Runx2 and proteases in chondrocytes from OA patients in vitro, suggesting that lowering HDAC activity could slow down OA progression. A KD should simultaneously induce weight-loss, decrease metabolic inflammation and increase BHB circulating levels, all of which would be beneficial in obesity-linked OA. To directly test this hypothesis, we set up a protocol to evaluate the impact of a KD in a murine OA model combining obesity and osteoarthritis (Cleret et al., ASBMR 2016).The first step of our project was to validate the animal model.CB57Bl6 male mice were fed an obesogenic high fat diet (HFD) from age 6 weeks. We bilaterally destabilized the medial meniscus of the knee at week 16 to induce OA. Then obese mice were fed one of three diets for 8 weeks ad libitum: HFD; KD; standard Control Diet (CD). Weight, fat/lean body composition, glycemia and BHB levels, and muscle strength (Kondziela test) were monitored. At 8 weeks after surgery (week 24) we collected joints for determination of disease severity (OARSI score) and bone analysis by micro-CT; we dissected tibia epiphysis and bones for biomolecular analysis. Serum, muscle, fat, renal and hepatic tissues were also collected.BHB levels increased tenfold in KD group only. Glycemia remained high in HFD group, but it decreased in CD group and even more in KD group. HFD mice continued to gain weight, while both CD and KD lost weight. Kondziela test showed no variation in muscle strength over the 8-week treatment in CD and KD groups and lower performance in HFD group.We have validated the efficacy of our KD protocol to induce a raise in BHB levels and a loss of weight

in obese OA mice, without a negative impact on muscle function. We can now appraise the effects of KD on OA in this model.

Effects of Metformin and Exercise on Material Properties of Ovariectomized Rat Femurs Matthew Tice*[1], Mats Mosti[2], Astrid Kamilla Stunes[2], Unni Syversen[2], Deepak Vashishth[1]. [1]Rensselaer Polytechnic Institute, United States, [2]Norwegian University of Science and Technology, Norway

Bone fragility fractures, caused by estrogen deficiency and type 2 diabetes, represent a significant economic burden with increased morbidity. As such, a better understanding of these conditions and the effectiveness of its treatment is crucial to alleviating the burden of bone fractures. Metformin, an oral antidiabetic drug, provides a promising solution. However, its interaction with other anabolic stimuli, such as exercise, is not well established. Here we explore the interaction of metformin with exercise under control condition.An ovariectomy (OVX) was performed in 15-week-old rats to mimic the estrogen drop characteristic of the postmenopausal state. The rats were divided into 5 groups: OVX sedentary control (n=11), OVX sedentary + metformin (n=11), OVX exercise + metformin (n=9), OVX exercise control (n=11), and sham control (n=12). An exercise regimen was mimicked by 6 jumps in 3 sets thrice a week. Metformin-treatment was delivered in dissolved water at a dosage of 100 mg/kg/day. Both regimens began 4 weeks after OVX and were conducted for 8 weeks. One femur per rat had a notch was placed mid-shaft with a diamond-tipped saw blade. The femurs then underwent microcomputed tomography imaging for measurement of bone cross-sectional parameters (cortical area, radii and bone mineral density) as well as notch angle (Viva CT40, Scanco). Following imaging, fracture toughness testing was performed on the notched femurs; samples were loaded in 3-point bending testing until failure at 0.001 mm/s (Instron System). All statistical analyses were done using one-way ANOVA (LSD Post-Hoc test, IBM SPSS).There were no significant differences between the geometric parameters and bone mineral density between groups (p>0.05). However, the metformin + exercise group exhibited a distinctive toughening effect (ΔK, difference of propagation and initiation toughness) when compared to other OVX groups (p<.05), reaching higher levels than those in the SHAM control group. ΔK is representative of bone's ability to sustain loading without fracturing when a microcrack is already present in bone. Reduced ΔK is hallmark of brittle materials and a decreased ability to resist crack propagation. These results suggest beneficial effects of metformin on bone fragility can be enhanced through exercise.

Effect of Kidney Disease Progression on Intestinal Phosphorus Absorption in Male Cy/+ Chronic Kidney Disease Rats Colby Vorland*[1], Pamela Lachick[1], Sharon Moe[2], Neal Chen[2], Kathleen Hill Gallant[1]. [1]Department of Nutrition Science, Purdue University, United States, [2]Department of Medicine, Indiana University School of Medicine, United States

The Cy/+ rat has been characterized as a progressive model of chronic kidney disease-mineral bone disorder (CKD-MBD). We aimed to determine the effect of kidney disease progression on intestinal phosphorus (P) absorption and whole-body P balance in this model. N=48 Cy/+ (CKD) and N=48 normal littermates (WT) rats were studied at two ages: 20wk and 30wk, to model early (~50% loss of kidney function) and moderate-late CKD

(~75% loss of kidney function), respectively. All rats were placed on a 0.7% Ca, 0.7% P casein-based diet to promote disease progression in the CKD rats. Intestinal P absorption efficiency was measured by ligated loops using ~5 µCi 33P in 0.5mL transport buffer (0.1 mmol/L KH2PO4, with or without sodium (Na)) injected into a ~5cm jejunal segment while rats were anesthetized. The 2 different transport buffers assessed Na-dependent and Na-independent components of P absorption (n=12/genotype/age/test). 33P activity was measured in the excised, digested loop by liquid scintillation counting. Absorption was determined by disappearance from the loop at 30min post-injection. P balance was determined over 4d prior to sacrifice. Diet, urine, and fecal P were measured by ICP-OES. Two-way ANO-VA was used to determine genotype and age effects and interaction with Tukey's post-hoc comparisons.There was a significant genotype x age interaction (p<0.05) for Na-dependent absorption with decreased absorption from 20wk to 30wk in the CKD rats (13 to 5%, p < 0.01) and no difference in WT rats. However, there were no differences for genotype, age, or interaction observed for Na-independent absorption efficiency (overall p=0.36). CKD rats had marginally lower P balance compared to WT (-10 vs -2 mg/day, p=0.06). There was a significant effect of age where 30wk rats had lower P balance compared to 20wk rats, regardless of genotype (-13 vs 1 mg/day, p<0.001). There was no significant genotype x age interaction.These results demonstrate decreasing Na-dependent P absorption with progression of CKD when assessed by an in situ ligated loop test.

EXD Chinese Herbal Formula Did Not Alter the Bone Protective Effects of SERMs in Mature Ovariectomized Rats Liping Zhou*[1], Ka Ying Wong[1], Christina Chui Wa Poon[1], Wenxuan Yu[1], Chi-On Chan[1], Daniel Kam-Wah Mok[1], Hui-Hui Xiao[2], Man-Sau Wong[1]. [1]The Hong Kong Polytechnic University, Hong Kong, [2]The Hong Kong Polytechnic University Shenzhen Research Institute, China

Er Xian decoction (EXD), a popular Chinese herbal formula containing Herba epimedii (HEP) and Curculigo orchioides Gaertn (XM), has been prescribed in China for management of postmenopausal osteoporosis over the past 60 years. Previous study demonstrated that EXD stimulated cell proliferation in rat osteoblastic-like UMR106 cells via estrogen receptors (ERs). The present study aimed to determine if the use of EXD will interfere with the bone protective effects of Selective Estrogen Receptor Modulators (SERMs, tamoxifen and raloxifene), which also exert their effects via ERs. Six month-old Sprague Dawley rats were randomly assigned to the following treatments for 12 weeks: 1) sham-operated control group with vehicle (sham), 2) ovariectomized group with vehicle (OVX), 3) OVX with 17ß-estradiol 17ß-estradiol (E2, 2.0mg/kg.day), 4) OVX with tamoxifen (Tamo, 1.0mg/kg.day), 5) OVX with Raloxifene (Ralo, 3.0mg/kg.day), 6) OVX with EXD (EXD, 1.6g/kg.day), 7) OVX with EXD+Tamoxifen (EXD+Tamo) and 8) OVX with EXD+Raloxifene (EXD+Ralo). EXD, tamoxifen, raloxifene and their combinations significantly increased bone mineral density (BMD) and improved micro-architectural bone properties, including bone volume/total volume (BV/TV), trabecular bone number (Tb.N) and trabecular bone separation (Tb.Sp) at distal femur, proximal tibia and lumbar vertebra in OVX rats. In particular, the optimal effects of EXD in improving BMD and bone properties appeared at lumbar vertebra, indicating the bone protective effects of EXD might be site-specific. Co-treatment with EXD did not alter the bone protective effects of either tamoxifen or raloxifene at all the three bone sites in OVX rats. In addition, SERMs, but not EXD, significantly increased uterus index in OVX rats. Our results indicate EXD alone exerted site-specific bone protective effects in OVX rats and did not alter the bone protective effects of SERMs in vivo. Disclosures: None

SUN-1039

Efficacy and Safety of Denosumab Treatment in Bisphosphonate-resistant Fibrous Dysplasia: a Case Series Natasha M. Appelman-Dijkstra*[1], Bas C.J. Majoor[2], P.D.Sander Dijkstra[2], Socrates E. Papapoulos[1], Neveen A.T. Hamdy[1]. [1]Leiden University Medical Center; Center for Bone Quality:Department of Medicine: Division Endocrinology, Netherlands, [2]Leiden University Medical Center; Center for Bone Quality: Department of Orthopedic Surgery, Netherlands

Fibrous dysplasia (FD) is a rare bone disorder due to a postzygotic activating mutation of theGNAS gene. In FD, skeletal lesions show increased bone turnover and upregulation of RANKL expression in GNAS-mutated skeletal progenitor cells leading to increased cAMP production. Exposure of GNAS mutation-harboring bone marrow stromal cells to a RANKL-antibody was associated with a decrease in cAMP production, suggesting that treatment with the monoclonal antibody to RANKL Denosumab may be beneficial in FD. Individual Case Studies have recently reported the effectiveness of Denosumab in FD. We present a case series of 12 FD patients (9 female), treated with denosumab for at least one year at the Leiden Center for Bone Quality between May 2013 and May 2016. All patients had been previously treated with bisphosphonates at high cumulative doses for a mean period of 8.8 years. One patient had monostotic craniofacial FD, 7 polyostotic FD and 4 Mc-Cune-Albright syndrome, 2 with growth hormone excess. Median Skeletal Burden Score was 20.8 (range 0.3–64.7). Denosumab was administered at a dose of 60 mg at 3 or 6-monthly intervals for a median of 14.5months (range 13–29M) on the basis of increased bone

turnover markers (BTM) and pain. At baseline, mean serum ALP was 226 ±152 U/L and P1NP was 369 ±385 ng/mL. Patients receiving Denosumab at 3-monthly intervals demonstrated sustained and more significant decreases in BTMs than those treated at 6-monthly intervals: ALP (p = 0.007) and P1NP (p = 0.025). BTMs normalized in 8 of the 12 treated patients after a median time of 4.7 months (range 2.1–24.0), in 5 of whom BTMs had not normalised after long-term treatment with bisphosphonates. Treatment was associated with decreases in bone pain. Denosumab was well tolerated and no side effects were reported, particularly no hypocalcaemia, for the duration of treatment. Our data show that Denosumab at a dose of 60 mg three-monthly is effective in decreasing BTMs and pain in FD. We also show that treatment was well-tolerated and safe in this selected group of FD patients with severe symptomatic FD despite long-term treatment with bisphosphonates, suggesting that Denosumab may represent a promising therapeutic option in FD patients refractory to treatment with bisphosphonates. Long-term studies in larger number of patients are warranted to confirm these findings.

Long-term complications of patients with hypophosphatemic rickets treated in a public institution Julia Oberger*, Tatiana Lemos Costa, Carolina Moreira, Victoria Borba. Serviço de Endocrinologia e Metabologia do Hospital de Clinicas da Universidade Federal do Paraná, Brazil

Objectives: describe clinical complications of patients with the diagnosis of hypophosphatemic rickets (HR) treated in a tertiary public care service. Methods: All patients diagnosed with rickets treated at Endocrinology Unit at the Universidade Federal do Paraná (SEMPR) were selected, and those with the diagnosis of HR were included. Patient's files were reviewed seeking for demographic and clinical data (etiology, age at diagnosis, results of initial laboratory tests, progression and of bone densitometry (BMD), radiographs and presence of complications). Results: 35 patients with rickets were selected, 13 excluded by hypocalcemic rickets and 22 (15 (69%) women) with HR were included. The mean follow up was 11 years (1 month - 27 y), with a mean age at the diagnosis of 8.75 (1.1 – 32 y). The first evaluation showed bone deformity in lower limbs in all patients, 11 (50%) had genu varum, 10 (45%) genu valgum and 1 patient varum and valgum (4%). Initial X ray showed in 12 (54%) deformities characteristic of rickets, 3 (13%) reduction of BMD and 2 (9%) presented fractures. Initial laboratory tests showed a normal calcium (Ca) 9.1 mg / dL (8.3-9.9 mg / dL), low phosphorus (P) 2.18 mg / dL (1.3-3.0 mg / dL) and phosphorus reabsorption rate 43% (9-82%), high alkaline phosphatase (ALP) 848 U / L (19.26-2109 U / L) and parathyroid hormone (PTH) 122 pg / mL (6-523 pg / mL). Treatment consisted of phosphate replacement in 14 (63%) patients [1.7 g / d (0.6-3.0 g)], calcitriol in 13 (59%) [0.32 mcg / day (0.125 -0.5mcg)] and in 9 (40%) combined treatment with phosphate and calcitriol. After treatment was observed a 76% (from 884 to 236 U / L) decrease in ALP, a 37% (0.5 to 0.8 mg / dL) increase in creatinine, and no change in PTH, P or Ca values. The complications present at the follow-up period of 6.8 years (3-14 years) were: fractures in 8 (36%) patients, mean of 2.12 (1-4) fractures / patient (femur 7 (41%) and tibia 4 (23%)); the delayed bone age was evaluated in 9 (40%) and present in all [mean delay of 19 (12 - 84 months)]; renal complication was evaluated in 17 (77%) patients by ultrasound and was positive in 7 (41%), 3 (17%) had nephrocalcinosis and nephrolithiasis and 4 (23%) had renal parenchymal disease, 1 (4%) patient had hyperparathyroidism. Conclusion: We observed a high prevalence of clinical complications mainly fractures and kidney abnormalities in a relatively young population, which alerts for the need of better care of these patients.

Low Bone Mineral Density and Increased Bone Resorption in Loeys-Dietz Syndrome Alison Boyce*, Caeden Dempsey, Samara Levin, Marjohn Rasooly, Pamela Guerrerio. National Institutes of Health, United States

Loeys-Dietz syndrome (LDS) is a rare connective tissue disorder resulting from dysregulation of TGF-ß pathway signaling, leading to a wide phenotypic spectrum involving the vascular, gastrointestinal (GI), and skeletal systems. While an association between LDS and osteoporosis has been reported, the skeletal phenotype has not been well-characterized, and the etiology of low bone mineral density (BMD) has not been established. The purpose of this study was to investigate bone metabolism in a large cohort of patients with LDS. Clinical, radiographic, and biochemical data from 51 subjects in an LDS natural history study were reviewed (median age 14, range 2-58). Mean DXA Z-scores were significantly decreased in all skeletal compartments compared to the reference population: lumbar spine -1.47 (±1.17, range-3.33-0.8)(p<0.001), 1/3 radius -1.54 (±1.78, -7.35-2.3), total hip -1.82 (±1.21, -4.27-0.34)(p<0.001), total body -1.89, (±1.49, -5-1.9)(p<0.001); 70% of subjects had low BMD (Z-score ≤-2) in at least one site. Subjects with a history of inflammatory or eosinophilic GI disease had significantly reduced BMD in the lumbar spine in comparison to subjects without GI disease: median Z-score -2.57 (-3.33-0.3) vs -1.13 (-3.33-0.9), p=0.03. There were no differences in BMD between groups of patients with different pathogenic mutations, TGFBR1 (n=17), TGFBR2 (n=21), SMAD3 (n=8), and TGFB2 (n=5). 19 subjects (37%) reported at least one long bone or vertebral fracture; 4 of 17 subjects (24%) who underwent screening lateral spine films had vertebral compression fractures. Mean serum procollagen 1-propeptide age-adjusted Z-scores were within normal limits (0.125, ±1.16, -1.81-2.5)(p=0.67), while serum C-telopeptide was increased compared to the reference

population (0.71, ±1.18, -1.36-3.45)(p=0.01). Two subjects, ages 11 and 17, were treated with zoledronate, which was well-tolerated and associated with an increase in BMD at all sites. Conclusion: LDS is associated with low BMD and fragility fractures, particularly in patients with co-morbid GI disease. There does not appear to be a correlation between genotype and BMD. Bone resorption markers are elevated, suggesting that anti-resorptives may be an effective treatment strategy.

Bone Mineral Status in Adults X-Linked Hypophosphatemia Rickets Rosa Arboiro Pinel*[1], Manuel Díaz Curiel[1], Natalia Bravo Martin[2], Manuel Quesada Gómez[3], Miguel Torralbo Garcia[1]. [1]Bone Mineral Department. Fundación Jiménez Díaz. Quironsalud, Spain, [2]Internal Medicine Department. Fundación Jiménez Díaz. Quinosalud, Spain, [3]Endocrinology Department. Hospital Reina Sofía., Spain

Introduction: X-linked hypophosphatemia (XLH) is the most common inherited form of rickets, and it is characterized by hypophosphatemia with renal phosphate wasting, and inadequate skeletal mineralization, usually acompanied by short stature and radiological signs of rickets. There are few reports on bone mineral measurements in adults with XLH, which are controversial. Several studies have shown that most patients have normal bone mineral densities, but others authors found some bone strength alteration related with the underlying mineralization defect.Objetive: The aim of this study was to assess bone mineral status in XLH using dual-energy X-ray absorptiometry (DXA), Trabecular Bone Score and Tridimensional-DXA software.Methods: Seven adult patients (age 29 to 67 years; 7 female) with clinical (short stature, leg deformities) and biochemical diagnosis of XLH were evaluated on its bone mineral densities (BMD) and bone quality. All patients were on treatment with calcitriol and phosphate supplementation. The BMD of the lumbar spine and femoral neck were determined by dual-energy X-ray absorptiometry scans (DXA), using Hologic QDR 4500C. Trabecular Bone Score (TBS), a texture parameter related to bone microarchitecture that may provide skeletal information that is not captured from the standard BMD measurement, was also determined in lumbar spine using TBS iNsight sofware. We analysed the standard hip DXA scan with the tridimensional-DXA algorithm (3D - SHAPER software) that quantifies the trabecular volumetric Bone Mineral Density (vBMD) and the Cortical Surface Density (sDens) both reflecting trabecular and cortical bone strength respectively. Results: All 7 female patients showed a normal BMD in lumbar spine with also normal TBS. With respects hip evaluation, 2 patients showed disminished femoral neck BMD with normal Trabecular vBMD but Cortical sDens below normal range (-1.7 and -2.4 T-score).Conclusions: All patients included in this study showed normal lumbar spine BMD and normal TBS. Most patients showed normal femoral neck BMD with vBMD and sDens at normal range which correlate with normal strength. With this data we can not affirm that TBS and 3·D DXA values are different in the evaluation of bone status at least in patients with XLH.

SUN-1043

Hypophosphatasia among patients presenting for osteoporosis evaluation Roger Fan*, Ananya Kondapalli, John Poindexter, Naim Maalouf, Khashayar Sakhaee. University of Texas Southwestern Medical Center, United States

IntroductionHypophosphatasia is a rare heritable disorder characterized by deficiency of tissue non-specific alkaline phosphatase leading to accumulation of phosphorylated molecules, including inorganic pyrophosphate, which causes impaired bone mineralization and fractures. Hypophosphatasia may be overlooked among adults diagnosed with osteoporosis. The distinction is important because bisphosphonate use is associated with atypical femoral fractures (AFF) in hypophosphatasia. A low serum alkaline phosphatase level (ALP) is the hallmark of hypophosphatasia. We sought to characterize patients presenting to an osteoporosis clinic with a low ALP and assess for features of hypophosphatasia.MethodsOur population included all patients presenting to a single university specialty clinic for osteoporosis from 7/1/2006-6/30/2016 with initial ALP ≤40 IU/L. We collected information on fracture history, bone mineral density (BMD), laboratory studies, medications, and secondary causes of low ALP. These patients were compared to controls matched for age, gender, race, and date of initial visit. We further compared features of patients with persistently vs. transiently low ALP, and patients in whom hypophosphatasia was suspected (based on clinic notes). ResultsOf 2810 patients presenting to clinic for osteoporosis, 159 patients had initial ALP ≤40 IU/L (5.66%). Compared to matched controls, low ALP patients had significantly lower BMI (p<0.001) and lower BMD Z-score at the femoral neck and total hip (p<0.05) but not

at the lumbar spine. Only 23 patients (14.5%) had a persistently low ALP, defined by ≥2 ALP values, with all values ≤40 IU/L. There was no significant difference in 24-hour urine calcium excretion between patients with persistently vs. transiently low ALP (226±134 vs. 222±188 mg/day, p=0.90). Of 10 patients suspected of having hypophosphatasia, vitamin B6 was checked in 9 patients, and was only elevated in one patient with hypophosphatasia confirmed by genetic analysis. Compared with the 149 patients not suspected of having hypophosphatasia, the 10 patients with suspected hypophosphatasia had significantly higher prevalence of AFF (20% vs. 0.67%), foot fractures (40% vs. 12.1%) and a history of unusual tooth loss/decay (20% vs. 1.34%).ConclusionsEven among patients with persistently low ALP, the diagnosis of HPP was rarely suspected. Patients suspected of having hypophosphatasia had higher rates of AFF, foot fractures and unusual dental history.

Table 2: Persistently low ALP versus transiently low ALP

	Persistently low ALP	Transiently low ALP	p-value
# of patients	23	107	
Average ALP (mean ± sd)	32.9 ± 4.3	45.0 ± 7.8	< 0.001
Urine calcium (mg/d)	226 ± 134	222 ± 188	0.9
Urine DPD/Cr[*]	3.8 ± 1.2	4.1 ± 1.7	0.6
History of fractures (n, %)	8 (35.8%)	48 (44.9%)	0.4
Atypical femoral fractures	0 (0%)	3 (2.8%)	0.4
Foot fractures	5 (21.7%)	11 (10.3%)	0.08
Vitamin B-6 checked	4 (17.4%)	5 (4.7%)	0.03
HPP suspected	4 (17.4%)	4 (3.7%)	0.01

SUN-1044

High Prevalence of Nephrolithiasis and Hypercalciuria in Women with Osteogenesis Imperfecta Vivian Rf Simoes*, Adriana M Fernandes, Manuela Gm Rocha-Braz, Regina M Martin, Bruno Ferraz-De-Souza. Endocrinology/ LIM-25, Hospital das Clinicas, University of Sao Paulo School of Medicine, Brazil

Increased risk of nephrolithiasis has been reported in children with osteogenesis imperfecta (OI), but studies in adults are scarce. The frequent finding of hypercalciuria in OI suggests a pathophysiologic association, but the mechanisms of hypercalciuria or nephrolithiasis in OI are not well understood. Hypercalciuria, and its potential link to nephrolithiasis, may hamper Ca and VitD supplementation in OI, with possible detriment to the bone. In this context, our objective was to assess the prevalence of nephrolithiasis and hypercalciuria in individuals with OI in relation to clinical, laboratory, imaging and molecular parameters.We have performed a retrospective analysis of OI patients followed in our institution. Sixty-five patients with OI were identified: 40 F, 25 M; 22 mild OI, 19 moderate, 24 severe; 16 to 71 yo, median 29 yo, 56 adults. Molecular diagnosis was available for 49 individuals, and 40 had COL1A1/COL1A2 defects. All patients were actively questioned about previous history of kidney stones and had 24-h urinary Ca (24-h uCa) determinations in at least 3 occasions; renal ultrasound was available for 82% of the cohort.Nephrolithiasis was found in 29% of the cohort (19/65), being more prevalent in females (15/40, 38%) than males (4/25, 16%) with OI. Twenty-six individuals (40%) had 24-h uCa excretion > 4 mg/kg, and 42% of these had nephrolithiasis. There was no association between hypercalciuria and OI severity, use of Ca or VitD supplementation or molecular etiology. Amongst individuals with nephrolithiasis, 58% had hypercalciuria; in particular, amongst women with nephrolithiasis, 73% had hypercalciuria. Institution of low sodium diet and adjustment of Ca intake were sufficient to normalize 24-h uCa in half of hypercalciuric patients, and for those that required thiazides, a complete response was seen in half.In conclusion, we have found a high prevalence of nephrolithiasis in adult women with OI (38% vs 9% in the general population), and high prevalence of hypercalciuria in these women (73%). Elevated 24-h uCa was seen in 40% of the cohort, but it was not associated with OI severity or underlying molecular defect, nor with Ca or vitamin D supplementation. Considering the bone health benefits of Ca and VitD adequacy, our data suggests that supplementation can be safely advised in adults with OI. Nevertheless, periodic monitoring of 24-h uCa and renal ultrasound emerge as important follow-up strategies, particularly in women with OI.

SUN-1045

A Comprehensive Study of Bone Manifestations in Adult Patients with Gaucher Disease type 1 Beatriz Oliveri*[1], Diana Gonzalez[2], Felisa Quiroga[3], Claudio Silva[3], Paula Rozenfeld[4], Camilo Lis[5], Omar Riemersma[5], Martin Kot[5]. [1]Conicet UBA Hospital de Clinicas, Argentina, [2]Mautalen Salud e Investigacion, Argentina, [3]Diagnostico Maipu, Argentina, [4]IIFP, Universidad Nacional de La Plata, CONICET, Facultad de Ciencias Exactas, Departamento de Ciencias Biológicas, Argentina, [5]Shire Argentina, Argentina

Gaucher disease (GD) is the most prevalent lysosomal storage disease and bone involvement is the most disabling condition. Purpose: Evaluate bone involvement in adult patients with GD and its relationship with parameters of bone mass, quality and remodeling

markers. Methods: observational, transversal and prospective analysis. Skeletal involvement was evaluated by X-rays (spine and lower limbs) bone densitometry (BMD) and magnetic resonance imaging (MRI) of lumbar spine (LS) and femur(F). Trabecular bone score (TBS) was calculated at LS and Bone Marrow infiltration (BMB) by MRI. Laboratory: hemogram, ferritin (FT), chitotriosidase (CHIT), ß cross laps (CTX), N terminal procollagen type1 (P1NP) and bone alkaline phosphatase (BAP). Results: 32 Type 1GD patients were included (19 females; age: 40±16 years; range 20-77). 9 patients referred history of long fractures. Patients have been receiving velaglucerase for 2.7±1.4 years, 19/32 were previously treated with imiglucerase. Ninety four % of the subjects met therapeutic goals (TG) for hematological parameters, 8 were splenectomized (SPX) and only one patient did not reach TG for visceromegalies. 19/32 patients had bone irreversible lesions (IL): avascular necrosis (n=14), bone infarction (n=16) and vertebral fractures (n=7). Bone MRI showed positive BMB in 71% of the patients in F and 22% in LS. Patients with IL had BMB higher than patients without IL (p=0.001). All splenectomized patients have IL, higher prevalence of bone marrow edema (p=0.02) and lower TBS (p=0.03) compared with those with preserved spleen. Only 18.7% of the patients had abnormal BMD without correlation with fractures (FX). TBS values were < 1350 in 53% of the patients and a tendency to lower TBS was observed in those with FX (p=0.06). Patients with P1NP in the lower quartile had lower TBS (p=0.03) and a higher prevalence of bone marrow edema compared to those in the higher quartiles. TBS correlated moderately but without reaching statistical significance with P1NP (r=0.32) and with BMB (r=- 0.44).Conclusions: Even after reaching hematological and visceral TG, a high prevalence of irreversible bone lesions was documented. Bone quality, evaluated by TBS, was more affected than BMD in fractured patients. Low bone formation active bone marrow infiltration and splenectomy might be implicated in IL.

6 years experience of a multidisciplinary approach to Osteogenesis Imperfecta in a Swiss Tertiary Health Center: bone management and quality of life Bérengère Aubry-Rozier*[1], Céline Richard[2], Sheila Unger[3], Didier Hans[4], Belinda Campos-Xavier[3], Luisa Bonafe[3], Aline Bregou[5]. [1]Rheumatology and Centre of Bone Diseases, Lausanne University Hospital, Switzerland, [2]ENT, Head and Neck Surgery Department, Lausanne University Hospital, Switzerland, [3]Service of Genetic Medicine, Lausanne University Hospital, Switzerland, [4]Centre of Bone Diseases, Lausanne University Hospital, Switzerland, [5]Orthopaedic Surgery UPCOT, Lausanne University Hospital, Switzerland

Osteogenesis imperfecta (OI) is a rare genetic connective tissue disorder with wide phenotypic and molecular heterogeneity, causing risk of fractures in early life, progressive bone deformity, tooth and hearing alterations, and poor quality of life. In rare diseases, there is a real lack of patient information and recognition. Starting in 2012, we have employed a multidisciplinary approach for OI in our tertiary hospital, the Centre Hospitalier Universitaire Vaudois (CHUV), and created the CHUV OI group. The purpose of the present study is to evaluate the efficiency of this approach after 6 years. An OI day is organized annually, and patients are invited to attend an individualized medical checkup, depending on their own situation and needs. Each patient receives a physiotherapeutic evaluation with a proposition of physical therapy or counselling in physical activity and sport. In the same day, a clinical and scientific information session about the latest updates of the disease is organized, open to families and professional caregivers. 50 patients have received a personalized medical evaluation since the beginning. 12 children (age1 to 17 years, mean 8.5) and 38 adults (age 18 to 69 years, mean 43.5) participated. All adults, except 1 without any site measurable, had at least one DXA measurement, with a mean spine T score of -2.55 (-5.6; +0.6), hip T score -1.4 (-3.3; +1.6), neck T score -1.58 (-3.5; +1.3). 34 patients had a bone texture measurement by TBS with a mean spine TBS of 1.259 (1.003; 1.501). Genetic evaluation was perform in 39 cases, and revealed mutation in 34 cases (table).The majority of patients experienced multiple fractures in childhood, and 12 had never received any bone active drug, apart from calcium/vitamin D substitution. The mean EQ5D at the beginning of the management was 0.74. It increased to 0.78 after the multidisciplinary management (p=0.11). The multidisciplinary approach, including the DXA and genetic evaluation resulted in personalized treatment adaptation/new treatment/ for all patients. The CHUV OI group multidisciplinary approach is efficient, resulting in better diagnosis, management and satisfaction of patients and their families as well as facilitating continuing education for the team members. Since 2012, the number of new patients has increased annually, with more patients benefiting of quality management including bone treatment and physical activity.

EFFECTS OF BUROSUMAB, AN ANTI-FGF23 ANTIBODY, IN PATIENTS WITH TUMOR-INDUCED OSTEOMALACIA: RESULTS FROM AN ONGOING PHASE 2 STUDY Nobuaki Ito*[1], Yasuo Imanishi[2], Yasuhiro Takeuchi[3], Yutaka Takahashi[4], Yumie Rhee[5], Chan Soo Shin[6], Hironori Kanda[7], Seiji Fukumoto[8]. [1]University of Tokyo Hospital Division of Nephrology and Endocrinology, Japan, [2]Osaka City University Graduate School of Medicine, Department of Metabolism, Endocrinology and Molecular Medicine, Japan, [3]Toranomon Hospital Endocrine Center, Japan, [4]Division of Diabetes and Endocrinology, Department of Internal Medicine, Kobe University Graduate School of Medicine, Japan, [5]Department of Internal Medicine, Yonsei University College of Medicine, Democratic People's Republic of Korea, [6]Department of Internal Medicine, Seoul National University Hospital, Democratic People's Republic of Korea, [7]Kyowa Hakko Kirin Co., Ltd., Japan, [8]Department of Molecular Endocrinology, Fujii Memorial Institute of Medical Sciences, Institute of Advanced Medical Sciences, Tokushima University, Japan

Burosumab, a fully human monoclonal antibody targeting FGF23, is under development for treatment of FGF23-related hypophosphatemia. The aim was to evaluate the efficacy and safety of burosumab on serum phosphorus (Pi) and osteomalacia in adults with tumor-induced osteomalacia (TIO) with unresectable or unidentifiable tumors.In an ongoing open-label, single-arm, Phase 2 study conducted in Japan and Korea, subjects receive subcutaneous burosumab (0.1-2.0 mg/kg) every 4 weeks, dose adjusted according to individual serum Pi concentration. Interim data were obtained for subjects who have completed ?72 weeks of therapy.Thirteen subjects with TIO (9 in Japan, 4 in Korea) were enrolled and 12 subjects completed 72 weeks. Mean age at entry was 60.5 years and all subjects had received prior oral phosphate and/or active vitamin D therapy with 2 weeks drug holiday before burosumab. At baseline (BL), serum levels of intact FGF23 ranged from 106-5150 pg/mL (median: 320) and mean (SD) BL serum Pi was 1.62 (0.49) mg/dL. Mean (SD) serum Pi substantially increased to 2.52 (0.68) mg/dL at Week (W) 16 and 2.73 (0.39) mg/dL at W72; this was accompanied by increases in TmP/GFR (BL=1.15 [0.43] mg/dL, W72=2.35 [0.56] mg/dL) and serum 1,25(OH)2D (BL=22.58 [11.87] pg/mL, W72=41.34 [8.53] pg/mL). Bone turnover markers increased at initial phase and then decreased. At BL, as assessed by bone scan, 13 subjects presented with 133 active fractures and 22 active pseudofractures. After 48 weeks of treatment, 15.0% of fractures and 17.4% of pseudofractures were healed. Bone histomorphometric findings related to osteomalacia assessed by paired bone biopsy samples also improved at W48. Mean (SD) distance walked in 6 minutes increased from 295.8 (96.0) meters at BL to 353.7 (115.8) meters at W48. Adverse events (AEs) were observed in 12 subjects. Two subjects had serious AEs, but none were drug-related. There were no meaningful changes in serum calcium or iPTH.In summary, burosumab treatment was well tolerated, increased serum Pi and 1,25(OH)2D in subjects with TIO and showed evidence of improvement of bone quality and fracture healing over 48 weeks, suggesting improvement in osteomalacia in subjects with TIO.

SUN-1048

Effectiveness of asfotase alpha in an 18-year-old prenatal benign hypophosphatasia patient with prolonged tibial pseudofracture. Minae Koga*, Yuka Kinoshita, Nobuaki Ito. Division of Nephrology and Endocrinology, The University of Tokyo, Japan

Background: Hypophosphatasia (HPP) is a rare inherited disorder caused by loss-of-function mutation in ALPL (alkaline phosphatase, liver/bone/kidney type) gene with

a reduction in TNSALP (alkaline phosphatase, tissue-nonspecific isozyme) activity. Disability in TNSALP inhibits dissociation oflocal PPi into phosphate, which subsequently cause hypocalfcification in the bone. As a result, symptoms including pathological fracture/pseudofracture, tooth loss and soft tissue calcification represent HPP. Recently, Asfotase Alpha: an enzyme replacement therapy has been introduced for the treatment of HPP. Case presentation: The patient was an 18 years old girl genetically diagnosed as HPP with compound heterozygous mutation in ALPL (c.979T>C/c.1559delT). At birth, her serum ALP was 89 IU/L and her left femur was severely bent. The gap in the length between legs increased as she grew up. At the age of 10, she was referred to our hospital and underwent epyphysiodesis in her right knee. She went through left humerus fracture at the age of twelve while exercising. At 18 years old, as she was suffering the pain with a peudofracture in her left tibia for more than one year, we finally decided to use Asfotase alpha on her. On admission, serum ALP was 74 U/L [106-322] and urine phosphoethanolamine (PEA) was 559.1 mmol/L [5.9-76.6]. X-ray revealed pseudofracture in her left tibia and bone scintigraphy accumulated in that lesion.Clinical course: Asfotase alfa was initiated at 80 mg (2 mg/Kg), three times a week. Her left tibia became painless in four and a half months, and she recovered and could do exercise in six months. Her urine PEA decreased to 89.8 nmol/L in 6 months and bone scintigraphy presented obvious improvement. Therapy related adverse events includes slight fever, fatigue and skin induration at the injection sites. However, these adverse events subsided and became tolerable.Discussion: While Asfotase alfa showed unarguable life-saving effect in perinatal and infantile HPP, the use of this drug in adult HPP or prenatal benign HPP with mild symptoms remains a matter of dispute. In a review article, there is a suggested indication of Asfotase alpha in adult HPP, for example, with pathological fracture or prolonged healing process of fracture. At least, we witnessed the invaluable effect of Asfotase Alfa in an 18 year old HPP patient who suffered prolonged tibial pain and anxiety for future fracture risk.

A Unique Case of Chronic Hypocalcemia and Ectopic Cushing Syndrome Lima Lawrence*, Susan Williams, Peng Zhang, Humberto Choi, Usman Ahmad, Vinni Makin. Cleveland Clinic, United States

BACKGROUND Mutations in the calcium-sensing receptor (CaSR) and G-proteins involved in signaling pathways that regulate PTH synthesis, secretion and action are implicated in hyper and hypocalcemia (hypoCa). These disorders may be familial or acquired due to CaSR antibodies. We present a patient with suspected, life-long asymptomatic hypoCa who developed an ACTH-secreting thymic neuroendocrine tumor causing ectopic Cushing syndrome. CLINICAL CASE A 54 year old man presented to Endocrinology for evaluation of asymptomatic hypoCa diagnosed at age 19. He had no Ca-related complications including renal stones, renal dysfunction or fractures. Exam was consistent with a normal adult male phenotype. He had no family history of Ca or endocrine abnormalities. Lab studies over 8 years revealed baseline Ca around 6.0 (8.4 – 10.2 mg/dL) with normal albumin. With a serum Ca of 6.1 mg/dL and 25 OH-Vitamin D of 28.1, his PTH was inappropriately normal 17.1 pg/mL, with elevated Phos 6.0 mg/dL and normal Mg 1.8 mg/dL. Twenty-four hour urine studies revealed hypocalciuria 14.3 mg/24 hours. DEXA scan revealed osteopenia and brain MRI noted dystrophic calcifications within the basal ganglia. He limited intake of Ca and Mg supplements due to muscle cramping and was eventually lost to follow-up. Six years later, he presented to the hospital with oral thrush, severe metabolic abnormalities including hypokalemia, metabolic alkalosis and hypoCa of 4.1 mg/dL. Extensive workup revealed a large mediastinal mass, found to be a thymic neuroendocrine tumor secreting ACTH causing ectopic Cushing syndrome. Patient underwent successful surgical resection of the mass and is receiving steroids until adrenal recovery. CONCLUSION Although we do not yet have genetic confirmation, we hypothesize that our patient has autosomal dominant hypoCa type 2 due to abnormalities in the Gα11 subunit from mutations in the GNA11 gene. CaSR signals via G-proteins including Gα11, and gain-of-function mutations in GNA11 lead to increased cell sensitivity to extracellular Ca. As he has no family history of hypoCa, it is likely that he has a de-novo mutation or variable penetrance. Additionally, GNA11 gain-of-function mutations are also implicated in the pathogenesis of uveal melanoma. As melanocytes and thymic cells have a common embryonic neural crest origin, it is important to consider the possible implications of GNA11 mutations that may underlie hypoCa and development of malignancy in later life.

SUN-1050

Long term health-related quality of life in patients with achondroplasia and hypochondroplasia Masaki Matsushita*[1], Hiroshi Kitoh[1], Kenichi Mishima[1], Naoki Ishiguro[1], Sayaka Fujiwara[2], Nobuhiko Haga[2], Taichi Kitaoka[3], Takuo Kubota[3], Keiichi Ozono[3]. [1]Department of Orthopaedic Surgery, Nagoya University Graduate School of Medicine, Japan, [2]Department of Rehabilitation Medicine, The University of Tokyo, Japan, [3]Department of Pediatrics, Osaka University Graduate School of Medicine, Japan

Achondroplasia (ACH) and hypochondroplasia (HCH) are the most common short-limbed skeletal dysplasias caused by activating mutations in the FGFR3 gene. Patients with ACH/HCH often need orthopaedic procedures for their disproportionate short stature or spinal involvement such as spinal canal stenosis and foramen magnum stenosis. Quality of life

(QoL) measures have gained recognition as essential tools for assessment of the impacts of diseases and therapeutic interventions, but only a few reports examined the QoL in individuals with ACH/HCH. In the current study, we assessed the health-related QoL (HRQoL) in adolescents and adults with ACH/HCH. Data for this cross-sectional study were collected from July 2016 to March 2018. Patients were recruited based on either a history of treatment to our institutions or registration to the patients' association of ACH in Japan. The HRQoL was assessed with the Short Form-36 as well as a disease-specific questionnaire, including presence or absence of growth hormone administration and surgical interventions for short stature or neurological impairments. The Physical Component Summary (PCS) and Mental Component Summary (MCS) from the patients were compared with those of the Japanese norm data by age groups and height groups. 201 patients with an average age of 25.6 years (10 to 67 years) were included in this study. The average MCS of the patients was similar to that of healthy subjects in all age groups. The average PCS of the patients, on the other hand, was significantly lower in all age groups than that of healthy subjects, and deteriorated with age. The physical QoL was rated poorly in the patients with a height of less than 140 cm, while favorable PCS scores were observed in the patients with a height of 140 cm or more, who are likely to attributable to currently standard medical interventions such as growth hormone administration and limb lengthening surgeries. Neurological impairments that required surgical interventions, which was increased with age, seem to be one of the factors associated with decreased PCS in elderly patients. Physical QoL appears to be impaired in adult patients with ACH/HCH especially in elderly populations. Treatment for short stature in ACH/HCH patients should be planned so that they can acquire a final height of 140 cm or more. In order to maintain the QoL of elderly patients, we should take care for neurological complications such as spinal canal stenosis in this specific disorder.

PCS and surgical intervention of spine for each age group

Age Group, y	PCS	P Value vs Norm Data	History of Spine Surgery, %
10-19 (n = 80)	44.22 ± 13.68	NA	5.0

Congenital Hypophosphatemia in Adults: Determinants of Bone Turnover Markers and Changes Following Total Parathyroidectomy Malachi Mckenna*, Rachel Crowley, Julie Grace-Martin, Patrick Twomey, Mark Kilbane. St. Vincent's University Hospital, Ireland

Introduction: Congenital hypophosphatemia (CH) results in defective mineralisation of bone that manifests as rickets in childhood; in adulthood osteomalacia prevails with residual disabling consequences. Bone turnover markers (BTMs) are a means of estimating disease severity and of guiding efficacy of therapy but published data on BTMs in CH in adults is limited. This is pertinent in view of the advent of KRN23, which is a recombinant human monoclonal antibody that binds to carboxy-terminal fibroblast growth factor 23 (FGF23) blocking its activity, as a treatment of CH in adults. We sought to review our experience of BTMs and their determinants in adults with CH.Methods: We studied 27 patients with CH, all presenting in childhood with rickets and all having reduction in the maximum renal threshold for phosphate reabsorption (TmP/GFR): 23 had X-linked hypophosphatemia (XLH) of whom 2 were hypoparathyroid post total parathyroidectomy; 2 had autosomal dominant hypophosphatemic rickets (ADHR), and 2 had unknown mutations. We measured TmP/GFR, fibroblast growth factor (FGF23), parathyroid hormone (PTH) ionised calcium, 25-hydroxyvitamin D (25OHD), 1,25-dihydroxyvitamin D (1,25D), and a panel of BTMs including: serum bone-specific alkaline phosphatase (bone ALP), osteocalcin (Oc), and total procollagen type I amino-terminal propeptide (PINP), and carboxy-terminal telopeptide of type I collagen (CTX); and urinary N-terminal telopeptides of type I collagen (uNTX).Results: TmP/GFR varied widely with the principal determinant being FGF23 and to a lesser extent ionised calcium and PTH. After excluding the two patients with XLH and total parathyroidectomy, BTMs (n=25) varied in sensitivity as follows: bone ALP (96%); CTX (72%); PINP (38%); uNTX (48%); Oc (32%). The strongest association with bone ALP was PTH. Those on phosphate supplements had significant elevation in CTX. The 2 patients with XLH and complete hypoparathyroidism had normalization of TmP/GFR and near normalisation of BTMs despite marked elevation in FGF23: 10.015 RU/ml and 4310 RU/ml.Conclusions: The clinical management of CH in adulthood continues to be challenging with most patients still manifesting with abnormalities in BTMs that indicates ongoing osteomalacia. The primacy of PTH over FGF23 in renal phosphate handling is suggested by the 2 cases with XLH and hypoparathyroidism, as suggested by our group in an earlier case report1.Reference: Crowley RK et al. J Med Case Rep 2014; 8: 84.

Osteogenesis imperfecta (OI) is a genetic disorder characterized by fragile bones and increased susceptibility to fracture. Currently, 20 genes have been identified as the causative candidate genes of OI. Since little is known about genotype-phenotype correlation in Japanese OI, we developed a novel panel of genes targeting OI for next generation sequencing (NGS) and analyzed Japanese patients . We enrolled 47 Japanese OI patients from 45 unrelated families. The panel was designed to include 15 OI candidate genes (COL1A1, COL1A2, FKBP10, SERPINH1, IFTIM5, SERPINF1, CRTAP, P3H1, PPIB, SP7, PLOD2, BMP1, CREB3L1, TMEM38B, and WNT1) and 19 genes (LRP5, LRP6, TNFRSF11A, TNFRSF11B, CBS, MTHFR, MTR, WNT4, CTNB1, WNT16, DKK1, LRP4, SOST, WLS, SFRP4, WNT5B, AXIN1, RSPO3, and TNFSF11) associated with bone fragility or Wnt signaling. After detecting mutations by NGS, we confirmed them by Sanger sequencing. We identified mutations in 36 out of 47 patients: 19 had reported mutations, 8 had mutations which were located in same codon with reported mutation but resulted in other amino acid change, and 9 had novel mutations. We also performed whole exome sequencing in 3 patients in whom we could not detect mutations by the panel, and identified 1 reported and 1 novel mutations. Twenty-seven, 10, and 1 patients had mutations in COL1A1, COL1A2, and IFITM5 gene, respectively, and all of them were heterozygous. In COL1A1, we identified 9 missense mutations including 8 glycine substitutions, 7 nonsense mutations, 6 splice site mutations, 4 frameshift mutations, and 1 intron mutation. In COL1A2, 6 missense mutations including 5 glycine substitutions, 1 splice site mutation, 1 intron mutation, and 2 duplications were detected. The IFITIM5 mutation was the reported one (c.-14C>T). We classified these COL1A1 and COL1A2 mutations into 4 groups (glycine substitutions; nonsense and frameshift mutations as non-functional allele; splice site and duplication mutations; other missense mutations) and analyzed them for genotype-phenotype correlation. As a result, patients with glycine substitution had severer symptoms than other patients, since more patients were diagnosed as type III OI in Sillence classification, and the numbers of fractures before treatment were significantly higher than in other groups. In bone mineral density (BMD), however, there was no significant difference among these groups, implicating that the bone fragility in OI could not be evaluated by BMD.

SUN-1053

Aortic Measurements in Children with Osteogenesis Imperfecta Remain Stable At Short Term Surveillance Interval Eric Rush*[1], Shelby Kutty[2], Rose Kreikemeier[3], Ling Li[2], Mary Craft[2], David Danford[2]. [1]Children's Mercy Hospital, United States, [2]University of Nebraska Medical Center, United States, [3]Children's Hospital and Medical Center, United States

Background: Osteogenesis imperfecta (OI) is a rare skeletal disorder that causes bone fragility, fractures, and short stature. There has been recent interest in the cardiopulmonary pathology of OI, however the onset and progression of cardiovascular disease is not well

known. Changes in left ventricular and aortic dimensions have been observed in young patients with OI. We report follow-up echocardiographic findings in 49 patients with OI derived from an inception cohort of 100 who had baseline echocardiography.Methods: This was a single-center prospective investigation from 2014 to 2016. Patients were phenotyped using modified Sillence criteria published in the Nosology and Classification of Genetic Skeletal disorders: 2015 Revision. Ventricular, valvular and aortic measurements were performed according to American Society of Echocardiography guidelines. Aortic measurements were made at end-diastole in parasternal long-axis view at annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta 2 cm from annulus. Z-score and percentile based comparisons were made between the baseline and follow-up measurements using paired t-test of corresponding data sets.Results: 49 patients were evaluated in this study, with a mean age of 12.1 years. 22 patients were male and 27 female. 26 patients had Type I OI, 16 had Type IV OI, and 7 had Type III OI. The mean time between studies was 2.3 years with range between 1.8 and 3.2 years. Raw aortic dimensions at each measurement site increased commensurate with somatic growth. Z-score comparisons did not show statistically significant increase in aortic dimensions at the annulus (p=0.32), the sinus of Valsalva (p=0.11), or the proximal ascending aorta (p=0.92). There was statistically significant increase in aortic diameter at the sinotubular junction (p=0.047). Analysis of patients by OI type also revealed no statistically significant increases at any aortic location, with p value between 0.12 and 0.98.Conclusion: This study confirms higher incidence of mild aortic dilation in patients with OI. There was no significant progression of aortic size over the short time frame of the study, indicating stable or slowly progressive changes. An ideal time interval for echocardiographic surveillance in the asymptomatic OI patient is not established based on these findings.

SUN-1054

Twelve Chinese Patients with Primary Hypertrophic Osteoarthropathy: Mutation Identification and Clinical Features Yang Xu*, Zhen-Lin Zhang. Department of Osteoporosis and Bone Diseases, Metabolic Bone Disease and Genetics Research Unit, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, China

Objective: Primary hypertrophic osteoarthropathy (PHO) is a rare inherited disease characterized by clubbing fingers, periostosis andpachydermia. Mutations in HPGDcause autosomal recessive 1 (PHOAR1) and mutations in SLCO2A1cause autosomal recessive 2 (PHOAR2). This study analyzed and compared pathogenic genes and clinical manifestations of two types of PHO to improve clinical knowledge.Methods: Clinical data of 12 patients with PHO were collected and radiographsof hands, the right tibias and fibulas, and the right knees were taken. Sanger sequencing was used to identify the pathogenic genes.Results: 6 patients were caused by SLCO2A1mutations and 3 were caused by HPGDmutations, and no mutations inSCLO2A1or HPGDwere detected in the remaining 3. Two novel mutations were identified in SLCO2A1(c.1375T>C, p.Cys459Arg; c.1657A>G, p.Ile533Val), and one novel mutation was identified in HPGD(c.1A>T, p.Met1Leu). The mutation, c.310_311delCT (p.Leu104AlafsX3) in HPGDmay be a common mutation, for 3 patients with PHOAR1 carried the same one. The 6 patients with PHOAR2 were all male, and the onset was during puberty. 2 of them had swelling knees and ankles which caused limited movement, and they also had progressive pachydermiain faces and heads and severe clubbing fingers which were accompanied with anemia, diarrhea, gastrointestinal ulcers. However, the other 4 only had clubbing fingers, and other symptoms including pachydermiaand swelling joints were not obvious. 3 patients with PHOAR1 had clubbing fingers since childhood and they also had swelling knees and ankles, while the pachydermia in face was not significant. 1 of them was female and had pain of ankles with menstrual cycle. 3 patients with undetected mutations were all male and 2 of them were from one family. The onset was from puberty, and pachydermia in faces and heads was the earliest symptom, followed by clubbing fingers and swelling knees and ankles. All of them had severe gastrointestinal ulcers and anemia. Radiographs of both patients with PHOAR1 and PHOAR2 showed periostosis in long bones, and patients with PHOAR1 also had dissolution of the extremities.Conclusion: PHO is a disease with genetic and clinical heterogeneity, clinical manifestations contribute to clinical classification, and molecular diagnosis ultimately depends on genetic detection. Further study in cases with undetected mutations may be significant to determine the exact mechanism of PHO and figure out related pathways.

SUN-1055

Loss of Gassignaling induces osteoblast differentiation in soft tissues of POH patients and during normal cranial bone development by activating Hedgehog signal Yingzi Yang*[1], Ruoshi Xu[2], Xuedong Zhou[3], Eileen Shore[4], Fred Kaplan[5]. [1]Harvard University, United States, [2]Harvard School of Dental Medicine and West China Hospital of Stomatology, United States, [3]West China Hospital of Stomatology, China, [4]University of Pennsylvania School of Medicine, United Kingdom, [5]University of Pennsylvania School of Medicine, United States

How osteoblast cells are induced during bone development is a central question for understanding the organizational principles underpinning a functional skeletal system. Abnormal osteoblast differentiation leads to a broad range of devastating diseases such as craniosynostosis (premature suture fusion), heterotopic ossification (HO) and osteoporosis. Molecular analyses of skeletal genetic diseases with abnormal osteoblast differentiation have provided important insights in the regulation of osteoblast induction. Progressive osseous heteroplasia (POH) (OMIM#166350) and Albright's hereditary osteodystrophy (AHO, OMIM 103580) are caused by loss function mutations in the GNAS gene, which encodes the stimulatory alpha subunit, Gαs, of heterotrimeric G protein that transduces signals from G protein coupled receptors (GPCRs). POH and AHO are characterized by progressive extra-skeletal bone formation through an intramembranous process. We have demonstrated that Gαs restricts bone formation to the skeleton by inhibiting Hedgehog (Hh) signaling in mesenchymal progenitor cells. More recently, we have investigated intramembranous ossification during cranial bone development in mouse models of POH. We find here while Hh ligand-dependent Hh signaling is essential for endochondral ossification, it is dispensable for intramembranous ossification, where Gαs regulates Hh signaling in a ligand-independent manner. We further show that Gαs controls intramembranous ossification during cranial bone development by regulating both Hh and Wnt signaling. In addition, sustained Gαs activation in the developing cranial bone leads to reduced ossification, but increased cartilage presence due to reduced cartilage dissolution, not cell fate switch. Small molecule inhibitors of Hh signaling can effectively ameliorate cranial bone phenotypes in mice caused by loss of Gnas function mutations. Our work shows that studies of genetic diseases provide invaluable insights in normal bone development and understanding both leads to better diagnosis and therapeutic treatment of bone diseases.

Hypoparathyroidism, real life experience in 55 patients Maria Belen Zanchetta*[1], Damian Robbiani[1], Fernando Silveira[2], Jose Ruben Zanchetta[1]. [1]IDIM, Universidad del Salvador, Argentina, [2]IDIM, Argentina

Hypoparathyroidism (HPT) is a rare disorder characterized by hypocalcemia and absent or deficient PTH. It is associated with an increased risk of various complications, but only few data is available on the natural history and correct management of this disease.Aim: Describe clinical characterists, treatment and complications in a group of patients with hypoparathyroidism followed in our Bone Clinic under routine clinical care. Secondary, describe how many patients reached guidelines recommendations for rhPTH(1-84) treatment (Brandi ML. JCEM. 2016).Materials and Methods:Patients with a diagnosis of HPT of ≥6 months seen between June 2013 and December 2017 were eligible for inclusion. Demographics, HPT etiology, HPT management, fractures, DXA values, biochemical values, including renal function; renal and cardiovascular events; soft tissue calcification and hospitalizations were collected via electronic data capture.Results:55 HPT patients were included; mean age was 49.1 ± 16.3 years, 46/55 were women. Treatment regimens were determined by the patients' physician, per usual clinical practice, and all were receiving calcium supplementation and calcitriol. Regarding etiology 48/55 (87.2%) was post-surgical, 3/55 DiGeorge Syndrome, one autoimmune, one pseudo-hypoparathyroidism and two unknown. Biochemical and DXA values at diagnosis are shown in table 1. 9/55 (16.3%) had history of hypocalcemia requiring hospitalization. 3/55 had fracture history (wrist, hip and tibia, last two fractures in patients with DiGeorge Syndrome). 3/55 has history of seizures. Only 14/55 (25,4%) had renal ultrasound done and 3 of them (21, 4%) had kidney stones. 65 % (36/55) had 24-hour urine calcium excretion measured and half of them had hypercalciuria confirmed. Only 4/55 patients had central nervous system imaging performed, and two of them had basal ganglia calcification confirmed. Finally, 19/55 met criteria to rhPTH (1-84) treatment according to the guideline; most of them (13) because their oral calcium requirements exceed 2.5 g of calcium.Conclusion. Although these patients were followed by specialists, clinical management and monitoring was heterogeneous and probably insufficient to assess all the potential complications of this chronic disease. rhPTH (1-84) is not yet available in Argentina, but 34,5% of our patients met criteria for this new treatment. Being awared of this situation is the first step to improve our medical management of HPT in the future.

Novel Mutation in the P4HB Gene in Chinese Patient of Osteogenesis Imperfecta with Cole-Carpenter Syndrome Hao Zhang*, Yangjia Cao, Zhenlin Zhang. Shanghai Jiao Tong University Affiliated Sixth People's Hospital, China

Purpose Cole-Carpenter syndrome (CCS) is commonly regarded as a rare osteogenesis imperfecta (OI) characterized by bone fragility, ocular proptosis, craniosynostosis, hydrocephalus, and distinctive facial features. CCS can be caused by homozygous mutations in CRTAP gene and heterozygous mutation in P4HB gene. To date, only one heterozygous missense mutation in exon 9 of P4HB (c.1178A>G [p.Tyr393Cys]) and one heterozygous deletion variation in exons 5 to 8 of the P4HB gene have been found to cause CCS. We sought to characterize the phenotypes and to identify the P4HB gene mutation associated with Chinese patient with CCS.Methods Using whole-exome sequencing in 1 CCS patient, we identified 1 novel heterozygous missense mutation of P4HB gene. The patient was a 54-year-old female; she had recurrent limb fractures from 2.5 years old to 13 years old. At the age of 36, she suffered a fracture of the left elbow due to sprain. At age 54, she suffered fractures of her left calf and left knee due to a fall and a sprain. The patient showed severe scoliosis and both legs were short and with bent deformity. She was unable to walk, and used two benches in place of wheelchair. She had ocular proptosis and protuberant forehead. But X-ray of the skull showed normal.Results We identified 1 novel heterozygous missense mutation of P4HB (c.1198T>C, [p.Cys400Arg]). The protein structure shows that the site is located in the center of the reaction of the gene encoding protein disulfide isomerase.Conclusions We discovered 1 novel heterozygous missense mutation of P4HB gene of Chinese CCS patient. Our study extended both the phenotypic and the genotypic spectrum of the CCS patient with P4HB mutation.

Bone Marrow Transplantation as a Therapy for Autosomal Dominant Osteopetrosis Type II in Mice Imranul Alam*, Erik Imel, Rita Gerard-O'Riley, Dena Acton, Dana Oakes, Marta Alvarez, Melissa Kacena, Michael Econs. Indiana University School of Medicine, United States

Autosomal dominant osteopetrosis type II (ADO2) is a heritable osteosclerotic bone disorder caused by missense mutations in the chloride channel 7 (CLCN7) gene. Clinical features of ADO2 include fractures, osteomyelitis, vision loss, and in severe cases, bone marrow failure. Currently, there is no effective therapy for ADO2. Theoretically, bone marrow transplantation (BMT) could be used to treat ADO2, although mortality from the procedure is high. Two of our severely affected ADO2 patients (females ages 16 and 41 years) recently under-went BMT and neither engrafted (one died shortly after BMT and the second died shortly after a second BMT). Recently, we created an ADO2 knock-in mouse model on the 129S1 background, which phenocopies human ADO2. To test whether BMT could restore osteoclast function and rescue the bone defect in ADO2 mice we transplanted bone marrow cells from 6-week-old male WT or ADO2 donor mice into 9-month-old (a model of the adult patient) recipient female ADO2 mice through tail vein injections after irradiation (1100 cGy split dose). Donor chimerism was determined using Y chromosome contribution. ADO2 recipient mice had more than 80% engraftment up to 6 months post-transplantation. DXA results demonstrated that compared to the ADO2 mice that received bone marrow from ADO2 mice (control group), ADO2 recipient mice with bone marrow from WT mice (experimental group) displayed greater % decreases of aBMD and BMC at 2 months post-transplantation (Figure 1). At 4 months post-transplantation, both control and experimental groups regained bone mass closer to the baseline, although experimental mice gained significantly lesser bone mass compared to the control mice. However, at 6-month post-transplantation percent bone mass gained from baseline was similar in both control and experimental groups (Figure 1). MicroCT results demonstrated that trabecular BV/TV at the distal femur decreased significantly in both groups at 2 months post-transplantation but returned to the baseline level by 4 months (Figure 1). In addition, serum CTX and CTX/TRAP ratio were increased in the experimental mice at 2 months post-transplantation and then returned to baseline levels afterwards. Our results suggest that BMT does not provide long-term beneficial effect in older

ADO2 mice; however, the outcome in younger mice remains to be determined. Studies in younger mice should be performed before attempting BMT in ADO2 patients.

Cystinosin Deficiency Primarily Affects Bone Remodeling In Cystinosis Giulia Battafarano*[1], Michela Rossi[1], Laura Rita Rega[2], Gianna Di Giovamberardino[3], Anna Pastore[4], Matteo D'Agostini[5], Ottavia Porzio[5], Francesco Emma[2], Anna Taranta[2], Andrea Del Fattore[1]. [1]Bone Physiopathology Group, Multifactorial Disease and Complex Phenotype Research Area, Bambino Gesù Children's Hospital, IRCCS, Italy, [2]Department of Nephrology and Urology, Division of Nephrology, Bambino Gesù Children's Hospital,IRCCS, Italy, [3]Laboratory of Metabolomics and Proteomics, Bambino Gesù Children's Hospital, IRCCS, Italy, [4]Laboratory of Metabolomics and Proteomics, Bambino Gesù Children's Hospital, IRCCS, Italy, [5]Clinical Laboratory, Bambino Gesù Children's Hospital, IRCCS, Italy

Purpose:Cystinosis is a rare disease caused by loss-of-function mutation of CTNS gene, encoding for cystinosin lysosomal transporter. It is characterized by cystine accumulation into the lysosomes leading to crystals formation and cellular damage. Cystinotic patients develop nephropathic Fanconi syndrome, bone deformity and fragility, osteomalacia and rickets. Skeletal alterations in cystinotic patients have been considered until now as a consequence of renal impairment. To understand if cystinosin deficiency primarily affects the skeleton, we studied ctns -/- (KO) male mice that develop skeletal alterations without Fanconi syndrome up to 9 months of age.Methods:The nephropathy was excluded by histological evaluation of kidney and biochemical analysis. Intra-lysosomal cystine accumulation in KO tissues was evaluated by HPLC. In vivo bone phenotype was studied by μCT, histomorphometry and bone turnover markers analysis. In vitro experiments were performed to identify alterations of osteoblasts and osteoclasts isolated from WT and KO animals.Results:HPLC analysis revealed that KO mice accumulates intra-lysosomal cystine in bones reaching higher levels than those observed in kidney. μCT analysis of 1-month-old KO femurs displayed a reduction of trabecular bone volume and bone mineral density (BMD mgHA/cm3, WT: 188.6±4.13; KO: 162.8±4.11. p<0.005) with a decrease of trabecular number and thickness and increased trabecular separation. Histomorphometric analysis revealed a reduction of osteoclasts (Oc.S/BS %, WT: 22.45±6.62; KO: 12.91±4.85. p<0.05) and osteoblast parameters (Ob.S/BS %, WT: 20.87±3.26; KO: 12.08±6.69. p<0.05) in KO animals compared to WT. These alterations were confirmed by reduced TRAcP and P1NP

levels in KO sera. In vitro analysis revealed intra-lysosomal cystine accumulation in KO osteoclasts and osteoblasts with a perinuclear engulfment of lysosomes. Cultures from bone marrow of ctns-/- mice displayed reduced number of osteoclasts (Osteoclast number %, WT: 100.70±4.59; KO: 75.34±26.44. p<0.05). Moreover a defect of differentiation (ALP+ cells %, WT: 99.67±0.58; KO: 59.63±20.65. p<0.05) with reduced runx2, sp7, alp and col1a2 expression was observed in KO osteoblasts compared to WT cells.Conclusion:All together these data reveal that the absence of cystinosin primarily affects bone cell differentiation leading to osteopenic phenotype in ctns-/- mice.

Enhanced activation of Rac1/Cdc42 and MITF as a possible mechanism of augmented osteoclastogenesis in autosomal dominant osteopetrosis type II with G215R mutation of chloride channel 7 gene Gun-Woo Kim*[1], Youn-Kwan Jung[2], Ji-Ae Jang[2], Min-Su Han[2], Seungwoo Han[3]. [1]Laboratory for arthritis and bone biology, Fatima Research Institute, Departmernt of Internal medicine, Daegu Fatima Hospital, Republic of Korea, [2]Laboratory for arthritis and bone biology, Fatima Research Institute, Daegu Fatima Hospital, Republic of Korea, [3]Department of Internal medicine, Kyungpook National University Hospital, Republic of Korea

The autosomal dominant osteopetrosis type II (ADOII) caused by the mutation of chloride channel 7 (ClC-7) gene is the most common form of adult-onset osteopetrosis. Despite of dysfunctional bone resorption, an augmented osteoclast differentiation was reported recently in ADOII patients. DNA sequencing analysis of patient's ClC-7 gene identified a known heterozygous ADO II mutation, c.643G>A in exon 7, encoding p.Gly215Arg. In vitro osteoclast differentiation from ADOII patient's peripheral blood mononuclear cells (PB-MCs) increased compared to control despite of their dysfunctional bone resorbing capacity. Osteoclasts from ADOII patient's PBMCs and ClC-7 knockdown bone marrow monocytes (BMMs) showed an enhanced Ser-71 phosphorylation of Rac1/Cdc42 and increase of the microphthalmia-associated transcription factor (MITF) and receptor activator of nuclear factor κB (RANK) that can be responsible for the enhanced osteoclast differentiation.

Antioxidant and anti-inflammatories dampen the PSACH chondrocyte pathology Karen Posey*, Jacqueline Hecht. McGovern Medical School at UTHealth, United States

Karen Posey1, Francoise Coustry1, Alka Veerisetty1, Mohammad Housain1 and Jacqueline T. Hecht1,21McGovern Medical School and 2School of Dentistry at UTHealth Mutations in the cartilage oligomeric matrix protein (COMP) gene cause pseudoachondroplasia (PSACH), a severe dwarfing condition associated with limb shortening, joint laxity and early onset osteoarthritis. Using our MT-COMP mouse that recapitulates PSACH, we defined the underlying mechanism resulting from massive mutant COMP chondrocyte retention, wherein intense cellular stress is activated through CHOP arm of the UPR culminating in an unrelenting inflammatory and oxidative stress environment, and ultimately chondrocyte death. By eliminating CHOP, there was a reduction in mutant COMP retention, alleviation of the devastating cellular inflammation and oxidative stresses and reduction in chondrocyte death. Based on these observations, we tested anti-inflammatories (aspirin and ibuprofen) and antioxidants (resveratrol, grape seed extract (GSE), turmeric, CoQ10, vitamin E) therapeutics to determine whether they reduced the chondrocyte stress cycle. Aspirin, ibuprofen, resveratrol, GSE, or vitamin E treatments decreased mutant COMP intracellular retention and chondrocyte death, and restored chondrocyte proliferation. Inflammatory markers associated with cartilage degradation and eosinophils were undetectable in treated mice. While, turmeric and CoQ10 reduced retention and chondrocyte death, they did not reduce all inflammation markers. We have recently identified a treatment window wherein aspirin and resveratrol treatments can be started as late at 2 wks of age in MT-COMP mice and still reduce the chondrocyte stress burden. Given that human skeletal growth spans 16-20 years and murine skeletal growth is 8-10 weeks, one week in mice growth approximates 2 years in human growth. This suggests that PSACH aspirin or resveratrol therapy would be most beneficial if started by 4 years of age. These are important therapeutic approaches that mitigate both the chondrocyte and long bone pathology in our PSACH mouse model and will be tested in human clinical trials.

SUN-1095

Upregulated Transforming Growth Factor Beta (TGFβ) Signaling in Osteoblast-like cells from Osteogenesis Imperfecta Patients Nathalie Bravenboer*, Elise Riesebos, Huib Van Essen, Marelise Eekhoff, Gerard Pals, Dimitra Micha. VU University Medical Center, Netherlands

Osteogenesis Imperfecta (OI) is primarily characterized by bone fragility as a result of mutations in genes responsible for collagen regulation. Recently excessive TGFβ signaling

has been demonstrated to underlie the mechanism of OI in Crtap−/− and Col1a2tm1.1Mcbr mouse models of the disease. This has introduced fresolimumab, an inactivating antibody against TGFβ, to clinical trials for OI. However, the effect of TGFβ in OI patient osteoblast cells has not yet been investigated. The objective of this study was to examine TGFβ signaling in trandifferentiated osteoblasts of OI patients. For this primary dermal fibroblasts from 2 patients with a CRTAP mutation, 2 patients with a COL1A2 mutation and 2 healthy donors were subjected to osteogenic transdifferentiation with human platelet lysate. The transdifferentiated osteoblasts were then stimulated with TGFβ1 and phosphorylated SMAD3 expression was analysed by western blotting. We also used immunohistochemistry to stain for phosphorylated SMAD3 in bone biopsies of OI patients.We observed increased expression of phosphorylated SMAD3 in transdifferentiated osteoblasts of OI patients with pathogenic CRTAP and COL1A2 mutations compared to the healthy controls following TGFβ stimulation. This difference was found to be less in the primary fibroblasts. Immunohistochemistry confirmed positive nuclear staining of phosphorylated SMAD3 in trabecular bone cells of OI patients.This study shows excessive TGFβ signaling in OI patient-derived transdifferentiated osteoblasts which is in line with the findings in the respective OI mouse models. This was also reflected in the bone tissue of OI patients. TGFβ signaling appears to be crucial in recessive and dominant OI pathogenesis; the outcome of the current clinical trials will determine its therapeutic potential.

SUN-1096

Igf1 Derived from Osteoclasts in Paget's Disease Increases Bone Formation via Signaling through EphrinB2/EphB4 Kazuaki Miyagawa*[1], Yasuhisa Ohata[1], Jolene J. Windle[2], G. David Roodman[1,3], Noriyoshi Kurihara[1]. [1]Medicine/Hematology-Oncology; Indiana University, United States, [2]Human and Molecular Genetics, Virginia Commonwealth University, United States, [3]Roudebush VA Medical Center, United States

We reported that Igf1 derived from osteoclasts (OCLs) increased EphrinB2 on OCLs, which bound EphB4 on osteoblasts (OBs) to enhance bone formation. Further, OCLs expressing measles virus nucleocapsid protein (MVNP), a model of Paget's Disease (PD), expressed higher levels of Igf1 than normal OCLs. However, the role of OCL-derived Igf1 in PD in vivo is unclear. Therefore, we conditionally deleted Igf1 in OCLs expressing MVNP by crossing Trap-MVNP (MV) mice to Trap-Cre (TC) and Igf1flox/flox mice to generate mice of the following four genotypes: MV+/TC+/Igf1flox/flox (MV/Igf1-), MV+/TC-/Igf-1flox/flox (MV/Igf1+), TC(+)/Igf1flox/flox (Igf1-) mice ,TC(-)-Igf1flox/flox (Igf1+ = WT). At 6 months of age, body weight and serum Igf1 and IGFBP3 levels were similar among the 4 genotypes. µqCT analysis of 12 month old male mice showed that BV/TV of the distal femur in MV/Igf1- mice was significantly decreased by 55% compared to MV/Igf1+ mice (p<0.05). BV/TV of Igf1- mice was similar to MV/Igf1- mice. OCL number and surface, and OB number and surface in MV/Igf1- and Igf1- mice were decreased by 40% compared to MV/Igf1+ and Igf1+ mice (p<0.01) respectively. We then measured Igf1 levels in media conditioned (CM) for 48 hours by purified OCLs from the 4 genotypes. Igf1 levels in MV/Igf1+ OCL CM were 250±23 pg/ml, while Igf1 in CM from the other genotypes were < 50 pg/ml (p<0.01). Igf1-receptor expression on OCLs was similar in all genotypes. OCL formation in RANKL treated bone marrow cultures of MV/Igf1- mice was decreased by 50% vs MVNP/Igf1+ mice, and the OCLs in MV/Igf1- marrow cultures were smaller and had ~ 20 nuclei/OCL compared to 50 nuclei/OCL in MV/Igf1+ cultures. Further, bone resorption capacity/OCL on bone slices in MV/Igf1- and Igf1- cultures was significantly decreased by 60% compared with MV/Igf+ and Igf1+ cultures respectively. As expected, EphrinB2 levels on purified OCLs from MV/Igf1- and Igf1- mice were much lower compared to MV/Igf1+ and Igf1+ mice. MV/Igf1- and Igf1- OCLs also expressed lower NFATc-1 and cathepsinK levels vs MV/Igf1+ and Igf1+ OCLs. Finally, osterix, EphB4 and Col-1A levels in OBs from MV/Igf1- and Igf1- mice were also significantly decreased compared to MV/Igf1+ and Igf1+ OBs, respectively (p<0.05). These results suggest that Igf1 derived from PD OCLs contributes to the increased bone formation in PD by enhancing bidirectional signaling through EphrinB2/EphB4 in vivo.

Kyphosis, moderate restrictive lung disease and sleep apnea of X-linked hypophosphatemia: a case study. Gregory Newman*, Carolyn Macica. Frank H. Netter School of Medicine Quinnipiac University, United States

X-linked hypophosphatemia (XLH) is the most common heritable renal phosphate-wasting disorder. Adults with XLH exhibit degenerative osteoarthritis and ossification of fibrocartilaginous tendons/ligaments that are not improved by standard therapy. Significant thoracic skeletal deformity can occur and may include kyphosis, scoliosis, ossification of spinal ligaments, vertebral body fusion by syndesmophytes and limited range of motion of costovertebral joints. We previously reported a case series of mild restrictive lung disease in 3 patients with XLH with radiographic evidence of kyphosis (ASBMR 2017). Here, we present an XLH case study of a 64 yo female with ossification of the cervical and thoracic spinal ligaments. The patient displayed severe kyphosis of the thoracic spine without scoliosis, had minimal expansion of the chest wall on inspiration and had chronic bibasilar atelectasis. Kyphosis and scoliosis were evaluated by Cobb angle; kyphosis > 40° and scoliosis ≥ 10° were considered abnormal. Spirometry measurements included forced

vital capacity (FVC), forced expiratory volume in 1 second (FEV1), the ratio of forced expiratory volume in 1 second to forced vital capacity (FEV1/FVC), total lung capacity (TLC), reserve volume (RV), functional residual capacity (FRC), and diffusing capacity (DLCO). A six-minute walk test (6MWT) was also used as a performance-based measure of functional exercise capacity. PFT data was read as restrictive lung disease, with decreased TLC, RV, FRC and DLCO. Oxygen desaturation was assessed by pulse oximetry and declined from 98% to 90% following 6MWT. Split-night polysomnography was also performed to evaluate suspected sleep disordered breathing. The patient was found to have mild obstructive sleep apnea and a score of 9 on the Epworth Sleepiness Scale, indicative of higher-normal range of sleep propensity in daily life. Use of continuous positive airway pressure (CPAP) therapy, indicated for obstructive sleep apnea, resulted in an increase in total sleep time of 37.5% to 100%. Bilevel CPAP with humidification was implemented with dual settings to facilitate increased inspiration and expiration and to reduce airway resistance and improve tolerance to CPAP therapy. We conclude that kyphosis secondary to spinal fusion and enthesopathy in XLH can give rise to restrictive lung disease and obstructive sleep apnea and that this patient population may benefit from CPAP therapy as an intervention.

SUN-1098

A Mutation in Cx43(R239Q) Causes Craniometaphyseal Dysplasia (CMD)-like Phenotype in Knock-in Mice Iichiro Okabe*, Jitendra Kanaujiya, Nelson Monteiro, Ernst Reichenberger, I-Ping Chen. University of Connecticut Health, United States

Craniometaphyseal dysplasia (CMD) is a rare craniotubular disorder characterized by hyperostosis of craniofacial bones and flaring metaphyses in long bones. A missense mutation (R239Q) in Connexin43 (Cx43), a major gap junction protein in bone cells, causes the autosomal recessive (AR) form of CMD. CMD pathogenesis remains largely unknown and treatment is limited to repetitive surgeries. We have generated knock-in (KI) mice expressing mutant Cx43(R239Q) protein by CRISPR/Cas and characterized their bone phenotype. Cx43KI/KI mice appear normal in size and are fertile. Skulls, femurs and mandibles from 3-month-old male and female Cx43+/+ and Cx43KI/KI mice (n=8/group) were analyzed by radiographs, microCT and histomorphometry. Cx43KI/KI mice showed CMD-like features, such as hyperostotic calvariae and cranial base; increased bone volume of jawbones; narrowing of cranial neural foramina; club-shaped femurs with increased diaphyseal cortical thickness. Although serum levels for calcium, phosphate, N-terminal procollagen type I (P1NP) propeptide and type I collagen cross-linked C-terminal telopeptide (CTX) were normal, Cx43KI/KI mice had increased osteoclast-like cells (shown by increased TRAP staining) on endosteal surfaces, active bone formation (shown by mineralization labeling) on periosteal surfaces and decreased density of osteocytes with reduced apoptosis in cortical bone of femurs. To study the Cx43 mutational effects in vitro, we derived mouse calvarial osteoblast (COB) and bone marrow macrophage (BMMs) cultures. Total Cx43 mRNA and protein levels were comparable between Cx43+/+ and Cx43KI/KI cultures shown by qPCR and immunoblotting. Increased proliferation and decreased apoptosis were found in Cx43KI/KI COB cultures by EdU and TUNEL assays, respectively. Cx43KI/KI BMM cultures showed delayed formation of TRAP+ multinucleated osteoclasts (nuclei ≥3) and significantly decreased resorption pits on bone chips. We previously published a CMD mouse model (AnkKI/KI) with a ANK Phe377del mutation for the autosomal dominant form of CMD. In contrast to AnkKI/KI mice which die at age of 6 months, Cx43KI/KI have normal life span and do not develop joint stiffness. In summary, Cx43KI/KI mice phenocopy human AR CMD. CMD-mutant Cx43 acts on osteoblasts, osteoclasts and osteocytes leading to disturbed bone remodeling. Studying both AnkKI/KI and Cx43KI/KI mouse models will help our understanding of the pathogenesis of CMD.

SUN-1099

Macrophages and TNFα Regulate Fibroproliferation and Muscle Degradation Preceding Heterotopic Ossification in an ALK2R206H Model of Fibrodysplasia Ossificans Progressiva Chuanmin Cheng*[1], Michael R Convente[2], Nicole Fleming[1], Yueqi Zhang[1], Amisha Kalra[1], Cody M Elkins[1], Eileen M Shore[2], Daniel S Perrien[1]. [1]Vanderbilt University Medical Center, United States, [2]University of Pennsylvania, United States

Fibrodysplasia Ossificans Progressiva (FOP) is a rare and currently untreatable disease characterized by heterotopic ossification (HO) in skeletal muscle. FOP is caused by mutations in ACVR1, encoding the Type 1 BMP Receptor ALK2, but little is known about the mechanisms that redirect muscle repair toward ectopic bone formation. FOP "flares" begin as hyperinflammatory, fibroproliferative swellings that transition to endochondral bone. Depletion of phagocytic macrophages (MΦ) from mast cell deficient FOP mice substantially reduces HO, but how these cells influence FOP are unknown. We hypothesized that inflammatory MΦ (iMΦ) cytokines are key regulators of muscle turnover and fibroblasts in FOP. Following muscle injury, flow cytometry confirmed elevation of intramuscular CD206-iMΦs, but not CD206+ anti-inflammatory MΦs (aMΦs) in ALK2R206H_FlEX (FOP) mice vs wildtype (WT) at 2 and 4 days post-injury (pi) (p<0.05). Significantly more muscle degradation occurred in FOP vs WT muscles, peaking at d4 pi (p<0.01). Fsp1+ fibroblasts were significantly greater (p<0.01) in FOP than WT mice at d7 and d14. IHC revealed iMΦs (F4/80+;CD206- or pStat1+) primarily localized to degrading muscle fibers at all timepoints.

aMΦs (F4/80+;CD206+ or Stat6+) were only in areas of fibroproliferation at days 4, 7, and 14. The expression of polarization markers in WT and FOP MΦs was measured by qRT-PCR. iMΦ markers Nos2, Tnfa, and Inhba were increased by LPS and IFNγ, while aMΦ markers Ym1 and Arg1 were increased by IL-4 in both genotypes, however, levels were not significantly different between WT and FOP cells. Treatment with BMP4, BMP6, or ActA did not influence MΦ polarization in either genotype. Since iMΦs are a major source of TNFα, its role in fibroproliferation and HO was tested in FOP mice. Injection of rTNFα into injured muscles of FOP mice significantly increased the volume of HO vs Veh injection (μCT; p<0.01). In contrast, inhibiting TNFα with 2mg/kg or 4mg/kg anti-TNFα (etanercept) twice-weekly from injury until sacrifice did not significantly alter HO volume. Interestingly, etanercept treatment significantly increased fibroproliferation in FOP muscles (p<0.05). These data indicate that the role of MΦs in FOP may be dependent on the abundance and balance of polarized MΦs rather than altered gene expression within each phenotype. Additionally, TNFα may have a dual role to promote HO but suppress fibroproliferation, likely via different, time-dependent mechanisms.

Cell-Autonomous And Systemic Alterations In Gorham-Stout Disease Michela Rossi*[1], Giulia Battafarano[1], Eda Mariani[1], Paola Sabrina Buonuomo[2], Ippolita Rana[3], Alessandro Jenkner[4], Rita De Vito[5], Simone Pelle[6], Matteo D'Agostini[7], Andrea Bartuli[2], Andrea Del Fattore[1]. [1]Bone Physiopathology Group Multifactorial Disease and Complex Phenotype Research Area Bambino Gesù Children's Hospital, IRCCS, Italy, [2]Rare Disease and Medical Genetic Unit, Bambino Gesù Children's Hospital, IRCCS, Italy, [3]UO Rare Diseases, Bambino Gesù Children's Hospital, IRCCS, Italy, [4]Division of Immunology and Infectious Diseases Department of Pediatrics, Bambino Gesù Children's Hospital, IRCCS, Italy, [5]Histopathology Unit, Bambino Gesù Children's Hospital, IRCCS, Italy, [6]Casa di Cura Villa Aurora-San Feliciano, Italy, [7]Clinical Laboratory, Bambino Gesù Children's Hospital, IRCCS, Italy

PurposeGorham-Stout disease (GSD) is a very rare disorder characterized by progressive osteolysis and angiomatous proliferation. The most common symptoms are swelling, fractures, pain and impairment of affected regions. The etiology of GSD is unknown and diagnosis is performed by exclusion criteria. Unfortunately, there are no set therapeutic approaches for patients. We aim to investigate the bone phenotype and to identify molecular and cellular defects in GSD patients.MethodsBone biopsy analysis was performed. Bone turnover markers were measured by ELISA. In vitro osteoclast and osteoblast cultures were performed to evaluate alterations of differentiation, morphology, and activity. Gene expression was evaluated by transcriptomic and Real-Time RT-PCR analysis.ResultsBone biopsy analysis revealed, in patients, fibrous tissue, increase of osteoclasts number, vessels and osteocyte lacunae area. In patient sera high levels of ICTP, VEGF-A, IL-6 and Sclerostin were revealed. Patient's osteoclast precursors showed a 2-fold increased ability to differentiate into osteoclasts, with more nuclei per cell. About 75% of GSD osteoclasts displayed a more motile phenotype. A 2-fold increased ability to resorb bone was observed in GSD osteoclast cultures compared to control. Transcriptome analysis revealed an enrichment of PI3 kinase, EGF receptor and beta-arrestin pathways. To investigate the involvement of systemic factors in GSD, Healthy Donor (HD)-PBMC were treated with GSD sera and showed increased osteoclastogenesis compared to control sera-treated cells (Osteoclast number/field, HD: 17.24±2.38; GSD: 26.27±2.43. p< 0.02). Bone Marrow Mesenchymal Stem Cells isolated from a patient revealed a defect of osteogenic differentiation, as shown by reduced ALP activity and expression compared to HD-MSC. Affected osteoblasts displayed reduced ability to form mineralized nodules. Transcriptome analysis revealed in GSD osteoblasts a modulation of pathways involved in bone morphogenesis and ossification and an increase of osteoclastogenic potential. Moreover, mature HD-osteoblasts treated with GSD sera showed decreased expression of ALP and COL1a2 and increased RANKL/OPG ratio.Conclusion-These results suggest that in GSD the bone remodeling defect could be related to bone cell autonomous defects and to involvement of systemic factors. Understanding the mechanisms leading to the progressive osteolysis could open the way for the identification of new therapeutic approaches.

SUN-1101

Osteoclast formation is inhibited by Activin-A in healthy controls and fibrodysplasia ossificans progressiva patients Ton Schoenmaker*[1], Fenne Wouters[1], Dimitra Micha[2], Coen Netelenbos[3], Marelise Eekhoff[3], Nathalie Bravenboer[4], Teun De Vries[1]. [1]Department of Periodontology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam and Vrije Universiteit, Netherlands, [2]Department of Clinical Genetics, VU University Medical Center, Amsterdam Movement Sciences, The Netherlands, Netherlands, [3]Internal Medicine, Endocrinology Section, VU University Medical Center, Netherlands, [4]Department of Clinical Chemistry, VU University Medical Center, Netherlands

Fibrodysplasia Ossificans Progressiva (FOP) is a genetic disease characterized by heterotopic ossification (HO) that occurs in muscle tissue, tendons and ligaments. The disease is caused by a mutation in the Activin receptor type 1 (ACVR1) gene, resulting in highly enhanced responsiveness to ligands including Activin-A. Binding of Activin-A to the mutated ACVR1 receptor induces osteogenic differentiation in osteoblast-like cells. The metabolism and composition of heterotopic bone formed in FOP patients appears to be comparable to skeletal bone in healthy subjects. Normal bone remodelling requires the coupled action of both osteoblast and osteoclast activity. In this study we investigated the effect of the FOP mutation and Activin-A on osteoclast formation.Firstly, the effect on the osteoclastogenic-inducing potential of periodontal ligament fibroblasts (PLF) was studied by coculturing CD14 positive osteoclast precursor cells from healthy donors with PLFs from healthy controls and FOP patients. Secondly, the effect on M-CSF and RANK-L induced osteoclast differentiation was investigated in a monoculture of CD14 positive precursors from healthy donors and FOP patients. Osteoclast differentiation was assessed by counting the number of TRAcP positive multinuclear cells. QPCR was performed to study gene expression. Cell proliferation was assessed by DNA measurement.Activin-A inhibited osteoclast formation induced by control and FOP PLFs. This inhibition was only significant in the cocultures with FOP PLFs. In these cultures Activin-A downregulated M-CSF and DC-STAMP expression, genes important for osteoclastogenesis. Similarly Activin-A inhibited osteoclastogenesis in M-CSF and RANKL stimulated monocultures from control and FOP CD14 positive cells. This inhibition was probably due to a decreased proliferation of the CD14 cells.Our study shows that Activin-A can inhibit osteoclast formation both in a PLF induced coculture system as well as in a M-CSF and RANKL induced CD14 positive monoculture. This inhibition seems to be mediated via a direct effect on the osteoclast precursors regardless of the presence of the FOP mutation. This study provides new insight into the pathophysiology of FOP; while Activin-A is known to evoke enhanced heterotopic bone formation this study shows that Activin A may also inhibit osteoclast formation, favouring the bone remodelling balance towards HO formation even more.

In Vitro and In Vivo Treatment Response of Osteogenesis Imperfecta Bone Tissue to Bone Forming Sclerostin Antibody Rachel Surowiec*[1], Lauren Battle[2], Stephen Schlecht[3], Michelle Caird[2], Kenneth Kozloff[1]. [1]Departments of Biomedical Engineering and Orthopaedic Surgery, University of Michigan, United States, [2]Department of Orthopaedic Surgery, University of Michigan, United States, [3]Departments of Mechanical Engineering and Orthopaedic Surgery, University of Michigan, United States

Osteogenesis Imperfecta (OI) is a rare, severe and highly variable heritable collagen-related bone dysplasia. Genotypic patient diversity may not only contribute to the heterogeneity of the disease but also impact individual patient response to therapy. We aim to determine the impact of baseline gene expression and morphological bone phenotype on response to bone forming sclerostin antibody (SclAb) therapy in vitro and in a novel xenograft model using OI patient-derived bone isolates.Cortical and trabecular bone samples (~2mm3) typically discarded as surgical waste (OI, n=5; non-OI control, n=5) were collected to media, randomly assigned to an untreated (UN), low-dose SclAb (TRL, 2.5 µg/mL), or high-dose SclAb (TRH, 25 µg/mL) group and maintained (37°C). TR occurred on day 2 and 4 and removed on day 5 for RNA extraction (Fig1A). Genes related to the canonical and non-canonical Wnt pathways (TWIST1, WISP1, DKK1, SOST, RANKL, OPG, SP7, RUNX2, BGLAP, COL1A1) were analyzed. Fold changes >1.5 were considered statistically significant (p < 0.05) via a Student's (baseline phenotypic comparison) and paired (treatment effect) t-test. A subset of bone was implanted s.c. into a nude mouse and TR (25 mg/kg s.c. 2x/wk for 2/4wks). Pre and post-µCT and dynamic histomorphometry was obtained. One sample per patient was formalin fixed at baseline for morphology (H&E).OI bone generally demonstrated lower baseline expression of downstream Wnt targets, variable-to-increased expression of inhibitory regulators, lower osteoblast markers and variable expression of progenitor markers compared to non-OI bone (Fig1C-D). SclAb induced an upregulation (compensatory response) in downstream and associated Wnt targets (SOST, DKK1, WISP1, TWIST1) with the greatest magnitude from OI cortical bone (OI2, 3) (Fig1E). OI bone demonstrated an upregulation of osteoblast activity with TR (except OI 3 whose low baseline expression had the greatest upregulation in TRH TWIST1, DKK1, RANKL and SP7). When implanted, OI4 demonstrated increased bone surface, corroborated by histomorphometry, and an upregulation in Wnt targets with concurrent in vitro TR (Fig1B,E).Heterogeneous baseline genes expression and TR response was observed in patient-derived OI bone tissue. Clinical

heterogeneity is a hallmark of OI; understanding a patient's genetic, cellular and morphological bone phenotype may play a crucial role in predicting treatment response and could help guide clinical decision making.

Figure 1. A) In-vitro study schematic for patient bone tissue TR with Scl-Ab. B) Bone isolates from OI-I and Non-OI 4 was concurrently implanted in a xenograft model and TR for 2 or 4wks and compared to UN controls. Bone was analyzed using µCT as a % change from pre-to-post (changes in bone surface (BS) depicted). Dynamic histomorphometry supported µCT measures revealing anabolic TR effects. C) Baseline morphology of patient bone tissue prior to initiating TR. D) **Baseline Phenotype:** Quantification of fold differences in baseline expression of TWIST1, WISP1, DKK1, SOST, RANKL, OPG, SP7, RUNX2, BGLAP, and COL1A1 of OI normalized to the average UN non-OI controls and corrected by HPRT1. E) **Within-Patient TR Effects:** Quantification of fold-changes in expression of the key genes of interest due to low and high dose TR with Scl-Ab normalized to the patient's UN condition normalized to HPRT1 (within patient analysis). Height of bar represents the mean of the relative fold changes and error bars represents the standard deviation among the three pooled samples within patient. * indicates p≤0.05. UN=Untreated; TRL=low dose treatment, TRH=high dose treatment.

Hyperphosphatemia in Hypophosphatasia of Childhood is Associated with Decreased FGF7 and Normal FGF23 Levels in the Circulation Michael P. Whyte*[1], Fan Zhang[1], Gary S. Gottesman[1], Steven Mumm[2], Rajiv Kumar[3]. [1]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, United States, [2]Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine, United States, [3]Division of Nephrology and Hypertension, Departments of Medicine and Biochemistry & Molecular Biology, Mayo Clinic College of Medicine, United States

Hypophosphatasia (HPP) is the inborn-error-of-metabolism caused by loss-of-function mutation(s) of the gene ALPL that encodes the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP). The disorder is characterized enzymatically by low serum ALP activity (hypophosphatasemia). TNSALP is a cell-surface phosphohydrolase abundantly expressed in bone, liver, and kidney. Inorganic pyrophosphate, pyridoxal 5′-phosphate, and phosphoethanolamine, its natural substrates, accumulate extracellularly. Our clinical experience indicates that hyperphosphatemia, from increased tubular maximum for phosphate (TmP/GFR), is common in HPP. Furthermore, treatment with asfotase alfa enzyme replacement does not correct elevated circulating phosphate levels. Herein, we verified this hyperphosphatemia of HPP in our study of 41 children representing the broad-ranging severity of pediatric HPP while also quantitating by batch assay fasting serum levels of the phosphatonins FGF23, FGF7, and FRP4. Data were obtained prospectively also from 73 children with XLH receiving standard-of-care [1,25(OH)2D3 and Pi] therapy and 15 healthy pediatric controls (PC). For the three subject groups, including their subgroup comprising exclusively the pre-teenage children, serum Pi was significantly elevated in HPP (P < 0.0001) and low in XLH (P < 0.0001) compared to the PCs (Table). No differences were observed in total or ionized calcium or intact PTH (P > 0.10) among the three groups. Serum creatinine levels for the HPP and XLH groups were low (P < 0.001) compared to the PCs. In XLH, serum FGF23 was, as expected, elevated (P < 0.002) and serum FGF7 concentrations were low (P < 0.04) while FRP4 levels were normal (P > 0.2). In HPP, serum FGF7 was distinctly low (P < 0.007) and FGF23 and FRP4 normal (P > 0.8). The decreased circulating FGF7 level in the hyperphosphatemia of HPP is intriguing, but its pathogenesis requires further investigation.

Serum	Mean (SD)		
	Pediatric Controls (n=15)	XLH (n=73)	HPP (n=41)

Plasma microRNA as novel biomarker for curve progression in Adolescent Idiopathic Scoliosis (AIS) – a 6 years longitudinal follow up study Jia Jun Zhang*[1,2], Yu Jia Wang[1,2], Ka Yee Cheuk[1,2], Carol Cheng[1,2], Tsz Ping Lam[1,2], Bobby Kin-Wah Ng[2,3], Yong Qiu[2,4], Jack Chun Yiu Cheng[1,2], Wayne Yuk-Wai Lee[1,2]. [1]Department of Orthopaedics and Traumatology, SH Ho Scoliosis Research Laboratory, The Chinese University of Hong Kong, Hong Kong, [2]Joint Scoliosis Research Center of the Chinese University of Hong Kong and Nanjing University, The Chinese University of Hong Kong, Hong Kong, [3]Department of Orthopaedics and Traumatology, The Chinese University of Hong Kong, Hong Kong, [4]Spine Surgery, The Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China

Purpose: AIS is a three-dimensional spinal deformity without clear etiopathogenesis. The outstanding clinical question is to develop effective prognostication for timely treatment. Low bone mass and cortical thickness are reported prognostic factors for curve progression. Last year, we reported overexpression of miR-145-5p in AIS osteoblasts impairing osteocytogenic differentiation (2017 ASBMR MO0570). Our bioinformatic analysis has identified a deferential miRNA profile in AIS iliac crest bone biopsies. We hypothesized that circulating miRNA(s) could be a new biomarker in predicting curve progression in AIS.Method: Fifty-two AIS girls were sequentially recruited from local Scoliosis Research Clinic at their first presentation and followed up longitudinally for 6 years. In addition to blood taking, anthropometry and curve severity were measured at first visit. The subjects were followed up clinically every 6 months with standard protocols. The subjects were sub-classified into progressive or non-progressive stable group based on changes in the Cobb angle according to SRS criteria (> 6 degrees or <6 degrees respectively) after completing the 6 years follow-up and reaching skeletal maturity. miRNA candidates were selected from bioinformatics analysis. miRNA expression was detected in plasma. Bone formation (P1NP) and resorption (CTX) markers were measured in serum. Mann-Whitney, Spearman's rank correlation test, area under ROC curve (AUC) and stepwise logistic regression were used for statistical analysis.Results: Twenty-two progressive and thirty stable AIS subjects were identified at the end of 6 years (Table 1). AIS girls with progressive spinal deformity had significantly higher P1NP (p=0.007) level. A lower plasma level of miR-145-5p (p=0.052) and miR-96-5p (p=0.017) were found in the progressive group. Plasma level of miR-224-3p was negatively correlated with serum P1NP and plasma miR-145-5p level in progressive group. In progressive AIS, the diagnostic efficacy of miR-96 (AUC=0.702, 95%IC=0.559-0.845) and P1NP (AUC=0.719, 95%IC=0.58-0.858) was markedly higher than other miRs. Logit model including miR-96, miR-145 and P1NP had higher predicted probability. Conclusion: This is the first study to demonstrate prognostic potential of serological markers for curve progression of AIS in a longitudinal cohort. Result of the study shed light on potential of novel biomarkers in addition to bone quality parameters, which may improve prognostic power to AIS.

Table 1. Anthropometric and radiological assessment in AIS subjects

	Age (1st visit)	Cobb angle (1st visit)	Cobb angle (after 6 yrs)	Treatment	
				Observation	Bracing
Progressive	12.77± 0.93	24.29± 7.18	35.43± 8.20	1	21
Stable	13.16±0.734	25.22±9.02	27.50±10.64	12	18

SUN-1128

Prospective Associations of Osteosarcopenia and Osteodynapenia with Incident Fracture and Mortality over 10 years in Community-dwelling Older Adults Saliu Balogun*[1], Tania Winzenberg[1], Karen Wills[1], David Scott[2,3], Michele Callisaya[1], Flavia Cicuttini[4], Graeme Jones[1], Dawn Aitken[1]. [1]Menzies Institute for Medical Research, University of Tasmania, Australia, [2]Department of Medicine, School of Clinical Sciences at Monash Health, Australia, [3]Faculty of Medicine, Nursing and Health Sciences, & Peninsula Clinical School, Central Clinical School, Monash University, Australia, [4]Department of Epidemiology and Preventive Medicine, Monash University, Australia

Aim: To determine whether older adults with low muscle mass (sarcopenia) and strength (dynapenia), in the presence of osteoporosis/osteopenia, have an increased risk of fracture and mortality over 10 years, compared to those with low muscle or low bone mass alone or with neither condition.Methods: 1032 participants (52% women; mean age 62.9±7.4 years) were studied at baseline, 2.5, 5 and 10 years. Mortality was ascertained from the death registry and fractures were self-reported. Baseline appendicular lean mass (ALM) was assessed using dual-energy X-ray absorptiometry and normalised to body mass index (BMI). Hand grip strength (HGS) was assessed by dynamometer. Osteosarcopenia and osteodynapenia were defined as having T-scores of the total hip and/or lumbar spine bone mineral density (BMD) < –1 combined with being in the lowest 20% of the sex-specific distribution for ALM/BMI or HGS respectively.Results: Incident fracture risk was significanlty higher in participants who were osteodynapenic (RR=2.07, 95% CI: 1.26–3.39), dynapenic alone (RR=1.74, 95% CI: 1.05–2.87), and osteopenic alone (RR=1.63, 95% CI: 1.15–2.31), compared to those without dynapenia or osteopenia. Mortality risk was significantly higher only in participants with osteosarcopenia (RR=1.49, 95% CI: 1.01–2.21) compared to those without sarcopenia or osteopenia. However, osteosarcopenia and osteodynapenia did not lead to a significantly greater fracture or mortality risk compared to having these conditions on their own.Conclusion: Osteopenia combined with low muscle mass or strength does not significantly increase the risk of fracture or mortality compared to having osteopenia or sarcopenia/dynapenia alone, suggesting that combined assessments may not add additional risk for fracture and mortality.

SUN-1129

Associations between home environmental modifications and falls from the Women's Health Initiative Daniel Beavers*[1], Laura Welti[2], Annie Mampieri[2], Stephen Rapp[1], Kristen Beavers[2], Edward Ip[1], Sally Shumaker[1]. [1]Wake Forest School of Medicine, United States, [2]Wake Forest University, United States

Purpose: Home environmental modifications (HEMs) are commonly used by older adults at risk of or in the presence of aging-related functional limitations. Adverse events such as a history of falls and fractures are often associated with HEM usage strategies. However, given the diversity of types of HEMs, it is unclear what are the patterns of HEM usage as relates to falls and major bone health events.Methods: Utilization of 9 types of HEMs were collected from 71,257 women currently active in the Women's Health Initiative (WHI) [78.6±6.3 years, 88.7% Caucasian] from a questionnaire administered Oct 2013 – Dec 2014. In addition to demographic and health data, information was collected regarding usage of hand rails, grab bars, ramps, non-slip surfaces, tacking down carpets/rugs, decreasing clutter,

Sunday Posters

increasing lighting, raised sink/counter heights, and other HEMs. Health event-related function measures included history of recent falls and broken hip. Odds ratios were estimated based on overall HEM use as well as for latent classes of HEM strategies adjusted for age, marital status, race/ethnicity, education, depression, and obesity. Results: Overall, 53% of women reported use of any HEM, and latent class analyses grouped HEM usage strategies into low utilization (56%), increased lighting and decluttering (18%), adding rails and grab bars to home (20%), and multiple combined HEM strategies (5%). Furthermore, 22.7% of women reported a fall at home in the past year, and 1.8% had history of a broken hip. Women with falls (OR 1.8; 95% CI 1.7, 1.9) and hip fracture (OR 1.7; 95% CI 1.5, 2.0) reported higher use of any HEM strategy. Women who experienced falls reported multiple HEM strategies (OR 3.2; 95% CI 2.9, 3.5), railings/grab bars (OR 2.6; 95% CI 2.5, 2.8), and lighting/declutter use (2.0; 95% CI 1.9, 2.2) compared to low HEM users; likewise, women with history of broken hip reported railing/grab bar use latent class (OR 2.89; 95% CI 2.4, 3.5), and multiple HEM strategies (OR 2.3; 95% CI 1.8, 3.1).Discussion: In this large, cross-sectional study, women with function-related health events such as falls and broken hip reported HEM use more frequently than women without such events. These women have likely adopted these strategies to help prevent future events or to maintain function in the presence of health insult. Given that we cannot directly measure risk, future research should explore whether HEMs are effective for the prevention of distal health outcomes.

Latent Class Models: Association between latent HEM classes and disease/health status.

Variable	Model	Low HEM Use (reference)	Railings/Grab Bars	High HEM Use	Lighting/Declutter
Fall at home	Unadjusted	1.00 (-,-)	2.62 (2.46, 2.78)	3.16 (2.90, 3.46)	2.01 (1.87, 2.15)
	Adjusted*	1.00 (-,-)	2.32 (2.18, 2.48)	2.89 (2.64, 3.16)	1.93 (1.79, 2.08)
Broken Hip	Unadjusted	1.00 (-,-)	3.48 (2.93, 4.14)	2.68 (2.04, 3.5)	1.30 (0.99, 1.71)
	Adjusted*	1.00 (-,-)	2.89 (2.39, 3.50)	2.33 (1.75, 3.11)	1.21 (0.88, 1.65)

Dynapenia and Muscle Loss in Older-Aged Women Francisco Torres-Naranjo*[1], Roberto González-Mendoza[2], Alejandro Gaytán-González[3], Hugo Gutiérrez-Hermosillo[4], Noé Albino González-Gallegos[5], Claudia Flores-Moreno[6], Pilar De La Peña-Rodríguez[7], Pedro Alberto García-Hernández[8], Juan López-Taylor[2]. [1]Centro de Investigación Ósea, Universidad de Guadalajara, Mexico, [2]Instituto de Ciencias Aplicadas a la Actividad Física y del Deporte, Universidad de Guadalajara, Mexico, [3]Universidad de Guadalajara, Mexico, [4]Universidad de Guanajuato, Hospital Aranda de la Parra, Mexico, [5]Departamento de Bienestar y Desarrollo Sustentable, Centro Universitario del Norte, Universidad de Guadalajara, Colotlán, Mexico, [6]Endocrinología/Centro de Osteoporosis, Hospital Universitario de Monterrey, Mexico, [7]Servicios Médicos De la Peña, Mexico, [8]Servicio de Endocrinología, Hospital Universitario, UANL, Mexico

Low skeletal muscle mass (LSMM) is associated with strength loss and disability. Epidemiological findings suggest that LSMM and dynapenia are associated with both mortality and physical disability. The association of muscle mass loss and dynapenia is still controversial.Purpose: This study aimed to examine the association between dynapenia and LSMM defined by several operational definitions in older-aged women.Methods: We evaluated a sample of 107 women 65 years of age and older from western of México. A whole body DXA scanning (Hologic QDR 4500) was performed to evaluate the body composition. The indicators and cut points used to diagnose LSMM were: 1) appendicular lean soft tissue absolute kilograms (ALSTKG) ≤15.02; 2) appendicular lean soft tissue corrected by body mass index (ALST/BMI) <0.512, both according to The Foundation for National Institutes of Health Sarcopenia Project (FNHISP); and 3) appendicular lean soft tissue corrected by squared height (ALST/HT2) ≤5.45 as stablished by The European Working Group on Sarcopenia in Older People (EWGSPOP). The criteria of dynapenia was a maximum isometric strength (MIS) of the hand and forearm muscles equal or lower the 20 kg evaluated by handgrip dynamometry (Jamar Handgrip Dynamometer).Results: Overall prevalence of dynapenia was 71.3%. The prevalences of LSMM and their respective prevalence of dynapenia are showed in Table 1. The probability for dynapenia was significant for women with LSMM defined by ALSTKG and ALST/BMI. No statistical probability was observed with ALST/HT2 . Conclusions: We observed a high prevalence in both loss of muscle mass and dynapenia in our sample. Prevalence of dynapenia is higher in women with LSMM defined by FNHISP criteria. Our findings suggest that several indicators should be taken in consideration in order to properly assess the impact of LSMM.

Loss of muscle mass criteria	Prevalence of LSMM	Prevalence of dynapenia	Odds ratio (*P<0.05)	95% confidence interval
ALSTKG	60.75	84.62	5.5*	2.22 - 13.6
ALST/BMI	38.32	90.24	6.4*	2.04 - 20.08
ALST/HT²	42.06	77.78	1.8	0.75 - 4.31

Insulin-like growth factor-I is required to maintain muscle volume in adult mice Satoshi Nakamura*, Arihiko Kanaji, Takeshi Miyamoto, Morio Matsumoto, Masaya Nakamura. Department of Orthopedic Surgery, Keio University School of Medicine, Japan

[Background & purpose]Sarcopenia is defined as mass reduction and dysfunction of skeletal muscle in elderly, and is a big concern causing a fall followed by fractures. Sarcopenia is developed with various factors such as aging, endocrine, nutrition and disuse, however, precise pathogenesis of sarcopenia were remained to be elucidated. Insulin-like growth factor-I (IGF-I) is a peptide protein, which has diverse functions including regulating embryonic development and bone homeostasis. Serum IGF-I levels decline in the elderly; however, IGF-I function in adults has not been clearly defined. Here, we show that IGF-I is required to maintain muscle mass in adults.[Methods]We crossed IGF-I flox mice with Mx1 Cre mice to yield Mx1 Cre/IGF1flox/flox (IGF-I cKO) mice. 8-week-old female mice were treated with polyIpolyC to delete IGF-I gene and sacrificed at 18-weeks-old. Serum IGF-1 levels were measured by ELISA, and blood glucose levels were monitored. Expressions of Eif4e, p70S6K, MuRF1 and Atrogin-1 mRNA were analyzed by qRT-PCR, accumulations of proteins were detected by Western blot, and bone mineral densities were analyzed by dual-energy X-ray absorptiometry (DEXA) measurements.[Results]We demonstrate that, although serum IGF-I levels significantly decreased in IGF-I cKO mice after polyIpolyC injection relative to controls, serum glucose levels were unchanged. We show that muscle mass and cross-sectional area decreased significantly, while bone mass did not after IGF-I down-regulation in after IGF-I cKO mice. In IGF-I cKO muscle, expression of anabolic factors such as Eif4e and p70S6K significantly decreased, while expression of catabolic factors MuRF1 and Atrogin-1 was normal and down-regulated, respectively, suggesting that observed muscle mass reduction was due to perturbed muscle metabolism.[Conclusion]Our data demonstrate a specific role for IGF-I in maintaining muscle homeostasis in adults. Our model, reducing serum IGF-1 levels, may recapitulate age-related muscle atrophy in adults.

SUN-1132

The body composition changes in elderly people which relations with dysmobility syndrome Woong Hwan Choi*[1], Sang Mo Hong[2], Ye Soo Park[3]. [1]College of medicine,Hanyang university, Republic of Korea, [2]College of medicine, Hanleem University, Republic of Korea, [3]Hanyang university hospital, Republic of Korea

Background: The total volume of bone and muscle are decreased in the elderly. These changes are risk factors for fracture and other metabolic disease. Recently, the prevalence of osteoporosis and sarcopenia in the elderly has dramatically increased along with bone fracture and metabolic syndrome. However the relationship between theses disease is not clear.Objective: We aimed to determine the independent relations of muscle mass to osteoporosis (femur neck) in relation to body weight, fat mass, and other confounders.Design: We analyzed body composition and BMD data of 570 Male and 734 female who are older than 65 years. Body composition and bone mineral density (BMD) of femur neck were measured by DXA(Hologic QDR 4000). Sarcopenia was defined as the appendicular skeletal muscle mass (ASM) divided by height squared (Ht)2 (kg/m2) of < -1 SD below the sex-specific mean for 20 - 39 years adults.Results: ASM/(Ht)2 and BMD were positive correlated with body fat mass/(Ht)2. Protein & fat, carbohydrate, calcium, phosphate, calories intake were also positive correlated with BMD. Exercise also had positive correlation with ASM/(Ht)2 and BMD. However Vitamin D only positively related with ASM/(Ht)2. With compounding factors adjusting, ASM/(Ht)2 had also positive relation with BMS in men (R2=0.171, B=0.027, p<0.001) and in women (R2=0.226, B=0.016, p=0.002). The adjusted odds ratios (95% CIs) of osteoporosis in sarcopenia patients were 1.24 (95%CI; 1.47-8.15) in men and not significant in women.Conclusions: BMD were decreased with the increase of insulin resistance in normal fasting glucose. And with the increase fasting glucose, these relations were weakening (IFG) and disappeared (DM).Bone mineral density was independently associated with muscle mass. Sarcopenia was independent risk factor for osteoporosis in men but not women.

Appendicular Lean Mass Adjusted for Body Mass Index: Reference Data for Australian Men and Women Julie Pasco*, Kara Holloway-Kew, Monica Tembo, Sophia Sui, Kara Anderson, Pamela Rufus, Natalie Hyde, Mark Kotowicz. Deakin University, Australia

PurposeRecommendations from the Foundation for the National Institutes of Health (FNIH) Sarcopenia Project are that appendicular lean mass (ALM, kg) adjusted for body mass index (BMI, kg/m2) be used for identifying low lean mass that discriminates the presence or absence of weakness; ALM/BMI cutpoints of <0.789 for men and <0.512 for women were proposed. Although cutpoints were derived by pooling data from multinational studies, Australian data were absent. Our primary aim was to report ALM/BMI reference ranges for men and women in Australia. Our secondary aim was to compare the prevalence of low lean mass by our definition, based on T-scores for BMI/ALM<-2.0, with those from the FNIH.

MethodsBody composition was measured by DXA (Lunar) for 1411 men and 960 women aged 20-93yr enrolled in the Geelong Osteoporosis Study (GOS), a population-based cohort study set in south-eastern Australia. Mean values were calculated for DXA-derived ALM (sum of lean mass for arms and legs) adjusted for BMI. Data are provided for men and women for each age decade, and cutpoints equivalent to T-scores of -2.0 for each sex were derived using reference data for 374 men and 308 women aged 20-39 years. Agreement between low lean mass estimates using our criteria in comparison with FNIH criteria were evaluated using the kappa statistic.ResultsFor men, mean±SD values for weight and height were 82.0±12.4 kg and 1.75±0.07 m; for women, 69.4±12.9 kg and 1.62±0.07 m, respectively. Mean ALM/BMI values were greater for men than for women, and decreased with age in both sexes (Table). Mean±SD values for ALM/BMI for GOS men and women aged 20-39yr were for men, 1.108±0.141 and for women 0.759±0.121. Cutpoints for ALM/BMI equivalent to T-scores of -2.0 were <0.827 for men and <0.518 for women. The overall agreement for identifying low lean mass using our criteria compared with FNIH criteria was 0.73 for men and 0.89 for women. For men aged 20+, the crude prevalence of low lean mass was 13.9% (95%CI 12.1-15.8) using our cutpoints and 8.5% (7.1-10.1) using FNIH cutpoints (p for difference 0.001); corresponding figures for women were 5.5% (4.2-7.2) and 4.5% (3.3-6.0), respectively, (p=0.3).ConclusionUse of cutpoints from our population corresponding to T-scores of -2 identified more individuals with low ALM/BMI than using FNIH criteria, but the difference was significant for men only. These data emphasise the importance of using universal criteria for identifying low lean mass.

Table: Mean±SD values for ALM/BMI by age and sex.

Age (yr)	Men		Women	
	n	ALM/BMI	n	ALM/BMI
20-29	180	1.138 ± 0.136	176	0.775 ± 0.118
30-39	194	1.081 ± 0.140	132	0.737 ± 0.121
40-49	203	1.032 ± 0.122	161	0.700 ± 0.090
50-59	215	0.984 ± 0.116	159	0.670 ± 0.107
60-69	206	0.935 ± 0.124	146	0.643 ± 0.092
70-79	225	0.899 ± 0.111	121	0.619 ± 0.093
80+	188	0.868 ± 0.113	65	0.617 ± 0.099

SUN-1134

Phenotypic Features of Sarcopenic Older Adults According to Current Operational Definitions: Data from the GERICO Study Mélany Hars*, Emmanuel Biver, Thierry Chevalley, René Rizzoli, Serge Ferrari, Andrea Trombetti. Division of Bone Diseases, Department of Internal Medicine Specialties, Geneva University Hospitals and Faculty of Medicine, Switzerland

Controversies regarding how best to define sarcopenia have impeded epidemiological and interventional research, and hindered efforts to elucidate whether sarcopenia overlap with other disease states. In order to contribute to the knowledge base on candidate sarcopenia criteria, we aimed to i) report and compare the prevalence of sarcopenia according to different current operational definitions in a large Swiss cohort of early-old aged community-dwelling healthy adults, and ii) compare the phenotypic features of sarcopenic individuals, with a focus on conditions typically associated with increased risk of fall and fracture, including osteoporosis, frailty, and obesity.Seven hundred sixty-seven participants (608 women; 67.9±1.5 years) enrolled in the ongoing Geneva Retirees Cohort (GERICO) were studied. Appendicular lean mass (ALM) was determined by dual-energy X-ray absorptiometry. Gait speed was measured over 4-m and grip strength using a handheld dynamometer. Six definitions were applied, among which three were based on low muscle mass alone (Baumgartner, Delmonico 1 and 2), and three required both low muscle mass and low muscle function (EWGSOP, IWG, FNIH). Degree of agreement was assessed using kappa statistics, and phenotypic features of sarcopenic individuals were compared, based on regression analyses.Low lean mass prevalence varied from 3.8% to 19.9% depending on the cutoff. Prevalence of low lean mass combined with either weakness or slowness was the lowest for FNIH (0.3%) compared with IWG (1.2%) and EWGSOP (1.6%), with higher prevalence found in women across all definitions. There was poor agreement between the groups identified according to the different criteria and definitions (all kappa values below 0.3). Individuals who met the low ALM/BMI criterion in comparison to those meeting the ALM/height2 or ALM criteria, were more likely to be obese (51.7% vs 0% vs 1.4%, respectively; p<0.001) and pre-frail or frail (44.8% vs 21.1% vs 20.7%, respectively; p<0.030), but were less likely to be osteopenic or osteoporotic (58.6% vs 85.3% vs 84.8%, respectively; p<0.001).Our results in a large Swiss cohort of 68-year old participants suggest that sarcopenia widely vary depending on the low muscle mass and low muscle function criteria applied, with poor agreement between classifications and with different phenotypes captured across definitions. The FNIH low ALM cutoff adjusted for BMI tends to capture sarcopenic obese and less robust individuals.

Greater visceral adiposity is associated with lower paraspinal muscle density: the Framingham Study Timothy Tsai*[1], Brett Allaire[2], Ilean Isaza[1], Marian Hannan[1,2,3], Mary Bouxsein[2], Douglas Kiel[1,2,3], Thomas Travison[1,2,3]. [1]Hebrew SeniorLife Institute for Aging Research, United States, [2]Beth Israel Deaconess Medical Center, United States, [3]Harvard Medical School, United States

Obesity is a significant contributor to premature death and disability. While its influence on cardiometabolic outcomes has been well-studied, less is known concerning its relation to musculoskeletal health and particularly muscle quality. In this analysis, we investigated the relationship between visceral adipose tissue and the density of the paraspinal muscle groups among 1,158 members of the Framingham Study Generation 3 cohort.Data were obtained from 645 men, 358 premenopausal women, and 155 postmenopausal women enrolled in the FHS multidetector CT substudy, selected for muscle morphology analysis on the basis of having QCT measurements at baseline examination occurring from 2002 to 2005. Fifty-seven participants lacking VAT measures were excluded. Abdominal CT scans from an 8-slice multidetector CT scanner (LightSpeed Ultra; General Electric, Milwaukee, WI) were used to assess visceral adipose tissue (VAT, cm3) and density (Hounsfield units, HU) of the paraspinal muscles in the lumbar region (bilateral erector spinae, transversospinalis, psoas major, and quadratus lumborum muscles). Multiple linear regression was used to quantify the cross-sectional relationship between VAT and muscle density. VAT volume was scaled such that slope estimates represent average differences in muscle density corresponding to 100 cm3 cross-sectional increases in VAT. Linear models adjusted for age, height, diabetes status, and menopausal status. Mean (standard deviation) VAT volume was 937 (858), 1061 (688), and 1377 (780) cm3 in men (ages 31 to 68 y), premenopausal women (33 to 55 y) and postmenopausal women (40 to 70 y), respectively. There was an inverse association between VAT volume and paraspinal muscle density which was nonsignificant in men (-0.042 HU, 95% confidence interval: -0.093 to 0.01 HU), but more evident among women irrespective of menopause status. Among women, each 100 cm3 greater VAT volume was associated with 0.221 HU (95% confidence interval: 0.152 to 0.290 HU) lower paraspinal muscle density. Additional adjustment for physical activity yielded no difference in slope estimates.These data suggest that visceral adiposity may lead to lower trunk muscle density with possible implications for trunk stability, postural sway and falls; however longitudinal studies and underlying mechanistic investigations are needed to confirm these findings.

Serum DHEA and its Sulfate Are Associated with Incident Fall Risk in Older Men - the MrOS Sweden Study Liesbeth Vandenput*[1], Maria Nethander[1,2], Magnus Karlsson[3], Björn Rosengren[3], Eva Ribom[4], Dan Mellström[5], Claes Ohlsson[1]. [1]Centre for Bone and Arthritis Research, Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [2]Bioinformatics Core Facility, Sahlgrenska Academy, University of Gothenburg, Sweden, [3]Clinical and Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University, and Department of Orthopaedics, Skåne University Hospital, Sweden, [4]Department of Surgical Sciences, University of Uppsala, Sweden, [5]Centre for Bone and Arthritis Research and Department of Geriatric Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden

The adrenal-derived hormones dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) are the most abundant circulating hormones and their levels decline substantially with age. Many of the actions of DHEAS are considered to be mediated through metabolism into androgens and estrogens in peripheral target tissues. The predictive value of serum DHEA and DHEAS for the likelihood of falling is unknown. The aim of this study was, therefore, to assess the associations between baseline DHEA and DHEAS levels and incident fall risk in a large cohort of older men.Serum DHEA and DHEAS levels were analyzed with mass spectrometry in the population-based Osteoporotic Fractures in Men study in Sweden (n=2516, age 69-81 years). Falls were ascertained every 4 months by mailed questionnaires. Associations between steroid hormones and falls were estimated by generalized estimating equations.During a mean follow-up of 2.7 years, 968 (38.5%) participants experienced a fall. High serum levels of both DHEA (odds ratio [OR] per SD increase 0.85, 95% CI 0.78-0.92) and DHEAS (OR 0.88, 95% CI 0.81-0.95) were associated with a lower incident fall risk in models adjusted for age, BMI and prevalent falls. Further adjustment for serum sex steroids or age-related comorbidities only marginally attenuated the associations between DHEA or DHEAS and the likelihood of falling. Moreover, the point estimates for DHEA and DHEAS were only slightly reduced after adjustment for lean mass and/or grip strength. Also, the addition of the narrow walk test did not substantially alter the associations between serum DHEA or DHEAS and fall risk. Finally, the association with incident fall risk remained significant for DHEA but not for DHEAS after simultaneous adjustment for lean mass, grip strength, and the narrow walk test. This suggests that the associations between DHEA and DHEAS and falls are only partially mediated via muscle mass, muscle strength, and/or balance.In conclusion, older men with high DHEA or DHEAS levels have a lesser likelihood of a fall.

Regucalcin Signaling Is Involved in Advanced Glycation End Products-induce Muscle Cell Senescence and Atrophy Rong-Sen Yang*, Chen-Yuan Chiu, Ding-Cheng Chan, Shing-Hwa Liu. National Taiwan University, Taiwan

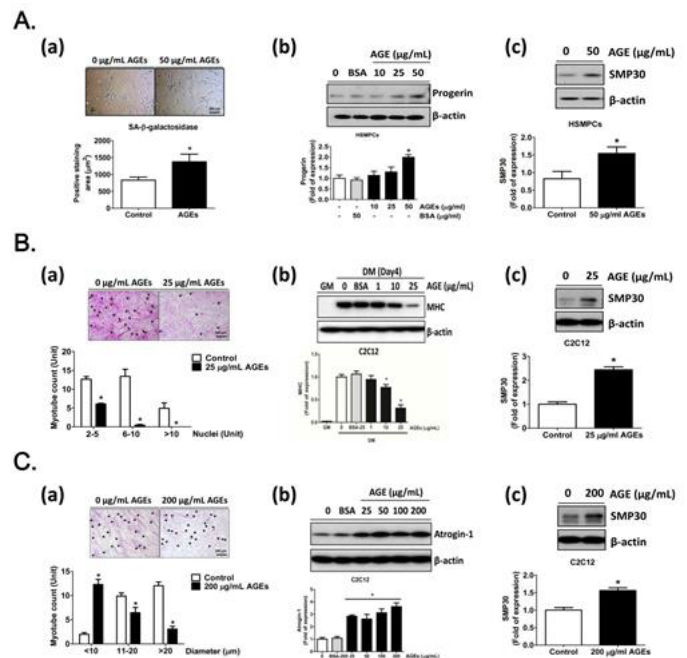
Introduction: Advanced glycation end products (AGEs) may contribute to aging-induced functional decline of cells and tissues. Elderly men with AGEs accumulation had lower muscle mass and strength. The fundamental mechanism of action of AGEs in sarcopenia still remains unclear. Regucalcin, also known as senescence marker protein-30 (SMP30), is involved in regulation of aging and metabolic disorders. Here, we investigated the molecular mechanism of action of AGEs in sarcopenia and assessed the therapeutic potential of AGEs inhibitors on sarcopenia in vitro.Methods: Human tissue sampling of the present study was approved by the Institutional Review Board and written informed consent from all participating subjects. Human skeletal muscle-derived progenitor cells (HSMPCs) isolated from rectus muscles of orthopedic surgery patients and mouse myoblast cell line (C2C12) were cultured to test the in vitro effects of AGEs (10-200 μg/mL) on the myotube formation and atrophy with or without AGEs inhibitors. The protein expressions were determined by Western blotting. Morphological and senescent examinations were performed by H&E staining and senescence-associated β-galactosidase (SA-β-Gal) staining, respectively. Results: AGEs significantly induced cellular senescence by measuring SA-β-Gal activity (about 66% increase, n=5, p<0.01; Figure 1A-a) in HSMPCs under growth medium. The protein expressions of progerin, another senescent biomarker, and regucalcin (SMP30) were up-regulated in AGEs-treated HSMPCs (n=5, p<0.01; Figure 1A-b and 1A-c). In addition, in C2C12 myoblasts and its differentiated myotubes, AGEs significantly reduced the myotube formation (about 52%, 97%, and 100% decreases in 2-5, 6-10, and over 10 nuclei myotubes, n=3, p<0.01; Figure 1B-a) and the myotube size (about 74% decrease in 20 μm diameter myotubes, n=3, p<0.01; detailed in Figure 1C-a) with a down-regulated protein expression of MHC (n=5, p<0.01; Figure 1B-b) and up-regulated protein expressions of Atrogin-1 (n=4, p<0.01; Figure 1C-b) and SMP30 (n=4, p<0.01; Figure 1B-c and 1C-c). Moreover, Alagebrium chloride (Ala-Cl, an AGEs cross-link breaker) and the receptor for AGE neutralizing antibody could efficiently protect against aforementioned injury induced by AGEs.Conclusion: These findings suggest that SMP30 may be as an etiological target in sarcopenic skeletal muscles with AGEs accumulation and AGEs inhibitors may be a therapeutic potential in sarcopenia.


Figure 1. Advanced glycation end products (AGEs) significantly suppressed myotube formation and hypertrophic myotubes via regucalcin (SMP30) activation under the cellular senescence process. Human skeletal muscle progenitor cells (HSMPCs) were cultured in growth medium with 50 μg/mL AGEs for 48 h (A). C2C12 myoblasts and myotubes were cultured in differentiation medium (DM) with AGEs (25 and 200 μg/mL) for 96 h (B) and 48 h (C), respectively. (a) The cellular senescence and cell morphology examined by SA-β-Gal and H&E stain; arrows indicate multinucleated myotube formation; quantification of senescent area and myotubes with different nuclei. (b, c) Western blot analysis of protein expressions of progerin, myosin heavy chain (MHC), Atrogin-1, and SMP30. Scale bar = 100 μm. All data are present as means±SEM for at least three independent experiments. *, p<0.05 as compared with control group.

Circulating miRNAs are associated with higher tibial cortical porosity in postmenopausal women with history of osteoporotic fractures Ursula Heilmeier*[1], Matthias Hackl[2], Susanna Skalicky[2], Janina Patsch[3], Thomas Baum[4], Fabian Schröder[5], Klemens Vierlinger[5], Andrew Burghardt[6], Ann Schwartz[7], Johannes Grillari[8], Thomas Link[9]. [1]Department of Radiology &Biomedical Imaging, United States, [2]TamiRNA GmbH, Austria, [3]Department of Biomedical Imaging and Image-Guided Therapy, Medical University of Vienna, Austria, [4]Department of Neuroradiology, Technical University Munich, Germany, [5]Department of Molecular Diagnostics, Austrian Institute of Technology (AIT), Austria, [6]Musculoskeletal Quantitative Imaging Research Group, Department of Radiology & Biomedical Imaging, University of California San Francisco, United States, [7]Department of Epidemiology and Biostatistics, University of California San Francisco, United States, [8]Department of Biotechnology, University of Natural Resources and Life Sciences, Austria, [9]Musculoskeletal Quantitative Imaging Research Group, Department of Radiology & Biomedical Imaging, University of California San Francisco, United States

Cortical bone porosity (Ct.Po.) has been shown to substantially impact bone strength, bone stiffness and fracture toughness and is therefore regarded as a key determinant of the bone fragility underlying fracture risk. Ct.Po. is defined as the fraction of non-mineralized tissues within cortical bone, and is routinely measured in vivo at peripheral skeletal sites in humans via high resolution peripheral quantitative computed tomography (HR-pQCT). However, the mechanisms driving increased cortical porosity are still not understood. MicroRNAs (miRNAs) are small non-coding RNA molecules that regulate gene expression at a posttranscriptional level. They are secreted from various cells into the blood where they can be accessed by venipuncture and can be taken up by recipient cells while altering the

recipient cell´s gene expression and mediating functional effects. Recently, miRNAs were found to be crucial players in bone homeostasis/remodeling as well as in bone diseases such as osteoporosis. Here, we aimed to explore potential pathomechanisms underlying Ct.Po. in osteoporosis. Thus, we tested the correlation between serum miRNA levels and tibial Ct.Po measured by HR-pQCT in a cohort of postmenopausal women with and without history of osteoporotic fractures. Postmenopausal women with (Fx, n=19) and without history of osteoporotic fragility fractures (Co, n=17) underwent HR-pQCT scanning of the ultradistal tibia. All women were mobile and otherwise free of bone affecting diseases or medications. Serum was collected from each subject and serum miRNA levels were quantified by qPCR-arrays for 20 miRNAs that were previously identified as promising discriminators of osteoporotic fractures. Spearman´s rank-order correlations were employed. Women were on average 61.6 ± 6.3 years old with a mean BMI of 25.8± 3.9 kg /m2. We found that in the postmenopausal women with history of fragility fractures miRNA expression levels of four out of 20 miRNAs were positively correlated with the extent of Ct.Po.: these were miR-19b-1-5p (R2= 0.560, p=0.013), miR323a-3p (R2=0.519, p=0.023), miR-32-3p (R2=0.439, p=0.060), and miR-143-5p (R2=0.504, p=0.028). Our findings suggest for the first time potential pathomechanistic links between miRNAs and cortical porosity. Further bone analyses are needed to validate our findings in vitro.

Serum Free Testosterone-Estradiol Ratio and Dehydroepiandrosterone Sulfate Levels Are Associated With Muscle Strength Independent of Muscle Mass in the Elderly Sung Hye Kong*[1], Jung Hee Kim[1], Ji Hyun Lee[1], A Ram Hong[1], Chan Soo Shin[1], Nam H. Cho[2]. [1]Seoul National University College of Medicine, Republic of Korea, [2]Ajou University College of Medicine, Republic of Korea

Purpose: Sex steroids including free testosterone (FT), estradiol (E2), and dehydroepiandrosterone sulfate (DHEA-S) is known to decrease over age, and has been suggested to be related with sarcopenia. However, the relationship between FT/E2 or DHEA-S levels and muscle strength has rarely been studied in a community-dwelling population. We aimed to evaluate whether serum FT/E2, and DHEA-S levels are associated with muscle mass and strength in a community-dwelling elderly population.Method: We analyzed 923 men over 60 years and 1,224 postmenopausal women from Ansung cohort study, which is a community-based cohort study in Korea. Body composition, and hand grip strength were measured by dual-energy X-ray absorptiometry, and hydraulic dynamometer, respectively. Weak muscle strength was defined as hand grip strength <26 for men, and <18 kg for women according to the Asian Working Group of Sarcopenia.Result: Subjects within higher FT/E2 tertiles tended to be younger and more physically active. Also, women within higher FT/E2 tertiles had higher BMI. Subjects within higher DHEA-S tertiles were likely to be younger, and men within higher DHEA-S tertiles had higher BMI. In correlation analyses, hand grip strength has a positive correlation with FT/E2 (r=0.278, p<0.001 in men, r=0.142, p<0.001 in women), and DHEAS (r=0.239, p<0.001 in men, r=0.157, p<0.001 in women). Correlation of hand grip strength with FT/E2 remained significant (B=0.081, p=0.002 in men, B=0.078, p=0.006 in women) after adjustments for age and appendicular muscle mass (ASM)/height2, physical activity, drinking, smoking, diabetes, and hypertension. In logistic regression models of FT/E2 for weak muscle strength, the odds ratio (OR), (95% confidence interval [CI]) of the 3rd tertile was 0.447 (0.260-0.769) in men, and 0.660 (0.473-0.922) in women compared with the 1st tertile after adjustments for all covariates. Also, comparing with the 1st tertile of DHEA-S, the OR (95% CI) was 0.558 (0.335-0.931) in men within 3rd tertile after adjustment for age and ASM/height2. Women within the 3rd tertile harbored a lower risk for weak muscle strength (OR [95% CI], 0.703[0.503-0.983]) than those within the 1st tertile after adjustments for all covariates.Conclusion: In a community-dwelling Korean population, serum FT/E2 and DHEA-S levels could be related with muscle strength independent of muscle mass in both genders. Therefore, FT/E2 or DHEA-S may have an independent role in muscle strength in the elderly.

LB SUN - 1154

Organic Matrix Quality discriminates between Age- and BMD-matched Fracturing versus Non-Fracturing Post-menopausal Women Eleftherios Paschalis*[1], Stamatia Rokidi[1], Klaus Klaushofer[1], Severin Vennin[2], Anastasia Desyatova[2], Joseph Turner[2], P Watson[3], Joan Lappe[3], Mohammed Akhter[3], Robert Recker[3]. [1]Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK and AUVA Trauma Centre Meidling, 1st Medical Department, Hanusch Hospital, Austria, [2]University of Nebraska, United States, [3]Osteoporosis Research Center, Creighton University, United States

Women with similar areal Bone Mineral Densities (BMD) may show divergent fracture incidence due to differences in bone quality.The hypothesis tested here is that postmenopausal (PM) women who have sustained osteoporotic fractures have altered organic matrix bone quality compared to those who have not. We used Raman microspectroscopy to analyze epoxy resin embedded transiliac biopsies (N=12) collected from fracturing (n=6, mean age 62.5 ± 7.4 yrs; Cases) and non-fracturing PM women (n=6, age- and BMD-matched; mean age 62.2 ± 7.3 yrs; Controls). Previous results show significant differences

in intrinsic material properties by nanoindentation that are more homogenously distributed and could propagate microcracks more easily in Cases, along with lower mineral carbonate/phosphate ratio by Fourier transform infrared spectroscopic imaging (FTIRI), and no differences in bone tissue mineralization by digitized microradiography (DM). No differences between groups were seen by conventional histomorphometry.Spectra were acquired 2 μm away from previously performed nanoindents, in cortical and cancellous compartments. Twenty such anatomical areas per biopsy per compartment were analyzed, the results averaged and the mean value treated as a single statistical unit for the biopsy compartment. The determined parameters were: mineral to matrix ratio (MM; positive correlation with bone stiffness), and tissue water (TW; positive correlation with bone strength), glycosaminoglycan (GAG; negative modulators of bone mineral homeostasis; responsible for keeping the canalicular network mineral-free), lipid, pyridinoline (Pyd; trivalent enzymatic collagen cross-link; strongly associates with fracture incidence), N(6)-Carboxymethyllysine (CML; advanced glycation endproduct; negative correlation with bone strength), and pentosidine (PEN; advanced glycation endproduct; negative correlation with bone strength) content.The results showed no changes in MM in either cortical or cancellous compartments in general agreement with previous FTIRI and DM results. Cases had significantly lower TW and GAG content and significantly elevated Pyd, CML, and PEN content in both anatomical compartments analyzed compared to Controls.In conclusion, the results of the present study indicate significant differences in organic matrix quality in PM women that sustain fragility fractures versus age- and BMD-matched controls, and highlight its importance as an independent determinant of fracture incidence.

The Influence of Maternal Diet on Offspring Bone Acquisition at Birth among Samoan Infants Rachel L Duckham*[1], Kendall J Arslanian[2], Ulai Fidow[3], Theresa Atanoa[4], Folla Unasa-Apelu[3], Abigail I Wetzel[5], Alysa Pomer[6], Take Naseri[7], Natalie Hyde[8], Nicola L Hawley[6]. [1]Institute for Physical Activity and Nutrition, Deakin University, Australia, [2]Department of Anthropology, Yale University, United States, [3]Yale-Ministry of Health Research Center, Samoa, [4]Community Studies Program, University of California-Santa Cruz, United States, [5]International Health Institute, Brown University, United States, [6]Department of Chronic Disease Epidemiology, Yale School of Public Health, United States, [7]Ministry of Health, Samoa, [8]Epi-Centre for Healthy Ageing, Deakin University, Australia

Purpose: Osteoporosis and obesity share many genetic and environmental factors and are suggested to have origins early in life. There are growing data indicating that maternal nutrition may play an important role in predisposing infants to both conditions. However, very few studies with a focus on maternal diet have been conducted in the Polynesian populations, who are known to differ in body composition from other ethnic populations. Furthermore, little is known about the role of maternal diet on offspring skeletal acquisition at birth in this population. The aim of this study was to determine the association between qualities of maternal dietary consumption and total skeletal bone content at birth. Methods: Subjects were 111 mother-infant pairs. Maternal dietary intake was assessed with a 115-item food frequency questionnaire to quantify intakes of total calories, fat, carbohydrate and bone-specific nutrients protein, calcium and potassium between 35-weeks gestation. At birth, trained personnel assessed infant weight and length. Dual-energy X-ray Absorptiometry (DXA) (GE iDXA, Madison, WI, USA) quantified total body bone mineral content less head (BMC-LH), in full-term Samoan newborns (mean + SD, 6.2 + 6.7 days old). Results: Mean maternal age was (mean + SD) 27.9 +5.6 years, and body mass index (BMI) was 34.3 + 6.9 kg/m2. Mean offspring birth weight was 3.5 + 0.5 kg and percent body fat (total fat mass/total lean + total fat mass) was 17.8 + 3.5%. BMC-LH was positively correlated with all measured nutrients (r=0.19-0.25; all p<0.05), except for protein, fat and calcium. Multivariable linear regression models adjusted for maternal calorie intake, height and age, and offspring weight and height, revealed a positive association between maternal potassium intake and offspring total BMC-LH (β0.003, 95%CI 0.001-0.005), p<0.05), but not other bone- promoting nutrients of protein (β0.000, 95%CI -0.009-0.010, p>0.05) or calcium (β-0.005, 95%CI -0.092-0.083, p>0.05). No further associations between maternal diet and offspring BMC-LH were detected. Conclusion: These preliminary data suggest that maternal dietary intake of potassium, but not protein or calcium; in Samoans play an integral role in positive bone acquisition at birth. Therefore, encouraging pregnant women to consume healthy potassium-rich foods such as bananas, rather than potassium-rich foods high in sodium, may optimize infant bone health within this population.

FGF23 induces ventricular arrhythmias in mouse hearts mediated through the phospholipase C pathway Jonah M. Graves*, Julian A. Vallejo, Chelsea Hamill, Michael J. Wacker. University of Missouri-Kansas City School of Medicine, United States

Fibroblast growth factor 23 (FGF23) is a phosphate regulating peptide hormone released by osteocytes. It becomes markedly elevated in chronic kidney disease (CKD), for which the leading cause of death is cardiovascular disease, particularly sudden cardiac death.

Sunday Posters

Previously, we found that FGF23 increases intracellular calcium in cardiac myocytes and alters cardiac contractility in mouse ventricles ex vivo. We have since observed that FGF23 induces contractile dysrhythmias and hypothesize that these aberrant rhythms are due to ventricular muscle hyperexcitability. Since FGF23 has been shown to induce cardiac effects via fibroblast growth factor receptor 4 (FGFR4) and phospholipase C (PLC), we hypothesize that these arrhythmias are mediated through the PLC signal transduction pathway. To test this hypothesis, isolated ventricles from CD1 mouse hearts were perfused ex vivo in a modified Langendorff model and paced at 1.8 Hz. Ventricular contractility and rhythm were analyzed by assessing isometric force during treatment with vehicle or FGF23 with and without pretreatment with a PLC blocker (U73122) or an IP3 receptor antagonist (2-aminoethoxydiphenyl borate, 2-APB). Ectopic contractile events were categorized using criteria from an adjunct on the Lambeth conventions on animal arrhythmias. In order to confirm our mechanical categorizations, we measured electrocardiographic (ECG) activity and intraventricular pressure via a balloon catheter inserted in the ventricle of isolated hearts. We found that hearts perfused with FGF23 displayed increased mechanical arrhythmias in the form of ventricular premature beats (VPBs), which increased in frequency from 0.2/min at baseline to 1.8/min (p <0.001, n=11). Additionally, FGF23 induced runs of bigeminy in 4 of 11 animals and tachycardia in 6 of 11 animals. Arrhythmias were prevented when hearts were pretreated with a PLC blocker (p<0.05, n=5) or an IP3 receptor antagonist (p<0.05, n=5). ECG recordings of FGF23 treated mouse hearts (n=5) confirmed that the contractile abnormalities corresponded to premature ventricular contractions (PVCs), PVCs in bigeminy, and ventricular tachycardia. Our results show that in Langendorff perfused mouse hearts, FGF23 induces ventricular arrhythmias that are prevented by blockade of PLC and IP3 receptor signaling. Since ventricular arrhythmias represent a leading cause of morbidity and mortality in CKD patients, this pathway may represent an important therapeutic target.

Identification of Novel Notch1 Interacting Partners in Osteosarcoma Cells

Haydee Torres*[1,2], Fang Fang[1], Danielle May[1], Kyle Roux[1,2,3], Jianning Tao[1,2,3]. [1]Sanford Research, United States, [2]South Dakota State University, United States, [3]The University of South Dakota, United States

Skeletal Notch proteins regulate embryogenesis and play a critical role in skeletal development and homeostasis. Pathological Notch gain of function has emerged as a critical disease mechanism for skeletal disorders and bone cancer. Human osteosarcoma is a major malignant bone tumor found predominantly in children, and the clinical outcomes for osteosarcoma patients with recurrence and metastasis are devastating. Recently, our and other studies suggest that hyperactivation of Notch1 signaling contributes to the pathogenesis of human and murine osteosarcoma and its inhibition may be a therapeutic approach for the treatment of osteosarcoma. As protein-protein interactions are essential for most proteins function including Notch1 nuclear complexes, targeting these interactions represents a broad range of targets and potential therapeutics. Canonical Notch pathway regulates its downstream targets through a transcription complex composed of Notch Intracellular Domain (NICD), Recombination Signal Binding Protein for Immunoglobulin Kappa J Region (Rbpj), Mastermind-Like Transcriptional Coactivator 1 (MAML1), and other unknown interacting proteins in a cell type specific manner. The objective of these studies is to identify Notch1 nuclear interactome using the proximity-based labeling method, BioID, to understand key regulators of its transcriptional activity and oncogenic function in osteoblast and osteosarcoma cells. We have generated and functionally verified a BioID construct for NICD, called Myc-BioID2-NICD, in which a Myc-tag and a new version of the promiscuous biotin ligase (BirA or BioID2) was cloned in frame to the N-terminus of NICD. We have completed a BioID proteomics study and found a large set of proteins (more than 214 highly confident genes) associated with NICD, including transcriptional regulators and protein modifiers. Moreover, we found that 47 potential interacting proteins are enzymes, which are easily druggable. 14 of them also overlapped with a total of 114 proteins recently identified by a Flag-tagged N1-ICD pull-down proteomics study. Functional analysis of Notch1 potential interacting proteins with enzymatic activity are being carried out in osteosarcoma cells. This study of interaction of Notch and its partners will improve our understanding of the molecular mechanism(s) underlying cancer stem cell self-renewal and maintenance, as well as identifying new druggable candidates for molecularly targeted therapeutics in precision treatment for cancer.

The Runt domain of RUNX2 induces the migration of melanoma cells to bone

Maria Teresa Valenti*[1], Michela Deiana[1], Michela Serena[1], Samuele Cheri[1], Francesca Parolini[1], Giulia Marchetto[1], Mihaela Mina[1], Antonio Mori[1], Alberto Gandini[1], Franco Antoniazzi[1], Natascia Tiso[2], Giovanni Malerba[1], Luigi Gennari[3], Monica Mottes[1], Donato Zipeto[1], Luca Dalle Carbonare[1]. [1]University of Verona, Italy, [2]University of Padova, Italy, [3]University of Siena, Italy

The mortality rate for malignant melanoma (MM) is very high since it is highly invasive and genetically resistant to chemotherapeutic treatments. Some transcription factors modulate and affect cellular processes influencing gene expression in MM. In particular, a higher expression of the osteogenic master gene RUNX2 in melanoma cells than in normal melanocytes has been reported. To better understand the role of RUNX2 in melanoma development

and to evaluate a therapeutic target, we applied the CRISPR/Cas9 technique to explore the role of the RUNT domain of RUNX2 in a melanoma cell line. A web-based interrogation of public databases for recurrent RUNX2 genetic and epigenetic modifications in melanoma showed that the transcript upregulation is the most common RUNX2 genetic alteration, followed by genomic amplification, mutation, and, finally, by multiple changes. Additionally, altered RUNX2 is involved in dis-regulated pathways promoting tumor progression, Epithelial Mesenchymal Transition (EMT) and metastasis. The RUNT-deleted clone harboring the deletion showed reduced proliferation, reduced EMT features and reduced migration ability in zebrafish model, suggesting the involvement of the RUNT domain in different pathways. In particular, RUNT KO cells showed a reduced relative migration distance to bone as well as the expression of bone specific genes associated to tumor invasiveness. All these findings suggest that the RUNT domain may represent an important oncotarget to prevent bone metastases in Malignant Melanoma.

Activation of PI3K in the Myeloid Lineage Results in Myeloproliferative Neoplasm, Increase in Myeloid-Derived Suppressor Cells and Bone Loss

Jungeun Yu*[1], Laura Doherty[1], Evan Jellison[2], Ernesto Canalis[1], Archana Sanjay[1]. [1]UConn Musculoskeletal Institute, UConn Health, Farmington, CT 06030, United States, [2]Department of Immunology, UConn Health, Farmington, CT 06030, United States

Subjects with myeloproliferative neoplasms (MPN), which are characterized by increased expansion of the myeloid lineage, are at an increased risk of osteoporotic fractures although the underlying mechanisms are unknown. Phosphoinositide 3-kinase (PI3K) is required for osteoclast differentiation and function, and plays a role in tumorigenesis. However, its role in the pathogenesis of MPN is not known. Here we report that PI3K activation in the myeloid lineage not only confers MPN but also results in bone loss. To activate PI3K in the myeloid lineage, we crossed R26StopFLP110* conditional mice, where the ROSA26 allele harbors sequences expressing constitutively active P110 alpha (P110*) preceded by a loxP flanked STOP cassette, with Lyz2Cre/WT mice. P110* mice had splenomegaly, hepatomegaly, increased number of granulocytes in peripheral blood and accumulation of erythrocytes under the skin which worsened with age. Flow cytometry of 10-week-old P110* mice revealed enhanced myelopoiesis as documented by an increase in monocytes, macrophages in the bone marrow and an increase in macrophages, neutrophils, eosinophils in spleen-derived myeloid populations. Moreover, osteoclast precursors (OCP) were increased in both cell compartments. Micro-CT and bone histomorphometry showed that 10-week-old P110* mice had osteopenia due to an increase in osteoclast number and bone resorption. Myeloid-derived suppressor cells (MDSC) are T cell suppressors that increase in number during tumor progression and recently found to be OCP in cancer and arthritis. P110* mice harbored a 1.4-2-fold increase in CD11b+Ly6G-Ly6Chigh monocytic-MDSCs in the bone marrow and spleen, and a 3.5-fold increase in CD11b+Ly6G+Ly6Clo polymorphonuclear-MDSCs in the spleen compared to control littermates. There was a 30% decrease in CD3+ T cells of P110* mice in vivo. Supporting these observations, sorted MDSCs from the bone marrow of P110* mice, and not from control mice, reduced T cell proliferation by 40% and MDSCs differentiated into functional osteoclasts in vitro. These results show that PI3K activation in the myeloid lineage causes MPN, and accumulation of MDSCs with the capacity to differentiate into osteoclasts and resorb bone.

PGC1α deficiency negatively regulates bone mass and strength

Graziana Colaianni*[1], Luciana Lippo[1], Lorenzo Sanesi[1], Giacomina Brunetti[2], Monica Celi[3], Nunzio Cirulli[2], Giovanni Passeri[4], Janne Reseland[5], Ernestina Schipani[6], Maria Felicia Faienza[7], Umberto Tarantino[3], Silvia Colucci[2], Maria Grano[1]. [1]Department of Emergency and Organ Transplantation, University of Bari, Italy, [2]Department of Basic Medical Science, Neuroscience and Sense Organs, University of Bari, Italy, [3]Department of Orthopedics and Traumatology, Tor Vergata University of Rome, Italy, [4]Department of Clinical and Experimental Medicine, University of Parma, Italy, [5]Department of Biomaterials, Institute for Clinical Dentistry, University of Oslo, Norway, [6]Departments of Medicine and Orthopaedic Surgery, University of Michigan, United States, [7]Department of Biomedical Science and Human Oncology, Pediatric Unit, University of Bari, Italy

Peroxisome proliferator-activated receptor-γ coactivator 1-α (PGC1α) is a transcription factor regulating adaptive thermogenesis, glucose metabolism and skeletal muscle fiber type specialization. Here we show that PGC1α plays a role in skeletal homeostasis since PGC1α-deficient mice (PGC1α-/-) display impaired bone structure and increased fragility. Micro-CT of the tibial mid-shaft showed a marked decrease of cortical thickness in PGC-1α+/- (-8.4%, p<0.05) and PGC-1α-/- (-11.9%, p< 0.05) mice compared to wild type littermates. Trabecular bone was also impaired in knock out mice which displayed lower trabecular thickness (Tb.Th) (-5.9% Vs PGC1α+/+, p<0.05), whereas trabecular number (Tb.N) was higher than wild type mice (+72% Vs PGC-1α+/+, p< 0.05), thus resulting in

increased (+31.7% Vs PGC-1α+/+, p< 0.05) degree of anisotropy (DA), despite unchanged bone volume fraction (BV/TV). Notably, the impairment of cortical and trabecular bone in PGC-1α knock out mice led to a dramatic ~48,4% decrease in bending strength (p< 0.01). Bone defects were paralleled by a significant increase in osteoclast number at the cortical bone surface and in serum levels of the bone resorption marker, namely C-terminal cross-linked telopeptides of type I collagen (CTX-I) (+42% Vs PGC-1α+/+, p< 0.05), whereas no difference was observed in serum levels of N-terminal propeptide of type 1 procollagen (P1NP) among the genotypes.In PGC-1α-/-, we also found a lower expression of mRNAs codifying for Osteocalcin (Ocn) in cortical bone and for Collagen I in bone marrow stromal cells. Moreover, we found that PGC-1α−/− mice displayed a lower ratio of inguinal WAT (iWAT)/body weight and histological analysis of iWAT revealed profound ~75% decrease in adipocyte area and a lower expression of Adiponectin (AdipoQ) mRNA, whereas Leptin mRNA was several folds higher than wild type mice. Overall, results presented herein suggest for the first time that PGC-1α may play a key role in bone metabolism.

Metabolic Fuel Selection During the Osteoblast to Osteocyte Transition Thomas O'Connell*, Matt Prideaux, Yukiko Kitase, Lynda Bonewald. Indiana University, United States

Osteocytes are the most abundant bone cells in the body and play key roles in regulating bone homeostasis. However, despite the importance of these cells, we still know relatively little regarding osteoblast to osteocyte transition and how energy metabolism may change during this process.To investigate metabolism changes during osteocyte differentiation, we used the IDG-SW3 cell line, which differentiate into mature osteocyte-like cells in culture. An untargeted NMR-based metabolomics approach was applied on cells and media taken at days representing the early osteoblast (day 4), osteoid osteocyte (day 9), mineralizing osteocyte (day 18) and mature osteocyte (day 28). Metabolic profiles of both cell media and cell extracts were obtained to monitor the consumption and release of metabolites and the metabolic processes within the cells. This profiling revealed novel features of fuel selection and cellular biosynthesis that develop during differentiation. Glucose consumption is relatively stable through day 9 with little production of lactate. At day 18, there is a nearly 3 fold increase in glucose consumption along with a nearly 10 fold increase in the production of lactate suggesting a dramatic switch to aerobic glycolysis. At day 28, glucose consumption is reduced and lactate production drops to about four fold higher than at day 9 indicating a return to oxidative metabolism. A consistently high level of glycerol is produced by the cells and excreted into the media, suggesting a sustained level of lipolysis and utilization of fatty acid oxidation throughout the differentiation process. Initial qPCR analyses show elevations in some lipase and fatty acid receptor genes, consistent with increased fatty acid utilization in the mature osteocyte. Increased production of acetate by the cells is also consistent with fatty acid utilization. A distinct spike in citrate production was observed at day 9 as the cells initiate hydroxyapatite deposition within the collagenous matrix. Citrate is critical for stabilization of the apatite nanocrystals in bone and may function to stabilize the mineral surrounding the newly embedded cell. Citrate is also known to be reduced in osteoporosis, a time of osteocyte death and reduced function.These studies have identified novel changes in metabolic pathways during osteocyte differentiation, which may maintain osteocyte function while depositing and then residing within their mineralized matrix.

Mechanically-stimulated ATP release from murine bone cells is regulated by a balance of injury and repair Nicholas Mikolajewicz*[1], Elizabeth Zimmermann[2], Bettina Willie[1], Svetlana Komarova[1]. [1]McGill University, Canada, [2]Shriners Hospital for Children-Canada, Canada

Mechanical environment is an important determinant of bone health. ATP release is one of the first events induced by mechanical stimulation of bone-forming osteoblasts and bone-resident osteocytes; however, the dominant pathways of ATP release remain disputed. We examined the mechanism of ATP release from mechanically-stimulated compact bone or bone marrow-derived osteoblasts. We demonstrated that 70 ± 24 amol ATP/cell were released in response to single cell membrane deformation and 21 ± 11 to 422 ± 97 amol ATP/cell in response to turbulent fluid shear stress. Mechanical stimulation induced exocytosis of quinacrine-positive ATP-containing vesicles. Pharmacological activation of protein kinase C (PKC) potentiated vesicular exocytosis, while PKC inhibition reduced exocytosis. Unexpectedly, increase in vesicular release coincided with a significant decrease in released ATP, and vice versa. To examine the contribution of injury to ATP release, we evaluated membrane integrity during and after mechanical stimulation using membrane impermeable markers. We demonstrated that in vitro or in vivo mechanical stimuli induced magnitude-dependent repairable cell membrane injury. Ca2+/PLC/PKC-dependent vesicular release was critical for successful repair of membrane damage, suggesting that rather than delivering ATP to extracellular space, vesicular exocytosis limits the much larger efflux of intracellular ATP through damaged membranes. Prior activation of PKC/vesicular signaling improved membrane integrity and limited ATP release induced by subsequent mechanical stimulation. Our study suggests a new model of biological adaptation to mechanical forces that combines

graded perception of mechanical environment through membrane injury and an ability to effectively counteract the destructive potential of mechanical forces through membrane repair.

Association of osteosarcopenia and cognitive impairment in a community dwelling older population: The Bushehr Elderly Health (BEH) program Bagher Larijani*[1], Gita Shafiee[2], Afshin Ostovar[3], Ramin Heshmat[4], Farshad Sharifi[5], Iraj Nabipour[6]. [1]Endocrinology and Metabolism Research Center, Endocrinology and Metabolism Clinical Sciences Institute, Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of Iran, [2]Chronic Diseases Research Center, Endocrinology and Metabolism Population Sciences Institute, Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of Iran, [3]Osteoporosis Research Center, Endocrinology and Metabolism Clinical Sciences Institute, Tehran University of Medical Sciences, Tehran, Iran., Islamic Republic of Iran, [4]Chronic Diseases Research Center, Endocrinology and Metabolism Population Sciences Institute, Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of Iran, [5]Elderly Health Research Center, Endocrinology and Metabolism Population Sciences Institute, Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of Iran, [6]The Persian Gulf Tropical Medicine Research Center, Bushehr University of Medical Sciences, Bushehr, Iran, Islamic Republic of Iran

Background: The combination of sarcopenia and osteopenia/osteoporosis (Osteosarcopenia) shows a high prevalence and further adverse outcomes in elderly. Also, the prevalence of cognitive impairment increases after 60 years old. The aim of this study is to investigate the relationship between Osteosarcopenia (OS) and cognitive impairment in a large sample of older adults in Iran.Methods:A total of 2426 Iranian adults aged ≥60 years, participating in the stage II of Bushehr Elderly Health (BEH) program, a population-based prospective cohort study; were included in this study. Sarcopenia was defined as having low muscle index (<7.0 in men and < 5.4 Kg/m2 in women) with low handgrip strength (<26 Kg in men, <18 Kg in women) or low usual gait speed (<0.8 m/s). Body composition was measured by dual X-ray absorptiometry (DXA). Subjects were divided into 3 groups: 1) nonsarcopenia- nonosteopenia (normal), 2) sarcopenia /osteopenia (BMD<-1.0 SD or sarcopenia), 3) sarcopenia + osteopenia (OS). Cognitive status was assessed by Mini Mental State Examination (MMSE), Category Fluency Test (animals naming), Functional Assessment (FAST) and history of dementia. Everybody who had problem at least in one of these tests were considered as subjects with cognitive impairment and those with normal condition in all tests were assumed as normal cognition.The multivariable logistic regression was used to investigate the association between OS and cognitive impairment.Results:Of the total participants, 484 (21.8%) of subjects were normal, 51.4% of subjects had sarcopenia /osteopenia and 26.8% of participants had OS.In univariate logistic analysis, sarcopenia/osteopenia and OS increased risk of cognitive impairment to OR=1.70(1.37-2.11) and 2.68(2.09-3.43), respectively. After adjustment for age and sex, the association remained statistically significant [OR=1.27(1.01-1.60) and OR=1.47(1.12-1.91), for sarcopenia/osteopenia and OS, respectively]. The association remained statistically significant only between OS and cognitive impairment [OR= 1.37(1.04-1.80)] in the full model (adjusted for age, sex, physical activity and smoking).Conclusions:This study provides evidence that the presence of osteopenia with sarcopenia (OS) independently increases risk of cognitive impairment. Common pathways, such as mitochondrial dysfunction, may have a role in both conditions.

Building a single-cell transcriptome atlas of mouse bone marrow mesenchymal lineage cells for analyzing MSC heterogeneity Robert Tower*, Leilei Zhong, Jihwan Park, Luqiang Wang, Rojesh Shrestha, Katalin Susztak, Ling Qin. University of Pennsylvania, United States

Stem cell heterogeneity and plasticity are common features of mammalian tissues. However, owing to a lack of investigative tools, whether bone marrow MSCs are made of heterogenic subpopulations has long been suspected, but never proven. The Col2-Cre Rosa-tdTomato (Col2/Td) specifically labels all mesenchymal lineage (MLin) cells, thus providing a perfect system to comprehensively analyze subpopulations of MLin cells in vivo. In this project, we enzymatically digested endosteal bone marrow from 1-month-old Col2/Td mice and sorted for the top 1% Td+ cells, which contained all the CFU-F forming cells found in unsorted cells. Cells were subjected to single-cell RNA sequencing using the 10X Genomics drop-seq platform. After rigorous quality control and exclusion of contaminating hematopoietic and endothelial cells, we identified 2,489 MLin cells expressing ~2500 sequenced genes per cell. Unsupervised clustering with Seurat divided those cells into 8 clusters (Fig. 1A). According to known markers, they are early MSCs (Sca1, CD34), late MSCs, chondrocytes (Col2a1, Col10a1), mesenchymal bi-potent progenitors (MBPs), osteoblasts (osteocalcin, Col1a1), osteocytes (SOST), adipoprogenitor (AP) 1, and AP2 (adiponectin, Lpl, Pparg). Interestingly, plots suggest that these cells exist in a continuum, rather than in discrete states. Cell cycle analysis based on the expression levels of >90 cell cycle-related genes revealed that early MSCs are quiescent; osteocytes are the least proliferative cells;

AP1 and late MSCs are the most proliferative cells. Monocle trajectory analysis generated three differentiation directions with the first branch separating chondrocytes from MBPs and the second branch bi-pronged into osteoblasts and APs (Fig. 1B). Cells in AP clusters, particularly those in AP2, highly and specifically express Cxcl12 and LepR, resembling the previously identified CAR/LepR+ MSC population. Fluorescence imaging confirmed that in Col2/Td mice, Td+ stromal cells have reticular shape and that almost all LepR+ bone marrow cells were Td+. Interestingly, sequencing data suggests that these AP cells are a major source of cytokines and chemokines such as Scf, RANKL, VEGFs, Il6, Cxcl12, etc, indicating that they play important roles in regulating the bone marrow environment. Taken together, our work demonstrates the heterogeneity of bone marrow MSCs by identifying their novel subpopulations and delineating their relative positions along the MSC tri-differentiation axes.

Investigating the Dose-Dependent Response of Black Tea Polyphenols in SaOS-2 Cells Riley Cleverdon*, Michael D. Mcalpine , William Gittings, Wendy E. Ward. Brock University, Canada

Many epidemiological studies suggest that the consumption of black tea is associated with reduced risk of several diseases, as well as higher bone mineral density. Polyphenols present in black tea, due to their potent antioxidant capacity, may mediate potential beneficial effects. Recently, our lab has shown increased mineral deposition with supplementation of black tea polyphenols (1 µg/mL) in an osteoblast cell model (SaOS-2 cells). The purpose of this study was to determine if a dose-dependent response exists between supplementation with black tea polyphenols and mineral deposition in SaOS-2 cells. SaOS-2 cells were cultured and differentiated for 8 days at 37ºC in 5% CO2. Mineralization was induced for 5 days in the presence or absence of 0.1, 0.5, 0.75, 1, 2, 5, or 10 µg/mL of black tea polyphenols. Black loose-leaf tea (English Breakfast) was steeped in accordance to manufacturer's recommendations. Total polyphenol content (TPC) of black tea was determined using Folin-Ciocalteau's reagent with a gallic acid standard. Alizarin red staining was utilized to quantify mineral deposition (n=6, each 'n' corresponds to 4 averaged biological replicates). Cells treated with concentrations of black tea polyphenols at or greater than 0.75 µg/mL resulted in a significantly greater (p<0.05) mineral deposition relative to control (% of control, 0.75µg/mL: 240% ± 0.44, 1µg/mL: 300% ± 0.36, 2µg/mL: 351% ± 0.57, 5µg/mL: 358% ± 0.81, 10µg/mL: 354% ± 0.96). Supplementation with 1, 2, 5, and 10 µg/mL of black tea polyphenols did not significantly differ in mineral deposition from one another. Intriguingly, this data exhibits a positive dose-dependent response which peaks at approximately 1 µg/mL of black tea polyphenols and higher concentrations resulted in negligible increases in mineral deposition, indicating that at higher concentrations of black tea polyphenols, the positive dose-dependent relationship is lost. These findings suggest that there is a dose-dependent response between black tea polyphenols and mineral deposition. The studied doses represent dietary through to supplemental levels of black tea polyphenols. Key cell signaling pathways are currently being analyzed to determine how black tea polyphenols mediates its effect in SaOS-2 cells.

The impact of tissue oxygenation on antibacterial immunity during Staphylococcus aureus osteomyelitis Caleb Ford*[1], Aimee Wilde[1], Nicole Putnam[1], Jacob Curry[2], Jim Cassat[1,2]. [1]Vanderbilt University, United States, [2]Vanderbilt University Medical Center, United States

Osteomyelitis is a highly morbid inflammatory state of bone most commonly triggered by Staphylococcus aureus infection. During osteomyelitis, the structural matrix and vascular architecture of bone is damaged, resulting in regions of necrotic, avascular tissue that increase risk of chronic infection. Extreme hypoxia occurs during osteomyelitis due to a disrupted vascular supply, inflammation, and the metabolism of invasive S. aureus. The host responds to hypoxia by initiating hypoxia-inducible factor (HIF) signaling, which is implicated in the regulation of bone development, bone healing, and antibacterial immunity.

However, the role of hypoxia and HIF signaling during osteomyelitis is unknown and may serve as an important clinical target to combat invasive infection. Using a murine model of post-traumatic S. aureus osteomyelitis, we found intense hypoxyprobe staining at the infectious focus that is out of proportion to hypoxyprobe staining of non-infectious fracture healing. Furthermore, cytokine profiling of infected femur homogenates demonstrates that VEGF, a well-characterized target of HIF signaling, is increased in vivo during osteomyelitis relative to mock-infected bone, consistent with the notion that HIF signaling is activated during invasive infection of bone. Via western blot, we found that stimulation with bacterial supernatants induces HIF-1a accumulation in primary osteoblasts not only under 1% O2 (hypoxia), but also when grown in 21% O2 (normoxia). These in vitro data led to the hypothesis that tissue oxygenation influences antibacterial immunity during S. aureus osteomyelitis. To begin testing this hypothesis, cytokine abundance was tested in conditioned media from primary murine osteoblasts that were grown in normoxia and hypoxia and stimulated with bacterial supernatants. The data indicate that osteoblasts sense and respond to both bacterial stimulation as well as environmental hypoxia. While bacterial supernatant stimulation almost universally induces cytokine production in osteoblasts compared to vehicle, hypoxia significantly altered the inflammatory profile of S. aureus-stimulated osteoblasts. Hypoxia augments bacterially induced VEGF production and inhibits production of important neutrophil-chemotactic cytokines such as KC, MCP-1, MIP-1b, and RANTES. These data and future in vivo experiments will further elucidate how oxygenation impacts skeletal cell biology and the innate immune responses to bacterial pathogens.

Antagonism between Bone Morphogenetic Protein and Activin signaling pathways in osteoprogenitor cells Madeline Totten*, Sydni Yates, Kelli Jestes, Sylvia Chlebek, Jordan Newby, Jon Arthur, Jonathan Lowery. Division of Biomedical Science, Marian University College of Osteopathic Medicine, United States

Osteoporosis is a disease characterized by low bone mineral density due to the rate of bone resorption exceeding that of bone formation. Substantial evidence indicates the Bone Morphogenetic Protein (BMP) pathway promotes bone formation through action of the effectors SMAD1/5/8 while the Activin pathway negatively influences bone mass through action of the effectors SMAD2/3. Recent studies suggest that BMPs and Activins regulate bone mass in a see-saw-like mechanism. Here, we seek to test this hypothesis in vitro via signaling responsiveness assays using pathway-specific western blot analyses in the osteogenic murine bone marrow stromal cell line W-20-17. We first confirmed that W-20-17 cells exhibit basal activation of SMAD1/5/8 and SMAD2/3 under serum-restricted conditions. Moreover, treatment with Follistatin, which sequesters Activin ligands in the extracellular environment, leads to an increase in BMP pathway activation. To determine the molecular mechanism allowing for this relationship, we treated W-20-17 cells with SB431542, which is an intracellular inhibitor of Activin signaling that functions downstream of receptor engagement, and found no effect on BMP pathway activation. In contrast, treatment of W-20-17 cells with BMP pathway inhibitor Noggin had no effect on Activin pathway activation despite robust inhibition of BMP signaling. Collectively, our results suggest Activin-mediated repression of BMP signaling in these cells is ligand-dependent but occurs upstream of SMAD2/3 activation. Gene expression analyses indicate that W-20-17 cells express Activin A and its receptors ALK4, ACVR2A, and ACVR2B. Given that ACVR2A and ACVR2B also have high affinity for BMP ligands, this raises the possibility that Activin-mediated repression of BMP signaling may occur via competition for a shared pool of receptors. Over-expression studies coupled with osteoblast activity assays are currently underway to examine this hypothesis. Collectively, our work seeks to elucidate the mechanism(s) that regulate antagonism of BMP and Activin signaling pathways in the osteoblast lineage to identify novel opportunities for treating low bone mass in humans.

Pattern recognition and IL-1 receptor signaling drive host immunity and altered bone homeostasis during Staphylococcus aureus osteomyelitis Nicole Putnam*, Laura Fulbright, Jacob Curry, Jenna Petronglo, Jim Cassat. Vanderbilt University Medical Center, United States

Osteomyelitis is an invasive and debilitating infection of bone, most frequently caused by the Gram positive pathogen Staphylococcus aureus. Treatment of osteomyelitis is difficult, in part due to pathogen-induced bone destruction that limits antibiotic penetration to the infectious focus. Understanding the mechanisms by which bacteria alter bone homeostasis is therefore a critical step in deciphering the pathogenesis of osteomyelitis. The objectives of this study were to define critical immune responses during osteomyelitis, and to understand how bone homeostasis is altered by innate sensing of bacteria. We hypothesized that pattern recognition receptor (PRR) signaling pathways are necessary for antibacterial defenses during osteomyelitis, but may contribute to pathogen-associated bone loss. To test this hypothesis, we used both in vitro assays and a murine osteomyelitis model to determine how S. aureus alters osteoclastogenesis and triggers bone loss in vivo. We discovered that in vitro, S. aureus dramatically enhances osteoclastogenesis of bone marrow macrophage (BMM)-derived pre-osteoclasts. In vivo, S. aureus triggers profound cortical bone destruction locally, but also increases the number of osteoclasts at trabecular sites distant to the infectious focus. To define how PRR signaling contributes to these processes, we used mice lacking the critical PRR signaling adaptor MyD88 or the Gram positive-sensing PRRs TLR2 and TLR9. Staphylococcal enhancement of osteoclastogenesis in vitro was found to be dependent on both MyD88 and TLR2. However, TLR2 was dispensable for both antibacterial defenses and pathogen-induced bone destruction in vivo. In contrast, both MyD88- and TLR9-deficient mice sustained significantly increased bacterial burdens during osteomyelitis. Since TLR9-deficiency also failed to impact bone destruction in vivo, we subsequently investigated the role of IL-1R signaling during osteomyelitis. Mice lacking the IL-1R were highly susceptible to S. aureus proliferation during osteomyelitis, yet had significantly greater new bone formation and a smaller increase in trabecular osteoclast number. Collectively, these data suggest divergent roles of IL-1 signaling in antibacterial host defense and pathologic bone remodeling during osteomyelitis. Additionally, MyD88-dependent PRR signaling significantly impacts osteoclastogenesis in vitro, but these effects may be masked in vivo by innate immune responses and inflammatory cytokines such as IL-1.

AP-002: A novel inhibitor of osteoclast differentiation and function without disruption of osteogenesis Yongqiang Wang*[1], Yixue Mei[1], Yushan Song[1], Carly Bachus[1], Chunxiang Sun[1], Hooshmand Sheshbaradaran[2], Michael Glogauer[1]. [1]University of Toronto, Canada, [2]Altum Pharmaceuticals Inc, Canada

AP-002 is a novel clinical stage oral gallium based compound. In this study we examined the effects of AP-002 on osteoclastogenesis, fusion and osteoclast function, as well as its effects on osteoblastogenesis. The early stages of osteoclast differentiation were impaired by AP-002, as evidenced by the significant down-regulation of TRAP and cathepsin K mRNA expression in murine osteoclast precursor cells RAW264.7 treated with AP-002 in the presence of RANKL. AP-002 (1 uM) was also found to block fusion of osteoclasts in these cultures. Importantly, AP-002 caused these inhibitory effects without causing osteoclast cell death in these cultures, which was in contrast to zoledronic acid (ZA) controls, where osteoclastogenesis inhibition and cell death overlapped. AP-002 is further differentiated from ZA in that it did not inhibit small GTPase Rac1 activation in these cultures. AP-002 had a similar inhibitory effect on RANKL-induced mouse primary bone marrow monocytes (BMMs) fusion. Similarly, human blood monocytes treated with AP-002 failed to form TRAP-positive cells. Furthermore, mouse BMMs-derived mature osteoclasts seeded on dentine slices and treated with AP-002 exhibited dramatically reduced numbers of resorption pits and resorption area. Analysis of AP-002 impact on RANKL-induced osteoclastogenesis related gene expression (in RAW264.7 cells) by gene microarrays, showed that AP-002 significantly reverses the effect of RANKL on 115 genes. These include several key osteoclast-differentiation/function associated genes such as: scinderin, Ocstamp, Atp6v0d2, Oscar, Rhou, Usp18, MMP9 and Trim30. Microarray data were confirmed by RT-qPCR. AP-002 is however not just a RANKL inhibitor, as for at least 50 genes, AP-002 effect adds to RANKL effect. Furthermore, AP-002 has no effect on NFATc1 mRNA levels, the master RANKL induced transcription regulator. The difference between AP-002 and ZA is also seen in its effects on osteoblastogenesis. Osteoblast mineralization was promoted by AP-002 (0.01-3.0 µM), whereas ZA showed toxicity to osteoblasts at the concentration >0.5 µM. ZA therefore has no therapeutic window in its toxic effect on osteoclasts and osteoblasts, while AP-002 has a therapeutic window, and in fact AP-002 promotes osteogenesis in this therapeutic window. We conclude therefore that AP-002 is a promising new anti-bone resorption agent, with a mechanism of action different from other currently marketed anti-bone resorption agents.

MicroRNA-335-5p Inhibits Alveolar Bone Resorption and Inflammation in Periodontitis Junxiang Lian*[1,2], Qisheng Tu[1], Jake Chen[1,3]. [1]Division of Oral Biology, Tufts University School of Dental Medicine, United States, [2]State Key Laboratory of Oral Diseases, West China School of Stomatology, Sichuan University, United States, [3]Department of Cellular, Molecular, Developmental Biology, United States

Objectives: Bone homeostasis is delicately maintained by osteoblasts and osteoclasts (OCs). Our laboratory has identified and characterized miR-335-5p that promotes osteoblast differentiation and bone regeneration in miR-335-5p transgenic (335-Tg) mice via inhibiting Wnt antagonist DKK1. This study was to investigate, for the first time, the effects of miR-335-5p constitutive overexpression on OC activity and experimental periodontitis (EP). Materials and Methods: OC differentiation of RAW264.7 cells were inducted by RANKL, and miR-335-5p mimics and inhibitor were transfected into RAW264.7 separately under the same culture condition. The level of miR-335-5p was detected via qRT-PCR. Expression of TRAP, Cathepsin K and MMP9 were examined and TRAP staining was performed to observe OC formation. To examine the effect of miR-335-5p on periodontitis, EP model was constructed by ligature on both sides of maxillary second molar in 8-week old male 335-Tg mice and C57BL/6 wild type (WT) mice. After 2 weeks of ligation, mice were sacrificed. For alveolar bone morphology observation and analysis, samples were scanned with 3-dimensional µCT, and the CEJ-ABC distance (cementoenamel junction to the alveolar bone crest) was measured at 6 predetermined points on buccal and palatal sides of treated molars. The levels of IL-1β and IL-6 in EP gingival were detected by qRT-PCR.Results: Expression level of miR-335-5p declined remarkably at the day 4 of osteoclastogenesis when OCs were fully developed. RAW264.7 cells transfected with miR-335-5p mimics hardly developed into mature OCs, which was demonstrated by the reduced level of TRAP, Cathepsin K, MMP9 and weakened TRAP staining. MiR-335-5p overexpression reduced alveolar bone loss and osteoclast activity, and attenuated gingival inflammation level (IL-1β and IL-6) compared with WT group.Conclusion We found that while miR-335-5p level decreased during OC differentiation, exogenous overexpression of miR-335-5p could significantly suppress this process. As a result, periodontitis in 335-Tg mice were less severe than that in WT mice due to the inhibiting effect on OCs and anti-inflammatory effect of miR-335-5p. Taken together, our results for the first time demonstrate that constitutive overexpression of miR-335-5p inhibits osteoclast differentiation and suppresses periodontitis in mice suggesting a promising and potent role of miR-335-5p in treating bone-loss disorders including periodontitis.

(A) Reduced expression of miR-335-5p was detected at the 4th day of RAW264.7 cells osteoclast differentiation.(B, C, D)The levels of TRAP, CTSK, MMP9 decreased dramatically in RAW264.7 cells transfected with miR-335-5p mimics compared with negative-control mimics after being cultured with RANKL for 4 days (E)Multinucleated giant cells differentiation was markedly inhibited in cells transfected with miR-335-5p mimics, which was confirmed by TRAP staining. (F)Experimental periodontitis (EP) model was generated on miR-335-5p-transgenic and wild type mice, respectively.(G)Less alveolar bone loss was observed in 335-Tg mice from the data of alveolar bone loss analyzed by µCT and measured distances from the cementoenamel junction (CEJ) to the alveolar bone crest (ABC), which were presented by µm. (I) The levels of IL-1β (a) and IL-6 (b) in gingival of 335-Tg EP group were found downregulated in comparison with WT group shown by qRT-PCR.

PPARγ: A Molecular Brake for Osteocyte Energy Metabolism and Bone Mass Sudipta Baroi*[1], Lance Stechschulte[1], Amit Chougule[1], Patrick Griffin[2], Beata Lecka-Czernik[1]. [1]University of Toledo College of Medicine, United States, [2]Scripps Research Institute, United States

Diabetes impairs systemic energy metabolism and affects bone which is reflected in low material quality and susceptibility to fractures. The etiology of diabetic bone disease is unclear, however it includes attenuation of bone remodeling. Plethora of evidence indicate that bone and energy metabolism share the same regulatory mechanisms including an activity of PPARγ, which simultaneously regulates cellular and systemic energy metabolism and is a key regulator of bone remodeling process. We hypothesized that, PPARγ plays an important role in regulation of energy metabolism in osteocytes (OT), which comprise 95% of bone

cells and play an essential role in regulation of bone remodeling. To test this hypothesis, we developed osteocyte specific PPARγ knock out animals (γOTfl/fl mice) using Cre-LoxP technology. We monitored these mice from 2 to 6 months of age for bone mineral density (BMD), body composition using NMR, and energy expenditure using indirect calorimetry. In addition, the PPARγ transcriptome in OT was analyzed using next generation sequencing (NGS). In a separate set of experiments, PPARγ effect on cellular energy metabolism was measured using Seahorse technology in OT-like MLO-A5 cells with PPARγ KD with lentiviral expression of shRNA. As compared to WT, male γOTfl/fl mice had higher oxygen consumption, carbon dioxide production, heat generation and increased locomotion at all analyzed ages. Females have opposite metabolic phenotype up to 5 mo of age, which at 6 mo shifts to that observed in males. γOTfl/fl mice have higher lean mass and higher BMD, but are insulin intolerant, as compared to age-matched WT. Activation of PPARγ in OT upregulates genes associated with lipid and carbohydrate metabolism. Surprisingly, PPARγ KD in MLO-A5 cells increases oxidative phosphorylation and ATP production. We conclude that PPARγ in OT acts as a molecular brake that regulates the extent of energy production and utilization, and OT function. When this brake is no longer active, as in γOTfl/fl mice, there is an increase in energy demand by OT which is reflected in elevated systemic energy metabolism. In support to this conclusion, another group has recently reported increased glucose uptake in bone of mice with PPARγ KO in OT. It is unclear at this point whether increased BMD is a result of increased energy metabolism or it results from different, but PPARγ-specific, mechanism in OT. These specific questions and relationships are currently under study.

Assessment of bone density using QCT on single and dual energy CT data. An Ex-vivo Study on Human Femur Philippe P Wagner*[1], Jean-Paul Roux[1], Quentin Chuzel[2], Francois Duboeuf[1], Roland Chapurlat[1,2], Helene Follet[1], Jean-Baptiste Pialat[2]. [1]Univ Lyon, Université Claude Bernard Lyon 1, INSERM, Lyos UMR1033, Lyon, France, [2]Hospices Civils de Lyon, Lyon, France

Introduction: Opportunistic diagnosis of osteoporosis during routine computed tomography (CT) may allow for earlier recognition of undiagnosed fracture. Mono energy multi-slice CT (MSCT) allows accurate assessment of bone density using calibration phantom and post-processing convolution kernel. Dual-energy CT (DECT) can produce a mono-energetic reconstruction from two different energy spectra. Depending on the convolution kernel selected (bone or standard), the ability to obtain accurate and reliable areal bone mineral density (aBMD) or bone mineral content (BMC) values has been questioned. The objective of this study was to quantify image inter-reliability filtering measurements of human ex-vivo femurs.Methods: Forty femurs from elderly donors were analysed for aBMD and BMC with the Dual x-ray absorptiometry (DXA) method. Two acquisitions (MSCT and DECT) were performed (Revolution CT™, GE Healthcare, USA) and reconstructed using either sharp kernel ("bone" for spatial resolution) or a smooth kernel ("standard" for contrast resolution). Density assessment was performed with a dedicated software (QCT PRO®, Mindways Software Inc., Austin, TX, USA)Statistics: Inter-reliability's ICC was assessed with a single measurement, absolute agreement, 2-way mixed-effects model. 95% confidence intervals were obtained by bootstrapping. Pearson coefficients were used to assess linear correlation.Results (see Table): With DXA, comparing kernels and MSCT, a significant correlation was found for aBMD and BMC: r=0.83-0.92 (p<0.001); a good to excellent agreement: ICC=0.83-0.92 and a negligible random measurement bias (<5%). With DXA, comparing kernels and DECT acquisition, a significant correlation was found for aBMD and BMC: r=0.84-0.94 (p<0.001); a good to excellent agreement: ICC=0.84-0.93; and a negligible random measurement bias (<5%). Comparing MSCT to DECT, a significant correlation was found for aBMD and BMC: r=0.93-0.99 (p<0.001); a good to excellent agreement: ICC=0.93-0.99; and a negligible random measurement bias (<2%). ConclusionCompared with DXA, we showed that aBMD and BMC assessment could be measured ex-vivo on femurs with a high inter-reliability regardless of the convolution kernel for both DECT and MSCT acquisitions. The mono-energetic reconstruction from a DECT do not disturb the ability to evaluate aBMD and BMC, independently of the convolution kernel filtering.

High Levels of Abdominal Aortic Calcification Predict Higher Health Care Costs John Schousboe*[1,2], Tien Vo[2], Lisa Langsetmo[2], Brent Taylor[2], Allyson Kats[2], Susan Diem[2], Pawel Szulc[3], Joshua Lewis[4], Kristine Ensrud[2]. [1]HealthPartners Institute, United States, [2]University of Minnesota, United States, [3]INSERM UMR 1033, University of Lyon, Hospices Civils de Lyon, France, [4]University of Western Australia, Australia

Purpose: Greater abdominal aortic calcification (AAC) assessed on lateral spine radiographs or densitometric images obtained at the time of bone densitometry is associated with increased risks of cardiovascular disease and all-cause mortality. However, to date no studies have assessed whether or not greater AAC is associated with higher health care burden and utilization. Our purpose was to estimate the associations of AAC with subsequent total and outpatient health care costs acute hospitalization, and post-hospital skilled nursing facility (SNF) care, before and after adjusting for known cardiovascular disease (CVD) risk factors. Methods: AAC was scored on lateral lumbar spine x-rays obtained at the baseline visit of the Osteoporotic Fractures in Men (MrOS) study, using a validated 24-point scale. Total and outpatient health care costs, acute hospital stays, and SNF stays were identified from Medicare Fee for Service claims over the 36 months following the baseline visit. The associations of AAC with total and outpatient health care costs were estimated with generalized linear models using gamma distribution and log link, and with hospital and SNF stays with logistic models.Results: Among 5994 men aged 65 and older enrolled in MrOS at baseline, 5083 had lateral spine x-rays interpretable for AAC and complete data for covariates; 2340 men (mean age 73.5 years) were also enrolled in Medicare FFS for 36 months after the baseline visit. Annualized median (IQR) total health care costs (2017 dollars) were $2209 (961-5960), $2932 (1112-8060), $3231 (1335-8774), and $4613 (1675-10881) for those with, respectively, AAC scores of 0-1, 2-4, 5-8, and ≥ 9. After consideration of CVD risk factors and diagnoses (Table), men with AAC level ≥ 9 compared with those with AAC level 0-1 had 29% and 43% higher total and outpatient costs, and 1.5- and 2.5-fold higher odds of ≥1 hospital stay and ≥1 SNF stay.Conclusion: Greater levels of AAC assessed using lateral spine radiographs performed for vertebral fracture detection are a marker of individuals with higher health care costs and utilization, even after accounting for clinical CVD risk factors and diagnoses. Further studies of clinical potentially modifiable characteristics associated with AAC that are driving health care utilization) are needed.

Long-term immobilization is associated with increased cortical porosity, osteocyte deficiency and high matrix mineralization Tim Rolvien*[1], Petar Milovanovic[2], Felix N. Schmidt[1], Matthias Krause[1], Klaus Püschel[3], Robert O. Ritchie[4], Michael Amling[1], Björn Busse[1]. [1]Department of Osteology and Biomechanics, University Medical Center Hamburg-Eppendorf, Germany, [2]Laboratory for Anthropology, Institute of Anatomy, Faculty of Medicine, University of Belgrade, Serbia, [3]Department of Legal Medicine, University Medical Center Hamburg-Eppendorf, Germany, [4]Materials Sciences Division, Lawrence Berkeley National Laboratory, United States

Immobilization as a result of long-term bed rest can lead to pronounced bone loss. Due to their distribution throughout the bone matrix and remarkable interconnectivity, osteocytes are the major mechanosensors in bone and translate mechanical into biochemical signals to trigger bone remodeling. To test whether immobilization affects the characteristics of the osteocyte network in human bone, femoral diaphyseal cortical bone specimens were analyzed in 20 aged formerly bedridden immobilized female patients and compared to eleven primary osteoporosis cases as well as seven young patients. Cortical porosity, osteocyte number and lacunar area, the frequency of hypermineralized lacunae (N.Mn.Lc/B.Ar), as well as cortical bone calcium content (CaMean) were assessed using bone histomorphometry and quantitative backscattered electron imaging. Bone quality characteristics and local mechanical competence were further assessed by Fourier transform infrared (FTIR) spectroscopy and reference point indentation, respectively. In immobilization cases, the cortical porosity was drastically reduced, while the overall matrix mineralization was significantly increased compared to osteoporotic bone (p=0.027, p=0.021, respectively) (Fig. 1 A-D), which was associated with a lower indentation distance increase. The number of osteocytes, osteocyte lacunar size and canaliculi showed a declining pattern from young to osteoporotic cases with further diminishment in immobilization cases (Fig. 1 E-H), whereas the number of hypermineralized lacunae changed in an opposing pattern reaching 71% more mineralized lacunae in immobilization. In conclusion, reduced osteocyte numbers and impaired connectivity in immobilization are associated with a dramatic bone loss pattern, reflecting a phenotype clearly distinguishable from postmenopausal osteoporosis. Immobilization periods may lead to loss of survival signals for osteocytes, provoking bone loss that is even higher than in osteoporosis states, while osteocytic osteolysis remains absent in immobilization.

Fragility Fracture Risk Reduction in Women with Breast Cancer on Aromatase Inhibitors Treated with Anti-Osteoporosis Therapy Yu-Chien Cheng*, Cydney Bullock, Shriya Gandhi, Andrea Sterenstein, Megan Randall, Sara Ahmad, Samarthkumar Thakkar, Michael Morkos, Garnet Meier, Sanford Baim. Rush University Medical Center, United States

The use of aromatase inhibitors (AI) for treatment of breast cancer is associated with significant loss of bone mineral density (BMD) and increased fracture risk. We aimed to determine whether concurrent AI and anti-osteoporosis therapy (anti-OP) is associated with reduced risk in fragility fractures in an oncology referral center spanning April 2011 to October 2017. Inclusion criteria included women with breast cancer diagnosis and AI use. Exclusion criteria included bone metastasis, AI use < 12 months, and inadequate clinical information. Longitudinal data on the use of AI and anti-OP therapies, fragility fractures, and baseline BMD were chart reviewed. Eligible women were grouped according to whether an anti-OP agent was used for a minimum duration of 12 months during AI or not. Hazard ratios of various anti-OP agents for fragility fractures were assessed using Cox regression analysis. Of 1519 eligible women, 64% were Caucasians. The mean age at AI initiation was 63 ±10 years. The group treated with anti-OP agents (N=346) had greater number of fragility fractures prior to AI initiation compared to the untreated group (10% vs 6%, P<0.05) and greater number of women diagnosed with osteopenia (41% vs 27%, P<0.05), and osteoporosis (24% vs 4%, P<0.05) at baseline. Anti-OP regimens consisted of oral bisphosphonates (BP) (N=183) for a median of 37 months (interquartile range [IQR] 24, 60), i.v. BP including zoledronate 4 mg every 6 months (N=10) and 5 mg every 12 months (N=30) for 30 months (IQR 17, 45), and denosumab 60 mg every 6 months (N=122) for 22 months (IQR 17, 28). Thirty-one fragility fractures (9%) occurred in women on anti-OP agents, compared to 98 (8%) in the untreated group (P>0.05). Time to first fragility fractures was 7.5 (±3.0) years in women on anti-OP agents vs 6.9 (±3.6) years in women without anti-OP agents (P>0.05). Incidence rates of fragility fractures were similar: 1.5 per 100 person-years (95% CI: 1.1-2.2) in the anti-OP treated women vs 1.7 per 100 person-years (95% CI: 1.4-2.0) in the untreated group (P>0.05). Among various anti-OP therapies, lower incidence rate of fragility fractures was observed in women on denosumab: 0.5 per 100 person-years (95% CI: 0.2-1.7) vs 1.7 per 100 person-years (95% CI: 1.4-2.0) in the untreated group (P<0.05). Hazard ratio for fragility fractures was 0.3 (95% CI: 0.10-0.95, P<0.05) with denosumab therapy but non-significant with BP after multivariable regression adjusting for age at AI initiation, baseline BMD, and presence of fragility fractures prior to AI. In conclusion, denosumab therapy during AI was associated with a lower incidence rate of fragility fractures and 70% fracture risk reduction. No significant fragility fracture reduction was observed with oral or i.v. BP treatment. In patients at high risk for fracture, denosumab should be considered as the preferred therapy prior to initiation of AI therapy.

Impact of Thyroid Hormone Therapy on Bone Health in Older Adults with Subclinical Hypothyroidism: a Randomized Clinical Trial Elena Gonzalez Rodriguez*[1,2], Axel Lennart Löwe[3,4], Cinzia Del Giovane[3], Martin Feller[3,4], Patricia Kearney[5], Jacobijn Gussekloo[6], Simon P. Mooijaart[6], Rudi Gj Westendorp[7], David J Stott[8], Daniel Aeberli[9], Doug Bauer[10], Didier Hans[1], Nicolas Rodondi[2,3]. [1]Center of Bone Diseases, Rheumatology Unit, Bone and Joint Department, CHUV, Switzerland, [2]Endocrinology, Diabetology and Metabolism Unit, Internal Medicine Department, CHUV, Switzerland, [3]Institute of Primary Health Care (BIHAM), University of Bern, Switzerland, [4]Department of General Internal Medicine, Inselspital, Bern University Hospital, University of Bern, Switzerland, [5]Department of Epidemiology and Public Health University College Cork, Ireland, [6]Departments of Gerontology and Geriatrics Leiden University Medical Center, Netherlands, [7]Department of Public Health and Center for Healthy Aging, University of Copenhagen, Denmark, [8]Institute of Cardiovascular and Medical Sciences, University of Glasgow, United Kingdom, [9]Department of Rheumatology and Clinical Immunology/Allergology, Bern University Hospital, Switzerland, [10]Departments of Medicine, Epidemiology and Biostatistics, University of California, United States

Introduction: The deleterious effect of high thyroid function on bone even at high-normal levels is well established. While subclinical hypothyroidism does not appear to impact on bone health, little evidence exists on the effect, if any, of levothyroxine therapy in subclinical hypothyroidism. The only data are conflicting results from 4 small randomized clinical trials (N= 17 to 73), from which only one showed a significant decrease of spine bone mineral density (BMD) accompanied by an increase in bone turnover markers (BTMs).Aim: To assess the effect of levothyroxine treatment on BMD, and crosslaps (CTX) and P1NP BTMs, in older adults with subclinical hypothyroidism.Methods: Randomized, double-blind, placebo-controlled trial, bone substudy of the TRUST trial on levothyroxine substitution in community-dwelling adults over 65 years with subclinical hypothyroidism, with a TSH target range 0.40 to 4.59 mIU/l. Participants from TRUST study centers in Switzerland were included without any additional exclusion criteria. Linear regression analysis on BMD (measured by dual-energy X-ray absorptiometry, n=117) and BTMs (measured by automated assays, Roche Elecsys, n=190) changes from baseline to 1-year follow-up, adjust-

ed for gender, were conducted.Results: All 117 participants completed the study (levothyroxine n=59); after application of ISCD guidelines, 105 and 114 DXA images for lumbar spine and hip respectively were included. At baseline, participants mean±SD values were: age, 74.1±5.6 years; BMI, 27.0±4.7 kg/m2; TSH, 6.4±2.0 mIU/l; free T4, 13.58±1.88 pmol/l; 43% were women. Baseline mean BMD: spine, 1.128±0.179 g/cm2; total hip, 0.969±0.168 g/cm2; and hip neck, 0.897±0.147 g/cm2. Baseline characteristics were balanced between groups.At 1 year, lumbar BMD change was similar in levothyroxine treated participants as compared to placebo in non-adjusted and gender-adjusted analysis (adjusted: +0.015 g/cm2, 95%CI [-0.0007 to 0.03], p=0.062) . There was no difference between the two groups in either analysis in total hip BMD change (lowest p-value=0.984) or hip neck BMD change (lowest p-value= 0.8059). BTMs changes were also similar in both groups (levothyroxine vs. placebo, adjusted): CTX +9.96 ng/l, 95%CI [-21.75 to 41.67], p=0.536, and P1NP +2.35 μg/l, 95%CI [-3.08 to 7.77], p=0.394.Conclusion: These data provide no evidence of a negative impact of levothyroxine treatment in subclinical hypothyroidism on bone density after one year of treatment.

PF708, a Therapeutic Equivalent/Biosimilar Teriparatide Candidate, Demonstrates Comparable Clinical Profiles Relative to Forteo in Osteoporosis Patients Hubert Chen*[1], Michael Noss[2], Jonathan Lee[1], Hongfan Jin[1], Carrie Schneider[1], Christine Thai[1]. [1]Pfenex Inc, United States, [2]Synexus, United States

PF708 is a teriparatide drug candidate being developed as a therapeutic equivalent/biosimilar to Forteo, which is approved for the treatment of osteoporosis patients at high risk of fracture. PF708 was previously shown to be bioequivalent to Forteo in healthy subjects (NCT02656810). In this study (NCT03002428), we compared the long-term effects of PF708 and Forteo in a 24-week, randomized, open-label, parallel-arm study in male and postmenopausal female osteoporosis patients in the US.We enrolled 181 patients: 90 (65 female/25 male) received PF708 and 91 (66 female/25 male) received Forteo. 82 patients completed the study in the PF708 group vs. 81 in the Forteo group. The primary endpoint was anti-drug antibody (ADA) incidence. Secondary endpoints included mean percentage changes in lumbar-spine bone mineral density (BMD), median percentage changes in bone turnover markers (BTM) and pharmacokinetic (PK) parameters after the first dose. Safety endpoints were incidences of adverse events (AE) and serious adverse events (SAE). Two PF708-treated patients (2.3%) and two Forteo-treated patients (2.2%) developed ADA during the study. These low rates of immunogenicity are consistent with historical Forteo results (~3%). At Week 24, there were two ADA-positive findings for PF708 vs. none for Forteo, but the difference was not statistically significant (P=0.50, Fisher's exact test). All PF708 ADA findings were low in titer (1:1) and returned to nondetectable during follow-up measurements. One PF708 patient had in vitro neutralizing activity transiently detected at Week 4, however this finding did not correlate with a loss of pharmacological activity. There were no apparent safety issues related to ADA or neutralizing activity findings.PF708 and Forteo demonstrated comparable effects on lumbar-spine BMD (Figure 1A) and two BTM (Figure 1B): N-terminal propeptide of type 1 procollagen (P1NP), a marker of bone formation, and cross-linked C-terminal telopeptide of type 1 collagen (CTX), a marker of bone resorption. There were no statistically significant differences between PF708 and Forteo in BMD and BTM. PK profiles after PF708 or Forteo injection were comparable. There were no significant imbalances in AE incidences or severity profiles between PF708 and Forteo.These results indicate that PF708 and Forteo have comparable profiles in osteoporosis patients and support the development of PF708 as a therapeutic equivalent/biosimilar candidate to Forteo.

Fragility Fractures after Initiation of a Drug Holiday in a Real Life Setting Michael Morkos*[1,2], Alessandra Casagrande[1], Paul Mahrous[1], Muriel Tania Go[2], Hasan Husni[2], Mirette Hanna[1], Sara Bedrose[2], Dingfeng Li[2], Yu-Chien Cheng[1,2], Sanford Baim[1]. [1]Rush University Medical Center, United States, [2]John H. Stroger, Jr. Hospital of Cook County, United States

We aimed to assess the difference in fractures rate between patients who were placed on drug holiday (DH) after minimum adequate therapy versus those who continued therapy (CT) in a real-life setting. This is a retrospective cohort study in a tertiary academic center in Chicago, IL. Inclusion criteria involved adults (aged ≥18 years) who received minimum adequate therapy (bisphosphates, raloxifene, or denosumab ≥ 3 years, or teriparatide ≥ 18 months), otherwise, patients were excluded. Of 1,814 charts randomly selected and reviewed, 274 patients met the inclusion criteria. In our cohort, females were 90.9%, White 50.0%, African American 40.5%, and Latino 8.0%. A DH was initiated in 43.4% of the total cohort. In the DH versus CT cohorts, mean duration of therapy was 5.7±2.3 vs 6.0±2.6 years (P<0.01), total duration of follow up 7.8±2.7 vs 6.1±2.9 years, and fractures occurred in 9.2% vs 11.7% respectively, not statistically significant. Further fracture risk stratification was used, high risk patients were defined as having a dual energy X-ray absorptiometry (DXA) with T-score ≤2.5 at the lumbar spine, femur neck, total hip, or distal 1/3 radius (DXA HR), history of fragility fracture, and/or FRAX risk assessment with probability of major osteoporotic fractures ≥20% or hip fractures ≥3% (FRAX HR). Fragility fractures in high risk versus lower risk patients in the DH cohort based on FRAX HR was 13.5% versus 6.0% (P=0.14), combined FRAX HR and DXA HR was 11.3% versus 6.3% (P=0.28), and based on the presence of fragility fractures during therapy was 14.3% versus 8.2% (P=0.30), respectively. Fragility fractures in high risk versus lower risk patients in the CT cohort based on FRAX HR were 16.5% versus 7.1% (P=0.01), combined FRAX HR and DXA HR was 13.2% versus 9.0% (P=0.20), and based on fragility fractures during first three years of therapy was 0.0% versus 13.2% (P=0.02) respectively. Fragility fractures in the DH versus CT cohorts among high risk patients were not statistically significant. The greater the duration of a DH, the higher the risk of fragility fractures: 0.0% in the first year, 6.7% in the second, 12.5% in the third, 5.0% in the fourth, and 26.3% for five years or more (P=0.04).In conclusion, based on the results from our cohort study, continued drug therapy did not provide additional protective benefit beyond the minimum adequate duration of therapy. However, the longer the drug holiday, the higher the risk of fractures emphasizing the importance of routine fracture risk assessment during drug holiday.

Fracture-free survival among patients who were started on drug holiday versus those who continued therapy

Fractures rate among patients who were started on drug holiday (red columns) versus those who continued therapy (blue columns) stratified by FRAX-based risk assessment

Patterns of Osteoporosis Medications Selection after Drug Holiday or Continued Therapy: A Real World Experience Michael Morkos*[1,2], Alessandra Casagrande[1], Paul Mahrous[1], Muriel Tania Go[2], Hasan Husni[2], Mirette Hanna[1], Dingfeng Li[2], Sara Bedrose[2], Mishita Goel[1], Yu-Chien Cheng[1,2], Sanford Baim[1]. [1]Rush University Medical Center, United States, [2]John H. Stroger, Jr. Hospital of Cook County, United States

We aimed to assess the pattern of medication selection for treatment of osteoporosis at the initiation of therapy (Rx), any subsequent changes, and re-initiation after drug holiday (DH) in a real-life setting. This is a retrospective cohort study in a tertiary academic center in Chicago, IL. Inclusion criteria involved adults (aged ≥18 years) who received a minimum adequate Rx (bisphosphates, raloxifene, or denosumab ≥ 3 years, or teriparatide ≥ 18 months), otherwise, patients (pts) were excluded. 1,814 charts were randomly selected and reviewed, 274 pts met the inclusion criteria. 61 pts received subsequent Rx before any interruption, 119 pts were placed on drug DH, and 21 pts were restarted on Rx after the DH.Among the 274 patients, Alendronate was the most common initial Rx (percentage, mean duration of Rx ± standard deviation in years): 69.0%, 5.4±2.4y. This was followed by ibandronate (9.5%, 4.9±2.1y), raloxifene (9.1%, 5.2±1.6y), risedronate (7.3%, 4.2±2.0y), denosumab (2.9%, 4.1±0.8y), teriparatide (1.8%, 2.1±0.1y), and zoledronate (0.4%, 7.8 years).Among

189 pts who received alendronate as the initial Rx, 35 patients were transitioned to subsequent therapies at different time points before going into any DH. Denosumab was the most common subsequent Rx prescribed accounting for 35.4% of the total 48 subsequent Rx, followed by zoledronate (25.0%), teriparatide (16.7%), alendronate (12.5%), ibandronate (4.2%), risedronate (4.2%), and raloxifene (2.1%). Among 25 pts who received raloxifene as initial Rx, eight pts received 11 subsequent Rx: Alendronate (54.5%), denosumab (27.3%), risedronate (9.1%), and zoledronate (9.1%). In 26 patients who received ibandronate as initial therapy, five pts received six subsequent Rx: Alendronate (50.0%), zoledronate (33.3%), and ibandronate (16.7%). Among 20 patients who received risedronate as initial Rx, ten pts received 13 subsequent therapies: Alendronate (38.5%), raloxifene (15.4%), teriparatide (15.4%), ibandronate, risedronate, denosumab, and zoledronate (7.7% each). Among five patients who received teriparatide as initial Rx, three pts received four subsequent therapies: Denosumab (75.0%) and zoledronate (25.0%). Eight pts received denosumab and one pt received zoledronate as initial therapies with no subsequent Rx. In this cohort, denosumab was the most commonly prescribed subsequent therapy (29.3%) followed by alendronate (24.4%), zoledronate (20.7%), and teriparatide (12.2%).Among the 21 pts who restarted Rx after DH, 10 pts (40.0%) received denosumab, eight pts (32.0%) received alendronate, four pts (16.0%) received zoledronate, two pts (8.0%) received teriparatide, and one pt (4.0%) received ibandronate.In conclusion, oral bisphosphonates constituted most of the initial therapy in our cohort. Denosumab was the most common subsequent therapy followed by Alendronate, Zoledronate, and Teriparatide in both continued therapy and drug holiday cohorts

Apparent Response Rate by PINP to Oral Bisphosphonates in Clinical Practice and Clinical Trial Settings Antonia Ugur*[1], Fatma Gossiel[1], Kim Naylor[1], Jennifer Walsh[1], Nicola Peel[2], Eugene Mccloskey[1], Richard Eastell[1,3]. [1]Academic Unit of Bone Metabolism, Oncology and Metabolism, University of Sheffield, United Kingdom, [2]Metabolic Bone Centre, Sheffield Teaching Hospitals, United Kingdom, [3]Mellanby Centre for Bone Research, United Kingdom

Background: Guidelines recommend bone turnover markers to monitor anti-resorptive treatments; to identify those not responding or non-adherent to oral bisphosphonates (BPs). In clinical practice, we use serum PINP as it is relatively unaffected by food intake or time of day. We wished to compare apparent response rates in serum PINP when using the geometric mean of a healthy premenopausal reference interval as the target, and associated changes in total hip BMD, between women recruited to a trial of oral BPs (the TRIO study) and an unselected cohort of patients receiving oral BPs in our clinic.Methods: A cohort of 92 unselected clinic-based patients (17 male; 75 female all postmenopausal), with osteoporosis on an oral BP for at least 3 months were matched to 92 untreated matched subjects as controls and compared to 135 postmenopausal women who had participated in TRIO, from whom pre-treatment serum provided same-subject controls.On a single serum sample from the treated and untreated clinical subjects, and TRIO baseline and week 48 serum samples, we measured Intact PINP using the IDS-iSYS assay, to calculate apparent response rates and perform ROC curve analysis. Implication for change in total hip BMD was examined in a subset of subjects where comparable baseline and follow up (TRIO 1-year n=128, Clinical 1-5 years n=30) DXA was available.Results: The demographics of the clinical cohort and TRIO were comparable with a mean age of 70.2 and 67.2years, and total hip T-score of -1.66 and -1.35, respectively. Comorbidities that affect bone metabolism were exclusion criteria in TRIO but were recorded in 51% of the treated clinical subjects, including fracture within 12 months (5%), significant glucocorticoid use (25%), thyroid disorder (15%) and diabetes mellitus (11%). Adherence was high in the TRIO cohort but unrecorded in the clinical cohort. The apparent response rate in the clinical cohort was high (75%) but lower than in the TRIO study (96%); the AUC was also lower in the clinical cohort as in table 1. Hip BMD improved to a greater extent in responders versus non-responders in both cohorts.Conclusions: Apparent response rates to oral BPs are lower in clinic patients than in clinical trial participants with poor adherence and secondary osteoporosis being possible contributory factors. Nonetheless, detection of an apparent positive biochemical response is associated with beneficial changes in BMD comparable to that seen in clinical trial settings.

		TRIO Oral Bisphosphonates n=135	CLINICAL Oral Bisphosphonates n=92
Apparent Responders by PINP Threshold Level %		96	75
AUC (95% CI)		0.98 (0.95-0.99)	0.77 (0.71-0.83)
BMD Mean % change Total Hip	Responder	2.06 n=124	2.96 n=26
	Non-responder	0.61 n=4	-1.64 n=4

Table 1. AUC for PINP by IDS iSYS automated assay to detect treatment response to oral bisphosphonate and percent of apparent responders when PINP is set at a female premenopausal geometric mean (threshold level). Mean percentage change in BMD of the total hip is given by biochemical "threshold" response.

Additive Adverse Effects: Use of Multiple Fracture Associated Drugs and Hip Fracture Risk Rebecca Emeny*[1], Chiang-Hua Chang[1], Jonathan Skinner[1], A. James O'Malley[1], Jeremy Smith[1], Gouri Chakraborti[1], Clifford J. Rosen[2], Nancy E. Morden[1]. [1]The Dartmouth Institute for Health Policy & Clinical Practice, The Geisel School of Medicine at Dartmouth, United States, [2]Maine Medical Center Research Institute, United States

Background: Many commonly used prescription drugs are known to increase fracture risk which raises concern for patients receiving two or more such drugs concurrently. The combined risk of taking multiple fracture-associated drugs (FADs) is unknown and may be additive, or worse, supra-additive - when risk exceeds the sum of the component risks. Methods: We used a 20% sample of Medicare fee-for-service data, 2004 -2014, to study hip fractures among beneficiaries receiving zero, one, two or three-or-more of 21 FADs. Data were structured at the person-day level. We used Cox regression models adjusting for patient age, sociodemographics, receipt of fracture protective drugs and morbidities. Preliminary analyses estimated the incremental hip fracture risk associated with current receipt of any one, two or three-or-more FADs. Our main analysis then explored risk associated with exposure to each specific single FAD and each two-way FAD combination, versus no FAD. All analyses were sex stratified. Results: Mean cohort age was 77 (SD 7.3) years. Of 11.3 million person years, 25.1% involved one FAD, 11.7% two FADs and 8.5% three-or-more FADs. In fully adjusted models, among women, risk associated with one, two and three-or-more FADs, versus no FAD, was Hazard Ratio (HR) 1.9 (95% CI 1.9, 2.0), HR 2.6 (95% CI 2.5, 2.7), HR 4.1 (95% CI 3.9, 4.2), respectively. Risks in men were slightly higher. Exposure-specific models revealed combinations conferring additive risk, including: opioids HR 3.0 (95% CI 2.8, 3.2), sedatives HR 1.5 (95% CI 1.4, 1.7), opioids plus sedatives HR 4.5 (95% CI 3.7, 5.5). Over thirty supra-additive pairs included: proton-pump-inhibitors plus sedatives, HR 2.6 (95% CI 2.1, 3.1) serotonergic-antidepressants plus antihistamines HR 4.3 (CI 3.0, 6.3), opioids plus muscle relaxers HR 5.9 (95% CI 3.7, 9.4) See Figure 1. Male risks were similar but with wider confidence intervals. Conclusion: Combination FAD use is common. Many drug pairs are associated with additive risks and some with supra-additive risks, suggesting synergistic adverse effects. Our results suggest judicious prescribing and caution in combining FADs when use is discretionary, alternatives exist, or fracture risk is high.

Bone Mineral Density and fracture risk in adult Hypophosphatasia
Franca Genest*, Lena Clausen, Silke Achtziger, Lothar Seefried. University of Wuerzburg, Germany

Introduction:Hypophosphatasia is a rare inherited metabolic disorder caused by in-activating mutations in the ALPL gene. Adult patients with HPP exhibit a wide spectrum of clinical symptoms including an increased fracture risk. Despite this awareness, data on clinical significance of DXA measurement in adult HPP is very limited. Accordingly, this evaluation aims at providing a systematic overview of technically consistent Bone Mineral Density (BMD) results from a large cohort of adult HPP patients in order to identify fundamental patterns of BMD values in HPP and potential associations of BMD results with fracture risk, ALP values and the prevailing genetic background. Methods:Retrospective single-center analysis of DXA-Scans conducted in adult HPP patients with confirmed ALPL-gene mutations, HPP-associated clinical symptoms and low alkaline phosphatase levels. All measurements were performed on the same Scanner (Hologic Discovery A). Further data evaluation included lab values (ALP, PLP, PEA), fracture type, medical history and childhood symptoms.Results:Analysis included data of 110 patients (84 female, mean age 46.2y) of whom 36.4% (n=40) were harboring two mutations. Average T-Score levels were -0.1 (SD 1.9) and -1.1 (SD 1.2) at the lumbar spine and total hip, respectively. Both lower ALP activity as well as higher substrate levels (PLP/PEA) were significantly correlated with higher BMD levels at the lumbar spine but not at the hip. Nearly half of the patients (n=53, 48.2%) had sustained at least one fracture in the past. Total hip BMD was sig. lower in patients with previous fractures while lumbar spine BMD was not associated with overall fracture incidence. Patients with two mutations had significantly higher lumbar spine BMD (p<0.001) which were in turn sig. associated with HPP specific metatarsal and diaphyseal long bone fractures (p=0,001).Discussion:Increased fracture risk in HPP patients is not universally associated with decreased BMD. Conversely, lumbar spine BMD appears to be particularly high in patients with lower ALP activity, higher substrate levels and compound heterozygous mutational status. Accordingly, high lumbar spine BMD might be a hallmark of severe disease and an indicator for an increased risk of HPP-specific fractures. Otherwise, overall fracture prevalence and the risk for non-HPP specific fractures appears to be higher in patients with lower hip BMD, i.e. hip BMD appears to be a valuable tool to predict vertebral and femoral neck fracture in HPP patients.

Asfotase Alfa Therapy in Adults with Pediatric-Onset Hypophosphatasia: Compassionate Use Results Michaël Laurent*[1], David Alster[2], Evelien Gielen[1], David Cassiman[1], Franz Jakob[3], Lothar Seefried[3]. [1]University Hospitals Leuven, Belgium, [2]Tucson Endocrine, United States, [3]University of Würzburg, Germany

BACKGROUND: Hypophosphatasia (HPP) is a metabolic bone disorder caused by mutations in the liver-bone-kidney isoform of alkaline phosphatase (ALPL). Asfotase alpha (AA, Strensiq®) is an enzyme-replacement therapy approved for the treatment of skeletal symptoms of severe (i.e. perinatal, infantile and childhood-onset) forms of HPP. Clinical trials with AA have been performed mostly in children, while reports in adults remain an-ecdotal. Here, we report outcomes in adults with pediatric-onset HPP treated in the global AA compassionate use program. METHODS: Treating clinicians of n=5/7 adults consented to aggregate data (3F/2M; age 33-69 years). RESULTS: Four patients had infantile-onset HPP and biallelic ALPL mutations, whereas one had childhood-onset HPP and a single mu-

tation. Follow-up ranged 2-6 years. Weekly AA dose was 6 mg/kg (n=3) or 3 mg/kg (n=2). All patients had rickety bone deformities and a history of (atypical) femoral fracture(s). Four patients had a history of multiple fractures, whereas during follow-up only one patient experienced 4 new fractures in 6 years, at times when dosing was temporarily reduced. Two patients had baseline pseudofractures and two had femoral non-unions, which healed within 1 year of AA treatment. All patients were wheelchair users at baseline; after 1 year, n=2 were walking unassisted and n=2 used mostly crutches. During longer follow-up, one could eventually use a rolling walker. Patients reported improvements in SF36-physical functioning (n=5/5) and SF36-health change (n=4/4). Six minute walking distance improved in n=4/4 patients. One patient required nocturnal oxygen support, which could be discontinued after 6 months. Pyridoxal-5-phosphate (n=4/4), inorganic pyrophosphate (=4/4) and urinary phosphoethanolamine (n=3/3) decreased, and PTH(1-84) increased (n=3/3). Bone mineral density improved in n=3/4 patients. Adverse events were mild injection-site reactions (n=5/5) and serious adverse events considered unrelated to AA (n=5/5); one patient developed symptomatic urolithiasis possibly attributable to AA. No AA-neutralizing anti-bodies were detected. Limitations of this report include lack of a control group and missing data. CONCLUSIONS: Compassionate-use AA was safe, and associated with decreased fracture burden, improved mobility/physical functioning, and biochemical and radiographic improvements in adults with pediatric (particularly infantile-onset) HPP. Further clinical trials in this population are warranted.

Successful treatment of osteoporosis with intermittent parathyroid hormone related peptide (Tymlos) injections in patients with Ehlers-Danlos syndrome Julianna Barsony*. Georgetown University Medical Center, United States

Intermittent administration of parathyroid hormone related peptide (PTHrP) in rodent models of osteoporosis increased osteoblast formation, and PTHrP increased type I collagen production by osteoblasts in culture. PTHrP (Tymlos) has recently been approved for the treatment of severe osteoporosis in postmenopausal women and early experience is highly valuable. Ehlers-Danlos Syndrome (EDS) is a group of inherited disorders of connective tissue that frequently causes osteoporosis due to defects in collagen synthesis and low bone formation. Clinical manifestations of EDS are variable and clinical diagnosis is made based on family history and combination of symptoms affecting bone, joints, skin, blood vessels, ligaments, gut, and brain (anxiety and chronic pain). We report results from four postmenopausal women with severe treatment resistant osteoporosis and EDS receiving Tymlos injections 80 mcg daily for one year. They also continued vitamin D supplement. Serum calcium and phosphorus and bone turnover markers were assessed before treatment and twice during treatment. Tymlos improved symptoms, markedly increased bone formation marker levels (P1NP 7-11-fold and osteocalcin 4-7-fold), and mildly increased bone resorption (urine NTX up to 2-fold), without increasing serum calcium. Bone density measurements of the hip/spine and vertebral fracture assessments were completed before and after this treatment and demonstrated improved bone mineral density 3-5% at the spine, 2.7-5.1% at the hip and 2.9-7.2% at the femoral neck. No new fractures noted. These findings suggest that Tymlos treatment should be considered for patients presenting with EDS and osteoporosis.

Homozygous knock-in Gly682Arg mutation in mouse Col27a1 gene phenocopies human steel syndrome with osteochondrodysplasia Kalyan Nannuru*[1], Claudia Gonzaga-Jauregui[2], Harikiran Nistala[2], Johanna Jimenez[1], Silvia Smaldone[1], Saathyaki Rajamani[1], Johnathon Walls[1], Chia-Jen Siao[1], Andrew Murphy[1], Sarah Hatsell[1], Aris N Economides[1]. [1]Regeneron Pharmaceutical Inc, United States, [2]Regeneron Genetic Center, United States

Homozygous rare missense variant p.Gly697Arg in collagen type XXVII alpha 1 (COL27A1) results in Steel syndrome (STLS, MIM #615155). This mutation arose as a founder mutation in Puerto Rican population. Steel syndrome is a rare osteochondrodysplasia characterized by short stature, congenital bilateral hip dysplasia, carpal coalitions, and scoliosis. To determine the pathogenicity and functional effect of the p.Gly697Arg variant, we developed a mouse model with the mutation at orthologous location (Gly682) in the murine Col27a1 gene. Embryonic and post-natal phenotyping of these mice revealed skeletal abnormalities similar to those observed in Steel Syndrome individuals including dwarfism, kyphosis, scoliosis, and a rounded skull shape. Significant post-natal lethality before day 7 was observed in homozygous knock-in mice. Analysis of E18.5 embryos reveal cranio-facial abnormalities and poorly developed alveolar space in lungs. Characterization of the phenotype revealed it is likely the result of abnormal collagen deposition in the extracellular matrix leading to the disorganization of the proliferative zone of the growth plate in long bones. Heterozygous mice were viable and did not display any gross skeletal abnormalities. Our study delineates the important role of Col27a1 in growth plate organization for endochondral bone formation during skeletal development.

MON-0036

Vitamin D and bone turnover markers dynamics during the first year after liver transplantation. Gonzalo Allo Miguel*[1], Soledad Librizzi[1], Mercedes Aramendi Ramos[2], Carlos Jiménez[3], Federico Hawkins[1], Guillermo Martínez Díaz-Guerra[1]. [1]Endocrinology Service, 12 de Octubre University Hospital, Spain, [2]Laboratory Service, 12 de Octubre University Hospital, Spain, [3]General Surgery Service, 12 de Octubre University Hospital, Spain

INTRODUCTION: In spite of the substantial morbidity (such as increased risk of fracture and low bone mineral density) caused by impaired bone health among patients after liver transplantation (LT), data on bone metabolism changes are limited. So, the aim of our study is to evaluate the evolution of vitamin D [25(OH)D] and several bone markers during the first year after LT.METHODS: 96 patients with LT were included in this study. We used prospectively collected samples for measurements of 25(OH)D and different serum turnover markers: sclerostin (SCL), β-Crosslaps (CTx), osteocalcin (OC) and bone alkaline phosphatase (BAP), at time of transplantation, 3, 6 and 12 months after the procedure. Statistics: Data are expressed as mean±s.d. for continuous variables. Student's t-test was used to compare 25(OH)D and bone markers levels (from baseline to 12 months). A p-value <0.05 was considered as statistically significant.RESULTS: 66:30 (male/female) patients were included in the study. Mean age was 57.3±10.4 years. At time of transplantation most of the LT recipients showed 25(OH)D deficiency [25(OH)D<20;60.4%). At the end of the study the number of 25(OH)D deficient patients dropped (45.9%), but deficiency remained a common finding. Bone markers levels at baseline were: SCL:0.77±0.34ng/ml; CTx-:0.57±0.12ng/ml; OC17.09±10.23ng/ml; BAP:34.86±17.79ng/ml. SCL levels decreased significantly during the study (3rd month: 0.62±0.22, p<0.001; 6th month 0.60±0.26, p<0.001; 12th month: 0.56±0.1, p=0.01). CTx levels increased significantly between measurement at transplantation and 3 (0.69±0.39 p<0.001) and 6 months (0.63±0.36 p<0.001), but there was a non-significant decrease after 12 months (0.50±0.32). OC increased significantly (doubling its value) throughout the study (3rd month: 31.11±18.1, p<0.001; 6th month: 37.21±17.08, p<0.001; 12th month: 39.13±27.9, p<0.001). BAP remained stable after 3 months (33,72±13.08) compared to baseline, which persisted after 6months (36.04±10.30). There were no significant differences in bone markers levels between patients with 25(OH)D deficiency and sufficiency.CONCLUSIONS: Our study shows high prevalence of 25(OH)D deficiency before and one year after liver transplantation. Also, our results showed that SCL decreased significantly during the study, which contrasts with the increase of other bone markers (such as OC and CTx). Based on our results, supplementation with vitamin D should be considered in liver transplantation recipients.

MON-0037

Persistently elevated PTH after parathyroidectomy at one year: experience in a tertiary referral center Marie Caldwell*[1], Marshall Clark[2], Lawrence Kim[2], Janet Rubin[2]. [1]University of North Carolina Hospitals, United States, [2]University of North Carolina, United States

The availability of effective minimally invasive outpatient parathyroid surgery, along with guidelines recommending surgery for patients with bone density T scores ≤2.5, and data suggesting improved bone quality after surgery, has led to increased parathyroidectomy for treatment of primary hyperparathyroidism (PHPT). Several small reviews have noted that, despite correction of hypercalcemia, 8-43% of patients will have persistently elevated PTH post-surgery. We set out to determine if clinical factors could identify this patient group. We queried a 12 year retrospective cohort who underwent parathyroidectomy at UNC-associated hospitals. We captured age, sex, race, BMI, PTH, calcium, vitamin D, creatinine and urinary calcium prior and up to 15 months post-surgery (Table I). After excluding patients with creatinine ≥2, pre-surgical data was available for 411 patients, and 1y (9-15 month) data for 69 patients. Loss of data at 1y reflected our referral base: the pre-surgical characteristics of patients with and without 1y follow up did not differ with respect to age, F/M, calcium, PTH, Ucalcium or vitD. Pre-op calcium averaged 11 with PTH 157±7 (nl 12-72 pg/mL). In patients with 1y data, 25% had persistently elevated PTH ("1y-highPTH"), despite correction of hypercalcemia, with average PTH 94±6. Elevated PTH was apparent in the 1y-highPTH group at 6 months post-surgery (95±8, p<0.001). Post-op calcium levels did not significantly differ between groups at any time. Pre-surgery, PTH in what would become the 1y-highPTH group was significantly higher than in the 1y PTH-normal group (208 vs 129, p<0.0001) and pre-op urinary calcium lower (208 vs 292, p<0.0001). Pre-op calcium, age, sex, and vitamin D were not significantly different. Our experience suggests that, despite success of surgery to normalize calcium, PTH remains elevated in large number of patients. At presentation, this group had higher PTH and lower calcium excretion. The physiology that results in persistently elevated PTH after successful correction of hypercalcemia is not well understood, but may be consistent with a higher calcium set point directing PTH secretion. This retrospective study did not address whether symptom relief was less successful in the PTH high group. Importantly, whether bone quality is equally improved in patients with persistently elevated PTH is unknown; such data will be important to guide recommendations for surgery aimed at improving bone density in PHPT patients.

Table

	Cohort (n=411)	Lost to f/u at 1y (n=341)	1y-nl PTH (n= 52)	1y-High PTH (n= 17)

A Novel Mutation in the Calcium Sensing Receptor Gene in an Italian Family Affected by Autosomal Dominant Hypocalcemia Filomena Cetani*[1], Simona Borsari[2], Federica Saponaro[3], Elena Pardi[2], Chiara Banti[2], Laura Mazoni[2], Matteo Apicella[2], Claudio Marcocci[2]. [1]University Hospital of Pisa, Endocrine Unit 2, Italy, [2]Department of Clinical and Experimental Medicine, University of Pisa, Italy, [3]Department of Surgical, Medical, Molecular Pathology and Clinical Area, University of Pisa, Italy

The G protein-coupled calcium sensing receptor (CaSR), widely expressed on the surface of parathyroid chief cells and in the kidney, plays a central role in calcium homeostasis. Activating mutations of CaSR gene are responsible for autosomal dominant hypocalcemia (ADH), a rare disorder caused by hypocalcemia, hyperphosphatemia, hypercalciuria and inadequately low concentration of parathyroid hormone (PTH).In this study, we report a family affected by ADH. The proband, a 26 year-old Italian woman, was referred to our Department in 2011 for a mild asymptomatic hypocalcemia detected in 2009 during routine blood tests. Biochemical evaluation confirmed a mild hypocalcemia (mean value: 8±0.26 mg/dl, normal range: 8.6-10.2), normal serum PTH (mean value 22±5.57 pg/ml, normal range 8-40) and relative 24h urinary calcium excretion (mean value: 171±30.3 mg/24h, normal range: <250). Instrumental evaluation excluded intracranic calcifications, kidney stones and nephrocalcinosis. Serum calcium of first-degree relatives showed hypocalcemia in her father (8.1 mg/dl) and brother (8.2 mg/dl), and normocalcemia in her mother (9.6 mg/dl). Genomic DNA of the proband and her family members was isolated from peripheral blood leukocytes and the entire coding region and exon-intron boundaries of the CaSR gene were directly sequenced. Mutational analysis revealed a novel heterozygous variant of the CaSR gene in the proband, leading to the substitution of serine to proline at codon 591 in exon 7 (S591P), localized in the CaSR extracellular domain where >85% of activating mutations occurs. All affected relatives carried the same alteration that was absent in her mother and in 100 chromosomes of unrelated healthy subjects. In silico tests, using Mutation Taster software that integrates data from different databases, predicted a probably deleterious effect of the detected variant.In conclusion, we identified a novel missense variant in the CaSR gene co-segregating with hypocalcemia.

Burden of Illness Among Patients With Chronic Hypoparathyroidism Not Adequately Controlled With Standard Therapy by Self-Perception Heide Siggelkow*[1], Bart L. Clarke[2], Helen Dahl-Hansen[3], Elizabeth Glenister[4], Davneet Judge[5], Nawal Bent-Ennakhil[5], Katie Gibson[5], John Germak[6], Kristina Chen[7], Claudio Marelli[6], Jens Bollerslev[8]. [1]Department of Gastroenterology and Endocrinology, University of Göttingen, Germany, [2]Mayo Clinic Division of Endocrinology, Diabetes, Metabolism, and Nutrition, United States, [3]Nordic hypoPARA Organisation, Norway, [4]Hypopara UK, United Kingdom, [5]Adelphi Real-World, United Kingdom, [6]Shire International GmbH, Switzerland, [7]Shire Human Genetic Therapies, Inc., United States, [8]Section of Specialized Endocrinology, Oslo University Hospital, Norway

Significant knowledge gaps exist regarding the humanistic effects of chronic hypoparathyroidism (HPT). We provide interim results from a global survey conducted to characterize the burden associated with chronic HPT from the patient perspective. An anonymous, self-reported survey was conducted in patients with chronic HPT, not adequately controlled with standard therapy by self-perception, from 12 countries through physicians or patient

Monday Posters

associations. Symptoms and impact of HPT were assessed via HPT Symptom Diary, a disease-specific, patient-reported outcome tool that recorded severity of symptoms experienced in the last 7 days. Health-related quality of life (HRQoL) was evaluated by the SF-36 v2 and EQ-5D-5L. Patient demographics and clinical characteristics were also captured. Of 226 patients (mean age, 51.6 years; 77% women; mean time since diagnosis, 7.8 years; surgery as main cause of HPT, 81%), 94% had persistent symptoms despite treatment and 63% were told by a physician that their calcium levels were poorly controlled. Most patients received oral calcium (77%) and/or activated vitamin D (74%). Self-perceived overall symptom severity was reported as mild, moderate, or severe in 56 (25%), 138 (61%), and 30 (13%) patients, respectively. Per symptom diary, 98% of patients reported physical fatigue (symptom severity: mild, 22%; moderate, 42%; severe, 26%; very severe, 9%), 90% reported muscle cramps (symptom severity: mild, 31%; moderate, 42%; severe, 13%; very severe, 4%), and 90% reported heaviness in limbs (symptom severity: mild, 24%; moderate, 46%; severe, 16%; very severe, 4%). An impact on daily life, rated as 'somewhat' or 'very much', was reported by 89% of patients for ability to exercise, 85% for sleep, 80% for ability to work, and 72% for family relationships. The correlation of higher symptom severity level and inferior HRQoL status was observed. Mean SF-36 summary scores were 44.3/36.6/28.2 (physical component summary) and 44.4/33.9/31.4 (mental health component summary) for patients reporting mild/moderate/severe HPT symptoms, respectively. Mean EQ-5D scores were 0.8/0.7/0.3 for patients reporting mild/moderate/severe HPT symptoms [n=132]). Findings from this analysis demonstrated a spectrum of symptom severity within a cohort of patients self-reporting inadequately-controlled HPT on standard therapy. The magnitude of patient-reported symptom severity appeared to correlate with extent of impact on daily life and reduction in HRQoL.

Adults With Hypophosphatasia Enrolled in the Global HPP Registry Have Delayed Diagnosis and Systemic Manifestations of the Disease
Lothar Seefried*[1], Wolfgang Högler[2], Hugo Gomes Da Silva[3], Anna Petryk[3], Shona Fang[3], Agnes Linglart[4], Keiichi Ozono[4], Cheryl Rockman-Greenberg[5], Craig Langman[6], Priya Kishnani[7]. [1]Orthopaedic Clinic King-Ludwig-Haus, University of Würzburg, Germany, [2]Department of Endocrinology and Diabetes, Birmingham Children's Hospital, and Institute of Metabolism and Systems Research, University of Birmingham, United Kingdom, [3]Alexion Pharmaceuticals, Inc., United States, [4]APHP, Bicêtre Paris-Sud, University Paris Saclay, France, [5]University of Manitoba, Rady Faculty of Health Sciences, Max Rady College of Medicine, and Children's Hospital Research Institute of Manitoba, Canada, [6]Feinberg School of Medicine, Northwestern University, and Lurie Children's Hospital of Chicago, United States, [7]Department of Pediatrics, Duke University Medical Center, United States

Purpose: Hypophosphatasia (HPP), a rare, inherited, systemic disease caused by mutation(s) within the ALPL gene, resulting in low activity of tissue-nonspecific alkaline phosphatase (ALP), has a poorly understood natural history in adults. Asfotase alfa, an enzyme replacement therapy, has been approved for treatment of patients with pediatric-onset HPP. The HPP Registry is collecting real world data on the epidemiology and clinical course of HPP in patients of all ages, regardless of treatment status.Methods: The HPP Registry is an observational, prospective, multinational study (NCT02306720; EUPAS13514). We report demographics, characteristics, and medical history of adults (age ≥18 y) at enrollment in the Registry. Patients included in this analysis had low serum ALP activity and/or ALPL mutation(s).Results: Of the 269 patients with pediatric- or adult-onset HPP from 11 countries who were enrolled in the Registry from January 2015 through September 2017, 148 were adults. Median (min, max) age of the adults at enrollment was 51.4 (18.5, 78.9) years; most adults were female (73.0%) and white (90.0%). Age at earliest HPP manifestation was 37.6 (0.2, 75.2) years, whereas age at diagnosis was 47.5 (0.2, 75.2) years, representing ~10-year delay in diagnosis. Common (>10%) HPP-related disease history included rheumatic symptoms (83.9%; pain: 74.5%), skeletal symptoms (48.2%; recurrent and poorly healing fractures: 36.5%), orthopedic procedures and therapies (44.6%), muscular symptoms (37.2%; muscle weakness: 30.7%), premature loss of deciduous teeth (24.8%), renal symptoms (16.1%; kidney stones: 5.1%) and neurologic symptoms (11.7%; seizures: 8.8%). Bone-related medication histories included bisphosphonates (17.6%) and/or parathyroid (PTH) hormone analog (13.5%). At enrollment, 26 (17.6%) adults were receiving asfotase alfa. Of the treated adults, all had pediatric-onset HPP; 11 were previously asfotase alfa clinical study participants. Conclusion: The delay in diagnosing HPP in symptomatic adults was substantial. Medical histories highlight the systemic nature of HPP in this population. The data also show that mostly ineffective therapies (PTH) or those currently considered inappropriate (bisphosphonates) were prescribed to patients with HPP . At present, the small proportion of adults receiving treatment with asfotase alfa may reflect differences in availability of asfotase alfa in various countries.

Value of periostin and tartrate-resistant acid phosphatase 5b as biochemical markers of activity in Paget's disease of bone Nuria Guanabens*[1], Xavier Filella[2], Silvia Ruiz-Gaspa[3], Helena Florez[1], Arantxa Conesa[4], Pilar Peris[1], Ana Monegal[1], Ferran Torres[5]. [1]Metabolic Bone Diseases Unit, Hospital Clinic, IDIBAPS, CIBERehd, Universisty of Barcelona, Spain, [2]Biochemistry and Molecular Genetics Department, Hospital Clinic, Spain, [3]Hospital Clinic, CIBERehd, Spain, [4]Rheumatology Department, Hospital General Universitario, Spain, [5]Biostatistics and Data Management Platform, Hospital Clinic, IDIBAPS, Spain

Periostin is a matricellular protein with a preferential location in cortical bone and periosteal tissue, and tartrate-resistant acid phosphatase 5b (TRAP5b) is a marker of osteoclast numbers. In Paget's disease of bone (PDB) there is increased cortical thickening, periosteal apposition and increased osteoclast numbers. Aim: To analyse if circulating periostin is a biomarker for PDB and if it is associated with disease activity, as well as whether TRAP5b is useful in the assessment of PDB. Patients and Methods: We recruited 41 patients with PDB (13F/28M; 71.1±11.8 yrs). 70.7% had active disease, defined as total alkaline phosphatase higher than the upper normal range. Blood and urine samples were taken between 8:00 and 10:00 am after an overnight fast. Periostin and TRAP5b were measured in serum using commercial ELISA assays (Biomedica and IDS, respectively). Serum PINP, CTX, bone ALP and urinary NTX were measured. Reference values for periostin and TRAP5b were obtained from 38 healthy subjects. Results: Serum periostin did not differ between patients and controls (966±210 vs 992±175 pmol/L, p=0.553), between patients with and without active disease (967±171 vs 1052± 176 pmol/L, p=0.160), involvement or not of long bones (1022±146 vs 952±204 pmol/L, p=0.209), monostotic or polyostotic disease (990±982 vs 988±143 pmol/L, p=0.897) and previous bisphosphonate treatment (964±199 vs 1007±163 pmol/L, p= 0.471). There were no significant correlations between periostin and any of the assessed bone turnover markers, except for TRAP5b (r=0.312, p=0.047). TRAP5b was significantly higher in patients than in controls (4.41±1.77 vs 3.24±0.95 U/L, p=0.0005), significantly correlated with PINP, CTX, bone ALP and NTX, and showed a high predictive capacity for PDB (ROC:0.715 [95%CI:0.600-0.829]), particularly when combined with age and gender (ROC:0.919 [95%CI 0.858-0.979]). Conclusions: Serum periostin is not useful for assessing Paget's disease. By contrast, TRAP5b may be a useful marker in Paget's disease assessment.

A Highly Sensitive Fluorescence Immunoassay for the Biomarker NOGGIN FluoBolt™: A New Tool for Bone Research Gerhard Hawa*, Linda Sonnleitner , Albert Missbichler. FIANOSTICS GmbH, Austria

Objective:NOGGIN is a potent inhibitor of bone morphogenetic proteins and involved in bone/cartilage regeneration, limb development and fracture repair (1,2). We developed a fluorescence immunoassay for this molecule by using a new technology based on plasmonic microtiter plates (3) that allows quantification of NOGGIN with prior unprecedented sensitivity and reliability. The assay has been proven useful in monitoring Denosumab therapy in patients with thalassemic osteoporosis (4). We hereby present a thorough analytical validation and reference values in a blood donor cohort.Methods:Microtiter plates, capable of metal enhanced fluorescence (MEF-MTPs) were coated with anti-NOGGIN capture antibody and blocked of unspecific binding o.n. at room temperature. 25μl of anti-NOGGIN antibody labeled with AlexaFluor 680 together with 20μl of human serum samples were incubated over night in the dark. Signals were read using a standard fluorescence microplate reader. Results:The detection limit of this MEF-FIA for NOGGIN (0 pM + 3xSD) was determined as 1,0 pmol/l . Intra- and inter-assay CVs (n=12) ranged from 2-5% and 3-7% respectively. Average recovery in human serum samples (n=4) was 87% (79-108%) and linearity of dilution was 104% (93-114%). Comparison of sensitivity with commercially available ELISA systems for NOGGIN revealed a 2 orders of magnitude higher sensitivity of the MEF-FIA. Titration experiments with BMP-2,-4 and -7 proved that the assay is highly specific for free, biological active circulating human NOGGIN. Analysis of NOGGIN in 100 serum samples of randomly selected blood donors (aged 18-60 years) showed no differences in sex and no dependency on age.Conclusion:We successfully demonstrated superior performance of our new MEF-MTP assay platform (FluoBolt™) to conventional NOGGIN-ELISA. It is fully compatible to standard fluorescence microplate reader technology, works with all fluorescence labels and will become a valuable new tool for bone research.(1) "Noggin", Krause C, Guzman A, Knaus P. MON-0044

Evaluation of a Radiophosphorus Method for Intestinal Phosphorus Absorption Assessment in Humans Kathleen M. Hill Gallant*[1], Mun Sun Choi[1], Elizabeth R. Stremke[1], George P. Mccabe[1], Munro Peacock[2], Meryl E. Wastney[3]. [1]Purdue University, United States, [2]Indiana University School of Medicine, United States, [3]Purdue University, New Zealand

Phosphorus(P) absorption is understudied in humans because methods applicable for clinical studies have not been promoted. Our aim was to test a radiophosphorus absorption test that can be used in studies in healthy subjects (HS) and patients with chronic kidney disease (CKD). 33P clearance from IV injection was obtained in 14 HS and 10 CKD patients from published studies (Farrington, 1981). Four HS (19-29y, 1 male, 3 females, all non-Hispanic white) underwent 2 oral 33P absorption tests with different stable P loads separated by ≥1 week. Ten µCi 33P was given in 4oz juice containing a P carrier load of 50 or 100 mg in crossover randomized order. Twelve serial blood draws occurred pre-dose through 24-hours post-dose. All urine was collected over 24-hours with specified collection end times. Subjects stayed on the research unit until 6-hours post-dose, then returned the next day for a 24-hour post-dose blood draw & urine collection. 33P activity in serum and urine was analyzed by liquid scintillation counting, serum P was measured by a Cobas Mira analyzer, and urine P was determined by inductively-coupled plasma spectrophotometry. 33P blood and urine curves were analysed by compartmental modelling with WinSAAM software. Fractional absorption was calculated from the 24-hour period and compared with 4-hours. Additionally, a comparison was made between fractional absorption calculated using IV tracer clearance data from HS and CKD subjects to determine the effects of reduced renal function on absorption estimates. A repeated-measures ANOVA model was used to compare mean differences using SAS 9.3, and significance set at $\alpha=0.05$. No statistically significant difference in fractional absorption was observed between carrier loads of 50 mg and 100 mg (mean±SE:0.68±0.02,0.69±0.02, p=0.82). There was no significant difference observed in fractional absorption calculated from the full 24-hours of data versus only 4 hours (0.68±0.01,0.67±0.01, p=0.59). However, calculating fractional absorption from CKD patient IV data resulted in significantly lower values than HS IV data (0.31±0.04,0.68±0.04, p<0.0001). We conclude that an oral 33P dose with 50 or 100 mg P carrier load and 4 hours sampling post-dose are sufficient for measuring fractional P absorption in HS. The significant difference in estimated absorption using IV data from HS versus CKD indicates that IV clearance of a tracer should be directly measured in subjects with known or suspected reduced kidney function.

The Design and Results of a Phase 1 TransCon PTH Trial in Healthy Volunteers David B. Karpf*[1], Susanne Pihl[2], Eva Mortensen[1], Kennett Sprogøe[2], Jonathan A. Leff[1]. [1]Ascendis Pharma Inc., United States, [2]Ascendis Pharma A/S, Denmark

Background:Hypoparathyroidism (HP), a condition of parathyroid hormone (PTH) deficiency, leads to abnormal calcium and phosphate metabolism. Standard of care (SOC), ie, large amounts of calcium and active vitamin D, causes hypercalciuria and increased calcium x phosphate product. Daily Natpara [PTH(1-84)] injections reduce calcium and active vitamin D doses but not 24-hour urinary calcium (uCa) excretion or incidence of hypo- and hypercalcemia, likely due to its 3-hour half-life (Natpara label).NIH studies of PTH(1-34) in patients with HP have shown that a single subcutaneous (SC) injection is superior to SOC, twice daily injections are superior to once daily, and continuous SC infusion normalizes serum calcium (sCa), serum phosphate (sP), and uCa.Ascendis Pharma is developing TransCon PTH, a sustained-release prodrug of PTH(1-34), for the treatment of HP. In its prodrug form, PTH is transiently bound to the TransCon carrier via a TransCon linker. Through autocleavage at physiological temperature and pH, unmodified PTH is released, providing free PTH at steady state with an infusion-like profile in the physiological range over 24 hours.Methods:This phase 1, randomized, placebo-controlled, single and multiple ascending dose (SAD and MAD) trial evaluated safety, tolerability, pharmacodynamics (PD), and pharmacokinetics (PK) of TransCon PTH in up to 130 healthy adults. Cohorts consisted of 10 subjects (8 active, 2 placebo) who received 7 SAD (3.5, 12, 32, 48, 72, 100, and 124 µg) or 6 MAD (3.5, 7.0, 12, 16, 20, and 24µg) for 10 days. The primary PD endpoints included sCa, uCa, sP, bone turnovers markers, and PTH(1-84). The primary PK endpoint was free PTH. Results:TransCon PTH was generally well tolerated. The PK showed dose-dependent increases in exposure, with T1/2 of ~60 hours. Single injections up to 124 µg showed dose-dependent increases in albumin-adjusted sCa sustained for ≥72 hours associated with reductions in PTH(1-84) but without change in urinary fractional excretion of Ca (FECa) and no evidence of anabolic activity with metabolic doses. The trial is ongoing; 7 SAD cohorts and 6 MAD cohorts, including relevant phase 3 doses, will be presented.Conclusion:TransCon PTH is being developed for HP as a once-daily SC injection. Interim data supports an infusion-like PTH profile, with a PTH T1/2 of ~60 hours and sustained increases in sCa without change in FECa or anabolic activity, potentially addressing limitations of available HP therapies.

MON-0046

Does Cerebral Vascular Stiffness Contribute to Altered Cognition in Primary Hyperparathyroidism? Minghao Liu*[1], Yunglin Gazes[1], Ivelisse Colon[1], Mariana Bucovsky[1], Kevin Slane[1], John Williams[1], Randolph Marshall[1], Ronald Lazar[2], James Lee[1], Jennifer H. Kuo[1], Shonni Silverberg[1], Marcella Walker[1]. [1]Columbia University Medical Center, United States, [2]University of Alabama at Birmingham, United States

We have reported cognitive changes in primary hyperparathyroidism (PHPT) that improved with parathyroidectomy (PTX) as well as an association between PTH and vascular stiffness. We hypothesized that PTH-dependent vascular stiffness impairs cerebral blood flow and cognition in PHPT. We compared cognition, vasomotor reactivity (VMR) by transcranial Doppler and neural activation by functional magnetic resonance imaging (fMRI) in postmenopausal women with hypercalcemic PHPT (calcium 10.7±0.5mg/dL, PTH 87±43pg/mL, n=28), normocalcemic PHPT (Ca 9.5±0.4mg/dL, PTH 120±43pg/mL, n=7), and non-PHPT ctrls (n=6). Women with PHPT having PTX were re-tested 6-mos post-PTX (n=21). VMR in PHPT was normal and not different from normocalcemic or non-PHPT controls (4.0±2.1 vs. 5.1±3.1 vs. 3.5±3.3% mmHgPCO2, p=0.09). VMR did not correlate with calcium or PTH. Depressive symptoms, verbal/visual memory, fluency, attention, and motor skills were normal and did not differ by group. VMR did not correlate with cognition. On fMRI, neural activation was lower during pattern recognition (k=152, p<0.005) only in the cerebellum in PHPT vs. non-PHPT ctrls (n=18). During verbal memory tasks, greater activation in the left precentral gyrus and insula correlated with higher PTH (r=0.72) while activation in the bilateral anterior cingulate gyrus (r=0.71) and left insula (r=0.69) correlated with higher calcium (all p≤0.0005). Post-PTX, 2 verbal fluency tests and motor skills improved (Z-score change 0.31-0.55; all p<0.05), but verbal recognition worsened. Depressive symptoms improved by 45% (p=0.007). There was no change in VMR (p=0.53). Post-PTX, activation during verbal memory tasks declined in some brain regions where activation correlated with higher calcium and PTH pre-PTX: the insula and cingulate gyrus (k=745 voxels, p<0.005). There was also a decrease in activation in other brain regions associated with language, motor skills and attention (all k>100 voxels, p<0.005). In summary, in PHPT, cognition and vascular function were normal and not associated with one another. Cortical activation correlated with biochemical severity of PHPT. Mood and some aspects of cognition improved after PTX while neural activation in areas associated with language, motor control, and attention decreased. Further work is needed to determine if post-PTX cognitive improvement and activation changes are due to cure of PHPT, learning and/or an improvement in mood.

MON-0047

A microRNA approach to diagnosing renal osteodystrophy Thomas Nickolas*[1], Neal Chen[2], Donald Mcmahon[1], David Dempster[3], Hua Zhou[3], Sharon Moe[2]. [1]Columbia University, United States, [2]Indiana Univeristy, United States, [3]Helen Hayes Hospital Regional Bone Center, United States

Background: A main impediment to the diagnosis and management of renal osteodystrophy (ROD) is the non-invasive identification of underlying bone turnover-type (low, normal or high). Bone biopsy, the gold standard method to diagnose ROD turnover-type is painful, invasive, expensive and not widely available in clinical practice, and the non-invasive biomarkers in current clinical use provide only mild to moderate diagnostic accuracy. We hypothesized that four circulating mircoRNAs (miRs) that regulate osteoblast (miR-30b, 30c, 125b) and osteoclast development (miR-155) would provide superior discrimination of low turnover from normal or high turnover than the biomarkers that are currently used for ROD diagnosis and management.Methods: In twenty-four patients with chronic kidney disease (CKD) Stages 3-5D, we obtained tetracycline double-labeled transiliac crest bone biopsy and measured levels of the current ROD biomarkers, parathyroid hormone (PTH) and bone specific alkaline phosphatase (BSAP), and circulating levels of miR-30b, 30c, 125b and 155. Spearman correlations assessed relationships between miRs and dynamic parameters of histomorphometry and PTH and BSAP. Low, normal and high turnover ROD were based on local reference ranges for bone formation rate/bone surface (BFR/BS) and adjusted apposition rate from quantitative histomorphometry. Diagnostic test characteristics for discriminating low or high turnover were determined by receiver operator curve analysis; areas under curve (AUC) were compared by χ2-test.Results: Circulating levels of miRs moderately correlated with BFR/BS and adjusted apposition rate at the endo- and intra-cortical envelopes (ρ 0.43-0.51; p<0.05). The AUCs and 95% confidence intervals for discrimination of ROD turnover-type for miRs, PTH and BSAP are in Table 1. miRs and BSAP but not PTH discriminated low versus non-low turnover ROD: AUCs 0.875, 0.825, 0.800 and 0.767 for miR-30b, 30c, 125b and 155 respectively, and 0.781 for BSAP. For all four miRs combined, the AUC was 0.983, which was superior to that of BSAP alone (p < 0.05). BSAP and all four miRs combined but neither the individual miRs nor PTH discriminated high versus non-high turnover.Conclusions: These data suggest that circulating miRs provide accurate non-invasive identification of bone turnover. Future work will discover and validate additional miR biomarkers of both high and low turnover and determine their impact on clinical decision making and outcomes.

Table 1: Area under the curve (AUCs): Parathyroid Hormone (PTH), Bone Specific Alkaline Phosphatase (BSAP) and miRNAs for the diagnosis of turnover

	Low vs. Non-Low		High vs. Non-High	
	AUC	95% CI	AUC	95% CI
PTH	0.478	0.209-0.763	0.593	0.294-0.921

Incidence of fracture in Kidney Transplantation: A population-based Healthcare administrative study Aboubacar Sidibé*[1], Sonia Jean[2], Philippe Gamache[3], Lynne Moore[4], Fabrice Mac-Way[5]. [1]Chu de Quebec-Université Laval, Institut National de Santé Publique de Québec, Canada, [2]Université Laval, Institut National de Santé de Publique, Canada, [3]Université Laval, Institut National de Santé Publique de Québec, Canada, [4]Chu de Québec-Université Laval Research center, Enfant-Jésus Hospital, Traumatology Axis, Canada, [5]Chu de Québec-Université Laval, Hotel-Dieu de Quebec Hospital, Canada

Administrative databases have been widely used to assess fracture risk in kidney transplant (KT). In the province of Quebec (Canada), there is a knowledge gap on whether fracture risk for KT patients is different from the general population. We therefore aimed to derive and validate a case definition for the identification of KT patients in physician claims database and measure the incidence of fracture in this population.Methods: Multiple algorithms combining diagnostic (ICD), surgical, hospitalization follow-up or immunotherapy billing codes related to KT were applied in physician claims database to identify all new cases of adult patients from 1996 to 2015. Algorithms were validated against the hospital discharge database. We linked cases identified in the hospital discharged database to those identified by the algorithms, using a unique identifier, and estimated sensitivity (Sen), specificity (Spe), positive (PPV) and negative predictive value (NPV) to assess the accuracy of each algorithm. Incidence of all first fracture after KT were identified with a validated algorithm and compared to a control group composed of adult Quebec patients, hospitalized in the same period and hospital, with similar age and sex (matching 3 controls /case) and to the Quebec general adult population of the same period, using a Poisson regression model (SAS Enterprise Guide 7.1).ResultsTwelve algorithms were derived. The validity of each algorithm is presented in Table 1. Sen ranged from 51.74 % to 99.49%. Spe and NPV were close to 100% for all algorithms. PPV ranged from 37.66% to 90.91%. Based on Sen and PPV, algorithm 4 and 7 are the most accurate with Sen at 98.92 and 95.28, and PPV at 86.53% and 90.91%, respectively. Incidence of first fracture was 15.78% in 5,407 KT patients, 12.69% in 14,723 controls and 8.70% in 8,514,424 Quebec adults. Using algorithm 7, the risk of all fractures and hip fractures were significantly higher in KT patients as compared to the control group (RR: 1.24 (95% CI: 1.15 to 1.34) and 2.60 (95% IC: 1.93, 3.50) respectively) and to general population (RR: 1.79 (95% CI: 1.69, 1.91) and 1.46 (95% CI: 1.18, 1.80)). ConclusionOur results demonstrate that algorithms using physician-claims database are accurate and reliable for identifying new cases of KT. Fracture risk in KT patients is higher than that observed in general population or in matched control group. Further studies should address some modifiable factors to reduce fracture risk in KT.

Table 1: Definition and Validation of Case definition if kidney transplantation in Physician-Claim database

N	Case Definition of algorithms	Medical service Billing or diagnosis Codes	Sen	Spe	PPV	NPV	Pre	Res
1	1P with a billing code for Kidney transplantation	I-(06221 or 06222 or 06223)	93.05	100	90.23	100	√	
2	1P with a billing code for diagnostic, therapeutic act before and after kidney transplantation, or 1P with a billing code for immunosuppressive therapy	II- (00699 or 00771 or 00773 or 00774 or 00775 or 00776 or 09489)	91.09	100	87.85	100	√	
3	1P with ICD-9 or ICD-10 diagnostic code of kidney transplantation	III- (V420 or Z940)	51.74	100	37.66	100		↑
4	Algorithm 1 or algorithm 2	IV- (I or II)	98.92	100	86.53	100	√	↑
5	Algorithm 1 or 1P with ICD-9 or ICD-10 diagnostic code for kidney transplantation	V- (I or II)	95.58	100	68.43	100	√	↑
6	Algorithm 2 or 1P with ICD-9 or ICD-10 diagnostic code for kidney transplantation	VI- (II or III)	94.36	100	66.71	100	√	↑
7	Algorithm 1 or 1P with a billing code for hospitalization for kidney transplantation	VII- (I or 15438)	95.28	100	90.91	100	√	#
8	Algorithm 2 or 1P with a billing code for hospitalization for kidney transplantation	VIII- (II or 15438)	91.91	100	90.10	100	√	#
9	Algorithm 4 or 1P with a billing code for hospitalization for kidney transplantation	IX- (IV or 15438)	99.20	100	80.45	100	√	#
10	Algorithm 4 or 1P with ICD-9 or ICD-10 diagnostic code for kidney transplantation	X- (IV or III)	99.49	100	67.37	100		↑
11	Algorithm 4 or (1P with ICD-9 diagnostic code of kidney transplantation and a billing code for hospitalization for kidney transplantation)	XI- (IV or (III and 15438))	99.16	100	84.41	100	√	
12	Algorithm 4 or (1P with ICD-9 diagnostic code of kidney transplantation and (a billing code for hospitalization for kidney transplantation or for visit during the first-year post transplantation))	XII- (IV or (III and (15438 or 1544))))	99.16	100	83.44	100	√	

Cases in the gold standard database (Hospital Discharged) were identified using intervention codes related to KT (CCADTC ICD-9 code 6759 or CCI ICD-10 codes 1PC85LAXXJ, 1PC85LAXXX)
N: Number of Algorithm, P: Physician claim, Sen: Sensitivity, Spe: Specificity, PPV: Positive Predictive Value, NPV: Negative Predictive Value,
Pre: A precision, Res: Restriction,
√ A second transplantation is considered if physician claims codes separated by at least 365 days; ↑ Only the first diagnostic code is considered,
 # Only the first code for hospitalization for Kidney transplantation is considered

Paget's disease of bone (PDB) is a very common late-onset metabolic bone disease affecting 1 million Americans. Measles virus nucleocapsid protein (MVNP) expression in osteoclast (OCL) precursors contributes to the development of abnormally active OCL in Paget's disease in concert with aberrant excess woven bone formation. In addition, MVNP expression targeted to OCL in transgenic mice induces pagetic-like lesions in vivo and OCL with a pagetic phenotype in vitro. We reported that MVNP activation of TBK1, an IKK family member, plays a critical role in mediating the effects of MVNP on OCL differentiation. Further, MVNP expression up-regulated TBK1 protein in BMM Importantly, over-expression of TBK1 in BMM by lentiviral transduction generated pagetic-like OCL. Therefore, to assess if over-expression of TBK1 was sufficient to phenocopy the effects of MVNP in mice, we generated a new mouse model with TBK1 targeted to the OCL lineage (TgTBK1). Analysis of all three founder lines (F1, F3, F4) compared to WT mice revealed that TgTBK1 BMM form increased OCL numbers with increased nuclei/OCL that were capable of resorbing bone at significantly higher rates (resorbing a greater pit area/OCL), had elevated Taf12 and Atf7, decreased Sirt1, and produced more IL-6 mRNA. Thus, indicating that the BMM isolated from TgTBK1 mice generated pagetic OCL in vitro. The TgTBK1-F4 bones had both increased OCL surface, and increased MS/BS and BFR (MAR trended up) when compared to WT at both 10 and 16 month. These led to a decrease in the trabecular number along with increased trabecular width at 10 month in TgTBK1 vs WT. These data indicate that increased expression and activity of TBK1 in OCL-lineage cells is sufficient to generate both increased OCL formation and increased bone formation characteristic of PDB. No lesions were found in the 4-month TgTBK1-F4 or WT mice. A combination of microCT and histologic analyses of vertebrae identified 2 pagetic bone lesions in 10-month TgTBK1-F4 mice (n=17), but none were found in 10-month WT mice (n=16). Similar analysis identified 3 pagetic lesions in 16-month TgTBK1-F4 mice (n=17) and in 2 pagetic lesions in 16-month WT mice (n=14). Thus, overall, vertebral pagetic lesions were found in 15% of TgTBK1-F4 mice and 7% of WT mice. Together these data indicate that increased TBK1 expression and activity in OCL lineage cells generates a pagetic-like bone disease in mice, with both increased osteoclast activity and increased bone formation.

Anatomic distribution of single and multiple parathyroid adenomas in primary hyperparathyroidism Gaia Tabacco*[1], Randy Yeh[2], Donovan Tay Yu-Kwang[1], Laurent Dercle[2], Jennifer Kuo[3], Leonardo Bandeira[1], Catherine Mcmanus[4], James Lee[3], John Bilezikian[1]. [1]Department of Medicine, Division of Endocrinology, College of Physicians & Surgeons, Columbia University, United States, [2]Department of Radiology Columbia University, New York, United States, [3]Department of Surgery GI/Endo, Columbia University, United States, [4]Columbia University, United States

Primary hyperparathyroidism is caused by a single adenoma in more than 85% of the cases. The remaining cases are due to double adenomas, hyperplasia and, rarely, parathyroid carcinoma. Adenomas occur in every parathyroid gland. In this study, a retrospective review of 400 consecutive patients with primary hyperparathyroidism (PHPT), we evaluated the anatomic distribution of parathyroid adenomas. All subjects underwent surgery and met Miami Criteria for post-operative reduction in PTH (intra-operative PTH levels falling by 50% or more in comparison to the higher of 2 pre-excision values). The reference standard for correct localization was the location of the gland(s) based on surgical reports, with pathological confirmation of resected glands as parathyroid adenoma or hyperplasia. 363 (90.7% of the total) had a pathological diagnosis of adenoma, the subject of this report.Of the patients with adenomatous disease, 319 (87.9%) had a single adenoma and 44 had double adenomas (12.1%). The distribution of single adenoma showed that LUQ and LLQ locations occurred with equivalent frequency (n=78 and n=75, respectively). RUQ location of a single adenoma was significantly more frequent (n=101, p=0.004 and the RLQ location of single adenoma

was significantly less frequent (n=65, p=0.031), than expected if equivalent frequency is expected at all sites. Double adenomas were more frequent in the upper quadrants (n=15 p=0.004). The right (n=4), left (n=7), lower (n=5) and diagonal RU-LL (n=11) and RL-LU (n=2) double adenomas showed similar distribution. Furthermore, also in the double adenomas, RUQ localization for 1 of the 2 glands was significantly more frequent (n=30, p=0.02) and RLQ localization was significantly less frequent (n=11, p=0.001).This study demonstrates that single and double adenomas are more frequent in the right upper quadrant and less frequent in the right lower quadrant. Furthermore, double adenomas showed a preferential distribution in upper quadrants (fourth pouch origin). Double adenomas most likely affect both sides of the neck, thus suggesting that when removal of a single adenoma does not lead to successful lowering of the PTH level, a contralateral adenoma is more likely than an ipsilateral one. These results may also be helpful in planning for surgery of patients who are suspected of multiglandular, adenomatous PHPT.

Single adenoma

Double adenomas (right/left; upper/lower, diagonal)

Estrogen Decreases Bone Turnover and Increases Bone Mineral Density in Transwomen: a Prospective Study Mariska Vlot*, Chantal Wiepjes, Annemieke Heijboer, Martin Den Heijer. VU University Medical Center, Netherlands

Purpose: Sex steroids play a key role in bone turnover, bone remodeling and preserving bone mineral density (BMD). Gender-affirming hormonal treatment (HT) therefore affects bone metabolism in transgender people. Yet, studies looking into the effect of HT on bone turnover are scarce. As a result, the aim of this study is to investigate the changes in bone turnover markers (BTMs) and BMD in transgender people during the first year of HT.Methods: This prospective cohort study was conducted in HT-naïve adult transgender people. Sclerostin, the bone resorption marker CTX and bone formation markers PINP and total alkaline phosphatase (ALP) were measured. A DXA scan was performed of lumbar spine (LS) and total hip (TH). BTMs and DXA scans were evaluated at baseline and after 1 year of HT. All analyses were performed separately for transwomen and transmen and stratified for age and sex steroid concentrations. Changes were described as mean percentage changes with corresponding 95% confidence interval (CI). Correlations were calculated between changes in BMD and BTMs.Results: 121 transwomen (median age 30 years, IQR 24-41) and 132 transmen (median age 24 years, IQR 21-33) were included. In transwomen, CTX, sclerostin and ALP decreased with 11% (95% CI -18 ; -4.0), 8% (95% CI -13 ; -4) and 19% (95% CI -21 ; -16) after 1 year of HT. P1NP did not change. In contrast, in transmen P1NP, ALP and sclerostin increased with 33% (95% CI 24 ; 42), 16% (95% CI 12 ; 20) and 15% (95% CI 10 ; 20) after 1 year of HT. CTX did not change. Furthermore, regarding age, transmen in the highest quartile (age 50 years or older) showed a decrease of all BTMs in contrast to the other quartiles, while this age difference was not seen in transwomen. Regarding BMD, the LS BMD increased with 3.9% (95% CI 3.1 ; 4.6) and TH with 1.0% (0.5 ; 1.5) in transwomen respectively, whereas in transmen an increase of LS BMD of 1.0% (0.4 ; 1.7) and 0.9% (0.4 ; 1.4) was seen after 1 year of HT.Conclusion: One year of HT resulted in decreased bone turnover in transwomen and an increased bone turnover in transmen. BMD LS and TH increased after 1 year of HT in both transwomen and transmen. This study supports previous data that estrogen plays a major role in preserving BMD, most likely due to inhibition of osteoclast activity during 1 year of HT.

Regional Analysis of Cortical Bone Using Second-generation High-resolution Peripheral Quantitative Computed Tomography (HR-pQCT) Sanchita Agarwal*, Fernando R Rosete, Ivelisse Colon, Mariana Bucovsky, Kyle K Nishiyama, Elizabeth Shane. Division of Endocrinology, Department of Medicine, Columbia University, United States

HR-pQCT permits 3D measurement of bone density and microstructure and can be combined with finite element (FE) analysis to estimate bone strength. The advent of 2nd-generation HR-pQCT, with its isotropic voxel size of 61 μm and direct measurements of cortical (Ct) and trabecular (Tb) compartments, has stimulated interest in studying Ct bone parameters. Conventional global analysis of the entire cortex obscures regional variation in the cortical structure, which may be important in assessing some clinical conditions and effects of therapeutic interventions.We assessed variation in Ct measurements (porosity, density, thickness) by regional analysis of the Ct compartment. Healthy adults (N=30, 20F/10M, age 42±15) were scanned at standard distal and contiguous proximal sites. After segmenting and analyzing the whole cortex for global measurements, it was divided into 6 regions: anterior (A), posterior (P), medial (M), lateral (L), endosteal (En), and periosteal (Pe); each region was analyzed separately. Regional were compared to global measurements by repeated measures ANOVA (RMANOVA) and Tukey's post-hoc test (Table).At the distal radius (RAD), Ct porosity (Ct.Po) is markedly lower (-78%) in Region A but does not appear to affect Ct. vBMD. It is highest (+32%) in Region M, with larger pore diameter (Ct.Po.Dm) and lower Ct. vBMD (-3%). Ct thickness (Ct.Th) is highest in Region P (+8%) and lowest in Region L. At the proximal RAD, differences are concentrated in Region A with markedly fewer (-90%) and smaller (-17%) pores, lower Ct.Th (-18%) and density (-4%). At the distal tibia (TIB), differences are also concentrated in Region A with fewer (-53%) and smaller (-19%) pores, lower Ct.Th (-12%) but higher density (+3%). At the proximal TIB, only Ct.Th was below global in Regions A and P. At all 4 measurement sites, Ct.Po and Ct.Po.Dm were higher in the En than the Pe Region; density followed the reverse pattern.In summary, we found significant heterogeneity in cortical porosity, pore diameter and thickness, most prominent in the Anterior Regions of the distal and proximal RAD and distal TIB. However, the differences did not consistently affect cortical density. Higher porosity and larger pores in the Endosteal Region likely reflect endocortical trabecularization. Our results resemble prior studies with 1st-generation HR-pQCT. Measuring regional variation could provide more insight into effects of diseases and therapeutic interventions on cortical bone.

Table: Percent difference between global and regional cortical measurements at distal and proximal radius and tibia with *p<0.05, **p<0.01 and ***p<0.001 compared to global.

Microgravity exposure diminishes trabecular microarchitecture and cortical bone structure differently in growing and skeletally mature mice Jennifer C. Coulombe*[1], Eric W. Livingston[2], Alicia M. Ortega[1], Ted A. Bateman[2], Eric A. Vance[3], Louis S. Stodieck[4], Virginia L. Ferguson[1]. [1]Department of Mechanical Engineering, University of Colorado, Boulder CO, United States, [2]Department of Biomedical Engineering, University of North Carolina, Chapel Hill, NC, United States, [3]Department of Applied Mathematics, University of Colorado, Boulder CO, United States, [4]BioServe Space Technologies, University of Colorado, Boulder, CO, United States

Microgravity causes extreme disuse and disrupts the rates of bone formation and resorption. Yet, the differential influence of microgravity and skeletal growth on net bone mass is not known, and outcomes vary greatly with animal age and flight duration. Here, we compare bone microarchitectural alterations in growing and skeletally mature mice following microgravity exposure.Female C57Bl/6 flight mice (FL) aged 9 (Young) and 32 wks (Mature) were flown on STS-118 (Space Shuttle; n = 12/group) and SpaceX-4 (SpX-4, International Space Station; 10/group) missions for 12.8 and 21 days, respectively. Equal group sizes were assigned to baseline (BL; at day 0) and ground controls (GC; at 12.8 and 21 days). Cortical and trabecular bone at the proximal tibia were evaluated using microcomputed tomography (μCT; 10μm; Scanco μCT80). SpX-4 μCT outcomes were pooled from wild-type and MURF-1 knockouts showing no differences between genotypes. One-way ANOVA and Tukey's HSD evaluated for age and flight differences. To compare across missions data are presented as growth rates (comparing BL vs. GC or FL) by determining the % change, for each parameter per study day (%/day). Significance is reported for p<0.01.In Young mice, growth (BL vs. GC) was marked by increasing Tb.BV/TV (+4.01%/day) and Tb.Th (+1.87%/day), with no change in Tb.Sp; microgravity exposure (GC vs. FL) reduced Tb.BV/TV (-2.97%/day), Tb.Th (-1.05%/day), and Tb. Sp (+0.88%/day). Similarly, in cortical bone, Ct.Th increased (+2.15%/day) and Ct.Po decreased (-2.26%/day) with growth, whereas microgravity reduced Ct.Th (-0.84%/day) but not Ct.Po. In contrast, Mature mice showed no growth effects vs. BL. However, microgravity exposure reduced Tb.BV/TV (-2.02%/day), Tb.Th. (-1.15%/day), and Ct.Th (-0.76%/day), while Ct.Po (+1.29%/day) increased. Highly significant interactions (p<0.001) were found comparing growth rates across missions for age and flight. Young mice exhibited a net +0.73%/day increase for Tb.BV/TV, +0.18% Tb.Th, +0.54% Ct.Po, and +0.02% Ct.Th. vs. Mature mice.Bone loss observed with microgravity exposure (BL vs. FL) in growing mice was dominated by both diminished formation and elevated resorption and through elevated resorption only in Mature mice. Overall, it appears that mature bone may be at greater risk of the deleterious microarchitectural changes from microgravity disuse than growing bone.

MON-0093

Effect of High Fat Diet on the Fracture Resistance of Bone in Mice with and without Type 2 Diabetes Amy Creecy*[1], Sasidhar Uppuganti[2], Alyssa Merkel[2], Deanna Bradley[1], Daniel Fernandes[1], Jeffry Nyman[2]. [1]Vanderbilt University, United States, [2]Vanderbilt University Medical Center, United States

Individuals with type 2 diabetes (T2D) have a greater likelihood of suffering a fragility fracture at multiple sites than age-matched individuals without the disease. Obesity is also a risk factor of fragility fractures at certain sites, and a high fat diet (HFD) is thought to negatively affect bone. We hypothesized that HFD independently lowers fracture resistance in both non-diabetic and diabetic adult mice. At 16-wks, male NONcNZO10/LtJ, a new model of T2D, and male NON/ShiLtJ mice, the recommended control, were switched from standard chow to either low fat diet (LFD; 10%kcal from fat) or HFD (45%kcal from fat). Non-fasting blood glucose levels and body mass were monitored weekly and then biweekly after maturity. Except for 11 mice euthanized early (lost body mass) or prematurely died (infection), the left femur and L6 vertebra (VB) were harvested at 37-wks (n≥12/group). Following μCT evaluations of each femur diaphysis (1.8 mm at mid-point) and VB (between endplates) to determine structural/architectural properties and tissue mineral density (TMD), each hydrated femur and VB was loaded-to-failure in three-point bending and in compression, respectively, to assess fracture resistance. Mice on HFD weighed more, irrespective of strain. The HFD significantly increased average blood glucose levels only in the diabetic strain, but HFD did not affect HbA1c at 37-wks (9% for NONcNZO10/LtJ and 5% for NON/ShiLtJ across diets). For the femur, HFD did not affect Imin, peak moment, bending strength, or toughness in either strain (Fig). Neither did HFD affect Ct/Tb.TMD (p=0.222). However, in the control strain, mice on the HFD had a higher cortical porosity. For the VB, HFD did not affect BV/TV in either strain. Interestingly, the peak force of the VB was lower for mice on HFD, suggesting bone quality was affected by diet. There were a number of differences in bone between NONcNZO10/LtJ and NON/ShiLtJ mice indicating that T2D weakens bone, but these mice are not littermate controls making it difficult to ascertain if the effect is strain- or T2D-related. In preliminary studies, many of the same strain-related differences existed at 15-wks (before persistent hyperglycemia). In contrast to prior HFD studies that feed growing mice a HFD, our study investigated the effect of HFD on bone after primary growth. HFD for 21-wks did not cause many changes to cortical bone, even when the mice were diabetic, but it did lower VB strength in non-diabetic and diabetic adult mice.

Finite Element Modelling based Prediction of Vertebral Bone Strength using Statistical Iterative Reconstruction (SIR) Anitha D.*[1], Kai Mei[2], Felix Kopp[2], Peter Noel[2], Thomas Baum[3], Subburaj Karupppasamy[1]. [1]Singapore University of Technology and Design, Singapore, [2]Technical University of Munich, Germany, [3]Technical University of Munich, Dominican Republic

Purpose: Regular monitoring of patients with a risk for osteoporotic vertebral fractures is limited due to radiation exposure concerns1. Advances in image reconstruction methods beyond the current standard, filtered back projection (FBP), can reduce radiation dose, while maintaining image quality. The goal of this study is to compare FBP and a novel Statistical Iterative Reconstruction (SIR) algorithm to access the clinical feasibility of SIR for assessing bone strength using multidetector computed tomography (MDCT) scans.Materials and Methods: Human vertebral specimens (n = 10) were retrieved MDCT imaging at clinical radiation dose, was performed and reconstructed with both FBP and SIR methods. Mechanical testing was performed to obtain experimental failure loads. Apart from image noise, contrast-to-noise ratio (CNR), and signal-to-noise ratio (SNR), bone mineral density (BMD) was also calculated from the images. Finite element (FE) analysis was performed on each specimen and the FE-predicted failure load was obtained 2. Pearson correlations were reported between experimental failure loads, FE-predicted failure load, and MDCT-based BMD values. Student's t-test was used to analyze differences between the two reconstruction techniques.Results: SIR produced significantly lower image noise (30.39 vs. 56.72; p<0.0001), better SNR (5.03 vs. 2.80; p<0.0001), and CNR (5.23 vs 2.73; p<0.0001) than FBP. Experimentally-determined failure load (Fexp) significantly correlated with FE-predicted failure load derived from FBP (FFBP) (R = 0.89, p=0.0002), and SIR (FSIR) (R = 0.92, p<0.0001). FFBP had a significant correlation with FSIR (R = 0.97, p<0.0001). A statistically significant correlation was also observed between BMDFBP and BMDSIR (R = 0.98, p<0.0001).Conclusion: SIR can produce better quality images, whilst maintaining accuracy in terms of FE analysis. Since FBP has a trade-off in reducing image noise and increasing image quality, SIR could be a better alternative in the clinical scenario. Reduction in radiation doses will go a long way in ensuring regular patient monitoring of skeletal conditions such as osteoporosis.

Supervised Machine Learning Techniques for Hip Fracture Prediction from DXA-based 3D Patient-Specific Femur Model Fall Simulations. Sara Guardiola*[1], Carlos Ruiz[2], Jérôme Noailly[2], Jordi Moretón[1], Silvana Di Gregorio[3], Ludovic Humbert[4], Luis Del Rio[3]. [1]CETIR Fundació Privada, Spain, [2]BCN MedTech, Universitat Pompeu Fabra, Spain, [3]CETIR Medical Centre, Spain, [4]Galgo Medical, Spain

Hip fracture risk prediction can be improved by enhancing anatomical and bone mineral density (BMD) descriptions from DXA with biomechanical information derived through DXA-based 3D modeling methods and patient-specific finite elements (FE) simulations. The variable Major Principal Stress (MPS) is the best descriptor for a robust classification of fracture and non-fracture cases. The objective of this work is to obtain a MPS estimation model and a hip fracture classificator using supervised machine learning techniques trained with estimated biomechanical variables obtained with FE simulation of hip fracture.Method: 156 DXA images from osteoporotic patients were collected: 85 fracture and 71 non-fracture cases. Patient-specific FE femur models were created by combining DXA-based 3D modeling method (3D-SHAPER, Galgo Medical) and mesh morphing algorithm. Models included volumetric BMD distribution, translated into element properties and linked to local Young's modulus values. Lateral fall simulations consisted in approaching the femur to a fixed plate. Movement velocity depended on gravity and patient's height.MPS regression models (multiple linear regression, regression tree and support vector machines) were fitted and cross-validated (10 folds). As a measure of comparison of the predictive capacity of the models obtained, the root mean square error (RMSE) was usedFinally, hip fracture/no-fracture predictive classification models (logistic regression, random forest, support vector machines and naïve Bayes) were fitted and cross-validated (10 folds). The area under the curve (AUC) was used to compare the predictive capacity of the models.Results: Fall simulations allowed identifying critical regions for fracture risk assessment. ROC-AUC analyses in these regions showed that MPS best discriminated fracture and non-fracture cases.The MPS model with the smallest root mean square error was the multiple linear regression, which also indicates that vBMD, weight and gender are significant and should be included in the regression model (R2=0.79).Finally, a first approach to get a hip fracture predictive classification tool obtained an AUC of 0.80 using a logistic regression.Conclusion: Though the sample size was small, results suggested that fracture can be predicted from virtually enhanced DXA 3D data, using biomechanical parameters that can be reasonably estimated using supervised learning techniques, bypassing the need to do simulations in each new patient.

Load Sharing of Cancellous and Cortical Bone in Rat Vertebrae Under Uniaxial Compression Determined Using Finite Element Analysis (FEA) Madeleine G. Driver*[1], W. Brent Lievers[2], A. Keith Pilkey[1]. [1]Department of Mechanical and Materials Engineering, Queen's University, Canada, [2]Bharti School of Engineering, Laurentian University, Canada

Uniaxial testing of rat vertebrae is often performed in drug treatment studies to evaluate the response of healthy versus osteoporotic tissue1. However, a recent experimental study by Morton2 found that the large vascular apertures in the cortical shell of rat vertebra have a strong influence on the observed failure behaviour, suggesting this model may have limitations. The relative importance of the vertebral cortical shell during loading may be another important difference. The objective of the present study is to use specimen-specific FEA models to investigate the load sharing of cortical versus cancellous bone of healthy and osteoporotic rat L4 vertebral bodies in order to better understand the challenges of extrapolating rat model results to human vertebral behaviour.Morton2 examined healthy (SHAM), osteoporotic (OVX) and treated osteoporotic (OVX+E) rat vertebrae (n = 31) under uniaxial compression while synchronously imaged with a micro-CT scanner. For the present study, these same images were converted into 3D finite element models using a voxel-based meshing procedure. The images were also processed using a separation algorithm3 to create another set of FE models, with the trabecular network removed from the vertebral body, to enable loading of just the cortical shell (Fig. 1). Assuming isotropic linear elastic behaviour, the models were subjected to a 2% uniaxial compressive strain. The relative load sharing of the cortical shell was determined as the ratio of cortical shell apparent stiffness to the whole vertebral body apparent stiffness.The cortical shell load contribution across all models (Tab. 1) was 70%, which is higher than the 52% reported for human vertebrae4. These mechanical differences are important to consider when extrapolating results from rat studies to humans. A confounding issue is the presence of large vascular apertures in the cortical surface of rat vertebrae; without their presence the proportional load bearing of the cortical shell might be even higher. Future work will study the effect of these vascular apertures on load distribution in the rat vertebral body.References:1. Rhee Y et al. MON-0097

Voluntary Jumping Exercise in Rats Produces a Greater Anabolic Response in the Forelimbs than the Hindlimbs Jon Elizondo*[1], Corinne Metzger[2], Scott Lenfest[1], Jessica Brezicha[1], Amelia Looper[3], Nicholas Igbinigie[2], Peter Phan[2], Susan Bloomfield[2], Harry Hogan[4]. [1]Department of Mechanical Engineering, Texas A&M University, United States, [2]Department of Health & Kinesiology, Texas A&M University, United States, [3]College of Veterinary Medicine, Texas A&M University, United States, [4]Departments of Mechanical Engineering and Biomedical Engineering, Texas A&M University, United States

To better understand exercise's effect on bone, we employed a novel rat jumping model for resistance exercise that uses positive reinforcement instead of negative. The goal of this study is to assess the effect of our jumping protocol on the forelimbs and hindlimbs of adult male rats, as there are apparent differences in loading on each set of limbs: rats jump exclusively with their hindlimbs, resulting in high muscular contractions, while the forelimbs

Monday Posters

327

absorb most of the impact loading of the landing. Over 5 weeks, sucrose pellet rewards were used to condition adult male Sprague Dawley rats (5 mo.) to jump onto and down from a 10" high platform. After training, rats were assigned to ambulatory control (AC, n=10) or exercise (JE, n=10). JE animals performed 30 jumps/d, 5 d/wk, for 4 weeks. Vertical ground reaction forces (GRFs) were measured with a custom force plate and analyzed with a mixed-model ANOVA and Tukey HSD. Peak GRFs were significantly higher than body-weight during both hindlimb jumps (1.6-3.5x BW) and forelimb landings (2.1-3.3x). GRFs were not different between forelimbs and hindlimbs. Ex vivo data collected after 4 weeks of exercise were analyzed with a paired t-test. pQCT scans of the distal femur metaphysis (DFM) and proximal humerus (PH) revealed significantly higher total vBMD in JE compared to AC at the DFM (+10.1%) and the PH (+12.0%). At both sites, the increase was due to higher cortical vBMD with no differences in cancellous vBMD. Histomorphometry at the proximal tibia metaphysis (PTM) and PH demonstrated significantly higher %BV/TV in JE compared to AC at the PTM (+29.5%) and at the PH (+80.3%). Exercise produced significantly higher osteoid surface and lower osteoclast surface at the PTM (+52.8% and -35.7%, resp.) and at the PH (+166% and -56.3%). Bone formation rate was significantly higher in JE compared to AC at the PTM (+36.8%) and PH (+70.5%). These data indicate that our new exercise protocol induces an anabolic bone response in both the hind- and forelimbs. Larger percent differences at the PH suggest the protocol has more pronounced anabolic effects in the forelimbs than hindlimbs. Since mean peak GRFs were not different between sites, other factors, such as differences in load transmission, loading rate, and bone strain distribution characteristics, should be further studied. Better understanding the relationship between loading and bone anabolism could help to focus future exercise interventions for improving bone mass.

Alterations in Gut Microbiome Secreted Vitamin K are Associated with Impaired Bone Quality Christopher J. Hernandez*[1], Jason D. Guss[1], Erik A. Taylor[1], C. Hazel Higgins[1], Eve Donnelly[1], M. Kyla Shea[2], Sarah L. Booth[3], Rodrigo C. Bicahlo[1]. [1]Cornell University, United States, [2]Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, United States, [3]Jean Mayer USDA Health Nutrition Research Center on Aging, Tufts University, United States

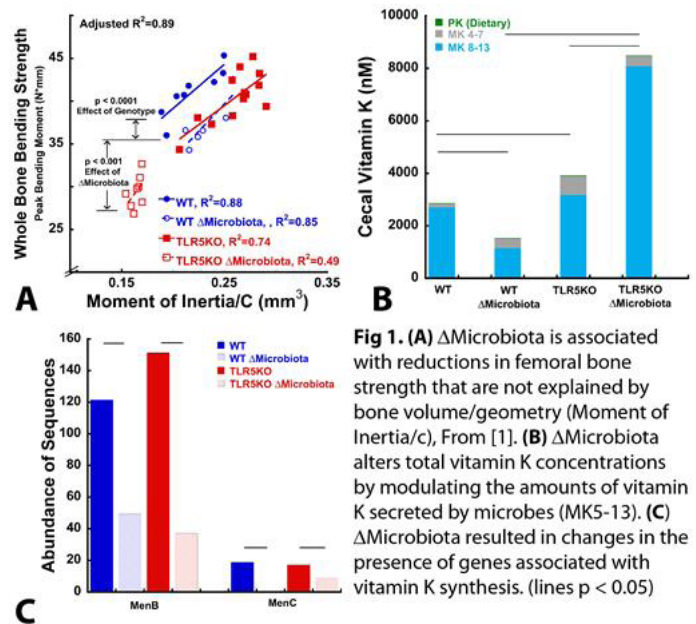
IntroductionPoor bone quality impairs bone strength beyond what can be explained by bone density. Recently we found that altering the gut microbiome in mice can cause impaired bone quality1(Fig. 1A), but the mechanism remains unknown. The gut microbiome a major source of vitamin K, a molecule required for the proper function of matrix proteins that influence bone strength2. To test the idea that microbiome-derived vitamin K explains the observed effects on bone quality we determined: 1) tissue vitamin K concentrations; 2) changes in the functional capacity of the gut microbiome (metagenomics); and 3) bone tissue quality determined with Raman spectroscopy. MethodsWe examined tissue from a prior study1(Fig. 1A, n = 7-10/group). C57Bl/6 WT mice and Toll-like receptor 5 deficient mice (TLR5KO, a strain with distinct gut microbiota) were either untreated or exposed to antimicrobials from 4-16 weeks of age to disrupt the gut microbiota (ΔMicrobiota). Samples were collected at 16 weeks of age. Shotgun metagenomics was used to determine the functional capacity of the microbiota. Cecal contents and liver and kidney were submitted to biochemical analysis using LC/MS.Raman spectroscopy was used to assess mineral quality (crystallinity, mineral-matrix and carbonate-phosphate ratio)in the tibial cortex. ResultsDisruption of the gut microbiota was associated with changes in total vitamin K concentrations, primarily due to changes in microbiome-derived forms of vitamin K (menaquinones MK 5-12, Fig 1B). Disruption of the gut microbiota altered the abundance of microbial genes in both mouse strains, and large changes in the abundance of microbial genes involved in vitamin K synthesis (Fig. 1C). ΔMicrobiota also led to changes in mineral crystallinity that mirrored the changes in vitamin K concentrations. DiscussionVitamin K has long been associated with fracture risk2. Vitamin K dependent proteins in bone matrix that influence bone strength include matrix Gla protein, and osteocalcin. Interestingly, alterations in matrix crystallinity like those observed here are present in osteocalcin deficient mice3. Impaired bone quality has been implicated in many patient populations that also have altered gut microbiota (obesity, diabetes, inflammatory bowel disease). Microbiome-derived vitamins may help explain increases in fracture risk not explained by BMD. 1Guss et al J Bone Miner Res20172Gundberg et al. Adv Nutr-20123Boskey et al. Bone1998.


Fig 1. **(A)** ΔMicrobiota is associated with reductions in femoral bone strength that are not explained by bone volume/geometry (Moment of Inertia/c), From [1]. **(B)** ΔMicrobiota alters total vitamin K concentrations by modulating the amounts of vitamin K secreted by microbes (MK5-13). **(C)** ΔMicrobiota resulted in changes in the presence of genes associated with vitamin K synthesis. Strength training performed prior to fracture improves oxidative profile and fracture healing in aging female rats Melise Jacon Peres Ueno*, Fernanda Fernandes, Amanda Pinatti, Camila Stringhetta Garcia, Angela Cristina Nicola, Mário Jefferson Quirino Louzada, Paulo Cesar Ciarlini, Rita Cássia Menegati Dornelles. UNESP, Brazil

Introduction: the incidence of bone fracture is high in the senile population and although there is evidence on the efficacy of physical exercise in improving bone quality, it is not yet clear whether physical exercise performed prior to fracture may improve oxidative stress and accelerate bone repair, especially in peri or postmenopausal women. Therefore, the present study aimed to analyze the influence of strength training (ST) on oxidative stress and healing fracture in aging female rats during peri-estropause after total tibial osteotomy. Methods: Eighty wistar female rats were distributed in: NT (untrained) and ST (strength training). For a total of 120 days, aging female rats at 18-21 months of age performed ST on a ladder three times per week and the overload used was equivalent to 80% of the maximal strength test. After the experimental period, unilateral total osteotomy was performed on the left tibia in all animals that were euthanized at two experimental times, 1 week and 8 weeks after the osteotomy, to evaluate the response to the initial fracture stage and healing fracture. For this, was evaluated the biochemical and oxidative profile (spectrophotometry) and analysis of soft (1 and 8 weeks) and hard (8 weeks) callus microarchitecture (micro-ct). Anova (two-way) with Tukey´s post-test (GraphPad Prism 6.0) were used. Results: The results show that 1 week after the osteotomy, there was a important decrease of malondialdehyde (MDA) in the animals that performed ST. Eight weeks after the osteotomy, ST was able to improve the oxidative profile, increasing the formation of the ferric reducing antioxidant potential (FRAP) and reducing the total oxidizing capacity (TOS), culminating with the action in favor of bone formation, increasing the plasma concentration of alkaline phosphatase. This ST action in the oxidative and biochemical profile resulted in a significant increase in the bone volume of soft and hard callus (BV/TV), trabecular number (Tb.N), decreases of trabecular separation (Tb.Sp) as well the increses of the soft and hard callus resistance shown by the polar moment (MMII polar) compared to those animals that did not perform strength training. Conclusion: According to these results, it can be suggested that strength training performed during the premenopausal phase improves the oxidative profile and interferes in the process of bone callus formation, improving healing fracture and increasing resistance to the bone stresses.

Composition of Hyperelastic Bone Comoposite Scaffolds Affects De Novo Bone formation Soyeon Jeong*[1], Adam Jakus[2,3], Chawon Yun[1], Ryan J. Lubbe[1], Adam Driscoll[1], Meraaj S. Haleem[1], Kevin Y. Chang[1], Wellington K. Hsu[1], Ramille Shah[2], Stuart R. Stock[4], Erin L. Hsu[1]. [1]Northwestern University Department of OrthoPaedic Surgery, United States, [2]Northwestern University Department of Materials Science and Engineering, United States, [3]Simpson Querrey Institute for BioNanotechnology, United States, [4]Northwestern University Department of Cell and Molecular Biology, United States

BACKGROUNDBone graft extenders for spine fusion include demineralized bone matrix (DBM) and ceramic-based products, but their efficacy is insufficient to qualify them as bona fide bone graft substitutes (BGS). We previously developed a novel 3D-printed composite scaffold containing synthetic hydroxyapatite particles (HA), osteoinductive DBM particles, and a poly lactic-co-glycolic acid (PLGA) binder to create hyperelastic "bone" composites (HBC). The current study evaluated the ability of various iterations of these HBC scaffolds to promote bone regeneration and spine fusion in a rat posterolateral spine fusion (PLF) model.METHODSSixty female Sprague-Dawley rats underwent PLF at the L4-L5 intertransverse space utilizing HBC scaffolds composed of 30 vol.% PLGA and 70 vol.% particles (N=12/group). For each group, the particle components consisted of the following ratios of HA:DBM: 1:0, 3:1, 1:1, 1:3, and 0:1. Eight weeks postoperatively, spine fusion was evaluated via radiography and manual palpation, and bone formation was assessed using both laboratory and synchrotron microCT imaging. Histology [Alcian blue-Hematoxylin/Orange G (ABHO) and Masson's Trichrome (MT)] was also used to visualize the bone-scaffold interface.RESULTS3:1 HA:DBM HBC scffolds had the highest fusion rate (92%), although this was only significantly higher than the 0:1 group (42% fusion). The 1:0, 1:1, and 1:3 scaffolds achieved fusion rates of 58%, 58%, and 67%, respectively. De novo spicule formation was only seen in scaffold that had both the HA and the DBM components, while the 1:0 and 0:1 scaffolds elicited none. Staining with ABHO and MT showed evidence of bone where bone-like spicules were seen in synchrotron microCT imaging.CONCLUSION-This study evaluated the combination of HA and DBM particles within this novel 3D-printed composite material and its potential to overcome the limitations of currently used BGS in spine fusion procedures. Varying the proportions of HA:DBM within each scaffold resulted in only slight differences in fusion rates. However, microCT showed that de novo bone spicule formation was only present within scaffold struts that contained both HA and DBM particles. This study suggests that 1) the presence of osteoinductive DBM is key to de novo bone formation, and 2) the hydroxyapatite provides the calcium and phosphate necessary to re-mineralize the DBM particles.

Panx3 is important for tibial morphogenesis during skeletal development and bone homeostasis Xian Jin*[1], Xiangguo Che[1], Na-Rae Park[1], Yu-Min Hong[1], Clara Park[2], Yu-Ra Choi[1], Je-Yong Choi[1]. [1]Department of Biochemistry and Cell Biology, Cell and Matrix Research Institute, BK21 Plus KNU Biomedical Convergence Program, Korea Mouse Phenotyping Center, School of Medicine, Kyungpook National University, Daegu, South Korea., Republic of Korea, [2]Division of Food and Nutrition Chonnam National University 77 Yongbong-ro, Buk-gu, Gwangju, Korea, Republic of Korea

Although Pannexin 3 (Panx3) has been known as a channel for ATP in chondrocytes, the function of Panx3 in bone formation and mineralization remains poorly understood. We addressed the role of Panx3 during skeletal development using Panx3 knockout (KO) mice. Panx3 KO mice had shorter femurs, tibia curvature defects and delayed endochondral ossification during the embryo stage. Microcomputed tomography (µCT) analysis resulted in greater femoral bone volume to tissue volume ratio (BV/TV), bone mineral density (BMD) and trabecular number (Tb.N) in Panx3 KO mice compared to wild type (WT) mice at 12 weeks. Lower tibial osteoclast surface to bone surface (Oc.S/BS) was observed in Panx3 KO mice compared to WT mice at 12 weeks through TRAP staining. By quantitative real-time PCR analyses, Panx3 KO mice showed less expression of osteogenic markers such as Runx2, Osterix and Osteocalcin compared with WT mice. Osteoclast differentiation and resorption activity were lower in osteoclasts derived from Panx3 KO than WT when bone marrow monocytes were cultured with M-CSF and RANKL. Collectively, the positive role of Panx3 on both osteoblast and osteoclast differentiation and morphological change during skeletal development suggests that Panx3 may play an important role in bone homeostasis as well as skeletal morphogenesis.

MON-0102

Guided Bone Regeneration with rhBMP-2 Improves Bone Quality Surrounding Dental Implants Trenton Johnson*[1], Jung-Suk Han[2], Toru Deguchi[1], Frank Beck[1], Do-Gyoon Kim[1]. [1]Ohio State University, United States, [2]Seoul National University, Republic of Korea

Guided bone regeneration (GBR) has been used to promote osteogenesis in a bone defect surrounding a dental implant. While bone quantity at the implant interface has been investigated to evaluate stability of the implant system, bone quality is also responsible for determining mechanical response of bone around the implant. The objective of this study is to examine the nanoindentation based elastic modulus (E) and plastic hardness (H) at different bone regions adjacent to titanium dental implants with GBR treated with demineralized bone matrix (DBM) and bone morphogenetic protein (BMP) during different post-implantation periods.Following IACUC approval, six adult male beagle dogs were used to create circumferential defects (Ø6.3 mm x 4 mm) with buccal bone removal at each implantation site of mandibles following 3 months post-extraction healing periods (Fig.1a). Four titanium dental implants were bilaterally placed in each dog mandible. The implant systems were randomly assigned to only GBR (control), GBR with DBM (DBM), and GBR with DBM+rhBMP-2 (BMP) groups. Three animals were sacrificed at each 4 and 8 weeks of post-implantation healing periods. The bone-implant constructs were buccolingually dissected for nanoindentation. The E and H values were assessed by 980 indentations at the defects (Defect),

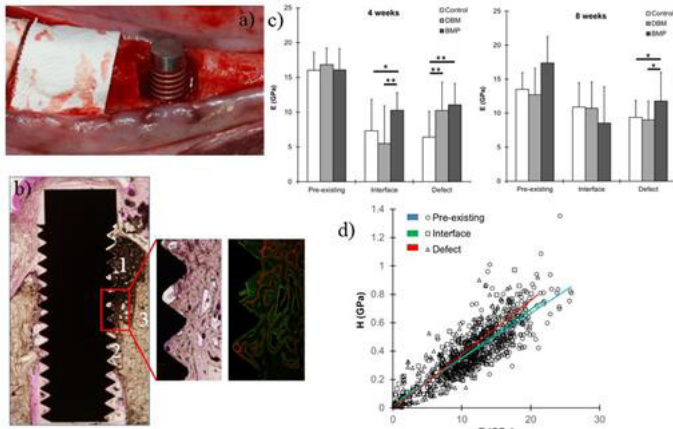
interfacial bone tissue adjacent to the implant (Interface), and pre-existing bone tissue away from the implant (Pre-existing) (Fig.1b). A mixed model ANOVA with the Tukey-Kramer procedure was performed. Pearson's correlation was tested between E and H. Significance was at p<0.05.The E and H values of BMP group had significantly higher than control and DBM groups for interface and defect regions at 4 weeks of post-implantation period and for the defect region at 8 weeks (p<0.043) (Fig. 1c). The DBM group had higher E and H values than control group only for the defect region at 4 weeks (p<0.001). Significant strong positive correlations of H with E were found (p<0.001). The correlation slope of the defect region was significantly steeper than those of other regions (p<0.011) (Fig. 1d).The current results indicate that treatment of rhBMP-2 with GBR accelerates bone tissue mineralization, which enhances bone quality of the defect region during early post-implantation healing and maintain it for longer healing period. The GBR likely facilitate a microenvironment to provide more metabolites with the open space of the defect region adjacent the titanium implant.


Fig. 1 a) The implant placement procedure for GBR placement, b) effects of treatment on regional variation of E at 4 and 8 weeks of post-implantation periods (*; p<0.045, **; p<0.001), c) representative histological image of the indent locations as 1) defect, 2) interface, and 3) pre-existing bone areas with fluorescence new bone labeling, and d) significantly different correlation slopes of E vs H between areas (p=0.01).

Morphology of bird bone during egg-laying Leeann Louis*. University of California, Berkeley, United States

Introduction Female birds require a large calcium load to create an eggshell. A typical chicken eggshell requires 2.4 g of calcium, or about 20% of the calcium present in their body1. To prepare, birds create a mineralized tissue, medullary bone, inside their bones. We know that medullary bone is used as a calcium resource during egg-laying2 and that its formation is initialized by high levels of estrogen. Here, we explore the relationship between estrogen and whole-bone structure.Methods Avian endosteal cells form medullary bone when androgens and estrogen are present3. Therefore, we created a model of medullary bone formation by implanting adult male zebra finches (Taeniopygia guttata) with an empty silastic tube (SH, n=4) or one filled with β-estradiol (ES, n=6). After 3 weeks, we performed micro-computed tomography (μCT35; Scanco Medical AG) on one humerus per bird. We analyzed the midshaft for cortical bone microarchitecture (Ct), and the proximal humerus for trabecular bone (Tb). We also measured bone mass (Sartorius Research R200D). For each bone parameter, we report the p-value of a Welch's t-test between groups.Results Estrogen-treated males grew medullary bone along endosteal surfaces (see Fig. 1). In the cortex, this treatment did not change total area (CtTtAr p=0.784) or cortical thickness (CtTh p=0.821), but did reduce marrow area (CtMaAr p=0.031). This resulted in a slight increase in polar moment of inertia (pMOI p=0.186) and bone mass (BoneMass p=0.474). In the trabecular region, medullary bone growth increased bone volume fraction (TbBVTV p<0.001) and trabecular number (TbN p=0.010), and increased trabecular thickness (TbTH p=0.025). Discussion Continuous treatment with estrogen resulted in osteogenesis in the male zebra finch. This process reduced marrow area due to encroaching medullary bone, and slightly increased pMOI and bone mass. These findings suggest that medullary bone may improve resistance to torsion and offset the reduction in whole-bone mechanical properties that occurs when a bird mobilizes calcium to lay an egg. Work is underway to use mechanical testing to confirm whether these changes result in whole-bone mechanical effects.References 1. Dumont, E.R., (2010). Proc. R. Soc. B, 277 p2193. 2. Influence of Age, Sex, and Anatomical Location on Human Cortical Bone Microarchitecture: A Synchrotron Radiation Micro-CT Study Lindsay Loundagin*[1], David Cooper[2], W. Brent Edwards[1]. [1]Human Performance Laboratory, Faculty of Kinesiology, University of Calgary, Canada, [2]Department of Anatomy and Cell Biology, College of Medicine, University of Saskatchewan, Canada

Microarchitecture is a function of bone remodeling, which is heavily determined by age, sex, and loading environment. Advanced age has been associated with increased porosity and larger canal sizes (1,2), while the shape and spatial distribution of osteocyte lacunae is thought to reflect local loading conditions (3). Although variations in microarchitecture have been observed, the relative influence of age, sex or loading is unknown. The purpose of this study was to determine the influence of age, sex and anatomical location on microarchitectural parameters.Cadaveric femoral and tibial shafts were obtained from 2 females (71 and 99 years old, n=26) and 1 male (77 years old, n=15). Cylindrical cores were extracted from the cortex of the femur (n=28) and tibia (n=13) and machined into a waisted geometry. A region 2.8x2.25mm was imaged using synchrotron x-ray microCT (BMIT, Canadian Light Source) with a resolution of 1.8μm. Within a cylindrical volume of interest (1.77mm3), pores were segmented using hysteresis thresholding, and Fiji software (NIH, Bethesda, MD) was used to quantify porosity, mean canal diameter (Ca.Dm) and osteocyte lacunar density (Ocy.Den). Three univariate ANCOVAs were performed to assess the effect of sex, anatomical location (fixed) and age (covariate) on each microarchitectural parameter (p≤0.05). Microarchitectural measures are summarized in Table 1. Sex explained 46% (p≤0.001) of the variation in porosity while 17% was accounted for by age (p=0.01). Ca.Dm was significantly affected by sex (p=0.001, partial η2=0.27) but not age (p=0.36, partial η2=0.023). Anatomical location did not affect any parameter, but an interaction between location and sex was observed for Ocy.Den (p=0.018). In females, Ocy.Den was higher in the femur when compared to the tibia, whereas the opposite trend was observed in the male.Although several studies report an age-dependent increase in porosity and canal size, the current results suggest that sex is more influential on these measures than age alone. Despite a 30-year age difference, both females demonstrated a more porous bone with larger canals compared to the male. Assuming Ocy.Den is indicative of the mechanical loading environment, an interaction of sex and location may indicate sex-specific loading conditions. Multiple samples were analyzed from a limited number of subjects, so these findings should be replicated with independent samples from a larger population.1.Cooper. (2007). Bone. 40: 957-965.2.Chen. (2010). Osteoporos Int.21: 627-636.3.Carter. (2013). Bone.52: 126-132.

Zoledronate and Raloxifene Combination Therapy Enhances Architecture and Mechanical Properties Katherine Powell[1][*], Joseph Wallace[1], Alexis Pulliam[1], Alycia Berman[2], Matt Allen[3]. [1]IUPUI Department of Biomedical Engineering, United States, [2]Purdue University Weldon School of Biomedical Engineering, United States, [3]IU School of Medicine Department of Anatomy and Cell Biology, United States

Bisphosphonates (BPs) are used to treat osteoporosis and other bone disorders, including Osteogenesis Imperfecta (OI). BPs increase BMD and bone mass in OI, but do not effectively enhanced bone quality. Alternatively, Raloxifene (RAL) increases tissue hydration, leading to increased bone toughness with modest changes in BMD. We hypothesized that a combination of RAL and Zoledronate (ZOL) would improve mechanical and material properties of normal and OI bone better than either monotherapy.Heterozygous males from the OI mouse model (Het; n=19) and wildtype littermates (WT; n=22) were treated starting at 8 weeks of age (4-6/group). RAL was given 5x/week in RAL and RAL+ZOL groups (0.5 mg/kg). ZOL and RAL+ZOL groups were treated with 80 µg/kg ZOL at 8 and 12 weeks of age. An untreated control group (CON) was included. Mice were euthanized at 16 weeks. Right femurs were scanned by micro-CT (10 µm resolution) and cancellous and cortical regions were analyzed. Bones underwent 3-point bending to obtain mechanical properties. One Way ANOVA with posthoc Dunnett's tests statistically analyzed effects of treatment versus control in each genotype.WT cancellous properties were enhanced in all treatment groups. Tissue mineral density (TMD) increased with RAL (+6.6%, p=0.037) and RAL+ZOL (+13.2%, p<0.001) versus CON. Bone volume fraction (BV/TV) dramatically increased by 178% with ZOL and 191% with RAL+ZOL compared with CON (both p<0.001). Trabecular thickness (Tb.Th) increased in both RAL (+14.1%, p=0.0485) and ZOL (+8.6%, p=ns) with a greater than additive effect in RAL+ZOL (+36.4%, p<0.0001). In Het, TMD in RAL+ZOL increased (+6.1%, p=0.0058), but RAL and ZOL groups did not change significantly. BV/TV increased 127% with ZOL and 139% with RAL+ZOL (both p<0.001). RAL+ZOL was the only treatment to increase Tb.Th (+16.6%, p=.0058). The only significant effect on cortical geometry was increased cortical thickness in the WT RAL+ZOL group versus CON (+17.3%, p=0.018). Minimal cortical effects confirm that changes in mechanical properties were driven by tissue level quality changes. Ultimate stress trended up with all treatments but only changed significantly in WT RAL+ZOL (+27.8%, p=0.017) and Het RAL (+37.5%, p=.004) when compared to their respective controls. Overall, this study demonstrates compelling changes with the use of combination therapies which both increase bone mass and enhance bone quality.

Investigating pharmaceutical-induced alterations to matrix maturation using the lactation during low calcium model. Ryan Ross*, Matthew Meagher, Rick Sumner. Rush University Medical Center, United States

Matrix maturation is a critical, yet oft-neglected component of bone remodeling. Our laboratory has recently demonstrated the utility of a low calcium during lactation model to study bone matrix maturation in cortical bone (1).In the current study we used the model to compare the effects of pharmaceutical agents on matrix maturation independent of their effects on bone remodeling. At parturition (13 weeks of age) 72 female Sprague-Dawley rats were fed a low calcium diet (0.01% Ca) for a 23-day lactation period. At weaning a cohort of 8 animals was sacrificed to establish baseline cortical structure. The remaining animals were fed a normal calcium diet (0.6%) and equally distributed into one of four treatment groups, control (saline weekly), sodium fluoride (NaF, 100 mg/L, drinking water), zoledronic acid (ZA, 1.5 µg/kg weekly), or sclerostin antibody (Scl-Ab, 5 mg/kg weekly). Fluorochrome labels were given to identify bone tissue-age. 8 animals per group were sacrificed at either 7 or 28 days. Cortical geometry and porosity at the distal femoral diaphysis were assessed using micro-computed tomography. Bone matrix composition (mineralization and crystallinity) was assessed at various tissue-ages within the endocortical and intra-cortical compartments using Fourier transform infrared imaging. Treatment and time effects were assessed using two-way analyses of variance.Both cortical area and porosity had significant time effects as all groups recovered lost bone mass by 28 days. There was no treatment effect for cortical area, but was in porosity. The normalization of cortical porosity was slightly delayed in the Scl-Ab group, but all groups showed similar levels by 28 days. Mineralization and crystallinity had significant time effects, consistent with matrix maturation. There was a significant treatment effect for mineralization. NaF treatment increased mineralization at each time point, while Scl-Ab treatment increased mineralization at the early time points compared to controls. Treatment effects were also noted in crystallinity with NaF and ZA treatment increasing crystallinity compared to controls.The results demonstrate the utility of the lactation during low calcium model and could help to identify matrix-related concerns with new osteoporosis treatments, such as those previously seen following NaF.(1)Ross and Sumner. Local and Global Microarchitecture Control Different Features of Bone Biomechanics Jean-Paul Roux*[1], Stephanie Boutroy[1], Mary L Bouxsein[2], Roland Chapurlat[1], Julien Wegrzyn[1,3]. [1]INSERM UMR 1033, Université de Lyon, France, [2]Center for Advanced Orthopedics Studies, Harvard Medical School - Beth Israel Deaconess Medical Center, United States, [3]Department of Orthopedic Surgery, Pavillon T, Hôpital Edouard Herriot, France

Purpose: Beside aBMD assessment, most previous in-vivo and ex-vivo studies evaluating the fragility fracture risk relied on measurement of whole bone specimen microarchitecture. The trabecular bone, however, is not a uniform network, especially in vertebrae. Therefore, this study aimed to: 1) evaluate local microarchitectural weakness inside the vertebral body, 2) compare the parameters of local weakness to those of global trabecular microarchitecture and 3) demonstrate which features of bone biomechanics the local and global trabecular microarchitecture controlled.Methods: Twenty-one L3 vertebrae were harvested from human donors (76±10 years). Microarchitecture was measured using HR-pQCT (XtremeCT, Scanco) with an 82μm nominal isotropic voxel size. The following global parameters of trabecular microarchitecture were measured: Tb.BV/TV (%), Tb.N (1/mm), Structure Model Index and connectivity density (Conn.D, 1/mm3). The image stack oriented along the cranio-caudal mechanical was extracted from the μCT images using Dataviewer and CTan software (Skyscan) to identify the minimal value of trabecular 2D-Tb.BV/TV for each vertebral body. The "local weakness" was therefore defined as Tb.BV/TVmin (Fig1). Uniaxial compression mechanical testing was performed in 3 phases with the initial compression phase until mild vertebral fracture, a 30-minute unloaded period of relaxation, and a second compressive phase until failure.Results: Initial and post fracture mechanics were significantly correlated with bone mass, global and local trabecular microarchitecture (table1). Notably, the correlation between Tb.BV/TVmin with initial and post failure load remained significant after adjustment for BMD or global tb.BV/TV (p=0.014 and 0.038 respectively). The combination of the most pertinent parameters of bone mass, global microarchitecture and local microarchitecture expressed by the equation "mechanical behavior= Tb.BV/TV + ConnD + Tb.BV/TVmin" demonstrated that global microarchitecture was most strongly correlated with initial and post-failure stiffnesses, while only local microarchitecture expressed by Tb.BV/TVmin explained initial and secondary failure loads.Conclusion: This study evaluated the effect of global and local microarchitecture on the initial and post mechanical testing behavior. The pre- and post-failure stiffnesses were controlled by global microarchitecture while the pre- and post-failure loads were controlled by local microarchitecture.

MON-0108

BMP-2 Revealed Enhanced Healing in Fractured Mouse Tibia using Micro-CT and Torsion Test Sotcheadt Sim*[1], Theresa Farhat[2], Martin Pellicelli[2], Martin Garon[1], Eric Quenneville[1], René St-Arnaud[2]. [1]Biomomentum Inc., Canada, [2]Shriners Hospital for Children, Canada

The purpose of this study was to investigate the ability of torsion tests to monitor the mechanical properties of fractured mouse tibias after treatment with BMP-2.An intramedullary rodded surgical fracture repair model was performed on 3-month old wild type female C57BL/6 mice. Two groups were defined: a vehicle group receiving water-loaded absorbable collagen sponge (ABS) and a treatment group receiving 10μg of recombinant human BMP-2 (rhBMP-2)-loaded ABS at the fracture site. The healing bones were collected and assessed through micro-CT and torsional testing at day 15 and 21 post-fracture. Tibiae were scanned, and reconstruction was performed to determine callus total volume (TVCallus), callus bone volume (BVCallus) and callus mineralized volume fraction (BV/TVCallus). Subsequently, torsional testing was performed using the mechanical tester Mach-1 model v500ct (Biomomentum) with a 70N multi-axial load cell. Specimens were kept hydrated during sample preparation and mounting, then subjected to a torsion test with a loading rate of 5 deg/s. The ultimate torque and torsional stiffness were extracted from the torque-rotational displacement curves. At 15 days post-fracture (Fig.1), mice that received BMP-2 displayed significant higher TVCallus (50±1mm3 vs 23±6mm3;p<0.0001), BVCallus

(9±1mm3 vs 5±1mm3;p<0.0001), ultimate torque (12±3N·mm vs 7±1N·mm;p=0.01) and torsional stiffness (0.5±0.1N·mm/deg vs 0.3±0.1N·mm/deg;p=0.008) than the vehicle group. However, the callus mineralized volume fraction was significantly lower in BMP-2 treated group (17±1% vs 20±1%;p=0.01). At 21 days post-fracture (Fig.1), significant higher TV-Callus (44±7mm3 vs 17±3mm3;p<0.0001) and BVCallus (5±1mm3 vs 3±1mm3;p=0.003) were still observed in the treated group while the mineralized volume fraction (12±1% vs 16±4%;p=0.06), the ultimate torque (11±3N·mm vs 13±3N·mm;p=0.9) and torsional stiffness (0.4±0.1N·mm/deg vs 0.6±0.04N·mm/deg;p=0.17) were similar in both groups. This suggests that mechanical competence of the bone (forces required to disrupt the callus), mechanical strength and elasticity of bone of the callus has been reached faster in the BMP-2 treated group.The present study is a first step toward the establishment of torsion testing as a means of understanding the mechanical behavior of callus tissues and their role in reestablishment of stiffness and strength during the fracture healing of bone.
Figure 1. The effects of BMP-2 on bone healing in mouse tibial fracture. Quantification of callus total volume, callus bone volume and callus mineralized volume fraction using micro-CT analysis and ultimate torque and torsional stiffness through torsional testing. Data are expressed as means ± SD.

Effects of Carboxymethyl-lysine on Bone Matrix Deepak Vashishth*, Grazyna Sroga, Ondrej Nikel. RPI, United States

CML, a non-fluorescent AGE crosslink, is 10-100 times more prevalent than PEN and accumulates in various tissues like skin, intervertebral discs, and arteries with age and diabetes. More CML is present in serum of T2D patients and recently, serum levels of CML were shown to be associated with hip fracture [1]. Here we demonstrate, for the first time, formation of CML in bone and show that, similar to skin, CML is 40-100 times PEN in human bone and is highly correlated to bone toughness [2]. Unlike PEN and fAGEs that form intramolecular crosslinks, CML is present as a side chain. Thus, it is likely that through molecular conformational changes CML modifies the collagen I-hydroxyapatite (HA) interface and alters energy dissipation in bone at the level of HA crystal. To this end we developed a technique using the C-13{P-31} rotational echo double resonance (REDOR) NMR pulse sequence that identifies carbon atoms that are spatially close to the phosphorus atoms of the mineral in the collagen-HA interface region by quantifying percent dephasing. Results obtained showed that REDOR dephasing was highly correlated to AGEs in bone (R-square = 0.89). In order to investigate the mechanistic aspects of this correlation, we developed an in vitro technique to form CML in fully mineralized bone and use it to successfully demonstrate the effects of CML on collagen-HA distance in bone. Comparison of Zoledronate and Pamidronate in Children with Skeletal Disorders: Short Term Safety Experience from a Single Institution Alison M. Boyce*[1,2], Andrea Estrada[2,3], Marianne Floor[2], Mirini Kim[2], Lindsay Weigley[2], Elizabeth Carlson[4], Christina Dollar[2], Austin Gillies[2], Mary Scott Roberts[2], Rachel I. Gafni[1,2], Laura L. Tosi[2]. [1]Skeletal Disorders and Mineral Homeostasis Section, National Institute of Dental and Craniofacial Research, NIH, United States, [2]Bone Health Program, Division of Orthopaedics and Sports Medicine, Children's National Health System, United States, [3]Division of Endocrinology and Diabetes, Children's National Health System, United States, [4]Children's National Health System, United States

Background: Bisphosphonates are frequently used in children with skeletal disorders, however optimal dosing and regimens are unknown. Early treatment focused on pamidro-

nate (PAM), a second-generation formulation, however use of zoledronate (ZOL), a more potent third-generation bisphosphonate, has recently increased due to shorter and less frequent infusions. The objective of this study is to compare short-term safety of ZOL and PAM in a pediatric population. Methods: Retrospective chart review including demographics, indications, and formulations. Adverse events (AEs) for 7 days post-infusion were categorized: 1) Acute phase reactions (APR): fever, bone pain, myalgia, decreased oral intake, and/or fatigue; 2) nausea/vomiting; 3) hypocalcemia (serum calcium <8.5 mg/dL); 4) seizures; 5) respiratory distress; 6) anaphylaxis; 7) emergency department evaluations and hospital admissions. Results: 119 patients (median age 8.6y, range 0.1-23.4) received 782 infusions (46 ZOL, 736 PAM) between June 2007 and August 2017. The most common diagnoses were osteogenesis imperfecta (31%), cerebral palsy (22%), and muscular dystrophy (12%). AEs were more common after ZOL than PAM: 50% vs 23.1% for initial infusions, p=0.03; and 18.8% vs 4.5% for subsequent infusions, p=0.0004. APRs occurred after 6/46 total ZOL infusions (13.0%) vs 28/736 total PAM infusions (3.8%)(p=0.003). Nausea/vomiting occurred after 4/46 ZOL (8.7%) vs 20/736 PAM infusions (2.7%)(p=0.02). Hypocalcemia occurred after 5/46 ZOL (10.8%) vs 4/736 PAM infusions (0.5%)(p<0.0001), and was managed with oral calcium and calcitriol. An increase over baseline seizure activity was reported after 2/46 ZOL (4.3%) vs 1/736 PAM infusions (p<0.0001). Respiratory distress occurred after 0/46 ZOL and 2/736 PAM infusions (p=0.72) There were no cases of anaphylaxis. Emergency department evaluations and/or admissions occurred after 2/46 ZOL (4.3%) and 4/736 PAM infusions (0.5%)(p=0.04). Conclusions: ZOL treatment is associated with a higher incidence of AE's compared to PAM, consistent with the increased potency of this formulation. While AEs following both ZOL and PAM are common, they are generally mild and treatable. Additional research regarding long-term safety, efficacy, and costs are needed to determine if ZOL's convenience justifies its routine use over PAM.

Diagnosis of recurrent fracture in a pediatric cohort Melissa Fiscaletti*[1], Craig Peter Coorey[2], Julie Briody[2], Andrew Biggin[2], David Little[2], Aaron Schindeler[3], Craig Munns[2]. [1]Children's hospital at Westmead, Canada, [2]Children's hospital at Westmead, Australia, [3]University of Sydney, Australia

Significant fracture history in children is defined as having at least one vertebral fracture, at least 2 fractures by age 10, or at least 3 fractures by age 19. Between September 2011 and December 2014, clinical data were collected on children with a significant fracture history that attended a major Australian children's hospital. Fifty-six patients were identified as having 305 fractures in total, including 44 vertebral fractures. 18% of patients (10/56) were diagnosed with osteogenesis imperfecta (OI) by a bone health expert, molecular testing or both, and they sustained 23% of all fractures (71/305). Analysis of serum bone biochemistry showed all median values to be within a normal range and no clinically significant differences between patients with and without OI. The DXA and pQCT derived bone mineral density (BMD) and bone mineral content (BMC) Z-scores were reduced overall. DXA derived total body and lumbar spine areal BMD-for-age and BMC-for-age Z-scores were significantly lower in children who had vertebral fractures or who were later diagnosed with OI. Similarly, pQCT performed on radii and tibiae showed Z-scores significantly less than zero. In conclusion, this study describes the bone phenotype of children referred to a tertiary hospital clinic for recurrent fractures and highlights a subset of children with previously undiagnosed OI, but a larger cohort without classic OI. Thus it can be clinically challenging to differentiate between children with OI type 1 (mild phenotype) and non-OI children without bone densitometry and genetic testing. We conclude that recurrent fractures in children should prompt a comprehensive bone and systemic health assessment to eliminate an underlying pathology.

Three Patient Kindred with Novel Phenotype of Osteogenesis Imperfecta due to a Mutation in the COL1A1 gene Nidhi Gupta*[1], Seth Gregory[2], David Deyle[3], Peter Tebben[3]. [1]Vanderbilt University Medical Center, United States, [2]Mayo Clinic Health System, United States, [3]Mayo Clinic, United States

Objective: Osteogenesis Imperfecta (OI) is a heterogeneous disorder characterized primarily by fractures and progressive bone deformities. We report a novel phenotype of a mutation in the COL1A1 gene in three members of a non-consanguineous family of European descent.Methods: Data were collected from the patients' and their medical records. Results: The first affected member (M1) was a 37-year-old female with nine non-traumatic long bone fractures (primarily femoral) before 5 months of age. Prenatal ultrasound findings were unknown. She did not receive bisphosphonate treatment, despite which she suffered no additional non-traumatic fractures. The second affected member (M2) was the son of M1. There was prenatal evidence of bowing of long bones. He sustained 10 fractures (femoral and humeral) within his first 4 weeks of life. He was treated with IV pamidronate every 2 months between 6 weeks to 18 months of age. No further fractures were noted after 4 weeks of age. He is now 15 years old and has normal ambulation. Both M1 and M2 were clinically diagnosed as OI type IV. During a subsequent pregnancy of M1, the third affected member (M3) was noted to have bowed proximal femurs bilaterally. After birth, he had multiple rib, femoral and tibial fractures. His last fracture occurred at 4.5 months of age. He was treated with IV zoledronic acid every 3 months between 3 weeks to 12 months of age. Extraskeletal

findings were not present in any of the three members (normal sclerae, hearing and dentition). There were no spinal or cranial deformities, no cardiovascular complications, and no joint hypermobility. Both M1 and M2 were of normal stature (25th and 75th percentile for height, respectively), while M3 is tracking along <2nd percentile for length-for-age. There was an unaffected 17-year-old daughter of M1. Conformation sensitive gel electrophoresis revealed that both M1 and M2 were heterozygous for C>T substitution (p.Pro1005Leu) in exon 49 of the COL1A1 gene.Conclusions: We described a previously unreported phenotype of OI due to a pathogenic dominant mutation in the COL1A1 gene. Affected members followed a pattern of congenital bone deformities with multiple fractures in long bones within the first few months of life followed by paucity of non-traumatic fractures thereafter. Proline to leucine substitution has been implicated in defects in collagen folding. The potential role of this substitution in explaining the phenotype of our patients remains unclear.

Calcemia and inflammatory markers in neonatal sepsis Stepan Kutilek*[1], Martina Vracovska[1], Kamila Pecenkova[1], Zlata Fejfarkova[2], Richard Pikner[2], Hana Brozikova[1]. [1]Dept. of Pediatrics, Klatovy Hospital, Czech Republic, [2]Dept. of Clinical Biochemistry; Klatovy Hospital, Czech Republic

Hypocalcemia, in particular low level of Ca2+, has been repeatedly described in neonates with sepsis. Ionised hypocalcemia (S-Ca2+) is considered a negative prognostic factor in the neonatal sepsis, together with calcitoninemia and serum levels of parathyroid hormone (S-PTH). Our aim was to retrospectively evaluate total calcemia (S-Ca) and its relationship to laboratory markers of sepsis/infection (C-reactive protein – CRP; procalcitonin - PCT) in neonates. Between the years 2012 and 2016, 3441 neonates were hospitalized at our neonatology ward. S-Ca was assessed in 988 samples drawn from 828 babies. Out of those, neonatal sepsis/infection was diagnosed in 29 children. The control assessments of inflammatory markers and S-Ca were based on the clinical situation of the patients. The children were treated by intravenously administered gentamicin and ampicilin for seven days. S-Ca, S-CRP, S-PCT were assessed on days 1, 2, 3 of the infection The mean values of S-Ca in neonates with sepsis were always significantly lower when compared to 799 children without infection (i.e.controls) (p<0.0001) There were no correlations between S-Ca and S-CRP or S-PCT on days 1, 2 and 3, nor between S-Ca on day 1 and S-CRP or S-PCT on days 2 and 3. respectively. The pooled values of S-Ca and S-PCT showed weak inverse correlation approaching statistical signifiakance (r= -0.22;p=0.06). There also was a poor negative correlation between pooled values of S-Ca and S-CRP (r= -0.19;p=0.09). In conclusion, total S-Ca was decreased in neonates with infection/sepsis and did not show any strong or significant correlation with S-CRP and S-PCT. We are aware of the limitations of our paper as S-Ca2+, albumin-adjusted-Ca, S-25-OH-vitamin D and S-PTH were not measured. However, pediatricians should be aware of the fact, that even low total S-Ca should alert their attention to the risk of neonatal sepsis.

MON-0131

The effect of growth hormone treatment in a child with a novel TRPS1 gene mutation Yael Levy-Shraga*[1], Shlomo Wientroub[2], Leonid Zeitlin[2]. [1]Pediatric Endcrinology Unit, The Edmond and Lily Safra Children's Hospital, Chaim Sheba Medical Center, Tel-Hashomer, Israel, [2]Pediatric Orthopaedics, Dana Children's Hospital, Israel

Background: Tricho-rhino-phalangeal syndrome (TRPS) is an autosomal dominant disorder characterized by craniofacial and skeletal malformations including short stature, cone shaped phalangeal epiphyses of the hand and Perthes-like changes of the hip. We report a case of a boy with TRPS type 1 and severe growth hormone deficiency.Case presentation: The patient presented at age 4 years for evaluation of short stature (87cm, -3.7 SD).On physical examination characteristic phenotype of TRPS was found: sparse thin hair, lateral rarefaction of the eyebrows, a pear-shaped nose, a long philtrum and a thin upper lip. Radiographs of the left hand at a chronological age of 4.8 years revealed a bone age of 2.8 years. Furthermore, cone- shaped epiphyses were identified. Two growth hormone stimulation tests revealed severe growth hormone (GH) deficiency (pick GH after stimulation of 3.3 and 1.7mcg/l) with low IGF1 (30.1ng/ml, normal 35-217). Further work up revealed bilateral Perthes-like changes of the hips on pelvis radiographs. GH treatment was initiated (0.03 mg/kg/day).Genetic analysis: Sanger sequencing of the TRPS1 gene was performed identified a heterozygous sequence variant, c.3698G > A, in exon 7. This missense mutation leads to an amino acid change at codon 1233, (p.Cys1233Tyr). To the best of our knowledge, this mutation was not described previously. Two prediction programs (PolyPhen, SIFT) rat this mutation as disease causing. Both his parents did not carry this mutation.Follow up: Growth velocity improved under GH treatment (8-9 cm/year). His current height at the age of 7.5 years is 116.4cm (-1.6 SD). Furthermore, marked improvement of the femoral epiphysis was shown on sequential pelvis radiographs.Conclusion: Our observations may suggest the benefits of growth hormone treatment on both height and epiphyses status in TRPS. Further studies are needed to support this observation.

Prevalence of Low BMD in Pediatric Cancer Survivors When Z Scores are Height Adjusted Chanthu Pillai*[1], Avni Shah[1], Anita Ying[2], Steven Waguespack[2]. [1]McGovern Medical School, United States, [2]The University of Texas MD Anderson Cancer Center, United States

Background: Pediatric cancer survivors are at higher risk of poor bone mineral deposition than the general population. There is a high degree of variablity to the exact prevalence of low bone mineral density (BMD) in pediatric cancer survivors. It has been reported as low as 8 % and high as 60%. Because of concern for increased fracture risk and its associated morbidities, pediatric cancer survivors are often screened for low bone mineral density with dual-energy X-ray absorpitometry (DXA). In DXA by current clinical guidelines, low BMD is defined as Z score ≤ -2.0. Currrently, the International Society of Clinical Densitometry reccomends that DXA scan Z scores be adjusted for height in children with short stature or growth delay. Children's Oncology Group Long-Term Follow-Up (COG-LTFU) Guidelines do not specifically recommend adjusting Z scores based on height. This study assessed the change in prevalence of low BMD in pediatric cancer survivors when DXA results were height adjusted. Methods: We retrospectively reviewed medical records of 91 pediatric cancer survivors at MD Anderson Cancer Center who underwent DXA between January 1, 2000 and October 31, 2010. We used the calculator from the Bone Mineral Density Childhood Study to height adjust Z scores.Results: Based on raw Z scores, seventeen cancer survivors (18%) had low lumbar spine BMD (raw z score ≤ −2.0) after completion of cancer treatment. When Z scores were height adjusted, only five patients (5%) had low lumbar spine BMD (modfied z score ≤ −2.0).Conclusion: In pediatric cancer survivors, low bone mineral density is less prevalent when DXA Z scores are corrected for height. Ninety five percent of pediatric cancer surivivors screened by DXA scan, did not have low bone mineral density. DXA Z scores should be height adjusted in pediatric cancer survivors to provide more accurate diagnosis of low bone mineral density. Current clinical practice may be over diagnosing low bone mineral density and perhaps increasing parental concern and medical cost.

MON-0133

Vitamin D level of toddlers with "physiologic" genu varum is lower than that of control toddlers: 1:2 case-control study Yuko Sakamoto *[1], Satoshi Nakano[2], Mitsuyoshi Suzuki[2], Akifumi Tokita[3], Ayaka Kaneko[4], Eri Maeda-Murohara[4], Masashi Nagao[4], Toshiaki Shimizu[2], Kazuo Kaneko[4], Masahiko Nozawa[1], Muneaki Ishijima[4]. [1]Department of Orthopaedics, Juntendo University Nerima Hospital, Japan, [2]Department of Pediatrics, Juntendo University Graduate School of Medicine, Japan, [3]Clinic Bambini, Japan, [4]Department of Medicine for Orthopaedics and Motor Organ, Juntendo University Graduate School of Medicine, Japan

When children around 2 yo show leg bowing, and diseases are ruled out based on radiograph without conducting blood tests, the bowing is classified as "physiologic" genu varum. "Physiologic" is named for physician's experiences that toddler's genu varum without radiographic abnormality usually resolves by itself. Recently we revealed that genu varum severity in toddlers was correlated with serum alkaline phosphatase (ALP) levels, suggesting that genu varum is not a physiologic condition in toddlers (J Bone Miner Metab, 2017). The present 1:2 case-control study was conducted to compare the bone metabolic conditions of toddlers with "physiologic" genu varum and those with normal alignment of lower limb. During 2013 to 2016, blood samples were obtained from 33 of toddlers with genu varum and 66 age and gender-matched subjects among toddlers in our previous study, which examined the vitamin D status in healthy Japanese children (J Nutr Sci Vitaminol 2018). Serum levels of ALP, intact parathyroid hormone (iPTH), 25-hydroxy vitamin D [s25(OH)D], calcium (Ca), and inorganic phosphorus (P) were measured in a postprandial state. The mean age of the control and genu varum groups were 17.1 and 17.8 months old, respectively, while the mean body weight of them were 10.2 and 10.1 kg, respectively. No difference for the frequency of summer born from spring was observed between them. The s25(OH)D levels of the subjects with genu varum (24.8 ng/mL) was significantly lower than those of the control subjects (33.6 ng/mL) (p<0.001). The frequency of vitamin D insufficiency (<20ng/mL) of the subjects with genu varum (39%) was significantly higher than that in control subjects (14%)(p=0.004). The odds ratio of the vitamin D insufficiency was 4.12 (95%CI: 1.5-11,1) in subjects with genu varum compared with those with control (p =0.004). sCa levels of the subjects with genu varum (10.2 ng/mL) was significantly higher than those of the control subjects (9.8 ng/mL) (p<0.001), although no difference of sP levels was observed between them (p=0.18). sALP (1057 IU/L) and siPTH (28.4 pg/ml) levels of the subjects with genu varum were significantly higher than those of the control subjects (740 IU/L, 8.8 pg/ml), respectively (p<0.001). siPTH levels were associated with s25(OH)D levels in subjects with genu varum (r=-0.57, p<0.001), while the association was not observed in the control subjects (r=0.11, p=0.36). As siPTH levels were associated with s25(OH)D levels, vitamin D insufficiency may increase siPTH levels in toddlers with genu varum, which may also increase sCa levels. Based on these results, we should not treat these toddlers as "physiologic" genu varum, but should recommend them to take vitamin D. In conclusion, toddlers with genu varum showed vitamin D insufficiency and hyper-ALP activity with relatively hypercalcemia within reference range than healthy toddlers without genu varum.

Measured Versus Calculated Free serum 25(OH)-Vitamin D Level: which one is better? Judith Vansickle*, Tarak Srivastava, Uttam Garg, Uri Alon. Division of Pediatric Nephrology, Children's Mercy Hospital, University of Missouri Kansas City, United States

Background: Serum 25(OH)D is mainly bound to Vitamin D Binding Protein (VDBP) (~85%) and to albumin (~15%) with only a minute amount circulating as free 25(OH)D. A stronger association of free 25(OH)D than total 25(OH)D was observed with serum calcium, PTH, bone mineral density, and vascular outcomes. Free 25(OH)D can be calculated from the concentrations of total 25(OH)D, VDBP, and albumin by a mathematical method or may be directly measured by ELISA. Previous studies questioned the accuracy of calculated vs. measured free 25(OH)D.Objective: To compare the validity of the mathematically calculated versus measured free 25(OH)-Vitamin D.Method: We collected blood samples from 74 children (ages 1-19 years old) and simultaneously measured total 25(OH)D on Tandem Mass Spectrometer, serum albumin by bromocresol green dye on COBAS chemistry analyzer, VDBP and free 25(OH)D by ELISA. Free 25(OH)D was calculated as follows:Calculated free 25(OH)D =(Total 25(OH)D)/(1+ (6*10,0000 * [albumin])+ (7*10,0000000 *[VDBP]))Pearson correlation analysis and Bland-Altman Plot were used to examine the true agreement between the two methods.Results: The mean age was 9.03 ± 5.07 years with 55% males and 76% Caucasians and 24% African-Americans. The mean ± SD for Total 25(OH)D was 37.12 ± 11.33 ng/mL, calculated free 25(OH)D 8.87 ± 3.66 pg/mL and measured free 25(OH)D 8.59 ± 3.41 pg/mL. Pearson correlation reflected a significant correlation between calculated and measured free 25(OH)D (r= 0.66, p< 0.0005) (Figure 1). Bland-Altman Plot reflected a tight agreement with in a 95% limit of agreement (mean = -0.026 ± 2SD) (Figure 2).Conclusion: The measured and calculated values of free 25(OH)D are in agreement and seem interchangeable. Depending on the availability of instruments and methods, free 25(OH)D can be either measured or calculated.

Figure 1: Bland-Altman Plot of calculated and measured Free D25(OH) levels, mean=-0.026 ± SD

Critical sex- and age-dependent role of osteocytic pannexin1 on bone and muscle mass and strength Alexandra Aguilar-Perez*[1], Lilian Plotkin[1], Hannah Davis[1], Emily Atkinson[1], Matthew Allen[1], Leland Gomez[2], Padmini Deosthale[1], Carmen Herrera[2], Julian Dilley[1], Angela Bruzzaniti[3], Teresa Zimmers[1], Ziyue Liu[2], Rafael Pacheco[4], Joseph Rupert[1]. [1]Indiana University School of Medicine, United States, [2]Indiana University, United States, [3]Indiana University School of Dentistry, United States, [4]Brazil, Brazil

Deletion of Pannexin1 (Px1) channels in osteocytes (Ot) in young 4mo female Px1f/f;8kb-DMP1 (Px1Δot) mice results in higher cancellous bone and bone formation compared to Px1fl/fl littermates. We now report the increased bone mass in female but not male mice with Ot Px1 deletion up to 13m of age. Pnx1f/f (n=9) control mice showed the expected age-induced bone geometry deterioration and reduced strength vs 4mo Px1f/f mice. Bone formation was low, with reduced P1NP (-54%) and ALP (-16%) in serum, osteoblast (Ob) activity (MAR;-45%, BFR/BS;-43%) and number/surface (N.OB/B.P.;-39%, OB.S/BS;-38%) in 13mo vs 4mo Px1f/f mice. Ot Px1 deletion prevented these aging effects. Further, femoral and spinal BMD were higher (5% and 13%) in Px1Δot (n=12) vs 13mo Px1f/f mice. Also, femoral cortical bone area (6%) and thickness (11%) were higher in aged Px1Δot mice vs Px1f/f at the same age. Vertebral osteoclast (Oc) number (-16%) was low in aged Px1Δot mice, whereas Obs were unchanged. Oc gene (TRAP, RANKL, NFATC1) levels in bone increased in aged Px1f/f and were lower in Px1Δot mice, suggesting that Ot Px1 is required for Oc differentiation in old female mice. Further, pre-yield mechanical properties (yield

force; +49%) were improved in femur of 13mo Px1Δot mice, with values similar to those of 4mo Px1f/f. This suggests that Px1 in Ot controls Obs and Ocs resulting in sustained increase in bone mass and mechanical properties. Surprisingly, in addition to a bone phenotype, female but not male Px1Δot mice showed transient increase in lean body mass and decrease in fat mass (2-5mo), although Px1 levels were decreased in bone and unchanged in skeletal muscle. Ot Px1 deletion result in higher soleus (SOL) weight (21%) and cross-sectional area (38%) only in female mice. Ex vivo SOL and extensor digitorum longus (EDL) contractility properties did not change with Ot Px1 deletion in either sex. EDL fatigue at a higher rate and in vivo maximum plantarflexion torque was lower in male Px1Δot (-11%) compared to Px1f/f, but muscle strength was unchanged in female mice. In summary, Ot Px1 deletion differentially increases bone mass in young and old and muscle in young female mice, but has deleterious effects on muscle strength only in males. Our studies suggest that Px1-mediated release of Ot factors affect bone and muscle cell generation/function. Thus, Px1 plays a critical role in Ot, regulating bone formation and resorption and muscle mass/strength in sex- and age-dependent manners.

Soft-tough cartilage scaffold with a patterned nanofibrous frame Haider Ali*, Kyung Won Kim, Moon Kyu Kwak, Young Hun Jeong, Gyu Man Kim, Cheol Woo Park. Kyungpook National University, Republic of Korea

Here, we presented a unique nanofiber/hydrogel composite mimicking native connective tissue, especially cartilage, which gains much attention in tissue engineering and regenerative medicine because of its limited-life but complicated mechanical properties such as soft-tough stiffness behavior induced by selective engagement of load carrying components. In order to mimic its mechanical properties, a patterned nanofibrous 3D frame with regular pores, which was fabricated using an improved electrospinning, was introduced to cell-laden hydrogel matrix as a reinforcement component. Particularly, we designed the composite with cell culture medium playing the role of physical separation between nanofibers and hydrogel to prevent strong cohesion, which could lead selective engagement of nanofibers and hydrogel in load carrying. Three types of nanofiber/hydrogel composites with different properties were prepared and their mechanical properties for compressive load were experimentally identified. Consequently, it was demonstrated that the proposed composite had sufficient biocompatibility as well as cartilage-like soft-tough properties. KEYWORDS: nanofiber, cartilage, cell-laden hydrogel, engagement, property ACKNOWLEDGMENTS: This study was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIP) (No. 2017R1A2B2005515, 2018R1A2B2009540).

The osteocyte apoptosis inhibitor IG9402 prevents bone loss of the mouse mandibular condyle during masseter muscle atrophy Sonja Buvinic*[1], Julián Balanta-Melo[2], Viviana Toro-Ibacache[3], María Angélica Torres-Quintana[4], Kornelius Kupczik [5], Lilian Plotkin[6]. [1]Institute for Research in Dental Sciences, Faculty of Dentistry; CEMC, Faculty of Medicine; Universidad de Chile, Chile, [2]Institute for Research in Dental Sciences, Faculty of Dentistry, Universidad de Chile, Chile; School of Dentistry, Universidad del Valle, Colombia; Max Planck Weizmann Center, Max Planck Institute for Evolutionary Anthropology, Germany, Chile, [3]Institute for Research in Dental Sciences, Center for Quantitative Analysis in Dental Anthropology, Faculty of Dentistry, Universidad de Chile, Chile; Department of Human Evolution, Max Planck Institute for Evolutionary Anthropology,Germany, Chile, [4]Department of Pathology and Oral Medicine, Faculty of Dentistry, Universidad de Chile, Chile, [5]Max Planck Weizmann Center, Max Planck Institute for Evolutionary Anthropology, Germany, [6]Department of Anatomy and Cell Biology, Indiana University School of Medicine, Roudebush Veterans Administration Medical Center, and Indiana Center for Musculoskeletal Health, United States

Background: The masseter muscle atrophy induced by botulinum toxin type A (BoNTA) results in altered loading of the temporomandibular joint and bone loss of the mandibular condyle in mice. Osteocytes are the most abundant bone cells and specifically their apoptosis is correlated with bone resorption during excessive mechanical stress. Thus, the inhibition of osteocyte apoptosis may prevent bone loss. Here we investigate whether a bisphosphonate analog that does not inhibit osteoclast activity but prevents osteocyte apoptosis (IG9402) preserves bone mass in the mouse mandibular condyle after BoNTA intervention. Methods: Random assignment of 24 adult BALB/c mice as follows: BoNTA(n=8); BoNTA + vehicle(n=6), BoNTA + IG9402(n=5), and IG9402-only (n=5). Mice from BoNTA groups received BoNTA injection once in the right masseter muscle at the beginning of the experiment, and saline solution in the contralateral side. IG9402 (0.6 mg/kg/day) or the vehicle were administered daily during the whole study. All animals were euthanized after 14 d and mandibles were dissected and scanned with high-resolution X-Ray Microtomography (microCT). Bone volume fraction (BV/TV), trabecular thickness (Tb.Th) and trabecular separation (Tb.Sp) were quantified from the resulting microCT scans of the mandibular condyles. Non-parametric analysis was performed to determine the differences between the groups.

All procedures were approved by the local ethical committee. Results: Both BV/TV and Tb.Th were significantly reduced in mandibular condyles from BoNTA-injected sides in the BoNTA (p< 0.05 and p< 0.001, respectively) and BoNTA + vehicle (both p< 0.05) groups as shown for Tb.Th in Figure 1. IG9402 prevented the loss of BV/TV by $36 \pm 6\%$ (p < 0.05) but not for Tb.Th (p > 0.05) in samples from BoNTA-injected sides. In addition, BV/TV and Tb.Th were both increased by 3% in samples from both sides of IG9402-only group when compared with condyles from saline-injected sides. No difference in Tb.Sp was found among groups. Conclusions: In this study, IG9402 prevented bone loss in the samples from BoNTA-injected sides. Also, an increase of BV/TV and Tb.Th in animals without BoNTA intervention may be evidence for the role of osteocyte apoptosis in the mature mandibular condyle remodeling. Taken together, these results suggest that IG9402 could prevent bone loss in the mouse mandibular condyle during masseter muscle atrophy induced by BoNTA.

Gut microbiota manipulation promotes bone formation mediated through regulatory T-Cell differentiation in obese mice Jyotirmaya Behera*, Suresh C Tyagi, Kimberly E Kelly, Nandan K Mondal, Neetu Tyagi. University of Louisville, United States

Aim: Probiotics are viable bacterial components that exert beneficial effects on the host, have been shown to prevent multiple comorbidities. However, the effects of probiotics in the pathological setting like obesity-induced osteoporotic bone phenotype via immune homeostasis are largely unknown. Therefore, we aimed to investigate the effect of probiotics on the gut microbiota eubiosis via epigenetic mechanism in the regulatory T-Cells (Tregs) function and bone formation using high-fat diet (HFD) induced obese mice. To test this hypothesis, 10-week-old female mice were fed on the high-fat diet (HFD; 42%) for 12 weeks. Probiotics (GSL#5) were given at the dose of 1 X 109 total bacteria 5 times/week through intragastric administration. Results: In vivo, μCT measurements revealed that probiotics induced a significant increase of trabecular bone phenotype (BV/TV; 30% in the femur) as compared to HFD condition. In vitro study also showed that mouse BMMSC derived osteoblast mineralization was indeed increased in probiotics treated HFD condition. Mechanistic studies revealed that probiotics epigenetically regulates immune homeostasis by up-regulating bone marrow (BM) regulatory T cells (Tregs CD4+Foxp3hi) differentiation via demethylation of Foxp3, as assessed by bisulfite sequencing PCR (BSP) and methylation-specific PCR (MSP). Additional studies revealed that probiotics administration attenuates the phosphorylation of S276 on RelA/p65 subunit of NF-κB is required for RelA/p65-DNMT-1 interactions, chromatin loading of DNMT-1. Thereby DNMT-1 mediated hyper-methylation of CpG islands of the FoxP3 promoter was abolished and subsequent Tregs-specific Foxp3 hypomethylation and Tregs differentiation. Small molecule inhibitor PTD-RelA/p65 (38–47 amino acid) peptide/5-azacytidine blocked the RelA/p65-DNMT-1 interactions and abrogated FoxP3 hyper-methylation and Tregs differentiation. In vivo blockade of Tregs expansion by treatment with anti CD25 Ab or silencing of Foxp3 by shRNA based RNA interference in mice prevented the bone anabolic activity of probiotics. Further, Tregs induced the release of the IL10 and TGF-β, leading to inhibit bone resorption assessed by TRAP+ staining in vitro, while increased bone formation (PINP expression) under probiotics treatment. Conclusion: Collectively, our data provide the evidence that probiotics administration maintain the gut microbiome/eubiosis dependent bone formation via immune homeostasis in HFD induced obese female mice.

Elucidation of mechanisms governing the activity of SOXC-inflammatory cytokine molecular axis in synovial fibroblasts Kyle Jones*, Veronique Lefebvre, Pallavi Bhattaram. Cleveland Clinic, United States

Purpose: Sox4, Sox11, and Sox12 encode the SOXC group of Sry-related HMG box (SOX) transcription factors. We recently identified a novel SOXC-inflammatory cytokine molecular axis that operates in synovial fibroblasts and plays a critical role in joint degeneration due to arthritis. The goal of this study is to identify the mechanism underlying the activation of the SOX-inflammatory cytokine axis.Methods: We used mouse primary synovial fibroblasts to study the effect of the pro-inflammatory cytokine, Tumor necrosis factor-alpha (TNF) on SOXC proteins. Proteomics assay was used to identify TNF-induced modifications in SOX11 protein. ENCODE chromatin immunoprecipitation-sequencing (ChIP-seq) data and reporter gene assays are being used to understand the relation between SOXC proteins and inflammation.Results: We previously showed that inactivation of the SOXC genes in the synovial and articular surfaces hampered the development of synovitis and cartilage degeneration in a mouse model of TNF-induced arthritis. We also showed that SOXC genes significantly contribute to the TNF-mediated upregulation of several inflammation-associated genes. TNF in turn stabilized SOX4 and 11 proteins. Here, we report that TNF induces the phosphorylation of SOX4 and 11. The C-terminal half of SOX11, which contains 7 of the 13 newly identified phosphorylation sites, is needed for protein stabilization. We also investigated the mechanism underlying the SOXC-dependent upregulation of TNF target genes. We hypothesized that RELA (TNF signaling transcription factor) and SOXC proteins bind to closely located regulatory domains of TNF-target genes. This notion is supported by ChIP-seq profiles available in the ENCODE database, which show that RELA is bound to the upstream genomic regions of the SOXC-TNF co-regulated genes, such as VCAM1 and EZH2 in multiple cell lines. RELA binding domains also contained putative SOX binding sites. The TNF-dependent activity of luciferase reporter genes encompassing the RELA binding sequences of VCAM1 and EZH2 was also enhanced by SOX11.Conclusions: Our study strongly suggests that the SOXC-inflammatory cytokine axis is regulated by SOXC protein phosphorylation. It also suggests that the SOXC proteins and RELA may bind to adjacent regulatory DNA sequences, leading to the enhanced expression of several inflammation-associated genes. This data will likely aid in the development of SOXC-targeted therapies for inflammatory joint diseases.

MON-0163

CARNITINE PALMITOYL TRANSFERASE-1A VARIANT 2: A NEW METABOLIC TARGET IN OSTEOPOROSIS RELATED SARCOPENIA? Umberto Tarantino*, Monica Celi, Chiara Greggi, Elena Gasbarra, Sabina Pucci. university of rome tor vergata, Italy

Introduction. Carnitine palmitoyl transferase-1A (CPT1A), a protein belonging to the carnitine / choline acetyltransferase family, transports long chain fatty acids into the mitochondria for β-oxidation and for the synthesis of ATP. CPT1A, whose classical form, (CPT1A v1), is involved in the metabolism and resides in the mitochondrion. Recently we have identified a variant of this enzyme, CPT1A variant 2 (CPT1A v2), found only in tumors and which resides in the nucleus, is involved in the epigenetic regulation of DNA. The main purpose of the present study is to investigate the regulation of muscle's energy metabolism in osteoporoticOP and osteoarthriticOA, characterizing the expression of the two variants (v1 and v2) of CPT1A and their role in these pathologies.Methods: To this end, 40 female patients (80.58 ± 6.3 years) were enrolled, 20 of whom underwent partial or total prosthetic replacement of the hip following femoral neck fragility fracture, and 20 patients (67.63 ± 8 years) undergoing the same type of surgery for hip osteoarthritis. The muscle tissue of 6 patients (19 ± 9 years) who underwent hip arthroplasty following a fracture (CTRL) was also taken. The bone mineral density of these patients was also evaluated by Lunar iDXA. Muscle biopsies were used for: mRNA extraction to evaluate the expression of CPT1A variants, proteins extraction, for the purpose of carrying out tests of enzymatic activity, and finally they werefixed in 4% paraformaldehyde for 24 hours and included in paraffin.Serial sections were used for morphometric and immunohistochemical evaluation.Results: Immunohistochemical analysis of muscle tissue showed that CPT1A protein appears to have a "polarized" expression in the muscle tissue of OP patients, as opposed to OA and CTRL patients, in which its expression is homogeneous. The mRNA expression analysis for CPT1A, showed a greater expression of the metabolic form (CPT1A v1), in the muscle tissue of OA patients; the same result was also obtained and in CTRL patients. In contrast, OP patients showed a strong expression of CPT1A v2. CPT1A metabolic activity assay on protein extracts from muscular tissue, confirmed a significant reduction in activity of this enzyme in OP patients as compared to OA. In addition, immunohistochemical data confirm that the presence of CPT1A v2 correlates with the histone H4 acetylation pattern in OP patients, in which a strong expression of acetyl histone H4 was found predominantly at nuclear level, as opposed to the OA patients, in which only a few cell nuclei are positive. Moreover quantification rates of intracellular ATP have shown that there are significant differences between the two experimental groups, confirming the result obtained through the enzymatic activity test of CPT1A protein.These data suggest an important role of CPT1A variant 2 as a new marker and potential therapeutic target in osteoporotic pathology

Fibroblast Growth Factor 9 (FGF9) Acts as an Inhibitory Osteokine in Mouse C2C12 and Human Skeletal Muscle Cells Jian Huang*[1], Kun Wang[2], Lora Shiflett[2], Leticia Brotto[1], Lynda Bonewald[3], Sarah Dallas[2], Marco Brotto[1]. [1]Bone-Muscle Collaborative Sciences, College of Nursing and Health Innovation, University of Texas at Arlington, United States, [2]Department of Oral and Craniofacial Sciences, School of Dentistry, University of Missouri-Kansas City, United States, [3]Department of Anatomy, Cell Biology and Orthopedics, Indiana Center for Musculoskeletal Health, School of Medicine, Indiana University, United States

Osteoporosis and sarcopenia occur together and evidence is accumulating for molecular crosstalk between muscle and bone that may play a role in these age-related diseases. We have identified positive mediators of crosstalk from bone to muscle, including PGE2 and WNT3a, and from muscle to bone, including β-aminoisobutyric acid (BAIBA). We have previously shown that FGF9 is an early osteocyte factor that prevents differentiation. Recently we have identified FGF9 as an osteocyte-produced factor that may negatively regulate myogenesis in C2C12 myoblasts. Here, we sought to elucidate the molecular mechanisms for FGF9 regulation of myogenesis and confirm whether it has a similar regulatory role in human primary myoblasts. In C2C12 myoblasts treated with FGF9, smaller and fewer myotubes were seen and the fusion index (FI) was significantly reduced compared to control (FI values: control= 47.6% ± 2.6; 2ng/ml FGF9 = 38.2 ± 4.8, p > 0.05; 10ng/ml FGF9 = 34.6% ± 6.99, p < 0.05; 50ng/ml = 17.0% ± 2.1, p < 0.0001). Although myotube differentiation was inhibited, FGF9 treatment strongly stimulated myoblast proliferation. FGF9 (10-50ng/ml) significantly decreased mRNA expression of myogenesis markers MyoG and Mhc while increasing expression of the myogenic inhibitor, Myostatin. Measurements of intracellular Ca2+ using Fura-2 revealed that FGF9-treated myotubes showed a lower Ca2+ peak and a shortened relaxation phase in response to caffeine, suggesting that FGF9 disrupts Ca2+ homeostasis in myotubes. RT-qPCR array revealed that FGF9 (10ng/ml) treated C2C12 cells, increased expression of Icam1 by 2.8-fold, while Hey1, Wnt1 and Wnt6 were decreased 3.1, 3.5 and 4.2 fold, respectively. Although human skeletal muscle cells were less sensitive than C2C12 muscle cells, both myotube formation and FI were significantly inhibited at 200ng/ml FGF9. These findings suggest that FGF9 may act as an inhibitory osteokine with the intrinsic capacity to modulate myogenic differentiation via a complex signaling mechanism that seems to involve the orchestration of myostatin with key regulators of muscle development (MyoG, Mhc, Hey1, Wnt1, Wnt6), cell proliferation (Icam1 and myostatin), and differentiation (Hey1, Wnt1, Wnt6). The fine-tuning of bone-muscle crosstalk mechanisms likely requires both stimulatory and inhibitory myokines and osteokines. Deciphering 'kines' mechanisms and their actions in bones and muscles could lead to a new era in the treatment of musculoskeletal disorders.

Muscle-Derived IGF-1 Affects Bone Elongation in a Gender-Specific Manner Gisele Martins*[1], Vitor Torres[1], Bianca Neofiti-Papi[1], Joao Silvestre[1], William Silva[1], Antonio Musarò[2], Anselmo Moriscot[1], Cecilia Gouveia[1]. [1]Institute of Biomedical Sciences, University of São Paulo, Brazil, [2]Sapienza Universita di Roma, Italy

There is growing evidence that paracrine interactions between bone and muscle tissue contribute to the regulation of bone and muscle mass, independently of the mechanical interaction. One putative factor to have a role in a non-mechanical muscle-bone interaction is insulin-like growth factor 1 (IGF-1), which is secreted by skeletal and muscle cells and plays important roles in both bone and muscle development, in addition to promote anabolic effects in both bone and muscle mass. The purpose of this study was to investigate whether muscle-derived IGF-1 affects bone growth and bone mass in female and male mice. We studied MLC/mIGF-1 transgenic mice (IGF-1TG) that overexpress mIGF-1 (a isoform synthesized in skeletal and cardiac muscle) in skeletal muscle fibers by means of a rat mIGF-1 cDNA driven by skeletal muscle specific regulatory elements from the rat myosin light chain (MLC)-1/3 locus. We characterized the bone and muscle mass phenotypes of IGF-1TG mice and their wild-type (WT) controls, at 1, 3, 5, 7, 9, 11 and 13 months of age. IGF-1TG females showed significant increases in body mass (BM), quadriceps muscle mass (QM) and tibiallis anterior muscle mass (TAM) at 3,5,9 and 11 months of age when compared to WT controls. On the other hand, the lengths of the body, femur, tibia, humerus and radius (BL, FL, TL, HL and RL, respectively) were normal in IGF-1TG females. By X-ray microtomography analysis (μCT) of the femur, we detected increases in trabecular bone volume and trabecular number, and decreases in trabecular separation and trabecular porosity in IGF-1TG females at 3 and 5 months of age. In IGF-1TG male mice, BM, QM and TAM were increased from 3 to 13 months of age. Differently from females, IGF-1TG males showed increased BL (at 9 months), FL (at 5,7 and 13 months), TL (at 5,7 and 13 months) and HL (at 11 and 13 months), but normal trabecular bone mCT parameters in the femur, when compared to WT control. In conclusion, muscle-derived IGF-1 does not affect trabecular bone in male mice. At this point, it is not possible to discriminate if the improvements in trabecular bone parameters observed in IGF-1TG female mice are due to IGF-1 overexpression or to the increased muscle mass. Interestingly, the data of the present study suggest that muscle-derived IGF-1 does not affect bone linear growth in female mice but has a positive effect in this process in male mice, revealing that paracrine interactions between bone and muscle may depend on sex factors.

MON-0166

Mechanisms Responsible for Pamidronate Rescue of Post-Burn Muscle Loss in Children Fabrizio Pin*[1], David Herndon[2], Andrea Bonetto[1], Celeste Finnerty[2], Christopher Nieten[2], Lynda Bonewald[1], Gordon Klein[2]. [1]Indiana University Medical Center, United States, [2]University of Texas Medical Branch, Shriners Burns Hospital, United States

Pamidronate has been shown to prevent inflammation-associated bone resorption following burn injury. We reported that burned children who received pamidronate also had reduced protein breakdown and positive protein balance in muscle (Borsheim et al JBMR 2014). The aim of this study was to identify the molecular mechanisms responsible for muscle mass rescue in pamidronate vs placebo/standard of care-treated patients. Mature myotubes generated by differentiating murine C2C12 myoblasts were exposed for 48h to 1 or 5% serum obtained from 3 groups of children: normal unburned (N), burned receiving placebo/standard of care after 30d (B), burned receiving pamidronate and standard of care (BP) after 30d. Exposure to B serum caused dose-dependent myotube atrophy compared to N serum (-13 or -40%, p<0.01), reproducing muscle atrophy induced by burn injury in humans and animals (Quintana et al Inflamm Res, 2015; Song et al , Shock 2015). When the C2C12 myotubes were treated with BP serum, their size was partially rescued compared to myotubes exposed to B serum (+9 and 15%, p<0.05). At the molecular level, atrophy induced by B serum was associated with reduced phosphorylation of AKT (-34%,p<0.05) and its downstream target mTOR (-51%, p<0.01), suggesting that muscle anabolism was down-regulated. In addition, muscle protein catabolism appeared to be greater in myotubes exposed to B serum, as shown by increased STAT3 activation (+100%, p<0.001) and reduced phosphorylation of FOXO3a (-53%, p<0.01). In accordance with the effects on fiber size, BP serum was able to restore the phosphorylation of AKT (+46%, p<0.05) and mTOR (+83%, p<0.05), as well as the protein ubiquitination (-58%, p<0.05) when compared to B serum alone. No differences were observed relative to STAT3 or FOXO3a activation. Of note, the exposure to ACVR2B/Fc had no effects suggesting that the TGFbeta signaling is not responsible for the effects of B serum on muscle. These data show that the rescue effect of serum from BP patients appears related to the reactivation of the anabolic AKT-mTOR pathway. The reduction of protein ubiquitination associated with BP serum is also consistent with previously-reported retrospective findings of stable isotope studies showing less muscle protein breakdown in the pamidronate- treated patients. These data suggest that bisphosphonate protection of bones from resorption prevents the release of muscle pro-catabolic factors into the circulation.

Electrical Stimulation of Hindlimb Skeletal Muscle has a Beneficial Effect on Sublesional Muscle and Bone in a Rat Model of Spinal Cord Injury. Wei Zhao*[1], Yuanzhen Peng[2], Yizhong Hu[3], Edward X. Guo[3], William A Bauman[1,2], Weiping Qin[1,2]. [1]Icahn School of Medicine at Mount Sinai, United States, [2]James J. Peters VA Medical Center, United States, [3]Columbia University, United States

Spinal cord injury (SCI) causes severe skeletal muscle atrophy and bone loss below the lesion. In this study, we evaluated the effect of a prolonged course of electrical stimulation (ES) on muscle mass and bone formation. In addition, we also tested whether the combination of ES and testosterone (TE) will have a synergistic effect on these musculoskeletal endpoints. Implantation of the electrical stimulators towards the bifurcation of the sciatic nerve of the left leg was performed immediately after neurologically complete spinal cord transection at T3-4; ES was initiated 2 weeks after SCI and continued daily for 4 weeks. Compared to sham-transected animals, significant reduction of the soleus, plantaris and EDL muscle mass was observed in animals 6 weeks post-SCI. Notably, ES or ES+TE combination resulted in a +13% increase of the EDL muscle mass, as well as a marginal increase of the plantaris and soleus muscles. ES or ES/TE significantly decreased expression of markers of muscle atrophy (e.g., the muscle-specific ubiquitin ligases MAFbx and MurF1 mRNA) in the EDL. Expression of secreted frizzled-related protein (sFRP) 1, a Wnt antagonist, also increased after SCI, and was drastically reduced by TE, ES or ES+TE treatment. In parallel, SCI for 6 weeks resulted in significant decreases in BMD (-27%) and trabecular bone volume (-49.3%) at the distal femur; notably, TE, ES and ES+TE treatment significantly increased the BMD and BV/TV% by +6.4% and +22.2%, +5.4% and +56.2%, and +8.5% and +60.2%, respectively. The larger magnitude of changes of bone mass in sublesional skeleton in ES+TE animals suggested potential synergistic effect of TE and ES on bone. Osteoblastogenesis was evaluated by colony-forming unit-fibroblastic (CFU-F) staining using bone marrow mesenchymal stem cells obtained from the femur. SCI decreased the CFU-F+ cells by -56.8% compared to sham animals. Excitingly, TE or ES+TE treatment after SCI increased osteoblastogenesis by +74.6% and +67.2%, respectively. An osteoclastogenesis assay revealed significantly increased TRAP+ multinucleated cells by +34.8% in SCI animals compared to sham animals. Both TE and TE+ES treatment following SCI markedly decreased TRAP+ cells by -51.3% and -40.3%, respectively. Collectively, our findings demonstrate that after neurologically complete paralysis, ES generated sufficient contractile force to initiate muscle hypertrophy, downregulate genes involved in muscle atrophy, and restored mechanical loading to sublesional bone to a degree that allowed for preservation of bone, either by inhibition of bone resorption and/or by facilitating bone formation.

Osteocytic Connexin Channels Regulate Skeletal Muscle Structure and Function Guo Bin Li*[1], Lan Zhang[1], Peng Shang[2], Jean X. Jiang[3], Huiyun Xu[1]. [1]Key Laboratory for Space Bioscience and Biotechnology, School of Life Sciences,Northwestern Polytechnical University, Youyi Xilu 127, 710072, Xi'an, Shaanxi, China, [2]Key Laboratory for Space Bioscience and Biotechnology, Research & Development Institute in Shenzhen, Northwestern Polytechnical University, Gaoxin Fourth South Road 19, 518057, Shenzhen, Guangdong, China, [3]Department of Biochemistry and Structural Biology, University of Texas Health Science Center, San Antonio, TX, United States

Bone and muscle are connected as a functional unit and show synchronization throughout lifespan. The mechanical coupling of bone and muscle is readily appreciated, with bone providing the attachment sites and muscle loading the bone for locomotion. Recently, it has been shown that the two tissues bi-directionally communicate through secreted factors. Given that osteocytes compose 90-95% of total bone cells compared to other bone cell types in adult, these cells are a likely source that secrets majority of circulating factors. Connexin (Cx) 43, a protein richly present in osteocytes, forms functional gap junctions and hemichannels that mediate cell-cell and cell-extracellular communication, respectively, in osteocytes. To test if these channels are functionally involved in bone-muscle crosstalk, we used two Cx43 dominant negative mutant transgenic mouse models: R76W, a dominant negative mutant that blocks only gap junction channels; and Δ130-136, a dominant negative mutant that inhibits both gap junctions and hemichannels. The muscle mass and contractile function were determined in vivo, and the effects of primary osteocytes secreted factors on myogenesis of C2C12 myoblast were measured.Hematoxylin and eosin (H&E) stain on paraffin sections of gastrocnemius (GS) showed a decrease (10.6%) of muscle mass only in Δ130-136 compared to that of WT mice, but not in R76W mice. qPCR showed significant down-regulation of important myogenic markers Mrf4 and Myf5 in GS of both Δ130-136 and R76W mice. Isometric force of GS in Δ130-136 and R76W was decreased by 43% and 36%, respectively compared to WT mice. A significant reduction of fiber number of soleus (SOL) was seen in both types of transgenic mice. Conditioned media (CM) were collected from primary osteocytes isolated from 3-month-old Δ130-136, R76W and WT mice, respectively, and were used to culture C2C12 myoblast. Interestingly, treatment of CM from osteocytes of Δ130-136 significantly inhibited the differentiation of C2C12, with a reduction of myotube number/diameter and fusion index, while this difference was not shown with CM from R76W-expressed osteocytes.Collectively, these findings reveal the important roles of osteocytic gap junctions and hemichannels in modulating skeletal muscle structure and function; hemichannels in maintaining of muscle mass and regulation on myogenesis, while gap junctions in regulating muscle force and myofiber number.

Effects of Sclerostin Depletion on Hematopoietic Stem Cells in the Bone Marrow and Spleen Cristine Donham*[1], Jennifer Manilay[1], Gabriela Loots[2], Aris Edonomides[3]. [1]University of California Merced, United States, [2]University of California Merced, Lawrence Livermore National Laboratory, United States, [3]Regeneron Pharmaceuticals, United States

The interactions between long-term hematopoietic stem cells (LT-HSCs) and cells in the bone microenvironment result in changes in stem cell behavior that are incompletely understood. Our overall goal is to define the molecular mechanisms that guide the behavior of LT-HSCs after exposure to an irregular bone marrow (BM) niche. Sclerostin (Sost) is a secreted Wnt antagonist protein that is important for bone homeostasis. We hypothesized that that loss of Sost would influence LT-HSC maintenance and self-renewal due to increased Wnt signaling in the bone. We performed transplantation of wild-type (WT) B6 hematopoietic progenitors into sclerostin-knockout mice (KO), and we have observed increased frequencies of LT-HSCs in WT -> KO recipients, indicating that SostKO microenvironment enhances LT-HSC self-renewal. This increase was also observed in WT mice treated with anti-sclerostin antibodies. This suggests that even relatively short-term depletion of Sost can have effects on LT-HSCs. As the SostKO mice age, we have observed evidence of extramedullary hematopoiesis (EMH) in the spleen; whether EMH is induced simply by physical occlusion in the bone marrow cavity, or a change in signaling or migration patterns of BM LT-HSCs to mobilize them to the spleen is not yet clear. To test if LT-HSCs from the spleens and bone marrow of SostKO mice have similar reconstitution potentials, we performed transplantation of lineage negative (Lin-) cells isolated from KO spleen, KO BM, and WT BM into WT hosts. Donor hematopoietic chimerism in recipients of KO splenic LT-HSCs was significantly lower compared to recipients of KO BM. Reduction in the frequencies of LT-HSCs, multipotent progenitors, and differentiated hematopoietic lineages was also observed from KO splenic LT-HSCs. Our data suggest that splenic HSCs lose self-renewal and differentiation capabilities when they leave the bone marrow. We are currently investigating whether estrogen can influence the extent of EMH in the SostKO mice by comparing transplants of splenic KO LT-HSCs from male and female donors into sex-matched recipients. Taken together, our data indicate that depletion of Sost in the bone regulates LT-HSC migration, self-renewal, and differentiation. Our results could have significant impact on the tracking of hematopoietic function in human patients treated with sclerostin-depleting antibodies for bone diseases.

MicroRNA-17-5p Facilitates Bone Remodeling in Periapical Periodontitis
Daimo Guo*, Xinyu He, Ruoshi Xu, Xin Zhou, Liwei Zheng, Xuedong Zhou. State Key Laboratory of Oral Diseases;West China School of Stomatology, Sichuan University, China

Aims:Periapical periodontitis is an acute or chronic inflammatory disease of the periradicular tissue which can destroy the alveolar bone surrounding the tooth root apex. In current study, we tried to identify the miRNAs expression profile in periradicular lesions. Futhermore, we tried to promotes bone remodeling by modulating the local concentration of miR-NAs.Methods:Periapical lesions were induced in rats mandibular first molars. Small RNAs were isolated from the total RNA of bone surrounding the tooth root apex and underwent a rat miRNA Microarray.AgomiR-17-5p, antagomiR-17-5p, and their respective negative controls were sealed in root canal. Micro-CT, histological and immunohistochemical analyses was performed to evaluate the presence of bone remodeling.Bioinformatic analysis was performed to further identify pathways related to the bone remodeling under the influence of selected miRNAs.Isolation and culture of BMSCs, miRNA mimic were used to suppress the expression of target genes in RNA level. Expression of the target proteins was detected using western blot assay.Results:We identified 49 differentially expressed miRNAs in periradicular bone tissue, including 28 upregulated miRNAs and 21 downregulated miRNAs. We validated miRNAs differentially expressed in microarray analysis by q-PCR and found that the expressing level of miR-17-5p was lower in periradicular bone tissue of periapical periodontitis. Locally elevated miR-17-5p level had less bone loss in periradicular tissue relative to control. Also we identified zinc finger FYVE-type containing 9 (ZFYVE9) as the direct targets of miR-17-5p in TGF-β signaling pathway.Conclusions:The current findings supported the view that miR-17-5p could directly target ZFYVE9 in TGF-β signaling pathway. And locally elevated miR-17-5p level could reduce bone defect of periapical disease. These result may provide potential targets for future treatment of periradicular bone defect.

SINGLE-CELL RNA SEQUENCING ANALYSIS OF FRESHLY ISOLATED HUMAN SKELETAL STEM/PROGENITOR CELLS FROM HUMAN BONE MARROW Randall Merling*, Joseph Featherall, Danielle Bonfim, Natasha Cherman, Sergei Kuznetsov, Pamela Robey. Skeletal Biology Section, National Institute of Dental and Craniofacial Research, National Institutes of Health, United States

Multipotential human skeletal stem cells (SSCs) are a subpopulation of bone marrow stromal cells (BMSCs) and are considered to be central mediators of skeletal homeostasis and support hematopoiesis. In order to better understand the character of BMSCs/SSCs, analysis of freshly isolated uncultured cells is needed. For enrichment of the SSCs, we used magnetic separation: RBC depletion followed by CD45+/CD31+cell depletion. FACS sorting was then used to isolate CD146+/CD271+double positive cells. There was a 220 to 720-fold increase in CFU-Fs, a close approximation of multipotent SSCs, from the CD146+/CD271+enriched fraction compared to unpurified cells. Single-cell RNA sequencing analysis (10X Genomics Chromium) of this fraction revealed two distinct osteogenic populations: one subpopulation with over-representation of mature osteogenic markers (RUNX2, SPP1, IBSP, BGLAP, COL1A1, IFITM5), another subpopulation with over-representation of pericyte/BMSC markers (CXCL12, LEPR, FRZB, VCAN, IGFBP4, TAGLN, FRZB). All genes indicated are in the top 20 differentially expressed genes for each cluster group (P-Value<10-6). Seurat, an R toolkit for single cell genomics was used to combine our data sets from CD146+/CD271+enriched cells with publically available data sets from total bone marrow mononuclear cells. The double positive cells localize specifically to the osteogenic cluster of cells and distinctly away from non-osteogenic bone marrow mononuclear cell lineages represented by tSNE plots. Additional transcriptome network analyses of the mature osteogenic and pericyte/BMSC markers suggest a regulatory role of the SMAD pathway differentiating the subpopulations within the double positive population. Future work will entail targeting unique candidate genes from the single-cell analysis findings for knockdown in BMSCs/SSCs for evaluation by in vitroand in vivoassays to provide a better understanding of the hierarchy, biological nature and function in the bone/marrow microenvironment.

Novel function of BMP-2 in inhibiting bone formation in marrow environment Ha Nguyen Thi *[1], Mitsuaki Ono [2], Yasutaka Oida[1], Emilio Satoshi Hara[3], Taishi Komori[1], Kentaro Akiyama[1], Ha Nguyen Thi Thu [1], Hai Thanh Pham [1], Kyawthu Aung[1], Toshitaka Oohashi[2], Takuo Kuboki [1]. [1]Department of Oral Rehabilitation and Regenerative Medicine, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Japan, [2]Department of Molecular Biology and Biochemistry, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Japan, [3]Department of Biomaterials, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Japan

Bone morphogenetic protein 2 (BMP- 2) is widely known as a potent growth factor in promoting bone formation. In some clinical cases, it is necessary to induce bone formation in marrow area; however, the efficacy of BMP-2 in the marrow environment has not been thoroughly investigated. This study aimed to investigate the BMP-2 function in the marrow environment. At first, defects were made in mouse femur and calvaria, then transplanted with freeze-dried collagen pellet containing 10 μg BMP-2 or distilled water (control) for 5 days and 14 days. Bone formation was evaluated by micro-CT and histological analysis. BMP-2 significantly enhanced bone formation in calvarial bone but dramatically inhibited bone formation in marrow-containing femur. Next, to investigate the effect of marrow cells on BMP-2 function, BMP-2/collagen pellet was transplanted into ablated femur with the confirmed decrease in the number of marrow cells. As expected, the capability of BMP-2 to induce bone formation was then recovered in the absence of marrow cells. Next, in an attempt to understand whether the marrow inhibits BMP-2-induced osteoblast differentiation, the appearance of osteoblasts was investigated in Col1a1-GFP mice. In control group, a high number of osteoblasts was observed in the surrounding of the pellet in marrow space after 5 days, and gradually decreased after 14 days. In BMP-2 group, the osteoblasts were detected markedly less in marrow space both at 5 days and 14 days after transplantation. To further analyze the effect of marrow on the inhibition of BMP-2-induced osteoblast differentiation, we investigated luciferase activity of C2C12 cells with BMP-responsive element (BRE) and ALP activity of MC3T3-E1 cells co-cultured with marrow or marrow components (cells and plasma). Similar to the in vivo findings, BMP-2 induced luciferase activity and ALP activity was significantly suppressed when marrow cells were co-cultured in direct contact with C2C12 or MC3T3-E1 cells. Marrow plasma only, blood cells (as the reference) or indirect co-culture did not affect BMP-2 function. Taken together, these results revealed that BMP-2-induced bone formation was significantly suppressed in marrow environment, and was associated with the depletion of osteoblasts. Marrow cells inhibited BMP-2-induced osteoblast differentiation as demonstrated by the repression of BMP-responsive luciferase activity and osteogenesis in a direct cell-cell contact manner.

The Effects of Interleukin-1 Receptor Antagonism on Endothelium-Dependent and Endothelium-Independent Vasodilation of Femoral Principal Nutrient Artery and Femoral Bone Parameters in Young Male Fischer-344 Rats Sunggi Noh*, Seungyong Lee, David Lee, Rhonda Prisby. University of Texas at Arlington, United States

We previously reported impaired endothelium-dependent vasodilation of the femoral principal nutrient artery (PNA; the primary conduit for blood flow to long bones) in the presence of marrow. The declines in vasodilator capacity were associated with augmented production of the pro-inflammatory cytokines interleukin-1α and -1β from the marrow cells. Thus, we surmised that treatment with an interleukin-1 receptor antagonist (IL-1RA) may blunt the production of marrow-derived IL-1α and IL-1β, serving to protect endothelium-dependent vasodilation. Young (5 months) male Fischer-344 rats were randomized to a control (CON; n=5) or IL-1RA (n=5) group and underwent surgery to create a small bone defect in the right femur. Following recovery from surgery, rats were injected intraperioneally with IL-1RA (3 μg/kg, 3 days/week) or phosphate buffered saline as a vehicle (100 μl/day, 3 days/week) for 3 weeks. At sacrifice, right femoral PNAs were isolated, cannulated, and pressurized to 60 cmH2O (44 mmHg) to assess vasodilator function. Endothelium-dependent (ACh; 10-9 - 10-4 M) and endothelium-independent (DEA NONOate; 10-10 - 10-4 M) vasodilation were determined in the absence and presence of marrow. In addition, bone microarchitectural properties (BV/TV, %; Tb.N, /mm; Tb.Th, μm; Tb.Sp, μm and Conn.D, /mm3) in the distal femoral metaphysis were determined by micro-computed tomography. The presence of marrow reduced (p<0.05) endothelium-dependent vasodilation in CON rats; i.e., vasodilation in CON+Marrow was impaired vs. CON and IL-1RA. Three weeks of IL-1RA treatment improved endothelium-dependent vasodilator capacity such that responses were similar between IL-1RA and IL-1RA+Marrow. In addition, vasodilation in IL-1RA was higher (p<0.05) vs. CON+Marrow. Endothelium-independent vasodilation did not differ between CON and CON+Marrow but responses in IL-1RA+Marrow were reduced (p<0.05) in comparison to CON. Further, vasodilator responses were higher (p<0.05) in IL-1RA vs. CON+Marrow and IL-1RA+Marrow. Bone volume did not differ between the CON (13±6%) and IL-1RA (15±4%) groups; however, Tb.N (2.4±0.1 /mm vs. 2.9±0.2 /mm, respectively) and Conn.D (41±2 /mm3 vs. 51±2 /mm3, respectively) were higher (p<0.05) in IL-1RA vs. CON. In this context, Tb.Sp was lower (p<0.05) in IL-1RA (345±22 mm) vs. CON (427±20 mm). IL-1RA treatment improved endothelium-dependent vasodilation in

the presence of marrow; however it may have served to impair endothelium-independent vasodilation.

Mitochondrial Function in Mesenchymal Stem Cells and New Bone Formation During Spinal Fusion Laura Shum*, Avionna Baldwin, Addisu Mesfin, Roman Eliseev. University of Rochester, United States

Iliac crest autografts are often used in spine surgery, and bone marrow-derived mesenchymal stem cells (MSCs) are believed to be responsible for new bone formation during spinal fusion. We have previously shown the importance of mitochondrial function in MSCs, and thus we designed the current study to determine the impact of mitochondrial function in MSCs on spinal fusion surgery outcomes. Iliac crest bone marrow samples were obtained from patients undergoing spinal fusion surgery (9 male, 4 female, average age 48.3, age range 16-73). Aliquots of whole bone marrow were reserved for CMXRos staining (mitochondrial function), and the remainder was spun, treated with Red Blood Cell Lysis Buffer, strained, and plated at either CFU density (25,000 cells per cm2) or at 20 million cells per 15 cm cell culture dish for expansion. CFU plates were grown for 14 days, then stained with crystal violet for CFU-fibroblastic (CFU-F) or with ALP-specific stain for CFU-osteoblastic (CFU-O). Surface markers were detected with fluorescently-labeled anti-human antibodies against CD105, CD31, and CD45 (BD Bioscience) using flow cytometry and 12-color FACS Canto II machine. At 6 months following spinal fusion surgery, surgeons assessed patient spinal healing by radiographic assessment (Lenke grading). A grade of A (best) – D (worst) was given. Human patient colony forming unit assay did not correlate with patient age or spinal fusion outcomes; and spinal fusion outcomes did not decrease with age within the studied age range. Additionally, we found that mitochondrial function of MSCs did not decrease with age. However, we found that higher mitochondrial function in in freshly isolated MSCs correlated with better spinal fusion outcomes. Our study revealed a correlation between mitochondrial function assessed in isolated MSCs and spinal fusion outcomes. This information could be used as a predictor of the need for additional modalities to improve surgical outcomes. Importantly, this study opens new research questions regarding whether improving mitochondrial function of MSCs prior to grafting would improve surgical outcomes for more patients.

MON-0213

Aplidin (Plitidepsin) is a Novel Anti-Myeloma Drug with Potent Anti-Resorptive Activity Mediated by Direct Effects on Osteoclasts. Jesus Delgado-Calle*[1], Noriyoshi Kurihara[1], Jessica H. Nelson[1], Emily G. Atkinson[2], Carlos Galmarini[3], G. David Roodman[1], Teresita Bellido[2]. [1]Indiana University School of Medicine, Dept. of Medicine, Hematology/Oncology, United States, [2]Indiana University School of Medicine, Dept. of Anatomy and Cell Biology, United States, [3]PharmaMar S.A., Spain

Despite recent progress in its treatment, Multiple Myeloma (MM) remains incurable and the associated bone disease persists even after complete remission. Thus, identification of new drugs that simultaneously suppress MM growth and protect bone is an unmet need. We examined the effects of Aplidin, a novel anti-cancer marine-derived agent isolated from Aplidium albicans, on MM and bone cells using in vitro and ex vivo approaches. Aplidin ≥1nM decreased human JJN3 and murine 5TGM1 MM cell numbers in a dose- and time-dependent manner (EC50~10nM), accompanied by increased cell death. The other anti-MM agents dexamethasone (Dex; 10-5M) or bortezomib (Btz; 3nM) also decreased MM cell numbers and significantly enhanced the effect of Aplidin by 1.6-fold and 2.5-fold, respectively. Aplidin ≥10nM also increased osteocyte and osteoblast cell death to 15%, and reduced osteoblast mineralization by 20%. These effects were enhanced by Dex, but partially prevented by Btz. Osteoclastic cells (Ocl) exhibited high sensitivity to Aplidin, as nM doses induced massive Ocl death. When tested at pM doses, Aplidin decreased GM-CSF colony formation by 15%, reduced M-CSF-mediated Ocl precursor expansion, and decreased RANKL-mediated Ocl differentiation by blunting ERK but not P38 kinase activation. In contrast, Dex increased Ocls numbers by 3.3-fold, while Btz decreased Ocls by ~50%. Co-treatment with Aplidin 0.1pM reduced Dex-induced Ocl numbers by 25% and further decreased Ocls when combined with Btz. Aplidin also decreased mature Ocl numbers, and either alone or in combination with Dex or Btz, markedly reduced the number of resorption pits formed by mature Ocls on bone slices. Lastly, we examined the effects of Aplidin on MM cell growth (IgG2b) and bone resorption (CTX) in conditioned media (CM) from ex vivo bone organ cultures that reproduce the 3D-organization and the cellular diversity of the MM/bone marrow niche. CM from bones bearing 5TGM1 MM cells exhibited increased CTX and IgG2b levels compared to bones without MM. Aplidin (10nM) decreased IgG2b and CTX levels by 80% and 50% respectively after 3d, and reduced IgG2b and CTX levels to control levels after 12d. Suboptimal doses of Aplidin alone (1nM, x3d) were ineffective; but combined with Dex or Btz, Aplidin significantly decreased IgG2b and CTX levels in bones with MM. Thus, Aplidin exhibits potent anti-myeloma and anti-resorptive activities, and enhances proteasome inhibitor blockade of MM growth and bone destruction.

Automatic Bone Measurement from X-Ray Computed Tomography and New Snake Osteosarcoma Alexander Hall*. Thermo Fisher Scientific, United States

Analyzing three-dimensional data often requires slow and tedious manual decision making by a trained user. Traditionally, decisions about what belongs to a material are made layer-by-layer for every single image in a z-stack of hundreds or thousands of images. For example, digitally extracting one single bone from a complete skeleton is often the most time consuming portion of comparative morphology projects. Using X-ray computed tomography data with sufficient information about biologically real boundaries (sutures, joints, etc.), one can use Thermo Scientific™ Amira-Avizo™ Software to automatically segment skeletons. In this project, I achieved a new workflow using an object separation process within the software (Fig. 1A). After optimizing the object separation parameters, individual bones were isolated and measured with only a fraction of the work required by manually selecting bones layer by layer. I will present a use case where I studied several snake skeletons at the single-bone level leading to the discovery of a neoplasm, currently thought to be an osteosarcoma (Figs. 1B and 1C). This process can be quite useful for studies of non-human systems, including mammals and reptiles. Anyone with this software or similar image analysis tools can implement this method, given some experimentation with optimizing for your data.

The effects of castration on prostate cancer tumor growth in bone Tiina E Kähkönen*[1], Mari I Suominen[1], Jenni Mäki-Jouppila[1], Jussi M Halleen[1], Jenni Bernoulli[1], Pascale Lejeune[2]. [1]Pharmatest Services, Finland, [2]Bayer AG, Germany

Advanced prostate cancer tumors typically lose their dependence on endogenous androgens, leading to aggressive growth and development of metastatic castration resistant prostate cancer (mCRPC). High incidence of bone metastases is typical for mCRPC patients and causes high morbidity. The aims of this study were to evaluate the effects of castration on tumor growth and tumor-induced changes in bone, and to establish a preclinical model that could be used for evaluation of efficacy of new therapies against mCRPC.NOD.Scid male mice aged 5-6 weeks were divided into three groups. One group was left intact and two groups were castrated either before or 4 weeks after inoculation of 2x106 VCaP human prostate cancer cells to proximal tibia. Tumor-induced bone changes (lesions) were followed by X-ray imaging during the study, and imaged by micro-computed tomography (μCT) at endpoint. Tumor growth was followed by measuring serum PSA levels, and evaluated by histology and immunohistochemical staining for androgen receptor (AR) and AR variant 7 (AR-V7) at endpoint.Castration decreased the weight of androgen-dependent organs, indicating decreased androgen levels. VCaP cells induced osteoblastic-mixed bone lesions and castration did not affect the lesion type. Bone lesion growth was similar in all study groups, but a trend towards decreased lesion area was observed in the mice castrated before cancer cell inoculation. μCT imaging showed less changes in cortical bone of the mice castrated before cancer cell inoculation. Castration was associated with a trend towards increased cortical bone area in healthy tibias. PSA levels were similar in intact mice and in the mice castrated 4 weeks after the cancer cell inoculation, and lower in the mice castrated before the cancer cell inoculation. Castration strongly induced AR and AR-V7 expression in the tumors, and decreased tumor take rate from 60% to 40 - 50% based on evaluation of X-ray images, PSA levels and histological findings.These results demonstrate that castration alters tumor growth rate, and suggest that early phases of tumor development into the bone are androgen-regulated. Castration may have direct effects on bone, and it may induce changes in marker expression in the tumor cells. Careful validation of preclinical models is essential in selecting most predictive models for evaluation of efficacy of new therapies against mCRPC.

α4β1 Integrin and vascular cell adhesion molecule (VCAM) 1 interactions regulate myeloid-derived suppressor cells (MDSC) mobilization from the bone metastatic tumor hosts Kyung Jin Lee*[1], Eun Jeong Lee[1], Bo Yeon Seo[1], Sun Wook Cho[2], Serk In Park[1]. [1]Korea University College of Medicine, Republic of Korea, [2]Seoul National University Hospital, Republic of Korea

MDSCs are a subset of immature bone marrow-derived cells that play diverse pro-tumorigenic roles such as suppressing T cell-mediated anti-tumoral immunity. We have previously reported that tumor-derived parathyroid hormone-related peptide (PTHrP) increased MDSC recruitment in tumor tissue. In contrast, little is known about how MDSCs are mobilized from the bone marrow of tumor hosts. In this study, we investigated whether interactions between α4β1 integrin expression in MDSCs and VCAM 1 expression in the bone marrow stromal cells (BMSC) regulate retention and release of MDSCs in the bone marrow. CD11b+Gr1+ cells (commonly defined as murine MDSCs) were isolated from the femurs by flow cytometry, and in vitro cell binding assays were performed. Briefly, MDCS were carboxyfluorescein succinimidyl ester (CFSE)-stained and co-cultured with MC3T3E1 pre-osteoblastic cells in the presence of anti-VCAM 1 and/or anti-β1 integrin neutralizing antibodies (0.5 to 2 µg/mL). After washing unbound cells, fluorescence intensity was measured to quantify MDSC-BMSC binding. VCAM-1 and/or β1 integrin neutralizing antibodies dose-dependently decreased MDSC-BMSC binding, suggesting that MDSCs bind to BMSC via VCAM-1 and β1 integrin. We further examined whether tumor-derived PTHrP disrupts the VCAM-1 and β1 integrin axis of MDSC-BMSC. PTHrP (1-34) administration rapidly increased MDSCs in the peripheral blood in vivo. In addition, PTHrP conditioned-media from calvarial osteoblasts reduced MDSC-BMSC binding in vitro compared with control conditioned media, and the effects were reversed by anti-interleukin (IL)-6 or anti-vascular endothelial growth factor (VEGF)-A antibodies, suggesting that PTHrP-induced IL-6 and VEGF-A expression in osteoblasts mobilize MDSCs. In addition, recombinant IL-6 and VEGF-A reduced MDSC-BMSC binding in vitro. Lastly, immunohistological analyses of the bones of tumor-bearing mice showed that CD11b+Gr1+ cells localized adjacent to trabecular osteoblasts. In summary, our data demonstrate that bone marrow stromal cells regulate MDSC trafficking from the bone marrow to the peripheral blood, and also that VCAM-1 (expressed in BMSC) and α4β1 integrin (expressed in MDSC) interactions regulate MDSC retention and mobilization. Further studies on the PTHrP-induced expression of proteinases such as matrix metalloproteinases and A Disintegrin and Metalloproteinase (ADAM) in bone will elucidate the mechanism of MDSC mobilization in the bone marrow of tumor hosts.

Microfluidic Platform for Investigation of Mechanoregulation of Breast Cancer Bone Metastasis Xueting Mei*[1], Kevin Middleton[2], Yu-Heng Ma[2], Liangcheng Xu[2], Noosheen Walji[1], Edmond Young[1,2], Lidan You[1,2]. [1]Department of Mechanical and Industrial Engineering, University of Toronto, Canada, [2]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Canada

Introduction: Approximately 70% of advanced breast cancer patients experience bone metastasis (1). Breast cancer cells (BCC) that invade across the endothelium to the bone reduce bone quality by altering normal osteoclast activity. Exercise, a common cancer intervention strategy, can regulate bone remodeling, thus potentially affect BCC metastasis to bone through mechanotransduction of osteocytes. Our recent in vitro studies showed that mechanically stimulated osteocytes can regulate BCC migration and modify endothelial cells (2). However, a more physiologically relevant platform is needed to better investigate the mechanisms leading to interactions between BCC and bone microenvironment under mechanical loading. We present here a novel in vitro microfluidic tri-culture lumen model for studying mechanical regulation of breast cancer metastasis.Methods: Highly metastatic MDA-MB-231 human BCCs were cultured inside a lumen lined with human umbilical vein endothelial cells (HUVECs) (3), which is adjacent to a population of either static or mechanically-stimulated osteocyte-like MLO-Y4 cells (Figure 1A). Soluble factors were diffused through hydrogel-filled side channels to instigate intercellular communication between MLO-Y4 cells and BCCs over 3 days. BCC transendothelial invasion distances were measured and normalized to the control without MLO-Y4 cells and osteoclast conditioned media (CM). Mechanical stimulation of osteocytes was validated by measuring intracellular calcium fluctuation under flow.Results: Photolithography and soft lithography were used to fabricate silicon SU-8 master and PDMS replicates. An HUVEC lumen was successfully cultured in the PDMS microfluidic device (Figure 1B). Experiments showed that BCCs invaded 37% (p<0.05) further for static osteocytes cultured in osteoclast CM comparing to no osteoclast CM (Figure 1C & D), likely due to osteoclast support of cancer cell growth (4). Discussion: We developed a novel microfluidic platform allowing the integration of physiological relevant fluid stimulation and real-time intercellular signaling between different cell populations in vitro. Future work with this platform will elucidate the effects of bone mechanical loading on BCC transendothelial invasion and determine the key mechanisms

IL-6 family cytokines and receptors regulate breast cancer bone colonization and tumor progression Tolu Omokehinde*[1], Miranda Sowder[1], Rachelle Johnson[2]. [1]Vanderbilt Center for Bone Biology, Vanderbilt University Medical Center, United States, [2]Vanderbilt Center for Bone Biology, Department of Medicine, Division of Clinical Pharmacology, Vanderbilt University Medical Center, United States

Breast cancer cells commonly metastasize to bone, where they may induce osteolysis, leading to increased fracture risk. Through mechanisms that remain unclear, bone-disseminated breast cancer cells may also enter a period of quiescence prior to inducing bone destruction. The interleukin-6 (IL-6) cytokine family includes IL-6, leukemia inhibitory factor (LIF), and oncostatin M (OSM), among others, and has known roles in bone colonization. Our lab has previously shown that LIF receptor (LIFR) expression on breast cancer cells promotes tumor cell dormancy in the bone marrow, but since LIF, OSM, and several other IL-6 cytokines are able to complex with LIFR, it remains unclear which ligand, if any, induces pro-dormancy signals through LIFR. To examine this, we performed qPCR analysis for OSM, LIF, OSMR and LIFR mRNA levels across a panel of breast cancer cell lines, including parental (MCF7, SUM159, D2.0R, MDA-MB-231, 4T1) and bone-metastatic variants (MCF7, MDA-MB-231, 4T1). Our goal was to identify patterns of expression of the ligands and receptors. LIFR and OSMR showed a similar pattern of expression and were highest in cell lines with low metastatic potential (MCF7, SUM159, and D2.0R). LIF and OSM expression did not correspond with metastatic potential but were detectable at the mRNA level across all breast cancer cell lines. Interestingly, LIFR, but not OSMR mRNA levels, were lower in the bone metastatic variants of MDA-MB-231 (70% lower) and 4T1 cells (86% lower, p<0.01) compared to parental cells, which already have low LIFR function. OSM had a similar expression profile, with decreases in expression for bone metastatic variants of MDA-MB-231 (90% lower, p<0.05) and 4T1 cells (85% lower), suggesting that OSM signaling through LIFR may prevent bone homing. In support of our in vitro data, breast cancer patient data from Kaplan-Meier (KM) Plotter indicates that patients with high OSM and OSMR levels experience significantly greater relapse free survival (p<0.05-p<0.0001), and we have previously shown that loss of LIFR corresponds with reduced patient survival. These data suggest that OSM signaling through LIFR or OSMR in breast cancer cells may confer tumor dormancy and prevent breast cancer bone dissemination. In future studies we will determine the effects of OSM and LIF in tumor dissemination to bone using CRISPR/Cas9 to knockout OSM, LIF, and OSMR in breast cancer cell lines and evaluate their ability to disseminate to and colonize the bone marrow.

Extracellular ATP Reduces Osteosarcoma Single and Collective Migration Through the P2X7 Receptor Daniel Shropshire*, Manuel Riquelme, Jean Jiang. UT Health Science Center San Antonio, United States

Osteosarcoma (OS) is the most common primary bone cancer and primarily affects adolescents. Metastasis is a usually fatal complication and responsible for the majority of mortality due to the disease. The primary tumor microenvironment is a crucial regulator of the metastatic process, which requires cancer cell motility and invasion. OS most commonly arises on long bone endosteum, an environment influenced by osteocyte connexin 43 hemichannels that release ATP and other paracrine signaling factors. Activation of the P2X7 ATP receptor drives differentiation in normal osteoblastic precursors and osteosarcoma, which is correlated with better prognosis. We therefore hypothesized that osteocytic connexin 43 hemichannels play a role in osteosarcoma progression. We found that extracellular ATP (200µM) and P2X7R-specific agonist BzATP reduce single and collective migration in OS-17 cells, an osteoblastic OS cell line that robustly expresses the receptor. Chondroblastic MOS-J OS cells do not express P2X7R but have an even greater migratory inhibition due to extracellular ATP, with chemotaxis inhibition at 10µM. In neither cell line did ATP metabolite adenosine (200µM) significantly alter cell migration. These findings point to osteocytic connexin 43 hemichannels as potential regulators in osteosarcoma metastasis through purinergic signaling.

A role for immunoglobulins in the osteolytic bone disease of multiple myeloma Marita Westhrin*[1], Vlado Kovcic[1], Albert Bondt[2], Stephanie Holst[2], Zeijan Zhang[3], Tobias Slørdahl[4], Anders Sundan[4], Anders Waage[4], Manfred Wuhrer[2], Therese Standal[1]. [1]Department of Clinical and Molecular Medicine/Centre of Molecular Inflammation Research, Norwegian University of Science and Technology (NTNU), Norway, [2]Leiden University Medical Center, Leiden University, Netherlands, [3]Key Laboratory of Glycoconjugate Research Ministry of Public Health, School of Basic Medical Sciences, Fudan University, China, [4]Department of Clinical and Molecular Medicine, Norwegian University of Science and Technology (NTNU), Norway

Most patients with multiple myeloma develop a severe osteolytic bone disease causing pain and fractures. The myeloma cells secrete immunoglobulins and the presence of monoclonal immunoglobulins in the patients' sera is the main diagnostic criteria. Immunoglobulins play a role in bone loss in rheumatoid arthritis, but have not, surprisingly perhaps, been linked with the bone disease in multiple myeloma. In this work, we isolated immunoglobulins from serum of myeloma patients using protein G coupled magnetic beads and columns. We found that immunoglobulins from patients with bone disease (n=18) promoted osteoclast differentiation when added to human monocyte-derived pre-osteoclasts in vitro, whereas immunoglobulins from patients without bone disease (n=13) did not. The effect was mediated, at least partly, by FcγRII, since inhibiting FcγRII reduced the effect of the immunoglobulins on osteoclastogenesis. FcγRII is known to bind primarily immune-complexes. Indeed, when we fractionated the immunoglobulin samples by size-exclusion chromatography we found that the "osteoclast promoting activity" was in the high-molecular weight fractions, suggesting that they are in complexes. Since extent of complex formation may be determined by immunoglobulin glycosylation, we next examined whether there is a difference in immunoglobulin glycosylation between healthy controls and patients, and whether it changes during disease progression. To this end we analysed IgG glycosylation in serum samples from patients (n=72) and age and sex matched controls (n=51). These analyses showed that patient IgG was less galactosylated (p= 0.02) and less sialylated (p=0.04) compared with control IgG. Moreover, patients with bone disease (n= 43) had significantly less galactose on IgG compared with patients without bone disease (p=0.02, n=29). Further, the glycosyltransferases ST6GAL1 and B4GALT1, which adds sialic acid and galactose to the sugar chain, respectively, are less expressed in plasma cells obtained from patients with bone disease (n=137) compared with those without (n=36, p<0.002, p<0.001). Importantly, we observed a significant reduction of IgG glycosylation (p= 0.02, n=8) in serum samples obtained from individual patients before and after the onset of bone disease. Taken together, our data support that immunoglobulins may directly promote bone loss in multiple myeloma.

HIF-2α is Sufficient to Cause Agressive Fibroproliferative Lesions in the Developing Limb Zachary Tata*, Christophe Merceron, Mohd Parvez Khan, Ernestina Schipani. Department of Orthopedic Surgery, School of Medicine, University of Michigan, United States

The Hypoxia Inducible Factors 1α and 2α (HIF-1α and HIF-2α) are critical mediators of the cellular response to low oxygen tension (hypoxia). In normoxia, the HIFs are ubiquitinated by the E3-ubiquitin ligase von Hippel Lindau (VHL) and targeted to the proteasome for degradation. However, in hypoxia, they are stabilized and translocate to the nucleus where they regulate transcription of numerous genes. The HIFs are also implicated in pathological states such as fibrosis and tumor initiation. We have previously established that loss of VHL in the limb bud mesenchyme produces fibroblastic tumors in proximity to the synovial joints. The onset of these tumors is HIF-1α dependent. Moreover, their frequency is reduced by the concomitant loss of HIF-2α. Our findings, in addition to the knowledge that VHL possesses both HIF dependent and independent functions, led us to question if the HIFs are sufficient to initiate fibroblastic tumors.Mice expressing a stabilized form of HIF-1α or HIF-2α in the limb bud mesenchyme (PRX;HIF-1dPAf/f and PRX;HIF-2dPAf/+) were generated. Both mutant proteins are constitutively active regardless of oxygen tension. Mutant mice were grown for 12 weeks and screened for the presence of fibroproliferative lesions by nanoCT and histology. PRX;HIF-1dPAf/f mice (n=30) did not show any lesion development up to 12 weeks of age. 35% of PRX;HIF-2dPAf/+ mice (n=30) developed masses, primarily in proximity to the radiocarpal joint. Similarly to the tumors observed in VHL mutant mice, these lesions were characterized by fibroproliferation, a core of amorphous, and most likely necrotic, material, and the ability to invade and destroy adjoining tissues. However, they developed more slowly and in different locations. Work is currently in progress to establish a PRX;HIF-2dPAf/+ xenograft model to determine the degree of malignancy of these fibroproliferative lesions and to conduct a microarray to compare their molecular signature to that of the VHL tumors.HIF2 overexpression is sufficient to generate discrete fibroproliferative lesions in proximity to synovial joints up to 12 weeks of age. These lesions share characteristics of the VHL tumors, yet differences render each unique. The significance of this study is twofold. It contributes to our understanding of the function of the hypoxia signaling pathway in mesenchymal cell biology in addition to offering insight into potential roles it may play in the development of human sporadic fibrosarcomas.

Opposite effects of TRAIL on the Sp1-c-FLIP survival pathway in myeloma cells and osteoclasts. Hirofumi Tenshin*[1], Jumpei Teramachi[2], Masahiro Hiasa[1], Asuka Oda[3], Mohannad Ashtar[1], Kotaro Tanimoto[1], Iwasa Masami[3], Ariunzaya Bat-Erdene[3], Takeshi Harada[3], Singen Nakamura[3], Hirokazu Miki[4], Itsuro Endo[3], Eiji Tanaka[1], Toshio Matsumoto[5], Masahiro Abe[3]. [1]Department of Orthodontics and Dentofacial Orthopedics, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, [2]Department of Tissue Regeneration, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, [3]Department of Hematology, Endocrinology and Metabolism, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, [4]Division of Transfusion Medicine and Cell Therapy, Tokushima University Hospital, Japan, [5]Fujii Memorial Institute of Medical Sciences, Tokushima University, Japan

Multiple myeloma (MM), a malignancy of plasma cells, induces receptor activator of nuclear factor kappa-B ligand (RANKL)-mediated osteoclastogenesis; thus activated osteoclasts (OCs) in turn enhance MM growth, thereby forming a vicious cycle between MM tumor expansion and osteoclastic bone destruction. Although TNF-related apoptosis-inducing ligand (TRAIL) induces apoptosis in MM cells, we reported that TRAIL enhances OC differentiation and activity. The present study was undertaken to dissect the underlying mechanism of this cell type-specific effects of TRAIL, focusing on regulation of the critical survival mediator c-FLIP. Intriguingly, TRAIL substantially reduced c-FLIP expression at mRNA and protein levels in MM cells, whereas further upregulating it in OCs. Because c-FLIP is a target gene of the transcription factor Sp1, we next looked at the role of Sp1 in c-FLIP expression in these cells. TRAIL was found to form complex II but not DISC to activate the TAK1-NF-κB-Sp1 signaling pathway in OCs; however, inhibition of Sp1 abrogated their upregulation of c-FLIP by TRAIL, indicating a critical role of Sp1. In contrast, TRAIL was able to activate caspase-8 and reduce Sp1 at protein but not mRNA levels in MM cells. The caspase-8 inhibitor Z-IETD-FMK restored Sp1 protein levels in parallel with resumption of c-FLIP mRNA expression in MM cells, suggesting caspase-8–dependent enzymatic degradation of Sp1 protein to reduce c-FLIP. In OCs, the TAK1 inhibitor LLZ1640-2 inhibited NF-κB activation to reduce Sp1 expression in the presence of TRAIL while inducing caspase-8 activation to trigger Sp1 protein degradation and cell death. In addition, cocultures with OCs upregulated c-FLIP expression to blunt TRAIL-induced cell death in MM cells. However, LLZ1640-2 substantially reduced c-FLIP expression to restore the TRAIL-induced caspase-8 activation and cell death in MM cells in the cocultures with OCs. These results demonstrate that c-FLIP levels are regulated in an Sp1-dependent manner by TRAIL in MM cells and OCs in the downward and upward directions, respectively, and suggest that TAK1 inhibition triggers TRAIL-induced apoptosis in OCs while potentiating its anti-MM action.

Disruption of a progressive vicious cycle between myeloma tumor growth and bone destruction by TAK1 inhibition Jumpei Teramachi*[1], Hirofumi Tenshin[1], Masahiro Hiasa[1], Asuka Oda[1], Ariunzaya Bat-Erdene[1], Takeshi Harada[1], Shingen Nakamura[1], Hirokazu Miki[2], Itsuro Endo[1], Toshio Matsumoto[1], Masahiro Abe[1]. [1]Tokushima University, Japan, [2]Tokushima University Hospital, Japan

Multiple myeloma (MM) has a unique propensity to develop and expand almost exclusively in the bone marrow and generates destructive bone disease. MM cell interaction to bone marrow stromal cells (BMSCs) confers cell adhesion-mediated drug resistance (CAM-DR) or secreted factor mediated drug resistance (SFM-DR) along with induction of bone destruction. We have reported that PIM2 is upregulated in MM cells and their surrounding cells in bone lesions, and that treatment with PIM inhibitors suppressed MM tumor growth and bone destruction. We subsequently identified TGF-b-activated kinase-1 (TAK1) as an upstream mediator responsible for PIM2 up-regulation in these cells. Here, we therefore aimed to clarify TAK1 activation status in MM-bone marrow interaction and the therapeutic impact of TAK1 inhibition. TAK1 was constitutively overexpressed and phosphorylated in all MM cell lines tested; the TAK1 inhibitor LLZ1640-2 suppressed NF-kB activation and thereby PIM2 expression to induce apoptosis in MM cells. Although Sp1, a transcription factor for TAK1 gene expression, is upregulated in MM cells, inhibition of NF-kB as well as TAK1 reduced Sp1 levels in MM cells. The Sp1 inhibitor terameprocol reduced TAK1 levels in MM cells, suggesting a progressive amplification loop in TAK1- NF-kB-Sp1 signaling. When BMSCs were co-cultured with MM cells, TAK1 phosphorylation was also induced in parallel with upregulation of VCAM-1, IL-6 production and the critical osteoclastogenic mediator RANKL in BMSCs; however, the TAK1 inhibition reduced the VCAM-1 and RANKL expression and IL-6 production by BMSCs and impaired MM cell adhesion onto BMSCs and CAM-DR to doxorubicin. Furthermore, treatment with LLZ1640-2 substantially suppressed osteoclastogenesis in cocultures of bone marrow cells with MM cells. The TAK1 inhibition also suppressed VEGF production and the expression of BCMA and TACI, receptors for BAFF and APRIL. These results collectively demonstrate that TAK1 plays a pivotal role in MM cell-bone marrow interaction to enhance tumor progression and bone destruction in MM. Therefore, TAK1 inhibition may become a unique anti-MM therapeutic option with bone-modifying activity.

In Situ Imaging of Collagen Degradation May Assess Myeloma Bone Disease Activity Donghoon Yoon*[1], Ikjae Shin[1], Juchan Lim[1], Carol Morris[1], Lucas Bennink[2], S. Michael Yu[2], Gareth Morgan[1], Maurizio Zangari[1]. [1]University of Arkansas for Medical Sciences, United States, [2]University of Utah Department of Bioengineering, United States

Collagen is the most abundant protein in bone matrix and continuously remodeled. Aberrant collagen remodeling are often found in pathological conditions including multiple myeloma (MM). Myeloma lytic bone disease (MBD) is associated with patient morbidity and mortality. The recently developed collagen hybridizing peptide (CHP) selectively binds to denatured collagen in vitro in conjunction and with near-infrared fluorescence (NIRF) dye indicates detection of the collagen degradation activity in vivo.We transplanted 1x106 Luciferase expressing 5TGM1 cells (5TGM1-Luc) into 8 ~ 12 week old non-obese diabetic-scid IL2rg-/- (NSG) mice via tail vein. Myeloma progression was monitored weekly by bioluminescence (BL) imaging using IVIS-200 (PerkinElmer). The median post-transplant animal survival was 40 days. When the mouse developed endpoint symptoms (i.e. >109 BL signals, hind limb paralysis, significant weight loss), 1nM of NIRF conjugated CHP was intravenously injected. NIRF imaging was taken using IVIS-200. At postmortem, spine and femur/tibia were surgically removed ex vivo images were obtained for BL and NIRF images. Extracted bones were scanned by micro-computer tomography (microCT400, Scano medical Inc) and prepared for the bone histomorphic analysis. In vivo BL image analysis showed that myeloma cells initially appears at spine level at 4th week and subsequently spread on 5th and 6th week. Micro-CT analysis confirmed osteolytic lesions at the lumbar spine. In in vivo, NIRF signals significantly increased in MM mouse compare to control mouse (P<0.0001) and showed a positive correlation to BL signal. In the ex vivo analysis, NIRF signals were found located in lumbar spine and joint areas of the femur/tibia. The area with high NIRF signal does not matched with areas of previous bone reabsorption indicated by micro-CT. This finding indicate that NIRF signal is specifically expressed in active bone osteolytic sites while micro-CT image shows previous location of osteolysis.Our data demonstrate that NIRF-CHP signals can detect extensive collagen degradation activity associated to MM growth and indicate active areas of Myeloma osteolysis. Since NIRF-CHP areas may show early active osteolytic site at much, NIRF-CHP imaging can be a promising non-invasive diagnostic method to indicate the osteolytic forming sites in MM.

Postnatal Chondrocyte-Specific RUNX2 Overexpression Results in Accelerated Development of Osteoarthritis Following Traumatic Knee Joint Injury Sarah Catheline*, Elizabeth Botto, Christopher Dean, Martin Chang, Jennifer Jonason. University of Rochester, United States

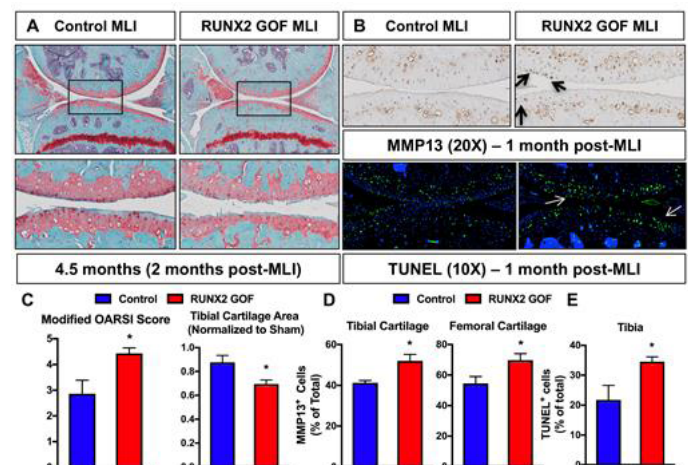
Osteoarthritis (OA) is a debilitating joint disease causing irreversible loss of cartilage within synovial joints. Studies show roughly 50% of patients with an ACL or meniscus tear will eventually develop knee OA. Despite the high prevalence of OA, molecular mechanisms underlying onset are unclear. RUNX2 is a transcription factor that promotes chondrocyte hypertrophy and expression of factors catabolic to the cartilage extracellular matrix. It is also known to regulate apoptosis in osteoblasts. Importantly, enhanced RUNX2 expression is seen in early stages of human OA and in murine models of injury-induced OA. Our preliminary data surprisingly show, however, that postnatal chondrocyte-specific RUNX2 overexpression alone is insufficient to induce OA. Here, we investigate whether cartilage-specific RUNX2 overexpression can accelerate OA progression following joint injury. At 2 months of age, Acan-Cre+/-ERT2; ROSA-Runx2f/+ (RUNX2 GOF) and littermate Cre-negative control mice received tamoxifen (100μg/g body weight) daily for 5 days (N = 6 per genotype). At 10 weeks of age, mice received meniscal-ligamentous injury (MLI) on the right hindlimb or a sham injury on the left hindlimb and were harvested 1 or 2 months post injury. Histology reveals that RUNX2 GOF mice have enhanced cartilage damage and Safranin-O staining loss compared to controls; these findings were confirmed by significantly increased modified OARSI scores and significantly decreased total tibial cartilage areas in RUNX2 GOF mice 2 months post-MLI (Figure 1A, 1C). RUNX2 GOF sham joints show no changes relative to controls. RUNX2 GOF mice also show significantly increased TUNEL-positive cells and MMP13 expression 1 month post-MLI in the articular cartilage (Figure 1B, 1D, 1E). Preliminary in vitro studies suggest that oxidative stress may promote RUNX2 activity, which could provide an explanation as to why RUNX2 GOF accelerates OA development following injury, but has no effect at homeostasis. Specifically, RUNX2 transcriptional activity measured by luciferase reporter assays is increased in ATDC5 cells overexpressing RUNX2 after treatment with oxidant tBHP. Overall, our results suggest chondrocyte-specific RUNX2 overexpression accelerates OA development after joint injury. These results highlight the contribution of genetic variability to the development of OA and suggest that genetic alterations affecting RUNX2 expression levels may in part predetermine the rate of OA onset following injury.


Figure 1. Postnatal RUNX2 overexpression accelerates articular cartilage degeneration following MLI. (A) Safranin-O/Fast Green staining of knee joint sections from *Acan-Cre+/-ER[T2]; ROSA-Runx2f/+* (RUNX2 GOF) and littermate Cre-negative control mice injected with tamoxifen (100 μg/g) daily for 5 days at 2 months of age, given MLI at 2.5 months, and sacrificed 2 months later (upper panel, 5X, lower panel 20X). (B) MMP13 immunohistochemistry (top, 20X) and TUNEL staining (bottom, 10X) from control and RUNX2 GOF mice as described in (A), but sacrificed 1 month post-MLI. (C) Modified OARSI and quantification of total cartilage area from control and RUNX2 GOF mice (p < 0.05, unpaired t-test, N = 6). (D) Quantification of MMP13+ and (E) TUNEL+ cells (p < 0.05, unpaired t-test, N = 4).

MON-0247

Fibroblast Growth Factor 1 (FGF-1) impinges on Chondrocyte Degradation in OA through Matrix Metalloproteinase 13 (MMP-13) and Connective Tissue Growth Factor (CCN2) Abdellatif Elseoudi*[1], Tarek Abd El Kader[2], Takashi Nishida[1], Eriko Aoyama[3], Takanori Eguchi[4], Masaharu Takigawa[3], Satoshi Kubota[1]. [1]Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences., Japan, [2]Assistant professor, Health and Social Sciences Cluster Singapore Institute of Technology (SIT), Singapore, [3]Advanced Research Center for Oral and Craniofacial Sciences, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences., Japan, [4]Dental Pharmacology, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences., Japan

PurposeOsteoarthritis (OA) involves the degradation of cartilage tissue with an overall shift toward catabolism over anabolism. CCN (Connective tissue growth factor/CCN2, Cysteine rich protein 61/CCN1, and Nephroblastoma overexpressed gene/CCN3) family proteins play critical roles in osteo/chondrogenesis and vasculo/angiogenesis. Particularly, CCN2 plays a crucial role in embryogenesis and skeletogenesis to promote proliferation, differentiation and chondrocyte maturation as well as matrix remodeling during chondrogenesis. CCN2 interacts with several growth factors involved in endochondral ossification, which include fibroblast growth factor 1 (FGF-1) showing a specific binding with this CCN2. Therefore, this study elucidates, the effect of FGF-1 on cartilage degradation through CCN2 and matrix metalloproteinase-13 (MMP-13) genes in vivo as well as in vitro in relation to OA.MethodsEffect of FGF-1 on CCN2 was evaluated in vitro with human chondrocytic HCS-2/8 cells. The cellular phenotype was estimated by the gene expression of chondrocytic metabolism markers (ACAN, COL2A1, and MMP13). Effect of FGF-1 on CCN2 mRNA and protein levels was evaluated by quantitative RT-PCR analysis and enzyme-linked immunosorbent assay (ELISA) respectively. Reporter gene assay was used to examine if CCN2 is regulated by FGF-1 through a particular genetic element involved in the proximal promoter. Involvement of FGF-1 and MMP-13 in OA development was evaluated in vivo by using immunohistochemistry.ResultsAn interesting finding was manifested through the analysis of FGF-1 addition to the chondrocytic cell culture. FGF-1 restrained the mRNA levels of the anabolic genes (ACAN and COL2A1) in chondrocytic HCS-2/8 cells; however, a catabolic gene (MMP13) was dramatically induced in those cells. FGF-1 drastically repressed the mRNA and protein levels of CCN2 in HCS-2/8 cells. Reporter gene assay suggested that FGF-1 down-regulated CCN2 gene expression at a transcriptional level. It is important to note that both FGF-1 and MMP-13 were produced in articular cartilage upon OA induction, which was evaluated in vivo by using a rat model.ConclusionsThese results suggest a critical effect of FGF-1 via MMP-13 on the balance of chondrocytic metabolism; with a remarkable shift toward catabolism over anabolism. Furthermore, their effect on CCN2 may lead to further degradation of cartilage tissue in OA.

Role of IL36α signaling in human chondrocyte homeostasis Tieshi Li*, Xin Jin, Arnavaz Hakimiyan, Susan Chubinskaya, Jie Jiang, Lai Wang, Alessandra Esposito, Joseph Temple, Anna Spagnoli. Rush University Medical Center, United States

Chondrocyte homeostasis is maintained via the balance between cartilage anabolism and catabolism. Disrupted balance in articular cartilage induces joint disease like osteoarthritis. Our previous studies and other reports showed that IL36α signaling might be involved in the catabolic and inflammatory response in chondrocytes. OA chondrocytes, treated with IL-36α, showed significant increase in the expression of MMP-13. IL-36α stimulated cells showed NFκB and p38 MAPK activated pathways. The present study is aimed at determining whether IL36α signaling also regulate anabolic factors, the other catabolic factors, inflammatory cytokines as well as the mechanism of how IL36α signaling does this. Healthy human primary chondrocyte harvested from human cadaver, (Collins Grade 0/1 Ankle articular cartilage) at passage 0 (cultured 5-6 days) were starved for 24 hours followed with different doses of IL36α treatment for 24 hours. Cells were harvested for mRNA extraction and RT-PCR. Conditioned media was also harvested for western blot. We found that IL36α treatment induced a dose-dependent increase in Adamts4, Mmp3, IL1β, IL6 and IL8 expression levels but dose-dependent decrease in Sox9, Collagen2 and Aggrecan expression levels suggesting that IL36α might play essential role for chondrocyte homeostasis as a catabolic factor. Furthermore, primary chondrocytes were cultured with the p38 MAP kinase inhibitor (SB203580, 10 μM), the MEK1/Erk inhibitor (PD98059, 10 μM) or the inhibitor of NFκB nuclear translocation (JSH23, 10 μM) in the presence or absence of IL36α for 24 h. Treatment with SB203580 but not PD98059 and JSH23 significantly attenuated the inductions of Mmp13, Adamts4 and Mmp3 by IL36α. Western blot analysis of Mmp13 further confirmed this result. PD98059 and JSH23 but not SB203580 significantly attenuated the induction of IL1β. SB203580 and PD98059 but not JSH-23 significantly attenuated the induction of IL8. All three inhibitors significantly attenuated the induction of IL6. These results suggest the involvement of P38 MAP kinase signaling in IL36α-mediated catabolic factors induction and mainly involvement of MEK1 kinase and NFκB signaling in IL36α-mediated inflammatory cytokine induction. Additionally, none of the inhibitors treatment significantly attenuated the suppression of Sox9, Collagen2 and Aggrecan expression levels with high dose of IL36α.

In conclusion, IL36α regulate chondrocyte homeostasis as a catabolic factor suggesting the viability of therapeutically intervening in the OA process by inhibiting IL36α signaling.

Targeted Deletion of Claudin (Cldn)-11 Gene Promotes Chondrocyte Differentiation and Reduces Articular Cartilage Thickness in Mice Richard Lindsey*[1,2], Weirong Xing[1,2], Catrina Godwin[1], Sheila Pourteymoor[1], Subburaman Mohan[1,2]. [1]Musculoskeletal Disease Center, VA Loma Linda Healthcare System, United States, [2]Department of Medicine, Loma Linda University, United States

The claudin (Cldn) family comprises 24 members of 20–34 kDa tetraspan transmembrane proteins of tight junctions. In addition to their established canonical role as barriers controlling the flow of molecules in the intercellular space between cells, a distinct non-canonical role for Cldns is now emerging in which they serve as mediators of cell signaling. In our studies evaluating expression of all 24 Cldn family members during osteoblast (OB) differentiation, Cldn-11 showed the largest changes during in vitro OB differentiation. In previous studies, we showed that mice with targeted deletion of Cldn-11 gene exhibited reduced trabecular bone mass. During our immunohistochemistry (IHC) studies of Cldn-11 expression in bone, we found high levels of Cldn-11 expression in articular chondrocytes. Therefore, we evaluated the articular cartilage phenotype in 12-week-old Cldn-11 knockout (KO) mice. Quantitation of articular cartilage revealed a 27% and 40% reduction in the thickness and area (P < 0.05), respectively, in the Cldn-11 KO mice. In contrast, growth plate cartilage thickness was not affected. IHC showed increased expression of differentiation marker Col10α1 and decreased expression of articular chondrocyte marker lubricin in the articular cartilage of KO mice. Overexpression of Cldn-11 using a lentiviral vector in ATDC5 chondrocytes increased mRNA expression of articular markers Col2 and lubricin by 75% and 160%, respectively (P < 0.01). Since Cldn-11 overexpression increased Notch signaling target Hey1 by 62% (P < 0.01), we evaluated whether inhibition of Notch signaling blocked the Cldn-11 effect on expression of articular cartilage markers. We found that treatment with DAPT, a Notch inhibitor, blocked Cldn-11-induced lubricin expression in ATDC5 chondrocytes. Based on these data, we propose a novel role for Cldn-11 in regulating articular chondrocyte differentiation and articular cartilage thickness in part via manipulating Notch signaling. Further confirmation of this role would make manipulation of Cldn-11 signaling in articular chondrocytes an effective therapeutic means to treat osteoarthritis.

SMPD3 Deficiency in Chondrocytes and Osteoblasts Affects Fracture Healing Garthiga Manickam*[1], Pierre Moffatt[2,3], Monzur Murshed[1,2,4]. [1]Faculty of Dentistry, McGill University, Montreal, Quebec, Canada, [2]Shriners Hospital for Children, McGill University, Montreal, Quebec, Canada, [3]Department of Human Genetics, McGill University, Montreal, Quebec, Canada, [4]Department of Medicine, McGill University, Montreal, Quebec, Canada

Traumatic bone fractures can be a serious and frequent problem for patients suffering from osteoporosis, metastatic bone cancer and congenital bone disorders. The promotion of new bone formation and mineralization at the fracture site can shorten the time of healing and yield stronger union. We recently demonstrated that sphingomyelin phosphodiesterase 3 (SMPD3), a lipid-metabolizing enzyme, plays a critical role during skeletal development. We generated Smpd3flox/flox;Osx-Cre (Smpd3DChOb) mice to ablate Smpd3 in both chondrocytes and osteoblasts in the embryonic skeleton. Our data showed that SMPD3 activity in both these cell types is required for the initiation of extracellular matrix (ECM) mineralization and apoptosis of hypertrophic chondrocytes.Interestingly, the function of SMPD3 in adult bones appears to be less critical as only mild bone mineralization defects were observed in 3 month-old Smpd3DChOb mice. Next, we performed rodded immobilized fracture surgeries on 2 month-old Smpd3DChOb and control mice. We observed an induction of SMPD3 expression at the fracture site of wild type mice, 2 weeks post-surgery. Although micro-CT analyses did not show any differences in callus size and the amount of mineralized tissues, histomorphometric analyses showed that there was a marked increase of unmineralized osteoid in the fractured bones of Smpd3DChOb mice in comparison to the control mice. As was the case in the embryonic bones, we also observed impaired chondrocyte apoptosis at the fracture sites of Smpd3DChOb mice. Considering the induction of Smpd3 expression at the fracture site, we next examined how Smpd3 expression is regulated in cultured chondrocytes. To address this aim, we looked at two major regulators of chondrogenesis, BMP-2 and PTHrP. Our data showed that BMP-2 positively regulates Smpd3 expression in ATDC5 chondrogenic cells via p38 MAPK and Sox9. On the other hand, PTHrP downregulates Smpd3 expression by suppressing the BMP-2 signaling pathway. This suggests that BMP-2 and PTHrP have opposing affects on the regulation of Smpd3 expression.Taken together, our data provides compelling evidence that SMPD3 plays an important role during fracture healing. The novel insight generated through this study will add to the current understanding of SMPD3 regulation in skeletal tissue regeneration and has potential to pave the way for the development of therapeutic approaches to expedite ECM mineralization and healing of fractured bones.

PTHrP+ Chondrocytes in the Resting Zone Maintain the Growth Plate Integrity Koji Mizuhashi*, Noriaki Ono. University of Michigan School of Dentistry, United States

The resting zone is a critical component of the postnatal growth plate that contains precursor cells for differentiated columnar chondrocytes and releases morphogens to maintain the tissue architecture. In vivo lineage-tracing experiments demonstrate that resting chondrocytes expressing parathyroid hormone-related protein (PTHrP) encompass skeletal stem cells that can populate columnar chondrocytes for a long period. However, the functional significance of PTHrP+ resting chondrocytes in maintaining the growth plate architecture is unknown. In this study, we set out to reveal such significance by specifically ablating PTHrP+ chondrocytes from the resting zone. To achieve this goal, we took advantage of a resting-chondrocyte specific tamoxifen-inducible PTHrP-creER line, a Rosa26-iDTA allele and a Rosa26-tdTomato reporter allele. In this system, PTHrP+ chondrocytes exposed to an active form of tamoxifen will undergo recombination in the Rosa26 locus and result in rapid cell death. PTHrP-creER; Rosa26lsl-tdTomato/lsl-tdTomato mice were mated with Rosa26lsl-tdTomato-DTA/+ mice to generate PTHrP-creER; R26RtdTomato/+ (Cont) and PTHrP-creER; R26RtdTomato/iDTA (DTA) littermate mice. These mice were pulsed with a single dose of tamoxifen at P6 (0.5mg), when PTHrP+ chondrocytes are actively formed within the resting zone, and subsequently analyzed at P21. Initial fluorescence microscopy analysis revealed that PTHrP+ cells were only partially ablated from the resting zone in the DTA mice, as the number of tdTomato+ cells only moderately decreased (Cont: 1329±505 vs. DTA: 927±406 cells), while the number of tdTomato+ columns was significantly reduced (Cont: 64±23 vs. DTA: 32±17 columns). Although the bone length was unchanged, the height of each layer of the growth plate was significantly altered in the DTA mice; the proliferating layer was significantly reduced associated with significant expansion of the resting and hypertrophic layers (Cont vs. DTA; resting: 63±16 vs. 83±10 μm, proliferating: 127±10 vs. 91±12 μm, hypertrophic: 116±11 vs. 162±25 μm). Therefore, partial loss of PTHrP+ chondrocytes in the resting zone is sufficient to alter the integrity of the growth plate by inducing premature hypertrophic differentiation of chondrocytes in the proliferating zone. This leads us to speculate that PTHrP+ skeletal stem cells in the resting zone can maintain the integrity of the growth plate by sending a forward signal (PTHrP) for their progeny.

Small molecule G-protein βγ subunit inhibition potentiates parathyroid hormone chondroprotection in osteoarthritis William Pinamont*, Fadia Kamal, Elijah Carlson. Penn State College of Medicine, United States

Osteoarthritis (OA) is a debilitating joint disease with no curative therapy. Chondrocyte hypertrophy (CH) is a hallmark sign of OA, leading to cartilage degeneration. Parathyroid hormone (PTH) is chondroprotective in OA, however the mechanism of action is unknown. Chondrocytes are rich in PTH type-1 receptor (PTH1R), a G-protein coupled receptor (GPCR). Ligand stimulation of a GPCR promotes physiological Gα signaling. Pathologically elevated Gβγ signaling leads to GPCR desensitization and Gα uncoupling in disease states. We previously showed that gallein, a small molecule Gβγ inhibitor, prevents GPCR desensitization and recovers normal Gα signaling in heart disease. However, the role of GPCR Gβγ signaling in OA is unknown. Thus we hypothesize that, in OA, elevated Gβγ signaling leads to PTH1R desensitization and loss of PTH chondroprotection. Destabilization of the medial meniscus (DMM) was used as the surgical OA mouse model to simulate clinical meniscal injury induced OA. Sham or DMM mice were treated with gallein or vehicle, knee cartilage was harvested, cultured ex vivo and stimulated with PTH. PTH1R-Gαs signal activation was quantified by measuring cAMP production. To confirm this pathway in human OA, articular cartilage was collected from knee arthroplasty patients and cultured ex vivo. Cultures were treated with vehicle, G, PTH, or in combination and cAMP production was quantified. Immunofluorescent staining for CH markers MMP-13 and ADAMTS-5 was used to determine the antihypertrophic effects of the treatments. DMM impaired PTH-PTH1R-Gαs-cAMP production in murine chondrocytes, suggesting PTH1R desensitization occurs in OA. Gβγ inhibition by gallein potentiated baseline chondrocyte cAMP production and recovered PTH1R-Gα-cAMP production in DMM cartilage (Figure 1). In human OA cartilage, both gallein and PTH attenuated CH with a synergistic effect of their combination. Similar to mouse OA cartilage, gallein increased baseline cAMP production in human OA chondrocytes and recovered PTH1R-Gα-cAMP production following PTH treatment. In conclusion, our data supports our hypothesis that Gβγ promotes PTH1R desensitization in OA. Gβγ inhibition by gallein prevents PTH1R desensitization and recovers its chondroprotective effects, suggesting a novel synergistic therapy for OA. Future experiments using knockout mouse models, and combination therapy in DMM mice will further elucidate the role of Gβγ signaling in PTH1R chondroprotection in OA.

Periosteal Cells Derived from Long Bone are Unique from those Derived from Calvaria Reut Shainer*[1], Vardit Kram[1], Tina M. Kilts[1], Carl G Simon Jr[2], Marian F. Young[1]. [1]Molecular Biology of Bones and Teeth Section, NIDCR, NIH, United States, [2]Biosystems and Biomaterials Division, NIST, United States

The periosteum, a thin membrane surrounding bone, is a source of progenitor cells needed for bone formation, remodeling and repair. Periosteum-derived cells (PDCs) have the capability to differentiate into multiple skeletal phenotypes, suggesting they have stem cell-like properties. Studies of bone healing after fracture show that the periosteum has an essential role in the repair process. PDCs from the long bones (lbPDCs) have been investigated over recent years but the differences between lbPDCs and PDCs from craniofacial bones or specifically from the calvaria (cPDCs) remain elusive. In this study, we established a protocol to isolate lbPDCs and cPDCs of adult mice where cells were expanded and differentiated within a novel 3D culture RAFT system to mimic the native environment of the cells in vivo. RNAseq analysis showed that the undifferentiated lbPDCs expressed several genes normally found in the extracellular matrix (ECM) of cartilage including cartilage intermediate layer protein (Cilp) and cartilage oligomeric protein (Comp). Interestingly, these genes were not expressed in the undifferentiated cPDCs. When cells were subjected to osteogenic differentiation in vitro, the differentiated lbPDCs, but not cPDCs, formed characteristic cartilage structures demonstrated by both H&E staining and scanning electron microscopy. Both analyses showed that differentiated lbPDCs formed chondrocytes that were incorporated into the matrix. RNAseq analysis also showed that differentiated bPDC, but not differentiated cPDCs, made high levels of collagen type II, aggrecan and collagen type X, further confirming our notion that lbPDCs undergo chondrogenic differentiation under osteogenic conditions. When the 3D RAFT scaffold with PDCs were transplanted into mice, both differentiated cPDCs and differentiated lbPDCs created mineralized ossicles 4w and 8w post implantation. Using μCT, we found that the lbPDC transplants had a greater increase in total bone volume compared to cPDC ransplants, which we suspect are calcified cartilage. In summary, our results indicate that PDCs from long bones but not from calvaria, cultivated in a 3D system create a distinct microenviroment that favors cartilage formation. Considering that long bones are formed via endochondral ossification while calvaria is not, our data suggest that PDCs retain a "memory" of their tissue origin, a feature that could be capitalized for future applications in their use in skeletal tissue regeneration.

Role of Glycolysis in PHD2/HIF-Iα-Mediated Chondrocyte Differentiation Aruni Wilsonsanthoshkumar*[1], Sheila Pourteymoor[1], Subburaman Mohan[2]. [1]VA Loma Linda Healthcare System, United States, [2]VA Loma Linda Healthcare System, Loma Linda University, United States

Studies using ascorbic acid (AA) deficient mutant mouse models have established an indispensable role of vitamin C in cartilage and bone biology. Mice with Gulo gene deletions are vitamin C deficient and exhibit spontaneous fractures and reduced articular cartilage thickness. In recent studies, we have determined that AA effects on bone cells are largely mediated via the prolyl hydroxylase domain (PHD)2 protein. Disruption of the Phd2 gene in chondrocytes promotes chondrocyte differentiation and increase trabecular bone mass dramatically in mice. Since PHD2 knockdown increased HIF1α levels and since HIF1α-dependent regulation of glycolysis is well established in cancer cells, we determined if PHD2 regulates glycolysis in chondrocytes. Both IOX-2-mediated chemical inhibition of PHD2 activity and lentiviral Phd2 shRNA-mediated knockdown of Phd2 expression increased expression of markers of glycolysis, Glut1, Gpd1, and Pgk1 (2.5 to 4.3-fold, P<0.01) in

primary cultures of epiphyseal chondrocytes. As expected, expression of Vegf, a HIF-1α target, is increased in IOX-2 treated and Phd2 shRNA knockdown cultures. To establish if PHD2 effect on glycolysis is mediated via increased HIF-1α levels, we used lentiviral Hif-1α shRNA to knockdown Hif-1α expression in epiphyseal chondrocytes. Hif-1α shRNA reduced expression of Hif-1α by 92% (P<0.002) compared to control shRNA treatment. Accordingly, expression of Vegf was reduced by 75% (P<0.01). Knockdown of Hif-1α expression reduced expression levels of markers of glycolysis, Glut1 and Pgk1 by 41% and 56% respectively (both P<0.05). While expression levels of markers of immature chondrocytes (Col2, tenascin C) were unaffected, Col10 and Mmp13 expression was reduced by 50% (P<0.05). Furthermore, IOX-2 treatment increased expression levels of Glut1, Pgk1 and Col10 (2.5-3-fold, all P<0.01) in control shRNA but not in lentiviral Hif-1α shRNA treated cultures. To determine the role of glycolysis in mediating PHD2/HIF-1α effects on chondrocyte differentiation, we inhibited glycolysis using 2-deoxy glucose (2-DG) and found that 2-DG treatment did not block increased expression of Col10 in IOX-2 treated cultures. Based on our data, we conclude that PHD2/HIF-1α regulates chondrocyte hypertrophy via both glycolysis-dependent and -independent pathways.

MON-0282

The Age-Dependent Decrease of Insulin Sensitivity in Mice is Unaffected by the Deletion of PPARγ in Mesenchymal Lineage Cells of the Appendicular and Craniofacial Skeleton and of Subcutaneous Fat Elena Ambrogini*, Michela Palmieri, Stavros C Manolagas, Robert L Jilka, Maria Almeida. Center for Osteoporosis and Metabolic Bone Diseases, University of Arkansas for Medical Sciences and the Central Arkansas Veterans Healthcare System, United States

Peroxisome proliferator–activated receptor γ (PPARγ) is a master regulator of energy metabolism and may also influence bone homeostasis. Previous studies in mice have suggested that osteocytes are involved in glucose homeostasis through a PPARγ-dependent mechanism. Like humans, mice exhibit an age dependent decline in insulin sensitivity. We therefore examined the effects of PPARγ deletion on glucose metabolism in 22 month old female mice. To do this, we deleted PPARγ in Prx1-Cre targeted cells (PPARγΔPrx1 mice), which include pluripotent mesenchymal progenitors, osteoblasts, and osteocytes of the appendicular and craniofacial skeleton as well as mesenchymal progenitors that give rise to subcutaneous white adipose tissue (WAT). Female PPARγ-fl/fl littermates were used as controls. All mice were on a C57BL/6J background. Deletion of PPARγ in bone was confirmed by qPCR of DNA from cortical bone. Consistently, and in contrast to cells from control mice, rosiglitazone failed to stimulate adipocyte differentiation or to inhibit osteoblast differentiation in ex-vivo bone marrow cultures of 22 mo old PPARγΔPrx1mice. PPARγ ΔPrx1 mice also exhibited a dramatic reduction in subcutaneous WAT whereas interscapular brown fat and visceral WAT were unaffected. Nonetheless, the age-associated gain in body weight and total body fat between 3 and 22 months of age was unaffected by the PPARγ deletion. Furthermore, fasting glucose levels were indistinguishable among 22 mo-old control mice, 22 mo-old PPARγΔPrx1 mice, and 6 mo-old female C57BL/6J mice. Glucose tolerance was tested by administration of 2 g glucose /kg body weight i.p. to mice fasted for 16 h; and blood glucose was measured immediately prior to glucose administration, and at 15, 30, 60, 90, and 120 min afterwards. Glucose levels were significantly lower at 60, 90 and 120 min in 6-mo old mice, compared to either 22-mo-old control or PPARγΔPrx1 mice. There was no difference in glucose levels between aged control and PPARγΔPrx1 mice. These findings indicate that the PPARγ expressed in osteoblasts and osteocytes of the appendicular and craniofacial skeleton, or in subcutaneous WAT, plays no role in the age-dependent decline in insulin sensitivity in mice.

MON-0283

A Greater Proportion of the Variance in Body Fat and Bone Mineral Content is accounted for by Serum Estradiol than Follicle Stimulating Hormone (FSH), and Estradiol not FSH Contributed to the Variance in Cortical and Trabecular Microarchitecture Camilla Andreasen*[1,2], Ann Kristin Hansen[1,2], Ken Sikaris[3], Clifford J Rosen[4], Åshild Bjørnerem[1,5]. [1]Department of Clinical Medicine, UiT The Arctic University of Norway, Tromsø, Norway, [2]Department of Orthopaedic Surgery, University Hospital of North Norway, Tromsø, Norway, [3]Melbourne Pathology, Melbourne, Australia, [4]Maine Medical Center Research Institute, Scarborough, Maine 04074, United States, [5]Department of Obstetrics and Gynecology, University Hospital of North Norway, Tromsø, Norway

At menopause bone remodeling becomes unbalanced, microarchitecture deteriorated, and bone loss and visceral adiposity increases. The important role of estrogen for bone health is well known, and serum estradiol (E2) is inversely associated with cortical porosity in elderly men not women. In rodents, a blocking antibody to follicle-stimulating hormone (FSH) increased bone mass and reduced adipose tissue. Human studies are yet controversial, but if such an effect exist in humans, novel treatment possibilities for bone fragility and adiposity may be developed. We hypothesized that serum E2 and FSH will be independently associated with body mass index (BMI), total body fat mass, lean mass and bone mineral content (BMC), and distal tibial microarchitecture and medullary adiposity index (MAI) in

postmenopausal women. Images of distal tibia were acquired using high-resolution peripheral quantitative computed tomography in 131 postmenopausal women aged 49-77 years in Melbourne, Australia. Bone microstructure and MAI were quantified using StrAx software. The women had a mean age of 58.5 ± 15.7 years, BMI 26.2 ± 4.9 kg/m², total body fat mass 26.7 ± 9.8 kg, lean mass 39.0 ± 4.9 kg, and BMC 2.4 ± 0.4 kg, serum E2 46.4 ± 14.7 pmol/L and FSH 67.4 ± 21.4 IU/L. Each SD higher serum E2 was associated with 0.47 SD higher BMI, 0.47 SD higher fat mass, 0.28 SD higher lean mass, 0.30 SD higher BMC of the total body and 0.35 SD higher trabecular number, 0.25 SD higher trabecular volumetric bone mineral density (vBMD) and 0.27 SD lower MAI at distal tibia (all p<0.01). Serum E2 was associated with 0.18 SD lower porosity of the inner transitional zone (p=0.044) and with 0.19 SD higher total vBMD (p=0.034). Each SD higher serum FSH was associated with 0.20 SD lower BMI, 0.18 SD lower fat mass, 0.17 SD lower lean mass, and 0.17 SD lower BMC of the total body (all p<0.05). FSH was not associated with microarchitecture at distal tibia. All results are adjusted for age and physical activity and mutually adjusted for E2 and FSH. Serum E2 explained 19-21%, and FSH explained 3-4% of the variance in BMI and total body fat mass. We infer that E2 contributes to a five-fold greater proportion of the variance in body fat than FSH, and E2 contributes to increased body fat, lean mass, bone mass and more robust microarchitecture. The independent contribution made by FSH to less body fat but not to the variance in bone traits, lends support to the possibility that humans are different from mice.

MON-0284

The consequences of postnatal androgenization in bone markers, micro and macro-architecture in a rodent model of polycystic ovary syndrome Fabio Comim*, Lady Serrano Mujica, Alfredo Antoniazzi , Paulo Gonçalves , Melissa Premaor. Federal University of Santa Maria, Brazil

Background: Polycystic ovary syndrome (PCOS) is a common health problem affecting 8-10% of all women during the menacme. The presence of reproductive and metabolic disorders characteristics of a majority of PCOS patients may have considered as potential factors with a role in bone metabolism. Animal models replicate many disruptions observed in women with PCOS and are widely employed for the study of the mechanisms related to the development of abnormalities. Therefore, the aim of this study was to investigate the role of androgens in bone metabolism and micro and macro-architecture in a rodent model of PCOS.Methods: Wistar female rats (n=7) were androgenized through the injection of 1.25 mg of testosterone propionate (TP) s.c. at postnatal day 5; controls (n=8) received the same amount of volume of corn oil. CT and micro-CT were performed in the rat femur, respectively, to define the dimensions of the bone, and the bone microarchitecture at the distal portion. The analysis of micro-CT was blind and performed at SCANCO, Co (USA). The length of the femur was compared by the use of Osirix X lite software. P1NP and CTX in plasma were determined by a specific rat ELISA kit assay.Results: Androgenized animals exhibited a typical phenotype of PCOS (PCOS rats). The length of the femur was similar between PCOS rats and controls. However, PCOS rats exhibited at the midline, higher diameter (mean +- SEM) 3.55 ± 0.03 mm versus controls 3.35 ± 0.08 (p=0.04) at the expenses of an increased cortical area (mean +-SEM) 9.79 ± 0.27 mm against control rats 8.98 ± 0.19 (p=0.03). Results of de Micro-Ct from the distal femur indicated an increased Cortical Bone Volume VOX-BV in androgenized animals (mean +- SEM) of 3.28 ± 0.09mm3 versus 2.89 ± 0.07mm3 than in controls (p=0.015). BV/BT (T) was also increased in androgenized rats (mean +- SEM) of 0.41 ± 0.04 in comparison to non-androgenized rats 0.27 ± 0.01 (p=0.01). Cortical thickness and Conn-Dens in this segment were also similar between the two groups. Finally, we observed a similar trabecular thickness, but an increased trabecular number (p=0.048) and decreased trabecular separation (p=0.049) in PCOS rats. CTX and P1NP levels were detectable and higher at day 60 than 100 of life, but no differences could be identified between androgenized rats and controls.Conclusion: As a whole, postnatal androgenization in young female rats had a positive influence on bone micro and macro-architecture.

Exercise increases UCP1 expression but decreases trabecular bone acquisition in mice during cold exposure and at thermoneutrality Amy Robbins*, Christina Tom, Rebecca Tutino, Miranda Cosman, Taylor Spencer, Cleo Moursi, Rachel Hurwitz, Maureen Devlin. University of Michigan, United States

Chronic cold exposure induces bone loss via increased sympathetic outflow to osteoblast beta-adrenergic receptors. Brown adipose tissue (BAT) can protect against such bone loss by inducing nonshivering thermogenesis (NST) and increasing body temperature, thereby reducing sympathetic tone. Exercise reportedly stimulates BAT, suggesting exercise during cold stress could have osteoprotective effects by increasing NST. To test this hypothesis, wildtype C57BL/6J male mice were housed at 26C (thermoneutrality), 22C (standard housing temperature), and 16C (moderate cold stress) from 3-6 wks of age with food and water ad libitum. Half of the mice at each temperature were housed with running wheels (exercise, EX) and half without (control, CON). Outcomes at 6 wks of age included body mass, food intake, leptin, uncoupling protein (UCP1) expression in BAT, whole body bone mineral density (BMD, g/cm2) and percent body fat (%) via PIXImus, and cortical and trabecular bone architecture at the midshaft and distal femur via μCT. Results indicate that body mass,

BMD, and percent fat did not differ in response to temperature or exercise, but mice at 16C ate more compared to mice at 22C or 26C. Serum leptin was lower in EX vs. CON mice at 16C and 22C but not 26C. Exercise led to lower trabecular bone volume fraction (BV/TV), connectivity density (Conn. D), and trabecular number (Tb.N) vs. controls at 16C and 26C (BV/TV -28% and -28%, Tb.N -7% and -8%, Conn.D -18% and -24%, p<0.05 for all). Cold stress decreased BV/TV in EX mice at 16C and 22C (-24% and -24%), and decreased Tb.N (-8% and -8%) and Conn.D (-25% and -35%) in both CON and EX mice (p<0.05 for all). There were no differences among groups in trabecular thickness or spacing, nor in midshaft femur cortical bone cross-sectional geometry. At 16C and 26C, both CON and EX mice had higher UCP1 mRNA (+43%, +50%, p<0.007 for both) and higher UCP1 protein expression (+52%, +31%, p<0.006 for both). Within each temperature, EX mice had higher UCP1 protein expression compared to CON (+32% at 16C, +91% at 26C, p<0.03 for both). These results indicate that both cold stress and exercise upregulated UCP1 mRNA and protein levels, but both exercise and cold also decreased trabecular BV/TV, Tb.N, and Conn.D. These data indicate increased NST as reflected in UCP1 expression does not protect trabecular bone mass during cold exposure. This unexpected result could reflect energetic tradeoffs between thermogenesis and skeletal acquisition.

Estrogen deficiency: the only cause behind senile osteoporosis? Deeksha Malhan*[1], Sabine Stoetzel[1], Diaa Eldin S Daghma[1], Fathi Hassan[1], Stefanie Kern[1], Markus Rupp[2], Christian Heiss[2], Thaqif El Khassawna[1]. [1]Institute for Experimental Trauma Surgery, Faculty of Medicine, Justus Liebig University of Giessen, Germany, [2]Department of Trauma, Hand, and Reconstructive Surgery, University Hospital of Giessen and Marburg, Germany

Estrogen deficiency results in both early and late osteoporosis in postmenopausal women. Higher osteoclast mediated resorption due to estrogen deficiency leads to an increase in pro-inflammatory cytokines and alters bone metabolism. This study aimed to gain an insight into the discrepancies in bone metabolism because of estrogen deficiency alone and/ or in combination with deficient diet in a senile rat model.46 Sprague-Dawley rats (age = 12 months) were randomly divided into: 1) Control group (M=Months) at 0M, 2) Sham (3M), 3) bilaterally ovariectomized (OVX, 3M), 4) Sham combined with deficient diet (Diet, 3M), and 5) OVX combined with deficient diet (OVXD, 3M). Bone mineral density (BMD) were measured using Dual X-ray absorptiometry (DXA). Lumbar vertebral samples were collected after euthanasia and histological analysis & serum analysis were carried out.Imbalanced bone metabolism and deteriorated bone quality is the hallmark of osteoporosis. DXA revealed lower BMD in OVXD group post-treatment and higher Fat% in Sham, OVX, Diet, and OVXD when compared with Control (p ≤ 0.05). This reflects on diminished bone quality in OVXD group. Further, increase in Fat% directs to disturbed bone metabolism after 3M. Therefore, histological analysis of bone formation (osteocalcin) and resorption (TRAP) markers were carried out. This study showed lower osteoblast and higher osteoclast activity in both OVX and OVXD group which directs to the prominent effect of estrogen deficiency. Our results correlates with the previous reports that suggested increased osteoclast mediated resorption in osteoporosis due to estrogen deficiency. Serum analysis of bone metabolic markers showed severe effect of treatments. Parathyroid hormone (PTH) serum level was higher in Diet when compared with OVXD, OVX, and Sham. PTH inversely affects Vitamin D which is important for bone mineralization. The higher PTH level in Diet group point to severe effect of diet deficiency alone. Another marker linked to Vitamin D deficiency is Adrenocorticotropic (ACTH), which was lower in Diet and higher in OVX group. This inverse link between PTH and ACTH directs towards the bone loss due to Vitamin D deficiency. Bone homeostasis is also maintained by osteocytes activity. Therefore, investigation of morphological changes in osteocytes using Silver Nitrate stain are being carried out. Moreover, higher amount of inflammatory cells were seen in OVX and OVXD groups after 3M. Therefore, histological analysis of inflammatory markers will be carried out.

Butyrate enhances myogenesis and muscle function through modulation of intracellular calcium and bioactive lipid mediators Chenglin Mo*[1], Zhiying Wang[1], Xuejun Li[2], Jianxun Yi[2], Leticia Brotto[1], Marco Brotto[1], Jingsong Zhou[2]. [1]College of Nursing and Health Innovation, the University of Texas-Arlington, Arlington, TX, United States, [2]Department of Physiology, Kansas City University of Medicine and Bioscience, Kansas City, MO, United States

Butyrate is a short-chain fatty acid synthesized by intestinal microbiota. Previous studies have shown that butyrate is important in the regulation of intestinal functions and anti-inflammation. In bone and muscle, butyrate can improve metabolism in both tissues, and reduce muscle atrophy during aging and pathological bone loss, respectively. Recently, Treatment with butyrate was found to significantly delay the progression of amyotrophic lateral sclerosis (ALS), a neuromuscular disease, in mice. To date, the knowledge concerned with the effect of butyrate in muscle, which could have significant impact on bone, is limited. In this study, we used C2C12 cells, isolated intact muscles, and the ALS mouse model to study the mechanisms behind the function of butyrate in myogenesis and muscle-related diseases. Our results indicated that treatment with 10µM butyrate significantly enhanced C2C12 myo-

genesis. Fusion index increased from 30% to 42% (p<0.05). Moreover, ex vivo treatment with 2mM butyrate for 30 min increased the contractile force of soleus muscle by 27 ± 4% (p<0.03) at 20Hz of stimulation. Normal and functional calcium homeostasis is critical for myogenesis and muscle function. Treatment with 10µM butyrate for 2 h induced a significant increase in calcium release from the sarcoplasmic reticulum after caffeine stimulation in C2C12 myotubes. It is therefore possible that modulating intracellular calcium homeostasis might underlie the effects of butyrate on myogenesis and muscle function. To seek a deeper understanding of ALS muscle metabolism, we used the ALS mouse model (G93A mice) with or without butyrate supplement. Skeletal muscles from these mice were analyzed with our new-targeted lipidomics method to determine how ALS and butyrate could affect the metabolism of lipid mediators (LMs). Compared with control, the levels of six LMs belonging to the arachidonic acid pathway and eight LMs in the DHA pathway were significantly higher in G93A mice, suggesting higher levels of inflammation and oxidative stress. When these mice were treated with butyrate for one-month (2% in drinking water), the levels of these LMs returned to the levels observed in the control mice.Overall, our data suggest that butyrate could play an important role in muscle regeneration and muscle function via mechanisms associated with the signaling of calcium and LMs. Further studies will provide new insights for potential clinical application of butyrate in musculoskeletal diseases.

Lysosomal Acid Lipase and Its Role in Osteoblast Differentiation Elizabeth Rendina-Ruedy*[1], Madalina-Cristina Duta-Mare[2], Dagmar Kratky[3], Clifford Rosen[1]. [1]Maine Medical Center Research Institute, United States, [2]Gerot Lannach Pharma, Medical University of Graz, Austria, [3]Gottfried Schatz Research Center for Cell Signaling, Metabolism and Aging Molecular Biology and Biochemistry Medical University of Graz, Austria

Lysosomal acid lipase (LAL) is an enzyme essential for cholesterol ester (CE) and triacylglycerol (TAG) hydrolysis, mediated by low density lipoprotein (LDL)-receptor endocytosis, as well as lipid droplet lipolysis via lipophagy. Clinical LAL deficiency is a rare, autosomal recessive disease that results from a mutation in the LIPA gene and presents as either Wolman disease (WD) or cholesterol ester storage disease (CESD). While both conditions are a result of the same genetic cause, WD is much more severe (i.e., hepatosplenomegaly, steatorrhea, abdominal distention, adrenal calcification) and often results in death < 1 yr of age. Conversely, the milder CESD is often described to be later-onset and manifests with variable CE and TAG accumulation in the liver, adrenal gland, and small intestine. Additionally CESD patients display premature atherosclerosis and hypercholesterolemia. However, to date, there has been no mention of the bone phenotype in CESD patients or within the LAL-/- mouse model. Therefore, given this gap in knowledge, along with the recently identified importance of lipolysis in osteoblast function, we sought to characterize the bone phenotype in 16-wk old, male and female LAL-/- mice. Structural analyses of the distal femur metaphysis revealed that male LAL-/- mice had a lower trabecular BV/TV (12%) compared to wild type (WT) mice (21%), which was primarily due to decreased trabecular number and increased trabecular separation. Interestingly, there was no change in BV/TV from the female LAL-/- compared to WT. While both the male and female LAL-/- mice displayed a decrease in cortical bone thickness and polar moment of inertia compared to WT, only the female LAL-/- mice had increased cortical porosity. Due to the previously characterized systemic derangements in LAL-/- mice, including lipodystrophy, malabsorption, and ectopic lipid deposition in the liver, spleen, and lymph nodes, primary calvaria osteoblasts (cOb) were isolated to determine the cell-autonomous role of LAL. Consistent with the low bone mass phenotype, cOb from LAL-/- mice demonstrated impaired osteoblastogenesis. Moreover, despite the ectopic lipid accumulation and reduced BV/TV in the LAL-/- mice, initial histological evaluation of the tibia revealed no differences in marrow adipocytes compared to WT mice. Collectively, these data suggest a cell autonomous role for LAL in osteoblasts, which may be related to impaired fuel utilization and altered bioenergetics.

Roles of macrophages and plasminogen activator inhibitor-1 in delayed bone repair induced by diabetic state in female mice Takeshi Shimoide*[1], Naoyuki Kawao[1], Yukinori Tamura[2], Kiyotaka Okada[1], Katsumi Okumoto[3], Shinji Kurashimo[3], Yoshitaka Horiuchi[3], Kohei Tatsumi[1], Osamu Matsuo[1], Hiroshi Kaji[1]. [1]Department of Physiology and Regenerative Medicine, Kindai University Faculty of Medicine., Japan, [2]Kobe Gakuin University, Faculty of Nutrition., Japan, [3]Life Science Research Institute, Kindai University., Japan

Diabetic patients suffer from various complications. It has been recently recognized that fracture risk is increased and its' repair process is delayed in diabetic patients. However, details in the mechanisms of diabetic delayed bone repair still remain unclear. It has been recently noted about the roles of macrophages in bone formation, however, there has been no reports available about the roles of macrophages in the delayed bone repair associated with diabetes. Here, we investigated the roles of macrophages and hematopoietic stem cells in diabetic delayed bone repair after femoral bone defect using streptozotocin (STZ)-treated or plasminogen activator inhibitor-1 (PAI-1)-deficient female mice. STZ treatment significantly decreased the numbers of F4/80-positive cells (macrophages), but not Gr-1-positive cells

(neutrophils), at the damaged site on day 2 after femoral bone injury in mice. It significantly decreased the mRNA levels of macrophage colony-stimulating factor, inducible nitric oxide synthase (iNOS), interleukin (IL)-6 and CD206 at the damaged site on day 2 after bone injury. Moreover, STZ treatment attenuated a decrease in the number of hematopoietic stem cells in bone marrow from damaged femurs induced by bone injury. Next, we investigated the involvement of PAI-1 in the decreased accumulation of macrophages at the damaged site during bone repair, since our previous studies revealed that PAI-1 is involved in delayed bone repair and osteopenia induced by STZ-treated diabetic state in female mice. PAI-1 deficiency significantly attenuated a decrease in the number of F4/80+ cells induced by STZ treatment at the damaged site on day 2 after bone injury in mice. Moreover, it significantly attenuated the phagocytosis of macrophages at the damaged site suppressed by diabetic state, when analyzed with a transmission electron microscope. On the other hand, PAI-1 deficiency did not affect the mRNA levels of iNOS and IL-6 in F4/80- and CD11b-double positive cells sorted by FACS from the bone marrow of the damaged femurs decreased by diabetic state. In conclusion, we demonstrated that diabetic state decreases the accumulation and phagocytosis of macrophages at the damaged site during the early stage of bone repair after femoral bone injury partly through PAI-1 related mechanism in female mice. These findings will give a novel insight that macrophages might be the potential target for the treatment of delayed bone repair in diabetic patients.

Inducible Sirt1 Knockout Mice Exhibit Increased Bone Mineral Density, Uphill Sprint Capacity, and Open Field Activity Ramkumar Thiyagarajan*, Kenneth Seldeen, Merced Leiker, Yonas Redae, Bruce Troen. University at Buffalo and VA Western New York Healthcare System, United States

Background: Age related chronic diseases are the major health and economic burden in the United States. Sirtuin 1 (Sirt1), an NAD-dependent deacetylase, regulates muscle mass and function, bone and energy metabolism, and mitochondrial biogenesis. Sirt1 expression declines with aging and overexpression in some organisms increases longevity. Endurance exercise increases Sirt1 expression in rats and further, constitutive muscle specific Sirt1 knockout (KO) in young sedentary mice results in reduced endurance capacity.Aim: To determine whether inducing whole-body Sirt1 knockout in adult mice will reduce their overall physical performance and bone mineral density (BMD), and whether the absence of active Sirt1 will decrease the response to exercise.Methods: We have crossed a ubiquitin promoter-CRE-ERT2 mouse with a loxP-Sirt1(exon4)-loxP mouse to create an inducible whole body Sirt1KO mouse line. A total of 60 mice (6-month-old C57BL/6J mice) were divided into Sirt1 (WT) or Sirt1KO (KO) groups. Both WT and KO groups were further divided into groups that were either sedentary (WT+SED and KO+SED) or treadmill exercised 30 minutes a day for 5 days a week over a 6 month period (WT+EX and KO+EX). We longitudinally assessed body weight and food consumption, body composition (lean and fat), and BMD. We also evaluated a battery of physical performance tests, including, voluntary wheel running, gait speed, treadmill endurance, uphill sprint, open field test, rotarod, grip hang time and grip strength.Results: Sirt1KO did not alter body composition in either exercised or sedentary mice. Exercise training increased endurance and uphill sprint capacity in both the WT+EX and KO+EX mice. The KO+SED mice had greater BMD (KO+SED: 51.4 ± 2.6 g/cm2 vs WT+SED: 49.3 ± 1.6 g/cm2, p=0.009), increased uphill sprint endurance (KO+SED: 143 ± 43.6 meters vs WT+SED: 111.1 ± 39.2 meters, p=0.024), and covered more distance in open field test (KO+SED: 51.2 ± 19.0 meters vs WT+SED: 39.8 ± 14.9 meters, p=0.043). The KO+EX mice exhibited better grip strength than KO+SED (KO+EX: 2.4 ± 0.2 N vs KO+SED: 2.2 ± 0.2 N, p=0.003).Conclusion: Inducing whole-body Sirt1KO in adult mice did not affect body composition, but unexpectedly increased bone mineral density, uphill sprint capacity and open field activity over a 6-month period. Additionally, the absence of Sirt1 did not attenuate the response to exercise training in these mice.

Association Between Changes in Bone Remodeling and Glucose Homeostasis After Biliopancreatic Diversion in Patients with Severe Obesity Anne-Frederique Turcotte*[1], Thomas Grenier-Larouche[2], Roth-Visal Ung[1], David Simonyan[3], Anne-Marie Carreau[2], André Carpentier[2], Fabrice Mac-Way[1], Claudia Gagnon[1]. [1]Laval University, Canada, [2]Sherbrooke University, Canada, [3]CHU de Quebec, Canada

Context: Preclinical studies revealed that bone regulates glucose homeostasis. Whether changes in bone remodeling contribute to the improvement in glucose homeostasis after biliopancreatic diversion with duodenal switch (BPD-DS)remains unknown.Objectives: To determine whether the increase in bone remodeling seenearly, in the mid- and longer-term following BPD-DSis associated with glucose homeostasis markers in patients with severe obesity, independently of weight loss and high molecular weight adiponectin.Methods: Ancillary study using fasting frozen plasma from 16 individuals with severe obesity (11F/5M, 69% with type 2 diabetes, mean BMI 49.4 kg/m2) assessed before, 3 days, 3 months and 12 months after BPD-DS. Serum bone turnover markers (C-terminal telopeptide (CTX), intact osteocalcin (OC)) and its regulators (sclerostin, osteoprotegerin (OPG)) were analyzed at each visit. Glucose homeostasis markers including insulin resistance indices (HOMA-IR, adipose tissue insulin resistance index (ADIPO-IR), insulin sensitivity index (Si)), insulin

secretion rate (ISR) and insulin disposition index (DI) were also assessed. Changes between baseline and each timepoint in bone turnover markers and its regulators were correlated with changes in glucose homeostasis markers using Pearson partial correlations adjusted for weight loss and adiponectin.Results: Weight did not change at 3 days but decreased by 33±27 kg at 3 months and 59±12 kg at 12 months. CTX was the only bone marker correlating with weight loss (r=-0.63, p=0.009 at 3 months and r=-0.58, p=0.039 at 12 months). The increase in CTX correlated with the reduction in HOMA-IR (r=-0.56, p=0.036) and the increase in Si (r=0.58, p=0.026) at 3 months and the reduction in ADIPO-IR (r=-0.70, p=0.013) at 12 months (Table 1). The increase in OPG also correlated with the decrease in ADIPO-IR (r=-0.62, p=0.039) at 12 months as well as with the increase in Si(r=-0.54, p=0.046) at 3 days. The increase in OC correlated with the improvement in Si at 3 days (r=0.56, p=0.025), but adjustment for weight loss and adiponectin weakened this association (r=0.48, p=0.082). Change in sclerostin did not correlate with any marker of glucose homeostasis. None of the bone turnover markers or its regulators correlated with ISR or DI.Conclusions: The early and longer term increase in bone remodeling (mainly CTX) after BPD-DS potentially contributes to the improvement in insulin resistance independently of weight loss and adiponectin.

Effect of Abaloparatide and Teriparatide on marrow adipose tissue in postmenopausal osteoporosis Annegreet G. Veldhuis-Vlug*[1], Rob J Van 'T Hof[2], Roland Baron[3], Dennis M. Black[4], Clifford J Rosen[5]. [1]Academic Medical Center Amsterdam and Center for Clinical and Translational Research, Maine Medical Center Research Institute, Netherlands, [2]Institute of Ageing & Chronic Disease, University of Liverpool, United Kingdom, [3]Department of Oral Medicine, Infection and Immunity, Harvard School of Dental Medicine, Harvard Medical School, United States, [4]Department of Epidemiology and Biostatistics, University of California San Francisco, United States, [5]Center for Clinical and Translational Research, Maine Medical Center Research Institute, United States

Purpose Increased marrow adipose tissue (MAT) is associated with decreased bone mass, osteoporosis and fractures in humans. In mice, treatment with parathyroid hormone (PTH) decreases MAT and increases bone mass. Abaloparatide, a recently developed PTH-related peptide (PTHrP) analog, and Teriparatide, a recombinant PTH protein, both increase bone mass and reduce fracture risk in patients with osteoporosis. We investigated the effect of Abaloparatide and Teriparatide compared to placebo treatment on MAT in women with osteoporosis from the Abaloparatide-SC Comparator Trial In Vertebral End-

Monday Posters

347

points (ACTIVE) trial and we hypothesized that both treatment with Abaloparatide and Teriparatide would decrease MAT.Methods In this cross-sectional study, we measured MAT and bone volume in Goldner's trichrome stained transiliac crest bone biopsies obtained after 18 months of treatment from 74 (26 Abaloparatide, 21 Teriparatide and 27 placebo treated) women with osteoporosis included in the histology study of the ACTIVE trial. Histomorphometric analysis was performed using FatHisto, a newly developed, open-source, semi-automated image analysis software based on Image J. We measured adipocyte volume per tissue volume (Ad.V/TV, %), adipocyte volume per marrow volume (Ad.V/Ma.V, %), and bone volume per tissue volume (BV/TV, %). We compared the combined active treatment groups versus placebo using T-tests.Results Overall, there was a trend towards lower MAT (Ad.V/TV) of 28.8% in the combined active treatment groups versus 31.6% in the placebo group (p=0.20). As observed previously using Bioquant Osteo for histology image analysis, active treatment increased bone volume (BV/TV) compared to placebo (21.2% versus 17.7%, p=0.02). There was no difference between the Abaloparatide and Teriparatide groups for both parameters. In addition, bone volume (BV/TV) and MAT (Ad.V/TV) were inversely correlated (r=-0.378, p=0.0007) as expected from previous studies using DEXA and MRI to measure bone volume and MAT in humans.Conclusion In this study we found a trend towards lower MAT after 18 months of treatment with Abaloparatide or Teriparatide compared to placebo in women with osteoporosis. Larger studies with a longitudinal design are needed to confirm these results. In addition, we observed the inverse relation between MAT and bone volume in both treated and untreated individuals. Ongoing studies will investigate the effect of active treatment on individual adipocyte size and number.

Characterization of Bone Marrow Adiposity with Computed-Tomography (CT) scan in Relation to Mineral and Bone Disorders in Dialysis Patients

Yue Pei Wang*, Cyrille De Halleux, Roth-Visal Ung, Nada Khelifi, Claudia Gagnon, Fabrice Mac-Way. CHU de Québec Research Center, Endocrinology and Nephrology Unit, Faculty and Department of Medicine, Université Laval, Canada

Introduction: Fractures and cardiovascular events are among the complications that characterize the Chronic Kidney Disease-Mineral and Bone Disorders (CKD-MBD). Recent studies suggest the potential role of bone marrow adipose tissue (MAT) in the development of bone loss in aging population. The optimal characterization of MAT in CKD is currently unknown. We conducted a pilot study to determine the feasibility of characterizing MAT, bone mineral density (BMD), visceral and subcutaneous adipose tissue in one acquisition by computed-tomography scan (CT-scan).Methods: CT-scan (Philips iCT256) slices were acquired at L3 and L5 vertebrae, at 1/3 and 2/3 non-dominant distal tibia using 80 kVp and 140kVp levels of energy and at the hip using 120 kVp. Cortical and trabecular bone parameters, visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) area as well as yellow marrow (YM) fraction were calculated with QCT-Pro software (Mindways, Austin, TX, USA). Spearman's correlations were performed between YM fraction and BMD, VAT, SAT using SPSS, version 20.0.Results: We recruited and imaged 15 hemodialysis patients (74.0 ± 9.2 years old, dialysis vintage 47.0 ± 27.9 months, 80% male) from CHU de Québec, Hôtel-Dieu de Québec hospital. MAT, VAT, SAT, cortical and trabecular volumetric BMD, as well as tibia cortical thickness can be evaluated with a five-minute CT-scan acquisition (Figure 1). Our analyses showed correlations between L3 and L5 yellow marrow (YM) fraction (R = 0.529, p = 0.043). On one hand, inverse correlations have been obtained between L3 YM fraction and L3 Z-score (R = -0.621, p = 0.013) and between L5 YM fraction and tibia BMD (R = -0.650, p = 0.009). On the other hand, positive correlations have been found between proximal tibia YM fraction and L3 BMD (R = 0.613, p = 0.020), L5 BMD (R = 0.556, p = 0.039) as well as tibia cortical thickness (R = 0.697, p = 0.006).Conclusion: CT-scan allows simultaneous evaluation of MAT, BMD, VAT, SAT in dialysis patients. A better characterization of MAT and its interrelation with bone components may help to understand the mineral and bone complications in CKD.

Bone Quality Analyses in Cases with Type 2 Diabetes Mellitus Reflect Patterns of Femoral Cortical Bone Reorganization Along with High Porosity

Eva Maria Wölfel*[1], Petar Milovanovic[1], Katharina Jähn[1], Felix N. Schmidt[1], Birgit Wulff[2], Michael Amling[1], Klaus Püschel[2], Graeme M. Campbell[3], Björn Busse[1]. [1]Department of Osteology and Biomechanics, University Medical Center Hamburg, Germany, [2]Department of Forensic Medicine, University Medical Center Hamburg, Germany, [3]Institute of Biomechanics, Hamburg University of Technology, Germany

Diabetes mellitus is a chronic systemic disease with increasing prevalence worldwide. Despite usually presenting with a high bone mineral density, type 2 diabetes mellitus (T2DM) patients suffer from an increased fracture risk. In the literature, clinical data on cortical porosity has been displayed with a high variability in the diabetes group. In our study we focus on human cortical bone obtained at autopsy on multiple length scales to understand the underlying mechanism affecting bone microstructure of patients with T2DM. In an ongoing collection of mid-diaphyseal femoral cortices of T2DM-diagnosed cases (n = 12) and age-matched controls (n = 11) we investigate geometrical parameters with contact radiography to identify resorption patterns. Here, the anterior quadrant of the cross-section was further analyzed with micro-computed tomography to assess cortical porosity and tissue mineral density. Static histomorphometry was performed on toluidine-blue and modified silver nitrate stained histological sections. Finally, mechanical properties were determined via nanoindentation, Fourier-transfer infrared imaging and material testing.Contact radiography data revealed a high variability in the T2DM group. Quantification with 3D micro-computed tomography showed a higher cortical porosity in the subgroup of the diabetic cases compared to control cases and T2DM cases without increased porosity (44.36±16.2 vs. 9.96±5.61 vs. 10.93 %, p<0.05). Image processing revealed a larger inner diameter in T2DM with high porosity leading to a larger buckling ratio compared to the non-diabetic control group (p<0.05). Osteonal density was lower in the endocortical region in T2DM group with high porosity compared to control and diabetic individuals (p<0.005 and p<0.05, respectively). Osteoclast activity was more pronounced, although not statistical significant, in the diabetes groups while the lowest Young's modulus value was measured in the endocortical region of the T2DM group with high porosity (18.12±1.73 GPa).Overall these results suggest the presence of two morphological patterns of bone reorganization in T2DM cases. In the T2DM group with high porosity mainly changes at the endocortical site were observed proposing pronounced endocortical reorganization. These results provide new insights into the possible mechanisms affecting the microstructure of bone and leading to an increased fracture risk in T2DM patients.

Cranial Neural Crest-Targeted Deletion of Cdc73 Results in Embryonic Lethality

Jessica Costa-Guda*[1], Lilia Shen[2], Wade Berry[1], Robert Romano[1], Haeyoung Yi[1], Justin Bellizzi[1], Andrew Arnold[1]. [1]UConn SDM, United States, [2]UConn, United States

Loss-of-function mutations of the CDC73 tumor suppressor gene (previously HRPT2) and aberrant expression of its encoded protein, parafibromin, contribute to the pathogenesis of a variety of tumor types. Germline mutations of CDC73 cause Hyperparathyroidism-Jaw Tumor Syndrome, an autosomal dominant disorder consisting of benign and/or malignant parathyroid tumors, (cemento-)ossifying fibromas of the mandible and/or maxilla and, a variety of kidney, renal and uterine tumors. Somatic (and sometimes germline) mutations of CDC73 are common in sporadic ossifying fibromas (OF) and parathyroid carcinomas. Little is known about the molecular pathogenesis of OF, a benign neoplasm virtually exclusive to the craniofacial skeleton, beyond the involvement of CDC73/parafibromin. The precise mechanism of tumor formation secondary to CDC73/parafibromin loss is unknown. Parafibromin is an essential component of the RNA polymerase II-associated Paf1 transcriptional regulatory complex, which functions in maintenance of stem cell pluripotency and may contribute to lineage commitment during development. Parafibromin can bind β-catenin and may function in canonical Wnt/β-catenin signaling but parafibromin's role in Wnt/β-catenin signaling is unclear. We sought to investigate the mechanisms through which CDC73/parafibromin loss contributes to tumorigenesis and model ossifying fibroma in mice. Cdc73-floxed mice were crossed with Wnt1-Cre mice, thereby targeting Cdc73 loss to craniofacial bone progenitors without significantly affecting parafibromin expression in long bone. Homozygous Cdc73 deletion in the Wnt1 expression domain was embryonic lethal by embryonic day 13, with increased apoptosis noted in the region of the developing mandible and midbrain. Heterozygous null mice were viable and healthy. Followed to 15 months, they exhibited no evidence of OF development or any other craniofacial abnormalities. Our results provide further evidence of a role for parafibromin in development: expression of Cdc73 is required for development. Tumorigenesis appears to require biallelic inactivation of Cdc73 in postnatal life; that the second allele did not become somatically inactivated in heterozygous null mice, resulting to tumor formation, is likely a reflection of the time required to acquire such genetic alterations. Further studies are required to elucidate the mechanisms through which CDC73/parafibromin loss contributes to tumorigenesis.

Enpp1-Fc treatment reduces renal calcifications in Npt2anull mice Jonathan Fetene*, Daniel Caballero, Xiaofeng Li, Dillon Kavanagh, Demetrios Braddock, Clemens Bergwitz. Yale School of Medicine, United States

Nephrocalcinosis (NC) is a condition caused by calcium phosphate (hydroxyapatite) deposits in the kidneys. The condition is a frequent complication of inherited renal phosphate (Pi) wasting disorders, such as infantile idiopathic hypercalcemia (IIH) and hereditary hypophosphatemic rickets with hypercalciuria (HHRH). These conditions can be caused by loss-of-function of the sodium-Pi cotransporter NPT2a and the related transporter NPT2c, respectively. In addition, calcium-Pi nidus formation is thought to be the initial event in the formation of Randall's plaques, which are thought to underliemost forms of NC and nephrolithiasis (NL) including idiopathic hypercalciuria (IH), although much about the pathophysiology is unclear. We used Npt2a-/-mice to model the renal calcifications observed in these disorders. We previously reported elevated urinary excretion of PPi in Npt2a-/-mice when compared to WT mice. Reduced levels of Extracellular nucleotide pyrophosphatase phosphodiesterase 1 (Enpp1), an enzyme that generates the mineralization inhibitor pyrophosphate (PPi), in Npt2a-/-;Enpp1asj/asjdouble mutant mice further worsens the NC and the intraperitoneal administration of sodium PPi reduces NC in Npt2a-/-mice. These findings suggest that mechanisms which can be blocked by supplemental PPi contribute to its pathogenesis. We here report that also once-daily subcutaneous injections of the fully bioactive Enpp1enzyme linked to the immunoglobulin Fc domain (Enpp1-Fc) is able to prevent the NC observed in Npt2a-/- mice.Enpp1-Fc from postnatal day (P) 15 through P30 days reduces the number, but not the size, of these deposits. Enpp1-Fc administered from P3 through P15 reduces mineral deposit size, but, in contrast to later treatment or treatment with PPi, the number of mineral deposits remains unchanged. This result suggests that Enpp1-Fc has an effect on mineral growth and nidus formation. More importantly, the effect on mineral growth may be independent of PPi and may reveal, previously unrecognized novel activities of Enpp1-Fc, which are currently under investigation in the lab. Because Ca-Pi deposits (Randall's plaques) are the common precursor of many forms of renal calcifications, if successful, treatment with Enpp1-Fc has the potential to be a game-changing therapy for preventing and/or reversing NC in IIH and HHRH and other rare genetic conditions such as primary hyperoxaluria or cystinuria which can lead to kidney failure and for which currently no cure exists, or for the most common form of NL/NC due to formation of renal Ca-oxalate mineral deposits.

Skeletal muscle mitochondrial dysfunction in the osteogenesis imperfecta murine (oim) mouse model of Osteogenesis imperfecta (OI) Victoria L. Gremminger*[1], Youngjae Jeong[1], Rory Cunningham[2,3], Grace Meers[2,3], R. Scott Rector[2,3], Charlotte L. Phillips[4]. [1]Department of Biochemistry, University of Missouri, United States, [2]Departments of Nutrition and Exercise Physiology and Medicine-GI, University of Missouri, United States, [3]Research Service-Harry S Truman Memorial VA Hospital, United States, [4]Departments of Biochemistry and Child Health, University of Missouri, United States

Osteogenesis imperfecta (OI), also referred to as brittle bone disease, is a heritable connective tissue disorder characterized by skeletal fragility, short stature, and more recently, muscle weakness. Homozygous oim/oim (osteogenesis imperfecta murine) mice model moderately severe human type III OI, as the result of non-functional α2(I) collagen chains and the production of homotrimeric type I collagen, α1(I)3. In addition to marked skeletal fragility, the oim/oim mice exhibit pronounced muscle weakness with reduced relative muscle mass and contractile function relative to age and sex-matched wildtype (WT) littermates. To further investigate the cause of this muscle weakness, we examined citrate synthase activity, an indirect measure of mitochondrial content, in oim/oim and WT mixed gastrocnemius muscle and found oim/oim mice had increased citrate synthase activity suggesting increased mitochondrial content. This was unexpected in light of poor oim/oim muscle contractile function and led us to further investigate mitochondrial content, turnover, and function. We evaluated mitochondrial content and gross morphology by and relative mitochondrial to nuclear DNA levels by qPCR and transmission electron microscopy (TEM). We examined known markers of mitochondrial biogenesis and mitophagy. oim/oim mice had elevated markers of mitochondrial biogenesis, including PGC1α and TFAM and decreased levels of mitophagy markers, specifically LC3. Protein content of complex IV of the electron transport chain was decreased in oim/oim compared to WT. In addition, state 2, state 3 and maximal uncoupled skeletal muscle mitochondrial respiration was severely decreased (>50% reduction) in oim/oim compared to age and sex-matched WT littermates. These findings suggest that skeletal muscle mitochondrial dysfunction likely contributes directly or indirectly to reported muscle weakness in the oim/oim mouse. Further studies to discern the pathogenic mechanisms responsible for the mitochondrial dysfunction in the oim/oim mouse model of osteogenesis imperfecta are warranted.

The 839(C/A) Polymorphism in the ECE1 Isoform b Promoter Associates with Hip Bone Mineral Density in Postmenopausal Women Karen Hansen*[1], Michael Johnson[2], Tonia Carter[3], Nicholas Keuler[1], Robert Blank[4]. [1]University of Wisconsin-Madison, United States, [2]Lucigen, United States, [3]Marshfield Clinic, United States, [4]Medical College of Wisconsin, United States

Secretion of the vasoactive peptide endothelin-1 (ET1) promotes breast and prostate cancer bone metastases by activating the Wnt signaling system. We found that variation in a QTL containing the murine gene encoding endothelin converting enzyme (Ece1) affected bone size, accounting for 40% of the variance in bone biomechanics and bone mineral density (BMD). We tested the hypothesis that polymorphisms within the human endothelin converting enzyme (ECE1) isoform b promoters, located at ECE1 b -338 (G/T) and ECE1 b -839 (C/A) that are known to affect transcription, would associate with BMD and fractures in postmenopausal women. We analyzed data from 3,564 postmenopausal women with banked DNA in the Marshfield Clinical Personalized Medicine Research Project (PMRP) and at least one BMD test at ≥60 years of age at Marshfield Clinic. Personnel at the University of Wisconsin-Madison Biotechnology Center genotyped DNA for the ECE1 -338(G/T) and -839(A/C) single-nucleotide polymorphisms (SNPs). We evaluated relationships between genotype and BMD using linear regression models, and between genotype and clinical fractures using logistic regression models. Women with the -839 C allele had lower femoral neck BMD than those with the A allele (0.856±0.145 g/cm2 vs 0.872±0.140 g/cm2, p=0.015). In single linear models predicting hip T-scores, the AC polymorphism was inversely associated with the lowest hip T-score (C allele, R -0.106, p=0.036). We found no relationship between the ECE1b -338 (G/T) and BMD or fracture. In multivariate models, neither polymorphism was significant in models predicting osteoporosis, fracture after age 50, fracture at any age, spine or hip T-score. In summary, the C allele of the ECE1 b -839 (C/A) promoter was associated with lower hip BMD in univariate models. However multivariate models found no association between the C allele and hip BMD. Our small sample size, largely Caucasian cohort, and exclusion of men are study limitations. Confirmation of our findings is needed in other, larger databases.

MON-0319

Understanding the Role of Protein Gamma-Carboxylation in Craniofacial Development Jane Hendrickson-Rebizant*[1], Juliana Marulanda Montoya[1], Omar Al Rifai[2], Genevieve Chiasson[1], Mathieu Ferron[2], Monzur Murshed[3,4]. [1]Faculty of Dentistry, McGill University, Canada, [2]Institut de Recherches Cliniques de Montreal, Canada, [3]Faculty of Dentistry and Department of Medicine, McGill University, Canada, [4]Shriners Hospital for Children, Canada

Congenital anomalies are a major cause of perinatal lethality, affecting 2-3% of all newborns. A significant number (1 in 3000) of these infants present with abnormal craniofacial development, such as midface hypoplasia. Midface hypoplasia is caused by impaired growth of the nasal, zygomatic, or maxillary bones. This trait is observed in many human disorders, including Keutel Syndrome, which is caused by autosomal recessive mutations in matrix Gla protein (MGP). MGP, a potent mineralization inhibitor, is expressed by chondrocytes. We recently demonstrated that MGP-deficient (Mgp-/-) mice showed shorter antero-posterior measurements of the skull (cranial, maxillary and palatine lengths), causing midface hypoplasia. Both the nasal septum and spheno-occipital synchondrosis (SOS) are abnormally calcified in Mgp-/- mice. Although cephalometry on Mgp-/- heads suggested a critical role for nasal septum in midface development, it is currently unknown whether calcification of the SOS, alone, is sufficient to cause midface hypoplasia.To study the relative contributions of the nasal septum and the SOS to midface development, we generated a unique mouse model (referred to as Ggcxch-/- in this application) in which only chondrocytes lack the enzyme gamma-glutamyl carboxylase (GGCX). GGCX modifies specific glutamic acid (Glu) residues of MGP and other Gla proteins to carboxylated glutamic acid (Gla) residues. Cephalometric analyses were performed on micro-CT scans of the heads from our experimental Ggcxch-/- mice and control mice at ages 2 and 3 weeks and 6 months. The Ggcxch-/- mice showed ectopic calcification of the SOS, which was first detected by 2 weeks of age, however nasal septum calcification was not observed at any age. Interestingly, cephalometric analyses demonstrated a complete absence of midface hypoplasia. Our findings suggest that GGCX activity is required for the prevention of SOS, but not nasal septum, calcification. Comparing the craniofacial phenotypes of Ggcxch-/- and Mgp-/- mice, we demonstrated that nasal septum calcification, not SOS calcification, is the primary cause of midface hypoplasia in the latter model.Our work provides information on the role of protein gamma-carboxylation and abnormal calcification of cartilaginous tissues in midface hypoplasia. Ongoing studies on various mouse models will be important in understanding the causes, onset, progression, and possible treatments for patients with craniofacial dysplasias.

Biomechanical evaluation of enthesopathy in a murine model of X-linked hypophosphatemia Jack Luo*[1], Steven Tommasini[2], Carolyn Macica[1]. [1]Frank H. Netter, M.D., School of Medicine at Quinnipiac University, United States, [2]Yale School of Medicine, United States

X-linked hypophosphatemia (XLH) is the most common heritable phosphate-wasting disorder, resulting in both rickets and osteomalacia. Although osteomalacia, growth, and skeletal deformities have been the primary clinical focus of XLH, patients typically develop severe paradoxical mineralization of fibrocartilaginous tendon/ligament insertion sites (enthesophytes) in their second and third decades.We have previously demonstrated the hyperplastic expansion of mineralizing fibrochondrocytes in the insertion sites of Hyp mice. Here, we test the hypothesis that hyperplasia of mineralized fibrocartilage is a compensatory mechanism to accommodate the abnormal transmission of mechanical forces that arise due to insertion into a hypomineralized bone matrix substrate. Tensile testing of the left Achilles enthesis from 6-month-old female HYP (n=9) and wild-type mice (n= 8) was performed using a pneumatic grip, gripping as close to the Achilles insertion site as technically possible, and pulled at a constant rate of 10 mm/min until failure. Stiffness, strain, and strength (max stress) were measured. There were no significant differences in stiffness (7.9±4.4 v. 7.3±3.2 N/mm), strain (58±22 v. 69±30%), or strength (116.3±65.2 v. 113.6±61.2 N/mm2) of the tendinous insertion site between HYP and wild-type mice, although there was a 27.8% decrease (p < 0.05) in the tendon width in HYP mice. The contralateral Achilles insertion was used for histological validation of mineralizing fibrocartilaginous hyperplasia by alkaline phosphatase staining and von Kossa staining to evaluate the degree of mineralization of the insertion and the subchondral calcaneus matrix. Relative to controls, staining confirmed a significant increase in alkaline phosphatase-positive fibrochondrocytes embedded in mineral matrix and osteomalacia in subchondral bone.Thus, the mineralizing enthesopathy in XLH provides a biomechanical compensatory mechanism that strengthens the Achilles insertion despite the compromised bone material properties at the calcaneus. Future studies are aimed at unloading the enthesis to evaluate if the compensatory fibrochondrocyte hyperplasia occurs in the absence of tensile forces on the insertion site.

Type 1 diabetes (T1DM) impacts bone phenotype and fracture healing in Akita mice Pei Hu*, Jennifer Mckenzie, Evan Buettmann, Nicole Migotsky, Matthew Silva. Washington University in St. Louis, United States

Type 1 diabetes (T1DM) impairs bone formation and delays fracture healing in human patients. Around 5 wks, male Akita mice become spontaneously diabetic, with high blood glucose levels, due to a mutation in one allele of the insulin-2 (Ins2) gene. We hypothesized that T1DM in Akita mice is associated with decreased bone mass,mechanical properties and impaired fracture healing. We used 18 wk old male Akita mice (Ins2Akita, Jax) and compared them to wildtype littermates (WT). Both Akita and WT mice gained weight from 3 to 18 wks of age, but Akita mice weighed less starting at 5 wks (-5.20%, p = 0.04). Akita mice were hyperglycemic by 6 wks, which continued at 18 wks (fasting glucose > 450 mg/dL; WT mice < 200 mg/dL). Phenotyping: Non-fractured left femurs were analyzed by microCT (cortical and cancellous bone) and mechanically tested (3-point bending/torsion). At 20 wks Akita mice had a shorter femur than WT (-1.9%, p<0.001) with reduced cortical bone total area (-6.5%, p<0.05), bone area (-16%, p<0.001), and cortical thickness (-17%, p<0.001). After adjusting for body mass, the cortical differences remained significant. Cancellous bone was largely unaffected by T1DM. Mechanical testing of non-fractured femurs showed decreases in structural and material properties of Akita bones. Terminal blood was collected and Akita mice had a serum insulin deficiency (-94%, p<0.01), lower osteocalcin (OCN, -44%, p<0.01) and higher C-telopeptide (CTX-1, 75%, p<0.05) on D14 after fracture. Fracture Healing: A closed, transverse diaphyseal right femur fracture was made in Akita and WT mice at 18 wks. Using CT on D14 Akita mice had a significantly smaller callus (-32%, p<0.01) with a significantly higher callus bone mineral density (BMD, 24%, p<0.05). D21 CT Akita mice had a significantly smaller callus volume (-26%, p<0.05) while BV/TV and callus BMD showed no differences between groups. D21 torsion tests showed a weaker callus in Akita femurs with lower stiffness (-42%, p<0.01), maximum torque (-44%, p<0.05) and work to fracture (-44%, p<0.05). In summary, cortical bone size was reduced in Akita mice, which is consistent with lower serum OCN levels and smaller fracture callus, suggesting a bone impairment. The higher callus BMD and higher serum CTX level found in D14 Akita mice might demonstrate an early remodeling after fracture, which needs further examination. Consistent with clinical features and bone changes in human T1DM patients, Akita mouse is a good T1DM model.

MON-0322

Generation and Characterization of a Conditional Mouse Model for Atypical Type VI Osteogenesis Imperfecta Samantha Robinson*, Frank Rauch, Pierre Moffatt. Shriners Hospitals for Children - Canada, Canada

Osteogenesis imperfecta (OI) is a rare heritable disorder that affects bones and leads to overall skeletal fragility, reduced height, and fractures. The majority of mutations in OI

affect type I collagens. Atypical type VI OI, however, is inherited in an autosomal dominant fashion and caused by a heterozygous mutation in the BRIL gene (also called IFITM5), introducing a single amino acid change at position 40 (S40L). Atypical type VI is clinically extremely severe with bowed and hypomineralized bones. A patient bone biopsy revealed accumulation of un-mineralized osteoid extracellular matrix, similarly to OI type VI caused by mutations in Serpinf1. We have generated a transgenic conditional mouse model expressing the human (h)S40L-BRIL protein under the tTA response element (TRE). Two founders were bred with the tTA-Osx-GFP-Cre mice and expression was induced by putting mice on regular diet ('on'), or repressed ('off') by administration of doxycycline-containing food. When hS40L-BRIL was expressed from conception, the skeletal phenotype was extremely severe with accompanied neonatal lethality. As assessed by alizarin red/alcian blue staining and μCT, all long bones were shorter, hypomineralized, and bowed. RT-qPCR indicated significant reduction in the expression of bone specific markers (Bglap, Ibsp, Col1a1) in E18.5 calvaria. Histological assessment showed that humeri were filled with hypertrophic chondrocytes and presented with Osx:GFP+ cells at a wedge like structure at the midhsaft. The mRNA and protein levels for hS40L-BRIL were also itself attenuated in mutant embryonic calvaria, suggesting feedforward deleterious effects. When hS40L was induced postnatally from 8 to 12 weeks of age, mouse body length was reduced. Strikingly, visual appearance of the mutant mice femur, tibia, vertebrae, and mandible were bulky and white. μCT imaging revealed massive expansion of the periosteal and trabecular compartment reminiscent of mouse models for fibrous dysplasia. Ongoing studies will provide further clues as to the histological features and molecular mechanisms at play and perhaps serve as a platform for more directed therapies.

MON-0323

Sexual Dimorphism in Skeletal Abnormalities in Down Syndrome Mice Jared Thomas*[1], Adam Knox[1], Randall Roper[1], Elizabeth Fisher[2], Victor Tybulewicz[3], Joseph Wallace[1]. [1]Indiana University-Purdue University Indianapoli, United States, [2]UCL Institute of Neurology, United Kingdom, [3]The Francis Crick Institute, United Kingdom

Down syndrome (DS), caused by three copies of human chromosome 21 (Hsa21), is characterized by a spectrum of phenotypes including cognitive and skeletal deficits. Sexual dimorphism in skeletal deficits has been hypothesized in individuals with DS, however, differences in age, methodology and tissue have impacted interpretation of these results. The Ts65Dn DS mouse model exhibits similar skeletal phenotypes as those associated with DS. Ts65Dn mice have some limitations including limited genetic composition (~104 human orthologs on Mmu16) and exclusion of female mice in previous studies because of fertility issues. Another model of DS, Dp1Tyb, was developed to contain three copies of all the Hsa21-orthologous regions on Mmu16 (~148 genes). Due to the presence of more orthologous genes at a dosage imbalance and, because both trisomic males and females are fertile Dp1Tyb mice may be a better model to study DS phenotypes. We hypothesized that there would be a difference in the skeletal deficits between trisomic Dp1Tyb male and female mice.Right femurs from both male and female mice at 6- and 16-weeks were imaged using microCT, resolution of 6μm, to determine trabecular microarchitecture (distal metaphysis) and cortical geometry (midshaft). The left femurs were subjected to three point bending test to determine bone mechanical integrity. ANOVA was used to determine the main and interactive effects of genotype, sex, and age.There was a sexual dimorphism in the effect of trisomy on the trabecular microarchitecture including percent bone volume, trabecular thickness and trabecular number. For cortical bone, there was a sexual dimorphism for the effect of trisomy on total cross sectional area in 6- and 16-week old but differing main and interactive effects at 6- and 16-weeks for other cortical measures. There was a main effect of sex and genotype on whole bone and material-level properties. In addition, there was an interaction of age and genotype for Dp1Tyb mice for both pre-yield and post-yield properties.These data suggest that with an increase in age, trisomic Dp1Tyb mice have weaker bones compared to their euploid counterparts. Overall, it appears that male mice have stronger bones in comparison to female mice across age and genotype. These results may be important to humans with DS because disruption in bone homeostasis appears during adolescence and continues throughout adulthood, and females have weaker bones than males with DS.

Knockout and Human Transgenic Mouse Models Reveal a Role for the Cathelicidin Antimicrobial Peptide (Camp/CAMP) Gene in Bone Metabolism Yang Zhang*[1], Carmen P. Wong[2], Richard L. Gallo[3], Amanda R. Gamboa[2], Dawn A. Olson[2], Malcolm B. Lowry[4], Mary L. Fantacone[5], Claudia S. Maier[6], Jan F. Stevens[7], Russell T. Turner[2], Urszula T. Iwaniec[2], Adrian F. Gombart[8]. [1]School of Biological and Population Health Sciences, Linus Pauling Institute, Oregon State University, United States, [2]School of Biological and Population Health Sciences, Oregon State University, United States, [3]Department of Dermatology, University of California San Diego, United States, [4]Department of Microbiology, Oregon State University, United States, [5]Linus Pauling Institute, Oregon State University, United States, [6]Department of Chemistry, Oregon State University, United States, [7]Linus Pauling Institute, Department of Pharmaceutical Sciences, Oregon State University, United States, [8]School of Biological and Population Health Sciences, Linus Pauling Institute, Department of Integrative Biology, College of Science, Oregon State University, United States

The cathelicidin antimicrobial peptide (CAMP/Camp) genes in humans and mice encode the hCAP18 and CRAMP pro-proteins, respectively. Both pro-proteins are processed into peptides (LL-37 in humans) that mediate their well-established antimicrobial properties. These peptides also modulate inflammation, cell proliferation, and wound healing, making them important in innate immunity. Expression of the gene is regulated by vitamin D in humans but not in mice. Both the human and mouse genes are highly expressed in bone marrow and in vitro studies suggest that CRAMP, the mouse peptide, is produced by osteoblasts and suppresses differentiation of osteoclasts. Furthermore, monocytes differentiated by LL-37 treatment appear to develop novel bone forming properties. While these in vitro studies suggest a role for CRAMP/LL-37 in bone metabolism, in vivo studies are lacking. To address this gap in knowledge, we evaluated the architecture of the cortical bone in the femur diaphysis and cancellous bone in the distal femur metaphysis using microcomputed tomography in skeletally mature 6-month-old male C57BL/6J mice. We compared wild type (WT/WT, n = 5), Camp knockout (KO/KO, n = 8), and human CAMP transgenic mice on the Camp knockout background (Tg+/Tg+;KO/KO, n = 8). Differences between genotypes were determined using Kruskal Wallis ANOVA followed by a Dunn's posthoc test. We did not observe significant differences between genotypes in cortical bone architecture (cross-sectional volume, cortical volume, marrow volume, cortical thickness, polar moment of inertia). In contrast, cancellous bone volume fraction tended to be lower (p = 0.1), trabecular number was lower (p = 0.03), and trabecular spacing was higher (p = 0.03) in KO/KO compared to WT/WT mice. Furthermore, KO/KO mice exhibited lower cancellous bone volume fraction (p = 0.0029), trabecular number (p = 0.0001) and connectivity density (p = 0.0006), and higher trabecular spacing (p = 0.0001) compared to Tg+/Tg+;KO/KO mice. Significant differences between Tg+/Tg+; KO/KO and WT/WT mice were not detected for any of the cancellous endpoints evaluated. Our findings suggest that Camp plays a role in the regulation of cancellous bone mass and architecture and that the human CAMP gene can substitute for the loss of the mouse gene. Future studies will focus on the molecular and cellular mechanisms responsible for the changes in bone architecture.

Circulating MicroRNA Expression is Upregulated after 30 Days of Head-Down Bed Rest Debra Bemben*[1], Breanne Baker[1], Samuel Buchanan[1], Carl Ade[2]. [1]University of Oklahoma, United States, [2]Kansas State University, United States

MicroRNAs (miRNAs) are short, non-coding RNA molecules that are negative regulators of gene expression. Recently, miRNAs have been identified that target on genes of osteogenesis (Lian et al. 2012) and/or muscle atrophy (Wada et al. 2011). Circulating miRNAs (c-miRNAs) can be measured in the blood as biomarkers of cellular activity, and they may play a role in cell to cell communication. Large decreases in BMD and muscle mass during prolonged exposure to microgravity are well-documented, but c-miRNA responses have not been examined. C-miRNAs have potential to be useful biomarkers of physiological changes during spaceflight. The purpose of this study was to examine c-miRNA and bone marker responses to a 30 day six-degree head-down bed rest protocol at an ambient 0.5% CO2. The study protocol was conducted at the bed rest facility located at the Institute for Aerospace Medicine in Germany. Eleven participants had fasting blood draws taken 3 days before and on the last day of the 30 day bed rest protocol. Serum levels of miRNAs associated with bone and muscle function (miR-21, -100, -125b, -126) were analyzed using real-time PCR. Sclerostin and TRAP5b concentrations were assayed using commercial ELISA kits. The normalized c-miRNA expression values and bone marker responses were analyzed by paired t-tests. TRAP 5b significantly increased (p=0.018) post bedrest but sclerostin was unchanged. MiR-21 was significantly upregulated (p = 0.019) from pre to post bed rest. MiR-125b showed a trend (p = 0.11) for upregulation with 10 participants showing increased expression and 1 showing decreased expression post bed rest. MiR-21 regulates bone cell activity; it is highly expressed in osteoclast precursors during osteoclastogenesis and it is upregulated in patients with osteoporotic fractures. The upregulation of miR-21 in this study may reflect an increase in osteoclast activity after 30 days of bed rest, which is corroborated by the increase in TRAP 5b. In conclusion, these findings suggest that c-miR-21 has potential as a biomarker of bone resorption and bone loss in an unloading condition.

Table 1. Circulating MiRNA Expression Pre and Post 30 days of Head-down Bed Rest (means ± SE)

Time Point	Expression (n=11)			
	MiR-21	MiR-100	MiR-125b	MiR-126
Pre bed rest	-0.536 ± 0.147	-8.926 ± 0.315	-5.666 ± 0.231	-0.901 ± 0.124
Post bed rest	-0.065 ± 0.107*	-8.487 ± 0.310	-5.342 ± 0.186	-0.608 ± 0.158

* p = 0.019 vs. pre

MON-0338

Novel genetic variants of OFD1 gene are associated with a familial form of stress fractures of long bones and a sporadic case of atypical femur fracture associated with bisphosphonate use Marie-Eve Boisvert*[1], Jacques P Brown[1,2], Rachel Laframboise[3], Maxime Vallée[1], Frédéric Fournier[1], Suzanne N Morin[4], Edith Gagnon[1], Arnaud Droit[1], Laetitia Michou[1,5]. [1]CHU de Québec-Université Laval Research Centre, Canada, [2]Department od medicine, Université Laval, Canada, [3]Department of Genetics, CHU de Québec-Université Laval, Canada, [4]Department of Medicine, McGill University, Canada, [5]Department of medicine, CHU de Quebec-Université Laval, Canada

Purpose - The pathogenesis of atypical femur fractures (AFFs), an insufficiency fracture of the subtrochanteric or diaphyseal region of femur, is incompletely understood. They are thought to be associated with long-term use of bisphosphonates but also occur in patients who are naive to pharmacological therapy or have genetic disorders such as hypophosphatasia and osteogenesis imperfecta. Here, we report the genetic analysis of a French-Canadian family in which eleven relatives have X-linked osteoporosis and/or dental and facial hypoplasia and/or adult-onset multiple stress fractures of long bones, with a radiological aspect akin to AFF. We also performed resequencing in a cohort of 49 individuals with AFF associated with bisphosphonate use.Methods – After having ruled out mutations in all exons of the Plastin3 gene by Sanger sequencing, we performed a whole exome sequencing to identify a causal genetic variant in relatives of this family. Data were analyzed by a first bioinformatic filtering and intrafamilial segregation analysis with emphasis on X chromosome genetic variants. The resequencing of the OFD1 gene was further performed in 49 patients from the Quebec AFF Registry, all exposed to bisphosphonates.Results - A novel variant, p.A642D, of the OFD1 gene, was our only candidate on the X chromosome perfectly segregating with the phenotype within the family. In the literature, mutations of OFD1 gene were reported to be associated with the oral-facial-digital syndrome, which belongs to the group of ciliopathies. Ciliopathies are genetic disorders of the cellular cilia or the anchoring structure of the cilia or cilia dysfunction. Oral-facial-digital syndrome is characterized by malformations of the face, oral cavity and digits, and is transmitted in an X-linked pattern of inheritance with lethality in males. Interestingly, the resequencing of OFD1 gene allowed us to detect another novel variant, p.K668N, of this gene in one woman with AFF who used bisphosphonate.Conclusions - This family demonstrates that such insufficiency fractures of long bones may occur in patients with oral-facial-digital syndromes. It may also contribute to a better understanding of the pathophysiology of these fractures and their association with dental and facial hypoplasia. Further studies are needed to increase improve our knowledge on the functional effects of these genetic variants on bone modeling and remodeling, and their contributions to bisphosphonate-associated AFF.

Is serum free DNA methylation a bone biomarker? Alvaro Del Real*[1], Carolina Sañudo[1], Carmen Garcia Ibarbia[1], Carmen Valero[1], Mario F. Fraga[2], Agustin F. Fernandez[3], Flor M. Perez-Campo[4], Maria Isabel Perez-Nuñez[5], Esther Laguna[5], Jose A. Riancho[1]. [1]Department of Internal Medicine, Hospital Universitario Marqués de Valdecilla-IDIVAL, University of Cantabria, Spain, [2]Nanomaterials & Nanotechnology Research Center (CINN-CSIC), University of Oviedo, Spain, [3]Cancer Epigenetics Laboratory, Institute of Oncology of Asturias (IUOPA), HUCA, University of Oviedo, Spain, [4]Department of molecular biology, University of Cantabria-IDIVAL, Santander, Spain, [5]Department of Traumatology/Hospital U M Valdecilla, University of Cantabria, Santander, Spain

Cell-free DNA (cfDNA) is present in fluids, such as urine and serum. It is an appealing molecular biomarker because it is easy to obtain without using invasive procedures. DNA methylation regulates gene expression and has specific profiles according to the tissue of origin. We have previously shown that methylation of SOST (gene encoding sclerostin) contributes to the regulation of sclerostin synthesis. In fact, there is an inverse correlation

Monday Posters

351

between SOST methylation and expression (Delgado-Calle et al, JBMR 2012). The aim of this study was to determine the methylation of the SOST promoter in cfDNA, in comparison with the methylation pattern in DNA from blood and bone cells.For this study, 30 patients with osteoporotic hip fractures undergoing replacement surgery were included. From each patient, bone tissue, blood and serum samples were obtained. A second group of 28 osteoporotic patients was also included. Serum samples were obtained at baseline and after 6-months therapy with alendronate, teriparatide or denosumab. DNA was analysed by pyrosequencing that allowed the interrogation of 3 CpGs of the SOST promoter. Sclerostin levels in serum were measured with ELISA.The methylation level of the sclerostin promoter was very similar in serum cfDNA (84±11%) and bone-derived DNA (86±3%), but lower than in blood cells DNA (94±3%). Pairwise comparisons revealed statistically significant differences between blood and serum (p=0.0001), and between blood and bone (p=0.007). However, there were no difference between serum and bone (p=0.21). Moreover, there was a positive correlation between DNA methylation in serum and DNA methylation in bone (r=0.56; p=0.000002). We did not find differences in sclerostin serum levels nor in cfDNA methylation before and after anti-osteoporosis therapy.In conclusion, methylation of the SOST promoter in serum cfDNA is lower than in blood cell DNA and similar to bone DNA, suggesting that serum cfDNA might originate in bone cells. However, since we did not find significant changes in either serum sclerostin or SOST methylation after therapy with bone-active drugs, the role of cfDNA as a bone biomarker cannot be confirmed yet.

Search for modifier genes by whole exome sequencing in familial form of Paget's disease of bone linked to the SQSTM1/P392L mutation Mariam Dessay*[1], Maxime Vallée[1], Frédéric Fournier[1], Arnaud Droit[1], Edith Gagnon[1], Jacques P. Brown[1,2], Laetitia Michou[1,2,3]. [1]CHU de Québec-Université Laval Research Centre, Quebec, Canada, [2]Department of Medicine, Division of Rheumatology, Université Laval, Quebec, Canada, [3]Department of Rheumatology, CHU de Québec-Université Laval, Quebec, Canada

Purpose: Paget's disease of bone (PDB) is a chronic disorder characterized by increased bone remodeling. Although the pathogenesis is still poorly understood, genetic and environmental factor are involved. The SQSTM1/P392L mutation was reported in 46% of familial forms of PDB with a high penetrance ≥ 80% after 60 years old. In our cohort, we identified families in which relatives with PDB carrying or not the SQSTM1/P392L mutation coexist, suggesting the presence of a modifier gene.In this study, we performed a whole exome analysis (30 Mb) in two familial forms of PDB linked to the SQSTM1 gene to seach for modifier genes.Methods: Whole exome sequencing (WES) was performed using a HiSeq 2500 with the Agilent XT protocol at 3 μg on four patients with PDB not carrier of any SQSTM1 mutation. These patients came from two different families (2 in each family) in which at least one other sibling with PDB was carrier of a SQSTM1/P392L mutation. The bioinformatic analysis relied on filtering on minor allele frequency <0.01 and on in silico predictions of any damaging effect of the variants, followed by the intra-familial segregation analysis within the two families. Targeted resequencing was performed using the same technology in four extended pedigrees (18 patients) linked to SQSTM1, including the two families studied by whole exome sequencing. Results: The intra-familial segregation analysis and filtering of the WES data identified 242 variants in 191 different genes. Interestingly, in silico prediction showed interaction of some of these genes with SQSTM1 gene such as: MPRIP and MAP3K5 (genetic interaction), TTN and PEX5 (same signaling), SH3TC1 nad HLA-A (co-expression). After filtering variants shared by the four studies patients based on rarity (allele frequency < 0.01) and expected deleteriousness, five shared variants were found in the following genes: PPIAL4G, FDFT1, KRT18, MPRIP and DOCK6. Therefore, amongst the 191 genes, 106 genes of interest were further selected for targeted resequencing. The resequencing identified relevant candidate genes which would be involved in bone metabolism such as: ZNF141 and VEZF1 (transcription factor), PEX5 and MTMR3 (autophagy), POSTN and BMP7 (bone formation), to name a few.Conclusions: This whole exome analysis allowed us to detect variants of interest in different candidate genes. The modifier effect of these variants on the SQSTM1/P392L mutation and the pagetic phenotypes needs to be further investigated.

Associations Between Single Nucleotide Polymorphisms in the Vitamin D Receptor and Vitamin D Binding Protein Genes and Tibia Bone Mineral Content, Density and Strength in Young Adults Entering Initial Military Training Erin Gaffney-Stomberg*[1], Laura Lutz[1], Anna Nakayama[1], Philip Fremont-Smith [2], Darrell Ricke[2], Martha Petrovick[2], James Mcclung[1]. [1]US Army Research Institute of Environmental Medicine, United States, [2]MIT Lincoln Laboratory, United States

Single nucleotide polymorphisms (SNPs) in vitamin D-related genes have been associated with risk of stress fracture as well as vitamin D status and 25-hydroxyvitamin D (25OHD) response to vitamin D supplementation during initial military training (IMT). The purpose of this study was to determine whether these previously identified SNPs are associated with measures of tibial bone density, content and strength collected using peripheral

quantitative computed tomography (pQCT) in young adults entering IMT. Baseline associations between SNPs (vitamin D receptor (VDR; n=2, Fok1 and Bsm1)) and vitamin D binding protein (DBP; n=2, GC1S and GC2), as well as a genetic risk score (GRS; calculated as the number of 25OHD lowering alleles in the DBP [GC1S] and VDR [Bsm1] SNPs) and vBMD, bone mineral content (BMC) and strength (either BSI or SSIp) at three bone sites (4, 14, and 66% of the tibia length) were evaluated in volunteers starting IMT (n=445; 220 male and 225 female, 64.5% Caucasian, age 24 ± 3 yr). Gene-bone parameter associations were analyzed by univariate ANOVA (SPSSv21) while controlling for race, sex, age, and body mass index. There were no associations between the GRS or VDR Bsm1 SNP and any bone parameter at any site. Several 3-way interactions were observed between race, sex and each DBP SNP, but sample sizes were too small to make meaningful post hoc comparisons. However, the VDR Fok1 SNP, which was previously associated with greater fracture risk, was associated with strength at the 4% site (BSI; p<0.001) with those homozygous for the minor allele having 16.3 +/- 6.5 mg/mm*4 lower BSI as compared to those homozygous for the major allele (p<0.05). This relationship differed by race (p<0.05) with the minor allele resulting in lower BSI in Caucasians, and higher BSI in African Americans. This study demonstrated an association between the VDR SNP and baseline bone strength at the distal tibia which differed by race. Whether SNPs in VDR affect bone responses to training and whether these SNPs would be useful in predicting stress fracture risk in military trainees remains to be determined.The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.Research supported by: USAMRMC and DHP.

Differential prevalence of CYP2R1 variants across populations reveals pathway selection for vitamin D homeostasis. Alex Casella*[1], Jingman Zhou[2], Lauren O'Lear[2], Caela Long[2], Zahra Tara[2], Ilana Caplan[2], Meizan Lai[2], Michael Levine[2], Jeffrey Roizen[2]. [1]University of Maryland, United States, [2]The Children's Hospital of Philadelphia, United States

When human populations moved away from the equator there was an associated loss of pigmentation; this pervasive pattern has been attributed to a need for increased vitamin D synthesis in the context of decreased sun exposure. Equally pervasive is the persistence of pigmentation in those close to the equator. We hypothesized that this persistence might indicate an evolutionary strategy to protect against vitamin D excess. To examine this hypothesis we measured the activity of all of the non-synonymous variants in CYP2R1, which encodes the principal 25-hydroxylase required for initial activation of vitamin D, reported in the 1000 genomes project as well as any variants occurring in the publically available databases more than once. We determined the effect of 41 non-synonymous polymorphisms in CYP2R1 on expression and function of the recombinant enzyme in HEK293T cells. Twenty-one of 41 amino acid replacements led to significantly decreased activity relative to wild-type CYP2R1 protein, while two variants have significantly increased activity. Three mutations led to frame shifts and truncated proteins. The combined prevalence of CYP2R1 alleles that encode enzymes with decreased 25-hydroxylase activity is three in every 1,000 Caucasians and seven in every 1,000 African-Americans, while in populations closer to the equator, where exposure to sunlight is high, hypomorphic alleles occur at frequencies as high as 7%. To further test our hypothesis, we theorized that there would also be similar patterns of variation in other proteins in the vitamin D pathway. To examine this possibility we examined the geographic prevalence of hypomorphic variation in the GC protein (the vitamin D binding protein). We observed a similar geographic prevalence with variants associated with decreased vitamin D being more prevalent in populations close to the equator. We conclude that CYP2R1 polymorphisms have important effects on vitamin D homeostasis, and that the geographic variability of CYP2R1 alleles represents an adaptation to differential exposures to UVB irradiation from sunlight.

Inhibition of FGF23 signaling corrects LPS-induced hypoferremia through the erythropoiesis-inflammation axis Rafiou Agoro*[1], Anna Montagna[1], Moosa Mohammadi[2], Despina Sitara[1]. [1]New York University, United States, [2]New York University School of Medicine, United States

Inflammation and iron deficiency have been described to stimulate the synthesis of the osteocyte-secreted protein FGF23. Activation of toll-like receptors (TLRs), the key sensors of the innate immune system, induces the hepatic expression and secretion of the iron-regulating hormone hepcidin. Hepcidin acts by causing degradation of the iron exporter ferroportin, resulting in hypoferremia and anemia during inflammation. Conversely, stimulation of erythropoiesis suppresses hepcidin expression via induction of the erythropoietin-responsive hormone erythroferrone. Here, we used the C-terminal tail of FGF23 to impair endogenous full-length FGF23 signaling in wild-type mice, and investigated its impact on hypoferremia induced by lipopolysaccharide (LPS), a TLR 4 agonist.Our data show that LPS-induced expression of the liver pro-inflammatory cytokines Tnf-α and Lipocalin-2 was significantly attenuated by inhibition of FGF23 signaling. Similarly, LPS-induced liver hepcidin expression was significantly reduced by FGF23 signaling disruption, consistent with upregulation of spleen erythroferrone. Accordingly, the increase in liver and spleen iron content caused by TLR4 activation was completely abrogated by inhibition of FGF23 signaling. Interest-

ingly, inhibition of FGF-23 signaling selectively upregulated spleen ferroportin expression, and increased serum iron and transferrin saturation.Moreover, we show that LPS-induced acute inflammation leading to hypoferremia upregulated bone Fgf23 expression. In addition, LPS-treated mice showed a decrease in serum phosphate associated with a decrease in renal phosphate reabsorption as demonstrated by significant downregulation of renal NaPi2a/2c expression. Importantly, inhibition of FGF23 signaling induced hyperphosphatemia and up-regulated renal NaPi2a/2c expression. Finally, our findings show that LPS induced a significant downregulation of Erythropoietin (Epo) and its receptor (EpoR) in kidney, liver, and spleen. Interestingly, inhibition of FGF23 signaling increased significantly the expression of renal and extra-renal Epo and EpoR when the mice were challenged with LPS.Taken together, our studies highlight for the first time that inhibition of FGF23 signaling attenuates LPS-induced inflammation and hypoferremia, while promoting erythropoiesis by increasing erythropoietin and erythroferrone expression.

Hypoxia enhances EPO-mediated FGF23 expression in hematopoietic cells Erica Clinkenbeard*[1], Maegan Capitano[1], Megan Noonan[1], Pu Ni[1], Mark Hanudel[2], Kenneth White [1]. [1]Indiana University School of Medicine, United States, [2]David Geffen School of Medicine at UCLA, United States

Fibroblast growth factor (FGF) 23 is a crucial phosphaturic hormone. Interestingly, FGF23 has been found to undergo regulation by factors outside of the normal phosphate, vitamin D, parathyroid hormone feedback loops. This was underscored by the fact that autosomal dominant hypophosphatemic rickets phenotype could be induced in FGF23-R176Q mutant mice with a low iron diet and in ADHR patients during anemia. In addition to possible localized tissue hypoxia, low iron elicits a renal induction of erythropoietin (EPO) which acts to induce red blood cell production by stimulating bone marrow hematopoietic cells. In accord with previous studies, and compared to saline controls, infusion with patient equivalent doses of recombinant EPO significantly induced circulating total FGF23 protein (274.8+33.3 vs 4514.6+1128; p<0.05) as well as full-length intact FGF23 (324.6+29.3 vs 556.8+57.2; p<0.05). In addition to osteoblast/osteocyte induction of Fgf23 mRNA expression with EPO administration (10-fold; p<0.01), Fgf23 mRNA was also significantly induced within the flushed bone marrow of the EPO treated mice compared to controls (26-fold; p<0.01), a novel site of FGF23 production. To better understand the mechanisms controlling FGF23, flushed marrow from wild-type (WT) mice were plated ex vivo and treated with 100 U/mL recombinant EPO. After 4 hours, EPO treatment only increased Fgf23 mRNA levels 2-fold compared to control treated cells in conjunction with a 4-fold increase in the EPO responsive factor erythroferrone (ERFE). It was shown that the bone marrow niche remains moderately hypoxic and cells collected under similar conditions retain their stem cell phenotype which improves grafting during bone marrow transplant. Therefore, we hypothesized isolating and culturing bone marrow cells under hypoxia will improve responses to exogenous EPO. Bone marrow cells were isolated in a hypoxia chamber (3% O2) from WT mice and lysed of red blood cells. Incubation under low oxygen tension with 1-10 U/mL EPO elicited a maximal response of a 4-fold increase in Fgf23 mRNA (p<0.01) and an 11-fold induction of ERFE mRNA (p<0.01), equating a 40- to 110-fold improvement in sensitivity, respectively. Stem cell factor (SCF), a normal supplement for culturing hematopoietic cells, did not further enhance EPO-mediated Fgf23 mRNA induction. In summary, hematopoietic cell production of FGF23 in response to EPO is enhanced under low oxygen tension which simulates in vivo conditions.

Chronic kidney disease patients commonly develop mineral metabolism abnormalities associated with reduction of bone mineral density and fractures. In these patients Fibroblast Growth Factor 23 (FGF23) is markedly increased. The direct effects of FGF23 on bone cells is not clear. In this study, the effects of high FGF23 on bone were investigated in vivo in an experimental model of heminephrectomized rats fed on a moderately high phosphate diet

(1/2Nx-HP) and compared with Sham rats on the same diet. Additionally, in vitro studies were performed to evaluate the effect of recombinant FGF23 (rFGF23) on osteocytes and osteoclasts formation. In vivo, our results showed that serum FGF23 levels were significantly increased in Nx1/2-HP as compared with sham animals after 21 days, while other parameters of mineral metabolism such as PTH, phosphate or calcitriol remains similar between both groups. Bone histomorphometric analysis revealed that animals with high FGF23 had a decreased bone volume and a high bone turnover. RNA analysis of bones revealed a decrease in the expression of specific osteogenic genes such as Runx2, Osterix or DMP1 and an increase of SOST expression that was also detected in plasma.In vitro, high rFGF23 was added during maturation of mesenchymal stem cells into mature osteoblasts or for 24 hours once mature. Alkaline phosphatase activity and osteoblast master genes expression were decreased in rFGF23-treated cells. In mature osteocytes, high rFGF23 downregulated osteoblast gene expression: Osterix, Osteocalcin, DMP1 and RANKL. Furthermore, high FGF23 levels decreased the nuclear translocation of ß-catenin after 24 hours. With Respect to osteoclasts formation, the presence of FGF23 enhanced TRAP staining, the number of nuclei and osteoclasts and cathepsin K expression. In conclusion, high FGF23 concentration decreases osteocyte maturation through inhibition of the canonical Wnt signaling and increases osteoclast differentiation.

Estrogen Receptor-a Knockout Affects Femoral Cortical Geometry and Trabecular Microarchitecture, but not Osteocyte Sclerostin Expression, in Aged Male Mice Rebecca Dirkes*[1], Nathan Winn[1], Thomas Jurrissen[1], Dennis Lubahn[2], Victoria Vieira-Potter[1], Jaume Padilla[1], Pamela Hinton[1]. [1]Department of Nutrition and Exercise Physiology, University of Missouri, Columbia MO, United States, [2]Department of Biochemistry, University of Missouri, Columbia MO, United States

Estrogen plays an important role in skeletal growth and maintenance throughout the lifespan, with differential effects on cortical and cancellous bone due to differences in the relative distribution of estrogen receptor-α (ERa) and ERβ. Hypoestrogenemia results in bone loss associated with increased osteocyte sclerostin expression and reduced bone formation. Here, we examined the effects of global ERα-knockout (ERKO) on femoral cortical geometry and trabecular microarchitecture and on osteocyte sclerostin expression in cortical and cancellous bone in male mice. In a longitudinal study, ERKO (n=6) and wild-type (WT) littermates (n=6) were allowed ad libitum access to a standard rodent diet from weaning until 16 months of age, at which time body composition was assessed via EchoMRI and hind limbs and blood collected. Circulating estradiol concentrations were measured via radioimmunoassay. Cortical geometry of the mid-diaphysis and trabecular microarchitecture of the distal right femur were assessed via mCT, and osteocyte sclerostin expression in these regions was assessed via immunohistochemistry. ANCOVA was used to test the effects of ERKO on cortical geometry with body weight as a covariate; t-tests were used to compare ERKO and WT for other outcomes. ERKO mice had 36% higher estradiol concentrations than WT, but this difference was not significant (p=0.286). ERKO mice had greater body fat percentage (p=0.026) than WT controls. ERKO mice had greater bone volume (p=0.005) and trabecular number (p=0.001) and decreased trabecular separation (p=0.002) of the distal femur compared to WT controls. Femur length did not differ between groups. ERKO had lower total area (p=0.042), cortical area (p=0.018), and cortical thickness (p=0.047) of the mid-diaphysis compared to WT controls. Robustness tended to be lower in ERKO than WT (p=0.075); cortical area to total area did not differ between groups. The percentage of sclerostin+ osteocytes was not altered by ERKO. In conclusion, estrogen receptor-a knockout

Monday Posters

affects femoral cortical geometry and trabecular microarchitecture, but not osteocyte sclerostin expression, in aged male mice.

Effects of Sodium Glucose Cotransporter 2 Deletion on Bone and Mineral Metabolism Claire Gerber*, Nicolae Valentin David, Susan Quaggin, Aline Martin, Tamara Isakova. Northwestern University, United States

Background: Type 2 diabetes mellitus (T2DM) and chronic kidney disease are associated with an increased risk of developing bone and mineral metabolism abnormalities. A new class of glucose-lowering agents, sodium-glucose cotransporter 2 (SGLT2) inhibitors, promotes urinary glucose excretion and improves renal and cardiovascular outcomes in patients with T2DM. However, SGLT2 inhibitors are associated with increased risk of bone fractures. Because loss of SGLT2 function may decreases urinary phosphate, we hypothesize that inhibition of SGLT2 induces mineral metabolism alterations that could contribute to increased bone fragility.Design: Slc5a2 nonsense mutation in Sweet Pee (SP) mice results in total loss of SGLT2 function in proximal tubules. To understand the effects of loss of SGLT2 function on mineral metabolism, urine and serum was collected from fasted wild type (WT) and SP mice. Levels of fractional excretion of calcium and phosphate; serum phosphate, calcium, PTH, 1,25(OH)2D, and FGF23 were evaluated at 15 and 25 weeks. To determine the longitudinal impact of loss of SGLT2 function on bone metabolism, bone architecture, remodeling, and mineralization was assessed in SP mice and WT mice at 15 and 25 weeks of age.Results: At 25 weeks, SP mice showed significantly decreased body weight compared to WT mice (21.6±3.8 vs 25.1±2.9 g, p<0.05). Consistently, femoral length was significantly shorter in SP mice compared to WT mice (14.1±0.4 vs 14.5±0.2 mm, p<0.05). Overall renal function was not impaired in SP mice compared to WT mice (blood urea nitrogen: 18±4 vs 21±5 mg/dL, NS). Fasted SP mice did not show modification of fractional excretion of calcium. Serum calcium, PTH, and 1,25(OH)2D levels were similar between WT and SP mice at 15 and 25 weeks. Fractional excretion of phosphate was significantly higher at 25 weeks in SP mice compared to WT (5.5±2.0 vs 2.5±1.9 %, p<0.05), despite unchanged levels of FGF23. SP mice had reduced cortical bone mineral density, compared to WT mice at 25 weeks (1240±16 vs 1264±14 mg/cm3, p<0.05).Conclusion: These results suggest that loss of SGLT2 function in the absence of T2DM may contribute to bone fragility. Future studies are required to determine how loss of SGLT2 function impacts bone fragility in T2DM.

Estrogens Suppress the Senescence-Accelerated Secretory Phenotype (SASP) in Osteoprogenitors by Restraining NF-kB Activation, but not GATA4 Expression or Transcriptional Activity Ha-Neui Kim*[1,2], Li Han[1,2], Srividhya Iyer[1], Aaron Warren[1,2], Maria Almeida[1,2], Stavros Manolagas[1,2]. [1]University of Arkansas for Medical Sciences, United States, [2]Central Arkansas Veterans Healthcare System, United States

Estrogen deficiency and old age are the two most critical factors for the development of osteoporosis in both women and men. However, it is unknown whether the pathogenic cellular and molecular changes responsible for the imbalance between resorption and formation in sex steroid deficiency versus old age are similar or distinct; or whether and how sex steroid deficiency influences the age-dependent involution of the skeleton. Nonetheless, in mice the protective effects of estrogens against cortical bone loss result from actions mediated via ERα signaling on mesenchymal cells (targeted by Prx1 or Osx1-Cre); and in both females and males, estrogens alone protect against the resorption of cortical bone, via actions on osteoprogenitors. Moreover, the age-dependent decrease of cortical thickness is associated with increased osteoclast numbers in the endosteal surface and classical features of osteoprogenitor senescence and the SASP, including some of the same osteoclastogenic cytokines that are upregulated acutely by estrogen deficiency in young and adult mice. Accumulation of the transcription factor GATA4 and the resulting activation of the canonical IKKβ/NFκB pathway play a seminal role in SASP. We examined the effects of 17β-estradiol (E2) on GATA4-stimulated SASP in primary calvaria cell cultures infected with a pMX vector containing a GATA4 expressing plasmid. GATA4-dependent transcription was determined by luciferase activity in C2C12 cells co-transfected with the GATA4 plasmid and a GATA4 3x-Luc promoter. GATA4 stimulated NF-kB as measured by the phosphorylation of the p65 subunit. E2 (10-8M) had no effect on the transcriptional activity of GATA4 or its protein levels. E2, on the other hand, potently suppressed NF-kB activation, in agreement with long standing evidence that ERα attenuates NF-kB. More importantly, E2 suppressed the GATA4-induced SASP, including IL-1α, IL-1β, TNFα, GM-CSF, and MMP-13. These results support the working hypothesis that in the aged skeleton, senescence of mesenchymal lineage cells and the SASP, driven by NF-kB activation, is the predominant mechanism of the increased osteoclast number and resorption in the endosteal surface. Because NF-kB is also upregulated by estrogen deficiency, NF-kB is the key molecular nexus where the two pathologies intersect and as a result estrogen deficiency accelerates the adverse effects of aging on cortical bone in both sexes.

Intestinal calcium absorption increases markedly during pregnancy and lactation despite absence of the vitamin D receptor (VDR) or calcitriol Beth J. Kirby*[1], Brittany A. Ryan[1], K. Berit Sellars[1], René St-Arnaud[2], Christopher S. Kovacs[1]. [1]Memorial University of Newfoundland, Canada, [2]Shriner's Hospital and McGill University, Canada

Intestinal calcium absorption (CaAbs) and calcitriol both increase during pregnancy and lactation. Does calcitriol stimulate the increase in CaAbs? Vdrnull mice increase CaAbs >2-fold during pregnancy (lactation was not studied), but have very high levels of calcitriol that may act on an alternate receptor.We investigated whether calcitriol is required for CaAbs during pregnancy and lactation, by comparing the effects of absence of calcitriol (Cyp27b1nulls) to absence of its receptor (Vdrnulls).WT and null sisters in both colonies were raised on a calcium and lactose-enriched "rescue" diet. Time points were pre-pregnancy, day 18.5 of pregnancy, and day 10 of lactation. Using DeLuca and Fleet's methodology, mice were fasted overnight and 0.5 microCi 45Ca was administered by oral gavage. After 10 min, blood was collected by cardiac puncture. Duodena were snap frozen for gene expression analysis by qPCR. Radioactivity in sera was adjusted for total blood volume, and expressed as percent of administered dose. Compared to pre-pregnancy, Vdrnull mice showed a 2.5-fold increase (p<0.05) of CaAbs during pregnancy that remained 2.1-fold increased during lactation; Vdrnull values were not different than corresponding WT at all time points. Cyp27b1nulls showed a marked 9.2-fold increase in CaAbs during pregnancy with no difference from corresponding WT value; lactation has not yet been assessed.Duodenal expression of Trpv6and S100gincreased 4-fold (p<0.01) and 2.4-fold (p<0.01) respectively in WT during pregnancy but did not change in Vdrnulls; pregnancy values were 6 and 5-fold fold higher in WT than respective Vdrnull (p<0.01). Pmca1showed no differences between time points or genotypes. Ncxdid not change in WT but decreased 0.35-fold during pregnancy in Vdrnulls (p<0.01).In summary, CaAbs increased over 2-fold during pregnancy and lactation in Vdrnulls, and 9-fold during pregnancy in Cyp27b1nulls, with all values being equivalent to respective WT. But WT and Vdrnull mice differed in duodenal gene expression patterns, with none of the observed changes explaining the increased CaAbs in Vdrnulls.In conclusion, CaAbs upregulates during pregnancy without calcitriol, since neither absence of VDR nor absence of calcitriol affect the achieved peak value in CaAbs. The persistence of increased CaAbs during lactation indicates that placental factors cannot explain it. The mechanisms that explain this reproductive increase in CaAbs remain to be elucidated.

Regulation of IGF-1- and Mechano-responsive Signaling by the RhoGAP MYO9B Monica Sun*[1], Emma Hassell[1], Benjamin Scandling[2], Beth Lee[1]. [1]The Ohio State University College of Medicine, United States, [2]The Ohio State University College of Engineering, United States

Purpose: Anabolic signaling in bone by IGF-1 and mechanical stimuli are closely intertwined due to interactions between IGF-1 receptors and integrins that perceive mechano-stimulation at the cellular level. By regulating both hormonal and mechanical pathways, the small G protein RhoA is likely to be central to this functional interaction. Previous studies demonstrated that a regulator of RhoA, the RhoGAP MYO9B, is required for normal skeletal growth in mice since the absence of MYO9B resulted in decreased growth and bone formation. Further, osteoblasts lacking MYO9B showed poor spreading and chemotactic responses to IGF-1, but not to other growth factors. Preliminary studies indicated this may be due to defects in IGF-1 receptor (IGF1R) localization. The goal of this study was to further characterize how IGF-1 signaling is affected in MYO9B-deficient cells and to determine their ability to respond to mechanical strain.Methods: Primary mouse osteoblasts and MC3T3-E1 cells expressing or lacking MYO9B were assessed for integrity of the IGF-1 signaling pathway by cell fractionation, western blot, and confocal microscopy. For measuring responses to mechanical stimuli, cells were subjected to uniaxial stretch on a Flexcell tension system, and the orientations of stress fibers were measured using FibrilTool software. Results: Osteoblasts deficient in MYO9B demonstrated abnormal trafficking, expression, and activation of IGF1R. These cells showed high levels of total and activated IGF1R in the nucleus, rather than in its normal distribution in focal adhesions and along stress fibers. Cells lacking MYO9B were also unable to undergo a normal downregulation of IGF1R following IGF-1 stimulation, leading to prolonged activation and probable desensitization of the signaling pathway. Further, cells lacking MYO9B were unable to align themselves appropriately to uniaxial mechanical strain.Conclusions: These results reveal that the RhoGAP MYO9B lies at the intersection of IGF-1- and mechanical-mediated signaling by regulating the function of the IGF1 receptor and the ability of cells to respond to mechanical stimuli. Because this RhoGAP plays a key role in mediating not only hormonal, but mechanical based signaling, these studies help elucidate the RhoA-mediated mechanisms that play key roles in bone growth.

Acute Calcitriol-Mediated PTH Suppression Attenuated by High Dietary Phosphate Intervention in Experimental Model of CKD Lok Hang Lee*, Mandy Turner , Cynthia Pruss, Kim Laverty , Rachel Holden, Michael Adams. Queen's University Department of Biomedical and Molecular Sciences, Canada

Chronic kidney disease (CKD) patients have impaired phosphate and calcium excretion. Vitamin D deficiency is also prevalent, due to a decline in functional kidney mass and reduction in renal CYP27B1 conversion of calcifidiol, which exacerbates secondary hyperparathyroidism (SHPT). SHPT leads to increased bone resorption and is a risk factor for vascular calcification and cardiovascular disease in the CKD population. Vitamin D is commonly prescribed to bypass this deficiency and reduce SHPT, however resistance to suppression often occurs. Resistance may be due to parathyroid hyperplasia and downregulation of receptors. This pathology is exacerbated by high dietary phosphate. The purpose of this study is to characterize the capability of single doses of calcitriol to acutely suppress parathyroid hormone (PTH) as kidney function declines and dietary phosphate is increased. In a dietary adenine rat model of CKD (N=10) Adenine was removed at 4.5 weeks and stable CKD was generated. An oral dose of calcitriol (160ng/kg) was given at baseline, 1, 3, and 5 weeks as CKD progressed on low (0.5%) dietary phosphate, and at 7 and 8 weeks following a high (1.0%) dietary phosphate intervention. At each dose, calcium, phosphate and PTH was assessed over a 24-hour period prior to and a 48-hour period after dosing. Serum creatinine elevated by one week of dietary adenine (p<0.01) and stabilized at ~300uM. Despite the alterations in dietary phosphate, at no point in the experiment were serum phosphate elevated above baseline. Throughout CKD generation (baseline to 5 weeks), the single dose of calcitriol consistently induced a PTH reduction by 24 hours. The responsiveness was maintained despite elevations in PTH from 79.6+/-25.8 pg/mL to 221.4+/-66.7 by week 5. Following the increase in dietary phosphate, PTH increased to 1207+/-176 pg/mL to 1342+/-310, at 7 and 14 days post-intervention, respectively. PTH was no longer reduced at 24 hours following the dose of calcitriol at both of these time points, despite causing an elevation in serum calcium at 48 hours. The response mediated by PTH and FGF-23 was independent of serum of phosphate and was not a result of daily fluctuations in the hormone. The suppression of PTH by an acute dose of calcitriol was attenuated by dietary phosphate in the setting of stable experimental CKD. This suggests that limiting dietary phosphate in the CKD population is critical to limiting mineral bone disease in this population.

Attenuated parathyroid megalin expression contributes to the pathogenesis in hyperfunctioning parathyroid tumors Daichi Miyaoka*[1], Yasuo Imanishi[1], Masayo Yamagata[2], Ikue Kobayashi[1], Noriyuki Hayashi[1], Masaya Ohara[1], Yuki Nagata[1], Katsuhito Mori[1], Masanori Emoto[1], Toshimi Michigami[3], Masaaki Inaba[1]. [1]Osaka City University Graduate School of Medicine, Japan, [2]Osaka Ohtani University, Japan, [3]Osaka Women's and Children's Hospital, Japan

Insufficient vitamin D status, measured as 25-hydroxyvitamin D (25OHD) in plasma, is associated a higher circulating parathyroid hormone (PTH) level in general population. PTH secretion from parathyroid cells is directly suppressed by 1,25-dihydroxyvitamin D (1,25(OH)2D), however, little is known about mechanisms of 25OHD on secretary PTH suppression. In addition, decrement of vitamin D receptor (VDR) expression and/or calcium-sensing receptor (CaSR) enhances PTH secretion from parathyroid tumors in primary hyperparathyroidism (PHPT) and secondary hyperparathyroidism of uremia (SHPT), however, these factors do not totally account for the role of 25OHD on PTH secretion. Megalin is a multiligand endocytotic receptor involving in the reabsorption of 25OHD and vitamin D binding protein in renal proximal tubules, and we attempted to determine the expression of megalin in the hyperfunctioning parathyroid tumors, and the roles of megalin and 1α-hydroxylase (CYP27B1) in PTH expression in parathyroid cells. Megalin expression was determined by immunohistochemistry in parathyroid tumors, obtained from PHPT and SHPT patients, and in normal parathyroid glands from thyroid carcinoma patients. To assess the role of megalin in incorporation of 25OHD, histidine-tagged soluble receptor-associated protein (His-sRAP) which binds and accelerates internalization of megalin, was administered to primary cultured parathyroid cells obtained by therapeutic parathyroidectomies from PHPT patients. The distributions of megalin and His-sRAP were analyzed by immunofluorescence. PTH expression was analyzed by real-time PCR. The megalin expressions decreased in tumors with PHPT and SHPT. In cultured cells, the megalin localized at the membrane, and added His-RAP is rapidly internalized in cytosol. 25OHD significantly reduced PTH mRNA, which was completely reversed by His-sRAP. CYP27B1 siRNA also reversed attenuated PTH mRNA by 25OHD. CYP27B1 siRNA, however, failed to reverse attenuated PTH mRNA by 1,25(OH)2D. To conclude, megalin has a crucial role in endocytosis of 25OHD in parathyroid cells. Incorporated 25OHD is converted to 1,25(OH)2D, which suppress PTH expression. These results highlight the direct inhibitory effect of 25OHD in PTH secretion. Reduced megalin expression is assumed to enhance PTH secretion in addition to reduced VDR and CaSR in hyperfunctioning parathyroid tumors. Megalin-CYP27B1 axis would be a next therapeutic target in PHPT and SHPT.

Directly targeting HIF activity controls FGF23 expression and has implications for translational outcomes Megan L. Noonan*[1], Erica L. Clinkenbeard[1], Pu Ni[1], Mircea Ivan[1], Matthew Prideaux[1], Gerald J. Atkins[2], William R. Thompson[1], Mark R. Hanudel[3], Kenneth E. White[1]. [1]Indiana University School of Medicine, United States, [2]The University of Adelaide, Australia, [3]David Geffen School of Medicine at UCLA, United States

Fibroblast growth factor-23 (FGF23) is a bone-derived hormone that regulates systemic phosphate homeostasis. In the common disorder chronic kidney disease (CKD), there is progressive anemia with concurrent elevation of FGF23 that continues to increase as kidney function declines. FGF23 has been shown to be markedly stimulated by anemia and hypoxia, and recently, by erythropoietin (EPO); however, the molecular mechanisms driving FGF23 in the context of CKD are not well understood. A new class of drugs, hypoxia-inducible factor prolyl hydroxylase inhibitors (HIF-PHI), stabilize HIFs to increase endogenous EPO production to correct anemia. The purpose of this study was to assess in vitro how FGF23 expression is potentially controlled by HIF-PHI. To address this, we used a novel murine mesenchymal progenitor cell line clone 2 (MPC-2) that when differentiated in osteogenic media expresses Fgf23. MPC-2 cells treated with 20μM or 50μM of HIF-PHI FG-4592 (Roxadustat) for 24 hours had an 8.8 and 15-fold upregulation of FGF23 mRNA, respectively (p<0.01), with concurrent upregulation of Hif-1α target gene Transferrin receptor (TfRc1) mRNA (2.8 and 3.9-fold respectively; p<0.05). These cells were also found to secrete (C-term) FGF23 protein when treated with 100μM HIF activator AG490 (2.8-fold). Additionally, after 4-hour treatment with FG-4592, MPC-2 cells showed Hif-1α stabilization at both doses via immunoblot. For translational relevance, FG-4592 was also tested in the human U2OS osteoblast/osteocyte cell line, showing a significant induction of FGF23 mRNA with treatment at both doses (10 and 11-fold, respectively; p<0.05) after 24 hours, also coinciding with increased TfRc1 mRNA expression at each dose. U2OS cells were also shown to stabilize Hif-1α protein after FG-4592 treatment. These data demonstrate expression of FGF23 in a novel cell line, likely via HIF stabilization, and highlight in vitro systems that can be used to elucidate the molecular mechanisms related to FGF23 expressional control during anemia and its treatment.

Interference with atrophy signaling prevents GC actions on bone and muscle in vitro and ex vivo. Amy Y Sato*[1], Lilian I Plotkin[1], Teresita Bellido[2]. [1]Department of Anatomy & Cell Biology, Indiana University School of Medicine, United States, [2]Department of Anatomy & Cell Biology, Indiana University School of Medicine, Roudebush Veterans Administration Medical Center, United States

Fracture risk induced by excess glucocorticoids (GC) is largely accounted for by decreased bone mass and skeletal deterioration combined with loss of muscle mass and strength leading to higher incidence of falls. Therefore, therapeutic approaches that interfere with GC actions in both tissues are needed. Earlier work demonstrated that GC increase the expression in both bone and muscle of the proteasomal degradation inducers E3 ubiquitin ligases atrogin1, MuRF1, and MUSA1 (named atrophy-related genes or atrogenes), which were traditionally considered muscle-specific. We examined here the role of this pathway in GC action. We found that blockade of proteasomal activity with bortezomib (Bor, 3nM) prevented the effects of GC on osteoblast function. Thus, the GC dexamethasone (dex, 10-6M, 24-72 h) increased apoptosis of OB-6 osteoblastic cells (~50%), and this effect was blocked by Bor at all times examined. Dex also inhibited (26-70%) matrix mineral production by OB-6 cells in a dose-dependent manner (10-9M-10-6M), quantified by alizarin red staining, and Bor blunted this effect, increasing mineralization to veh control levels. Further, dex failed to inhibit mineralization of cultured OB-6 silenced for MuRF1 using pGFP-C-shLenti vectors, whereas significantly reduced it in scrambled control cells. These results suggest that GC action on osteoblasts is controlled by proteasomal-mediated events that depend on MuRF1. Because the active metabolite of Vitamin D (1,25D3) has beneficial musculoskeletal effects and might prevent falls by acting directly on muscle, we examined its effect on GC action. We found that the increased mRNA expression of atrogin1, MuRF1, MUSA1 induced by dex (10-6M) was fully prevented by co-treatment with 1,25D3 (10-8M) in ex vivo organ cultures of bone as well as muscle (N=8-10). In addition, dex increased mRNA expression of Sost (200%) in bone organ cultures, which was prevented by 1,25D3. 1,25D3 also prevented the ~20% reduction in the diameter of C2C12 myotubes induced by dex (10-6M, 24h, N=6), quantified by OsteoMetrics (100 myotubes scored/well). Collectively, these findings support the notion that atrogene upregulation is a common mechanism underlying GC actions in bone and muscle, and suggest that therapeutic genetic and pharmacological approaches interfering with atrophy signaling will simultaneously prevent harmful actions of GC in both tissues.

Tributyltin Increases Trabecular Bone in Female C57BL/6J Mice and Protects Against Ovariectomy-Induced Trabecular Bone Loss Jennifer Schlezinger*[1], Rachel Fried[1], Amira Hussein Ali[2], James Watt[1], Paola Divieti Pajevic[2], Elise Morgan[3], Louis Gerstenfeld[2]. [1]Boston University School of Public Health, United States, [2]Boston University School of Medicine, United States, [3]Boston University College of Engineering, United States

Bone mass and quality are determined by genetic and environmental factors. Risk factors for poor bone quality include estrogen loss at menopause and exposures to drugs/chemicals that activate peroxisome proliferator activated receptor gamma (PPARγ). We unexpectedly observed that the environmental PPARγ and retinoid X receptor (RXR) ligand, tributyltin (TBT), represses periosteal bone formation but enhances trabecular bone formation in young, female C57BL6/J mice. This is in contrast to TBT's known ability to suppress osteogenesis in vitro and the greater sensitivity of female-derived, versus male-derived, bone marrow multipotent mesenchymal stromal cells (BM-MSCs) to suppression of osteogenesis by TBT. In vivo, oral gavage of 12 week old female, C57Bl/6J mice with 10 mg/kg TBT 3x per week for 10 weeks resulted in femurs with a smaller cross-sectional area and thinner cortex. Surprisingly, TBT induced significant increases in trabecular thickness, number, and bone volume fraction. TBT marginally inhibited the number of osteoclasts that differentiated, in spite of significantly suppressing expression of osteoclast markers Nfatc1, Acp5 and Ctsk. In contrast, expression of Ctf1, an osteoblastogenic cytokine secreted by osteoclasts, increased. TBT induced expression of RXR- and LXR-dependent genes in whole bone and in vitro mouse primary osteoclast cultures. However, only an RXR antagonist, but not a liver X receptor antagonist, significantly inhibited TBTs ability to suppress osteoclast differentiation. Next, we examined the interaction of estrogen loss and TBT exposure in C57BL/6J mice. Mice underwent either sham surgery or ovariectomy (OVX) at 10 weeks of age. At 12 weeks of age, mice were treated by oral gavage 3x per week with TBT (1 or 5 mg/kg) for 14 weeks. TBT treatment protected against OVX-induced trabecular bone loss. Serum CTX was significantly reduced in TBT-treated, OVX mice, while serum PINP and osteocalcin were not significantly affected. Gene expression analyses on cortical bone and bone marrow are being conducted and will provide information on TBT's disparate effect in the cortical and trabecular compartments These results suggest that TBT has a distinct effect on cortical versus trabecular bone, likely resulting from independent effects on osteoblast and osteoclast differentiation that are mediated via RXR. Our novel observations will provide new information on basic bone biology, potential therapeutic targets and toxicological pathways.

Dynamics of Vitamin D Metabolism in the Maternal-Fetal Dyad in Response to Vitamin D Supplementation Inez Schoenmakers*[1], Kerry Jones[2], Shima Assar[2], Stefania D'Angelo[3], Ann Prentice[2], Nick Bishop[4], Stephen Kennedy[5], Aris Papageorghiou[5], Robert Fraser[5], Saurabh Gandhi[5], Elisabeth Curtis[3], Sarah Crozier[3], Rebecca Moon[3], Keith Godfrey[3], Hazel Inskip[3], Elaine Dennison[3], Richard Eastell[7], Kassim Javaid[8], Cyrus Cooper[3], Nick Harvey[3], The Mavidos Study Group (Arden, Carr, Mughal, Reid, Robinson)[3]. [1]Department of Medicine, University of East Anglia and MRC Elsie Widdowson Laboratory, United Kingdom, [2]MRC Elsie Widdowson Laboratory, United Kingdom, [3]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [4]Academic Unit of Child Health, Sheffield Children's Hospital, University of Sheffield, United Kingdom, [5]Nuffield Department of Women's & Reproductive Health, John Radcliffe Hospital, University of Oxford, United Kingdom, [7]Academic Unit of Bone Metabolism, University of Sheffield, United Kingdom, [8]NIHR Oxford Biomedical Research Centre, University of Oxford, United Kingdom

Fetal vitamin D supply is dependent on maternal status. It is unclear whether the relationships between maternal and cord blood vitamin D metabolite concentrations are linear over a wide range of maternal vitamin D supplies and status and whether the maternal free or total 25(OH)D concentration best reflects fetal 25(OH)D availability. We investigated the effect of maternal vitamin D supplementation on maternal and cord concentrations of total and free 25(OH)D, 3-epi-25(OH)D3 and 24,25(OH)2D3 and their interrelationships.This study utilised a subset of maternal (34 weeks gestation) and cord (umbilical vein) bloods from the MAVIDOS study, a UK-based double-blind, placebo-controlled vitamin D supplementation (1000IU/d) trial in pregnancy (n=100 pairs; 1:1:1:1 from the supplementation/placebo group and winter/summer births). Vitamin D metabolites were quantified by UPLC-MS/MS and free 25(OH)D by ELISA (Diasource).Maternal and cord concentrations of all vitamin D metabolites (mean(SD)) were significantly higher with supplementation (all P< 0.001). Total 25(OH)D and 24,25(OH)2D3 concentrations were lower, 3-epi-25(OH)D3 comparable and free 25(OH)D higher in cord blood than in maternal blood. The maternal free: total 25(OH)D ratio was lower than in cord. Maternal and cord concentrations of individual metabolites were highly correlated. In multiple regression models, concentrations of total 25(OH)D strongly predicted those of free 25(OH)D, 3-epi-25(OH)D3 and 24,25(OH)2D3 within and between the maternal and cord compartments. There were significant interactions between total 25(OH)D and supplementation group and season for all these metabolites when relationships were assessed within the maternal compartment and between maternal and fetal compartments but not within cord plasma.In conclusion, although cord vitamin D metabolite concentrations were highly dependent on those in maternal plasma, differences in absolute and relative concentrations between compartments suggest that: (1) maternal total and free 25(OH)D concentrations may not fully reflect availability to the fetus; (2) an active transport mechanism for 25(OH)D and (3) partial autonomy of fetal vitamin D metabolism.

	Maternal		Cord	
	placebo	1000 IU/d	placebo	1000 IU/d
Total 25(OH)D (nmol/l)	62(28)	95(24)	36(17)	54(21)
Free 25(OH)D (pmol/l)	7.1(2.9)	11.1(3.0)	9.6(5.3)	15.0(6.7)
3-epi-25(OH)D (nmol/l)	3.8(1.9)	6.1(2.5)	3.6(2.1)	5.5(2.5)

IN PGE1 BONE ANABOLIC PREDOMINATES MODELING-BASED FORMATION WITHOUT HYPERCALCEMIA Francisco Velasquez-Forero*, Mariela Esparza, Pedro Valencia Mayoral. Hospital Infantil de México Federico Gómez, Mexico

Purpose: to evaluate the PGE1 bone anabolism and to test our hypothesis that PGE1 primarily elicited modeling bone formation while decreasing resorption.Methods: to evaluate the PGE1 anabolic bone effects and its mechanism of formation-based on the rabbit orthodontic palate disjunction, 30 rabbits were divided in 3 groups: ten control, ten sham and ten PGE1 subjects. Basal Rx, repeated days 3 and 22. Using an orthodontic appliance in the sham and the PGE1 groups were submitted to palate disjunction for five days, after it was fixed with a steel bar. All received double tetracycline bone labeling. Control and sham groups a daily IV vehicle solution, and the third group, vehicle with 50 µg of PGE1. On day 22 blood and urine samples were taken, to analyze bone formation biochemical markers (Ca, Mg, P, calciotropic hormones, calciuria and N-telopeptides) and them they were killed. Bone palate samples were processed undecalcified. The sutural bone (sB) was histomorphometrically evaluated using a Osteomeasure software, following the ASBMR recommendations.

Remodeling and modeling bone formation were analyzed on the mineralization front stained with toluidine blue. The scalloped lines reflect initial resorption phase (remodeling formation), whereas modeling cycle are associated with smoother lines (modeling formation). Data were statistically analyzed.Results: radiology verified the suture palate disjunction. The PGE1 group, exhibited significant calcitriol and calciuric increments. The other calciotropic hormones, calcemia and N-telopetides were normal (Table 1). Histomorphometric the PGE1 the sBV/TV, sBAr and sBTb (structural parameters) exhibited a significant increased when compared with the sham. Remodeling bone formation (RBF) in the sham group was 20% ± 6.1 and the modelation bone formation (MBF) was 6% ± 2.5. In the PGE1 group the results were significantly inverted (RBF was of 8.6% ± 1.3 and the MBF was of 17% ± 4.4). So the PGE1 bone anabolism was mainly through MBF. Table 1. The PGE 1 group exhibited accelerated mineralization parameters (Omt, MLT). On the contrary, the resorption indexes (ES/BS and OcS/BS) showed mild decreased activity which may explain the normocalcemia. Table 1.Conclusions: this model confirmed that PGE1 is an important osseous anabolic molecule by predominated MBF with scanty resorption and no hypercalcemia. Hopefully this finding could guide researchers to investigate options for osteopenic treatments.

Salt inducible kinases control responses to parathyroid hormone in the renal proximal tubule Maureen Omeara*[1], Han Xie[1], Alexandra Clifford[1], Jinhua Gray[2], Nathanael Gray[2], Kei Sakamoto[2], Michael Mannstadt[1], Marc Wein[1]. [1]MGH Endocrine Unit, United States, [2]Dana Farber Cancer Institute, United States

Background: We recently described a central role for salt inducible kinase 2 (SIK2) in parathyroid hormone (PTH) signaling in osteocytes. PTH-induced cyclic AMP signaling, via protein kinase A, leads to inhibitory SIK2 phosphorylation. Therefore, small molecule SIK inhibitors mimic the skeletal actions of PTH. However, role of SIKs in other PTH-responsive organs remains to be determined. PTH signaling in the renal proximal tubule plays a central role in controlling blood phosphate and 1,25-(OH)2-vitamin D levels. Here, we tested the hypotheses that (1) renal PTH signaling involves PKA-mediated SIK phosphorylation, and that (2) small molecule SIK inhibitors mimic the renal actions of PTH. Methods: Opossum kidney (OK) cells were treated with PTH and small molecule SIK inhibitors (YKL-05-099, crenolanib, and AZD-7762). Effects on CYP27B1 gene expression were measured by RT-qPCR, and effects on phosphate uptake were measured by 32P uptake assays. C57B6 mice were treated with YKL-05-099 (18 mg/kg) or PTH (300 mcg/kg) for 1, 2, and 4 hours. Serum was collected at all time points, and 1,25-(OH)2-vitamin D, phosphate,

PTH, and calcium were measured. Kidney RNA was collected from mice after one hour treatment (n=8/group) with vehicle, PTH, or YKL-05-099 for RNA-seq analysis.Results: PTH signaling in OK cells leads to rapid (within 5 minutes) SIK3 phosphorylation at T469, a known PKA target site. Both PTH and SIK inhibitor treatment up-regulate CYP27B1 expression in OK cells. Both PTH and SIK inhibitors block 32P uptake in OK cells in a dose dependent manner. In vivo, both PTH and YKL-05-099 acutely reduce serum phosphate levels (veh 9.38±1.37 mg/dl, PTH 7.81±1.49, YKL 7.38±1.68, p<0.05) and increase serum 1,25-(OH)2-vitamin D (veh 90.3±39.9 pM, PTH 157.9±37.0, YKL±188.9±61.6, p<0.05) after 2 hours. Importantly, YKL-05-099 accomplishes these changes in mineral metabolism without affecting levels of serum PTH, serum calcium, or urinary cAMP. RNA-seq profiling 1 hour after acute treatment reveals a remarkable concordance between the global effects of PTH and YKL-05-099. Of the 157 genes whose expression is significantly (>2-fold, FDR<0.05) up-regulated by PTH, 63 (40.2%) are co-upregulated by YKL-05-099 (including CYP27B1).Conclusions: SIK inhibition is a key component of PTH signaling in the renal proximal tubule, with respect to both the ability of this hormone to promote phosphaturia and to drive 1,25-(OH)2-vitamin D synthesis.

Loss of Bone Volume and Bone Strength from Unloading is Mouse Strain-Dependent Michael Friedman*[1], Yue Zhang[1], Jennifer Wayne[1], Charles Farber[2], Henry Donahue[1]. [1]Virginia Commonwealth University, United States, [2]University of Virginia, United States

Astronauts in space and patients experiencing prolonged bed rest are exposed to mechanical unloading of bones, decreasing bone volume and strength by up to 3% per month.1 Similar levels of bone loss result from aging and lead to increased risk of fragility fracture. It is well known that variability in accretion of bone mass and risk of osteoporosis is influenced by genetics. However, it remains unclear how genetic variation affects bone's response to unloading or the efficacy of countermeasures. Diversity Outbred (DO)2 mice are highly diverse outbred mice derived from 8 inbred founder strains. As a first step towards examining the genetic basis of the unloading response in bone, we examined unloading in DO founder strains. We hypothesized that there would be differential, strain-dependent effects of unloading on mice of the founder strains C57Bl/6J, PWK/PhJ and WSB/EiJ after 3 weeks of unloading using single limb immobilization (SLI).At 16 weeks old, 6 male mice of each strain had the left limb immobilized in a cast for 3 weeks. The unaltered right limb was used as a control. Bone geometry was analyzed by micro-CT. Mechanical properties were tested by 3-point bending. One-way ANOVAs with Tukey's tests were used to test for significant group differences, and paired t-tests for significant effects of immobilization (p<0.05).All strains had significantly decreased BV/TV in immobilized versus control limbs (Fig. 1). The magnitude of bone loss was significantly greater in the B6 and WSB strains compared to the PWK strain. Losses of cortical area fraction and Young's modulus were significantly greater in the B6 strain compared to the WSB strain. The PWK strain was most resistant to bone loss. This occurred despite the B6 strain having greater body weight, and the WSB strain having lesser body weight than the PWK strain. These results indicate that different strains respond to unloading from SLI differently, and this could be explained by genetic differences. Future studies examining gene expression differences between strains may provide clues as to the molecular basis of bone loss in response to unloading. More importantly, these results suggest that DO mice will be a useful model for examining the genetics of differential, strain-dependent bone response to unloading.References: 1. Lang T et al. CLINICALLY RELEVANT DOSES OF VITAMIN A DECREASES THE ANABOLIC BONE RESPONSE TO MECHANICAL LOADING BY INHIBITING BONE FORMATION Vikte Lionikaite*, Petra Henning, Christina Drevinge, Sara Windahl, Ulf Lerner. Centre for Bone and Arthritis Research, Institute for Medicine, Sahlgrenska Academy at University of Gothenburg, Sweden

Increased vitamin A consumption has been associated with decreased cortical bone thickness and increased fracture risk in humans. With increasing intake of supplements in the population as well as fortification of foods, excess vitamin A may affect many individuals. Rodent studies have shown that increased osteoclastogenesis and resorption of cortical bone at the periosteal surface are important mechanisms leading to bone fragility in hypervitaminosis A. We have recently shown that also clinically relevant doses of vitamin A given to mice during a longer period of time have a negative impact on cortical bone mass. The effect could be blocked by simultaneous treatment with bisphosphonates, indicating that osteoclasts are important for the response. The in vivo effects of vitamin A on osteoblasts and bone formation have been less studied.The aim of the present study was to investigate if clinically relevant doses of vitamin A affect loading-induced bone formation. C57BL/6 female mice were fed control (4.5µg retinyl acetate/g chow) or vitamin A supplemented (60µg retinyl acetate/g chow) diets for 4 weeks, after which the right tibiae were subjected to axial loading three times per week for 2 weeks (40 cycles, peak strain 2250 µε), whilst continuing on the diets. Left limbs were used as internal controls. Bone architecture was analyzed by micro-CT. Micro-CT analysis showed that vitamin A decreased the loading-induced increase in trabecular bone volume. Vitamin A treated mice also had decreased cortical bone area compared to controls and the loading-induced increase in bone area was robustly reduced in mice treated with supplemented dose of vitamin A. Dynamic histomorphometry demonstrated that vitamin A suppressed the loading induced increase in periosteal and endocortical bone formation due to decreased osteoblast activity. Vitamin A treatment inhibited the loading-induced increase in the expression of the osteoblast genes Sp7, Alpl, and Col1a1 in cortical bone. To conclude, using a model of induced bone formation, we show that clinically relevant doses of vitamin A for long duration can suppress the anabolic bone response to mechanical loading. This results in less bone formed, an effect that can be attributed to decreased osteoblast activity.

Fluid Shear Stress Affects Morphology and Osteogenic Differentiation of Pre-osteoblasts Jianfeng Jin*[1], Richard T. Jaspers[2], Astrid D. Bakker[1], Gang Wu[3], Johanna F.M. Verstappen[1], Mohammad Haroon[2], Joannes A.M. Korfage[4], Behrouz Zandieh-Doulabi[1], Jenneke Klein-Nulend[1]. [1]Dept Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam and Vrije Universiteit Amsterdam, Amsterdam Movement Sciences, Netherlands, [2]Laboratory for Myology, Faculty of Behavioral and Movement Sciences, Vrije Universiteit Amsterdam, Amsterdam Movement Sciences, Netherlands, [3]Dept Oral Implantology and Prosthetic Dentistry, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam and Vrije Universiteit Amsterdam, Amsterdam Movement Sciences, Netherlands, [4]Dept Functional Anatomy, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam and Vrije Universiteit Amsterdam, Amsterdam Movement Sciences, Netherlands

Introduction: Mechanical stimuli, e.g. fluid shear stress, are known to affect osteogenic differentiation of osteogenic precursor cells through hereto unknown mechanisms. Interestingly, mechanical stimuli are also known to influence cell morphology, while the morphology of a cell (spread vs. round) determines osteogenic differentiation of osteogenic precursor cells. We hypothesized that the enhancing effect of mechanical stimulation on osteogenic differentiation of osteogenic precursor cells is determined by its' effect on precursor cell morphology. Therefore, we first aimed to determine bone cell responses to fluid shear stress in terms of osteogenic differentiation state and precisely determined cell morphology. Methods: MC3T3-E1 pre-osteoblasts were stimulated for 1 h by pulsating fluid flow (PFF; peak shear stress rate: 6.5 Pa/s, amplitude: 1.0 Pa, 1 Hz) or kept under static conditions (control). The cell mechanoresponse was quantified as nitric oxide (NO) release. F-actin was visualized using phalloidin, and cell nuclei by DAPI. Cell morphology and orientation were assessed using scanning electron microscopy and confocal microscopy, respectively. Osteogenic differentiation was assessed in static and PFF-stimulated cells post-incubated for 3 weeks by quantifying alkaline phosphatase (ALP) activity, collagen protein (Sirius Red), and matrix mineralization (Alizarin Red). Expression of osteogenic genes (RUNX2, BMP2, FGF2), proliferation (Ki67), and angiogenesis-related gene (FGF2) was analyzed (qPCR). Results: PFF rapidly increased NO production (4-fold) at 10 min. PFF also increased actin cytoskeletal (green) and nuclear DAPI staining (blue). Static control cells were more oval-shaped, while PFF-treated cells seemed more polygonal-shaped (Fig. 1). PFF also affected cell orientation, reduced cell spreading, and increased number and length of pseudopodia. PFF stimulated collagen protein (1.8-fold), and slightly (n.s.) increased ALP activity (1.2-fold) and mineralization (1.3-fold). Finally, PFF strongly increased BMP2 (9.3-fold), and slightly KI67 (1.3-fold), and FGF2 (1.4-fold) expression, but decreased (n.s.) RUNX2 expression (0.7-fold).Conclusion: Our results indicate that mechanical stimuli in the form of fluid shear stress affect cell morphology and osteogenic differentiation of MC3T3-E1 pre-osteoblasts. Future studies will determine whether, and which morphology changes drive osteogenic differentiation, and try to unravel the underlying mechanism.

Bone (Re)modeling in Response to Load is Targeted to Mechanically Advantageous Structures and Further Enhanced with PTH Treatment Samuel Robinson*, Yizhong Hu, X. Edward Guo. Bone Bioengineering Lab, Columbia University, United States

Bone modeling and remodeling are distinct biochemical regimes that may hold unique opportunities for optimizing bone mass (remodeling being coupled resorption followed by formation on bone surfaces, and modeling being uncoupled instances of these events). Mechanical loading and intermittent parathyroid hormone (PTH) are both known to enhance total bone mass, though the regime(s) through which these ends are achieved remain less clear. Dynamic in vivo morphometry utilizing high resolution micro-CT and image registration has only recently become feasible and thus holds an untapped and expanding potential for analyzing bone metabolism through quantifying and localizing formation/resorption and thus modeling/remodeling events.C57Bl/6 mice 16 weeks of age were given 2 weeks of baseline weekly micro-CT scans of both tibiae prior to the initiation of daily treatment with PTH and/or unilateral tibia loading. The contralateral tibia served as a nonloaded control. Weekly scanning and daily treatment continued for 5 weeks. Registered images for each mouse in a global coordinate system revealed the time course of each voxel, allowing for changes in bone mass to be quantified as modeling or remodeling starting at the onset of

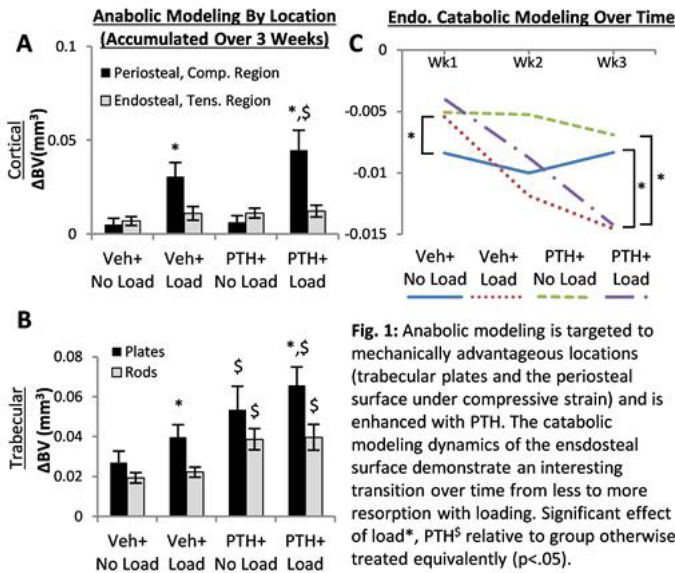
treatment. In cortical bone, after an initial response to treatment in both anabolic modeling and remodeling, modeling developed as the dominant response. Differences between groups were starkest in areas of mechanical significance. For example, anabolic modeling on the periosteal surface on the half of the tibia in compression under axial load presents a strong effect of treatment, whereas the same measure on the endosteal surface in the area in tension showed no differences between groups (Fig 1A). Similarly, in trabecular bone anabolic modeling was significantly increased with loading on trabecular plates, the major contributor to trabecular bone strength, but not rods (Fig 1B). In both bone types, PTH tended to enhance the effects of both modeling and remodeling but without bias towards these mechanically relevant locations. Curiously, the catabolic modeling response on the endosteal surface showed a remarkable transition over time. Loading initially suppressed catabolic modeling, but over time increased it to levels significantly beyond that of nonloaded controls, with and without PTH (Fig 1C). In total our data demonstrate strong independent and combined effects of PTH and load, with load directing the response to favorable locations.


Fig. 1: Anabolic modeling is targeted to mechanically advantageous locations (trabecular plates and the periosteal surface under compressive strain) and is enhanced with PTH. The catabolic modeling dynamics of the ensdosteal surface demonstrate an interesting transition over time from less to more resorption with loading. Significant effect of load*, PTH$ relative to group otherwise treated equivalently (p<.05).

Cyclosporin A Enhances Loading Induced Trabecular and Cortical Bone Formation at Senescence Sundar Srinivasan*, Dewayne Threet, Philip Hubber, Ted Gross, Steven Bain. University of Washington, United States

Age-related degradation in bone mechanotransduction markedly reduces the efficacy of exercise in augmenting bone mass in the elderly. In previous studies exploring underlying mechanisms, we identified specific age-related deficits in bone mechanotransduction that could be counteracted by low-dose Cyclosporin A treatment (CsA). In follow-up studies, we observed that loading supplemented with low-dose CsA restored cortical bone formation in senescent animals to the robust levels observed in young. Given the significant age-related loss of trabecular bone mass and its contribution to fracture risk, we proposed that CsA supplementation could also serve as a means to augment bone mass in this compartment. However, considering the differences in structure, cell populations and bone remodeling dynamics between bone compartments, we hypothesized that distinct dosages of CsA supplementation will be required to enhance trabecular and cortical bone formation induced by loading at senescence. To examine our hypothesis, the right tibiae of three groups of senescent female C57BL/6 mice (19 Mo, n = 4/grp) were subject to dynamic loading (off-axial compression, -0.01 N static preload, -3.6 N dynamic loading at 1-Hz, 50 cycles/d, 3 days/week, 3-weeks) either without (0.0 mg/kg) or with CsA supplementation (0.1 or 3.0 mg/kg s.c.). Upon sacrifice, trabecular adaptation was assessed via μCT (d 22) and mid-shaft cortical bone formation via dynamic histomorphometry (Calcein d 10, 19). In trabecular bone, we found that loading without or with 0.1 mg/kg CsA did not significantly enhance BV or BV/TV vs contralateral. In contrast, loading supplemented with 3.0 mg/kg CsA significantly enhanced BV (0.08 ±0.01 vs 0.06 ±0.01 mm3) and BV/TV (3.8 ± 0.8 vs 2.7 ± 0.3%; p < 0.05). In cortical bone, loading without or with 0.1 mg/kg CsA did not influence MAR, MS or BFR vs contralateral bone. However, loading supplemented with 3.0 mg/kg CsA significantly enhanced MAR (0.47 ± 0.07 vs 0.37 ± 0.05 μm/d), MS (22 ± 5 vs 12 ± 4%) and BFR (0.11 ± 0.03 vs 0.05 ± 0.02 μm3/μm2/d) vs contralateral bone (p < 0.05). Unexpectedly, we found that the same dose of CsA that enhanced loading induced cortical bone formation also enhanced trabecular adaptation in senescent animals. While preliminary, use of this low-cost, approved drug as a supplement that augments loading-induced bone formation at senescence holds potential as a novel countermeasure against skeletal fragility across bone compartments.

Is Chronic Hypergravity Able to Protect the Musculoskeletal System in a Murine Model of Knee Osteoarthritis? Benoit Dechaumet*, Damien Cleret, Norbert Laroche, Arnaud Vanden-Bossche, Marie-Hélène Lafage-Proust, Laurence Vico. INSERM, U1059, University of Lyon, UJM Saint-Etienne, France

Osteoarthritis (OA) patients do little physical activity, which is known to maintain musculoskeletal health although its role on OA remains a matter of debate. Hypergravity was shown to act as endurance training on muscle (Bojados and Jamon, 2014) and to improve bone (Gnyubkin et al., 2015) in growing mice. Here, we tested the effects of acceleration at 2g during 8 weeks in mature mice with or without OA on the musculoskeletal system and OA progression. Male C57BL/6J were randomized in centrifuged (2g) and non-centrifuged (1g) group, after destabilization of the medial meniscus of the right knee in half of them, giving 4 groups: 1g, OA-1g, 2g and OA-2g (n=16/ group). 2g mice, housed in gondolas hanging at the periphery of the 1.4 m radius centrifuge were provided with food and water for 4 weeks. The centrifuge was stopped once at mid-time for animal husbandry and at 7 and 2 days before the end of the experiment for fluorochrome labelling. Tibias (nanoCT, bone and vascular histomorphometry), calf muscles (typing, fiber size) and molecular markers (tibia and gastrocnemius muscle), right side, were analyzed. OA-1g mice had increased OARSI score, subchondral bone sclerosis and thinning of articular cartilage; all were still present in OA-2g mice. In the tibia proximal metaphysis, trabecular bone loss (-28%) and increased resorption activity were observed in OA-1g vs 1g. Hypergravity in OA prevented trabecular bone loss, increased mineralization rate (+18%), but decreased cortical thickness (-9%). Bone marrow vascular density decreased in 2g groups but less in OA than non OA. OA increased bone (Runx2, 149%), adipocyte (C-EBPα, 98%) and inflammatory (TNFα, 175%) markers; these increases being prevented in OA-2g. Soleus and gastrocnemius mass increased in 2g groups. OA-2g soleus had greater fiber area (+43%) with increases in type I fibers and decreases in type II fibers compared to OA-1g. Soleus vascular density decreased in 2g groups (-37%, vs 1g or OA-1g). In the gastrocnemius 2g (with or without OA) increased the expression of myostatin, FNDC5 and visfatin. Further, hypergravity in OA prevented increases of serum inflammatory markers observed in OA-1g.Thus, if 2g has no bone effect in intact mice, it prevents trabecular bone loss but reduces cortical thickness in OA mice. In all cases, hypergravity improves muscle parameters, as does endurance exercise. In conclusion, chronic 2g reinforces muscles and prevents trabecular bone loss and inflammation in OA.
1.4 m radius centrifuge (COMAT Aérospace, Flourens, France)

The contribution of TRPV4-dependent calcium influx and purinergic calcium oscillations to the regulation of sclerostin during osteocyte mechano-sensing Katrina Williams*, Derek Jones, Christopher Ward, Joseph Stains. University of Maryland, United States

Skeletal remodeling is driven in part by the osteocyte's ability to respond to its mechanical environment and regulate sclerostin (a negative regulator of bone mass) abundance. We have recently shown that the osteocyte responds to fluid shear stress (FSS) via the microtubule network-dependent activation of NADPH oxidase 2-generated reactive oxygen species and subsequent opening of TRPV4 cation channels, thus leading to calcium influx, activation of CAMKII, and rapid sclerostin protein downregulation. In addition to the initial calcium influx, purinergic receptor signaling and calcium oscillations have been observed downstream from mechanical load; however, the role of TRPV4 and the initial calcium influx versus downstream calcium oscillations in the rapid sclerostin protein downregulation remains unclear. Here, using pharmacologic gain (GSK1016790A, 15μM, 30 minutes) and

loss (GSK2193874, 15µM, 30 minutes) of function approaches, we confirm that activation of the TRPV4 channel is required for the initial calcium influx, CaMKII activation, and rapid loss of sclerostin protein following FSS. TRPV4 antagonist significantly reduces downstream oscillations (% cells oscillating, intensity of calcium signal, and number of oscillations per cell) following FSS; however, TRPV4 agonist does not induce high levels of oscillations (% cells oscillating) as seen with ATP (100nM), demonstrating that TRPV4 is necessary, but not sufficient, for the downstream calcium oscillations seen in these osteocytes using live cell calcium imaging with Fluo-4 AM calcium indicator dye. Furthermore, inducing calcium oscillations alone with ATP in Ocy454 cells is not sufficient to induce rapid sclerostin protein downregulation, although oscillations can activate CaMKII. This suggests that pathways downstream of TRPV4 and parallel to CaMKII activation are obligated for sclerostin downregulation. In total, our data suggest that activation of the TRPV4 channel is the primary response required for CAMKII phosphorylation and rapid sclerostin protein downregulation, whereas the calcium oscillations downstream from TRPV4 likely serve independent roles in tuning osteocyte function.

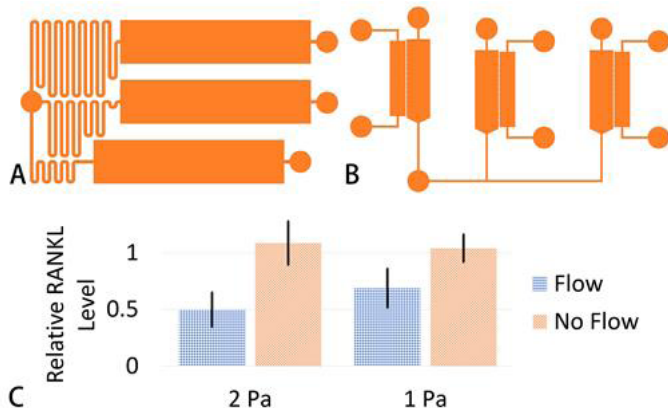
Novel in vitro Microfluidic Platforms for Osteocyte Mechanotransduction Studies Liangcheng Xu*[1], Lilia Fuller-Thomson[2], Lidan You[1,2]. [1]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Canada, [2]Department of Mechanical and Industrial Engineering, University of Toronto, Canada

Osteocytes are the major mechanosensing cells in bone remodelling [1]. Current bone mechanotransduction research use macro-scale devices, however in vitro microfluidic devices provide an optimal tool to better understand this biological process with its flexible design, physiologically-relevant dimensions, and high-throughput capabilities. Our recent work on co-culture platform has demonstrated the feasibility of building more complex microfluidic devices for osteocyte mechanotransduction studies [2]. However, there still lacks a robust system where multi-physiological flow conditions are applied to bone cells to study their intercellular communication.OBJECTIVE: This project aims to design and fabricate a multi-shear stress, co-culture platform to study interaction between osteocytes and other bone cells under varying flow conditions.METHODS AND RESULTS: Standard microfluidic principles utilize changing geometric parameters to induce different flow rates that are directly proportional to the levels of shear stress. All channels within the same device will share a common inlet, while adjusting the resistance of each individual channel will result in a different flow rate (Figure A). Devices are fabricated using PDMS and bonded to glass slides of equal sizes. MLO-Y4 osteocyte-like cells seeded in the device are stimulated with oscillatory fluid flow with a custom in-house pump. Significant differences in RANKL levels are observed between channels (Figure B), demonstrating that proper cellular response to flow can be elicited from each distinct shear stress channels as designed.Furthermore, we paired these multi-shear stress channels with corresponding culturing chambers connected through perfusion pores (Figure C). Through perfusion between the multi-shear stress channels and culturing chambers, different cell population can communicate to each other as they are stimulated by varying levels of shear stress.DISCUSSION: Using this platform, we will be able to mimic the interaction between osteocytes and other bone cells in vitro. Future integration with on-chip analytical methods will allow for detection of molecular factors, leading to better understanding of bone cell intercellular communication under physiologically relevant conditions, and ultimately, discovery of novel therapeutic targets.[1] Santos. Osteoporos Int. 2009. [2] Middleton. J. Biomech. 2017.


A) Layout design for multi-shear device, each chamber containing osteocytes stimulated by shear stress levels 0.5 Pa, 1 Pa, 2Pa, from top to bottom, respectively. B) Layout design for multi-shear co-culture device, with each flow channel paired with an osteoclast growth chamber. Scale bar for A and B equals 4.5 mm. C) RANKL expression level measured in multi-shear device normalized to the 0.5 Pa channel levels in each device.

Mechanical loading regulates Hippo signaling in a three-dimensional osteocyte culture model Mylène Zarka*[1], François Etienne[2], Morgane Bourmaud[1], Christophe Helary[3], François Rannou[2], Eric Haÿ[1], Martine Cohen-Solal[1]. [1]Inserm UMR1132, Hôpital Lariboisière; Univ Paris Diderot, Sorbonne Paris Cité, Paris France, France, [2]Inserm UMR-S1124, Université Paris Descartes, Sorbonne Paris Cité, Paris France, France, [3]Sorbonne Universités UPMC Univ Paris 06, CNRS, Collège de France, Laboratoire Chimie de la Matière Condensée de Paris UMR7574, France

Purpose: Osteocytes are mechanosensitive cells that control bone remodeling in response to mechanical loading. To date, signaling pathways modulated by mechanical loading in osteocytes are not clearly described. Since YAP/TAZ, the mains effectors of the Hippo pathway, mediate the mechanotransduction process, we hypothesized that they also induce osteocyte response to mechanoloading. In addition, YAP/TAZ interacts with several signaling pathways regulated during osteoblastogenesis. The objective of our study is to define the response of osteocytes in response to mechanical loading and identify the mechanism of cell activation via the Hippo pathway.Methods: MLO-Y4 osteocyte cell lines were cultured in concentrated collagen hydrogels for 14 days. Osteocytes were submitted to mechanical loading using the Flexcell Compression Plus System® with a regimen of sinusoidal compression at 1 Hz, 40 kPa during 9 hours. RNA sequencing was performed to determine gene expression modifications. Immunofluorescence and Western blot analysis were carried on, respectively, from paraffin embedded hydrogel sections and total protein lysate.Results: Mechanical loading induced an increase of the expression of mechanosensitive target genes, permitting us to validate our experimental model (E11GP38 and COX2, x3 fold increase p<0.05). Mechanical compression induced a large increase in the expression of osteoprotegerin (OPG, x4 fold increase p<0.05) associated with a decrease in the expression of RANK ligand (RANKL, 25% of decrease p<0.05), suggesting a negative role for osteoclastogenesis. RNA sequencing results indicates that 83% of YAP/TAZ target genes modulated by compression in osteocytes were up-regulated, this being confirmed by RTqPCR regarding gene expression analysis of YAP/TAZ target genes (ANKRD1, x3 fold increase p<0.05). We also observed that mechanical compression increase nuclear translocation of YAP/TAZ by immunofluorescence, and increase total protein level of YAP/TAZ as shown by western blot. In addition, mechanical compression reduced osteocyte apoptosis (50% decreased apoptosis).Conclusion: our model allowed highlighting the activation of Hippo signaling in osteocytes in response to mechanical loading. These results show the contribution of YAP/TAZ signaling in the mediation of mechanical loading through osteocytes and in the regulation of bone remodeling.

A WINDOW OF OPPORTUNITY: IDENTIFICATION OF MEDICALLY HOSPITALIZRED PATIENTS WITH FRAGILITY FRACTURE RISK Vafa Tabatabaie*, Wanda Horn, Brandon Tauberg, Gabriel Lopez Vega, Mikhail Bekarev, Paul Levin, Sara Merwin. Montefiore Medical Cener, United States

Background: Despite increasing prevalence, osteoporosis is widely undiagnosed and undermanaged with fragility fracture risk (FFR) under-documented. 90% of fragility fractures (FF) occur in people >60 years. Fracture Risk Assessment Tool (FRAX) is a validated instrument to predict FFR in ensuing 10 years.Objective: To increase FFR awareness in providers. Inpatient admission offers an opportunity to intervene with human alert methodology previously demonstrated as effective. We hypothesized increased surveillance, documentation and referral to outpatient services to prevent FF in at-risk patients identified as a result of the intervention.Methods: IRB-approved educational intervention via alerts to providers of at-risk patients identified by concurrent chart review on medical units at an urban tertiary care teaching hospital. Study instruments were FRAX calculator and script for provider encounters. Patient inclusion: females ≥65 years, males ≥70 years, and known osteoporosis risk factors. Exclusion: age <18 or >100 years, current consult with endocrine service, admission to orthopaedic or palliative service, predicted survival <6 months, current/previous antiresorptive or anabolic agents. Primary outcome measure was FFR documentation or initiation of treatment.Results: Pre-intervention chart review revealed 0 % documentation for FFR. During the initial 8 weeks of the intervention, 36 of 118 screened charts met inclusion criteria. Mean age 85 ±SD 6.5 years, female 53% (N=19), most prevalent admitting diagnosis was pneumonia (16%). Mean FRAX:13% major osteoporotic fracture (MOF), 6.5% hip fracture (HF). Eight patients (22%) had FFR documentation on discharge summary: mean age 85 ±SD 6.7 years, mean FRAX: 17.1% MOF, 8.4% HF.Conclusion: To our knowledge and confirmed by preliminary data, documentation of FFR of medically hospitalized patients is uncommon. With our intervention we have verified an increase in documentation as hypothesized, suggesting that medical providers recognize the importance of enhanced prevention measures to offset the risk of fragility fractures. This study lays groundwork for the integration of a systems-based approach using electronic alerts to complement human alert methodology to enhance communication and support continuity across transitions of care.

MON-0433

Trends towards Decreased Cortical Thickness and Increased Cortical Porosity in a One-Year Pilot Study of Premenopausal BRCA Mutation Carriers Undergoing Prophylactic Salpingo-Oophorectomy Angela Cheung*[1,2], Madeline Dwyer[2], Jeevitha Srighanthan[1], Joan Murphy[3], Amy Finch[4], Joanne Kotsopoulos[5], Marcus Bernardini[1], Michelle Jacobson[5], Gabrielle E.V. Ene[1], Irene Ho[1], Suzanne Cohen[1], Paula Harvey[5], Barry Rosen[1], Steven Narod[5]. [1]University Health Network, Canada, [2]University of Toronto, Canada, [3]Trillium Health Partners, Canada, [4]Sunnybrook Health Sciences Centre, Canada, [5]Women's College Hospital, Canada

Introduction:Women who carry a mutation in the BRCA1 or BRCA2 genes are at increased risk for breast and ovarian cancer. Prophylactic salpingo-oophorectomy (PSO) has been shown to effectively reduce the risk of breast and ovarian cancer by 50% and 90%, respectively. However, this leads to an abrupt decrease in circulating estrogen levels among premenopausal women, which can cause BMD loss and increase fracture risk.Objectives:This pilot study aims to assess the effects of PSO on bone structure and strength using high resolution peripheral quantitative computed tomography (HRpQCT). Materials and Methods:This pilot 1-year cohort study assesses bone structure and strength in pre-menopausal women who are BRCA mutation carriers undergoing PSO compared to pre-menopausal age-matched women who are not oophorectomized and are non-carriers. All women were scanned at the distal radius and tibia on the Xtreme CT (Scanco, Switzerland) at baseline and 1 year. Standard HRpQCT parameters, such as volumetric BMD, cortical thickness, trabecular BV/TV, were obtained. In addition, scans were analyzed for cortical porosity as well as bone stiffness, ultimate stress and failure load using finite element analysis. The percent change from baseline to one year post-surgery was calculated for all parameters for both BRCA carriers and non-carriers. Depending on data distribution, t-tests or Wilcoxon rank-sum tests were used to assess differences between BRCA carriers who underwent PSO and non-oophorectomized non-carriers.Results: A total of 21 PSO BRCA carriers (mean age (SD): 41.8 (5.32) years) and 12 non-oophorectomized non-carriers (mean age (SD): 46.6 (3.77) years) were included in this analysis. 85% of the study population are Caucasian. Our preliminary analyses showed no differences in total, cortical and trabecular vBMD, trabecular BV/TV, trabecular thickness, separation or number at the distal radius or tibia (p>0.1). There were trends of decreased cortical thickness and increased cortical porosity at the distal radius and tibia (p= 0.045 to 0.09). No statistically significant differences in estimated bone strength were observed.Conclusions:This preliminary analysis of bone structure and strength in premenopausal women with BRCA mutations undergoing PSO showed trends towards decreased cortical thickness and increased cortical porosity at 1 year. Our pilot study was limited by small sample size and short duration. Larger sample sizes and longer follow-up duration are required to clarify these findings.

Hyperkyphosis and Self-reported and Objectively Measured Sleep Quality in Older Men Christopher Kaufmann*[1], Jian Shen[1], Katie Stone[2], Deborah Kado[1]. [1]University of California San Diego, United States, [2]California Pacific Medical Center Research Institute, United States

Hyperkyphosis (HK), or increased thoracic curvature, is associated with restricted pulmonary function and posture, potentially contributing to poor sleep. A previous study reported that older women with HK had worse self-reported sleep quality, but it is unknown if such an association exists in men. Thus, we studied 754 U.S. MrOS men, average age of 78.1 (SD = 4.8), who had kyphosis measured during the 3rd clinic visit (2007-2009) and future subjective and objective sleep quality assessed between 2009-2012, an average of 2.9 years later. To measure kyphosis, 1.7 cm thick blocks were placed under the participant's head to achieve a neutral spine position while lying supine on a DXA table. We collected data on both subjective (Pittsburgh Sleep Quality Index [PSQI], and Epworth Sleepiness Scale [ESS]) and objective (based upon wrist actigraphy: Total Sleep Time [TST], Wake After Sleep Onset [WASO], Sleep Efficiency [SE], Sleep Onset Latency [SOL]) sleep measurements. Based upon a previously used definition of HK in MrOS, those requiring ≥4 blocks were considered hyperkyphotic (n=145 or 19.2%). In simple and multivariable linear regression analyses, men with HK did not report having worse self-reported sleep characteristics in unadjusted or age and site adjusted models with the PSQI Global Score: β=0.26, 95% CI=-0.29, 0.81 and ESS: β=0.50, 95% CI=-0.22, 1.22. Similarly, there were no significant associations between HK and objective sleep measures including TST: β=4.78, 95% CI=-7.25, 16.80; WASO: β=0.90, 95% CI=-4.84, 6.64; SE: β=-0.19, 95% CI=-1.45, 1.07 or SOL: β=3.21, 95% CI=-3.30, 9.73. When examined as a continuous predictor (blocks ranging from 0-8), there was no difference in the results. Although it would seem that worse fixed posture might interfere with sleep, in this sample of older men, worse kyphosis was not associated with self-reported or objectively measured poor sleep quality.

The Role of Megakaryocytes and Osteomacs in Skeletal Homeostasis and Aging Kevin Maupin*[1], Safa Mohamad[1], Alexandra Aguilar-Perez[2], Artur Plett[1], Hui Lin Chua[1], Paul Childress[1], Marta Alvarez[1], Joydeep Ghosh[1], Irushi Abeysekera[1], Evan Himes[1], Chi Zhang[1], Jung Min Hong[2], Louis Pelus[1], Christie Orschell[1], Angela Bruzzaniti[2], Melissa Kacena[1]. [1]Indiana University School of Medicine, United States, [2]Indiana University School of Dentistry, United States

Aging is associated with many debilitating bone degenerative diseases, including osteoporosis. A growing body of evidence shows that megakaryocytes (MKs) stimulate bone formation by increasing osteoblast (OB) and osteomac (OM) proliferation. Our studies also suggest that age-associated bone degeneration is due to a decrease in the ability of MKs to regulate skeletal homeostasis, despite an increase in total MK number in aged mice. In support of this, transplantation of cells enriched for MKs from young donor C57BL/6 mice increased BV/TV and Tb.N in age-matched recipients by 60% and 49%, respectively. However, similar graft cells from old donor mice did not change BV/TV in young recipients, confirming the reduced efficacy of old MKs to stimulate bone formation. Our studies also show that MKs from young mice (3-4 month) were 1.5-fold more active than MKs from old mice (22-25 month) in stimulating the proliferation of neonatal calvarial cells (which are 95% OB lineage and 5% OM cells), with the predominant effect being the stimulation of OM proliferation (3.6-fold increase). In contrast, neither MKs from young nor old mice were able to increase the proliferation of bone marrow macrophages (BMMs). We found that OMs and BMMs can undergo differentiation into mature osteoclasts (OCs) capable of bone resorption, whereas MK conditioned medium robustly inhibits this process. Moreover, osteoclastogenesis was higher with OM populations from both young (150% increase) and old mice (87% increase), compared to age-matched BMMs, further demonstrating that OMs are functionally distinct from BMMs. To examine the mechanisms behind the functional differences between OMs and BMMs, freshly isolated OMs and BMMs from young and old mice were subjected to single cell RNAseq. Non-biased, bioinformatics analyses identified the oxidative phosphorylation pathway as being the predominant pathway upregulated in old versus young OMs (p=7.3e-5). Likewise, the oxidative phosphorylation pathway was significantly enriched in young OMs compared to young BMMs (p=0.001), providing a possible mechanism for the increased osteoclastogenesis of OMs compared to BMMs. Taken together, these findings suggest that MKs increase OB and OM populations, while simultaneously inhibiting OC development, leading to a net increase in bone mass. However, aging decreases the ability of MKs to stimulate bone formation, as well as increases the ability of OMs to undergo osteoclastogenesis.

MON-0436

Comparing CT bone density values of middle-aged daughters with their elderly fall-prone mothers confirms heritability of BMD except in cases of maternal hip fracture Kenneth Poole*, Monika Kondratowicz, Karen Blesic, Daniel Chappell. University of Cambridge, United Kingdom

If a mother fractures her hip before the age of 80, her daughters are more than twice as likely to fracture their own hips from the age of 65 onward. Suprisingly, this increased risk appears independent of the daughters' femoral neck bone mineral density (BMD) score at age 65. We further explored the familial determinants of daughters' hip BMD, focusing on the influence of maternal hip BMD.20 older women were recruited who had sustained fragility hip fractures (mean age 77.8±9.5), along with 25 of their daughters (51.4yrs ±9.9),. Also recruited were 25 mothers (72.5yrs ±6.2), who had sustained falls (but not hip fracture) and 32 of their daughters (44.9yrs ±6.8). BMD of the femoral neck was measured using CTXA by Quantitative Computed Tomography.Mothers with hip fracture had lower femoral neck BMD than mothers without. In the absence of hip fracture, fall-prone mothers and their daughters had positively correlated age-adjusted femoral neck BMD (r2 0.30, p=0.0007) indicating familial inheritance. However, the bone density of mothers with hip fracture did not correlate with their daughters' BMD (r2 0.06, p=0.24), irrespective of whether the mothers were aged> 80 years at the time of injury. Age-related differences among the daughters' BMD values (-0.5% per annum across the sample aged 32-72 years) did not point to excessive post-menopausal bone loss in daughters of mothers with hip fracture. Heights were strongly correlated between mother and daughter in all groups.Studying these mother-daughter pairs indicated heritability of BMD only in daughters of fall-prone women without hip fracture. Apparently, a maternal hip fracture did not confer low BMD onto her daughters and neither was there an apparent acceleration of BMD loss around the menopause. The aetiology of hip fracture inheritance remains elusive, but may relate to musculoskeletal attributes other than bone density.

MON-0437

Increased Cortical Porosity and Reduced Trabecular Density are Not Necessarily Synonymous With Bone Loss and Microstructural Deterioration Roger Zebaze*[1,2], Elizabeth J. Atkinson[3], Yu Peng[2], Ali Ghasem-Zadeh[1], Sundeep Khosla[3], Ego Seeman[1,2,4]. [1]Depts. Medicine and Endocrinology, Austin Health,University of Melbourne, Australia, [2]Straxcorp Pty Ltd, Australia, [3]Mayo Clinic, United States, [4]Australian Catholic University, Australia

Measurements of cortical porosity and trabecular density are used to estimate fracture risk. However, absolute values of these traits are the net result of their growth-related assembly and age-related deterioration. As bone loss affects both cortical and trabecular compartments, we hypothesized that the desirable characteristic of a surrogate of bone fragility is a measure of the deterioration of both compartments relatively free of growth-related determinants of bone strength. Accordingly, we developed a Structural Fragility Score (SFS) which quantifies the coexisting age-related increment in cortical porosity and decrement in trabecular density relative to their premenopausal mean values. We compared ultra-distal radial microstructure in 99 postmenopausal women with forearm fractures and 105 controls using high resolution peripheral computed tomography. Results are presented as Odds Ratio (95% confidence intervals CI). Cortical porosity was associated with fractures before excluding women with deteriorated trabecular density ($2.30, 1.30 - 4.05, p = 0.004$), not after ($0.96, 0.50 - 1.86; p = 0.91$). Trabecular density was associated with fractures before excluding women with high cortical porosity ($3.35, 1.85 - 6.07, p < 0.0001$), not after ($1.60, 0.78 - 3.28, p = 0.20$). By contrast, the SFS, capturing coexisting deterioration in cortical porosity and trabecular density, was associated with fractures ($4.52, 2.17 - 9.45, p < 0.0001$). BMD was associated with fracture before accounting for the contribution of the SFS ($5.79, 1.24 - 27.1, p = 0.026$), not after ($4.38, 0.48 - 39.9, p = 0.19$). The SFS was associated with fracture before ($4.67, 2.21 - 9.88$) and after ($3.94, 1.80 - 8.6$, both $p < 0.0001$) accounting for BMD. Measurement of the coexisting cortical and trabecular deterioration is likely to identify women at risk for fracture more robustly than absolute values of cortical porosity, trabecular density, or BMD.

Impaired tooth development and mineralization in Slc20a2-deficient mice Laure Meramedtjian*[1], Céline Gaucher[2], Nina Bon[1], Sophie Sourice[1], Jérôme Guicheux[1], Sarah Beck-Cormier[1], Laurent Beck[1]. [1]INSERM UMR 1229, France, [2]EA 2496, France

The importance of phosphate (Pi) in hydroxyapatite crystals suggests a role for membrane proteins controlling Pi uptake during tooth mineralization. Accordingly, we recently identified the Slc20a2 Pi transporter as a potential important player of tooth mineralization (Meramedtjian et al. JDR 2017). Slc20a2 was expressed 2- to 10-fold higher in teeth than the other Pi transporters, and was predominantly expressed in the stratum intermedium and the subodontoblastic cell layer. Interestingly, Slc20a2 knockout mice showed a disrupted dentin mineralization. Here, we extended these initial observations by performing quantitative morphometric and histological analyses. Micro-CT analysis demonstrated decreased incisor and molar volumes in 1-month-old Slc20a2-/- mice ($p<0.0001$). Dentin and enamel volumes were also reduced, and accompanied by an increased pulp volume ($p<0.0001$). Similar abnormalities were also present in incisors from 8-month-old mutants. Movat's pentachrome staining demonstrated normal organization of odontoblast and ameloblast palisades in Slc20a2-/- mice. Nevertheless, there was a marked increase in the unmineralized predentin layer and reduction of the mineralized dentin layer in mutant mice ($p<0.05$), indicating a mineralization defect consistent with the increased pulp volume. Consistent with these data, we illustrated a severe dental fragility of 4-month-old Slc20a2-/- mice evidenced by a high incidence of incisor fractures. At 8 months, Slc20a2-/- incisors exhibited an irregular yellow-brown discoloration and chipping that further illustrated increased fragility. Energy Dispersive X-Ray Spectroscopy revealed an increased Ca/Pi ratio in Slc20a2-/- mice in incisor enamel and mantle dentin at 1 month, and in incisor mantle and circumpulpar dentin at 8 months ($p<0.01$). Consistent with our histological studies, Scanning Electron Microscopy analysis showed that dentin matrix morphology was abnormal in mutant mice, with irregular intertubular dentin, unfused calcospherites and increased interglobular spaces. Interestingly, these latter features being shared with the hypophosphatemic HYP and DMP1 mice, immunohistochemistry analyses revealed that PHEX and DMP1 expression were strongly increased in the predentin of Slc20a2-/- mice. In summary, we illustrated the role of Slc20a2 in dentin mineralization, morphology and fractures, a finding that arise in absence of hypophosphatemia and may involve the role of local regulators of teeth mineralization.

Gestational exposure to nicotine administered by e-cig juice accelerates osteogenesis and bone formation in dams, but suppresses bone growth and development in the pups. Alyssa Falck*, Marcus Orzabal, Raine Lunde, Shannon Huggins, Alexis Mitchell, Josue Ramirez, Vishal Naik, Jayanth Ramadoss, Dana Gaddy, Larry Suva. Texas A&M University, United States

Electronic cigarette (e-cig) use is gaining favor with pregnant women, as it is considered a safer alternative to smoking since e-cig smoke delivers nicotine as aerosol without tobacco or the burning process. However, studies of the effects of e-cig vaping on the adult and developing skeleton are sorely lacking. Therefore, we sought to determine whether maternal exposure during gestation to a conventional vaping base medium with or without nicotine, at levels approximating adult human maternal and neonatal exposure, affected the skeleton of the dams and/or pups. Bred virgin female rats were housed individually in modified chambers and pair-fed. Controls and nicotine-exposed (NIC) dams of similar weight were pair-fed throughout the duration of the study to control for caloric intake. E-cig juice dams (JUICE) were exposed for 2hr to a 1 second puff, every 20 seconds of a vaping base medium (80:20 propylene glycol:vegetable glycerin blend) and matched by weight with NIC dams and pair-fed accordingly. In the NIC group, dams were exposed to an identical duration of the same vaping medium with nicotine added. Rats were acclimatized with a nicotine exposure of 50 mg/ml from gestational days (GD) 5-10 and continued a 100 mg/ml dose from GD 11-21, 5 days/wk. Dams and pups were exposed for postnatal days (PND) 4-10 for a total number of 34 GD exposed hrs and 14 PND exposed hrs prior to tissue collection. Proximal tibia microCT showed that BV/TV and TbN of dams (PND10) was unchanged by JUICE. However, NIC significantly increased tibial BV/TV and TbN, which was associated with an increase in serum P1NP. Ex vivo bone marrow cultures demonstrated that exposure to JUICE or NIC suppressed recruitment of cells into the osteoblast lineage (% AP+ CFU-F). However, further osteoblast differentiation into bone nodules was unaffected by JUICE but significantly increased by NIC. Neonatal measurements on PND10 demonstrated that NIC exposure, but not JUICE, significantly inhibited skeletal element development. Together, these findings demonstrate that gestational nicotine exposure either through conventional tobacco products or e-cig vaping significantly suppresses osteoblast recruitment into the lineage and accelerates osteoblast development and bone formation in vivo. Exposure of pregnant dams to e-cig NIC vaping significantly suppressed fetal growth and skeletal development. It is thus highly likely that e-cig smoke is hazardous to both the dam and the developing fetal skeleton.

Deletion of the Auxiliary Voltage Sensitive Calcium Channel Subunit and Gabapentin Receptor α2δ1 Results in Impaired Skeletal Density, Mass, and Strength Madison Kelly*[1], Karan Sharma[1], Xin Yi[2], Christian Wright[2], Megan Noonan[2], Taylor Gorrell[2], Aaron Gegg[2], Brandon Chenoweth[2], Uma Sankar[2], Julia Hum[1], Alexander Robling[2], Mary Farach-Carson[3], William Thompson[2]. [1]Marian University, United States, [2]Indiana University, United States, [3]University of Texas Health Science Center at Houston, United States

Voltage sensitive calcium channels (VSCCs) tightly control Ca2+signaling. The mechanisms by which the pore-forming (α1) subunit of VSCCs regulates skeletal formation has been well-defined; however, little is known about how the auxiliary subunits, which influence VSCC activity, regulate skeletal health. As α2δ1 is the only known receptor for the antiepileptic and neuropathic pain drug gabapentin, which has deleterious skeletal effects, we examined how α2δ1 regulates bone formation and strength in vivo. Targeted deletion of exon 2 of Cacna2d1, the gene encoding α2δ1, resulted in global peptide loss, with no compensation of other α2δ variants. DXA analyses were carried out at 6, 9, 12, 15, and 18 weeks of age. Body weight of Cacna2d1-/- mice was reduced by an average of 11% over the ages examined. BMD in Cacna2d1-/- mice (n=10) was reduced starting at 6 weeks of age (17% femur, 10% spine, and 7% total BMD) compared to Cacna2d1+/+ littermate controls (n=18). BMC changes were similar, with decreases of 22%-femur and -spine, and 20%-total in Cacna2d1-/-mice (n=10) compared to controls (n=18). Femoral μCT analysis showed decreased trabecular BV/TV (31%, p<0.01), BMC (38%, p<0.05), and TbTh (12%, p<0.05). Reductions in cortical thickness (6%, p<0.05), BMC (9%, p<0.01), and polar moment of inertia (29%, p<0.01) were observed with no changes in cortical BMD. Vertebral μCT showed Cacna2d1-/-mice had decreases in trabecular BV/TV (16%, p<0.05), BMC (25%, p<0.05), and connectivity (23%, p<0.01) compared to control mice. Additionally, trabecular spacing was increased by 12% in Cacna2d1-/-mice. Reductions in endosteal MS/BS (82%, p<0.05), MAR (83%, p<0.05), and BFR (85%, p<0.05) were observed at the midshaft femur, showing impaired bone formation. No changes in serum CTX concentration was observed between Cacna2d1-/- and control (Cacna2d1+/+) mice. Femurs were tested in three-point bending to failure where Cacna2d1-/- mice (n=13) had reductions in stiffness (28%, p<0.01) and ultimate force (20%, p<0.01) compared to controls (n=8). Our results suggest that deletion of the α2δ1 subunit results in reduced trabecular and cortical bone, likely due to impaired bone formation, leading to compromised strength. We propose that α2δ1 is a critical regulator of VSCC activity to control bone formation. As α2δ1 is the receptor for gabapentin, these studies reveal and potential mechanism to understand how this antiepileptic and neuropathic pain drug influences skeletal health.

Global and Conditional Disruption of the Igf-I Gene in Osteoblasts and/ or Chondrocytes Reveals Cell Type- and Compartment-Specific Effects of IGF-I in Bone Chandrasekhar Kesavan*[1], Jon Wergedal[2], Catrina Godwin[2], Subburaman Mohan[1]. [1]VA Loma Linda Healthcare System, Loma Linda University, United States, [2]VA Loma Linda Healthcare System, United States

Recent studies have established that the increase in thyroid hormone levels during the prepubertal growth period is essential for the endochondral ossification that occurs at the epiphyses and secondary spongiosa (SS) of long bones. Thyroid hormone effects on endochondral bone formation are predicted to be mediated via activation of a number of growth factor signaling pathways. One such mediator of TH effects is IGF-I which acts as an endocrine hormone as well as a local autocrine/paracrine regulator in different bone cell types. To establish the relative importance of IGF-I expression in various cell types for endochondral ossification, we used microCT to evaluate the trabecular bone phenotypes at the distal femoral epiphysis and SS of 8–12-week-old male mice with a global knockout (KO) of the Igf-I gene as well conditional KO (cKO) of the Igf-I gene in osteoblasts (OBs) and/or chondrocytes (CCs), and their corresponding control wild type (WT) littermates (n = 6–9 per genotype). OB- and/or CC-specific Igf-I cKO mice were generated by crossing Igf-I floxed mice with transgenic Cre mice in which Cre expression is under the control of regulatory regions of Col1α2 (OB) or Col2α1 (CC) genes, respectively. The reduced trabecular bone mass at the SS in OB- and/or CC-specific Igf-I cKO mice is caused by reduced trabecular number and increased trabecular separation. Immunohistochemistry studies revealed that expression levels of CC (COL10, MMP13) and OB (BSP) markers were reduced in the SS and epiphyses of global IGF-I KO mice. Summary: 1) Disruption of the Igf-I gene globally reduces bone size (TV) to a much greater extent than conditional disruption in OBs. 2) Trabecular bone mass is similarly reduced in the SS of all four genotypes studied. 3) Global Igf-I KO but not cKO of Igf-I locally reduces trabecular bone mass in the epiphysis. Conclusion: Local and endocrine IGF-I actions in bone are pleotropic and dependent on cell type as well as the bone compartment where IGF-I acts.

Genotype	SS - TV	SS - BV/TV	Epiphysis - TV	Epiphysis – BV/TV
Global KO	19.7*	78.5*	31.5*	76.6*
OB-specific cKO	73.8*	81.8*	75.3*	101.6
CC-specific cKO	109.1	83.4*	98.5	105.5
OB/CC double cKO	68.9	81.9*	76.3*	101.5

Values are the % of littermate WT control; * = p< 0.05 vs. control; TV, tissue volume; BV, bone volume

Vertebrate Lonesome Kinase is Required in Early Stages of Skeletogenesis David Maridas*, Laura Gamer, Leila Revollo, Malcom Whitman, Vicki Rosen. Harvard School of Dental Medicine, United States

Vertebrate Lonesome Kinase (VLK) is a novel secreted tyrosine kinase capable of phosphorylating extracellular proteins. Human mutations of Vlk have recently been identified to cause skeletal abnormalities. Accordingly, Vlk-/- mice showed remarkable shortening of their long bones caused by a failure of transition from proliferative to hypertrophic chondrocytes. However, whether the chondrogenic phenotype was caused by loss of Vlk specifically in bone or due to a general loss of Vlk was unknown. Therefore, we investigated the effects of conditional loss of Vlk during development in mice. Using a Prx1-CRE deleter strain with Vlkfl/fl mice, Vlk was removed in the limb bud mesenchyme of the progeny (cKO). At E13.5, we observed a delayed initiation of the primary ossification center in mutant hindlimbs. This lack of primary ossification center persists to E15.5 when the mutant limbs are shorter with absence of mineralization. Interestingly, we noted that the ulna and tibia are both curved with deletion of Vlk. At birth, limbs of cKO mice had developed primary ossification centers but the long bones remain markedly shorter. Unlike Vlk-/- mice, cKO mice survive postnatally. At 1 week of age, the long bones remain shorter and the tibias remain curved. Interestingly, we observe an accumulation of marrow fat at the curvature of the tibia. At 10 days of age, the marrow fat expanded in the tibias. 4 days later, the long bones of cKO mice appear straight but still 8% shorter than the littermate controls. mCT analysis revealed that cortical fraction and thickness are markedly reduced in 2-week-old cKO femurs. Trabecular parameters are also decreased but only trabecular number and separation reached statistical significance. Our data indicates that Vlk is required for embryonic bone development. Prx1-specific deletion of Vlk is sufficient to recapitulate the skeletal growth retardation reported in the Vlk-/- mice. However, the cKO mice are able to survive after birth with shorter limbs. Postnatal bone acquisition appears to be altered with targeted loss of Vlk. So, in addition to its role during bone development, it is possible that VLK is necessary to achieve peak bone mass acquisition. Phosphorylated targets of VLK have also yet to be confirmed but our results suggest that VLK regulates proteins essential for the proper timing of skeletogenesis. Ongoing experiments attempt to resolve those questions and to test if VLK is important during fracture repair.

High Bone Mass Phenotype is Present as Early as 8 weeks in CFW Mice Meghan Moran*[1], Kelsey Carpenter[1], Brittany Wilson[1], Abraham Palmer[2], D. Rick Sumner[1]. [1]Rush University Medical Center, United States, [2]University of California San Dieto, United States

Some Carworth Farms White (CFW) mice have abnormally high aBMD1; 2. This commercially available outbred strain can be stratified into distinct high (HBM) and normal bone mass (NBM) groups using either radiography or microcomputed tomography (μCT) measurements of trabecular BV/TV or vBMD2. In the current study we sought to characterize the anatomic distribution of the phenotype, the timing of its appearance and its relationship to bone resorption and formation. Right femora, tibiae, humeri and vertebral columns of 48 CFW mice equally divided among males and females at 8 and 16 weeks of age were surveyed. Contact radiography showed the presence of the HBM phenotype, as evidenced by greatly enhanced radio-opacity (Fig. 1A), in the distal metaphysis in 13 of 48 femora. Of these 13 mice, 10 were HBM positive in the proximal tibia and 6 of these 10 mice were also HBM positive in the proximal humerus. The HBM phenotype was unaffected by sex (χ2, p=0.653) or age (χ2, p=0.512). The HBM phenotype was not observed in the vertebrae. Histology showed more trabecular bone in HBM mice with no difference in osteoblasts or osteoclasts and no evidence of pathology (Fig. 1B). μCT showed a bimodal distribution of distal femoral metaphyseal BV/TV and vBMD (Fig. 1C, 1D), consistent with our previous findings. μCT measurements, body weight, femur length and bone remodeling markers were subjected to ANOVAs with radiographic classification for HBM, age and sex as the main factors (Table 1). Distal femoral metaphyseal BV/TV and vBMD were significantly higher in the HBM group regardless of sex or age (Fig. 1E, 1F). Midshaft femoral cortical area (Ct. Ar) was greater in males compared to females, greater in the HBM group and the greatest between-group difference was present at 16 weeks (Fig. 1G). Body weight, femoral length and the bone remodeling biomarkers, CTX-1 and PINP did not vary as a function of HBM phenotype (Fig. 1H, 1I).The prevalence of the radiographic HBM phenotype was ~30% in the surveyed mice, did not differ between males and females and was not associated with variance in either bone length or body size. The lack of difference in the bone remodeling markers suggests that any differences in bone resorption or formation responsible for the phenotype had equilibrated by 8 weeks. Thus, the HBM phenotype in CFW mice is first evident before the cessation of longitudinal bone growth, is stable through the acquisition of peak bone mass and has a site-specific distribution.

Trajectories of Human Trabecular Bone Adaptation within a 4D Landscape of Tissue Anisotropy Nicolas Piche*[1], Natalie Reznikov[2], Ievgeniia Morozova[3], Iskandar Tamimi[4], Jun Song[2], Faleh Tamimi[2]. [1]Objects Research Systems Inc., Canada, [2]McGill University, Canada, [3]Trikon Technologies Inc, Canada, [4]Hospital Carlos Haya, Spain

Anisotropy of trabecular bone is a result of life-long functional adaptation. Anisotropy physiologically increases from infancy to adulthood, and it is more pronounced where mechanical loading is predictable, consistent and strenuous. There are conflicting reports in the literature regarding anisotropy in the context of bone pathology. For example, increased anisotropy accompanies decreased bone mineral density in osteoporosis (causing fragility), whereas in osteoarthritis, increased anisotropy leads to joint degeneration attributable to excessive subchondral bone stiffness. The reason for these inconsistent effects of anisotropy on bone biomechanics is that there are several independent pathways that lead to bone anisotropy. Such pathways include enhanced preferred orientation of the bone-marrow interface, and enhanced volume orientation which can be achieved either by coarsening of certain trabecular elements and/or by thinning of other elements. We present a machine-learning algorithm for identification of salient characteristics of trabecular bone. Samples were imaged by μCT and analyzed using a set of independent parameters, such as interface orientation, volume moment of inertia and network connectivity orientation (all of which contribute to net mechanical anisotropy), and trabecular thickness distribution that accounts for volume fraction. We present these parameters as "coordinate axes" in a 4D landscape. Normal and pathologic bone samples characterized by these coordinates were mapped onto the 4D landscape. We used 20 μCT volumes of human bones unaffected by pathology (proximal femur, distal femur and calcaneus), and more than 80 μCT volumes of pathologic bone samples (hip osteoarthritis, osteoporotic femoral neck fracture, talar joint ankylosis and clubfoot). Mapping the specimens onto the 4D landscape allows principal component analysis to be conducted for identification of the trabecular bone adaptation trajectories in both health and disease. This illustrates how continuous bone adaptation can result in its over-adaptation, which is an exaggerated narrow specialization to monotonous, repetitive loading. Thus, over-adaptation undermines the biomechanical fitness of bone to accidental, non-stereotypical loading. We explain the endpoints of trabecular bone adaptation trajectories as disuse, overuse or abuse in the context of common and rare skeletal pathologies.

Forward-genetic ENU screen identifies genes regulating skeletal development in mice Jonathan Rios*[1], Carol Wise[1], Bruce Beutler[2]. [1]Texas Scottish Rite Hospital for Children, United States, [2]University of Texas Southwestern Medical Center, United States

Embryonic and post-natal skeletal development is a highly regulated and dynamic process that is impacted by numerous genetic and non-genetic factors. Genome-wide association studies have identified numerous loci associated with variation in bone quality (bone mineral density, BMD). However despite these efforts, the current catalogue of genes regulating proper skeletal development is far from complete. To discover additional genes regulating proper skeletal development, we initiated live-animal skeletal screening as part of a high-throughput N-ethyl-N-nitrosourea (ENU)forward-genetic screen in mice. Briefly, pups from inbred (C57BL/6J) ENU-mutagenized mice are back-crossed to produce ~600 G3

mice weekly that undergo dual-energy X-ray absorptiometry (DEXA) and X-ray imaging. Images are evaluated for tibia and femur lengths and BMD, and ENU-induced mutations tested for statistical association with dominant, additive, and recessive phenotypes.As proof-of-concept, we present preliminary results from G3 mice harboring ENU-induced damaging mutations cumulatively targeting ~1% of all genes in the mouse genome. First, the 'bone-loss'mouse harbors a recessive ApsaF261Imutation associated with a ~20% reduction in tibia and femur BMD. Mutations in human ASPA, encoding Aspartoacylase, cause Canavan disease. Second, the 'cooper'mouse carries a recessive IduaD202Emutation associated with a ~20% increase in tibia and femur BMD. Recessive loss-of-function mutations in human IDUA, encoding Alpha-L-Iduronidase, cause Hurler syndrome. Skeletal development is also subject to hormonal regulation. The 'ito4'mouse harbors a recessive TgI1352Kmutation in Thyroglobulin that results in a dwarf mouse with significant reductions in tibia, femur, and pelvis lengths, as well as changes in fat deposition. In contrast to other large-scale mouse knockout efforts, the ENU-induced forward screen is capable of detecting significant association with gain-of-function missense mutations. We detected significant association of a Bicc1T469Mmutation in the 'Pebbles' mouse with a dominant increase in tibia and femur BMD. Interestingly Bicaudal C Homolog 1, the protein encoded by Bicc1, positively regulates osteogenesis and was recently associated with BMD in humans. Our results show the feasibility of an unbiased high-throughput ENU forward-genetic approach to discover genes relevant in human skeletal development and disease.

NF-kB Activation in BMSC's Drives Bone Loss Via Cell Intrinsic and Extrinsic Effects Manoj Arra*, Gaurav Swarnkar, Gabriel Mbalaviele, Yousef Abu-Amer. Washington University in St. Louis School of Medicine, United States

The skeletal system undergoes constant turnover due to an interplay between osteoclast and osteoblast activity, with bone loss occurring due to an imbalance between these two cell types. However, there exist many other cells that affect bone quality by regulating the number and function of osteoclasts and osteoblasts. BMSC's are a numerically minor population in the marrow but play an extremely critical role by acting as the precursors for osteoblasts and marrow adipocytes, thus requiring great attention for understanding the physiology of bone loss. One of the most studied and recognized drivers of bone loss is inflammation, which has been shown extensively to promote osteoclastogenesis by activating the NF-kB pathway, the key signaling pathway of the inflammatory response. However, the effect of inflammation and NF-kB signaling on osteoblasts and their precursor BMSC's is less clear and somewhat controversial. Here, we describe the use of genetic models to study the effect of chronic inflammation on BMSC differentiation and function. We use a constitutively active form of IKK2 (IKK2ca), which is an essential kinase required for activating NF-kB transcription factor, which we have previously shown is a model of chronic inflammation that consistently activates NF-kB in the absence of inflammatory stimuli while sparing the pleiotropic effects of these exogenous stimuli. IKK2ca was expressed under the control of the PRX1-cre to target BMSC's in vivo, resulting in a profound phenotype when activated in utero, including severe runting and low bone mass. Further, the bone marrow was found to be extremely dense and filled predominantly with inflammatory cells, and lacked the presence of marrow adipocytes. Histology showed elevated osteoclast activity and decreased osteoblast activity, likely contributing to the severe bone loss. In vitro studies supported these in vivo findings and displayed that IKK2ca inhibits BMSC differentiation, while also increasing their ability to support myeloid cell survival and differentiation into osteoclasts through the secretion of extracellular factors. These results highlight the response of BMSC's to inflammation and their ability to drive an inflammatory phenotype in vivo to cause bone loss. This work identifies BMSC's as a critical cell type for promoting bone loss. Future work involves studying the effect of IKK2ca activation in BMSC's in adult mice as well as the mechanisms of differentiation inhibition.

Loss of the histone methyltransferase Ezh2 induces cellular senescence in mesenchymal stem cells Amel Dudakovic*, Catalina Galeano-Garces, Christopher Paradise, Daniela Galeano-Garces, Farzaneh Khani, Roman Thaler, Andre Van Wijnen. Mayo Clinic, United States

Ezh2, a histone 3 lysine 27 (H3K27) methyltransferase, plays a critical role during skeletal development and osteoblast differentiation. We previously showed that pharmacological inhibition of Ezh2 enhances osteogenesis, stimulates bone formation, and mitigates bone-loss associated with estrogen depletion. However, conditional genetic loss of Ezh2 early in the mesenchymal lineage (Ezh2 cKOPrrx1, Ezh2flox/flox: Prrx1-Cre) causes skeletal abnormalities as a result of patterning defects. Interestingly, Ezh2 cKOPrrx1 animals exhibit enhanced marrow adiposity and premature suture fusion. These observations suggest that Ezh2 may protect mesenchymal stem cells from premature aging and senescence. Here, we examined the impact of mesenchymal loss of Ezh2 on cellular senescence in vitro and in vivo. Treatment of adipose-derived mesenchymal stem cells (AMSCs) with GSK126, a specific Ezh2 inhibitor, up-regulates the expression of many senescence-associated secretory phenotype (SASP) genes (e.g., IGFBP2, ICAM, IL6) as measured by mRNA-Seq analysis. Similarly, Ezh2 inhibition up-regulates the expression of the CDKN2A, a key marker of

cellular senescence that encodes the cell cycle inhibitor p16/INK4A and the p53 related p19/ARF protein. Immunofluorescence (IF) microscopy demonstrates enhanced staining of several senesce-related markers including p16, phosphorylated p53 (p-Ser15), and γH2AX (p-Ser139) in GSK126-treated AMSCs. Prolonged exposure of AMSCs to GSK126 significantly increases senescence-associated β-galactosidase (β-gal) staining. Similar to AMSCs, mRNA-Seq assessment of primary calvaria derived from control (CON) and Ezh2 cKOPr-rx1 demonstrates that several SASP genes and Cdkn2a are up-regulated with the loss Ezh2 in the mesenchyme. Indeed, IF results show enhanced p16 staining in proximal tibias derived from Ezh2 cKOPrrx1 three-week old animals. Additional assessment reveals enriched detection of lipofucin (Sudan-Black-B staining), an established hallmark of senescent cells, in mouse tibias that lack Ezh2 expression in mesenchymal cells. Taken together, Ezh2 loss in the mesenchymal compartment induces cellular senescence. Thus, while Ezh2 serves as a critical inhibitor of osteogenic differentiation as seen in previous studies, our current study shows that this epigenetic regulator also protects mesenchymal stem cells from undergoing premature senescence.

The Effect of Ascorbic Acid on BMP-2 Treated C3H10T1/2 Mesenchymal Stem Cells in Phosphate Deficient Conditions Matthew Bui*, Amira Hussein, Louis Gerstenfeld. Boston University School of Medicine, United States

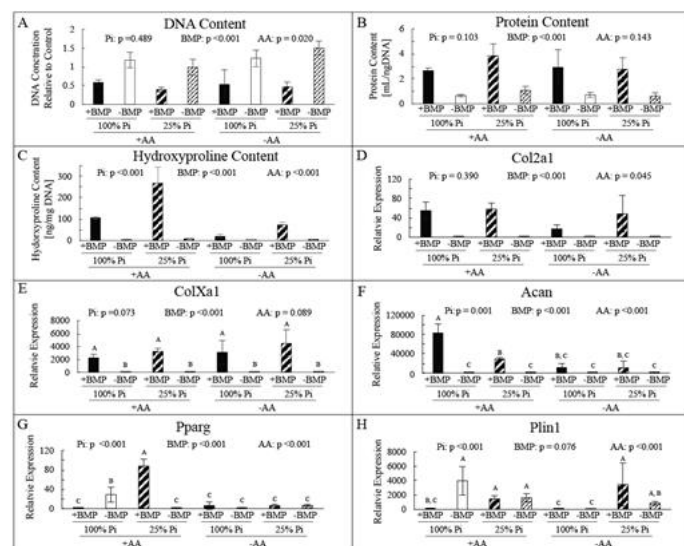
Introduction: Our prior in vivo studies showed that dietary phosphate deficiency impairs oxidative phosphorylation and decreased BMP-2 signaling that promoted MSC chondrogenic differentiation during fracture healing. In this study we examine the molecular relationship between BMP-2 mediated chondrogenic differentiation and energy consumption. We further assessed the extent to which collagen hydroxylation that increases during chondrocyte differentiation contributes to energy use. Methods: C3H10T1/2 murine cells were expanded in growth medium DMEM with 10% FBS). At 60% confluence (day 0), cells were switched to differentiating media (α-MEM with 5% FBS and 1X insulin-transferrin-selenium) containing either 100% (1mM) or 25% (0.25mM) inorganic phosphate (Pi), ± 200ng/mL BMP-2 (BMP), and ±0.2 mM L-ascorbic acid (AA; to facilitate collagen hydroxylation). Cells grown in α-MEM with 10% FBS were used as a baseline control. At day 8, total DNA, protein, and hydroxyproline (HP) content were examined. Chondrocyte and adipocyte gene expression were measured.Results: The +BMP media groups contained less DNA and more protein than the –BMP differentiation media groups (p<0.001). There was a significant interaction between Pi and AA treatment (p=0.030), with 25% Pi +AA groups producing more protein than 100% Pi +AA groups. Hydroxyproline production was greater in +BMP, +AA, and 25% Pi groups (p<0.001). Col2a1, Acan, and ColXa1 expression were increased in +BMP groups. AA treated groups expressed significantly more Col2a1and Acan than –AA groups. 100% Pi media had greater Acan expression than 25% Pi groups (p=0.001) while 25% Pi media trended to lead to greater ColXa1 expression over 100% Pi groups (p=0.073). Pparg and Plin1 expression were increased in the 25% Pi mediums. There were no differences in Ucp1 expression.Discussion: BMP-2 promoted both chondrogenic and adipogenic differentiation while Pi deficiency in the presence of BMP-2 increased adipogenesis while diminishing chondrocyte maturation. Hypertrophic chondrocyte expression was decreased in Pi deficient media, which coincides with increased protein and hydroxyproline production observed in low Pi conditions. AA increased HP production in all BMP-2 treated samples independent of Pi levels however HP levels were the highest in low Pi +BMP +AA cultures. Together, the results indicate that increased energy consumption is related to BMP-2 mediated differentiation and promotion of collagen hydroxylation.


Figure 1. Relative to Day 8 controls: (A) DNA content; (B) total protein; (C) hydroxyproline content; (D-H) Gene expression. If Pi*BMP*AA p <0.05, different letters indicate statistically significant differences between groups.

MON-0492

Notch and Wnt Signaling Crosstalk Regulates Skeletal Stem/Progenitor Cell Behavior during the Early Stages of Fracture Repair Sooyeon Lee*[1], Anna Josephson[2], Philipp Leucht[1]. [1]Dept. of Orthopaedic Surgery, NYU Langone Orthopedic Hospital, United States, [2]Dept. of Cell Biology, NYU School of Medicine, United States

Bone regeneration is a complex process that requires the coordinated efforts from multiple different cell types and tissues. When bone healing fails, patients are often left with painful disability and deformity. During fracture healing, recruitment of skeletal stem/progenitor cells (SSPCs) to the injury site is one of the first steps. Once SSPCs have migrated to the fracture site, they begin to divide in an effort to provide a sufficient number that then can undergo osteogenic differentiation to form a bony callus. There is evidence that the Notch and Wnt signaling pathways are essential for bone regeneration after injury, and preliminary data point towards a regulated interplay between the two pathways. We hypothesize that Notch signaling predominates in the initial fracture callus to support the expansion of the SSPC pool; this is followed by an increase in Wnt responsiveness, indicating onset of differentiation. The coordinated activity between Notch and Wnt signaling shapes the initial repair process of a skeletal injury site.We first focused our attention to the temporal expression profile of members of the Notch and Wnt signaling family within the injury site. Using qPCR, we detected that Notch target genes are significantly up-regulated in the early phase of fracture healing, while Wnt downstream targets were upregulated at a later stage during fracture repair. This switch from Notch to Wnt occurred around 7 days post-injury, a time when osteogenic differentiation dominates within the injury site. We then used immunofluorescence to characterize the spatial signaling profile and demonstrated that Notch pathway components were expressed during the early proliferative phase of fracture healing. Using a Wnt reporter mouse, we showed that Wnt-responsive cell appeared during the early differentiation phase (day 7) and that these cells were also osterix-positive, indicating their osteogenic lineage commitment. Transcriptional analysis of SSPCs isolated by flow cytometry during early fracture healing revealed a temporal expression of Notch and Wnt downstream targets consistent with the previous immunostaining. Finally, in vitro studies provided evidence that Notch and Wnt signaling regulate each other, e.g. inhibition of Wnt signaling leads to an enhanced/prolonged Notch activation. Taken together, we provide evidence that SSPC proliferation and differentiation is tightly regulated by Notch and Wnt signaling during healing.

Differences in osteoprogenitor populations between bone compartments Brya Matthews*[1], Francesca Sbrana[2], Sanja Novak[2], Danka Grcevic[3], Ivo Kalajzic[2]. [1]Department of Molecular Medicine and Pathology, University of Auckland, New Zealand, [2]School of Dental Medicine, University of Connecticut, United States, [3]Department of Physiology and Immunology, University of Zagreb, Croatia

The aim of our study is to evaluate the frequency of mesenchymal stem/progenitor cells in different bone compartments. Studies often consider bone as whole without dissecting periosteum versus endosteum or bone marrow (BM). Flow cytometry is a proven technique to identify stem/progenitor cells, and has recently been applied to the skeletal system. Populations of 'skeletal stem cells' (SSC, CD51+CD90-Ly51-CD105-) and 'bone, cartilage and stromal progenitors' (BCSP, CD51+CD90-Ly51-CD105+) were identified in whole bone of neonatal mice (Cell 160:285, 2015). These results were not validated in adult animals. We identified long term progenitors as label retaining cells (LRC) by doxycycline-inducible H2B-GFP, with labelling from P10-P45, then 13+ weeks chase. Col2.3-GFP reporter mice were used to identify osteoblasts. Analyses were done on the 'mesenchymal' fraction, CD45/Ter119/CD31- (CD45- cells).Periosteal CD45- cells are enriched for Sca1, PDGFRα, CD51 and CD90. Sca1 and PDGFRα are present on ~15% of periosteum, 1% of endosteum and 0.1% BM cells. In contrast, endosteal cells are CD105+ (~50%) compared to 10% in periosteum. CFU-F assays indicate that CD45- cells from periosteum form 20x more colonies than endosteal cells. 1% of cells in periosteum and endosteum had a BCSP phenotype, and <0.1% in the BM. SSC were more common, representing 11% periosteum, 2.5% endosteum and 2% BM. The endosteum contains Col2.3GFP+ osteoblasts that do not express Sca1, PDGFRα and CD90, but are CD51+ (31.5%) and CD105+ (13.8%). A large proportion of osteoblasts have BCSP or SSC phenotype, and over 30% of BSCP and SSC in the endosteum are osteoblasts.LRCs identified by H2B-GFP were present in all tissue compartments, and showed enrichment of Sca1, CD51 and CD90, but reduced CD105. Periosteal LRCs formed more CFU-F than negative cells, although greater enrichment for CFU-F was achieved sorting for Sca1+ or CD90+ cells. LRCs also contributed to in vivo bone formation, as did Sca1+ cells. Our results show that BCSP and SSC do not specifically identify stem cells in adult bone as many mature osteoblasts express these marker panels. However, the periosteum of adult mice is enriched for skeletal stem/progenitor cells compared to endosteum and BM. Label retention along with Sca1, CD51, CD90 and PDGFRα, but not CD105, are useful for identifying these populations. In conclusion, developmental stem cell biology cannot be simply translated to adult stem cells.

Cartilage is Derived from Nerve in Trauma-Induced Heterotopic Ossification
Elizabeth Olmsted-Davis*[1], Elizabeth Salisbury[2]. [1]Baylor College of Medicine, United States, [2]UTMB, United States

Our studies suggest that cartilage forms at exactly the same time as bone in heterotopic ossification (HO) and not before bone as would be expected for an endochondral process. Its formation is a direct result of the hypoxic microenvironment established by transient brown adipocytes (tBAT). We have previously shown that tBAT is derived from perineurial fibroblasts associated with peripheral nerves. However, the cartilage progenitor in this model has yet to be elucidated. Previous data suggests that it's derived from a macrophage-like cell, and here we present that it is a subset of tBAT. A murine model of HO that involves the delivery of low levels of BMP2 was used in these studies. This is model has been shown to match the early stages of human HO. Preliminary studies using the tamoxifen-inducible Wnt1-cre: R26RTdTomato red system, suggest the presence of the red reporter in some of the chondrocytes. However, it is unclear whether the lack of more of the red reporter is due to the pulse-lineage tracing methodology, where an intermediate such as the labeled perineurial fibroblasts, are more delayed in their appearance. To address this we have employed other lineage tracing models including the tamoxifen-regulated GLASTcre: R26RTomato red and the UCP1Cre-R26TdTomato red reporter mice. We selected lineage tracing with GLAST, since it appears in a small subset of our perineurial cells on peripheral nerves, after induction of HO. These cells appear to migrate and expand at the site of bone formation. Previously it was reported that GLAST was expressed in the chondrocytes made during HO. Lineage-tracing studies do show the presence of GLAST in chondrocytes. Cartilage formation correlates with perineurial cells using the UCP1 lineage-tracing model. However, surprisingly, UCP1 is quickly down regulated in the cells prior to chondrogenesis. Only a subset of these cells appeared to contribute directly to cartilage. Additional analysis of these cells supports the idea that they also express key macrophage markers. The data collectively suggests that these perineurial cells function similarly to astrocytes in the central nervous system, in that they display a large amount of heterogeneity and have a variety of functions. Recent data suggests that astrocytes express a large number of cartilage matrix proteins and may function as cartilage under specific conditions. Thus the cartilage formed during HO may be unique in that it forms from perineurial progenitors.

Nucleoskeletal Actin-Lamin Architecture Regulates MSC Runx2 Directed Osteogenesis Jeyantt S. Sankaran*[1], Buer Sen[1], Zhihui Xie[1], Cody Mcgrath[1], Maya Styner[1], Amel Dudakovic[2], Andre J. Van Wijnen[2], Janet Rubin[1]. [1]UNC Chapel Hill, United States, [2]Mayo Clinic, United States

Nucleoskeletal lamin scaffolds genetic material critical to mesenchymal stem cell (MSC) fate. A dynamic actin cytoskeletal network, comprised of monomeric and polymeric actin, interacts with this scaffold, regulating its shape and structure. We previously showed that actin transfer into the nucleus profoundly promoted MSC differentiation; further, structural changes in internal nuclear actin structure were crucial to MSC lineage. Here we wished to understand how intranuclear actin structure epigenetically specified osteogenic differentiation. Specifically, we aimed to alter internal nuclear actin structure without changing the cytosolic actin network in murine MSC. We first found that the diaphanous formins, which regulate actin polymerization, are compartmentalized: mDia1 is cytoplasmic while mDia2 is almost exclusively intranuclear. Thus, we knocked down nuclear mDia2 using siRNA. Compared to MSC treated with control siRNA, mDia2 KD robustly and rapidly stimulated osteogenesis: at 3d, osterix (Sp7) and osteocalcin (Bglap) gene expression increased by 4-fold, and alkaline phosphatase activity (at 5d) was upregulated 3 fold (p<0.05). Upregulation of multiple other osteogenic genes was confirmed by unbiased mRNAseq. Importantly, mDia2 KD did not promote adipogenic differentiation. We thus hypothesized that nuclear F-actin might support a nucleoskeletal architecture that silences the osteogenic genome. Confocal microscopy showed that F-actin ring co-localizes with laminB on the inner surface of the MSC nuclear envelope. After mDia2 KD, structural changes were prominent: 67% of mDia2 KD cells showed >2 lamin folds extending into the nucleus whereas only 7% control cells had lamin folding. On average, mDia2 KD cells had 4x lamin folds extending 3x longer than in control cells (p<0.05). LaminB staining was decreased by 22% (cf control, p<0.05) and pixel intensity was more variable in mDia2 KD nuclei cf to control (75% vs 58%, p<0.05) indicating a non-uniform distribution of the nuclear envelope. LaminB folding due to mDia2 KD was accompanied by intense nuclear staining with Runx2 Ab. In sum, our findings indicate that actin polymers provide structure to the nucleoskeleton. Inhibiting F-actin polymerization by nuclear mDia2 knockdown leads to a profound alteration in laminB structure that activates nucleoskeletal bound Runx2. This suggests that the actin-lamin interface dynamically silences the osteogenic Runx2 cistrome.

Oxidized Phospholipids Are Ligands for LRP6 in Bone Marrow MSCs
Lei Wang*, Weiping Su, Xiaonan Liu, Janet Crane, Xu Cao, Mei Wan. Johns Hopkins University School of Medicine, United States

Human mutations in Low-density lipoprotein receptor–related protein 6 (LRP6), a known positive regulator of osteoblast bone formation, have been linked to early onset hyperlipidemia, atherosclerosis, and osteoporosis. Our objective is to define whether and how LRP6 is involved in hyperlipidemia/atherosclerosis-associated bone loss. LRP6 is a co-receptor for Wnt and can be recruited by multiple growth factors/hormones, such as PTH, PDGF-BB, TGFβ and BMP, to their receptors facilitating intracellular signaling activation. However, these factors are not actual ligands of LRP6 as their direct binding to LRP6 has not been recognized. Here, we report that oxidized phospholipids (oxPLs) are native ligands of LRP6. oxPLs are bioactive components in oxidized LDL particle (oxLDL), which serves as a hallmark for hyperlipidemia and atherosclerosis. We detected high levels of oxPLs in bone marrow in mice fed a Western high fat diet. Importantly, bone marrow mesenchymal stromal cells (MSCs) had a reduced cell surface LRP6 expression with an impaired osteogenic differentiation capacity. Consistently, direct treatment of MSCs with oxLDL and individual biologically active oxPLs, including POVPC and PGPC, caused a rapid decrease in cell surface LRP6. Thus, MSC surface LRP6 may act as a specific sensor of oxPLs in bone marrow. By employing multiple approaches, including flow cytometry analysis, fluorescence spectra-based ligand-receptor binding assays, biotin-precipitation assays, protein-lipid overlay assays, and subcellular localization assays, we showed that LRP6 directly bound and mediated the uptake of oxPLs by MSCs. The binding of oxPLs and LRP6 led to endocytosis of LRP6 through a clathrin-mediated pathway, decreasing the responses of MSCs to osteogenic factors such as Wnt, PTH, and BMP. As a result, osteoblast differentiation of MSCs was diminished. We also tested whether increasing cell surface LRP6 expression could restore the impaired MSC function. A specific inhibitor of clathrin-dependent endocytosis pathway elevated cell surface LRP6 level, and almost restored the blunted response of MSCs to osteogenic factors by oxPLs. Similarly, expression of Mesd, an ER chaperone protein specifically targeting LRP6 on cell surface, increased oxPL-impaired osteogenic differentiation of MSCs. Thus, LRP6 functions as a receptor and molecular target of oxPLs for their adverse effect on MSCs. Our study reveals a potential mechanism underlying hyperlipidemia-associated bone loss.

The Power and Potential of Alternative Splicing to Dictate Stem Cell Fates in Bone Yuanyuan Wang*[1], Rene Chun[2], Emad Bahrami-Samani[3], Lan Lin[3], Yi Xing[3], John Adams[4]. [1]Bioinformatics Interdepartmental Graduate Program, University of California, Los Angeles, United States, [2]Department of Orthopaedic Surgery, University of California, Los Angeles, United States, [3]Department of Microbiology, Immunology and Molecular Genetics, University of California, Los Angeles, United States, [4]Department of Orthopaedic Surgery, Department of Molecular, Cell & Developmental Biology, University of California, Los Angeles, United States

Almost all multi-exonic genes in human genome are subject to alternative splicing (AS) under the regulation of RNA binding proteins (RBPs). Despite the critical role of AS in the establishment of tissue identity and development, there has been no unbiased, transcriptome-wide analysis of AS of human mesenchymal stem cells (hMSC) that reside in the human skeletal niche. As such, the primary goal of this study is to comprehensively evaluate how AS, under control of RBPs, affect the differentiation fates of hMSCs. Initially, pair-wise comparisons between hMSC and its terminally differentiated progeny in the osteoblast and adipocyte lineage were performed using RNA-seq data from the ENCODE consortium; these studies revealed widespread changes in AS between the MSC and the two derivative cell types. We then provoked osteogenic differentiation of human bone marrow-derived MSC (hbmMSC) and performed RNA-seq in triplicate wells of cells on day 0-to-12. Transcriptome-wide analysis identified temporal coordination of numerous significantly differential exon-skipping (SE) events and significantly differentially expressed RBPs during stepwise differentiation. By co-expression-splicing analysis, we identified 5304 correlative temporal patterns in expression of a specific RBP and a specific SE event (r2>0.5), some of which reside in known osteogenesis-related genes and others in transcription factors (TFs) known to shape the MSC-to-osteoblast pathway. Six RBPs with the following characteristics were identified as key drivers of AS during this differentiation: i) differentially expressed; ii) temporally correlated with differential SE events; and iii) cognate RNA binding motifs enriched within the alternative exon or its adjacent flanking introns. Perturbation RBP expression was then performed to ascertain if those RBPs impact differentiation trajectories. Robust siRNA knockdown of one of these six candidate RBPs, KHDRBS3, significantly inhibited osteoblastogenesis and bone formation in vitro, as indicated by both alkaline phosphatase staining and maturation-dependent gene expression (see Figure). Our findings support the hypothesis that creation of developmentally-regulated AS isoforms, especially of TFs, is controlled, at least in part, by differential expression of key RBPs. Delineating time-dependent, coordinate AS and RBP expression-action changes are crucial to understanding the molecular mechanisms underlying the hbmMSC-to-osteoblast differentiation program.

Multipotent Schwan cell precursors contribute to chondro- and osteo-progenitors during embryogenesis Meng Xie*[1], Dmitrii Kamenev[2], Baoyi Zhou[1], Maria Eleni Kastriti[1], Kaj Fried[2], Igor Adameyko[1], Viacheslav Dyachuk[2], Andrei Chagin[1]. [1]Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm SE-171 77, Sweden., Sweden, [2]Department of Neuroscience, Karolinska Institutet, Stockholm SE-171 77, Sweden., Sweden

The Schwan Cell Precursors (SCPs) are emerging as a new type of multipotent stem cells. Their contribution to melanocytes, parasympathetic nerves, tooth mesenchymal cells and adrenal cells has recently been shown. The cellular and developmental origin of osterix (Osx) positive chondro- and osteo-progenitors has long been debated. Here, employing genetic tracing we show that a number of Osx-positive progenitor cells is originated from the SCPs. Additionally, we revealed that SCPs differentiate into chondrocytes and osteocytes during mouse embryonic development. The process seems to be evolutionary conservative since such a contribution was also observed in zebrafish. Our findings expand the multipotent potential of the SCPs by revealing their connective tissue fate and provide a novel link between the nervous and skeletal systems.

The perivascular progenitor cell vesicular secretome incites bone repair via pleiotropic effects on endogenous skeletal progenitor cells Jiajia Xu*[1], Carolyn Meyers[1], Leslie Chang[1], Leititia Zhang[1], Yiyun Wang[1], Kristen Broderick[1], Bruno Peault[2], Aaron James[1]. [1]Johns Hopkins University, United States, [2]University of California, Los Angeles, United States

Human perivascular progenitors are known to incite bone defect healing, predominantly via paracrine means. Adipose resident perivascular progenitors (perivascular stem cells, PSC) may be derived by fluorescence activated cell sorting. Here, we detail how extracellular vesicles obtained from the perivasculature incite bone healing via modulation of endogenous skeletal stem cell (SSC) behavior. Methods:Human white adipose tissue was processed using previously established protocols to isolate PSC, including CD146+CD34-CD45-CD31- pericytes and CD34+C146-CD45-CD31- adventitial cells. PSC were first examined in non-contact co-culture with human bone marrow, culture derived SSC. Next, PSC derived extracellular vesicles (PSC-EV) were obtained by ultracentrifugation. Validation was performed based on ISEV minimal experimental requirements, including Western blot and electron microscopy. The effects of PSC-EV were either examined in vitro on human SSC, or in vivo in a mouse calvarial defect. For in vitro studies, SSC proliferation, migration and osteogenic differentiation were assessed (1, 2.5, and 5 ug/mL). Affymetrix microarray examined the SSC transcriptome before and after PSC-EV treatment. For in vivo studies, PSC-EV were applied by injection to mouse calvarial bone defects, and healing was assessed by microCT and histology.Results: Human PSC induced significant changes in SSC behavior in non-contact co-culture, including an increase in proliferation, migration, and osteogenic differentiation. These in vitro effects were accompanied by release of PSC-derived, fluorescently labelled extracellular vesicles (PSC-EV), which fused with recipient cells. These findings were replicated by addition of PSC-EV to SSC cultures. Transcriptomic analysis of PSC-EV treated SSC demonstrated a robust change in key signaling pathways, as observed by principal component analysis, gene ontology, and ingenuity pathway analysis (Fig. 1A,B). When applied to a calvarial defect model, PSC-EV led to a marked increase in bone healing overtime (up to 70.0% increase in healing), accompanied by increased SSC proliferation, migration, and in situ osteogenic differentiation (Fig. 1C).Our data suggest that PSC derived extracellular vesicles (PSC-EV) induce marked changes in SSC behavior that converge to yield successful bone defect repair. Identifying the essential cargo delivered by PSC-EV that dictates the bone forming effects is the ongoing focus of study.

Specific Knockout of Gsα in Murine Osteoblast Precursors Leads to Blunted Response to Intermittent PTH Administration in vivo Mingxin Xu*, Deepak H. Balani, Sophia Trinh, Henry M. Kronenberg. Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, United States

A lineage-tracing strategy, using a tamoxifen-dependent, promoter-driven cre system, has identified Sox9-expressing cells as a group of early osteoblast precursors. Intermittent PTH administration can significantly increase the number of these precursors through direct action on the PTH receptor. As a G protein-coupled receptor, PTH receptor can activate multiple G proteins, including Gsα. To assess whether Gsα has a role in the PTH-mediated increase of Sox-expressing precursors, Sox9-creERT2; R26RTomato; Gsαfl/fl triple-transgenic mice (called floxed mice here) and Sox9-creERT2; R26RTomato; GsαWT/WT mice (called WT mice here) received 2 mg tamoxifen intraperitoneally at P42 and received vehicle or PTH (100ng/g body weight) administration daily for 7 days. Knockdown of transcripts encoding Gsα was confirmed by FACS-sorted tdTomato+ cells from floxed mice 2 days after tamoxifen injection. TdTomato+ cells were counted blindly in pre-determined boxes in 12 sections from each of three tibiae per condition. In WT mice, PTH treatment significantly (P<0.05) increased the number of tdTomato+ cells in metaphyseal (105.09±15.61 vs. 23.09±9.45) and cortical (39.95 ±12.82 vs.17.77±4.30) bone of tibia when compared to vehicle. However, PTH could only increase the number of tdTomato+ cells in metaphyseal (58.29±14.19 vs. 10.39± 0.59, P<0.05), but not in cortical bone (10.07±8.50 vs. 12.20±2.55), in mice with specific knockout of Gsα. The increase in tdTomato+ cells in the metaphysis of floxed mice was lower than the increase in the metaphysis of WT mice (105.23.09±15.61 vs. 58.29±14.19, P<0.05). These findings indicate a role for Gsα-PKA-cAMP signaling in the PTH-mediated increase of Sox9-expressing osteoblast precursors.

Quantitative analysis of juxta-articular osteoporosis by HR-pQCT in patients with rheumatoid arthritis Ko Chiba*[1], Kounosuke Watanabe[1], Oki Nozomi[2], Naoki Iwamoto[3], Narihiro Okazaki[1], Atsushi Kawakami[2], Makoto Osaki[1]. [1]Department of Orthopedic Surgery, Nagasaki University Graduate School of Biomedical Sciences, Japan, [2]Department of Radiological Sciences, Nagasaki University Graduate School of Biomedical Sciences, Japan, [3]naoki_iwa@hotmail.com, Japan

[PURPOSE] HR-pQCT is a high-resolution CT dedicated to human extremities with a voxel size of 61 μm. It has been used for the study of osteoporosis and rheumatoid arthritis (RA) as well, enabling quantitative analysis of bone microstructure, bone erosion, and joint space. The purpose of this study is to investigate a correlation between bone deterioration (juxta-articular osteoporosis and erosion) and cartilage loss in patients with RA by HR-pQCT.[METHOD AND MATERIALS] Twenty patients with RA (70±8 years, 15 female, 5 male) participated in this study. The second and third MCP joints were scanned by HR-pQCT (XtremeCT II, Scanco Medical, Switzerland) at the voxel size of 61 μm.The following parameters were measured semiautomatically using dedicated software (TRI/3D-BON, Ratoc System Engineering, Tokyo) based on previous studies (Burghardt AJ, et al. Ann Biomed Eng. 2013 / Yang H, et al. Int J Rheum Dis. 2017 / Chiba K, et al. Eular 2017). 1) bone microstructure of metacarpal head: volumetric bone mineral density (vBMD), trabecular thickness (Tb.Th), trabecular number (Tb.N), and structure model index (SMI), 2) total volume of erosions (ER-volume) on the metacarpal head, 3) Average joint space width (ave-JSW) of MCP joints[RESULTS] vBMD of the metacarpal head was 131.4 (54.3-263.5) mg/cm3, Tb.Th was 213.1 (166-329.3) mm, Tb.N was 0.95 (0.69-1.50) /mm, and SMI was 1.68 (0.65-2.52). The total number of erosions was 31, and an average number of erosions on each metacarpal head was 0.9 (0-4). Total ER-volume on the metacarpal head was 1.96 (0-16.7) mm3. Ave-JSW of MCP joints was 1.47 (1.00-1.89) mm. Ave-JSW had significant correlations with vBMD, SMI and ER-volume (R=0.37, -0,40, -0.42, P<0.05).[CONCLUSION] Juxta-articular osteoporosis and bone erosion was correlated with cartilage loss in RA patients. Quantitative evaluation of total joint structure (joint space, bone microstructure, and erosion) by HR-pQCT would be useful for the pathophysiological research and drug development of RA.

The Therapeutic Effect of GPNMB in a Traumatically-Induced Osteoarthritic Model Bryson Cook*[1], Asaad Aladlaan[1], Matthew Desanto[2], Fayez Safadi[1,3]. [1]Musculoskeletal Research Group, NEOMED, United States, [2]Musculoskeletal Research Group, United States, [3]Akron Children's Hospital Research Institute, United States

Osteoarthritis is a severe joint disease that affects millions of people. At this time, the current treatment for osteoarthritis is total joint reconstruction surgery. GPNMB plays a key role in bone remodeling and bone growth. Data from our lab suggested that GPNMB is positive regulator of osteoblastogenesis and a negative regulator of osteoclastogenesis. Furthermore, the role of GPNMB in cartilage has not been investigated before. Here we present that damaged human cartilage has significantly higher levels of GPNMB compared to undamaged cartilage. In addition, human osteoarthritic chondrocytes treated with GPNMB showed a protective response to inflammation induced by IL1-beta. In this study, we examined whether recombinant GPNMB has an anti-inflammatory effect in a model of post-traumatic osteoarthritis. The destabilization of the medial meniscus (DMM) surgery in mice has been found to be an excellent model for studying post-traumatic osteoarthritis. We performed the DMM surgery on 21 C57/BL6 mice. These mice were divided into three intra-articular injection treatment groups consisting of a control, low dose GPNMB, and high dose GPNMB. Moderate to severe osteoarthritis develops around six to eight weeks with this model. Based on studies performed in our lab, we expected cartilage degeneration to be dramatically decreased in response to the therapeutic effects of GPNMB. A protective factor against osteoarthritis progression, GPNMB-injected mice had significantly reduced cartilage damage and OARSI scores in comparison to the control group, proving GPNMB a promising therapy in lieu of total joint reconstruction. GPNMB-injected mice also had reduced expression of IL-6 and MMP13 but significantly increased expression of aggrecan in comparison to control mice. We also tested the effects of rGPNMB on chondrocytes pre-treated with IL1b and found that rGPNMB has anti-inflammatory effects over IL-1b response. The GPNMB response was mediated by the CD44 receptor. Taken together, GPNMB has a significant, therapeutic potential as anti-inflammatory, repair response for osteoarthritis.

CCL21 Promotes Post Knee Injury Inflammation and Osteoarthritis Progression In part via Inducing T-Cell Recruitment Bouchra Edderkaoui*[1], Neha Mohindroo[2], Salma Khan[3], Mohan Subburaman[1]. [1]VALLHCS, LLU, United States, [2]VALLHCS, United States, [3]Loma Linda University, United States

Osteoarthritis (OA) is characterized by progressive cartilage loss, with resultant joint pain that worsens over time.T cells are responsible for activating cells of the monocytic lineage and have been predicted to play a key role in OA development since more than 50% of patients with OA have mononuclear cell infiltrates consisting of CD3+ T, CD4+ and CD8+ cells in the synovial membrane. In terms of molecular pathways involved in the pathogenesis of OA, a recent study has reported an increased expression of CCL21 in the destabilized joints of both young and old mice that went through medial meniscectomy destabilization (MMD). Furthermore, the findings that CCL21 and CXCL13, ligands for CCR7 and CXCR5, which are known markers of CD4+ and CD8+ cells, respectively, suggest CCL21 and CXCL13 may be involved in attracting these two T cell sup-populations to the injury site.To test a role for CCL21 and CXCL13 on OA development, we first evaluated the expression profile of these two chemokines in response to partial MMD in a rat knee injury model. Expression levels for both chemokines were increased by 6-fold compared sham

operated knees at 3 days post-surgery (P<0.01). However, only Ccl21 mRNA levels were significantly elevated (3.5-fold) in MMD knees compared to sham operated knees at 4 weeks post-surgery (P=0.04). These data suggest that CXCL13 is only involved in the first stages of OA development, while CCL21 is involved in both the early inflammation and the later stages of OA. We next assessed the infiltration of inflammatory cells post-MMD. A significant increase in the infiltration of CD4+ and CD8+ cells in the MMD knees was observed at 1 and 3 days post-surgery. MMD knees treated with the CCL21 neutralizing antibody caused a significant reduction in post-surgery inflammation. This was reflected by a reduction in the expression of the major inflammatory cytokine IL-6 as well as both T cell and B cell makers at three days post-surgery. In addition, there was a significant reduction in the expression of matrix metalloproteinase 13 (MMP13) but not MMP3. Based on our data, we conclude that chemokines such as CCL21 play an important role in mediating injury-induced inflammatory response and progression of OA by recruiting T-cells and promoting MMP13 expression.

Cell Death and IL-1β Release Induced by TI Particles Depends on Lysosomal Membrane Disruption Brian Fort*, Edward Greenfield, Givenchy Manzano, Alexander Rascoe, Matthew Hoffa, George Dubyak. Case Western Reserve University, United States

Aseptic loosening is the major cause of revision surgeries and occurs when osteolysis is stimulated around the implant by pro-inflammatory cytokines including IL-1β. Production of active IL-1β in response to orthopedic wear particles depends on processing by the NLRP3 inflammasome which requires priming followed by activation. We found that pathogen associated molecular patterns (PAMPs) adherent to wear particles are necessary to prime the NLRP3 inflammasome. In contrast, in pre-primed macrophages, particles themselves are sufficient to activate the NLRP3 inflammasome and induce secretion of active IL-1β. Particles themselves also induce cell death, kinetically preceding the release of active IL-1β. Phagocytosis of particles is required to initiate both responses as the phagocytosis inhibitor cytochalasin blocks cell death and IL-1β release. Lysosome membrane destabilization is also critical as inhibition of lysosomal function with bafilomycin or chloroquine significantly abrogated the release of active IL-1β and cell death in response to wear particles. The pan-cathepsin inhibitors Ca-074-Me or K777 also inhibit cell death and IL-1β release indicating that cathepsin release from lysosomes is also a necessary step in the particle-induced response. Our results open the possibility of clinical intervention with lysosomal or cathepsin inhibitors to treat aseptic loosening as these drugs have better specificity and less in vivo toxicity than the phagocytosis inhibitors. Testing of these inhibitors in vivo in models of particle induced osteolysis is a key future direction.

MON-0529

Circulating sclerostin is associated with preserved joint space in non-weight bearing joints in a population enriched for high Bone Mineral Density April Hartley*, Lavinia Paternoster, Aaron Murphy, Sarah Hardcastle, Jon H Tobias, Celia L Gregson. Bristol Medical School, University of Bristol, United Kingdom

Animal studies suggest Wnt signaling is a risk factor for osteoarthritis (OA) and that sclerostin, a Wnt inhibitor, may protect against cartilage degeneration. Hence we aimed to determine the association between plasma sclerostin levels and OA endophenotypes, ie. osteophytosis, joint space narrowing (JSN), in different joints.We analysed adults with unexplained generalized high BMD (Z-score>+3.2) and their unaffected relatives/spouses. Sclerostin levels were measured by ELISA immunoassay. Pelvis, bilateral knee and dominant hand radiographs were graded for osteophyte and JSN severity using an established atlas. Binary variables were generated for any osteophyte and JSN at four sites: either hip, either knee, the index distal interphalangeal (DIP) and the first carpometacarpal (CMC) joints. Associations between sclerostin and OA endophenotypes were assessed by logistic regression using generalized estimating equations to account for within-family correlation. Models were adjusted a priori for age & sex, then height & weight.360 adults (231 with high BMD; 129 unaffected relatives/spouses) had hand radiographs (mean age 59.6 [SD 14.7] years; mean plasma sclerostin 83.1 [41.0] pmol/L [standard range 0–80pmol/L]); 334 had knee and 295 hip radiographs. Before adjustment, sclerostin was positively associated with osteophytes in all joints assessed; age & sex adjustment attenuated associations, although sclerostin remained weakly associated with knee osteophytes (OR per SD increase in sclerostin=1.28 [95%CI 0.99, 1.66], p=0.06); however 95%CIs widened with further adjustment for height/weight. Regarding JSN, a strong inverse association was observed between sclerostin and CMC JSN (age & sex-adjusted OR=0.68 [0.53, 0.87], p=0.002) which persisted after adjustment for height/weight. A similar pattern was seen between sclerostin and bilateral hip JSN (0.65 [0.43, 0.98], p=0.042), even after adjusting for height/weight. Associations between sclerostin and JSN measured at the knee and DIP joints were consistent, although 95%CIs were wider.In a population augmented by individuals with high BMD, we identified an inverse association between sclerostin and a measure of cartilage loss at the hips and thumb base; a common site for hand OA. Our findings highlight the importance of stratifying by endophenotypes in studies of OA, as these may be explained by differential aetiologies. Whether sclerostin is protective against cartilage loss warrants longitudinal evaluation.

Blood-Induced Bone Loss In A Mouse Model Of Hemophilic Arthropathy Is Prevented By Blocking The iRhom2/ADAM17/TNFα Pathway Coline Haxaire*[1], Narine Hakobyan[2], Tania Panellini[1], Camila Carballo[1], David Mcilwain[3], Tak W. Mak[4], Suchitra Acharya[5], Dan Li[1], Jackie Szymonifka[1], Scott Rodeo[1], Xiangqian Song[5], Sébastien Monette[6], Alok Srivastava[7], Jane Salmon[1], Carl Blobel[1]. [1]Hospital for Special Surgery at Weill Cornell Medicine, United States, [2]Pediatric Hematology/Oncology, Rush University Medical Center, United States, [3]Baxter Laboratory in Stem Cell Biology, Department of Microbiology and Immunology, Stanford University, United States, [4]Campbell Family Institute for Breast Cancer Research, Princess Margaret Cancer Center, University Health Network, Canada, [5]Pediatric Hematology/Oncology, Northwell Health, United States, [6]Laboratory of Comparative Pathology, Memorial Sloan Kettering Cancer Center, The Rockefeller University, Weill Cornell Medicine, United States, [7]Department of Hematology, Christian Medical College, India

A major manifestation of Hemophilia A, an X-linked bleeding disorder, is hemophilic arthropathy (HA), a debilitating degenerative joint disease that is caused by intraarticular bleeding. HA typically begins with hypertrophy of synoviocytes with inflammation of the synovium and neovascularization, ultimately leading to arthropathy with cartilage destruction and erosion of the underlying bone. HA has features in common with inflammatory arthritides such as Rheumatoid arthritis (RA). The pro-inflammatory cytokine tumor necrosis factor a (TNFα) is a major target for treatment of RA, TNFa is synthesized as a membrane-anchored precursor that is released by the TNFα convertase (TACE, also referred to as ADAM17). We have recently uncovered a crucial role for TACE and its regulator, iRhom2, in the pathogenesis of inflammatory arthritis in mice. Since RA is caused, at least in part, by inappropriate release of TNFα, we hypothesized that iRhom2/TACE/TNFα also have pivotal roles in promoting HA.Here, we show that addition of blood or its components to macrophages activates iRhom2/ADAM17-dependent TNFα shedding, providing the premise to study the activation of this pathway by blood in the joint in vivo. For this, we studied hemophilic FVIII-deficient mice (F8-/- mice), which develop a hemarthrosis following needle puncture injury with synovial inflammation and significant osteopenia adjacent to the affected joint. Needle puncture-induced bleeding led to increased TNFα levels in the affected joint of F8-/- mice. Interestingly, treatment of punctured F8-/- mice with etanercept to block TNFα, or genetic inactivation of Tnfα (F8-/-/TNFα-/-) or iRhom2 (F8-/-/iRhom2-/-) reduced synovial inflammation after 2 weeks. Moreover, μCT analysis showed that inactivation of TNFα and iRhom2 prevented the severe osteopenia observed in F8-/- mice punctured knee. TRAP staining and gene expression demonstrated that the bone loss in F8-/- mice was mainly due to a significant local increase in osteoclasts, absent in etarnecept-treated F8-/-, TNFα-/-/F8-/- and iRhom2-/-/F8-/- mice.Taken together, our results suggest that blood entering the joint activates the iRhom2/ADAM17/TNFα pathway, thereby contributing to osteopenia and synovitis in mice. Therefore, this proinflammatory signaling pathway may provide an attractive new target to prevent osteoporosis and joint damage in HA patients.

Vitamin D Status in Patients with Hip Dysplasia Undergoing Periacetabular Osteotomy and Its Influence on the Postoperative Results Taro Mawatari*[1], Kazuki Kitade[1], Shinya Kawahara[1], Satoshi Ikemura[2], Gen Matsui[1], Takahiro Iguchi[1], Hiroaki Mitsuyasu[1], Reima Sueda[1]. [1]Hamanomachi Hospital, Japan, [2]Kyushu University, Japan

Purpose: Vitamin D is widely known as an important factor for bone health and mineralization, while high prevalence of vitamin D deficiency is reported worldwide. Periacetabular osteotomy (PAO) is accepted as an effective treatment for hip dysplasia in young to middle-aged patients. The purpose of our study was to clarify the relationships between vitamin D levels and postoperative complications including ischio-pubic stress fracture or delayed union of the osteotomy sites.Methods: PAO was performed of 46 hips in 39 patients with symptomatic hip dysplasia and followed for more than 8 months after surgery. There were 3 men and 36 women, and the mean age of the patients at operation was 41.0 (16-59) and the mean body mass index (BMI) was 21.5 (15.8-29.3). All surgeries were performed by a transtrochanteric approach. Partial and full weight-bearing started two and five weeks after operation, respectively. Diagnosis of postoperative ischio-pubic stress fracture or delayed union of the osteotomy sites were evaluated by symptoms and radiographs. A correlation between postoperative complications and age at surgery, BMI, smoking, preoperative center-edge angle, and serum 25-hydroxyvitamin D (25(OH)D) levels were explored. This study was approved by institutional review board.Results: Ischio-pubic stress fracture and delayed union of the greater trochanter osteotomy site occurred in 3 (6.5%) and 5 (10.9%) patients, respectively, while no delayed union were seen at pelvic osteotomy site. Average serum 25(OH)D concentrations was very low (11.9 ng/mL, 6-23) and most of the patients were vitamin D deficient (serum 25(OH)D < 20 ng/mL, 92.3%), and none of them were sufficient. A multivariate analysis demonstrated that serum 25(OH)D < 9 ng/mL and smoking were significantly associated with ischio-pubic stress fracture, and only serum 25(OH)D < 11 ng/mL with delayed union of greater trochanter.Conclusions: A very high prevalence of vitamin D deficiency was revealed in these relatively young patients undergoing PAO. Although development of nonunion or fatigue fracture may be multifactorial complications, our study suggests that severe vitamin D deficiency such as serum 25(OH)D < 11 ng/mL

may have negative impact on bone remodeling and healing and result in worse outcomes in patients undergoing PAO although it is still unclear whether vitamin D supplementation may improve the results of not.

Chronic Antibiotic Use Pre-Injury Reduces Severity of Post-Traumatic Osteoarthritis on ACL rupture STR/ort Mouse Models Melanie Mendez*[1], Deepa Murugesh[2], Jillian Mccool[1], Edward Kuhn[2], Allison Hsia[3], Blaine Christiansen[3], Gabriela Loots[4]. [1]University of California-Merced, Lawrence Livermore National Laboratory, United States, [2]Lawrence Livermore National Laboratory, United States, [3]University of California-Davis, United States, [4]Lawrence Livermore National Laboratory, University of California-Merced, United States

The gut microbiota has a key role in human physiology, one of its most important functions involves immunoregulation. It gives positive protective activation to the immune system by constantly releasing microbial associated molecular patterns (MAMPs) that help naïve immune cells mature. Perturbations to the gut microbiome are linked to changes in bone mass, fracture healing, and susceptibility to inflammation. Post-traumatic osteoarthritis (PTOA) develops in ~50% of people who suffered a severe joint injury such as anterior cruciate ligament (ACL) rupture. Although PTOA is not classified as an inflammatory disease, it has been suggested that inflammation could be one of the contributing factors to the initiation and progression of PTOA. To determine the role of the gut microbiome on the severity of PTOA we examined post-injury joint degeneration in STR/ort mice, a strain known to develop OA spontaneously due to systemic high levels of inflammatory cytokines. We treated mice with oral antibiotics [ampicillin (1000mg/L); neomycin (500mg/L)] in the drinking water starting at 4 weeks of age, continuously for a six week period prior to injury at 10 weeks of age. Antibiotic treatment efficacy was monitored by qualitatively using the Lawrence Livermore Microbial Detection array and quantitatively via 16s ribosomal RNA (rRNA) sequencing which combined assessed bacterial diversity and abundance in fecal samples, collected weekly. Antibiotic treatment was stopped immediately prior to injury. The right knee of each mouse was injured using a single non-invasive tibial compression overload to induce ACL rupture. Injured and contralateral joints were analyzed at 6 weeks post injury using micro-computed tomography and histology. Both uninjured and injured STR/ort mice treated with antibiotics had thicker articular cartilage than the untreated groups, suggesting lower chondrocyte apoptosis in the antibiotic treated mice. Treated mice also showed reduced cellular infiltration in the synovium than untreated groups, indicative of a reduced inflammatory response in the mice treated with antibiotics. There was also a statistically significant reduction in osteophyte formation in these mice. These data suggest that the gut biome composition can dramatically impact PTOA outcomes, and that antibiotic treatment prior to injury reduces the overall systemic inflammation in STR/ort mice and improves PTOA outcomes.

An ectosteric tanshinone inhibitor of cathepsin K prevents the progression of joint inflammation and destruction in an arthritis mouse model Preety Panwar*, Dieter Bromme. University of British Columbia, Canada

Cathepsin K (CatK) is a validated drug target for musculoskeletal diseases. Active site-directed inhibitors of CatK have demonstrated efficacy in osteoporosis and osteoarthritis human clinical trials but were never approved due to significant safety concerns. Side effects were likely caused by on-target effects due to the inhibition of the entire activity of this multifunctional protease. To avoid side effects, we developed the ectosteric inhibitor concept that specifically allows blocking the disease relevant collagenase activity of CatK. Using the collagen-induced arthritis (CIA) mouse model, we demonstrated that the orally applied ectosteric CatK inhibitor tanshinone IIA sulfonate (T06) effectively reduced joint inflammation and erosion. T06 markedly inhibited cartilage degradation and also had significant effects on bone destruction and pannus formation. Serum biochemical assays confirmed that T06 reduced collagen I and II degradation markers and prevented the expression of various inflammatory markers such as TNFα, IL-6, and IL-1β. No systemic toxicological effects were observed. In contrast, odanacatib, a highly potent active site-directed CatK inhibitor, had a weaker effect on inflammation and joint preservation. Moreover, odanacatib had no significant effect on the inflammatory cytokines and careful histological tissue examination revealed fibrotic alterations in several organs, which also reflected some of the safety issue in the clinical trials. The T06 treatment did not show any of these adverse effects. These data support that T06 inhibits immune-receptor signalling, has direct antiresorptive activity, and suggest that T06 might represent a promising therapeutic drug for patients with rheumatoid arthritis and warrants further investigation.

Synovial B-cell infiltration as a novel candidate mediator of OA in obese mice and humans Eric Schott*[1], Jacquelyn Lillis[1], Christopher Farnsworth[2], Javier Rangel-Moreno[1], John Ketz[1], Douglas Adams[3], Jennifer Anolik[1], Cheryl Ackert-Bicknell[1], Robert Mooney[1], Michael Zuscik[1]. [1]University of Rochester School of Medicine and Dentistry, United States, [2]Washington University in St. Louis, United States, [3]University of Connecticut, United States

Obesity is a major risk factor for osteoarthritis (OA), a disease that currently afflicts 31M Americans and has no accepted disease modifying treatment. Recent studies implicate a primary role for immune cell infiltration and corresponding inflammation of the synovial membrane in disease pathogenesis. These findings led us to hypothesize that in the OA of obesity, the synovium is the primary driver of accelerated cartilage and joint degeneration. To test this hypothesis, we performed a transcriptomic analysis of synovial tissue from lean and obese mice at a time point that precedes any evidence of cartilage degeneration. Starting at 5 weeks of age, male C57BL/6J mice were fed a low fat or high fat diet for 16 weeks, at which point the synovial membrane was removed for RNA isolation and sequencing. Significantly differentially expressed genes were then analyzed using CTen and Ingenuity Pathway Analysis (IPA) to identify enriched cell types, canonical pathways, and diseases and functions. These analysis tools identified a significant induction of inflammation in the obese synovium compared to lean, despite an absence of histologic evidence of joint pathology under either condition. Cell type enrichment analysis identified the macrophage as a significant mediator of early synovial pathobiology, correlating with pathway analysis identifying significant induction of inflammatory pathways including NF-kB, macrophage activation, and joint inflammation. Notably, the RNAseq identified the B-cell as a candidate mediator of early disease. Cell type enrichment analysis revealed a significant B-cell signature in the obese synovium, correlating with activation of canonical pathways and diseases and functions related to the B-cell. Flow cytometric analysis revealed increased abundance of B-cells in the obese synovium, confirming the RNAseq results. Suggesting that this B-cell phenotype is present in obese humans, synovium from low (<27, N=6) and high (>27, N=10) BMI total knee replacement patients revealed significant increases in the number (p<0.0001) and size (p<0.001) of ectopic lymphoid structures that contained B20+ cells in the high BMI group. In conclusion, synovial pathobiological change occurs well before evidence of joint degeneration is discernable, with both murine and human data supporting a potentially pathogenic role of the B-cell in the OA of obesity.

Blocking Transforming Growth Factor-β1 By Oral Intake Of Losartan Can Improve Microfracture-Mediated Cartilage Healing- A Rabbit Model Hajime Utsunomiya*[1], Xueqin Gao[2], Zhenhan Deng[2], Gilberto Nakama[1], Haizi Cheng[2], Sudheer Ravuri[2], Julia Goldman[2], Tamara Alliston[3], Walter Lowe[2], William Rodkey[1], Marc J Philippon[1], Johnny Huard[1]. [1]Steadman Philippon Research Institute, United States, [2]University of Texas Health, United States, [3]University of California San Fransisco, United States

Background: Microfracture is often the first choice for clinical treatment of cartilage injuries; however, fibrocartilage, not pure hyaline cartilage, has been reported to develop after microfracture surgery. Transforming growth factor (TGF)-β1, which can result in fibrosis, can be inhibited by losartan.Hypothesis: We hypothesized that blocking TGF-β1 would improve cartilage healing in a rabbit knee microfracture model by decreasing the amount of fibrocartilage formation and increasing hyaline-like cartilage formation.Study Design: Controlled laboratory study.Methods: An osteochondral defect (diameter: 5 mm, depth: 2 mm) was made in the patellar groove of 21 New Zealand White rabbits. The rabbits were divided into three groups (N=7/group) randomly, a control group (defect only, group 1), a microfracture group (osteochondral defect + microfracture, group 2), and a losartan-treated group (osteochondral defect + microfracture + losartan, group 3). Microfracture was performed using a 0.7-mm burr with a 2-mm depth. For the rabbits in group 3, losartan was administrated orally from the day after surgery through the day of euthanasia. Rabbits were sacrificed 6 week postoperatively. Macroscopic appearance, microcomputed tomography (microCT) and histological assessment were evaluated. Results: At 6 weeks after surgery, group 3 scored highest in the International Cartilage Repair Society (ICRS) macroscopic assessment (mean[SD], group 1: 7.9 [1.9], group 2: 6.9 [2.7], group 3: 9.0 [1.0], p < 0.05). MicroCT showed healing of the bony defect in group 3, in comparison to no healing in group 1 and partial healing in group 2. Histologically, the results obtained using the Modified O'Driscoll ICRS grading system yielded significantly superior scores in group 3 compared to both group 1 and 2 (group 1: 23.3 [7.2], group 2: 28.0 [1.4], group 3: 33.0 [2.0]). Conclusion: On blocking TGF-β1 with losartan, the healed tissue after microfracture was more similar to that of normal hyaline cartilage than that obtained without blocking TGF-β1. These results are encouraging for the clinical application of losartan in microfracture for the repair of chondral defects. Clinical relevance: TGF-β1 has been believed to be essential for the homeostasis of the articular cartilage. The current results demonstrate that an optimal expression of TGF-β1 is also required for the healthy joint cartilage, and losartan can provide a less fibrotic healing of cartilage after microfracture surgery.
Figure: Histology findings at 6 weeks after surgery. **A:** Hematoxylin&Eosin (HE) staining (20x). **B:** HE staining (100x). **C:** Alcian blue staining. **D:** Safranin O staining. The defect only group showed poor quality of repaired cartilage. Repaired cartilage in the microfracture (MCFX) group revealed fibrocartilage healing. The MCFX + losartan group showed hyaline-like cartilage healing with plenty of collagen matrix.

Conditional Bone and Muscle Correlates of Osteoarthritis Influenced by Use of Antiresorptive Therapy in Postmenopausal Women– the AMBERS study Andy Kin On Wong*[1], Shannon Reitsma[2], Hana Gillick[2], Abinaa Chandrakumar[3], Eva Szabo[3], Justin Chee[3], Angela M Cheung[3], Jonathan D Adachi[2]. [1]Joint Department of Medical Imaging, University Health Network, Canada, [2]Department of Medicine, McMaster University, Canada, [3]CESHA, University Health Network, Canada

Previous trials have shown mixed effects of antiresorptive therapy on osteoarthritis (OA). Understanding ways antiresorptives could influence bone and muscle properties in OA could help delineate pathways or patient groups to target.Objective: to determine the effect of bone and muscle properties on knee OA (KOA) in those who have or have not used antiresorptives.312 women 60-85 yrs old from the Appendicular Muscle and Bone Extension Research Study (AMBERS) completed baseline imaging and annual follow-up of fractures, falls, and frailty for 3 years. This study is a cross-sectional analysis of baseline data for women 76-85 yrs old (N=170). Peripheral QCT (pQCT) and MRI scans of the mid-leg (66% site) measured muscle density and % inter- and intramuscular fat (%IMF). 4% distal tibia pQCT scans quantified bone density and microarchitecture. Total hip and lumbar spine DXAs were converted to T-scores. OA and KOA were self-reported. Antiresorptive use over the last 5 years was captured.General linear models compared muscle and bone properties between antiresorptive users and non-users among those with OA or KOA. Binary logistic regression examined the effect of bone and muscle properties on OA or KOA conditional on use of antiresorptive therapy.Among 170 women (age:80±3yrs, BMI:29.1±5.5kg/m2) in whom 63 had OA and 37 KOA, 39.7% and 32.4% used antiresorptives within the last 5 years, respectively. Antiresorptive use was associated with thinner trabeculae after adjusting for lowest BMD T-score (p=0.048) among those with OA, and lower BV/TV (p=0.004), vBMDtr (p=0.050), and larger Tb.Sp (p=0.005) in those with KOA. Antiresorptive therapy showed marginally significant interaction effects with Tb.Sp (p=0.063) and BV/TV (p=0.085) on associations with KOA, with apparent associations shown only when antiresorptives were not used. Conversely in models examining muscle interaction effects (p-interaction=0.041), having a higher %IMF was associated with KOA when antiresorptives were used (OR: 4.10(1.26,13.37)) but was not associated with KOA when not used (OR: 0.95(0.53,1.70)).Use of antiresorptive therapy is associated with less dense and thinner trabeculae in OA patients after accounting for confounding by indication. The differential effects of bone and muscle on OA conditional on antiresorptive therapy could be explained by potential resolution of bone abnormalities in OA, but exposing a residual impact of muscle adiposity on OA.

Dephosphorylation of NACA by PP1A enhances c-JUN transcriptional activity William N. Addison*, Martin Pellicelli, René St-Arnaud. Shriners Hospitals for Children - Canada, Canada

The transcriptional cofactor NACA (nascent polypeptide-associated complex and co-regulator alpha, αNAC) is a critical regulator of osteoblast maturation and activity. NACA functions, at least in part, by binding to the AP-1 transcription factor c-JUN and potentiating the transactivation of AP-1 targets such as Osteocalcin and Mmp9. Knock-in mice deficient in nuclear NACA exhibit a significant reduction in bone formation leading to a marked reduction in bone mass. The activity of NACA is mediated by multiple post-translational modifications including phosphorylation. Although several kinases have been shown to phosphorylate NACA, a phosphatase capable of dephosphorylating NACA has not yet been identified.In this study, we utilized an affinity purification approach combined with mass spectrometry to purify NACA protein complexes from HEK293T cells and identified the serine-threonine protein phosphatase PP1A as a novel NACA-associated phosphatase. Notably, we found that NACA was associated with multiple components of the PP1A holoenzyme complex including the catalytic subunit, PPP1CA as well as the regulatory subunits PPP1R9B, PPP1R12A and PPP1R18. Independent immunoprecipitation assays confirmed that NACA interacts with endogenous PPP1CA in MC3T3-E1 osteoblast cells. Consistent with this, in vitro dephosphorylation of NACA with recombinant PP1A resulted in a faster migrating hypo-phosphorylated form of NACA. By mass spectrometry analysis, we also demonstrated that co-expression of NACA with PPP1CA in HEK293T cells leads to dephosphorylation of NACA at residues Thr89, Ser151, Ser166 and Thr174. Moreover, NACA dephosphorylation was correlated with the recruitment of novel NACA interactants. PP1A-dephosphorylated NACA, but not phosphorylated NACA, interacts with the basic transcription factor BTF3 and its homologue BTF3L4. In addition, promoter studies showed that NACA and PP1A could synergistically potentiate c-JUN transcriptional activity on the AP-1-responsive Mmp9-luciferase reporter. This synergy was abolished when Thr89, Ser151 or Ser166 were mutated into phosphatase-resistant phosphomimetic aspartate residues.Collectively, these data suggest that PP1A dephosphorylates NACA at specific residues, which leads to recruitment of novel NACA interactants such as BTF3 to ultimately regulate c-JUN transcriptional activity. This unique transcriptional regulatory mechanism advances our understanding of NACA in the regulation of osteoblast gene expression.

miR-219a-5p Regulates Rorβ During Osteoblast Differentiation and in Age-related Bone Loss Ruben Aquino-Martinez*, David Monroe. MAYO CLINIC, United States

Osteoporosis and increased fracture risk in the aging population is correlated with deterioration in quality of life and loss of autonomy. To improve upon the limited efficacy of current clinical therapies, we investigated new molecular targets to stimulate bone accrual. We have reported that retinoic acid receptor-related orphan receptor beta (Rorβ) is upregulated in bone marrow-derived osteoprogenitor cells and in osteocytic bone fractions isolated from aged mice and humans, that Rorβ expression is inhibited during osteoblastic differentiation,

and that deletion of Rorβ in mice results in preservation of bone during aging. Collectively, these data suggest that Rorβ is an inhibitor of osteogenesis and that proper control of Rorβ expression is essential for bone homeostasis. Here, we investigated the interaction between Rorβ and a specific subset of microRNAs (miRs) to establish their roles in osteoblast differentiation and in the context of aging. We used the miR target prediction database TargetScan to identify a subset of miRs as potentially Rorβ-regulating. To determine any potential involvement of these miRs in the regulation of Rorβ levels, MC3T3-E1 mouse osteoblastic cells were differentiated and assayed for Rorβ and miR expression. As Rorβ levels declined with differentiation, the expression of multiple miRs was upregulated, suggesting possible involvement in the suppression of Rorβ. We also demonstrated that miR-219a-5p was downregulated (p<0.001) in osteocytic bone fractions from old mice, concomitant with increased Rorβ expression. We further showed that miR-219a-5p directly suppressed Rorβ and that miR-219a-5p inhibition using a lentiviral antagomir vector in MC3T3 cells (resulting in ~90% inhibition) led to increased Rorβ expression and impairment in osteoblastic differentiation. RNA sequencing analysis further confirmed that pathways involved in osteoblast function (i.e. extracellular matrix, calcium signaling, adhesion and Wnt signaling) were dysregulated in miR-219a-5p inhibited cells. Our findings thus demonstrate that miR-219a-5p is involved in the regulation of both Rorβ and differentiation-related pathway in osteoblasts, suggesting that miR-219a-5p mimics may be useful tools to stimulate bone formation.

Blastema formation and periosteal ossification in the regenerating adult mouse digit. Lindsay A. Dawson*, Connor Dolan, Felisha Imholt, Osama Qureshi, Katherine Zimmel, Ken Muneoka. Texas A&M University, United States

Purpose: Mammalian regeneration in response to amputation is restricted to the distal digit tip, the terminal phalanx (P3). Successful regeneration in the mouse is amputation-level dependent; amputations nearing the epiphysis of P3 fail to stimulate regeneration, instead culminating in bone truncation and associated scar formation. What distinguishes regeneration from scar formation is the formation of the blastema, defined as a heterogeneous population of proliferating cells that function to regenerate the amputated structures. We used the amputation-level dependent regeneration response to investigate blastema formation and associated bone regeneration. We report that blastema cells associated with the periosteum and endosteal/marrow regions are stimulated to undergo ossification in endogenous regeneration, and the periosteum is required for bone regeneration distal to the amputation plane.Methods: Regenerative (distal) and non-regenerative (proximal) amputations were performed on adult, female, 8-week-old CD-1 mice. The periosteal tissue was surgically removed prior to amputation, with sham operated digits analyzed in parallel. Bone regeneration was quantified using Micro-computed tomography (μCT) and digits were assayed via histology and immunohistochemistry.Results: In response to distal amputation, sequential μCT analysis demonstrated P3 regeneraton is characterized by restoration of amputated skeletal length and enhanced bone volume associated with the periosteal compartment. Conversely, proximal amputation does not induce bone length regeneration but intringuingly results in enhanced bone volume associated with the endosteal/marrow compartment. Analysis of distal amputations revealed blastema formation is characterized by proliferation and osteogenesis initially compartmentalized to the periosteal and endosteal/marrow regions. In contrast, proximal amputation induces proliferating osteoblasts restricted to the endosteal/marrow region, and distal fibrotic tissue formation. P3 digits lacking periosteum showed attenuated bone length and volume regeneration compared to sham operated control digits. Discussion: The non-regenerative proximal amputation is associated with a blastema-like structure restricted to the endosteal/marrow region. These findings identify the periosteum as a therapeutic target for designing strategies to enhance mammalian regeneration.

CALM1 and GARS: novel biomarkers to diagnose Pseudarthrosis Thaqif El Khassawna*[1], Stefanie Kern[1], Deeksha Malhan[1], Markus Rupp[2], Christian Heiss[2]. [1]Institute for Experimental Trauma Surgery, Faculty of Medicine, Justus Liebig University of Giessen, Germany, [2]Department of Trauma, Hand, and Reconstructive Surgery, University Hospital of Giessen and Marburg, Germany

Fracture non-union (or pseudarthrosis) is a critical problem in pre-clinical as well as clinical research. Decreased osteoblasts, increased fibroblasts, impaired vascularization, and bone matrix alterations results in the pathogenesis of pseudarthrosis. Bone morphogenetic proteins (BMP) are commonly used in clinic to treat pseudarthrosis. But BMP's also increase fibroblast cell types along with osteoblasts resulting in severe complications. Our study aimed to identify the potential biomarkers using Mass spectrometry (MS) approach to diagnose pseudarthrosis.Human reaming debris were used to harvest mesenchymal stem cells (MSCs) and fibroblasts and then osteogenic differentiation were carried out using BMP-2 stimulation. Nano-HPLC-ESI-MS/MS were carried out to extract, digest, and purify proteins. Post-normalization and analysis, differentially expressed proteins were obtained using fold change (FC) = |2| and p ≤ 0.01. Additionally, RNA was isolated from obtained cells and relative gene expression were measured. Immunostainings of biomarkers on human pseudarthrotic samples and previously established Nf1Prx1 mouse model were carried out for validation.MS analysis showed 193 common proteins between

osteogenic differentiated MSCs and fibroblasts out of 2470 total proteins prior to filtering. Collagen-alpha-2(I)-chain, Calmodulin-1 (CALM1) and Glycine-tRNA-synthetase (GARS) were significantly down-regulated in osteogenic differentiated fibroblasts when compared with differentiated MSCs. This downregulation indicates the pathogenesis of Pseudarthrosis. Previous studies reported the incidence of metastasis and cell cycle abnormalities in GARS knock-down model. Bone mass is maintained by CALM1 and its downregulation directs to the impaired healing. Intriguingly, relative gene expression showed similar downregulation of CALM1 and GARS. Further, immunostainings of CALM1 and GARS showed relatively lower signal in human and Nf1Prx1 samples. Taken together, MS-based approach showed higher potential in disease diagnosis and biomarker discovery. Further, targeted upregulation of CALM1 and GARS can help in the treatment of pseudarthrosis. Establishing a correlation between biomarkers discrepancies in the tissue and their serum level concentration can provide information about the healing status of surgically revised non-unions. Cell-specific molecular analysis of pseudarthrotic tissue is the main outlook of the study.

Long Non-coding RNA RP11-45A16.3 Promotes Osteoblast Differentiation of Human Periodontal Ligament Stem Cells via Runt-Related Transcription Factor 2 by Sponging miR-103a-2-5p Fuchun Fang*[1,2], Jianjia Li[2], Qisheng Tu[1], Jake Chen[1,3]. [1]Division of Oral Biology, Tufts University School of Dental Medicine, Boston, MA 02111, USA, American Samoa, [2]2Department of Stomatology of Nanfang Hospital, Southern Medical University, Guangzhou 510515, China, [3]Department of Cellular, Molecular and Developmental Biology, Tufts University School of Medicine, Boston, MA 02111, USA, American Samoa

Background: The great potential for differentiation into osteoblasts showed in human periodontal ligament stem cells (HPDLSCs) might make them a promising therapeutic option for periodontal tissue regeneration. Recently, long non- coding RNAs (lncRNAs) were reported to function as a competitive endogenous RNAs (ceRNAs) to regulate the effect of microRNAs (miRNAs) on their target genes. However, the molecular mechanism how (whether) lncRNAs regulates the osteoblast differentiation of HPDLSCs still remains poorly understood.Materials and Methods: Expression patterns of lncRNA, miRNA and messenger RNA (mRNA) during osteoblast differentiation of HPDLSCs at 14 days were profiled using microarray analysis. The function and regulating mechanism of RP11-45A16.3, as the most up-regulated lncRNA (fold change: 78.67), were investigated. First, the expression of lncRNA RP11-45A16.3 and miR-103a-2-5p in HPDLSCs cultured with or without an osteoblast inductive cocktail was explored using qRT-PCR. The recombinant lentiviral vectors knocking down RP11-45A16.3 or inhibiting miR-103a-2-5p were constructed and transfected into HPDLSCs to regulate their endogenous expression. The mineralized nodules formation and the expressions of ALP, COL1A1, RUNX2 expressions were used as specific markers for osteogenesis.Results: RP11-45A16.3 was up-regulated during osteoblast differentiation of HPDLSCs. Knockdown of RP11-45A16.3 suppressed osteoblast differentiation of HPDLSCs. The expression level of miR-103a-2-5p decreased during osteoblast process and inhibiting miR-103a-2-5p promoted osteoblast differentiation. Luciferase reporter assays revealed that RP11-45A16.3 had binding sites with miR-103a-2-5p, and RP11-45A16.3 knockdown increased miR-103a-2-5p expression level, demonstrating that RP11-45A16.3 may act as a ceRNA for miR-103a-2-5p. Luciferase reporter assays also demonstrated that miR-103a-2-5p could target RUNX2. Inhibiting miR-103a-2-5p led to an increased RUNX2 expression during osteoblast differentiation. Moreover, RP11-45A16.3 knockdown resulted in a decreased RUNX2 expression, which could be partly rescued by inhibiting miR-103a-2-5p. In addition, reduced osteoblastogenesis resulting from RP11-45A16.3 knockdown was partly rescued by miR-103a-2-5p inhibition.Conclusions: This research revealed that lncRNA P11-45A16.3 promotes osteoblast differentiation of HPDLSCs through acting as a ceRNA to sponge miR-103a-2-5p molecules enhancing RUNX2 signal pathway.

Grainyhead-like 3 Mediates BMP and Wnt Signaling in Skeletal Stem Cells during Bone Formation and Repair Laura Gamer*, Valerie Salazar, David Maridas, Vicki Rosen. Harvard School of Dental Medicine, United States

While there is general agreement that BMPs and Wnts are fundamental regulators of bone formation and bone repair, aspects of osteoblast specification and function controlled by either pathway remain largely undefined. Previously, we identified Grainyhead-like 3 (Grhl3), a transcription factor with critical roles in epithelial tissues, as a new mediator of both BMP and Wnt signaling during osteoblast differentiation using bone marrow stromal cells. To examine the connection between Grhl3 and signaling pathways that mediate osteoblast physiology, we first defined Grhl3 expression during limb development using in situ hybridization. Grhl3 transcripts are present in the perichondrium of nascent bones at E14.5, where the Grhl3 expression domain overlaps with Lrp5 and Bmp2. At E16.5, Grhl3 is expressed by hypertrophic chondrocytes, bone collar cells and subchondral bone. After birth, Grhl3 localizes to the periosteum and nascent trabecular bone. To verify a connection between Grhl3 expression and function, we obtained mice carrying a conditional allele for Grhl3 and crossed them with the Prx1-cre deleter mice to remove Grhl3 from skeletal stem cells. Grhl3 cKO mice have normal skeletons at birth with no obvious defects in size or shape of individual limb skeletal elements. Strikingly, at 2 weeks of age, Grhl3 cKO mice have a profound deficit in postnatal bone formation that affects both the cancellous and cortical bone compartments and results in Grhl3 cKO mice lagging behind control littermates in the aquisition of bone mass. To gain information on the potential importance of Grhl3 in the adult skeleton, we looked for Grhl3 expression after femur fracture and found a substantial increase 5 days after fracture, consistent with a regulatory function for this factor in skeletal stem cell differentiation. Our findings suggest a potential role for Grhl3 as a node that coordinates inputs from the BMP and Wnt pathways on cells of the osteoblast lineage. Future studies are aimed at understanding if Grhl3 is a key determinant of bone mass acquistion and fracture repair in the postnatal skeleton.

MACF1 Promotes Osteoblast Differentiation by Sequestering Repressors of Wnt Signaling Lifang Hu*, Chong Yin, Zixiang Wu, Zizhan Huang, Airong Qian. Laboratory for Bone Metabolism, Key Laboratory for Space Biosciences and Biotechnology, School of Life Sciences, Northwestern Polytechnical University, China

Microtubule actin crosslinking factor 1 (MACF1), a versatile cytoskeletal crosslinker, has been shown to promote osteoblast differentiation by our previous study. The underlying mechanism of MACF1 promoting osteoblast differentiation is still unclear. Here we aimed to clarify the mechanism of MACF1 regulating osteoblast differentiation by adopting MACF1-knockdown (MACF1-KD) MC3T3-E1 cells, based on the previous study. We found that MACF1 knockdown suppressed mineralization and ALP activity, and impaired the osteogenic genes' expression during osteoblast differentiation (Figure 1). RNA sequencing (RNA-seq) and gene ontology analyses revealed that MACF1 knockdown affected the expression of genes that linked to the Wnt, Hippo, or PI3K-AKT pathways, all involved in osteoblast differentiation. Further cluster analysis demonstrated that MACF1 knockdown significantly downregulated key transcription factors of Wnt signaling, especially T-cell factor 7 (TCF7) and lymphoid enhancer-binding factor 1 (LEF1). Real time PCR and western blot confirmed the decrease in both expressions and activities of TCF7 and LEF1 in MACF1-KD cells. As the activation of Wnt signaling promotes osteoblast differentiation via TCF7 and LEF1, we further investigated how MACF1 regulated the expression of the transcription factors. Chromatin immunoprecipitation sequencing (ChIP-seq) analyses displayed the enrichment of MACF1 binding at the promoter sites in MACF1-KD cells and gene ontology analyses revealed that Wnt signaling pathway was highly affected. In addition, two transcription factors, TCF12 and E2F6, were identified to be regulated by MACF1. The functional analyses showed that knockdown of TCF12 and E2F6 promoted osteoblast differentiation and Wnt signaling, indicating them as repressors of Wnt signaling. Thus, we proposed that MACF1 promoted osteoblast differentiation through sequestering TCF12 and E2F6, and preventing them translocate into nucleus, thus enhancing the expression of active transcription factors of Wnt signaling (e.g. TCF7). The luciferase reporter assay further confirmed that MACF1 regulated the balance between active (TCF7) and repressive transcription factors (TCF12) to regulate the Wnt signaling and osteoblast differentiation. Taken together, these findings suggest that MACF1 promotes osteoblast differentiation by sequestering repressors of Wnt signaling. This study uncovers a new mechanistic insight of MACF1 regulating osteoblast differentiation.

How Acid Transport Supports Formation of Dense Bone Mineral Quitterie C Larrouture*[1], Harry C Blair[2], Irina L Tourkova[3], Jing H Bian[3], Li Liu[3], Donna Beer Stolz[4], Deborah J Nelson[5], Paul H Schlesinger [6]. [1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, Botnar Research Centre, Oxford University, United Kingdom, [2]Veteran's Affairs Medical Center and Department of Pathology, University of Pittsburgh, United States, [3]Department of Pathology, University of Pittsburgh, United States, [4]Department of Cell Biology, University of Pittsburgh, United States, [5]Department of Pharmacological and Physiological Sciences, University of Chicago, United States, [6]Department of Cell Biology, Washington University, United States

Osteoblasts secrete collagen I and isolate the bone-matrix from extracellular space. In the matrix, alkaline phosphatase generates phosphate that combines with available calcium to form bone mineral. Amorphous calcium phosphate crystals form on the collagen template, but must be matured into a stable hydroxyapatite–collagen composite, this process liberates eight protons for each ten calcium atoms deposited. This proton load must be removed from the mineralizing bone matrix. However, pH dependent hydroxyapatite deposition in bone collagen had not been demonstrated. Directly to address this, we determined pH and phosphate dependency of hydroxyapatite deposition on type I collagen by surface plasmon resonance in 0-5 mM phosphate with 1 mM calcium at pH 6.94-7.6. Mineral deposition was sensitive to phosphate concentration but was saturated by <1 mM Ca++. Initial mineral deposition was rapidly reversible consistent with amorphous precipitation but more stable deposition appeared with time and required EDTA removal. Importantly, at pH 6.94 little hydroxyapatite deposited on collagen, but mineral accumulation increased 10 fold at pH 7.4 (Figure). Previously we demonstrated NHE1, NHE6, ClC-3, and ClC-5 to be highly expressed. We hypothesized that in combination these proteins, transcellularly, move protons across the osteoblast cell layer to the general extracellular space. Directly to determine whether osteoblast membranes mediate proton transport consistent with this model, we made membrane vesicles from human osteoblasts by nitrogen cavitation. With these vesicles, we used acridine orange quenching to characterize proton transport. We found H+ transport dependent on gradients of chloride or sodium, consistent with ClC-family Cl-,H+ antiporters at apical surfaces and NHE-family Na+/H+ exchangers in basolateral surfaces of osteoblasts. In contrast to osteoclast membranes, little, if any, active H+ transport, supported by ATP or other energy sources, occurred. We conclude that mineral deposition in bone collagen is pH dependent, in keeping with a model of H+ removal by Cl-,H+ antiporters and Na+/H+–exchangers on the apical and basolateral faces of osteoblasts. Periodic orientation hydroxyapatite is organized on type I collagen coiled-coils, in keeping with earlier extensive work on organization of mineral during initial amorphous crystallization.

Bone formation in osteoblast cell culture Elena Makareeva*, Edward Mertz, Anna Roberts-Pilgrim, Sergey Leikin. NICHD, NIH, United States

Cell culture is widely used for mechanistic studies of osteoblast biology, testing osteogenic potential of progenitor cells, and tissue engineering. Formation of nodules or extended regions of mineralized extracellular matrix (ECM) in osteogenic media containing β-glycerophophate (bGP) is commonly used as a proxy for bone formation. However, it is still unclear how well these assays characterize osteogenic potential of the cells. It is known that artificial mineralization can be induced by alkaline phosphatase expressing cells that hydrolyze bGP, producing mineralized ECM with different structure and appearance from bone. Cell culture and in vivo observations are often inconsistent; and many researchers believe that bone formation in culture is impossible. Here, we reevaluated bone formation by cultured osteoblasts in the absence of bGP. To characterize cell differentiation, we combined imaging of cells expressing osterix with analysis of different osteoblast and osteocyte marker genes in the whole culture and individual cells. We imaged mineral deposition by fluorescent labeling and examined ECM and cell structure, ultrastructure, and morphology by light and electron microscopy. We measured mineral composition and orientation relative to collagen fibers by Raman micro-spectroscopy. In the absence of bGP, both primary mouse calvarial osteoblasts and MC3T3 cells formed mineralized matrix that had the appearance, ECM structure and ultrastructure, and mineral composition and organization consistent with bone. Embedded cells had the morphology, ultrastructure and gene expression consistent with mature osteocytes. Without bGP, ECM mineralization started around embedded osteoblasts transitioning into osteocytes and gradually extended throughout the matrix, similar to bone formation in vivo. In the presence of bGP, ECM mineralization was more diffuse and did not produce large, contiguous bone-like regions. The resulting mineralized ECM had lower density and abnormal ultrastructure of collagen fibers as well as random hydroxyapatite orientation. Nevertheless, expression of genes marking different stages in osteoblast differentiation was qualitatively similar with and without bGP. Overall, we concluded that cultured osteoblasts can produce ECM that has the same appearance and properties as bone. While accelerating osteoblastic differentiation, bGP induces artificial mineralization and inhibits more physiological bone matrix formation and mineralization.

Opposing Effects of Inorganic Phosphate and Trps1 Transcription Factor on Expression of SerpinB2 in Bone and Tooth Mairobys Socorro*, Daisy Monier, Sana Khalid, Victoria Smethurst, Dobrawa Napierala. Center for Craniofacial Regeneration, Dept. of Oral Biology, McGowan Institute for Regenerative Medicine, University of Pittsburgh School of Dental Medicine, United States

Inorganic Phosphate (Pi) is essential for normal skeletal and dental mineralization. This function is accomplished, in part, by regulating expression of genes involved in this process. In our interest to study the Pi-regulated mineralization process, we use 17IIA11 osteogenic cells, which undergo rapid mineralization in standard osteogenic conditions. Pi-regulated gene expression was analyzed by RNA-sequencing after exposing the cells to 5mM Pi for 24h. Besides the classic Pi-responsive genes to be upregulated in osteogenic cells (Spp1, Dmp1, Ank and Slc20a1), we identified SerpinB2 as one of the novel genes highly upregulated by Pi. Interestingly, this gene has never been implicated in formation nor homeostasis

of mineralized tissues. SerpinB2 gene codes for plasminogen activator inhibitor-2 (PAI-2), a protein that is widely studied in the context of immunity and cancer. Moreover, SerpinB2 is considered a stress protein, which under physiological conditions is highly expressed only in endothelial cells, but becomes highly expressed in response to stress. Encouraged by this novel observation, we analyzed in vivo expression of SerpinB2, in bone and tooth. Additionally, we compared expression of SerpinB2 in WT and transgenic mice overexpressing Trps1 specifically in osteoblasts and odontoblasts (Col1a1-Trps1 mice). To accomplish this, skeletal and dental tissues were analyzed at different developmental stages. Immunohistochemical detection of SerpinB2 in alveolar bone and tooth uncovered that this protein is highly expressed not only in endothelial cells, but also in cells producing mineralized ECM. Specifically, osteoblasts lining alveolar bone, odontoblasts and ameloblasts were highly positive for SerpinB2. Of note, osteocytes express very low levels of SerpinB2. Furthermore, we determined that overexpression of Trps1 leads to decreased expression of SerpinB2. In summary, we identified that SerpinB2 is highly and specifically expressed by cells producing mineralized ECM, and showed that SerpinB2 is upregulated by Pi and repressed by Trps1.

PTHrP (1-36) and Abaloparatide: Weaker Modulators of SIK2/CRTC2-CRTC3 Signaling Axis Compared with PTH (1-34) Florante Ricarte*[1], Carole Le Henaff[2], Nicola Partridge[2]. [1]New York University School of Medicine, United States, [2]New York University College of Dentistry, United States

In 2017, abaloparatide (ABL), an analog of parathyroid hormone-related protein (PTHrP 1-36), was approved by the FDA and became the second osteoanabolic after teriparatide (PTH 1-34). This study aims to elucidate the mechanisms that underlie the actions of PTH (1-34), PTHrP (1-36), and ABL in the osteoblast. Previously, we have shown that in primary murine calvarial osteoblasts, PTHrP (1-36) and ABL resulted in a significantly reduced cAMP response compared with PTH (1-34). Similarly, activation of protein kinase A (PKA) was observed at 1-2.5min and dose response analyses showed 1/2 max values of 1nM, 13nM, and 30nM for PTH (1-34), PTHrP (1-36), and ABL, respectively. Additionally, CREB activation by all three peptides reflected the relative differences in time and dose-dependent effects observed in the cAMP/PKA responses. qRT-PCR of osteoblastic genes showed that while all three peptides similarly regulate a subset of genes (e.g., SOST, ALPL, RUNX2), two genes, the transcription factor, c-Fos and RANKL, are differentially modulated. PTH (1-34) results in 2-fold greater c-Fos expression and 3-fold greater RANKL expression compared with PTHrP (1-36) and ABL (n=9, p<0.05). Co-treatment with the PKA agonist, 8-bromo-cAMP, increased RANKL mRNA and was decreased by the PKA-specific inhibitor, myristoylated protein kinase inhibitor. Recently, others have shown that in the osteocyte, PTH, through PKA, negatively regulates Sik2 and Sik3 (salt inducible kinases), which allows the nuclear translocation of the transcriptional cofactor, Crtc2, and transcription of RANKL. To determine the downstream signaling axes utilized by these peptides in the osteoblast, knockdown of reported effectors, Mef2c, Hdac4, Sik2, Sik3, Crtc2, Crtc3, and Creb were performed. While knockdown of Mef2c, Hdac4, Sik3, Crtc2, and Creb did not affect RANKL mRNA, Sik2 knockdown increased the effects of all three peptides, while Crtc3 knockdown decreased their effects. Confocal microscopy demonstrated that PTH (1-34) induces greater nuclear localization of CRTC2 and CRTC3 compared with PTHrP (1-36) and ABL. Knockdown of SIK2 mimics the effects of PTH (1-34) on CRTC2 localization, but does not affect CRTC3, suggesting that alternative mechanisms are employed by PTH (1-34) to exert its effects on CRTC3. Taken together, these data show that in the osteoblast, the effects of PTH (1-34), PTHrP (1-36), and ABL on RANKL are governed by differential regulation of the cAMP/PKA/SIK2/CRTC3 signaling axis.

A Comparison Between Osteoactivin and Bone Morphogenetic Protein-2 in Rat Spinal Fusion Model Jeremey Robinson *[1], Scott Mcdermott[1], Kevin Budge[2], Nazar Hussein[2], Fatima Jaber[2], Omar Azem[3], Matt Desanto[4], Adnan Raslan[4], Maleck Saleh[5], Bradley Inkrott[1], Fayez Safadi[4]. [1]Department of Orthopedic Surgery, SUMMA Health, United States, [2]School of Biomedical Sciences, Kent State University, United States, [3]Musculoskeletal Research Group, Northeast Ohio Medical University, United States, [4]Musculoskeletal Research Group, NEOMED, United States, [5]Musculoskeletal Research, NEOMED, United States

The search for osteoinductive therapeutic compounds remains critical to help accelerate bone healing in orthopaedic procedures including boney trauma and fusion surgeries. Osteoactivin/GPNMB (OA) is an osteoinductive compound that has previously been shown by our group to stimulate bone regeneration in vivo in the rat and sheep models without any deleterious side effects. Our goal is to compare OA to a currently accepted osteoinductive therapeutic compound, namely bone morphogenetic protein-2 (BMP-2). Specifically, the goal of this project is to compare BMP-2, which is widely accepted in the spine community for its role in spinal fusion, to OA in using a rat model for spinal fusion. The surgical protocol for posterolateral fusion was performed according to Yamaguchi et al. This method has already been accepted for spinal fusion results and allows for high standardization processes across each animal. Seventy male Sprague-Dawley rats were utilized and randomly divided

into seven groups with 10 rats in each group. Group 1: OA treated, Group 2: OA treated with autologous bone graft, Group 3: BMP-2 treated, Group 4: BMP-2 treated with autologous bone graft, Group 5: OA and BMP-2 treated with autologous bone graft, Group 6: no treatment with autologous bone graft, Group 7: no treatment without bone grafting. We analyzed fusion using μCT assessment, along with histological comparison of tissues for toxicity. Serum analysis using ELISA to detect OA protein levels was also investigated. Quantitative data from Avizo 3D software shows that BMP-2 has a greater amount of osteogenesis at the site of spinal fusion when compared to OA. Samples with BMP-2 show a larger amount of grossly disorganized bone growth and ossification of surrounding soft tissues. OA without graft shows bone growth with a well distributed boney fusion at the spinal transverse processes. The addition of graft enhanced osteogenesis in both BMP2 and OA treated groups. Histologic analysis of BMP-2 treated groups showed increased indicators of soft tissue inflammation, especially in lung tissue, when compared to OA treated groups. Dermal, cardiac, and neural soft tissue samples lacked any apparent difference between treatment groups. ELISA for OA protein levels did not show any difference in serum levels of OA Overall, it appears OA has no systemic soft tissue inflammatory effects and has more organized boney fusion compared to BMP-2 when used in spinal fusion.

Global Gene Expression Analysis Identifies Mef2c as a Wnt16 Target in Osteoblasts Aimy Sebastian*, Nicholas Hum, Cesar Morfin, Deepa Murugesh, Gabriela Loots. Lawrence Livermore National Laboratory, United States

Wnt16 is a major Wnt ligand involved in the regulation of postnatal bone homeostasis. Genome-wide association studies (GWAS) identified WNT16 as a key gene associated with low bone mineral density, reduced cortical thickness and high fracture risk. Studies in animal models and in vitro systems have shown that Wnt16 promotes bone formation and inhibits osteoclastogenesis, suggesting that this molecule could be targeted for therapeutic interventions to treat bone thinning disorders such as osteoporosis. It has also been suggested that Wnt16 signals via both canonical and non-canonical Wnt signaling pathways to perform its function. To better understand the molecular mechanisms by which Wnt16 promotes bone formation and to identify genes regulated by Wnt16 in osteoblasts (OBs), we treated calvarial OBs purified from C57Bl/6 mice with recombinant Wnt16 and profiled the gene expression changes by RNA-seq at 24h post-treatment. We also compared gene expression profiles of Wnt16-treated OBs to gene expression profiles of canonical Wnt3a- and non-canonical Wnt5a-treated OBs. We found 576 genes differentially expressed in Wnt16-treated OBs; these included several members of Wnt signaling pathway (Wnt2b, Wnt7b, Wnt11, Axin2, Sfrp2, Sfrp4, Fzd5, Rspo2 etc.) and TGF-β/BMP signaling pathway (Bmp7, Inhba, Inhbb, Tgfb2 etc.). We also found that about 37% (215/576) of the Wnt16 targets overlapped with Wnt3a targets and ~15% (86/576) overlapped with Wnt5a targets, suggesting that Wnt16 activates both canonical and non-canonical Wnt signaling targets in OBs. Only ten genes including Cxcl14, Kcnj15, Prg4 and Aqp5 were differentially expressed in response to treatment with all three Wnts. Transcription factor binding motif enrichment analysis in the promoter regions of Wnt16 targets identified Wnt/JNK pathway activated transcription factors Fosl1 and Fosl2 as significantly enriched transcription factors associated with genes activated by Wnt16 while Mef2c was the most significantly enriched transcription factor associated with genes repressed by Wnt16. We also found that Wnt16 transcriptionally down-regulates Mef2c, suggesting that a subset of genes repressed by Wnt16 treatment are normally activated by Mef2c. This is consistent with the negative feedback loop involving Mef2c and sclerostin where Mef2c deletion is anabolic by transcriptionally repressing Sost expression. Wnt16 also up-regulated Fstl3, a mediator of exercise-driven bone formation.

Potential usefulness of osteogenic exosomes as a therapeutic agent for bone engineering Takaki Sugihara*[1], Yoshinori Sumita[2], Myumi Iwatake[2], Naomi Sakashita[2], Izumi Asahina[1]. [1]Department of Regenerative Oral Surgery, Unit of Translational Medicine, Graduate School of Biomedical Science, Nagasaki University, Nagasaki, Japan, [2]Basic and Translational Research Center for Hard Tissue Disease, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan

Exosomes are extracellular vesicles with a diameter of 50 to 150 nm, contain miRNAs and proteins in its membrane structure, transport them without damage even in plasma or serum rich in degrading enzymes, it is thought that it contributes to intercellular communication. In this study, we focused on the exosomes secreted from bone marrow-mesenchymal stem cells (BM-MSCs) that received the osteoblastic differentiation stimulus by bone morphogenic protein (BMP) 2 and investigated the usefulness for applying them for bone engineering. As experiments, the osteogenic exosomes (O-EVs) were firstly obtained from the rat BM-MSCs after induced to the osteoblastic differentiation by exposing to recombinant human (rh) BMP2. Then, O-EVs were analyzed for their character via gene or protein expressions and evaluated further for their osteoblastic inducibility in BM-MSC culture. Lastly, O-EVs were transplanted to the rat cranial bone defects with alloplastic substitutes, and then the histological and immunohistological analyses were performed to observe the new bone formation in harvested specimens. Exosomes (EVs) obtained from non-induced BM-MSCs were employed as an experimental control. As results, mRNA expressions of osteo-

genic genes such as runx2, alp, or bmp2 in O-EVs were up-regulated compared with those of EVs. Moreover, some of microRNAs (miRNAs) related to the regulation of osteoblastic differentiation on MSCs were significantly up- or down-regulated in O-EVs. Then, when BM-MSCs were treated by O-EVs or EVs in culture, O-EVs could promote the osteogenic gene expressions in cells compared to EVs. We are currently carrying out an in vivo experiment to clarify the actual usefulness of O-EVs as an alternative option for bone engineering.

Bone Morphometric and Immunohistological Study on Mechanism of Longitudinal Overgrowth of Femur of Developing Rat Following Circumferential Periosteal Division Shinjiro Takata*. Tokushima National Hospital, National Hospital Organization, Japan

Here we report the mechanisms of longitudinal overgrowth of femur after CPD. Twenty-four Wistar rats aged 8 weeks were used for this study. Periosteum of diaphysis of the right femur was divided circumferentially (CPD group), and the left femur was control (Control group). Longitudinal length of CPD and Control groups 4 weeks after CPD were 39.43+/-1.2 and 38.48+/-0.75 mm (p=0.0086, n=6), respectively, indicating that overgrowth of longitudinal length reached to approximately 2.5% of Control group. Distal growth plate is responsible for approximately 91.5% of longitudinal overgrowth (n=6). Bone histomorphometry showed that CPD increased longitudinal growth rate, mineral apposition rate, bone volume, osteoid volume, trabecular number and thickness of femur (n=6). Analysis of three-dimensional trabecular microarchitecture and bone mass measurement by microcomputed tomography showed that trabecular number of CPD group was significantly greater than that of Control group (p=0.0116). Trabecular separation and trabecular spacing of CPD group were significantly smaller than those of Control group (p=0.0332, p=0.0261). Histological findings showed that the width of distal growth plate and the number of hypertrophic chondrocytes of CPD group were greater than those of Control group 4 weeks after CPD. Immunohistogical expression of Runx2 and IHH of CPD group in the growth plate was higher than that of Control group. HE and AB staining analysis in distal growth plate of rat femur showed an increased number of hypertrophic chondrocytes and width of hypertrophic zone of the distal growth plate of rat femur of CPD group compared with Control group. These results showed that CPD stimulates endochondral ossification of growth plate to produce longitudinal overgrowth of femur of developing rat. These facts suggest that periosteum plays an important role to regulate endochondral ossification of growth plate, and that CPD might become promising treatment to lengthen tubular bone of pediatric patients with leg length discrepancy.

Lnc-OIF, A newly identified Long noncoding RNA, Inhibits Osteoblast Differentiation and Bone Formation Ye Tian*, Chong Yin, Xue Wang, Chaofei Yang, Zixiang Wu, Xiaoli Ma, Zizhan Huang, Airong Qian. Northwestern Polytechnical University, China

Long non-coding RNAs (lncRNAs) correlates with multiple physiological and pathology processes including development, carcinogenesis and osteogenesis. However, reports on lncRNAs regulating bone formation were relatively limited. The maintenance of bone formation relies on the activity and differentiation of osteoblast. It has been proved that lncRNAs participate in the regulating of osteoblast differentiation.Previously, we identified MACF1 with ossification-promoting properties. MACF1, a cytoskeletal protein, enhances osteoblast differentiation by mediating translocation of β-catenin into nuclear. We assume MACF1 may be a regulator of osteogenic non-coding RNAs as well.In this study, we screened osteogenic lncRNAs through mRNA/lncRNA-microarray in MACF1 low/normal expressed MC3T3-E1 cell line combined with gene coexpression analysis. The lncRNAs with most significant average coexpression levels (<-0.85) were selected. While, only lnc-OIF was enriched in skeletal tissues of mice. And it progressively decreased in bone-derived mesenchymal stem cells (MSCs) isolated from 12 to 24 month mice of age. In addition, the expression level of lnc-OIF decreased with the progress of osteoblastic differentiation in MC3T3-E1 cells. The biological function of the screened lnc-OIF was assessed both in vitro and in vivo. Down-regulating lnc-OIF by siRNA in MC3T3-E1 cells up regulated osteogenic gene ALP and Col-I expression, and augmented ALP activity and calcium nodules. Administrating si-lnc-OIF with EntransterTM In Vivo Transfection nanoparticles subcutaneously over the calvarial surface, increased 21.7% (p<0.001) of average calvarial thickness, 99.6% (p<0.001) of mineral apposition rate and protein levels for osteogenic marker genes (OCN and OPG) compared to negative control.To further clarify the regulation mechanism of lnc-OIF to ossification, we evaluated the expression and activity of osteogenic transcription factors after si-lnc-OIF transfection both in vitro and in vivo. Interference of lnc-DA2 expression increased RUNX2, LEF1 and TCF7 mRNA level, RUNX2 protein expression in mouse cranium, and LEF1/TCF7 transcriptional activity.In conclusion, we have revealed lnc-OIF as a novel osteogenic regulator. Lnc-DA2 inhibits osteoblast differentiation and bone formation through suppressing osteogenic transcription factors. This newly identified lncRNA has provided a fresh mechanism of osteogenic differentiation and target for treatment of skeletal disorders.

JNK MAP Kinase is required for both BMP and Notch induced Human Osteoblast Differentiation Yadav Wagley*, Kurt D. Hankenson. Department of Orthopaedic Surgery, University of Michigan, United States

Earlier studies from our laboratory have shown that human mesenchymal stem cells (hMSCs) undergo osteoblast differentiation in response to BMP-6 stimulation or by culturing them in presence of immobilized Jagged-1. However, the converging point of these different signaling cascades on osteoblast differentiation of hMSCs has not been identified. Since mitogen activated protein kinase (MAPK) components are known to affect gene expression in response to various stimuli, and ERK has been previously shown to intersect with Runx2, we examined the role of MAPK pathways during both BMP-6 and Jagged-1 mediated osteoblastogenesis in three independent donor cell lines. Histochemical staining for ALP expression and extracellular matrix mineralization using Alizarin red S in the presence of MAPK inhibitors showed that only c-jun N-terminal kinase (JNK) activity was required for immobilized Jagged-1 mediated osteoblastic differentiation whereas both p38 MAPK and JNK activity were required for BMP-6. Interestingly, inhibiting ERK increased ALP expression and accelerated mineralization in response to both stimuli. Gene expression analysis revealed that disruption of the p38 MAPK and JNK in BMP-6 stimulated cells resulted in decreased expression of Osterix, although Runx2 expression remained variable. However, in response to Jagged-1, the protein levels of both Runx2 and Osterix remained unaffected suggesting a different mode of osteoblast differentiation. Finally, to examine if BMP-6 signaling utilized MAPK signals to couple to Notch activation, immunoblot analyses were carried out, which showed that abolishing both p38 MAPK or JNK activity affected Notch-2 processing and expression of full length Notch-3 protein. Collectively, these results suggest that MAPK activity may integrate BMP and Notch signaling pathway to augment human osteoblast differentiation.

The Regulatory Actions of TRPC3 Channels in the Differentiation and Functions of Osteoblastic Cells Yu-Mi Yang*, Dong Min Shin. Department of Oral Biology, Yonsei University College of Dentistry, Republic of Korea

Mechanical stress plays an important role in bone remodelling and maintenance. However, the mechanism of intracellular Ca2+ entry by canonical transient receptor potential 3 (TRPC3) channels and mechanical stress in bone cells is not well known. This study investigated the role of TRPC3 channels for the Ca2+ signal transduction in the osteoblastogenesis using TRPC3 knockout (KO) mice. The deletion of TRPC3 markedly increased of the bone density of the femur (~1.39-fold in 4-week old) in an age-dependent manner. After treatment with RANKL, TRPC3 KO bone marrow-derived monocytes/macrophages (BMMs) significantly reduced NFATc1 translocation to the nucleus, bone resorption activity, and multinucleated cells formation. The potency of osteoblastic differentiation in TRPC3 KO mice showed enhanced effects compared to wild-type mice by the methods of alkaline

phosphatase and alizarin red staining. Mechanical stress induces extracellular ATP release. TRPC3 contributed to an ATP-induced increases of intracellular Ca2+ in osteoblast cells (~2.33-fold), providing a pathway for receptor-operated Ca2+ entry in osteoblastic cells of TRPC3 KO mice. These results suggest that TRPC3 channels play an important regulatory action in the activation of receptor-operated Ca2+ entry and differentiation and functions of osteoblasts.

Effect of Cannabinoid Receptor Ligands on Osteogenic Differentiation Chawon Yun*[1], Adam Driscoll[1], Ryan Lubbe[1], Soyeon Jeong[1], Kevin Chang[1], Meraaj Harleem[1], Richard Pahapill[1], Mark Oyer[1], Stuart Stock[2], Wellington Hsu[3], Erin Hsu[3]. [1]Northwesten University Department of Orthopaedic Surgery, Chicago, IL, United States, [2]Northwestern University Cell and Molecular Biology, United States, [3]Northwestern University Feinberg School of Medicine Department of Orthopaedic Surgery, United States

BACKGROUND CONTENTS : After spine surgery, most patients receive opioids for pain, but controversy exists because of widespread abuse. The endocannabinoid system has been shown to have anti-nociceptive activity in animal models of acute tissue and nerve injury, and is thought to be important to bone homeostasis via activity at the CB1 and CB2 receptors. In this study, we explore the potential for the use of WIN55 as an alternative post-operative analgesic. METHODS: In vitro: Rat bone marrow stromal cells (BMSC) were cultured under standard or osteogenic media and subsequently exposed to either the vehicle control (DMSO) or the cannabinoid receptor agonist, WIN55,212-2 (WIN55). Expression of Runx2 and Alkaline phosphatase were quantified via qPCR. ALP activity and bone matrix mineralization were also measured. In vivo: Female Sprague Dawley rats underwent L4-L5 posterolateral spine fusion (PLF) with bilateral placement of absorbable collagen sponge (ACS) pre-loaded with 0.5 μg of recombinant bone morphogenetic protein-2. Animals (n=15/group) received DMSO, low-, or high-dose WIN55 via intraperitoneal injection for 5 days post-operatively. All animals received routine post-operative pain control. Bone regeneration was assessed using radiography, manual palpation-based fusion scoring, and microCT imaging. For fusion scoring, an established scoring system was used whereby 0 = no bridging bone, 1 = unilateral bridging, and 2 = bilateral bridging between the L4-L5 transverse processes. RESULTS: In vitro: mRNA expression of Alp and Runx2 was similar between DMSO and WIN55 treated cells. Exposure to WIN55 did not inhibit ALP activity or bone matrix mineralization. In vivo: No significant differences were found among groups in regards to mean fusion scores or fusion rates, (Fig. 1A), or in the volume of newly formed bone (representative fused specimens shown, Fig. 1B). Histological sections show bridging bone in fused specimens from each group. CONCLUSION: Here, we present pre-clinical evidence that WIN55, a dual cannabinoid receptor agonist, does not adversely affect osteogenic differentiation in vitro or bone regeneration and spine fusion in vivo. These results support the notion that cannabinoid receptor agonists should be further pursued as a potential alternative approach for post-operative analgesia following spine surgery and other orthopaedic procedures requiring bone healing.

Phlpp1 controls osteoclastogenesis and bone resorption Dana Begun*, David Molstad, Jennifer Westendorf, Merry Jo Oursler, Elizabeth Bradley. Mayo Clinic, United States

Bone remodeling processes are disrupted in many diseases, including osteoporosis, periodontitis, tumor-induced bone disease and arthritis. Decreased bone mineral density in these conditions is often caused by enhanced osteoclast function. Phlpp1 is a protein phosphatase that is poised to be a critical regulator of bone mineral density because it dephosphorylates and inactivates numerous pathways (e.g., Akt, PKC, MAPK) that regulate osteoclast differentiation and function. Previous results demonstrate that Phlpp1 germline deficiency reduces bone volume, but the cell-type specific functions of Phlpp1 remained to be elucidated. To evaluate the function of Phlpp1 in bone resorbing osteoclasts, we generated Phlpp1fl/fl mice via a TALEN-based approach. Phlpp1 fl/fl mice were then crossed with Ctsk-Cre expressing mice to conditionally delete Phlpp1 in mature osteoclasts. MicroCT analyses of 12-week-old mice demonstrated that female Phlpp1 cKOCtsk mice exhibit increased femoral bone volume, BV/TV, BMD and trabecular number with a corresponding decrease in trabecular spacing. Vertebral body trabecular parameters were also enhanced in Phlpp1 cKOCtsk mice. No changes in bone parameters of male Phlpp1 cKOCtsk male mice were observed via microCT. Histomorphometric analyses confirmed increased BV/TV, but also revealed increased osteoclast numbers in Phlpp1 cKOCtsk female mice. Phlpp1 deficiency elevated osteoclast number and osteoclast size in ex vivo osteoclastogenesis assays, but reduced Alizarin red staining of calvarial osteoblast cultures. This was accompanied by enhanced bone marrow macrophage expression of c-fms and hyper-responsiveness to M-CSF. Western blotting demonstrated that Phlpp1 deficient osteoclasts have enhanced activation of Mek1/2, Erk1/2 and Akt2 in response to M-CSF, but activation of conventional PKCα/β isoforms was unchanged. In addition to regulating the activity and stability of conventional PKC isoforms, Phlpp1 also inactivates the atypical PKCζ isoform to establish cell polarity. We observed increased PKCζ activity and diminished actin ring formation in Phlpp1 deficient osteoclast cultures. Likewise, serum markers of bone resorption (CTX-1) were not elevated in Phlpp1 cKOCtsk despite enhanced osteoclast numbers. In contrast, serum P1NP levels were elevated by 35% in Phlpp1 cKOCtsk mice. These results suggest that Phlpp1 deficiency enhances osteoclast number, but diminishes bone resorption by disrupting osteoclast polarity.

Trpm8 Knockout causes compartment-specific bone loss and altered osteoclast number and activity Adriana Carvalho*, Trevor Morin, Katherine Motyl. MMCRI, United States

Trpm8 (transient receptor potential melastatin 8) is a cold-sensing channel expressed by pain- and temperature-sensing neurons known to be the principal detector of environmental cold. Recent data suggest environmental temperature impacts bone density. Our aim was to investigate the role of these sensory neurons in regulating bone turnover using the Trpm8 knockout (KO) mice. Bones were collected from 8-week-old male wild-type (WT) and Trpm8KO mice. Bone mineral density (aBMD) and body composition were measured by DXA. Trabecular and cortical bone were evaluated by micro-computed tomography (μCT). Trpm8KO mice had lower body mass compared to WT due mostly to fat mass loss. aBMD was similar between groups. However, Trpm8KO mice had reduced trabecular BV/TV in the femur compared to WT (WT=28.22±1.59%vs.Trpm8KO=23.29%±2.45;p<0.05). Similarly, trabecular BV/TV (WT=38±2%vs.Trpm8KO=33±3%;p<0.05) was also reduced in the vertebrae of Trpm8KO mice with significantly lower connectivity density (Conn.D) and trabecular thickness (Tb.Th) compared to WT. Cortical bone was similar between groups. We previously found that Trpm8 deletion increases Rankl expression and suppresses osteoblast differentiation. To determine if Trpm8 deletion directly impacts bone resorption, we differentiated WT and Trpm8KO bone marrow stromal cells to osteoclasts (OCL). TRAP positive OCL numbers were decreased in Trpm8KO cultures compared to WT; however, Trpm8KO OCL resorbed more synthetic calcium phosphate surface compared to WT OCL. OCL markers (Acp5 and Ctsk) had increased expression throughout differentiation, but no differences existed between groups. Despite these differences in vitro, there was no convincing Trpm8 expression in OCL at any stage of differentiation. Interestingly, brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) were significantly elevated in the Trpm8KO group at day 7, which may explain increased resorption as both have direct effects on OCL. In summary, male Trpm8KO mice had low trabecular BV/TV. Although Trpm8 showed little to no expression in OCL, the deletion affected the number and functionality of the cells ex vivo. BDNF and NGF data suggest that deletion of Trpm8 may influence bone density by altering neurotrophic factor-receptor signaling in OCL in vivo. Our future directions will be to investigate and sensory neuron crosstalk and whether the Trpm8 deletion specifically in sensory neurons triggers uncoupled bone remodeling.

Models of Elevated Cortical Bone Remodeling in the Rabbit: Platforms for Longitudinal Imaging of Basic Multicellular Units Beverly Hiebert*[1], Kim Harrison[1], Arash Panahifar[2], Amir Ashique[1], Terra Arnason[1], Janna Andronowski[3], Kurtis Swekla[1], David Cooper[1]. [1]University of Saskatchewan, Canada, [2]Canadian Light Source, Canada, [3]University of Akron, United States

Background: Regulation of Basic Multicellular Units (BMUs) in cortical bone remodeling has been the subject of a great deal of theoretical and/or in silico research due to a lack of direct empirical evidence. Synchrotron-based imaging combined with an appropriate animal model has the potential of tracking individual cortical bone remodeling events and thereby directly testing hypotheses related to BMU spatio-temporal regulation. The rabbit is the smallest model system which exhibits cortical remodeling that, like humans, creates secondary osteons; however, this process is slow and experimental approaches to elevate remodeling in rabbits have primarily focused on trabecular bone.Objective: Our objective is to develop model systems of elevated cortical remodeling in rabbits to optimize 4D synchrotron-based imaging of BMUs in vivo.Methods: Four mechanisms for elevating remodeling were explored in groups (n=7) of skeletally mature New Zealand White Rabbits – primary osteoporosis (ovariectomy; OVX), secondary osteoporosis (glucocorticoid; GC), a combination of OVX and GC (OVXGC) and finally, parathyroid hormone (PTH), a potent regulator of remodeling. The OVX groups (OVX and OVXGC) and control (SHAM) were operated upon eight weeks prior to the commencement of pharmaceutical treatments. GC (1.5 mg/kg/day), PTH (30 μg/kg/day), or vehicle (1 mL saline/day) dosing were carried out for four weeks with two day calcein labels administered at two and four weeks. Cortical microarchitecture was assessed by micro-CT (cortical porosity) at 10 μm voxel size and histomorphometry (resorption space and labelled osteon numbers). Results: Cortical porosity on the scale of resorption spaces was higher than SHAM for only the PTH group (p<0.01). Within all groups, pores on this scale included classic cutting cone configurations as well as more complex clustered resorption spaces particularly for the PTH group. Resorption space number was greater than SHAM for both PTH and OVXGC (p<0.01) while a combined measure of remodeling activity (resorption spaces plus labelled osteons) was greater than SHAM for OVX (p<0.05) and PTH (p<0.01).Conclusions: While variance within the groups limited the number of parameters which were significantly different from the SHAM group, all groups demonstrated trends towards increased remodeling activity. This suggests they may all be good targets for longitudinal synchrotron-based imaging and comparative analysis of four dimensional BMU behavior.

miR-29 Targets E-cadherin Complex Members in the Osteoclast Lineage
Henry Hrdlicka*, Sun-Kyeong Lee, Anne Delany. UConn Health, United States

miR-29 is a positive regulator of osteoclastogenesis; miR-29 inhibition decreases pre-osteoclast motility, and causes the formation of smaller and fewer osteoclasts in vitro. Two members of the Rho-GTPase family are validated direct (Cdc42) or indirect (Rac1 via srGAP2) miR-29 targets. These molecules positively regulate actin remodeling needed for osteoclast formation and function. Rac1 and Cdc42 also contribute to the E-cadherin signaling complex (see Figure). E-cadherin is a transmembrane protein that promotes strong cell-cell interactions, including those important for pre-osteoclast fusion. The E-cadherin complex is composed of α-, β-, and p120-catenins, actin remodeling proteins (i.e. Formin-like 2; Fmnl2), Rho-GTPases, and GTPase regulatory proteins. Of these complex members, E-cadherin, Fmnl2, and β- and p120-catenins are predicted to be novel miR-29 targets. We investigated the E-cadherin complex and the impact of miR-29 on E-cadherin complex members in osteoclasts.qPCR showed that E-cadherin and Fmnl2 mRNA were well expressed in osteoclast progenitors isolated from whole mouse bone marrow, but their expression decreased >80% as progenitors were differentiated toward osteoclasts with RANKL. This inversely correlated with the increase in miR-29 during osteoclastogenesis. To validate miR-29 regulation of E-cadherin complex members, we cloned the E-cadherin, Fmnl2, and β-catenin 3'-UTRs into the pMIR-REPORT luciferase construct. RAW264.7 cells were transfected with luciferase constructs, in the presence of either miR-29b inhibitor or a non-targeting control. For each luciferase construct, we observed a 2 fold increase in luciferase activity upon inhibition of miR-29b (p<0.01; n=5-6), indicating that E-cadherin, Fmnl2, and β-catenin are indeed miR-29 targets.To evaluate the regulation of the E-cadherin complex by miR-29 in primary cells, osteoclast progenitors were isolated from mice globally expressing a miR-29 competitive inhibitor (tough decoy) from the ROSA26 locus. In osteoclast precursors from miR-29 decoy mice, E-cadherin and Fmnl2 mRNA were increased more than 2 fold (p<0.05; n=3-4).In summary, we identified novel miR-29 targets in the osteoclast lineage: E-cadherin, Fmnl2, and β-catenin. The E-cadherin complex facilitates cell-cell interactions necessary for pre-osteoclast fusion, and the fine tuning of these complex members by miR-29 may be necessary to ensure the formation of appropriately sized osteoclasts.

IgG complex with protein A of Staphylococcus aureus enhances osteoclastogenesis and bone resorption. Asana Kamohara*[1], Xianghe Xu[1], Makoto Shiraki[2], Hirohito Hirata[1], Toshio Kukita[3], Akiko Kukita[1]. [1]Department of Microbiology, Faculty of Medicine, Saga University, Japan, [2]Department of Orthopedic Surgery, Faculty of Medicine, Saga University, Japan, [3]Department of Molecular Cell Biology & Oral Anatomy, Faculty of Dentistry, Kyushu University, Japan

Staphylococcus aureus is a main pathogen of osteomyelitis which is associated with inflammation and bone destruction. S. aureus protein A (SpA) is a virulence factor which has highly affinity for IgG. Recent reports demonstrated that immune complexes produced in pathogenetic condition regulate not only inflammation but also osteoclastogenesis. In vivo, IgG complex with S. aureus may play a role in bone resorption caused by bacterial infection. In this study, we investigated whether S. aureus has effect on differentiation and bone resorption of osteoclasts through IgG binding capacity of SpA.While addition of S. aureus to POc induced osteoclast (Oc) differentiation moderately, S. aureus pretreated with mouse serum dramatically increased OC differentiation to 2-10 fold from POc in mouse bone marrow culture. Serum pretreated S. aureus also strongly induced the expression of cathepsin K whereas SpA deficient mutant S. aureus did not increase the expression of cathepsin K. In addition, S. aureus but not SpA deficient mutant induced bone resorptive Ocs. Instead of mouse serum, S aureus pretreated with IgG polyclonal, IgG1 or IgG2a monoclonal antibodies strongly induced Oc differentiation, demonstrating that IgG is responsible for osteoclastogenesis. Because IgG complex may bind to Fc receptor on POc, we analyzed the effect of blocking of Fc receptor using CD16/32 antibody and found that Oc differentiation induced by S. aureus was strongly inhibited. Although SpA is also released from bacterial surface, SpA alone did not induce significant number of Ocs even if it was pretreated with mouse serum. To analyze the contribution of cell wall components and mechanism, we analyzed whether S. aureus stimulate OC differentiation from POc of TLR2 and Myd88 KO mice. Oc differentiation induced by S. aureus was markedly decreased in comparison with WT mice, suggesting TLR2 signaling is involved. Consistently, stimulation of POc with both of serum pretreated SpA and TLR2 ligand Pam3CSK4 enhanced Oc differentiation in comparison with Pam3CSK4 alone. In addition, NFATc1 and NFkB but not p38 MAPK inhibitors suppressed Oc differentiation induced by S. aureus. Finally, local injection of S. aureus but not SpA deficient mutant into mouse calvaria formed erosion of bone surface. Taken together, we show here that IgG complex with SpA formed on cell surface of S. aureus play a new role in bone destruction, which is mediated by both Fc receptor and TLR2 in POc.

Effect of C-X-C Motif Chemokine 12 in Lipopolysaccharide-induced Osteoclast Formation and Bone Resorption Hideki Kitaura*, Kazuhiro Shima, Keisuke Kimura, Masahiko Ishida, Akiko Kishikawa, Saika Ogawa, Jiawei Qi, Wei-Ren Shen, Fumitoshi Ohori, Takahiro Noguchi, Aseel Marahleh. Division of Orthodontics and Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan

C-X-C motif chemokine 12 (CXCL12), also known as stromal cell-derived factor 1 (SDF1), belongs to the family of CXC chemokines. In recent years, it has been reported that CXCL12 has been associated with survival of osteoclast progenitor cells, differentiation, fusion, and functions. Therefore, it is important to investigate the relationship between osteoclast formation and CXCL12 to elucidate mechanisms of diseases that induce bone resorption. Lipopolysaccharide (LPS) is a major component of cell wall of gram-negative bacteria that is able to induced osteoclast formation and pathological bone resorption. In the present study, we investigated the effects of CXCL12 on LPS-induced osteoclast formation and bone resorption. LPS with or without CXCL12 was administered to mouse calvariae by daily subcutaneous injection. The number of osteoclasts and bone resorption were significantly higher in LPS and CXCL12-co-administered mice than in mice administered LPS alone. Receptor activator of NF-kB ligand (RANKL) and tumor necrosis factor-α (TNF-α) mRNA expression levels were higher in the CXCL12 and LPS-co-administered group than in the LPS-administered group. Our in vitro results also showed direct stimulatory effects of CXCL12 on RANKL- and TNF-α-induced osteoclast formation. Furthermore, TNF-α mRNA expression was enhanced in CXCL12 and LPS-co-treated macrophages compared with cells treated with LPS alone in vitro. However, there was no effect of CXCL12 on LPS-induced RANKL expression in stromal cells in vitro. These results suggest that CXCL12 enhances LPS-induced osteoclast formation and bone resorption in vivo by increasing LPS-induced TNF-α production in macrophages and directly enhancing osteoclast formation.

Haptoglobin acts as a novel ligand for TLR4, suppressing osteoclastogenesis via activation of TLR4 - INF-β signaling pathway Zang Hee Lee*, Hong-Hee Kim, Jun-Oh Kwon. Department of Cell and Developmental Biology, Dental Research Institute, School of Dentistry, Seoul National University, Republic of Korea

Inflammatory molecules such as cytokines and small molecules are well known to play a major role in the regulation of bone homeostasis, but the effects of anti-inflammatory molecules among inflammatory molecules on osteoclasts are not fully unveiled. Haptoglobin (Hp), a kind of acute protein, is known to play as an anti-inflammatory function systematically and to modulate inflammation by directly affecting immune cells such as T cells, dendritic cells, and macrophages. However, the effect of Hp on osteoclast differentiation is not well studied, even though osteoclast precursor cells belong to macrophage-monocyte lineage. Here, we confirmed that the bone volume of the Hp-deficient mice was reduced and observed an increase in the number of osteoclasts. Besides, in vitro studies, we have shown that Hp inhibits osteoclastogenesis by suppressing post-translation of c-Fos at the early phase of osteoclast differentiation. We found that Hp-induced suppression of c-Fos was mediated by an increase of interferon beta (INF-B) levels, a well-known to inhibit post-translation of c-Fos. Further, Hp stimulates IFN-B via toll-like receptor 4 (TLR4) dependently. Taken together, these results demonstrate that Hp plays a protective role against excessive osteoclastogenesis via the Hp-TLR4-IFN-B signaling pathway.

MON-0645

RANK PVQEET560-565 and PVQEQG604-609 Motifs play important roles in Porphyromonas gingivalis-mediated regulation of osteoclastogenesis Yuyu Li*[1], Shenyuan Chen[2], Zhenqu Shi[3], Xu Feng[3], Ping Zhang[4]. [1]Sichuan University, China, [2]Stomatological Hospital of Chongqing Medical University,Chongqing Key Laboratory of Oral Diseases and Biomedical Sciences, Chongqing Municipal Key Laboratory of Oral Biomedical Engineering of Higher Education, Chongqing, 400015, China, [3]Department of Pathology, University of Alabama at Birmingham, AL35284, United States, [4]Department of Pediatric Dentistry, University of Alabama at Birmingham, AL35294, United States

Porphyromonas gingivalis (Pg) is a major pathogen of periodontitis, an inflammatory osteolytic disease characterized by the damage of tissues surrounding the teeth, including alveolar bone. The receptor activator of NF-?B ligand (RANKL) and its receptor RANK are crucial regulators for the differentiation and activation of osteoclasts. Our previous studies have shown that Pg was able to potentiate RANKL-induced osteoclastogenesis in RANKL-committed osteoclast precursors. In addition, we have identified two functional motifs in the RANK cytoplasmic domain: PVQEET560-565(Motif 2) and PVQEQG604-609(Motif 3) that are critical for RANKL-mediated osteoclast differentiation. In this study, we aimed to clarify whether Motif 2&3 are involved in Pg-mediated regulation of RANKL-induced osteoclastogenesis. Bone marrow macrophages (BMMs) were isolated from 6- to 8-week old wild type (WT) mice and homozygous knockin (KI) mice bearing inactivating mutations in Motif 2&3 (RANKmut/mut). Cells were maintained with macrophage colony-stimulating factor (M-CSF), pretreated with RANKL for 24h, and then stimulated with Pg. Pg induced the formation of tartrate-resistant acidic phosphatase (TRAP)-positive multinucleated cells in WT BMMs after 4-day culturing, while Pg failed to induce osteoclast differentiation in RANKmut/mut BMMs. We also examined osteoclast formation on bone slices by assessing the presence of multinuclearation and actin ring, both of which are important features of mature osteoclasts. Similarly, osteoclast formation was only detected in WT but not RANKmut/mut BMMs treated with Pg. To understand the underlying mechanism, we examined the effect of Pg on RANKL-induced expression of osteoclast genes, as well as the activation of transcription factors important in osteoclast differentiation. Our results showed that 24h treatment of RANKL-pretreated WT BMMs with Pg significantly increased the expression of osteoclast genes including carbonic anhydrase II (Car2), cathepsin K (Ctsk), matrix metal-

lopeptidase 9 (MMP9), and TRAP, whereas no up-regulation of these genes was observed in RANKmut/mut BMMs following Pg treatment. Furthermore, Pg increased the activation of c-fos and NFATc1 in WT BMMs but not in RANKmut/mut BMMs. Taken together, our results suggest that RANK Motif 2 and 3 are critical in Pg-mediated regulation of osteoclastogenesis. These motifs may represent potential therapeutic targets for periodontitis.

Asiatic Acid Attenuates Bone Loss by Regulating Smad7/TAK1/NF-κB Signaling Pathway in Osteoclastogenesis Sien Lin*[1], Haixing Wang[1], Bo Wei[2], Yuk Wai Lee[1], Liao Cui[2], Gang Li[1]. [1]The Chinese University of Hong Kong, Hong Kong, [2]Guangdong Medical University, China

ObjectiveRecently we have demonstrated that partial loss of Smad7 in mice leads to compromised bone quality. This study is to examine the role of Asiatic acid (AA), an activator of Smad7, in the regulation of osteogenesis and osteoclastogenesis, and further to investigate its effect on bone quality in overiectomized (OVX) mice and Smad7-deficient mice model.MethodsFor in vitro studies, the effects of AA at different doses on mice bone marrow derived mesenchymal stem cells (MSCs) proliferation and osteogenic differentiation potentials were tested. The effects of AA on bone marrow derived mononuclear cells (BM-MNCs) osteoclastogenic differentiation were also tested by TRAP stain and bone resorption activity in HA-coated plates. Real time-PCR and western blot were performed to measure the changes of key markers including Smad7, Smad2/3, pSmad2/3, TAK1, pTAK1, NF-κB, and RANK involved in osteoclastogenesis. For in vivo studies, female ICR mice were subjected to either OVX or sham operation. The OVX animals were treated with saline, AA, Alendronate (ALN), or a combination of AA and ALN. Another in vivo study was performed to verify the effect of AA on Smad7 deficient mice using the same approach. Micro-computed tomography (μCT) examinations, four-point bending test, and histomorphometric analysis were performed at the endpoint.ResultResult shown that AA exhibited no cytotoxic effect on MSCs and no significant effect on osteogenesis. Interestingly, AA significantly inhibited osteoclastogenesis of MNCs at a dose-dependent manner. Results also shown that Smad7 was upregulated, and pSmad2/3, pTAK1, NF-κB, and RANK were downregulated by AA in MNCs during osteoclastogenesis. In the animal study, AA significantly restored trabecular bone and increased bone mechanical properties in the two animal models. Histomorphometry and TRAP stain revealed that the activity of osteoclasts was significantly inhibited by AA. However, a combination of AA and ALN didn't show any synergistic effect on bone quantity and quality. ConclusionAA shown significant inhibition effect on ostoclastogenesis dose-dependently by upregulating the expression of Smad7, and then inhibiting the phosphorylation of TAK1 and activation of NF-κB. AA also attenuated bone loss by inhibiting activity of osteoclasts in both the OVX mice and Smad7-deficient mice. In a word, we found that AA effectively prevented osteoporosis by regulating Smad7/TAK1/NF-κB pathway in the osteoclastogenesis.

Protease Activated Receptor 2 (PAR2): A Novel Regulator of Osteoclastogenesis Sarah Mcgrath*[1], Leif Hultin[2], John C Lockhart[3], Carl S. Goodyear[1]. [1]Institute of Infection, Immunity, and Inflammation, University of Glasgow, United Kingdom, [2]Respiratory, Inflammation and Autoimmunity, Innovative Medicines and Early Development, AstraZeneca, Sweden, [3]Institute of Biomedical & Environmental Health Research, University of the West of Scotland, Paisley, United Kingdom

Protease activated receptor 2 (PAR2) is a G protein coupled receptor responsive to serine proteases, which plays a key role in inflammation and pain perception. We have previously demonstrated that Par2-/- mice are protected from Freund's Complete Adjuvant (FCA) induced arthritis. Moreover, rheumatoid arthritis (RA) patients have up-regulated

Monday Posters

surface expression of PAR2 in circulating monocytes, and the level of expression correlates with disease activity. Monocytes play a dual role in the progression of RA, through their capacity to differentiate into both inflammatory monocyte-derived macrophages and bone resorbing osteoclasts (OCs). In order to investigate the role of PAR2 in osteoclastogenesis we investigated the impact of loss of PAR2 on both the non-adherent bone marrow compartment and osteoblasts.Non-adherent bone marrow (BM) cells from 6-10 week old Par2-/- and control C57BL/6 mice were cultured in pro-osteoclastogenic media for 5 days and mature OCs, identified as tartrate-resistant acid phosphatase positive (TRAP) multinucleated cells, counted. The resorption potential of these cells was assessed using osteolysis plates and the total osteo-resorption quantified after 7-14 days of culture. Transcript levels of osteoclast associated genes were analysed. Pre-osteoblasts (pOBs) were digested from calvaria of 3-5 day old pups from WT and Par2-/- genotypes and matured in cell culture. Transcript of OB associated genes were analysed in mature OBs and their potential to initiate osteoclastogenesis was assessed in a prostaglandin E2 (PGE) and vitamin D supplemented co-culture with BM monocytes.In vitro osteoclastogenesis assays exhibited increased numbers of mature OCs generated from Par2-/- non-adherent BM compared to WT, which corresponded with elevated levels of resorption. Transcript levels of OC-associated genes (i.e. NFATc1, Cathepsin K, TRAP, and DC-STAMP) were all increased compared to WT comparators. Co-culture of monocytes with mature OB revealed Par2-/- OB had the capacity to increase osteoclastogenesis in both WT and Par2-/- monocytes. This seems to be in part due to diminished production of the regulatory factor osteoprotegrin, found in Par2-/- OB transcript. In conclusion, we propose that PAR2 contributes to the regulation of osteoclastogenesis via the mesenchymal arm of the bone remodelling unit; suggesting a potential regulatory role for protease activity and sensing via PAR2 in bone remodelling and osteoclastogenesis.

Targeted Deletion of TAF12 in Osteoclasts Decreases Osteoclast Activity in Vivo Kazuaki Miyagawa*[1], Yasuhisa Ohata[1], Jolene J. Windle[2], G. David Roodman[1,3], Noriyoshi Kurihara[1]. [1]Medicine/Hematology-Oncology; Indiana University, United States, [2]Human and Molecular Genetics, Virginia Commonwealth University, United States, [3]Roudebush VA Medical Center, United States

We previously reported that TAF12, a member of the TFIID transcription family, also acts as a coactivator of VDR-mediated gene expression, by forming a complex with ATF7 and TAF4 that binds VDR via TAF12. TAF12 is upregulated in osteoclasts (OCL) from Paget's Disease (PD) patients and the increased TAF12 levels enhance the 1,25-Dihydroxyvitamin D3 (1,25-D3) responsivity of PD OCL-precursors. This allows OCL formation at physiologic levels (10-11M) of 1,25-D3. However, the role of TAF12 in normal OCL activity in vivo is unclear. Therefore, we generated Taf12flox/flox mice using CRISPR/Cas9 technology and bred them to TRAP-Cre (TC+) mice to develop TRAP-Cre/Taf12flox/flox (TC(+)/Taf12) mice with targeted deletion of TAF12 in OCL. Purified OCL from TC(+)/Taf12 mice expressed 60-75% less TAF12 than OCL from TC(-)/Taf12 mice. TAF12 expression in osteoblasts and bone marrow stromal cells was similar in both genotypes. μqCT analysis at 8 month old mice showed a 1.3 fold increase in BV/TV in TC(+)/Taf12 vs.TC(-)/Taf12 mice (p<0.05). Histomorphometric analysis revealed that OCL number and surface were decreased by 40% in TC(+)/Taf12 mice vs. TC(-)/Taf12 (p<0.01), while osteoblast numbers and surface were similar. These findings suggest that increased bone mass results from decreased OCL activity. To further characterize the OCL defect in TC(+)/Taf12 mice, OCL formation and activity in bone marrow cultures of purified OCL precursors from TC(+)/Taf12 mice treated with 1,25-D3 (10-8 M) were determined. OCL numbers, CYP24A1, VDR, cathepsinK and IL-6 expression in OCL and bone resorption capacity/OCL on bone slices were significantly decreased in TC(+)/Taf12 compared to TC(-)/Taf12 cultures. Although OCL formation with RANKL (50 ng/ml) treatment was similar in TC(+)/Taf12 and TC(-)/Taf12 marrow cultures, bone resorption capacity/OCL remained greatly decreased in TC(+)/Taf12 cultures. Since autophagy regulates bone resorption and 1,25-D3 may induce Syntaxin17 expression, we then measured LC3 and Syntaxin17 levels in OCL. LC3-II and Syntaxin17 were decreased in TC(+)/Taf12 OCL regardless if the OCL were induced by 1,25-D3 or RANKL. Syntaxin17 immunostaining of bone sections confirmed decreased Syntaxin17 expression in OCL of TC(+)/Taf12 vs.TC(-)/TAF12 mice. Thus, these data suggest that TAF12 is an important contributor to OCL activity in vivo, in part through its effects on autophagy in OCL.

Effects of advanced glycation end products on bone cells Hyoung-Moo Park*[1], Ho-Yeon Chung[2], In-Jin Cho[2], You Cheol Hwang[2], In-Kyung Jeong[2], Kyu Jeung Ahn[2]. [1]Grace woman's Hospital, Republic of Korea, [2]Kyung Hee University, Republic of Korea

Diabetes mellitus adversely affects the skeleton and is associated with an increased risk of fragility fractures in dependent of BMD. In diabetes mellitus, high glucose and advanced glycation end products (AGEs) may be involved in bone quality deterioration. Here, we examined the effects of high glucose and AGE on osteoclast formation using bone marrow-derived macrophage and osteoblast function using MC3T3-E1 cells.AGE significantly inhibited RANKL-induced TRAP-positive multinucleated cell formation in bone mar-

row-derived macrophages cultures in a dose-dependent manner. The suppression of JNK, p38 mitogen-activated protein kinases engaged by RANK were observed in Western blotting after AGE treatment in mouse marrow cells. AGE also suppressed ICAM-1 and LFA-1 expression in mouse marrow cells in RT-PCT assay. Furthermore, AGE suppressed osteoblastic specific genes such as RUNX2, osterix in RT-PCR. The expressions of lysine hydroxylase (LH) and lysyl oxidase (LOX) genes were decreased by AGE treatment in MC3T3-E1 cells. These results demonstrate that AGE may affect bone quality through low bone turnover and the changes of collagen crosslink activity.

SLIT2 inhibits osteoclastogenesis and bone resorption via the suppression of Cdc42 activity So Jeong Park*[1], Beom-Jun Kim[2], Mi Kyung Kwak[3], Seung Hun Lee[3], Jung-Min Koh[3]. [1]ASAN Institute for Life Sciences, Republic of Korea, [2]ASAN MEDICAL CENTER, Republic of Korea, [3]Division of Endocrinology and Metabolism, Asan Medical Center, University of Ulsan College of Medicine, Republic of Korea

Axon-guidance molecules including neurotrophins, semaphorins, and netrins have been receiving great attention due to their critical roles to regulate the coupling process linking bone resorption to formation. Recently, the axon-guidance molecule SLIT3 was identified as a novel clastokine that influences bone formation and resorption by promoting osteoblast migration and suppressing osteoclast differentiation. By the extension of these backgrounds, we investigated the effects of SLIT2, one of SLIT proteins, on osteoclastic differentiation and bone resorption. Quantitative RT-PCR revealed that Slit2 was comparably expression in both pre-osteoclasts and mature osteoclasts. SLIT2 suppressed RANKL-stimulated osteoclast differentiation, mainly in the early-stage of osteoclastogenesis, and in vitro bone resorption using dentine discs. Consistently, the expression of osteoclastic differentiation markers, such as tartrate-resistant acid phosphatase (Trap) and calcitonin receptor (Ctr), was significantly decreased by SLIT2. Pre-osteoclast fusion was decreased in the presence of SLIT2, whereas pre-osteoclast viability was unaffected. Western blot showed that SLIT2 suppressed Cdc42 expression among small GTPases, although the expression of RANKL-dependent signals was not changed by SLIT2. Importantly, Cdc42 overexpression almost completely reversed the SLIT2-mediated suppression of osteoclast differentiation. Among ROBO1-4, the SLIT receptors, ROBO1 and ROBO3 were known to be predominantly expressed in osteoclast lineages. A binding ELISA experiment in mouse bone marrow-derived macrophages showed that ROBO1, rather than ROBO3, was directly associated with SLIT2, and gene silencing with Robo1 siRNA blocked the SLIT2-mediated suppression of osteoclastogenesis. Finally, SLIT2 injection in mouse calvaria markedly reduced LPS-induced inflammatory bone destruction. Taken together, our results indicate that SLIT2, one of axon-guidance molecules, inhibits osteoclastogenesis and the resultant bone resorption by decreasing Cdc42 activity, and thus plays an osteoprotective role in bone metabolism.

CD55 is a negative regulator of inflammation induced osteoclastogenesis Bongjin Shin*, Sun-Kyeong Lee. University of Connecticut Health Center, United States

CD55 is a glycosylphosphatidylinositol (GPI)-anchored protein, which regulates complement-mediated as well as innate and adaptive immune responses. We have found that CD55 is expressed in multiple cells in bone marrow and mediates the survival and bone-resorption activity of osteoclasts by regulating Rac activity. CD55KO female mice have increased trabecular bone volume compared to WT and are reported to have a reduced severity of inflammatory arthritis with K/BxN serum transfer or collagen injection.In the current study we examined how an inflammatory stimulus, produced by local TNFα treatment, affected bones in CD55KO mice and their osteoclast precursor (OCP) pools. WT and CD55KO female mice were injected with TNFα for 4 days over their calvariae and examined 1 day later. We found that TNFα treatment augmented osteoclast formation in calvaria of CD55KO mice in vivo (3.8 fold) compared to WT. This was associated with an increase in the RANKL/OPG ratio (6.5 fold) and the expression of the inflammatory cytokines (IL-1 and IL-6) and chemokines (CCl2 and CCL3) in thecalvariae. We also found that a differential response to TNFα was observed in the spleen compared to bone marrow. CD55KO mice had an increase in the weight and number of cells in the spleen (by 57% and 68%, respectively) in response to TNFα treatment while WT mice did not. In the bone marrow, the most efficient OCP (CD45R- CD3- CD11b-/lo CD115+ CD117hi) was increased (26%) in response to TNFα in both WT and CD55KO mice. Further, TNFα treatment increased the absolute number of peripheral OCP in spleen from both WT and CD55KO mice (2.3 fold and 8.4 fold, respectively). In vitro spleen cells from CD55KO mice formed more TRAP(+) OCL while bone marrow cells from CD55KO mice formed fewer, indicating that there were more peripheral and fewer bone marrow OCP available.We speculate that because the size and cell number in the spleen of CD55KO mice was significantly larger than WT, there were more OCP available for recruitment to the inflammatory site, in the calvariae, resulting in an enhancement of osteoclast formation. These results indicate that CD55 is an inhibitor of the osteoclastic response to the acute inflammatory sitmulus, TNFα. TNFα specifically augmented available peripheral OCP in CD55KO mice while decreasing bone marrow OCP.

Unlike previous studies that examined the role of CD55 in an arthritic mouse model, we report an important role for CD55 in inflammatory bone disease.

Sialic acid-binding immunoglobulin-like lectin 15 (Siglec-15) plays important roles in the induction of both bone-resorbing activity of osteoclasts and osteoblast differentiation Nobuyuki Udagawa*[1], Masanori Koide[2], Shunsuke Uehara[3], Atsushi Arai[2], Toshihide Mizoguchi[2], Teruhito Yamashita[2], Midori Nakamura[4], Yasuhiro Kobayashi[2], Naoyuki Takahashi[2], Seiichiro Kumakura[5], Chie Fukuda[5], Eisuke Tsuda[5]. [1]Department of Biochemistry, Institute for Oral Science, Matsumoto Dental University, Japan, [2]Institute for Oral Science, Matsumoto Dental University, Japan, [3]Department of Biochemistry, Matsumoto Dental University, Japan, [4]Department of Biochemistry, Institute for Oral Science, Matsumoto Dental University, Japan, [5]Rare Disease & LCM Laboratories, R&D Division, Daiichi Sankyo Co., Ltd., Japan

We previously reported sialic acid-binding immunoglobulin-like lectin 15 (Siglec-15) as a gene product expressed in giant cell tumor of bone. The expression of Siglec-15 was increased with osteoclast formation in mouse bone marrow cultures. Treatment of bone marrow macrophage cultures with anti-Siglec-15 antibody (Siglec-15 Ab) inhibited TRAP-positive multinucleated cell formation induced by RANKL and M-CSF. However, Siglec-15 Ab failed to suppress TRAP-positive mononuclear cell (mononuclear osteoclast) differentiation. We then examined the effects of Siglec-15 Ab on the appearance of osteoclast precursors, which express RANK and c-Fms but not TRAP, in mouse co-cultures of osteoblasts and bone marrow cells. Siglec-15 Ab showed no effects on the appearance of osteoclast precursors in the co-culture. Osteoclasts prepared from mouse co-cultures were further cultured on dentin slices in the presence or absence of Siglec-15 Ab. Pit-forming activity of osteoclasts was inhibited by Siglec-15 Ab. The actin rings in osteoclasts on dentin slices completely disappeared within 8 hours in the presence of Siglec-15 Ab. In contrast, treatment of alendronate for 1 hour completely disrupted actin rings of mature osteoclasts. Treatment of Siglec-15 Ab for 24 hours decreased the number of multinucleated osteoclasts, but alendronate treatment did not.We next examined effects of Siglec-15 Ab on sclerostin expression in UMR106 rat osteosarcoma cells. Sclerostin, an antagonist of Wnt/beta-catenin signaling, is secreted from osteocytes and inhibits bone formation. We previously reported that conditioned medium from osteoclast cultures suppressed sclerostin expression in UMR106 cells. In vitro experiments revealed that osteoclasts secreted leukemia inhibitory factor (LIF), which in turn inhibited sclerostin expression. Interestingly, conditioned medium from osteoclasts treated with Siglec-15 Ab for 48 hours also inhibited sclerostin expression in UMR106 cells. Siglec-15 Ab did not inhibit LIF expression in osteoclasts. These results indicate the possibility that maintenance of LIF expression may be involved in promoting bone formation in osteoclasts treated with Siglec-15 Ab.We previously showed that osteoblasts derived from Wnt5a-deficient mice had decreased alkaline phosphatase activity and Wnt5a produced by osteoclasts acted on osteoblastsleading to promotion of their differentiation. In this study, Wnt5a expression was increased in osteoclasts by treatment with Siglec-15 Ab, suggesting that Wnt5a induced by Siglec-15 Abis involved in osteoblast differentiation. Our findings suggest that Siglec-15 plays important roles in the induction of both bone-resorbing activity of osteoclasts and osteoblast differentiation.

IL-3 inhibits osteoclastogenesis by upregulating the cytoprotective enzymes and diverts the cells toward M2 macrophages Suhas Mhaske*[1], Anil Kumar[1], Mohan Wani[1]. [1]National Centre for Cell Science, India

IL-3, a cytokine secreted by activated T lymphocytes is a haematopoietic regulatory protein that stimulates the proliferation, differentiation and survival of haematopoietic stem cells. IL-3 is known to inhibit both RANKL- and/TNFα- induced osteoclast differentiation in vitro. However, the molecular mechanism(s) for the inhibitory role of IL-3 on osteoclastogenesis is not yet delineated. In present study, we used iTRAQ-based quantitative proteomics approach to analyze the differential regulation of proteins in mouse bone marrow-derived osteoclast precursors treated with RANKL and IL-3. We observed that IL-3 significantly upregulates the expression of cytoprotective enzymes such as heme oxygenase-1, NQO2, G6PD, glutathione peroxidases, glutathione S transferase and catalase; and also downregulates the expression of NFκb1 (p50) and NFκb2 (p52). The cytoprotective enzymes are known to be involved in scavenging and detoxification of reactive oxygen species (ROS). RANKL generated ROS are crucial for activation of NFκB pathway and expression of NFATc1, a master regulator of osteoclast differentiation. Our results suggests that IL-3 inhibits osteoclast differentiation by masking ROS and inhibition of NFκB signaling. It was also observed that IL-3 upregulates the expression of arginase-1, a known negative regulator of osteoclast differentiation and a competitor of nitric oxide synthase. Moreover, IL-3 upregulates the expression of macrophage galactose-type C-type lectin 2 (CD301b), platelet glycoprotein 4 (CD36) and macrophage mannose receptor 1 (Mrc1), which are the phenotypic markers of anti-inflammatory M2 macrophages. Thus, our results suggest that

IL-3 inhibits osteoclast differentiation by regulating the cytoprotective enzymes and diverts the cells toward M2 macrophages.

Zscan10 Suppresses Osteoclast Differentiation through Expression of Haptoglobin. Yuta Yanagihara*[1], Kazuki Inoue[1], Noritaka Saeki[1], Yuichiro Sawada[2], Jiwon Lee[3], Tadahiro Iimura[3], Yuuki Imai[1]. [1]Division of Integrative Pathophysiology, Proteo-Science Center, Ehime University, Japan, [2]Department of Urology, Ehime University Graduate School of Medicine, Japan, [3]Division of Bio-Imaging, Proteo-Science Center, Ehime University, Japan

Zscan10 (zinc finger and SCAN domain containing 10) was identified as a novel transcription factor in osteoclast differentiation by our genome-wide chromatin structure remodeling analysis, DNase-seq (JBMR 2014). However, the biological functions of Zscan10 have not been fully understood except its role in maintenance of genome stability and pluripotency in embryonic stem cells. Therefore, the aim of this study is clarification of Zscan10 function in osteoclastogenesis. First, Zscan10 KO RAW264 (KO) cells was established using CRISPR/Cas9 system and single cell sorting. Then, Control (Ctrl) and KO cells were differentiated into osteoclast by RANKL stimulation. TRAP activity, mRNA expression of differentiation markers such as Nfatc1 and inhibitory factors such as Irf8 were determined. As a result, TRAP activity and the marker genes expression were significantly increased and the expression of inhibitory factors was decreased in KO cells as compared to Ctrl cells. Furthermore, Zscan10 overexpression successfully suppressed increased TRAP activity of KO cells to the same extent as Ctrl cells. These results suggested that Zscan10 might regulate transcription of the genes which negatively control osteoclastogenesis. To understand the transcriptomes controlled by Zscan10, RNA-seq were performed and stringent analyses identified down-regulated 35 genes and up-regulated 18 genes in KO cells. GO analyses displayed that defense and immune response genes were enriched among down-regulated genes. To investigate direct target gene of Zscan10, integrative genome-wide analyses were performed using RNA-seq data, Zscan10 binding sequence motif and DNase-seq data. In consequence, Haptoglobin (Hp) was identified as a possible direct target gene because its expression was significantly decreased in Zscan10 KO cells, the Zscan10 binding motif was located near the genomic region of Hp gene locus, and chromatin structure of its gene locus was remodeled by RANKL stimulation. To examine the effect of Hp under Zscan10 mediated osteoclastogenesis, recombinant Hp was administered into KO cells. As a result, Hp treatment could suppress the elevated TRAP activity in KO cells without affecting cell proliferation. In addition, it has been reported that Hp KO mice exhibited decreased bone mass and increased number of osteoclasts. These results reveal that Zscan10 negatively regulates osteoclastogenesis through transcription of Hp.

Enhancement of Morphological and Functional Changes of Osteocyte in Osteoporotic Metaphyseal Fracture Healing Model with Low-Magnitude High-Frequency Vibration Man Huen Victoria Choy*[1], Ronald Man Yeung Wong[1], Simon Kwoon Ho Chow[2], Meng Chen Li[2], Jack Chun Yiu Cheng[1], Wing-Hoi Cheung[1]. [1]Department of Orthopaedics and Traumatology, Faculty of Medicine, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, NT, Hong Kong, [2]Department of Orthopaedics and Traumatology, The Chinese University of Hong Kong, Shatin, NT, Hong Kong SAR, China, Hong Kong

INTRODUCTION Osteoporotic fracture is mostly occurring in the metaphyseal region. It is considered a prevailing challenge for clinicians due to its impaired healing process and limited treatment options. Previous studies have reported low-magnitude high-frequency vibration (LMHFV) as a non-invasive biophysical intervention in promoting osteoporotic healing [1]. Osteocytes has been shown to be responsible for mechano-sensing in initiating bone healing processes [2]. We hypothesize that LMHFV can enhance fracture healing in ovariectomized metaphyseal fracture through morphological and functional changes in the osteocyte and osteocyte lacuno-canalicular Network (LCN). METHODSA total of 72 six-month old female Sprague-Dawley rats (n=72) underwent bilateral ovariectomy (OVX) and kept for 3 months for osteoporosis development (animal ethical approval ref: 16-037-MIS). Metaphyseal fracture on left distal femur was performed and fixed. Rats were then randomized to (1) OVX+LMHFV (20 mins/day and 5 days/week with 35 Hz,0.3g), (2) OVX without LMHFV. Assessments of healing (X-ray, MicroCT), morphological changes of the LCN and osteocytic functional expression (Scanning Electron Microscopy, FITC-Imaris, immunohistochemistry) were performed at week 1, 2 and 6 post-fracture. RESULTS Significant enhancement of fracture healing was found in the OVX+LMHFV group with MicroCT evidence of increase in bone density and 26% increase in canalicular length at week 2. At week 6, the osteocytes in OVX+LMHFV group exhibited densely-branched canaliculi, with a 50% increase in length. In addition to the morphological changes, DMP1 expressions were significantly enhanced after week 1 and 2 (p<0.05) in OVX+LMHFVgroup. Sclerostin expressions were dramatically reduced in OVX+LMHFV group at early stage followed by a gradual increase at week 6.DISCUSSION Our findings supported the hypothesis that LMHFV can enhance the osteoporotic fracture healing through morphological and functional

changes in osteocyte and the LCN. Additionally, expressions of DMP1 and sclerostin increased after vibration at early and late phase, respectively which could imply that osteocyte might play an important role through the regulation of DMP1 and sclerostin. This could stimulate further mechanistic investigation with significant potential clinical implications. REFERENCES1.Shi, H.F., et al., Bone, 20102.Sapir-Koren., et al, Osteoporosis Int, 2014

Osteocyte regulates osteoclasts formation through Neuropilin1 Ehab Azab*[1], Kevin Chandler[2], Yuhei Uda[1], Amira Hussein[3], Raghad Shuwaikan[1], Ningyuan Sun[1], Mark Mccomb[2], Paola Divieti Pajevic[1]. [1]Molecular and Cell Biology, Boston University, United States, [2]Department of Biochemistry, Boston University, United States, [3]Department of Orthopedics, Boston University, United States

Osteocytes control bone modeling and remodeling through direct contact with adjacent cells and via secreted factors that can reach cells in the bone marrow microenvironment. Osteocytes express several receptors including G protein-coupled receptors (GPCRs). Previous studies have shown that Gsα-signaling in osteocytes controls myelopoiesis. Myeloid cells give rise to macrophages and osteoclasts, suggesting that osteocytes might regulate both macrophages and osteoclasts through Gsα mediated mechanisms. To investigate the crosstalk between osteocytes and osteoclasts, CRISPR/Cas9 was used to knockout, in vitro, Gsα expression in the Ocy454 osteocytic cell line. Conditioned media (CM) from Ocy-GsαControl Ocy-GsαKO cells were used to treat bone marrow mononuclear cells (BMNCs) isolated from long bones of C57/Bl6 mice. BMNCs were treated with M-CSF(50ng/ml) for 48 hr. and with RANKL(50ng/ml) for additional 3-5 days. CM from Ocy-GsαControl and Ocy-GsαKO (50/50 vol/vol) was added at the beginning of the culture and maintained during the whole culture period. TRAP activity, resorption pits, F-actin ring and mRNA expression were used to evaluate osteoclasts differentiation and function after 3 and 5 days of RANKL treatment. BMNCs treated with CM from Ocy-GsαControl or Ocy-GsαKO showed a significant increase in proliferation as compared to untreated BMNCs. Both the numbers and activities of osteoclasts were significantly suppressed by treatment with CM from Ocy-GsαControl and further suppressed by CM from Ocy-GsαKO compared to non-treated cells. Proteomic analysis of CM from Ocy-GsαControl and Ocy-GsαKO identified several proteins differentially expressed in KO compared to controls, including neuropilin1 (NRP-1) and semaphorin3A (Sema3A), two axon guidance proteins. NRP-1 expression was significantly increased in Ocy-GsαKO cells compared to control whereas Sema3A was significantly suppressed. Next we investigate if Nrp-1 was responsible for the osteoclasts inhibition seen in BMNCs treated with CM from Ocy-GsαKO cells, Treatment of BMNCs with Nrp-1, in the presence of CM from Ocy-GsαControl significantly suppressed osteoclastogenesis, compared to CM treated control. This data demonstrates, that osteocytes control osteoclast formation and function, in part through secreted NRP-1. Sem3A binds to Nrp-1 and suppress osteoclast formation. Sem3A and Nrp-1 are both expressed in osteocytes suggesting an important role of these proteins in these cells.

MLO-Y4 osteocyte response to simulated microgravity in a 3D scaffolding Roxanne Fournier*, Rene Harrison. University of Toronto, Scarborough, Canada

The negative effects of spaceflight on astronaut bone homeostasis is currently limiting our ability to undergo long-term manned missions beyond low-Earth orbit. Here, we studied an osteocyte cell line, MLO-Y4, under simulated microgravity achieved with the Synthecon Rotary Cell Culture System (RCCS) to investigate how the lack of mechanical forces influences the transcriptome and morphology of these bone cells. The study also aimed to validate the RCCS with a novel 3D physiologically relevant collagen and mineral scaffolding for the cells and compare their gene expression and morphology to studies conducted in true microgravity. This work will lead to a better understanding of the osteocyte's role in astronaut osteoporosis and provide a more 3D-relevant platform for studying bone

cells in a ground-based microgravity simulator. Gel scaffolds composed of collagen I and calcium phosphate were used to produce a bone-like environment for the cells. The gel was inoculated with a cell suspension and mixed to ensure homogenous cell distribution. The mixture was then formed into droplets to allow compatibility with the RCCS. Our results of cell distribution in the scaffolding indicate that cell viability is maintained in the core of the droplets. We also show that the droplets coalesce in the RCCS and achieve stable free-fall in the culture media. Quantitative Real-Time PCR data from cells exposed to free-fall for 3 days in the scaffolding will determine if MLO-Y4 cells are being mechanically loaded or unloaded. Once an optimized simulated microgravity environment is achieved, a transcriptome analysis will be performed. The data obtained will be used to determine novel genes affected by mechanical unloading in osteocytes which can be further studied as potential therapeutic targets to combat astronaut bone loss. We will also observe the changes in morphology between cells in simulated microgravity and static control conditions to better inform the mechanisms responsible for osteocyte dysregulation in unloaded environments.

Exogenous Irisin Treatment Ameliorates Inflammatory Changes in Osteocyte Proteins and Altered Bone Turnover in Chronic DSS-induced Inflammatory Bowel Disease Corinne E Metzger*[1], S Anand Narayanan[2], Anne Michal Anderson[1], David C Zaweija[2], Susan A Bloomfield[1]. [1]Texas A&M University, United States, [2]Texas A&M University Health Science Center, United States

Inflammatory bowel disease (IBD) patients incur bone loss resulting in a 40% greater fracture incidence than the average population. Treatments for IBD often have negative side effects, such as greater loss of bone (corticosteroids) or increased risk of serious infections (anti-TNF therapies). We previously discovered treatment with exogenous irisin, a protein derived from skeletal muscle FNDC5, resolved inflammatory changes in the colon, lymphatics and bone in chronic TNBS-induced IBD (Narayanan, Metzger, FASEB J, 2018). In this current study, we aimed to study the impact of irisin treatment in chronic DSS-induced IBD that exhibits greater disease severity compared to TNBS. We hypothesized that irisin treatment would mitigate bone loss, decrease osteoclast surfaces (%, Oc.S), and increase bone formation rate (BFR). Male Sprague Dawley rats were either given standard drinking water (CON) or 2% dextran sulfate sodium in drinking water (DSS) for 4 weeks. Beginning in the second week, half of each group (CON+Ir and DSS+Ir) received intraperitoneal injections of irisin twice weekly for 3 weeks. n=8/group. At the end of 4 weeks, standard histomorphometry of the proximal tibia revealed 50% lower bone volume (%BV/TV), 2x higher Oc.S, and 65% lower BFR in DSS compared to CON. DSS+Ir had 50% lower Oc.S and 55% greater BFR compared with DSS alone, though the %BV/TV values were not different. DSS+Ir had restored Oc.S back to CON levels while BFR was 24% lower than CON. Immunohistochemical analysis of the distal femur cancellous bone demonstrated an elevation of osteocytes positive for pro-inflammatory factors in DSS (8-fold higher TNF-α and 3-fold higher IL-6 vs. CON). These values in DSS+Ir were comparable to that of CON. Similarly, the DSS-induced increases in osteocytes positive for RANKL, OPG, and sclerostin were reduced in the DSS+Ir group back to CON levels. While treatment with exogenous irisin did not mitigate the DSS-induced bone loss, it did resolve the pro-inflammatory changes in osteocytes and restored osteocyte regulators of bone turnover back to control levels. These changes in osteocyte proteins corresponded with lower osteoclast surface and increases in bone formation rate. We hypothesize these changes in bone turnover would result in improvements in bone mass at later time points than those examined here. These data corroborate our TNBS data demonstrating irisin as a potential anti-inflammatory treatment for inflammatory diseases impacting bone.

Osteocytes Maintain Mechanosensing Following Long-Term Dosing with Sclerostin Antibody Andrea Morrell*[1], Samuel Robinson[1], Jingyi Wang[2], Gill Holdsworth[3], Hua Zhu Ke[3], X. Edward Guo[1]. [1]Columbia University, United States, [2]Southern University of Science and Technology, China, [3]UCB Pharma, United Kingdom

Despite continuous and progressive increase in BMD with long-term administration of antibodies to sclerostin (Scl-Ab), the response of bone formation markers such as P1NP are attenuated after repeat dosing of Scl-Ab. Recent work has demonstrated an up-regulation of other Wnt antagonists following multiple doses of Scl-Ab, which may contribute to self-regulation of the bone formation response. Here, we investigate whether this attenuation is associated with changes in osteocyte mechanosensitivity as measured by real-time Ca2+ signaling ex vivo.Scl-Ab or PBS vehicle was administered weekly to 12-week-old female Balb/c mice at 25 mg/kg/week s.c. per the following groups: vehicle (PBS), short-term (2 doses of Scl-Ab), or long-term treatment (8 doses of Scl-Ab) (Fig.1). Serum was collected

immediately before and 4 days following the 1st, 7th, and 8th treatment doses and P1NP measured using competitive EIA. At the conclusion of treatment, tibiae were explanted, maintained in cell culture media, and dyed with Fluo-8 AM. Tibiae were secured in a custom mechanical loader used with a confocal microscope for simultaneous loading and imaging of osteocyte Ca2+ signaling, where cyclic loading was applied at a peak load of 12N to tibiae from all groups.Pre-dose P1NP levels in Scl-Ab treated groups were comparable to those of vehicle and a significant increase in P1NP was observed 4 days following the first Scl-Ab dose administered to both long-term and short-term groups. This peak in P1NP was absent following the 7th and 8th doses of Scl-Ab, confirming a reduced bone formation marker response with long-term dosing, despite a significant increase in BMD. However, osteocytes exhibited robust load-induced intracellular Ca2+ responses with no differences in percentage of responsive cells or number of Ca2+ peaks per cell between vehicle and long-term treated mice.Osteocyte Ca2+ responses provide a measure of mechanosensitivity to whole bone loading. Our data suggests that osteocytes maintain mechanosensing after long-term Scl-Ab treatment whilst the bone formation effect was attenuated. This study uses real-time Ca2+ signaling to demonstrate for the first time osteocyte mechanosensitivity was maintained after long-term Scl-Ab treatment.
Fig. 1. *Ex vivo* osteocytes exhibit load-induced Ca2+ oscillations and dampened P1NP response with long-term Scl-Ab treatment. A. Ca2+ signaling parameters for osteocytes in vehicle and Scl-Ab treated mice. B. Serum P1NP levels immediately before and 4 days following treatment doses. ***P<0.001 compared with vehicle control (t-test); N=2-4/group. Values are mean ± SD.

Voluntary Wheel Running Exercise Maintains Osteocyte Connectivity and Muscle-Secreted Osteocyte Protective Factors in Aged C57BL/6 Mice
Leann Tiede-Lewis*[1], Yukiko Kitase[2], Kaitlyn Tom[1], Mark Dallas[1], Hong Zhao[2], Yixia Xie[1], Michael Wacker[1], Marco Brotto[3], Lynda Bonewald[2], Sarah Dallas[1]. [1]University of Missouri, Kansas City, United States, [2]Indiana University, United States, [3]University of Texas, Arlington, United States

Age-related osteoporosis and sarcopenia occur together and evidence suggests that molecular crosstalk between muscle and bone may regulate the function of the other tissue. Using an aged mouse model, we have shown that aging is associated with decreased osteocyte connectivity due to a linear decline in dendrite number, followed by reduced osteocyte number. We also showed that factors secreted by contracted muscle from young 5-6mo C57BL/6 mice protected osteocytes from oxidative stress-induced cell death and that this ability is lost in muscle from aged 22-24mo mice. As exercise has beneficial effects on both muscle and bone, we sought to determine if exercise, in the form of voluntary wheel running (VWR), can protect against osteocyte degenerative changes in aged mice.12mo female C57BL/6 mice(n=8) were given access to VWR for 6 or 10mo, with daily running activity recorded electronically. Controls were singly housed without wheel access. The 6mo VWR mice ran an average of 3.4km/day and 10mo VWR mice ran 3.9km/day. In both groups, running activity was maximal in the first 8-10wks then plateaued to ~2.5km/day. Although there was no significant difference in body weight, the heart weight and heart to body weight ratio were significantly increased in VWR mice vs. controls. 6mo of VWR (harvest age 18mo) significantly increased osteocyte dendrite number by 27% vs. controls with no significant change in osteocyte number/mm3. This increased osteocyte dendricity was not maintained in the 10mo VWR group (harvest age 22mo).Trabecular BV/TV and cortical BV/TV, perimeter, thickness and porosity were not significantly different in VWR mice vs. control and plotting the mean distance run by individual mice against osteocyte or µCT parameters did not reveal statistical correlations. VWR for both 6mo and 10mo restored the ability of conditioned media from static and contracted soleus and EDL muscles to protect MLO-Y4 osteocytes from oxidative stress-induced cell death, similar to effects with muscles from 5mo old mice. These results suggest that voluntary exercise has beneficial effects even when initiated in 12mo old

mice by slowing the degeneration of osteocyte connectivity, which may be mediated in part by maintaining muscle secretion of osteocyte protective factors. Although no significant differences in bone mass/structural properties were observed, maintenance of osteocyte connectivity may enhance bone function, strength and/or preserve crosstalk with other tissues.

The Role of Osteocyte Estrogen Receptor β in Bone Turnover and Skeletal Mechanotransduction Differs in Male and Female Mice.
Xiaoyu Xu*[1], Haisheng Yang[2], Rachel Embry[3], Whitney Bullock[4], Teresita Bellido[4], Russell Main[3]. [1]Weldon School of Biomedical Engineering Purdue University, United States, [2]Beijing University of Technology, China, [3]Musculoskeletal Biology and Mechanics Lab, Department of Basic Medical Sciences, Purdue University, United States, [4]Department of Anatomy and Cell Biology, Indiana University School of Medicine, United States

Estrogen receptors (ERα, ERβ) have long been recognized as regulators of bone physiology and bone's anabolic response to mechanical load. While previous studies have largely focused on the role of ERα in the skeleton, recent studies suggest that ERα may play a minor role in osteocyte-regulated bone turnover and mechanotransduction. Therefore, ERβ may be the primary ER isoform regulating estrogen-related and ligand-independent ER actions in osteocytes. Targeted deletion of ERβ in osteocytes was achieved by crossing Dmp-8kb1-Cre+/-ERβflox/flox mice with ERβflox/flox mice to produce Cre+/-ERβflox/flox (ERβKO) and Cre-/-ERβflox/flox (WT) mice. DXA was performed on male and female WT and ERβKO mice from 4- to 52wks of age for femur and lumbar spine BMD measures (n=5-10/group/age). MicroCT analysis of L5 was conducted in 30wk old mice. Two-week tibial loading studies were conducted in 10- and 28wk-old male and female WT and ERβKO mice (n=9-10/group). Loaded and non-loaded tibiae were scanned by microCT for analysis of cortical bone morphology. Between 32- and 48wks of age, male ERβKO mice showed greater spine BMD (+13%) and femur BMD (+8%, 32wks only) than WT. There was not a consistent BMD phenotype in female ERβKO mice. By microCT, 30wk old male ERβKO mice showed a trend for greater L5 cancellous BV/TV (+28%, p=0.10), increased Tb.N (+18%, p=0.01) and decreased Tb.Sp (-18%, p=0.01) compared to WT, while 30wk old female ERβKO mice showed reduced L5 cancellous BV/TV (-29%, p=0.01), decreased Tb.N (-22%, p=0.01) and increased Tb.Sp (+28%, p=0.01). These results demonstrate that ERβ in osteocytes may exacerbate age-related cancellous bone loss in male mice but may be protective in females. Tibial loading induced greater cortical bone mass in ERβKO and WT mice of both sexes at 10wks and 28wks of age. At 28wks of age, the response to load was similar in ERβKO and WT mice. However, 10wk-old female ERβKO mice showed an attenuated cortical bone response to load for the minimum moment of inertia relative to WT mice (KO +21%, WT +35%, p=0.005). A similar (non-significant) trend was found in 10wk male ERβKO and WT mice. These results suggest that osteocyte ERβ may enhance the load-induced cortical adaptive response in younger female mice but does not affect cortical bone adaptation in adult mice. Future work will examine the role of osteocyte ERβ in regulating the cancellous bone response to mechanical load and its role in sex hormone regulation of adult bone turnover.

IMMINENT RISK OF NEW VERTEBRAL FRACTURE IN PATIENTS WITH RECENT CLINICAL VERTEBRAL FRACTURE
Enrique Casado*[1], Silvia García-Cirera[1], Marta Arévalo[1], Luís Del Río[2], Joan Carles Oliva[3], Jordi Gratacós[1]. [1]Rheumatology Dpt. University Hospital Parc Taulí (UAB), Spain, [2]CETIR Centre Medic, Spain, [3]Statistics Dpt. University Hospital Parc Taulí (UAB), Spain

INTRODUCTIONThe risk of vertebral fracture in patients who have already had a previous vertebral fracture is high, especially in the first year after the fracture. However, it is unknown if this risk is greater in the first months and what clinical factors may be associated. PURPOSETo evaluate the radiological progression in patients who present a recent clinical vertebral fracture and to analyze what clinical factors are associated with the appearance of a new fracture or the radiographic progression of some previous one.PATIENTS AND METHODSAll patients from a rapid Rheumatology Clinic who had been referred for a recent clinical vertebral fracture in the last 3 years (January 2015-December 2017) were systematically evaluated for inclusion. We excluded cases of intense trauma such as falling down the stairs or accidents, pathological fractures or patients with vertebroplasty. At baseline we collected demographic data, a VAS Pain score, fracture risk was assessement according to FRAX, biochemical parameters of bone metabolism in all patients. A bone densitometry (DXA, Lunar GE Prodigy) and a spine X-ray were also performed, using the semi-quantitative scale of Genant to stablish the severity of the fracture.At 2 and 6 months, a clinical and radiological control was performed in all patients.RESULTSWe included 83 patients (57 women and 26 men), of which 33 patients had 2 or more vertebral fractures. Age 72 ± 9.8 years. The most frequent cause was postmenopausal osteoporosis (39 patients), while 37 patients had secondary osteoporosis, mainly early menopause, diabetes and glucocorticoid-induced osteoporosis. 31% of the patients had at least one severe vertebral fracture. The absolute risk of major and hip fracture at 10 years according to FRAX was 15.7±12.3% and 8.3±10.7%,

respectively. The baseline VAS Pain score was 9.2±1.2. The 25OHD and PTH levels were 23.6±17.6 and 66.0±42.6 respectively, with 54% of patients having values of 25OHD <20 ng/ml. 67% of patients had osteoporosis by DXA. 18% and 26% of patients had at least one new vertebral fracture at 2 and 6 months; and 54% and 68% showed radiographic progression in at least one degree over an existing fracture. Only FRAX for major fracture and hip fracture was associated with the incidence of a new fracture in our population.CONCLU-SIONSThe risk of new vertebral fracture in patients with a recent clinical vertebral fracture is very high, even at 2 months after the fracture and increases at 6 months, being especially significant in patients with a high fracture risk according to FRAX.

High bone marrow fat in osteopenic older adults may cause overestimation of DXA-measured BMD: A quantitative MRI study Wing P. Chan*[1], Shiou-Ping Lee[1], Yi-Chien Lu[1], Hou-Ting Yang[2], Yi-Jui Liu[3]. [1]Department of Radiology, Wan Fang Hospital, Taipei Medical University, Taiwan, [2]Department of Nuclear Medicine, Chang Gung Memorial Hospital, Taiwan, [3]Department of Automatic Control Engineering, Feng Chia University, Taiwan

Purpose: It is well known that a shift of differentiation of mesenchymal stem cells to adipocytes rather than osteoblasts partly contributes to osteoporosis. Whether bone marrow fat has a protective role for fractures and bone loss in older adults is still debated. Yet more than 40% subjects with vertebral compression fractures are not classified in osteoporosis category as defined by T-score. DXA precision declines with increasing BMI due to an obesity artifact. This study aimed to investigate bone marrow fat relating to vertebral BMD in older adults using quantitative MRI. Methods: We prospectively recruited 135 participants (88 women, 47 men), age > 50 years men and postmenopausal women, who underwent MRI and DXA scans in this study. MRI and DXA were performed within 1 week. All subjects were categorized into three groups: normal (T-score ? 1), low bone mass (LBM) (-1 < T-score <-2.5) and osteoporosis (T-score ?-2.5) as examined by DXA scan. All subjects received 1.5-T MRI of lumbar spine (center at L1 & L2) using axial gradient-echo sequential acquisitions at six TEs for 6-point IDEAL reconstruction. The initial 85 subjects (47 females, 38 males) were also received STEAM 1H-MRS sequence without water suppression. The fat fraction ratio was calculated as Ifat/(Ifat+Iwater) x100% (I = signal intensity). A P value < 0.05 was considered as statistically significant. For comparison, 27 patients with compression fractures were prospectively enrolled, with use of the same protocols. Results: Excellent linear correlation was shown for 6-pt IDEAL and MRS (R2=0.758, P<0.001), indicting accurate fat quantification by Dixon technique. In postmenopausal women, the results showed no significant correlation between regional fat fraction and BMD (p=0.170) (Table 1), but fat fraction differences of normal vs LBM (p<0.01) and normal vs. osteoporosis (p<0.01) reached statistical significance. In men, the results showed no significant correlation between regional fat fraction and BMD (p=0.053), fat fraction differences of normal vs LBM (p=0.276) and normal vs. osteoporosis (p=0.696). For comparison, nine (33.3%) and 18 subjects (66.6%) with vertebral compression fractures were classified as LBM and osteoporosis, respectively. Of these, fat fraction differences of LBM vs osteoporosis were not significant (p=0.639). Conclusion: Our results revealed that high marrow fat in LBM group, comparable to osteoporosis group, in both non-fractured and fractured subjects, and that BMD of LBM group could be overestimated by DXA due to marrow 'obesity' artifact.

Table 1. Fat ratio and BMD of non-fractured patients among three groups

	Normal	LBM	Osteoporosis
Female	N=9	n=46	n=33

MON-0721

Trabecular Bone Score in Conditions of Extremely High BMD. Does it have any utility? Manju Chandran*[1], Ann Kerwen Kwee[2], Matthew Bingfeng Chuah[2]. [1]Osteoporosis and Bone Metabolism Unit, Singapore General Hospital, Singapore, [2]Department of Endocrinology, Singapore General Hospital, Singapore

Purpose: TBS quantifies grey-level texture variations between adjacent pixels in raw DXA images. Conceptually, a dense trabecular network produces many grey-level texture variations of small amplitude and therefore a steep variogram slope with a high TBS value. In contrast, a sparse network produces fewer variations of larger amplitude with resultant low TBS value. It's utility in assessing bone microarchitecture in patients with extremely high BMD due to genetic and non-genetic causes has not been explored.Method: 2 cases are presented 1) A 32-year old Chinese woman presented with persistent headaches. A cervical spine X-ray showed occipital bone scalloping. Brain MRI showed Arnold Chiari malformation with minimal cerebellar tonsillar descent. X rays showed rugger jersey spine appearance with sclerosis of the superior and inferior vertebral end plates. Physical examination was normal. Hematological parameters and bone turnover markers were normal. Hepatitis panel was negative. The patient herself had no fractures so far but her sibling had a history of vertebral fractures. DXA scan showed Z-scores of +6.6, +5.7 and +4.4 at the femoral neck (NOF), total hip and lumbar spine (LS) respectively. TBS (L1-L4) was 1.829 and that of an age matched normal control was 1.471. Next Generation Sequencing revealed a pathogenic c.643G>A transition in exon 7 of the CLCN7 gene associated with autosomal dominant Osteopetrosis.2) A 67-year old Chinese man presented for bone health evaluation after renal transplantation. He had sustained a NOF fragility fracture, 2 years prior to the transplant. A DXA scan done at the time of transplant showed Z-scores of +4.8, +4.3 and +5.6 at the NOF, total hip and LS respectively. TBS (L1-L4) was 1.692. That of a matched control was 1.418. X-ray showed superior and inferior vertebral end plate sclerosis and a rugger jersey spine appearance. He had biochemical evidence of low burn turnover with levels of Serum Osteocalcin 8 mcg/l (12-51) and Bone Specific Alkaline Phosphatase (6.7 mcg/l (7.1-28.4). Conclusion:TBS may not be a good index of skeletal microarchitecture in conditions causing diffuse osteosclerosis and complete absence of grey-level texture variation. High values obtained in such situations may erroneously overestimate the structural integrity of bone. Modalities such as micro indentation that can evaluate bone material strength may be preferable in diseases that cause fragility fractures despite having extremely high BMD.

The association between muscle mass deficits estimated from bioelectrical impedance analysis and osteoporosis in elderly people Hee-Jeong Choi*[1], Han-Jin Oh[1], Hyeok-Jung Kweon[2]. [1]Department of Family Medicine, Eulji University School of Medicine, Republic of Korea, [2]Department of Family Medicine, Konkuk University School of Medicine, Republic of Korea

Background: Osteoporosis is a global public health problem that affects an enormous number of people and its prevalence will increase as the population ages. Throughout life, bone mineral density (BMD) is influenced by many factors and body weight is an important determinant of BMD. Muscle mass affects the body weight and may contribute to BMD because bone functions with muscle as a musculoskeletal unit and adapts to the load and strain exerted by muscle. The aim of this study was to investigate the association between muscle mass deficits (MMD) estimated from bioelectrical impedance analysis (BIA) and BMD in elderly aged between 50 and 75.Methods: Data was gathered from 2661 males and females who visited a health promotion center. Lumbar spinal BMD was measured by dual-energy absorptiometry. Body composition analysis was performed using BIA. MMD is the difference between ideal fat-free mass and real fat-free mass of the subject and is expressed as the muscle control (kg) on the result sheet. The subjects were divided into three groups according to the tertile of MMD in each gender. Multivariate linear regression analysis was done to identify the major predictors of the BMD. A logistic regression analysis was used to estimate the odds ratios for osteoporosis in the MMD groups.Results: The mean age of the 1471 males and 1190 females was 56 years old. The mean MMD of the males and females were 2.0±2.7 kg and 2.0±2.2 kg, respectively (NS). MMD had the strongest influence on the lumbar spine MBD when age and all other variables were included in the regression models in both the males and females. MMD, weight, and height explain up to 9.1% of the variation in the lumbar spine BMD in males. In females, MMD, weight, waist circumference, and age explain up to 23.7% of the variation in the lumbar spine BMD. In males, the adjusted odds ratio of Group 2 (0 kg<MMD≤3.05kg) and Group 3 (MMD>3.05 kg) for osteoporosis were 3.58 (95% CI, 1.62-7.91) and 4.30 (95% CI, 1.98-9.35), respectively. This association was similar after adjusting for other covariates including lifestyle-related variables. In females, the adjusted odds ratio of Group 3 (MMD>2.7 kg) was 2.07 (95% CI, 1.04-4.14) after adjusting for all covariates.Conclusion: MMD estimated by BIA showed a significant association with lumbar spine BMD and could be regarded as an independent risk factor for osteoporosis in males and females aged 50-75.

Cortical and Trabecular Bone Response in Proximal Femur from Women with Osteoporosis Treated with Denosumab or Zolendronic Acid using 3D Modelling Techniques obtained from DXA. Fidencio Cons Molina*[1], Mario Feuchter[1], Luis Ernesto Bejarano[1], Diana Wiluzanski[2], Carla Altieri[2], Edison Edgardo Romero Galvan [2], Jose Luis Mansur[3], Yves Martelli[4], Ludovic Humbert[4]. [1]Centro de Investigacion Artritis & Osteoporosis, Mexico, [2]CENTROSEO, Uruguay, [3]Centro de Endocrinología y Osteoporosis, Argentina, [4]Galgo Medical, Spain

Purpose: Assess changes that occur after 2 years with denosumab(DMAb) or zolendronic acid(ZOL) treatment in areal bone mineral density (aBMD) obtained by DXA and in volumetric BMD(vBMD) evaluating 3 bone compartments (trabecular,cortical & integral) assessed with 3D modelling techniques from a standard proximal femur DXA(hip-DXA). Methods: We retrospectively analysed 160 patients with postmenopausal osteoporosis.The cohort was stratified by treatments: DMAb naïve n=50; DMAb Pretreated n=50; Naïve treatment n=30, Zolendronic Acid(ZOL) n=30 for comparison purposes. Patients came from Mexico,Uruguay & Argentina. From a hip-DXA acquisition in addition to aBMD,volumetric trabecular total(vBMDTrab), cortical surface density(CSD) and volumetric BMD Integral(vBMDInt) were assess, using a 3D-Shaper software 2.6ver (Galgo Medical,Spain). The changes observed at 2 years were evaluated in terms of (%) of change in vBMD. A paired T-student test were used to compare parameters from baseline. All hip-DXA were acquired using GE-Prodigy devices.Results: After 2years, in the naïve treatment group, a significant decrease was observed in all 3D parameters when compared to baseline,additionally to decreasing aDMO. In ZOLgroup only a significant increase was observed in CSD(2.3%) and in vBMDInt(2.4%). A greater trabecular response was observed in DMAb naïve group vBMDTrab(6.9%) vs.DMAb Pretreated(2.4%). The response to treatment was analyzed in both DMAb groups dividing in tertiles vBMD at baseline (low,medium,high) for all 3D parameters showing only in DMAb naïve group a greater response in those from lowest tertile vs. medium and high (vBMDTrab 13.3%,4.0%,0.2%), CSD 6.2%,2.2%,1.3%), vBMDInt (5.7%,2.5%,0.1%). On the other hand, DMAb Pretreated group showed no differences between tertiles in response to treatment.Conclusions: Significant vBMD increases were observed in cortical & trabecular compartments in both ZOL group and both DMAb groups. The finding of a more pronounced response to treatment for patients with vBMD in the lower tertile in the group with naïve DMAb (trabecular vBMD & cortical surface density), suggests that identification of those patients using 3D-SHAPER may provide a personalized treatment in this subgroup of patients at high risk of fracture. 3D modelling techniques are a promising new technology for identification/monitoring of vBMD changes in patients with osteoporosis. More studies are required to confirm our results.

Sandwich Immunoassay for the Specific Detection of Circulating Bioactive Sclerostin in comparison with other Sclerostin ELISA Jacqueline Wallwitz*, Elisabeth Gadermaier, Gabriela Berg, Gottfried Himmler. The Antibody Lab GmbH, Austria

Purpose: Sclerostin is a glycoprotein of the DAN/Cerberus protein family and is mainly secreted by osteocytes. It has long highly flexible N- and C-terminal arms and the core consists of a cystine-knot with three loops. The bioactive function of sclerostin is the regulation of bone formation as an antagonist of the osteoanabolic Wnt signaling pathway by binding with its second loop to the LRP5/6 complex. In a clinical setting, blocking sclerostin by therapeutical antibodies is an important approach to decrease bone resorption. There are some ELISAs on the market, but they neither specifically detect bioactive sclerostin, nor specify the epitopes of their antibodies. Therefore it is not clear which forms or fragments of sclerostin are detected. Our ELISA specifically detects the bioactive sclerostin in human serum and plasma samples.Methods: We have developed an immunoassay for the detection of bioactive sclerostin in human samples. The ELISA contains a monoclonal capture and a horseradish-peroxidase conjugated affinity-purified polyclonal detection antibody. Both antibodies were characterized regarding their epitopes, affinities and kinetics. The assay performance was validated according to ICH and EMEA guidelines. Measured bioactive sclerostin con-

centrations in apparently healthy individuals as well as in diseased patients were compared with other commercially available ELISA (Biomedica, Teco and R&D Systems).Results: Epitope mapping revealed a distinct epitope within the bioactive site of sclerostin for the monoclonal capture antibody and five linear epitopes distributed throughout sclerostin for the detection antibody. Both antibodies have good binding kinetics of kdis of <1.0E-07 s-1 for the monoclonal antibody and 1.19E-05 s-1 for the polyclonal goat antibody, respectively. All validation parameters were within the standard of acceptance demonstrating the robustness, accuracy and precision of the assay. The correlation between the assays was dependent on the sample type and disease state of the patients.Conclusion: This validated ELISA is a tool for the defined detection of bioactive Sclerostin in human samples and may be helpful to further investigate sclerostin as a biomarker in the diagnosis of bone remodeling disorders and in the assessment of therapeutic effectiveness.

Combined model of QCT derived bone mass and microarchitecture parameters for improved vertebral fracture discrimination Lukas Maximilian Huber*[1], Timo Damm[1], Stefan Reinhold[2], Wolfram Timm[3], Jan Borggrefe[4], Julian Ramin Andresen[5], Claus-Christian Glüer[1], Reimer Andresen[6]. [1]Section Biomedical Imaging, Department of Radiology and Neuroradiology, UKSH, Christian-Albrechts-Universität zu Kiel, Germany, [2]Department of Computer Science, Multimedia Information Processing Group, Christian-Albrechts-Universität zu Kiel, Germany, [3]MINDWAYS CT, United States, [4]Department of Diagnostic and Interventional Neuroradiology, University Hospital Cologne, Germany, [5]Medical School, Sigmund Freud University, Austria, [6]Institute of Diagnostic and Interventional Radiology/Neuroradiology, Westkuestenklinikum Heide, Academic Teaching Hospital of the Universities of Kiel, Luebeck and Hamburg, Germany

ObjectivesWe compared the performance of multiparameter quantitative computed tomography (QCT) and CTXA based areal bone mineral density (aBMD) in discriminating patients with and without vertebral fractures. Automatic segmentation was applied for detailed analyses of bone density and microarchitecture.Methods135 female patients (mean age 69[40–89] years) were examined for osteoporosis, 67 with at least one fractured vertebral body (cases) and 68 without fractures (controls). Clinical QCT images of the spine (120kVp,90-420mAs,st 0.8mm,reconstructed increment 0.4mm,in-plane px size 0.5–0.7mm) and CTXA of the hip were evaluated using standard QCT software (Mindways). Simultaneous calibration to mg/cc K2HPO4 and additional analysis of the spinal images was performed using StructuralInsight (SI), our in-house CT software. Segmentation process: cortical ridge surface is modeled by a statistical shape model (automatically constructed meshes extracted from pre-segmented images (EuroGIOPs)). Following automated landmark generation and alignment process, model parameters are optimized to maximize BMD along the surface. After manual correction to improve accuracy, the detected ridge surface is used to generate the final mask. Fracture status was evaluated by an experienced radiologist (RA). Fracture discrimination was assessed in age-adjusted logistic regression models (per SD) and ROC analysis (AUC) using JMP and MedCalc. Investigated parameters: mean BMD (typically L1-3; meanBMDspine) and aBMD of total proximal femur (aBMDhiptot). Using SI we calculated bone volume fraction (BV/TV), BMD and SD of trabecular separation (Tb. Sp-SD) of the spongiosa along with weighted cortical thickness (whole cortex, wCt.Th). Combined models (CM) were constructed.ResultsCM1: BMDspongiosa (p=0.0001)&Tb. Sp-SDspongiosa (p=0.002)&wCt.Thcortex (p=0.02) with AUC=0.920; CM2: BV/TVspongiosa (p=0.513)&Tb.Sp-SDspongiosa (p=0.002)&wCt.Thcortex (p=0.02) with AUC=0.892. AUC of CM1 was significantly larger than for aBMD (DeLong p=0.04) but not versus QCT based BMD (p=0.1).ConclusionAll parameters investigated were found to discriminate patients with and without vertebral fractures. Combined analyses of bone mass and microarchitecture yield numerically highest AUCs but statistical improvement was only achieved compared to CTXA based aBMD, not versus QCT based BMD. Semiautomatic model based segmentation facilitates image analysis and is helpful for standardized QCT based fracture risk assessment.

Prevalence of Diabetes in Patients with Osteoporotic Hip Fractures: A tertiary Care Center Fratcure Consultation Service Experience Sabrina Huq*, Lakshmi Das, Arti Bhan, Mahalakshi Honasoge, Sudhaker D. Rao. Henry Ford Hospital, United States

Osteoporotic fractures are a major cause of disability, morbidity and mortality. Both diabetes mellitus (DM) and hip fractures contribute to morbidity and mortality. Although DM is a known risk factor for osteoporotic fractures and the risk of hip fracture is increased 1.3-2.1 folds in DM, little is known about the prevalence of DM in patients admitted to hospital for hip fractures.The aim of our study was to determine the prevalence of DM among patients admitted to hospital with acute proximal femur fractures over a five year period (January 1st, 2011 to December 31st 2016). The electronic health records of 163 patients with acute hip fractures in our tertiary care setting were reviewed to determine the prevalence of DM in patients with hip fractures.There were 72 Caucasians (44%), 52 African Americans (32%), 4 Hispanics (2%), 1 Asian, 1 Arab and 33 patients (20%) who had no race documented. The prevalence of DM was 36%, four fold higher than in the general population, and the majority (93%) were Typ 2 DM. Both serum 25-hydroxyvitamin D and PTH levels were numerically lower in DM patients compared to non-DM patients (19.3 ± 12.2 Vs. 22.3 ± 12.9 ng/ml, and 62.3 ± 38.2 Vs. 87 ± 103 pg/ml, respectively).It is postulated that fracture risk is increased in patients with DM most likely due to increased glycation of collagen leading to decreased plasticity and bone strength without necessarily affecting bone density. In addition lower PTH levels in DM imply a low bone turnover state resulting in "aged" bone, which compromises bone strength. Further studies are needed to confirm our finding of very high prevalence of DM in hip fracture patients.References:https://www.ncbi.nlm.nih.gov/pubmed/29502187Saito M, Fujii K, Mori Y, Marumo K. Role of collagen enzymatic and glycation induced cross-links as a determinant of bone quality in spontaneously diabetic WBN/Kob rats. Peripheral Quantitative Computed Tomography Based Finite Element Modeling (pQCT-FE) in the Classification of Fracture Patients Hongyuan Jiang*[1], Dale Robinson[1], Peter Lee[1], Christopher Yates[2], John Wark[1]. [1]The University of Melbourne, Australia, [2]The Royal Melbourne Hospital, Australia

PURPOSE Dual energy x-ray absorptiometry (DXA) has limitations in identifying individuals with increased fracture risk. Volumetric data and density distribution acquired by peripheral quantitative computed tomography (pQCT) can be used to generate finite element models providing bone strength assessment. The current study aimed to assess the ability of this FE modeling framework in the classification of fracture patients and aged-matched healthy controls. METHODS Seventy-eight patients (61 females, 17 males) with recent low-trauma fracture and 85 aged-matched healthy controls (66 females, 19 males) were recruited. Participants underwent DXA scans of the hip and lumbar spine, and pQCT scans of the radius and tibia at 4% and 66% sites. Peripheral QCT images were used to establish a cross-sectional FE model. Stiffness and strength of four loading cases (compression, torsion, shear, bending) were obtained from the FE models. Area under the receiver operating curve (AUC) was calculated to assess the ability of each variable to classify fracture patients and controls. RESULTS No difference was observed in DXA, standard pQCT radius, and pQCT-FE radius variables between groups for both males and females (p>0.05). Differences in most standard pQCT tibia measures were observed in males, while only vBMD at 4%

tibia was significantly different between groups in females p<0.05). Most pQCT-FE tibia variables at the 4% site were significantly different between groups in both females and males, while most pQCT-FE variables at the 66% site were significantly different only in males (p<0.05). In females, vBMD, compression stiffness and strength, shear stiffness and strength, bending strength at 4% tibia had higher AUC than DXA measures (0.80~0.84 vs 0.79), while no variables of radius or 66% tibia out-performed DXA measures. In males, the highest AUC was 0.94 observed for torsion strength at 4% radius compared to 0.89 for DXA hip BMD. Various variables from standard radius (0.90~0.93) and tibia (0.91~0.93) pQCT analysis, radius (0.90~0.94) and tibia (0.90~0.91) pQCT-FE out-performed DXA measures (0.88~0.89) in the classification between groups. CONCLUSION FE modeling of single pQCT cross sections of trabecular-dominant tibial epiphysis had highest ability to classify fracture patients and healthy controls. In combination with our recent validation study, this FE modeling framework has the potential to enhance fracture risk assessment and may be useful in clinical settings.

Table 1. Comparison in DXA, standard pQCT analysis and pQCT-FEA between fracture and control in females and males (only variables with significant difference displayed)

Table 2. AUCs for each variable in females and males (only variables with higher AUC than DXA measures displayed)

Bone Marrow Fat and its Associations with Bone Quality in the Proximal Femur Roland Krug*[1], Julio Carballido-Gamio[2]. [1]Department of Radiology and Biomedical Imaging, University of California, San Francisco, CA, United States, [2]Department of Radiology, School of Medicine, University of Colorado Denver, Denver, CO, United States

The proximal femur plays a central role in the diagnosis of osteoporosis and assessment of fracture risk. Low BMD and bone quality are expected in patients with osteoporosis. However, the complex interrelationships between bone properties —even in healthy subjects— are mostly unknown, especially at the proximal femur —which deep-seated location represents a challenge for medical imaging— and those involving bone marrow fat. Here, we investigated the interrelationships between bone imaging features assessing composition and structure in healthy postmenopausal women using QCT and MRI of the proximal femur.Ten postmenopausal women (62.7±7.9 yr) without fragility fractures were included in this study. Images of the proximal femur were acquired using QCT (0.938x0.938x1.25mm3) and MRI, including high resolution (0.234x0.234x0.5mm3) and fat fraction (0.469x0.469x2mm3) acquisitions enabling the quantification of: 1) volumetric BMD (vBMD), 2) cortical bone thickness (Ct.Th), 3) Ct.vBMD, 4) vBMD in a layer adjacent to the endosteal surface (EndoTb.vBMD), 5) trabecular bone microarchitecture (fuzzy bone volume fraction=f-BVF; trabecular bone thickness, spacing and number=Tb.Th, Tb.Sp and Tb.N), 6) bone marrow fat content, and 7) R2* —an MRI parameter commonly associated with trabecular bone microarchitecture. Using image registration, common volumes of interest (VOIs) were defined in all scans: 1) total hip 2) femoral head, 3) femoral neck, and 4) trochanter. Mean parametric values were then obtained for the different VOIs and used in general linear models aimed to evaluate the different interrelationships of bone properties, adjusting for age, height and weight. Table 1 summarizes the results of this study, where bone marrow fat shows a clear negative linear association with trabecular bone number in all VOIs, a positive linear association with trabecular bone spacing in the femoral neck and trochanter, but no association with BMD. The linear fits in Fig. 1 also suggest that the association of bone marrow fat with trabecular bone number in the femoral neck might differ from those in the rest of the proximal femur, although further testing is needed to confirm this observation.In this study, we have performed for the first time, an in vivo validation of the expected associations of bone marrow fat with measures of bone quantity and quality at the proximal femur. Larger sample sizes are warranted to further validate these observations and uncover new ones.

Table 1. Interrelationships of bone properties at the proximal femur.

The linear dependence of parameter A on parameter B was tested as:

$A = \beta_0 + \beta_1 \cdot B + \beta_2 \cdot Age + \beta_3 \cdot Height + \beta_4 \cdot Weight$

The nonlinear dependence of parameter A on parameter B was tested as:

$A = \beta_0 + \beta_1 \cdot B + \beta_2 \cdot B^2 + \beta_3 \cdot Age + \beta_4 \cdot Height + \beta_5 \cdot Weight$

Significant (p<0.05) linear association of A and B in:	TH	FH	FN	TR
Significant (p<0.05) quadratic association of A and B in:	TH	FH	FN	TR

Abbreviations: FF=fat fraction; Tb.vBMD=trabecular volumetric bone mineral density; Ct.Th=cortical bone thickness; Ct.vBMD=cortical vBMD; EndoTb.vBMD=vBMD adjacent to the endosteal surface; f-BVF=fuzzy bone volume fraction; Tb.Th=trabecular bone thickness; Tb.Sp=trabecular bone spacing; Tb.N= trabecular bone number; TH=total hip; FH=femoral head; FN=femoral neck; TR=trochanter; + = positive association; - = negative association.
Fig. 1 Plots representing the linear associations of bone marrow fat fraction (FF) with trabecular bone number (Tb.N) at four different volumes of interest in the proximal femur of postmenopausal women without fragility fractures.

Low-grade morphometric vertebral deformities result from historical events and are unlikely to be primarily osteoporotic in provenance Brian C Lentle*[1], Jacques P Brown[2], Linda Probyn[3], Ian Hammond[4], Jeffrey Hu[1], Ben Fine[3], Kevin Lian[1], Arvind Shergill[3], Jacques Trollip[1], Claudie Berger[5], William D Leslie[6], Jerilynn C Prior[1], David A Hanley[7], Jonathan D Adachi[8], Robert G Josse[3], Angela M Cheung[3], K Shawn Davison[9], Stephanie M Kaiser[10], Tanveer Towheed[11], Christopher S Kovacs[12], Andy Ko Wong[3], David Goltzman[13]. [1]University of British Columbia, Canada, [2]Université Laval, Canada, [3]University of Toronto, Canada, [4]University of Ottawa, Canada, [5]Research Institute of the McGIll University Health Centre, Canada, [6]University of Manitoba, Canada, [7]University of Calgary, Canada, [8]McMaster University, Canada, [9]A Priori Medical Sciences Inc, Canada, [10]Dalhousie University, Canada, [11]Queen's University, Canada, [12]Memorial University, Canada, [13]McGill University, Canada

We have previously reported on the radiology of vertebral fractures (VFs) from the Canadian Multicentre Osteoporosis Study (CaMos). We compared two diagnostic methods: identifying fractures by morphometric and morphologic criteria respectively. Suspecting a difference in the natural history of these two types of "fracture" we have re-evaluated serial radiographs performed every 5 years in a sub-set of 595 from the 4465 women and 1771 men aged 50 or more years entered into the CaMos Study. These subjects were from three of the nine CaMos centres, chosen randomly, who have available radiographic images of the spine at baseline and for 15 or 16 years of follow-up.Of the 595 subjects, 170 (38.6%) had incident spinal abnormalities: 121 women had 246 such events and 49 men had 123. The ratio of morphologic to morphometric findings was 1.93 in women and 1.20 in men, indicating that

morphometric deformities were proportionately more common in men.At study entry (age 50 or more), 165 subjects had grade 1 and 22 subjects had grade 2 morphometric deformities; 5 and 10 years later only 5 and 3 subjects respectively had sustained new grades 1 or 2 morphometric deformities. Contrastingly, 34 subjects had grade 1 and 72 subjects had grade 2 morphologic fractures at entry but 5 and 10 years later, 46 and 47 subjects respectively had new grades 1 or 2 fractures, 11-times as many in total. Thus incident morphometric deformities were common at study entry (age 50) but rarely occurred thereafter, with most of the incident fractures being of the morphologic type.This extended analysis of our data adds to the body of evidence to suggest that morphometric deformities and morphologic fractures constitute relatively distinct entities with the latter conforming much more closely to our clinical understanding of OVF. In addition to the differences already reported, these two types of abnormalities evolve differently in time, differ in prevalence between the sexes, and have different radiological characteristics and prognoses.

Feasibility of QCT internal density calibration for site-specific osteoporosis assessment Andrew Michalski*, Bryce Besler, Geoff Michalak, Steven Boyd. University of Calgary, Canada

Quantitative computed tomography (QCT) is a well-defined method to assess skeletal health for osteoporosis. Volumetric bone mineral density (BMD) is a primary QCT outcome. To measure density, CT numbers are converted to equivalent densities by phantom-based or asynchronous density calibration. However, the inclusion of a density calibration phantom in clinical CT scans is limited to specific scanning protocols. Therefore, internal density calibration has been proposed for retrospective clinical scan analysis, but there is insufficient evidence supporting its use at major osteoporotic fracture sites. We designed our study to establish the feasibility of internal calibration, as compared with phantom-based and asynchronous scans, at the lumbar spine and proximal femur. Additionally, we evaluated intra- and inter-operator reanalysis precision for each site.The lumbar spine and pelvis from intact fresh-frozencadavers (N=10) were imaged with clinical CT (Revolutions CT, GE Healthcare) to derive integral BMD. Density calibration was performed for each scan using phantom-based, asynchronous and internal calibration. Our internal density calibration method, based upon fundamental X-ray imaging physics, used five regions of interest within each scan to derive a relationship between CT number and equivalent density.Phantom-based and internal calibration BMD results were compared using linear regression, where a slope of 1 signifies agreement. For both the spine (Figure 1A) and pelvis (Figure 1B), the slope of the regression was not different than 1 (spine p=0.99, pelvis p=0.08). Similarly, comparing asynchronous and internal calibration resulted in a regression slope that was not different than 1 (spine p=0.93, pelvis p=0.08) at both the spine and pelvis. Precision measures for internal calibration were determined by performing measurements in triplicate and by three independent operators. Intra-operator root mean square coefficient of variation was 2.66% at the spine and 3.42% at the pelvis. Inter-operator coefficient of variation was 4.93% at the spine and 5.44% at the pelvis.These data demonstrate that our internal density calibration is feasible for accurate QCT BMD assessment at both the spine and the pelvis. However, due to large precision outcomes, our method needs to be further refined before application to clinical monitoring. With further work, internal calibration is a promising technique for opportunistic CT assessment of skeletal health.
Figure 1: Linear regression plots comparing internal calibration and phantom-based calibration in the spine (A) and the pelvis (B).

Utility of the Forearm Dual X-ray Absorptiometry (DXA) as a Screening Tool for Early Osteoporosis Diagnosis in Postmenopausal Women with Primary Fragility Fractures at Distal Radius Satoshi Miyamura*[1], Kosuke Ebina [1], Kohji Kuriyama[2], Kunihiro Oka[1], Hiroyuki Tanaka[1], Tsuyoshi Murase[1]. [1]Department of Orthopaedic Surgery, Osaka University, Graduate School of Medicine, Japan, [2]Department of Orthopaedic Surgery, Japan Community Health Care Organization Hoshigaoka Medical Center, Japan

Purpose: Previous reports have demonstrated that primary osteoporotic fragility fractures in postmenopausal women frequently occur at distal radius. Nevertheless, the guidelines of osteoporosis recommend assessment of bone mineral density (BMD) by dual x-ray

Monday Posters

387

absorptiometry (DXA) at either spine or hip as a screening for osteoporosis. The purpose of this single center, retrospective study was to verify which part of the BMD measurements is most sensitive as a screening tool for early osteoporosis diagnosis.Methods: One hundred and ten postmenopausal women with primary fragility fractures at distal radius, who had no past history of osteoporotic fractures and osteoporosis treatment were recruited. Spine, hip and forearm DXA (Hologic Discovery Wi; Hologic Inc., Waltham, MA, USA) and spinal radiograph were performed at the time of injury. BMD measurements with T-score were recorded for the lumber spine (LS; L2-4 with exclusion of degenerated lesions), femoral neck (FN), and unfractured distal forearm (DF) [ultradistal end (UD), middistal (MID), and one-third distal (1/3) of the radius]. T-scores and patients with T-score ≤−2.5SD according to the WHO definition of osteoporosis, were compared between those in LS, FN, and DF, by using Wilcoxon signed-rank test and Pearson's chi-squared test, respectively.Results: The mean age of the study participants were 69.5 years (range, 42 to 88 years). T-scores (mean ± SD) and proportions of patient with T-score ≤−2.5SD were LS [−2.1 ± 1.2; 39% (43/110)], FN [−2.1 ± 0.8; 40% (44/110)], UD [−2.5 ± 1.0; 57% (63/110)], 1/3 [−2.6 ± 1.5; 58% (64/110)], and MID [−3.3 ± 1.4; 71% (78/110)], respectively. Compared with LS and FN, T-scores of UD (vs LS: P = 0.012; vs FN: P < 0.001), 1/3 (vs LS: P = 0.036; vs FN: P = 0.024), and MID (vs LS: P < 0.001; vs FN: P < 0.001) were significantly lower, and proportions of patient with T-score ≤−2.5SD in the UD (vs LS: P = 0.007; vs FN: P = 0.010), 1/3 (vs LS: P = 0.005; vs FN: P = 0.007), and MID (vs LS: P < 0.001; vs FN: P < 0.001) were significantly higher.Conclusion: In postmenopausal women with primary fragility fractures at distal radius, BMD measurements of unfractured DF, especially in MID of the radius, hold promise as a screening tool for early osteoporosis diagnosis.

Bars indicate mean values. The cutoff is set to -2.5SD (dotted line). * Significant difference from Wilcoxon signed-rank test (P < 0.05). † Significant difference from Pearson's chi-squared test (P < 0.05).

MON-0732

Opportunistic Screening of FDG-PET/CT Reveals Undiagnosed Low Bone Mass in Patients Being Evaluated for Oncology Purposes Fernando Kay*[1], Edmund Dosunmu[2], Keenan Brown[3], Orhan Oz[2]. [1]UT Southwestern Medical Center, United States, [2]UT Southwestern Medical Center - Radiology, United States, [3]Mindways Software, United States

PurposeTo assess the prevalence of undetected low bone mineral density (BMD) with quantitative computed tomography (QCT) in a cohort of potentially at risk patients undergoing PET/CT.MethodsA retrospective survey was conducted in a high complexity US county hospital to identify PET/CT studies obtained between Oct/2015 and Jan/2016 in a Biograph 64 scanner (Siemens). Images were processed with the QCT Pro software (Mindways). A calibration CT scan was obtained in the same PET/CT scanner using the asynchronous Model 4 QCT Phantom. Two radiologists (one a certified clinical densitometrist) and a trained research technician performed the analyses of trabecular BMD at vertebral bodies L1 and L2. The American College of Radiology (ACR) criteria was used for diagnosing low BMD. Total BMD of femoral necks were measured on DXA-equivalent images (CTXA) of the hips and used to generate FRAX-scores for calculating absolute fracture risks. We obtained clinical data from institutional medical records. Requirement for signed informed consent was waived by the IRB. ResultsSixty-nine studies were identified, two studies excluded due to severe scoliosis and one excluded due to Schmörl node affecting the analysis. The final cohort comprised 66 subjects (20F/46M, mean age: 53.8, SD: 12.1). Mean coefficient of variation (CV) for trabecular BMD in L1-2 between the 3 readers was 1.2%. Distribution of subjects according to ACR category is shown in Table 1. Thirty-two percent (21/66) of subjects showed low lumbar spine BMD on QCT. Twenty-four percent (5/21) of subjects with low BMD on QCT had a prior DXA scan, all of which showing low BMD. None of the subjects with normal BMD on QCT had a prior DXA scan. Femoral neck BMD was assessed with CTXA in 20 of 66 subjects by one radiologist and the research technician. Mean CV between the readers was 6.1%. Fifteen percent (3/20) of the subjects had at least a 3% risk of hip fracture within 10 years. Only 33.3% (1/3) of these subjects had a prior diagnosis of low BMD.ConclusionLow BMD was an under recognized condition in our sample. PET/

CT provides a unique opportunity to assess for occult low BMD in unscreened populations by leveraging the quantitative capabilities of CT. Identification of subjects at risk for future osteoporotic fractures may not only improve outcomes, but also decrease downstream costs. Future analysis will correlate metabolic activity (FDGuptake) with bone mass.

Table 1			
ACR Category	N	Trabecular BMD – L1	Trabecular BMD – L2
Osteoporosis (< 80 mg/cc)	6 (9%)	65.1 ± 12.5	65.7 ± 16.3
Osteopenia (80-120 mg/cc)	15 (23%)	103.4 ± 13.6	100.5 ± 12.7
Normal (> 120 mg/cc)	45 (68%)	166.8 ± 39.1	163.0 ± 40.1
Total	66 (100%)	143.1 ± 49.0	140.0 ± 48.8

MON-0733

Lower Trabecular Bone Score is Associated with the Use of Proton Pump Inhibitors Young Ho Shin*[1], Hyun Sik Gong[2]. [1]Department of Orthopedic Surgery, Asan Medical Center, Republic of Korea, [2]Department of Orthopedic Surgery, Seoul National University Bundang Hospital,Seoul National University College of Medicine, Republic of Korea

Purpose: Trabecular bone score (TBS) provides indirect indices of trabecular microarchitecture and bone quality. Several studies have evaluated the influence of PPIs on bone mass and geometry parameters, but no studies have evaluated the influence of proton pump inhibitors (PPIs) on TBS. The purpose of this study was to determine whether TBS is associated with the use of PPIs.Methods: We reviewed 1505 women aged 40-89 years who had bone mineral density (BMD) examination as a part of the medical diagnosis and disease prevention program and did not have osteoporotic fractures or conditions that could affect bone metabolism. Among these, we identified 223 women with exposure to PPIs and selected the same number of age- and body mass index (BMI)-matched control patients. We compared TBS and BMD between the PPI exposure group and the control group and performed multivariate regression analyses to determine whether TBS is associated with age, BMI, and PPIs exposure. We also examined whether TBS is associated with PPIs exposure timing (current, recent, and past).Results: TBS and BMDs were significantly lower in the PPI exposure group than the control group. In a multivariable linear regression analysis, TBS was significantly associated with age (p < 0.001) and PPI exposure (p = 0.02). Lower TBS was associated with current PPIs use (p = 0.005), and not with recent or past PPIs usage.Conclusions: This study found that TBS is lower in subjects with PPIs exposure than in controls. The association of lower TBS with current PPIs use suggests that trabecular bone quality could be affected early by PPIs and the effect might be reversible.

Percent total body fat, independent of muscle mass, is negatively associated with bone mineral density in women Harshvardhan Singh*[1], Roshita Rathore[2], Gary Hunter[3], Debra Bemben[4], Zhaojing Chen[5], Kenneth Saag[6]. [1]Department of Physical Therapy, University of Alabama at Birmingham, United States, [2]Department of Physical Therapy, Temple University, United States, [3]Nutrition and Obesity Research Core, University of Alabama at Birmingham, United States, [4]Department of Health and Exercise Science, University of Oklahoma, United States, [5]Department of Kinesology, California State University San Bernardino, United States, [6]School of Medicine, University of Alabama at Birmingham, United States

Background: Obesity and osteoporosis are two of the most common chronic conditions associated with aging. Although obesity has been positively associated with bone mineral density (BMD); recent evidence suggests that obesity, when defined by percent total body fat, is negatively associated with BMD in Korean and South American adolescents. Notably, relationship between percent total body fat and BMD is unknown in American women across pre- to post-menopausal stages.Methods: Data from two separate studies with identical data collection methodologies are presented in this abstract. Dual energy X-ray absorptiometry (DXA) was used to measure the total hip BMD, femoral neck BMD, and body composition (percent total body fat) in 326 women (age range = 21 - 85 years; percent total body fat range = 24.7 - 55.9). Appendicular skeletal muscle mass (ASM) was quantified as the sum of the lean soft-tissues of the arms and legs. Relative skeletal muscle mass index (RSMI) was quantified as RSMI = ASM (kg) relative to body height2 (m2). Data normality was checked with Shapiro-Wilk test. We used multi-variable regression analysis to examine associations of body fat with BMD.Results: Out of 326 women, there were 218 premenopausal (age range = 21.3 - 48.7 years; average age = 34.2 ± 6.2 years; percent total body fat range = 33 - 54.2; average percent total body fat = 43.4 ± 3.9) and 108 postmenopausal women (age range = 55.2 - 85.8 years; average age = 67.4 ± 6.5 years; percent total body fat range = 24.7 - 55.9; average percent total body fat = 39.9 ± 6.6). Regression analysis after adjusting for age, race, body weight, and RSMI showed that percent total body fat negatively predicted the 1) total hip BMD in premenopausal women (β = -0.290, 95% CI = -0.014 to -0.005, P < 0.0001) and postmenopausal women (β = -0.358, 95% CI = -0.010 to -0.001, P = 0.016), and 2) femoral neck BMD in premenopausal women (β = -0.235, 95% CI = -0.013 to -0.004, P < 0.0001) and postmenopausal women (β = -0.504, 95% CI = -0.011 to -0.003,

P = 0.001).Conclusion: Our findings suggest that, irrespective of muscle mass, total percent total body fat has an independent negative association with the total hip and femoral neck BMD in women across pre- to post-menopausal stages. This knowledge is important for musculoskeletal rehabilitation and decisions about weight loss in overweight/obese women.

The risk of incident vertebral fractures in current or former heavy smokers with and without COPD is associated with baseline vertebral bone attenuation and prevalent vertebral fractures: a 3-year chest-CT follow-up study Mayke Van Dort*[1], Johanna Driessen[1,2,3], Piet Geusens[4], Elisabeth Romme[5], Frank Smeenk[5], Emiel Wouters[6], Joop Van Den Bergh[7]. [1]NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), Netherlands, [2]CAPHRI Care and Public Health Research Institute, Netherlands, [3]Department of Clinical Pharmacy and Toxicology; Maastricht University Medical Centre+ (MUMC+), Netherlands, [4]Department of Internal Medicine, Rheumatology, Maastricht University Medical Centre+ (MUMC+), Netherlands, [5]Department of Respiratory Medicine, Catharina Hospital, Eindhoven, Netherlands, [6]Department of Respiratory Diseases, Maastricht University Medical Centre+ (MUMC+), Netherlands, [7]Department of Internal Medicine, VieCuri Medical Centre, Venlo; and Department of Internal Medicine, NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), Netherlands

Background Patients with chronic obstructive pulmonary disease (COPD) have increased risk of osteoporosis and vertebral fractures (VFs). Bone attenuation (BA) on CT scans, which are often made for pulmonary evaluation in COPD patients, is associated with bone mineral density on DXA and prevalent VFs. The association with incident (vertebral) fractures is largely unknown. Therefore our aim was to evaluate the association of BA on chest CT scans with prevalent and incident VFs in current or former smokers with and without COPD.Methods Participants of the ECLIPSE study with baseline, one and three year follow-up CT scans were included. BA was measured semi-automatically using 3D cubic areas of approximately 275mm3 each in vertebrae T4-T12. Prevalent and incident VFs within one and three years were evaluated on superposed sagittal reconstructions of the CT scans. VFs were scored according to the grading system proposed by Genant. Logistic regression and Cox proportional hazard models were used to assess relationships between clinical parameters and prevalent or incident VFs resp. Additionally, subjects were divided into three groups based on BA tertiles, to assess the effect of low or middle BA on incident VFs compared to high BA.Results 1239 subjects were included (mean age 61.3 ±8.0, 61.1% men, 999 COPD patients, mean baseline BA 155.6 ±47.5 Hounsfield Units (HU)). In multivariate models, lower BA (per -10HU OR=1.21 [95%CI 1.16-1.27]) and male sex (OR=1.89 [1.35-2.64]) were significantly associated with prevalent VFs. Baseline BA and prevalent VFs were significantly associated with incident VFs within one (BA per -10HU HR=1.08 [1.02-1.13]; VF HR=3.99 [2.67-5.93]) and three years (BA per -10HU HR=1.05 [1.02-1.08]; VF HR=3.12 [2.43-4.01]). In subjects without prevalent VFs, baseline BA was significantly associated with incident VFs (one year: per -10HU HR=1.09 [1.01-1.18]; and three years per -10HU HR=1.07 [1.02-1.12]). In addition, in absence of prevalent VFs the lowest BA tertile was significantly associated with three year VF incidence (low vs. high group HR=2.0 [1.3-3.0], figure 1) but not with one year incidence (low vs. high group HR=1.7 [0.8-3.3]). Conclusion Baseline BA was an independent determinant for prevalent and incident VFs in (former) smokers with and without COPD, but a prevalent VF was a stronger determinant. This indicates that BA measurements combined with VF assessment on CT are useful for VF risk assessment.

Investigation of Second-Generation HR-pQCT to Improve Assessment of Hip Fracture Risk in Women Danielle E Whittier*, Lauren A Burt, Prism S Schneider, Steven K Boyd. McCaig Institute for Bone & Joint Health, Cumming School of Medicine, University of Calgary, Canada

Areal bone mineral density (aBMD) measured using dual-energy X-ray absorptiometry (DXA) is a reasonable predictor of bone strength, but it has limitations. Most people who have had a fragility fracture of the hip are not considered osteoporotic (T-Scores above -2.5). High-resolution peripheral quantitative computed tomography (HR-pQCT) offers a promising approach to improve assessment of fracture risk, as it allows for the evaluation of bone microarchitecture, which has been shown to be independently correlated with fracture risk. The objective of this study was to determine what measurable bone microarchitecture properties differentiate women with and without hip fractures, but who would not be captured using current clinical tools for assessing fracture risk.Six women (aged 78.4 ± 5.0 years) who have had a hip fracture in the past 6 months and sixteen healthy women (aged 75.1 ± 5.7 years) with no prior history of fragility fractures had their distal radius and tibia scanned using the second-generation HR-pQCT (XtremeCT II, Scanco Medical, 61 μm). Standard bone density and microarchitecture parameters obtained from HR-pQCT were assessed, in addition to DXA-based total hip (TH) aBMD. Differences in measured bone parameters between women with and without a hip fracture are described using two-sided t-tests, and the association between measured bone parameters and fracture status was determined using univariate logistic regression expressed as odds ratios (OR) per standard deviation (SD) change (with 95% CI).Women with hip fractures had an average T-Score of -1.8 (range -3.0 to -0.8), with only one below -2.5. TH aBMD, total BMD (TtBMD), and cortical BMD (CtBMD) at the tibia were significantly (p<0.05) lower in women with hip fractures, and each SD decrease in these parameters was associated with a significant increase in fracture risk (ORs between 4.78 to 6.04). Significant differences in trabecular number (TbN), and trabecular separation (TbSp) at the distal tibia were also observed, but were not associated with fracture risk. No significant differences were observed at the distal radius.Overall, women who had a hip fracture had lower bone density and lower quality trabecular microarchitecture at the tibia. These initial results suggest density and trabecular microarchitecture at the tibia may provide a basis to identify those at risk of a hip fracture, not previously captured using DXA-based measures alone.

Table 1: Mean and SD of TH aBMD and HR-pQCT parameters measured at the distal tibia for women with hip fractures and controls. Percent difference between group means, and association between parameters and fracture status, expressed as ORs per SD change are provided.

Parameter	Controls (N = 16)	Hip Fractures (N = 6)	Difference (Hip Fracture vs Control)	OR (95% CI)
TH aBMD [g/cm²]	0.93 ± 0.13	0.78 ± 0.10	-16%*	5.93 (1.43 – 58.7)*
TtBMD [mgHA/cm³]	278.7 ± 48.3	216.5 ± 40.7	-22%*	6.04 (1.57 – 40.9)*
CtBMD [mgHA/cm³]	787.8 ± 69.9	676.1 ± 110.7	-14%*	4.78 (1.39 – 36.8)*
TbBMD [mgHA/cm³]	179.6 ± 40.1	142.4 ± 51.2	-21%	2.77 (0.93 – 12.7)
TbN [1/mm]	1.37 ± 0.17	1.15 ± 0.30	-16%*	2.99 (1.04 – 13.8)
TbSp [mm]	0.71 ± 0.11	0.91 ± 0.31	28%*	3.12 (1.04 – 18.3)

The true relationship between bone marrow adipose tissue and volumetric BMD in the human spine Xiaoguang Cheng*[1], Kai Li[1], Yong Zhang[1], Ling Wang[1], Li Xu[1], Yangyang Duanmu[1], Cliff J Rosen[2], Glen M Blake[3]. [1]Department of Radiology, Beijing Jishuitan Hospital, China, [2]Center for Clinical & Translational Research, Maine Medical Center Research Institute, United States, [3]Biomedical Engineering Department, King's College London, United Kingdom

Objectives: In osteoporosis, a reduced level of bone formation associated with a reduction in the number and activity of osteoblasts is coupled with a corresponding increase in bone marrow adipose tissue (BMAT). Chemical shift-encoded magnetic resonance imaing (CSE-MRI) and single-energy quantitative computed tomography (SEQCT) offer precise ways of measuring BMAT and volumetric bone mineral density (vBMD) and studying their relationship. However, SEQCT vBMD measurements are subject to errors due to variations in the fat content of bone marrow. We have developed a novel method of using BMAT measurements to correct these errors and hence investigate the true relationship between vBMD and bone marrow composition.Materials and Methods: Four hundred healthy Chinese subjects (233 females, 167 males) aged between 21 and 82 years were enrolled in the study and had QCT and CSE-MRI scans of the L2-L4 vertebrae. Care was taken to ensure that matching regions of interest were used in both scans. Raw vBMD measurements were standardized to the European Spine Phantom (ESP) and then further corrected for the errors caused by the variations in BMAT. Scatter plots were drawn of BMAT, ESP adjusted vBMD and BMAT correted vBMD against age and analyzed by linear regression to determine the rate of change with age between age 20 and 80 years and the standard error of the estimate (SEE) (Figure 1). Results: BMAT in the L2-L4 vertebral bodies increased progressively with age in both sexes, with a statistically significantly faster rate of change in women compared to with men (0.54%/y vs. 0.27%/y, P < 0.0001). In women there was a statistically significant change in the slope of the regression line with age after the vBMD measurements were corrected for BMAT (-3.00 ± 0.13 mg/cm3/y before correction vs. -2.16 ± 0.10mg/cm3/y after correction, P < 0.0001). In addition, there was a statistically significant decrease in the SEE (30.6 mg/cm3 vs. 23.3 mg/cm3, P < 0.0001). There were similat findings in the men.Conclusions: Our approach reveals the true relationship between BMAT and vBMD, and provides a new tool for study the interaction between marrow adipose tissue and bone.

Fall Risk Is a Predictor of Fracture Independent of Bone Mineral Density and Bone Strength: Results from the FOCUS study Annette L. Adams*[1], Heidi Fischer[1], David L. Kopperdahl[2], David C. Lee[2], Tony M. Keaveny[3]. [1]Kaiser Permanente Southern California, United States, [2]O.N. Diagnostics, United States, [3]University of California, Berkeley, United States

Fall risk remains a poorly quantified etiological factor in hip fractures, in part because of the difficulty in obtaining robust clinical metrics for fall risk. Addressing this issue, we assessed for both sexes the association between incident hip fracture and a fall risk metric that was characterized by the widely available Fall Risk Assessment Tool (FRAT), com-

monly used in geriatric evaluations and adapted here for use with electronic health record (EHR) data. We also accounted for other major risk factors, including hip BMD T-score and finite element-derived femoral strength from CT scans, as well as age, body mass index, race/ethnicity, prior history of fracture, and use of bisphosphonates and/or glucocorticoids. Our study population consisted of over 110,000 Kaiser Permanente Southern California (KPSC) patients aged ≥65 years with a pre-existing abdominal or pelvic CT exam between 01/01/2006 and 12/31/2014, who had no fragility hip fracture before the CT, and a DXA within three years of the CT. From that population, we identified a sex-stratified, randomly sampled subcohort and all incident hip fracture cases with available EHR data. The control group (without fracture) was randomly selected in approximately equal numbers to the cases. DXA-equivalent hip BMD T-scores and femoral strength were measured by analysis of the CT scans. The FRAT metric (0–4 point scale) included elements on falls within the previous year, number of medications used daily, diagnoses of stroke or Parkinson's disease, and evidence of gait or balance problems (1 point per category). Data are presented for 1019 women (645 cases) and 482 men (284 cases) with complete data at 5 years of follow-up. We found that, compared to women with a FRAT score of 0 or 1, women with a score of 2 (21.4% of the cohort) were nearly twice as likely to sustain a hip fracture, after adjustment for all other risk factors including the BMD T-score or bone strength; and women with a FRAT score of 3 or 4 (7.7% of the cohort) were approximately 5 times as likely to have a hip fracture (Table 1). The effect was stronger for men, with those with a FRAT score of 2 (23.4% of the cohort) being nearly 3 times as likely to have a hip fracture, and those with a score of 3 or 4 (7.1% of the cohort) being 10-12 times as likely (Table 1). These findings demonstrate that the FRAT score is a potent and independent risk factor for hip fracture. As such, its use may improve clinical assessment of hip fracture risk.

Table 1. Cox proportional hazard ratios per SD change (or binary change) for incident hip fracture, for univariate and multivariate (MV) models.

Characteristic	Women N=1019			Men N=482		
	Univariate Model	Hip BMD MV Model	Bone Strength MV Model	Univariate Model	Hip BMD MV Model	Bone Strength MV Model
FRAT, 2 vs. 0 or 1	2.4 (1.7-3.3)	1.8 (1.2-2.6)	1.8 (1.2-2.6)	3.0 (1.9-4.9)	2.9 (1.6-5.2)	2.9 (1.6-5.2)
FRAT, 3 vs. 0 or 1	6.7 (5.2-14.1)	4.9 (2.2-10.8)	5.2 (2.3-11.4)	16.1 (3.8-68.2)	10.4 (2.5-47.4)	10.7 (2.4-48.5)
Hip BMD T-score	2.6 (2.2-3.0)	1.9 (1.6-2.3)	—	3.3 (2.5-4.4)	2.6 (1.8-3.7)	—
Bone Strength	3.3 (2.7-4.0)	—	2.4 (1.9-3.0)	3.3 (2.5-4.2)	—	2.6 (1.9-3.6)

All multivariate models also adjusted for age, body mass index, race/ethnicity, prior history of fracture, and use of bisphosphonates and/or glucocorticoids.

Cognitive Decline Is Associated with an Accelerated Rate of Bone Loss and Increased Fracture Risk in Women 65 years or Older in the Population-based Canadian Multicentre Osteoporosis Study (CaMos) Dana Bliuc*[1], Thach Tran[1], Tineke Van Geel[2], Jonathan Adachi[3], Claudie Berger[4], Joop Van Den Bergh[2], John Eisman[1], Piet Geusens[2], David Goltzman[5], David Hanley[6], Robert Josse[7], Stephanie Kaiser[8], Christopher Kovacs[9], Lisa Langsetmo[10], Jerilynn Prior[11], Tuan Nguyen[1], Jacqueline Center[1]. [1]Bone Biology Group, Garvan Institute of Medical Research, Australia, [2]Maastricht University Medical Center, Netherlands, [3]Department of Medicine, McMaster University, Canada, [4]CaMos National Coordinating Centre, McGill University, Canada, [5]Department of Medicine, McGill University, Canada, [6]Department of Medicine, University of Calgary, Canada, [7]Department of Medicine, University of Toronto, Canada, [8]Department of Medicine, Dalhousie University, Canada, [9]Faculty of Medicine, Memorial University, Canada, [10]School of Public Health, University of Minnesota, Twin cities, United States, [11]Department of Medicine and Endocrinology, University of British Columbia, Canada

Background: Cognitive deficit is prevalent among older people with fractures; some evidence suggests recent bone loss predicts it. However, it is not clear whether this association is independent of ageing. Longitudinal studies that assess the complex relationships among cognitive decline, loss of areal bone mineral density (BMD) and fracture risk are lacking. Objective: To determine the association between: 1) change in cognitive function and BMD loss, and 2) cognitive decline of ≥3 points on MMSE between baseline (Y0) and Year 5 (Y5) and incident fracture risk (between Ys 5 and 15). Design and setting: CaMos population based study with 9 centres across Canada. Participants: 2443 women and 844 men aged ≥65 years, mean 73±6 years at baseline (1995/97) followed for an average of 10 years (±5) until 2013. Exposure: Annual % change in Mini Mental State Examination (MMSE) (Y0, 5 and 10), and cognitive decline of ≥ 3 points loss on MMSE. Cox proportional hazards models were adjusted for age, BMD, education, co-morbidities, weight, falls, and smoking. Main outcome measures: Annual % change in femoral neck BMD (Y0, Ys-3, 5 and 10); incident fragility fractures (except skull and digits) assessed from Ys 5 to 15. Results: Over 95% of participants had normal cognition at baseline (MMSE≥24). The annual % change in MMSE was similar for both genders [women -0.33 (IQR:-1.00 to +0.02) and men -0.33 (IQR:-0.72 to 0.00)]. Similarly, the rate of BMD loss was similar for both genders [women -0.32 (IQR: -0.81 to +0.14) and men -0.36 (IQR: -0.91 to +0.19)]. After confounder adjustment, cognitive decline was significantly associated with BMD loss (p=0.0008) in women but not in men (p=0.29). Approximately 13% of participants lost ≥3 MMSE points by Y 5. Women with cognitive decline were older, had lower weight and had increased fracture risk [HR,

1.45 (95% CI, 1.00-2.10)]. After adjusting for bone loss, the magnitude of fracture risk decreased only slightly but was no longer significant [HR, 1.39 (95% CI, 0.93-2.06)]. Men with cognitive decline did not have an increased fracture risk [HR, 0.60 (0.20-1.59)]. Conclusion: Cognitive decline is associated with bone loss in older women but not in men. Cognitive decline was also associated with fracture risk, although this was not independent of bone loss. These findings suggest a close link between bone loss and cognitive decline, at least in women. Further studies are needed to determine mechanisms that link these common conditions.

Thiazide Diuretics and Fracture Risk: A Systematic Review and Meta-Analysis of Randomized Clinical Trials Louis-Charles Desbiens*, Nada Khelifi, Yue-Pei Wang, Aboubacar Sidibe, Alexis F-Turgeon, Fabrice Mac-Way. CHU de Québec - Université Laval, Canada

Introduction: Thiazide diuretics are commonly prescribed for the treatment of high blood pressure and have been associated with decreased fracture risk in observational studies. We aimed to conduct a systematic review and meta-analysis of randomized clinical trials to evaluate the effect of thiazides on fractures and bone mineral density.Methods: We searched MEDLINE, EMBASE, CENTRAL and the WHO's International Clinical Trials Registry Platform databases from inception to March 2018. Two independent reviewers assessed studies for eligibility criteria: 1) randomized clinical trials; 2) comparing thiazide diuretics, alone or in combination; 3) to placebo or another medication; 4) in adults; and 5) reporting fracture as outcome or adverse events and/or bone mineral density (BMD) measurements. Studies comparing diuretics to anti-resorptive or anabolic bone therapy were excluded. Primary outcome was total fractures (any reported anatomical site or not). Secondary outcomes were osteoporotic, hip fractures and bone mineral density at the femoral neck, lumbar spine and/or total hip. Risk of bias was assessed with the Cochrane risk of bias tool. Meta-analysis was conducted with random-effects models.Results: From 14 611 unique citations retrieved, 19 trials including 85 772 patients have been included. All, but two trials were at high risk of bias, notably due to fracture assessment, pharmaceutical funding and incomplete outcome data. Thiazide diuretics were associated with a significant reduction in total fractures (RR= 0.87 [0.77, 0.99]; I2= 0%, 17 trials; Figure 1) and osteoporotic fractures (RR= 0.82 [0.70, 0.97]; I2= 0%, 10 trials) but not hip fractures (RR= 0.91 [0.51, 1.64]; I2= 0%, 3 trials). In subgroup analyses, thiazides were also associated with a significant reduction of total fractures in trials with patients over 65 years, baseline blood pressure between 140/90 and 160/100 mmHg, where antihypertensives were used as comparator and fractures measured as an outcome. Four trials reported BMD at different anatomical sites and units. A meta-analysis could not be conducted for this outcome.Conclusion: Thiazide diuretics are associated with decreased total and osteoporotic but not hip fractures compared to placebo or other antihypertensives. BMD was insufficiently and inconsistently reported. Further studies specifically designed to investigate the impact of thiazide diuretics on fractures are required. Registration: CRD42018078083

The association between prevalent vertebral fractures and coronary artery calcification on chest CT in smokers with and without COPD Johanna Driessen*[1], Mayke Van Dort[2], Piet Geusens[3], Elisabeth Romme[4], Frank Smeenk[4], Braim Rahel[5], Emiel Wouters[6], Joop Van Den Bergh[7]. [1]CAPHRI Care and Public Health Research Institute, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Clinical Pharmacy and Toxicology, Maastricht University Medical Centre+ (MUMC+);, Netherlands, [2]NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), Netherlands, [3]Department of Internal Medicine, Rheumatology, Maastricht University Medical Centre+ (MUMC+), the Netherlands, Netherlands, [4]Department of Respiratory Medicine, Catharina Hospital, Eindhoven, the Netherlands;, Netherlands, [5]Department of Cardiology, VieCuri Medical Centre, Venlo, the Netherlands;, Netherlands, [6]Department of Respiratory Diseases, Maastricht University Medical Centre+ (MUMC+), the Netherlands;, Netherlands, [7]Department of Internal Medicine, VieCuri Medical Centre, Venlo and Department of Internal Medicine, NUTRIM School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre+ (MUMC+), the Netherlands;, Netherlands

Background Patients with chronic obstructive pulmonary disease (COPD) have increased risk of osteoporosis and vertebral fractures (VFs), and have more often coronary artery disease and higher coronary artery calcification (Agatston) scores as compared to controls without COPD. Bone attenuation (BA) on chest CT scans has been shown to correlate with Agatston score, but it is unknown whether VFs are associated with Agatston score in COPD patients. Therefore our aim was to investigate the association between prevalent VFs and Agatston score in (former) smokers and COPD patients.Methods Current and former smokers with and without COPD from the ECLIPSE study with baseline, one and three year follow up CT scans were included. Agatston score was measured on baseline CT in a subset of the ECLIPSE study. Subjects were divided into three groups based on Agatston units (AU): low (0 AU), medium (1-400 AU), or high (>400 AU). Prevalent VFs were assessed on superposed sagittal reconstructions containing the spine. Bone attenuation was measured semi-automatically in 3D areas in vertebrae T4-T12. Logistic regression models were used to assess the relationship between VFs and Agatston score.Results 586 subjects were included (mean age 59.8 ±8.3, 62.3% men, 70.1% with COPD). There were 196 subjects in the low Agatston group, 266 in the medium, and 124 in the high group (table 1). Subjects with ≥1 prevalent VF had significantly more often medium (OR=2.62 [95%CI 1.52-4.51]) or high Agatston scores (OR=4.51 [2.49-8.16]) than subjects without prevalent VFs.After adjustment for age, sex, BMI, smoking status (current or former), pack years and presence of COPD, subjects with one or more prevalent VF had significantly more often medium or high Agatston scores (OR=1.83 [1.01-3.31] and OR=3.04 [1.43-6.45] resp.) than subjects without prevalent VFs.After additional adjustment for BA the result remained significant (OR=1.58 [0.86-2.90] and OR=2.47 [1.12-5.42], for medium and high Agatston scores respectively). Conclusion In smokers with and without COPD, the presence of ≥1 prevalent VF was associated with higher coronary artery calcium (Agatston) scores.

	Low Agatston group n = 196		Medium Agatston group n = 266		High Agatston group n = 124

MON-0786

Impact of Comorbidity and Prognosis on Hip Fracture and Mortality Incidence Among Women in Late Life Kristine Ensrud*[1,2], Allyson Kats[1], Cynthia Boyd[2], Susan Diem[1,2], John Schousboe[3], Brent Taylor[1,2], Douglas Bauer[4], Katie Stone[4], Lisa Langsetmo[1]. [1]University of Minnesota, United States, [2]Johns Hopkins University, United States, [3]HealthPartners Institute / University of Minnesota, United States, [4]University of California - San Francisco, United States

Concerns about comorbidity burden and limited life expectancy increase the complexity of managing osteoporosis (OP) in late life. To determine the effects of comorbidity burden

and prognostic information on cumulative incidence of hip fracture in women in late life who might be considered candidates for drug treatment, we studied 1556 community-dwelling treatment-naïve women (mean age 84.1 years, SD 3.4) with OP (BMD T-score ≤−2.5, history of hip or vertebral fracture, n=761) or without OP at high fracture risk (BMD T-score >−2.5, 10-year FRAX + BMD fracture probabilities ≥ NOF intervention thresholds, n=795). Comorbidity burden was assessed by self-report of 14 medical conditions. Prognosis was estimated using a validated mortality prediction index incorporating demographics, functional status and medical diagnoses. Women were contacted every 4 months to ascertain vital status and hip fracture. 5-year hip fracture probability was calculated for each of the two distinct groups accounting for the competing risk of mortality. During follow-up, 125 (8.0%) experienced a hip fracture and 292 (18.8%) died before experiencing this event. Mortality incidence increased with greater comorbidity burden and worsening prognosis and was similar among osteoporotic women and those without OP at high fracture risk (Table). Hip fracture incidence also generally increased with greater comorbidity burden and worsening prognosis in both groups, but the probability was markedly higher among osteoporotic women. Among women with the highest comorbidity burden (≥3 conditions), hip fracture probability at 5 years was 18.1% among osteoporotic women vs. 2.4% among women without OP at high fracture risk. Among women with the worst prognosis (≥14 points), hip fracture probability was 25.3% among osteoporotic women vs. 4.5% among women without OP at high fracture risk. In summary, osteoporotic community-dwelling women in late life with greater comorbidities or poorer prognosis have a high 5-year hip fracture probability despite accounting for their competing risk of mortality and may still be candidates for drug treatment to prevent hip fracture. Data regarding efficacy and safety of drug treatment in this patient population is needed. The absolute benefit of drug treatment is likely to be less among women without OP at high fracture risk who have greater comorbidities or poorer prognosis as the probability of mortality far outweighs the probability of hip fracture.

Table: 5-Year Probability (95% CI) of Mortality and Hip Fracture by category of Comorbidity Burden and Prognostic Index

High Prevalence of Vertebral Fractures in Healthy Community-Dwelling Oldest Old: Longevous Study Fernanda Gazoni*[1], Jane Erika Frazão Okazaki[2], Daniela Regina Brandão Tavares[1], Lais Abreu Bastos[3], Flavia Kurebayashi[4], Fania Cristina Santos[5]. [1]Doctorate Student at São Paulo Federal University, Brazil, [2]Associated Physician at São Paulo Federal Universisty, Brazil, [3]Affiliated physician at São Paulo Federal University, Brazil, [4]Pos-graduate studant at São Paulo Federal University, Brazil, [5]Professor at São Paulo Federal University, Brazil

Introduction: Vertebral fractures (VFs) are associated with elevated morbimortality in aging and remain as the main risk factor for new fractures in the same site or in others. Although, they are still underdiagnosed in the very elderly population. VFs can be identified by X-ray image or by dual-emission x-ray absorptiometry (DXA), known as vertebral fracture assessment (VFA). Objectives: To evaluate VFs in elderly patients using two methods, VFA and conventional radiography (x-ray), and to describe their prevalences, characteristics and associated factors. Methods: This is a subanalysis of an observational study with elderly people of 80 years of age or older who were enrolled at the "Longevous Study" which take place at São Paulo, Brazil. This subanalysis included patients recruted from July 2014 to May 2016 and who were admitted at the Geriatrics outpatient of São Paulo Federal University. The VFs were diagnosed by VFA and X-ray, using the semi-quantitative technique of Genant applied by two trained physicians. Only moderate and severe VFs comprised between T4-L4 were included. FVs detected by VFA were analysed by demographic, anthropometric, clinical, laboratory and densitometric data. The correlation analyzes were performed according to the x2 and ANOVA tests, and a logistic regression model was applied. Results: This subanalysis was composed of 125 individuals with mean age of 86.7 years, with majority of females (71.2%). According to DXA, osteopenia were diagnosed in 47.6% of the participants and osteoporosis in 35.5%. Prevalence of FVs were 30.4% by VFA method (p <0.001) and 20.8% by x-ray (p <0.001). There were statistically significant correlations of VFs with: bone mineral density (BMD) and T-score of the total femur (p = 0.04 and p = 0.05, respectively) and creatinine clearance (p = 0.01). For other variables such as demographic, anthropometric, clinical and laboratory data there were not a statistically significant correlations of VFs in this population. Conclusion: High prevalence of VFs was observed in this population, regardless of the methods used. Also, the low total femoral t score (or BMD) and

creatinine clearance were important risk factors for VF in longevous people. The applicability of VFA in the diagnosis of VF in our routine pratice could be an important way to a wide stratification of fracture risk in longevous.

Impact Microindentation in Impaired Fasting Glucose and Diabetes Kara Holloway-Kew*[1], Pamela Rufus[1], Adolfo Diez-Perez[2], Lelia De Abreu[1], Mark Kotowicz[1], Muhammad Sajjad[1], Julie Pasco[1]. [1]Deakin University, Australia, [2]Autonomous University of Barcelona, Spain

Background:Individuals with diabetes are at increased fracture risk with BMD measurements underestimating risk. Impact microindentation, a novel technique that measures bone microindentation distances, expressed as bone material strength index (BMSi), may improve fracture risk estimation in individuals with diabetes. This study describes the relationship between BMSi, femoral neck BMD (FNBMD), lumbar spine BMD (LSBMD) and dysglycaemia in men.Material and Methods:Participants were 211 men aged 33-92yr from the Geelong Osteoporosis Study. Impaired fasting glucose (IFG) was defined as fasting plasma glucose (FPG) 5.5-6.9 mmol/L and diabetes as FPG≥7.0mmol/L, use of antihyperglycemic medication and/or self-report. BMSi was measured using the OsteoProbe® at the mid-tibia following international standardized procedure. FNBMD and LSBMD were assessed using DXA (Lunar Prodigy Pro GE).Using linear regression techniques, the relationship between dysglycaemia and BMSi and BMD was evaluated, adjusting for age, BMI, smoking, alcohol, physical activity, medication use and prior fracture.Results:There were 140(66.4%) men with normoglycaemia, 37(17.5%) with IFG and 34(16.1%) with diabetes. Duration of diabetes ranged from 2.8-28.0yr (median 11.1yr) and age of onset 42-91yr (median 65yr). FNBMD values were not different between normoglycaemia and IFG or diabetes (adjusted mean values 0.959 g/cm2 (95%CI 0.938-0.979), 0.951(0.912-0.990; p=0.7) and 0.965(0.923-1.007; p=0.8), respectively). LSBMD was also not different between the three dysglycaemia groups (1.305(1.273-1.337), 1.326(1.265-1.387; p=0.6) and 1.335(1.269-1.401; p=0.4, respectively). Adjusted BMSi values were 83.4(82.4-84.4), 83.6(81.7-85.6) and 80.6(78.9-82.9) for normoglycaemia, IFG and diabetes, respectively. Compared to normoglycaemia, there was no difference in BMSi for IFG (p=0.8), however, men with diabetes had a lower BMSi (p=0.03).Conclusions:Men with diabetes had lower BMSi whereas no differences in FNBMD or LSBMD were detected between the glycaemia groups. The OsteoProbe® may be useful for improving fracture risk prediction in individuals with diabetes.

Comparing Utility Loss Due to Fractures, in Cohorts With and Without a Previous Fracture Helena Johansson*[1], John A Kanis[2], Anders Odén[3], Nicholas C Harvey[4], Vilmundur Gudnason[5], Kerrie Sanders[6], Gunnar Sigurdsson[5], Kristin Siggeirsdottir[5], Lorraine Fitzpatrick[7], Mattias Lorentzon[8], Fredrik Borgström[9], Eugene Mccloskey[10]. [1]Institute for Health and Aging, Australian Catholic University, Melbourne, Australia, Sweden, [2]Institute for Health and Aging, Catholic University of Australia, Melbourne, Australia, Austria, [3]Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, United Kingdom, [4]MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton, United Kingdom, [5]Icelandic Heart Association Research Institute, Kopavogur, Iceland, [6]Department of Medicine, The University of Melbourne and Western Health, Sunshine hospital, Melbourne, VIC, Australia, [7]Radius Health, Waltham, MA, United States, [8]Centre for Bone and Arthritis Research, Geriatric Medicine, Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden., Sweden, [9]LIME/MMC, Karolinska Institutet, Stockholm, Sweden, [10]Mellanby Centre for bone research, Department of Oncology and Metabolism, University of Sheffield, Sheffield, United Kingdom

Purpose: With the ageing population, osteoporotic fractures are increasingly a major public health issue as well as impacting on an individual's quality of life. We wished to examine the mean utility loss in the 10 years in a cohort of patients following a sentinel fracture of the hip, clinical spine, forearm or humerus, compared to the mean utility loss from the whole population (fractured and unfractured).Method:sThe study comprised a population-based cohort of 18,872 persons born between 1907 and 1935 in the Reykjavik Area. Cumulative loss of utilities was calculated using utility multipliers derived from the EQ-5D 3 Levels descriptive system for osteoporotic fracture sites. Multipliers were applied to health state values published for the UK general population for each subsequent osteoporotic fracture that occurred during 10 years of follow up. The cumulative loss of utility and mean utility loss was calculated for the whole population, and also for the sub-cohort followed from the occurrence of a sentinel major osteoporotic fracture.Results: 18,872 individuals (52% female), aged on average 52.8 years (range 33-81) were included. Sentinel hip fractures were sustained in 2074 men and women; for clinical spine, forearm and humerus fractures, the respective numbers were 1365, 2364 and 1092, respectively. Utility loss over 10 years was much greater in sentinel fracture cases than in the whole cohort, when adjusted for age and gender. Loss was greatest following a vertebral fracture (0.92; 95% CI: 0.89-0.95), followed

by hip (0.63; 95% CI: 0.61-0.65), humeral (0.51 (95% CI: 0.49-0.53) and forearm fracture (0.32; 95% CI: 0.31-0.33). The utility loss during the first 10 years after a sentinel fracture was greater in women, and decreased with age. In women at the age of 70 years, the mean utility loss due to fractures in the population was 0.081 whereas this was 12-fold greater in women with a sentinel hip fracture, and was increased 15-fold for spine fracture, 4-fold for forearm fracture and 8-fold for humeral fracture.Conclusions: Sentinel major osteoporotic fractures are associated with significantly greater utility losses in the subsequent 10 years than in the population as a whole. These data can inform health economic models examining the impact of therapies to prevent major osteoporotic fractures and subsequent fracture-related utility loss.

MON-0790

Impact of a personal history of breast cancer on bone mineral density among women with a BRCA1 or BRCA2 mutation undergoing prophylactic bilateral salpingo-oophorectomy Joanne Kotsopoulos*[1], Elizabeth Hall[2], Amy Finch[1], Barry Rosen[3], Joan Murphy[4], Steven A. Narod[1], Angela M. Cheung[5]. [1]Women's College Research Institute, Women's College Hospital, Canada, [2]University of Toronto, Canada, [3]Beaumont Health, United States, [4]Trillium Health Partners, Canada, [5]University Health Network, Canada

Background: Surgical removal of the ovaries and fallopian tubes (prophylactic bilateral-salpingo-oophorectomy; PBSO) is recommended to women with a BRCA1 or BRCA2 mutation to reduce their risk of developing ovarian cancer. The impact of early, surgical menopause and the ensuing endogenous hormone deficiencies on bone health in this high-risk population is unclear. Thus, we evaluated the impact of PBSO, as well as a personal history of breast cancer, on bone mineral density (BMD) among BRCA mutation carriers enrolled in a longitudinal study.Methods: The study population included women who underwent PBSO at the University Health Network (Toronto, Canada) between January 2000 and May 2013. Eligibility criteria included having a BRCA mutation, at least one ovary intact prior to surgery, and no personal cancer history other than breast cancer. Information regarding medical history, medication use, and lifestyle factors was collected via questionnaire. BMD measurements using dual energy x-ray absorptiometry were collected at baseline (prior or prior to surgery) and at a follow-up visit (>1 year following surgery). The % change in BMD from baseline to follow-up was calculated for the lumbar spine, femoral neck, and total hip. The analysis was stratified by a personal history of breast cancer.Results: There was a total of 98 women included in the analysis: 56% were premenopausal at the time of surgery and 44% were postmenopausal. Mean age at PBSO was 47 years (range 35-75). Mean time to first follow-up was 1.8 years (range 0.4 - 6.5). Among women with a history of breast cancer (n = 43), there was a significant decrease in BMD from baseline to first follow-up across the lumbar spine (-1.95%; 95%CI -0.14 to -3.76), femoral neck (-1.91%; 95%CI, -0.33 to -3.49), and total hip (-1.77%; 95%CI, -0.43 to -3.10), respectively. Among women without a history of breast cancer (n = 55), there was a significant decrease in BMD across the lumbar spine (-5.84%; 95% CI, -4.00 to -7.68), and femoral neck (-4.87%; 95% CI, -2.99 to -6.75), and for total hip (-3.16%; 95% CI, -1.73, -4.59).Conclusions: Although preliminary, these findings suggest that PBSO is associated with a significant decline in BMD. Of interest is that the decrease in BMD was stronger among women without a personal history of breast cancer. This data adds to the emerging literature indicating that clinical guidelines should integrate the routine monitoring of BMD in this unique population.

MON-0791

Calcaneal Quantitative Ultrasonography Measures and Cardiovascular and All-Cause Mortality in Older Women: a Prospective Study Joshua Lewis*[1], Kun Zhu[2], Wai Lim[3], Richard Prince[4]. [1]School of Medical and Health Sciences, Edith Cowan University, Australia, [2]University of Western Australia, Australia, [3]Sir Charles Gairdner Hospital, Australia, [4]Medical School, University of Western Australia, Australia

Background: To further progress previous studies on the importance of bone for mortality outcomes, especially cardiovascular mortality, we evaluated the relationship between calcaneal broadband ultrasound attenuation (BUA) with all-cause and cardiovascular (CV) mortality. We also investigated the modifying effects of measured covariates on the strength of the relationship.Methods: 1404 older women over 70 years (mean age 75.2±2.7 years) were recruited into the Perth Longitudinal Study of Ageing Women in 1998. Calcaneal BUA was measured at baseline using a Hologic Sahara machine (Hologic, Waltham, USA). Complete mortality and primary cause of death data were ascertained from linked mortality records.Results: Over 15 years (17,955 person years) of follow up there were 584 deaths (223 CV, 158 cancer, 200 other causes of death, 3 cases where cause of death remained under investigation). For every SD decrease in calcaneal BUA there was a 16-19% increase in the relative hazards of 15-year total mortality (HR 1.16 95%CI 1.06-1.26, P=0.002) and CV mortality (HR 1.19 95%CI 1.03-1.37, P=0.020) after adjusting for other measures of cardiovascular and mortality risk including age, BMI, smoking history, diabetes, systolic blood pressure, prescription of anti-hypertensive medications, prevalent myocardial infarction, stroke or revascularization, prevalent cancer, prevalent fractures and prevalent chronic obstructive pulmonary disease. These associations also remained significant after the addition

of total hip BMD to the multivariable-adjusted analyses (all-cause mortality HR 1.19 95%CI 1.06-1.33, P=0.002 and CV mortality HR 1.26 95%CI 1.05-1.52, P=0.016, respectively). Interaction testing between calcaneal BUA and baseline risk factors identified BMI as a potential effect-modifier of the relationship between calcaneal BUA and CV mortality (P=0.020) and all-cause mortality (P=0.009). In women with a BMI of 25-29 kg/m2 per SD reduction in calcaneal BUA was associated with a 29% higher relative hazard for all-cause and CV mortality (HR 1.29 95%CI 1.12-1.48, P=0.001 and HR 1.29 95%CI 1.01-1.64, P=0.038, respectively).Conclusion: Calcaneal BUA, independent of total hip aBMD, appears to reflect a novel aspect ageing not captured by conventional cardiovascular and mortality risk factors. Further studies are required to identify other potential pathways of relationship including chronic inflammation and cell senescence.

MON-0792

Influence of combined hormonal contraception on 10-year areal bone mineral density change in premenopausal women in the population-based Canadian Multicentre Osteoporosis Study (CaMos) Heather Macdonald*[1], Claudie Berger[2], Suzanne Morin[2], Christopher Kovacs[3], David Hanley[4], Tassos Anastassiades[5], Stephanie Kaiser[6], David Goltzman[2], Jerilynn Prior[1]. [1]University of British Columbia, Canada, [2]McGill University, Canada, [3]Memorial University of Newfoundland, Canada, [4]University of Calgary, Canada, [5]Queen's University, Canada, [6]Dalhousie University, Canada

Combined hormonal oral contraceptives (CHC) are the most common method of contraception for women and are also used to treat menstruation-related problems such as cramps and acne. Supra-physiological estrogen in CHC may impact women's bone health and fracture risk. However, the nature of this relationship is unclear due, in part, to a lack of prospective population-based data. Thus in CaMos data we examined the influence of CHC use, stratified by never (N-CHC) or ever (E-CHC, ≥3 months) lifetime use, on areal bone mineral density (aBMD) at baseline and aBMD change in a population-based sample of premenopausal women (recruited 1995-7) ages 25+ years (y).We identified 915 premenopausal women at baseline (42.9 ± 8.2 y), 356 at Y3, 513 at Y5 and 311 at Y10 of follow up. We fit hierarchical models using up to 10 years of longitudinal data to determine the association of CHC use with lumbar spine (L1-L4), total hip (TH) and femoral neck (FN) aBMD at baseline and changes over time. Secondarily, in E-CHC, we fit hierarchical models to examine associations between aBMD (baseline and change) and: a) self-reported reason for first CHC use (contraception or therapy); and b) age at first CHC use (continuous). All models were adjusted for age, height, BMI, study centre, current smoking (yes/no), calcium intake, calcium and vitamin D supplement use, number of live births, sedentary time (hours/day), alcoholic drinks/week and physical activity (kcal/week).At baseline most women reported ever use of CHC (781, 85%). Among E-CHC, 88% of women used CHC for contraception; mean age at first CHC use was 21.5 ± 4.3 (range 12-48) y. Average follow-up was 5 ± 4 y. At baseline, CHC use was not associated with aBMD at any site. Over time E-CHC demonstrated less FN aBMD loss than N-CHC (0.002 g/cm2/y [95% CI: 0.0007; 0.0032]). In E-CHC, women who first used CHC for therapeutic reasons had lower baseline FN aBMD compared with women who started using CHC for contraception (adjusted difference of 0.03 g/cm2; 95% CI: 0.003; 0.056). Reason for first CHC use was not associated with aBMD change. Age at first CHC use was not associated with aBMD at baseline but women who started using CHC later in life demonstrated significantly greater loss over time in L1-L4, FN and TH aBMD (Figure).In summary, these population-based, prospective data suggest that CHC ever use may attenuate femoral neck aBMD loss in premenopausal women, particularly when CHC use is initiated earlier in life.

Figure 1: Modeled aBMD over 3, 5 and 10 years, for an average woman, by age at first use of Combined Hormonal Contraceptives (CHC) in CaMos using adjusted* hierarchical models. Error bars represent the upper bound of the 95% C.I.

* The adjusted BMD values represent an average woman and are graphed for 3 specific but arbitrarily different ages at first CHC use.

MON-0793

Osteoporosis risk factors in elder Chinese and Caucasian Canadians: the Canadian Multicentre Osteoporosis Study Suzanne N Morin*[1], Claudie Berger[2], David A Hanley[3], Steven K Boyd[3], Jerilynn C Prior[4], Andy Ko Wong[5], Angela M Cheung[5], Alexandra Papaioannou[6], Elham Rahme[1], David Goltzman[1]. [1]McGill University, Canada, [2]Research Institute of the McGIll University Health Centre, Canada, [3]University of Calgary, Canada, [4]University of British Columbia, Canada, [5]University of Toronto, Canada, [6]McMaster University, Canada

Purpose: Ethnicity is an important factor that influences the prevalence of osteoporosis, associated risk factors and fractures. The Chinese population is the second largest visible minority group in Canada, and is projected to double over 20 years. To date, there have been no Canadian studies on osteoporosis and risk factors for fractures in the Chinese Canadian population. We aimed to compare risk factors for osteoporosis between Chinese and Caucasian Canadians.Methods: We used the baseline data (1995-1997) from the population-based longitudinal Canadian Multicentre Osteoporosis Study (CaMos). We included participants aged ≥ 65 years who reported Chinese or Caucasian ethnicity. Chi-square tests of independence and T-tests were used to compare categorical and continuous variables, respectively. Linear regressions were used to examine the association of calcium intake, SF-36 domains and bone mineral density (BMD) with ethnicity. All regressions were adjusted for body mass index (BMI), height, age and history of previous low trauma fractures.Results: We studied 78 Chinese (37 women and 41 men; mean age 73.2 [6.0] y) and 4400 Caucasian (3220 women and 1180 men; mean age 73.1 [6.1] y) Canadians. Chinese participants had a lower prevalence of low trauma fractures than Caucasians (5.4% vs 32.9% in women and 12.2% vs 24.1% in men). They also differed on important risk factors such as BMI, height, dairy calcium intake and tea consumption (Table 1). Chinese participants had significantly lower femoral neck BMD than Caucasians with a T-score of –2.1 (1.1) vs -1.7 (0.9) in women and -1.8 (0.8) vs -1.2 (1.0) in men. In adjusted models, these differences were no longer significant but dairy calcium intake was lower in Chinese by 277 mg/day (95% CI: 74-480) in women and by 369 mg/day (95% CI: 216-521) in men compared to Caucasians. In adjusted models, SF-36 physical and mental component summaries did not differ between groups; however, Chinese participants had better bodily pain and mental health scores but lower social functioning scores than Caucasians.Conclusion: Predictors of fracture risk differ across populations of different origins in Canada. This supports the importance of characterizing bone health predictors in Chinese Canadians and the development of population-specific fracture prevention strategies.

Table 1: Comparison of osteoporosis risk factors and fractures between elder CaMos Chinese and Caucasian participants.

	Women		Men	
	Chinese	Caucasian	Chinese	Caucasian

MON-0794

Prospective Study of Body Mass Index, Waist Circumference and Risk of Clinical Vertebral Fracture in Women Julie M Paik*[1], Harold N Rosen[2], Jeffrey N Katz[1], Bernard A Rosner[1], Catherine M Gordon[3], Gary C Curhan[1]. [1]Brigham and Women's Hospital, Harvard Medical School, United States, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, United States, [3]Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, United States

Background: Recent evidence suggests that the relation between obesity and fracture risk may be site-specific. Previous studies on the association between body mass index (BMI) and risk of vertebral fracture (VF) have been inconsistent, and there have been no prospective studies to date on the relation between waist circumference, a measure of central obesity, and vertebral fracture risk.Methods: We conducted a prospective study in 54,940

women participating in the Nurses' Health Study without prior history of any fracture. BMI was assessed from biennial questionnaires. Waist circumference was assessed in the year 2000. Self-reports of vertebral fracture were confirmed by medical record review. Cox proportional-hazards models were used to simultaneously adjust for potential confounders. When BMI and waist circumference are included in the same model, BMI reflects lean body and waist circumference reflects abdominal adiposity.Results: Our analysis included 536 incident vertebral fracture cases (2002-2014). Compared with women with BMI 21.0-24.0 kg/m2, the multivariable-adjusted relative risk (MVRR) of VF for women with BMI ≥ 32.0 kg/m2 was 0.84 (95% CI 0.61, 1.14). The p value for trend across all five BMI categories = 0.09. After further adjusting for waist circumference, the MVRR of VF for women with BMI ≥ 32.0 kg/m2 was 0.70 (95% CI 0.49, 0.98; ptrend=0.004). Compared with women with waist circumference < 71.0 cm, the MVRR of VF for women with waist circumference ≥ 108.0 cm was 1.77 (95% CI 1.06, 2.93; ptrend=0.02), and after further adjusting for BMI was 2.50 (95% CI 1.44, 4.34; ptrend<0.001).Conclusion: Larger waist circumference, a measure of central obesity, was independently associated with higher risk of VF in women. Greater lean body mass was independently associated with lower risk of VF in women. These findings suggest that the distribution of fat is an important predictor of vertebral fracture, and that avoiding central adiposity, as well as maintaining muscle strength, may potentially reduce the risk of vertebral fracture in older women. Further research is warranted on body composition, particularly central adiposity, lean body mass, and vertebral fracture risk.

MON-0795

Long-Term Effect of Aromatase Inhibitors on Fracture Risk Compared to Tamoxifen: a "Real World" Cohort Study of Continued Treatment Up to Ten Years of Follow-Up Marta Pineda-Moncusí*[1], Natalia Garcia-Giralt[1], Adolfo Diez-Perez[1], Ignasi Tusquets[2], Sonia Servitja[2], Joan Albanell[2,3], Daniel Prieto-Alhambra[4], Xavier Nogues[1]. [1]IMIM (Hospital del Mar Research Institute), Centro de Investigación Biomédica en Red de Fragilidad y Envejecimiento Saludable (CIBERFES), Spain, [2]Cancer Research Program, IMIM (Hospital del Mar Research Institute), Spain, [3]Medical Oncology Department of Hospital del Mar- CIBERONC, Spain, [4]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, and NIHR Oxford Biomedical Research Centre, United Kingdom

Recommended adjuvant treatments for estrogen receptor positive breast cancer include aromatase inhibitors (AI) and tamoxifen (TAM). AI therapy has been associated with increased bone loss and excess fracture risk in pivotal RCTs. Bisphosphonates (BP) are recommended in clinical guidelines to minimize bone loss. We conducted an observational cohort study to assess fracture risk during long-term AI therapy compared with tamoxifen, and to study the association with BP use.Data on 27,695 breast cancer women on either AI or TAM were obtained from primary care records in Catalonia (SIDIAP database) between 2006 and 2015. Patients were included from the first day of TAM or AI treatment until the earliest of: AI/TAM or BP (if applicable) cessation, death or migration, end of data availability, or fracture event. BP use was introduced as a time-varying exposure, with patients considered non-users at first, but contributing to the BP user cohort from BP therapy initiation. Survival analyses were performed by a)Kaplan–Meier to estimate cumulative probability plots, and b)Cox proportional hazards models accounting for competing risk of death (Fine and Gray models) adjusted for propensity scores to calculate event-specific hazard ratios (SHR [95%CI]) according to exposure and using TAM as reference group.A total of 9,233 TAM, 564 TAM+BP, 17,028 AI, and 3,914 AI+BP records were included, with fracture incidence rates [95%CI] of 5.45/1,000 person-years [4.49 to 6.56], 24.95 [15.02 to 39.14], 15.08 [13.88 to 16.36], and 25.71 [22.02 to 29.85] respectively (Fig. 1). TAM-treated patients had the lowest fracture risk: propensity-adjusted SHR 2.15 [1.26 to 3.68] in TAM+BP, 1.77 [1.43 to 2.21] in AI, and 2.42 [1.86 to 3.15] in AI+BP. Significant higher risk was observed in AI+BP (SHR 1.33 [1.10 to 1.61]) compared to AI users.AI therapy is associated with substantial increase in fracture risk compared to TAM, where the BP users manifested the worst outcomes. Monitoring fracture risk factors in AI patients is recommended. More data are needed on the protective efficacy of BP therapy in AI-induced bone fragility.

Community dwelling Premenopausal Women with Polycystic Ovary Syndrome/Anovulatory Androgen Excess (PCOS/AAE) Experience more Prevalent Fractures than Regional Population-based Control Women from the BC Centre of the Canadian Multicentre Osteoporosis Study (CaMos) Azita Gostasebi *, Shirin Kalyan, Bernice Liang, Jerilynn Prior. University of British Columbia, Canada

PCOS has many known health risks; low bone mineral density (BMD) or fracture risk have not been included. We recently showed that AAE related to lower pQCT strength-strain index of the radius (R2=0.25, P=0.018)1; a Japanese administrative study documented increased fractures in PCOS2 (androgen excess unclear). Our cross-sectional aim was to determine the prevalent fracture rate, age and sites in women with androgenic excess PCOS versus (vs) age-similar, population-based controls.Community premenopausal women diagnosed with PCOS enrolled in two local studies (n=136); diagnosis by AE/PCOS criteria3 was confirmed. All completed interviewer-administered CaMos questionnaires including prevalent fracture (fragility plus higher trauma, age, site minus skull, hands and feet)4, plus height and weight measures. A local control group included women in regional Adult (n=72) and Youth (n=38) CaMos cohorts. Eligibility = spontaneously menstruating, no PCOS diagnosis, on no steroids or osteoporosis drugs. All control and 22 PCOS women had total hip (TH) and femoral neck (FN) BMD data. Statistical analysis used descriptive, T and Chi square tests, ANOVA for menarche age vs BMI and binary regression to assess contributors to prevalent fracture.The 246 women averaged 36.8±11 years (y), BMI 27.7 and height 164.5 cm with menarche at 12.8 y. The 136 PCOS and 110 CaMos controls did not differ in age at menarche, FN or TH BMD but the former were slightly younger (35.1 y), significantly taller (165.4) with higher BMI (29.6). In PCOS, younger menarche age related significantly to higher BMI (F= 4, p=0.001) but not in controls (F=1.96, p= 0.081). More women with PCOS had experienced a prevalent fracture—29% vs 13% (Chi2= 10.5, p= 0.01). The mean age at prevalent fracture was similar (15.4 y), but there were multiple fractures in PCOS: two—PCOS 7, CaMos 3; three—PCOS 2, CaMos 0. Sites of prevalent fracture didn't differ (Figure) Chi2= 3.92, p= 0.27. Binary regression analysis for prevalent fracture (n=246) including age, BMI, height, age at menarche and PCOS diagnosis showed that PCOS diagnosis (OR 2.77; 1.27, 6.03) and height (OR 1.07; 1.01, 1.13) made important contributions.In conclusion, this is the first study to our knowledge showing increased prevalent fractures in premenopausal women with PCOS/AAE vs population-based controls. Why does low self-rated health increase the risk of hip fractures? Hans Ranch Lundin*, Helena Salminen. Karolinska Institutet, Sweden

From the Study of Osteoporotic Fractures, Cummings and colleagues showed in 1998 that low self-rated health (SRH) was a risk factor for hip fractures independent of previous fracture and bone mineral density (BMD). Since then, no further studies on SRH and fracture risk seems to have been published. The aim of this study was to investigate which known risk factors for hip fractures, could be responsible for the increased fracture risk in persons with low SRH. Our population-based prospective cohort study included 350 Swedish women, aged 69-79 years. At inclusion they rated their global health between "worst imaginable health" and "best imaginable health" by putting an "x" on a line drawn between these two extremes. The distance from "worst imaginable health" to the "x" was measured in millimeters so that the range of observations was 0-100. Maximum gaitspeed was measured over 30 meters with a 180 degree turn halfway. One-leg standing time was measured with eyes open as the best result from two attempts on each leg. The FRAX calculations included a measure of femoral neck T-score. Follow-up ten years later was based on data on incident fractures and mortality from Swedish medical records. The main outcome was a hip fracture. No participant was lost to follow up. During 10 years follow-up, 40 participants (11%) had a hip fracture. Women with a SRH below 50 had an age-adjusted HR of 2.00 (1.06–3.80) for a hip fracture compared to women with a SRH between 50 and 100. This HR was even higher after adjustment for femoral neck BMD (HR 2.33, 1.19–4.54) or FRAX-estimated hip fracture risk (2.35, 1.24–4.44). Adjustment for the maximum time to stand on one leg (OLST) or maximum gait-speed made the HR non-significant. Analyses of mediated effect showed that after adjustment for age and OLST, 36% of the effect of SRH on hip fracture risk, was mediated by gaitspeed. The effect mediated by OLST was non-significant after adjustment for gaitspeed. It seems that the increased risk of hip fractures associated with low SRH could be more related to balance and muscle strength, than to BMD and the risk factors included in FRAX.

Differences in Geometric Strength at the Contralateral Hip between Men with Hip Fracture and Non-Fractured Comparators Alan Rathbun*[1], Jay Magaziner[1], Michelle Shardell[2], Thomas Beck[3], Laura Yerges-Armstrong[4], Denise Orwig[1], Gregory Hicks[5], Shabnam Salimi[1], Alice Ryan[1], Marc Hochberg[1]. [1]University of Maryland School of Medicine, United States, [2]National Institute on Aging, United States, [3]Beck Radiological Innovations, United States, [4]GlaxoSmithKline, United States, [5]University of Delaware, United States

Older men who sustain hip fracture experience accelerated bone mineral density (BMD) declines and are at an increased risk of secondary fractures. However, BMD is a surrogate marker of mechanical strength and not a geometric property of bone tissue. Thus, our objective was to compare changes in bone geometry between older men after hip fracture and community-dwelling older men using two existing cohorts: the Baltimore Hip Studies 7th Cohort (BHS-7) and the Baltimore Men's Osteoporosis Study (MOST). BHS-7 was conducted from 2006 to 2011 and recruited older adults who fractured a hip (N=339) and had assessments at baseline (within 15 days of hospitalization) and 2, 6, and 12 months follow-up. MOST was conducted from 2000 to 2003 and enrolled community-dwelling older men (N=694) and collected data at baseline and a second visit between 10 to 31 months later.

Monday Posters

The combined sample (n=170) comprised Caucasian men from BHS-7 and MOST with ≥ 2 DXA scans that were read using Hip Structural Analysis (HSA) and were propensity score matched (1:1) on baseline variables: age, height, weight, smoking, alcohol consumption, comorbidities, use of bone-active drugs, and BMD. HSA was used to derive metrics of bone geometry at the narrow neck (NN), intertrochanteric (IT), and femoral shaft (FS): surface area (cross sectional area [CSA]), bending strength (section modulus [SM]), and cortical stability (buckling ratio [BR]). Mixed-effects models estimated individual rates of change in geometric parameters, and annual percent changes were calculated. Robust regression models adjusted for covariates evaluated between-cohort differences in change. BHS-7 participants had greater declines (Table 1) in NN CSA (-2.81%; 95% CI: -3.29, -2.33) and NN SM (-1.89%; 95% CI: -2.71, -1.08) and larger increases in NN BR (3.45%; 95% CI: 2.91, 4.00). Between-group differences in change in IT geometric parameters were similar to NN estimates. Conversely, BHS-7 participants had larger increases in FS CSA (2.06%; 95% CI: 1.93, 2.19) and FS SM (2.74%; 95% CI: 2.43, 3.05) and greater declines in FS BR (-1.91%; 95% CI: -2.57, -1.25). Hip fracture in older men is associated with geometric changes at the contralateral hip characterized by declines in bone tissue, strength, and cortical stability at the distal portions of the proximal femur and increases in these parameters at the diaphyseal region. Better medical management is needed for older men after hip fracture to reduce the risk of future fractures.

Table 1. Adjusted Annual Changes and Differences in Change in Geometric Parameters between BHS-7 and MOST participants

Site	Parameter	BHS-7 (% Change, 95% CI)		MOST (% Change, 95% CI)		Δ^b	
NN	CSA	-2.64	(-2.28, -2.46)	0.17	(-0.01, 0.35)	-2.81	(-3.29, -2.33)
IT	CSA	-0.90	(-0.93, -0.86)	0.01	(-0.03, 0.04)	-0.91	(-1.03, -0.79)
FS	CSA	2.04	(1.99, 2.08)	-0.02	(-0.06, 0.02)	2.06	(1.93, 2.19)
NN	SM	-1.46	(-1.83, -1.09)	0.43	(0.05, 0.90)	-1.89	(-2.71, -1.08)
IT	SM	-2.49	(-2.59, -2.39)	0.05	(-0.04, 0.15)	-2.54	(-2.82, -2.27)
FS	SM	2.58	(2.46, 2.69)	-0.16	(-0.28, -0.04)	2.74	(2.43, 3.05)
NN	BR	3.70	(3.38, 4.02)	0.25	(-0.07, 0.56)	3.45	(2.90, 4.00)
IT	BR	4.24	(4.08, 4.40)	0.22	(0.07, 0.38)	4.02	(3.62, 4.42)
FS	BR	-2.05	(-2.42, -1.69)	-0.14	(-0.50, 0.21)	-1.91	(-2.56, -1.25)

BHS-7 = Baltimore Hip Studies 7th Cohort; BR = Buckling Ratio; CI = Confidence Interval; CSA = Cross Sectional Area; FS = Femoral Shaft; IT = Intertrochanteric; MOST = Baltimore Men's Osteoporosis Study; NN = Narrow Neck; SM = Section Modulus.

[a]Cohort-specific annual change holding model covariates at their sample mean.

[b]Adjusted for age, height, weight, smoking status, alcohol consumption, glucocorticoids, hormone therapy, bisphosphonates, calcium supplements, comorbidity count, and baseline aerial BMD.

The Impact of a Beta Trabecular Bone Score (TBS) Algorithm Accounting for Soft Tissue Thickness Correction on the Prediction of Incident Major Osteoporotic Fracture (MOF) Risk in Postmenopausal Women: The OsteoLaus Study Enisa Shevroja*, Olivier Lamy, Berengere Aubry-Rozier, Gabriel Hans, Elena Gonzalez Rodriguez, Delphine Stoll, Didier Hans. Center of Bone Diseases, Bone and Joint Department, Lausanne University Hospital, Switzerland

Introduction: TBS is a texture measurement extracted from lumbar spine (LS) DXA scans reflecting bone microarchitecture. Current versions of the TBS software account for soft tissue variability by integrating a correction for body mass index (BMI) in the TBS algorithm (TBSBMI). A residual negative correlation has been reported between TBS and BMI. To address this issue, a new correction of the TBS algorithm, based on the tissue thickness as estimated by the DXA machine (TBSTH), is currently being tested. We aimed to compare the validity of TBSTH and TBSBMI in MOF prediction.Methods: This study was embedded in the OsteoLaus Study, a prospective population-based cohort of 1,500 women living in Lausanne, Switzerland. All women had data on LS and hip BMD, TBS, incident MOF and FRAX. The correlation between BMI and TBSBMI or TBSTH was studied using Pearson`s correlation coefficient. Binary logistic regression models were used to obtain the risk estimates for MOF per standard deviation decrease in TBSBMI or TBSTH in three different models (M): M1: adjusted for age and osteoporotic (OP) treatment; M2: adjusted for M1 and LS-BMD; M3: adjusted for M2 and FRAXFN-BMD-MOF. To evaluate the prediction models and the performance of both TBSBMI and TBSTH, the area under the receiver-operating-characteristic curve (AUC) was calculated for M, M+TBSBMI, and M+TBSTH. Results: This analysis included 1,331 women (mean age=64.6±7.5 y; mean BMI=25.9±4.5 kg/m2). During the mean follow-up period of 5 years, 199 women sustained a MOF. BMI correlated negatively with the standard TBSBMI (r= -0.21) and positively with TBSTH (r=+0.26). In overall, lower TBS scores were significantly associated with an increased risk for incident MOF, but TBSTH was shown to be a better predictor of fracture risk than TBSBMI (Table). The AUC (95% CI) for M1 was 0.59 (0.54;0.63), M1+TBSBMI 0.62 (0.58;0.66), and M1+TBSTH 0.63 (0.58;0.67); for M2 was 0.59 (0.54;0.63), M2+TBSBMI 0.62 (0.58;0.67), and M2+TBSTH 0.63 (0.59;0.67); M3 was 0.60 (0.56;0.65); M3+TBSBMI 0.63 (0.59;0.674); and M3+TBSTH 0.64 (0.59;0.68).Conclusion: The residual negative correlation between BMI and TBSBMI disappeared with the new TBSTH. Furthermore, the superiority of TBSTH versus TBSBMI in MOF risk prediction was demonstrated. This study contributes to the validation of the newly tested TBS algorithm in osteoporotic fractures prediction, aiding in the improvement of the osteoporosis management.

Table. The results of the logistic regression analysis

	Model 1		Model 2		Model 3	
	TBS$_{BMI}$	TBS$_{TTH}$	TBS$_{BMI}$	TBS$_{TTH}$	TBS$_{BMI}$	TBS$_{TTH}$
OR / SD (95% CI)	1.38 (1.17;1.62)	1.41 (1.19; 1.70)	1.44 (1.20; 1.72)	1.65 (1.34; 2.04)	1.37 (1.14; 1.64)	1.53 (1.23; 1.92)

Model1: adjusted for age, osteoporotic treatment; Model2: adjusted for age, osteoporotic treatment, lumbar spine BMD; Model3: adjusted for osteoporotic treatment, FRAX$_{BMD}$ of MOF, and lumbar spine BMD; OR / SD odds ratio per standard deviation decrease; CI confidence interval; TBS$_{BMI}$ trabecular bone score corrected for body mass index; TBS$_{TH}$ TBS corrected for the soft tissue thickness.

Weight Gain is Associated with Increased Bone Mineral Density (BMD) Even in Postmenopausal Women Sikarin Upala*, Amber Olson, Tamara Vokes. University of Chicago, United States

Background: In population studies, body weight is positively associated with BMD. While it is well known that weight loss causes bone loss, it is less clear that weight gain in adults leads to an increase in BMD. In this study, we examined whether the BMD changes in response to weight changes are bidirectional and whether the association between BMD and weight changes differs by age and sex.Methods: This is a retrospective cohort study of 2,067 patients who had repeated BMD testing as a part of their clinical care at the University of Chicago between 2006-2017. We performed regression analyses with %change in BMD at the lumbar spine (LS), femoral neck (FN) and total hip (TH) as an outcome variable and %change in weight as a predictor stratified by age (under 50 and over 50) and sex. Subjects with BMD change of less than 3% and/or weight change of less than 2% were excluded from the analysis.Results: The results of the regression analyses are shown in the Table. We found a bidirectional association between change in weight and change in BMD in all subgroups except men over 50, possibly due to small sample size and presence of other medical problems.Conclusion: The effect of weight change on BMD is bidirectional even in postmenopausal women suggesting that weight manipulation may be considered as a novel approach to improving bone health.

Table: % change in BMD (p-value) per 10% change in weight (WT) in Male (M) and Female (F) over and under age of 50 years

	F >50 (n=1570)		F<50 (n=214)		M>50 (n=178)		M<50 (n=105)	
	WT↓	WT↑	WT↓	WT↑	WT↓	WT↑	WT↓	WT↑
LS	↓1.1 (p<0.01)	↑0.8 (p=0.01)	↓2.0 (p<0.01)	↑3.7 (p<0.01)	NS	NS	↓4.1 (p<0.01)	↑2.5 (p<0.01)
FN	↓2.9 (p<0.001)	↑1.7 (p<0.001)	↓2.1 (p=0.01)	↑2.8 (p<0.001)	NS	NS	↓5.1 (p<0.001)	↑2.2 (p=0.03)

Fracture Risk is not Increased in Transwomen and Transmen Receiving Long-term Gender-affirming Hormonal Treatment: a Nationwide Cohort Study Chantal Wiepjes*, Christel De Blok, Renate De Jongh, Martin Den Heijer. VU University Medical Center, Netherlands

Purpose: Gender-affirming hormonal treatment (HT) in transgender people can influence bone mineral density (BMD). Earlier studies found an increase in BMD in transwomen, and a maintenance or increase in BMD in transmen. However, the effects of HT on fracture risk are not known. Therefore, we aimed to investigate the fracture incidence in transwomen and transmen using long-term HT and to compare this with an age-matched male and female control population.Methods: All adult transgender people who started with HT before 2013 at the VU University Medical Center, Amsterdam, the Netherlands were included. This population was linked to a Dutch random control sample of 5 age-matched males and 5 age-matched females per person. Fracture occurrence in 2013 and 2014 was provided by Statistics Netherlands (CBS), which stores all diagnoses from visits to the hospital emergency rooms nationwide. The occurrence of fractures is expressed as percentages. Relative risks (RR) with 95% confidence intervals (CI) were calculated separately for transwomen and transmen.Results: A total of 1,725 transwomen (mean age 50 years, standard deviation (SD) 13 years) who used HT for median 15 years (inter quartile range (IQR) 8 – 23 years) were included. Fractures occurred in 2.5% of the transwomen (n=43), while 1.9% of the age-matched control men (RR 1.33, 95% CI 0.94 – 1.86) and 2.2% of age-matched control women (RR 1.14, 95% CI 0.82 – 1.60) had a fracture. A total of 729 transmen (mean age 44 years, SD 12 years) who used HT for median 14 years (IQR 6 – 23 years) were included. Fractures occurred in 1.4% of the transmen (n=10), while 1.6% of the age-matched control men (RR 0.85, 95% CI 0.43 – 1.66) and 2.0% of age-matched control women (RR 0.69, 95% CI 0.35 – 1.34) had a fracture.Conclusion: This large population of both transwomen and transmen using long-term HT does not demonstrate an increased fracture risk compared

with an age-matched control population. This increases the evidence that HT in transgender people does not negatively affect bone health.

Decreased mortality risk, but unchanged subsequent fracture risk after introduction of a fracture liaison service: a 3 year follow-up survey
Caroline E Wyers*[1,2], Johanna Hm Driessen[2], Lisanne Vranken[3,4], Irma Ja De Bruin[3,4], Piet P Geusens[5], Robert Y Van Der Velde[3,4], Heinrich M Janzing[6], Sjoerd Kaarsemaker[7], Jacqueline Center[8,9], Dana Bliuc[8], John A Eisman[10], Joop Pw Van Den Bergh[3,4]. [1]Department of Internal Medicine, VieCuri Medical Center, Netherlands, [2]Maastricht UMC+, CAPHRI Care and Public Health Research Institute, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Clinical Pharmacy and Toxicology, Netherlands, [3]VieCuri Medical Center, Department of Internal Medicine, Netherlands, [4]Maastricht UMC+, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Internal Medicine, Netherlands, [5]Maastricht UMC+, CAPHRI Care and Public Health Research Institute, Department of Internal Medicine subdivision of Rheumatology; Hasselt University, Netherlands, [6]VieCuri Medical Center, Department of Surgery, Netherlands, [7]VieCuri Medical Center, Department of Orthopedic Surgery, Netherlands, [8]Osteoporosis and Bone Biology Program, Garvan Institute of Medical Research, Australia, [9]Clinical School St Vincent's Hospital, Faculty of Medicine, UNSW Australia, Australia, [10]Osteoporosis and Bone Biology Department, Clinical Translation and Advanced Education, Garvan Institute, Clinical School, St Vincent's Hospital, Faculty of Medicine UNSW Australia, School of Medicine, University of Notre Dame, Australia

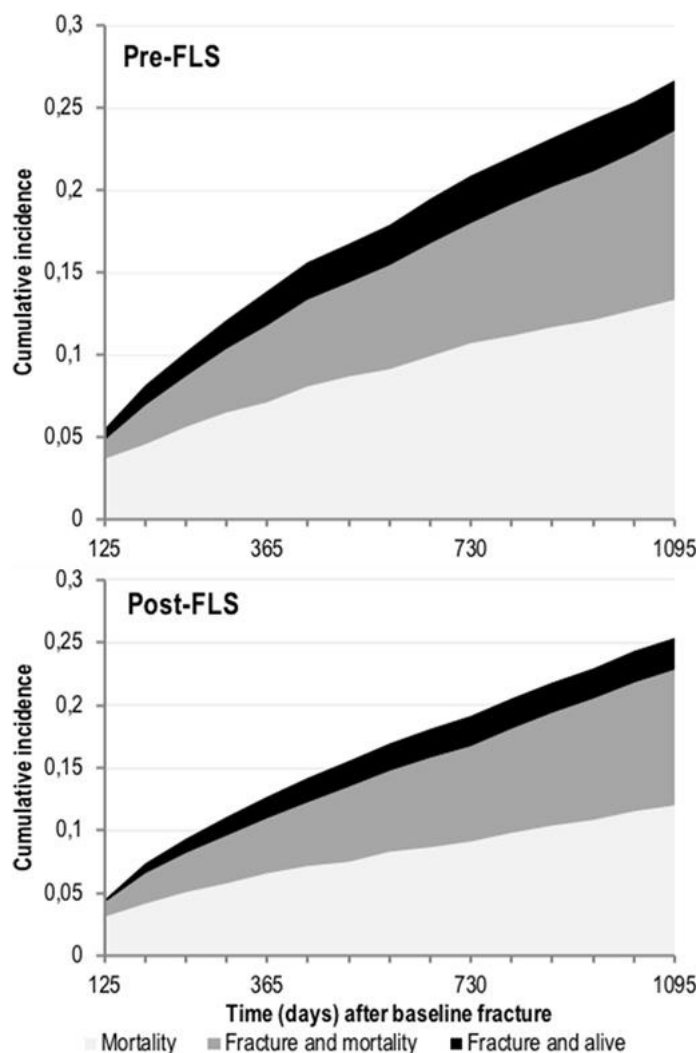
Purpose: Our aim was to evaluate the risk of a first subsequent fracture within 3 years after a fracture, before and after the introduction of a Fracture Liaison Service (FLS).Methods: Historical cohort study of all consecutive patients aged 50-90yrs with a fracture presenting at the Emergency Department. From 2005-2007, only acute fracture treatment was performed (pre-FLS). From 2008-2013 (post-FLS), a nurse screened medical records and invited patients to the FLS for evaluating fracture risk and underlying disorders that contribute to bone loss and treatment according to Dutch guidelines. Patients with finger, toe or skull fracture, osteomyelitis, metastasis, periprosthetic fracture, Paget's disease or multiple myeloma were excluded at baseline and follow up. All fractures were radiographically confirmed and categorized into hip, major (pelvis, proximal humerus or tibia, vertebral, multiple rib, distal femur) and minor (all other). Cox Proportional Hazard analyses adjusted for age, sex and baseline fracture were used. To adjust for mortality, the subdistribution hazard approach (SHR) by Fine and Gray was applied.Results: In the pre-FLS group 2,653 patients were included (72% women, mean age 69yrs, 56% minor, 28% major, 16% hip). Post-FLS, 6,415 were included (69% women, mean age 69yrs, 54% minor, 32% major, 14% hip), 47% attended of which around 50% were indicated for anti-osteoporosis treatment. In total, 950 patients sustained a subsequent fracture (10.2% pre-FLS vs. 10.6% post-FLS, p=ns), 16.6% died pre-FLS vs. 14.6% post-FLS (p=0.15), see figure. Mortality risk was lower after introduction of the FLS (HR:0.82 95%CI:0.70-0.95), subsequent fracture risk, also when adjusted for mortality, was not different (HR:1.02 95%CI:0.89-1.18; SHR:1.03 95%CI:0.90-1.19, resp.). Only in men, lower subsequent fracture risk was observed (SHR:0.61 95%CI:0.52-0.73). Elderly and those with a major fracture had a higher subsequent fracture risk compared to younger patients (50-59yrs) and those with a minor fracture (SHR:1.04 95%CI:1.03-1.04; SHR:1.21 95%CI:1.04-1.40, resp.).Conclusion: Overall, mortality risk was 18% lower while subsequent fracture risk was comparable in the first 3 years after introduction of the FLS. The limited effect of the introduction of the FLS on subsequent fractures needs exploration of the effect of decreased mortality, unchanged fall risk, low number of treatment indications and lack of information on adherence to treatment.


Fig 1. Cumulative incidence of subsequent fracture, subsequent fracture and mortality, and mortality outcomes within 3 yrs after a fracture Pre-FLS and Post-FLS

MON-0818

Health Literacy and Readiness to Initiate Treatment for Osteoporosis in an At-risk Sample of US Women Michael Miller*, Maria I. Danila, Amy Mudano, Ryan Outman, Elizabeth Rahn, Kenneth Saag. University of Alabama at Birmingham, United States

Objective: Many women at high risk for fragility fractures do not initiate or stop osteoporosis treatment. Contributing factors may include perceived fracture risk, knowledge and lack of trust in medications, and perceived unfavorable risk-benefit profiles of osteoporosis therapies. Understanding health literacy and its relationships with other factors affecting osteoporosis treatment initiation may assist in the design of targeted patient activation interventions.Methods: Women (n=1,759) with self-reported fracture and no current osteoporosis medication use reported at screening were derived from the Activating Patients at Risk for OsteoPOroSis trial, which recruited participants from the Global Longitudinal Study of Osteoporosis in Women (GLOW) cohort. Path models with fixed relationships were used to evaluate associations among sociodemographics, health literacy, perceived fracture risk, receipt of osteoporosis medication information, distrust in osteoporosis medications, and readiness to initiate osteoporosis treatment. Multiple models were evaluated to ascertain the best fit. Criteria for optimal model fit were: nonsignificant model $\chi 2$ test, a standardized root mean square residual (SRMR)<0.08, root mean square error of approximation (RMSEA)<0.05, and the Bentler comparative fit index (BCFI)>0.95. Model significance criterion = alpha of 0.01. Results: Age, education, health literacy, distrust in medications, perceived fracture risk, and having received medication information within the past year were associated with readiness to initiate osteoporosis therapy (p<0.01). Age, race, and education were also associated with health literacy (p<0.01). Age was associated with perceived fracture risk (p<0.01). In turn, perceived fracture risk was associated with medication distrust (p<0.01). Health literacy was not associated with perceived fracture risk or distrust for medications. A model approaching optimization was identified (SRMR=0.02, RMSEA=0.09, BCFI=0.94, $\chi 2$=33.43,

Monday Posters

p<0.0001). The significant model χ2 likely resulted from the large sample.Conclusions: Health literacy contributes to a patient's readiness to initiate osteoporosis medication. Effective patient activation intervention design should be sensitive to age, education level, and health literacy needs. Interventional strategies should raise awareness and understanding of fracture risk, mitigate distrust in medications, and ensure medication information is derived from credible and trusted sources.

The Burden of Recurrent Fragility Fractures in a Regional Hospital in Singapore Linsey Gani*, Nicholas Tan , Vivien Tan , Joan Khoo, Thomas King. Changi General Hospital, Singapore

Background: There remains a significant treatment gap in osteoporosis management globally. Following an initial fragility fracture, the risk of subsequent fracture increases by 1.6 to 4.3 fold at any given age. We aim to assess the burden of recurrent fractures in our Asian population in the Eastern Region of Singapore.Methods: Retrospective analysis of patients presenting to Changi General Hospital, Singapore with fragility fracture. Data were extracted from all admissions during the period of 2009 – 2015 using ICD 10 codes. Patient demographics, frequency and location of prior fractures, calcium, vitamin D and antiresorptive treatment initiation status 1-year post admission, and bone mineral density (BMD) evaluation were recorded. Patients were divided into first-onset or recurrent fractures.Results: During the period of 2009-2015, there were 8,771 admissions for fragility fractures , median age 73.0 (50-105) years , 65 % female. Of these, 1,686 (19.2 %) admissions were recurrent fractures (1-3 recurrent fractures). Average time to 1st recurrent fracture was 696 days (1 year 11 months). The most frequent sites of these 783 second fractures were hip and vertebrae at 37.9 % (n= 297) and 16.2 % (n= 127) respectively. Of these 297 second fractures that were hip fractures, 52.1% (n= 153) patients had initially presented with a 1st hip fracture. Initiation of anti-resorptive treatment was low in both first and recurrent fracture population at 2.6% and 6.6 % ; as was BMD testing at 18.8% and 16.2 % respectively in both populations.Conclusion: Nearly one fifth of all fragility fracture admissions between 2009-2015 in the eastern region of Singapore were recurrent fractures with an average time to next fracture of less than two years. The majority of second fractures were hip fractures and more than half had initially presented with a first hip fracture. Diagnosing osteoporosis with a first fragility fracture is critical to prevent recurrent fractures. A fracture liaison service may reduce fracture recurrence by timely initiation of anti-resorptive therapy and BMD testing.

Service level predictors of bone treatment recommendations after a fragility fracture: Baseline findings from the first UK patient level Fracture Liaison Service Audit Muhammad Javaid*[1], Xavier Griffin[1], David Stephens[2], Tim Jones[3], Sonya Stephenson[3], Michael Stone[4], Clare Cockill[5], Alison Smith[6], Iona Price[6], Celia Gregson[7], Frances Dockery[8], Rachel Bradley[9], Neil Gittoes[10], Daniel Prieto-Alhambra[1], Cyrus Cooper[11], Catherine Gallagher[12], Naomi Vasilakis[12]. [1]NDORMS, University of Oxford, United Kingdom, [2]NHS West Kent CCG, United Kingdom, [3]National Osteoporosis Society, United Kingdom, [4]Bone Research Unit, University Hospital Llandough, United Kingdom, [5]Rheumatology Department, Yeovil Hospital, United Kingdom, [6]Patient representative, Royal College of Physicians, United Kingdom, [7]School of Clinical Sciences, University of Bristol, United Kingdom, [8]Ageing and Health Services, Guy's and St Thomas' NHS Foundation Trust, United Kingdom, [9]Geriatric Medicine, University Hospitals Bristol NHS Foundation Trust, United Kingdom, [10]Centre for Endocrinology, Diabetes and Metabolism, University of Birmingham, United Kingdom, [11]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [12]Royal College of Physicians, United Kingdom

Background: Fracture Liaison Services (FLSs) are recommended nationally to provide effective secondary fracture prevention after a fragility fracture. Bone therapies vary in cost, adherence and effectiveness. The United Kingdom Department of Health has produced NICE guidance to define first, second and third line treatment choices.Objective: We wished to identify the proportion, type and service level determinants of bone protection therapy recommendations by FLSs.Methods: Each FLS in the United Kingdom was required to submit data on all patients they managed aged 50 or over and who had sustained a fragility fracture diagnosed between 1st January and 30th December 2016. Part of the audit focused on the treatments recommended by the FLS. Outcomes included treatment clinically inappropriate, patient declined, referred to primary care physician or another clinician, specific anti-osteoporotic medication, don't know and missing. We excluded FLS with less than 50 patients submitted. Where more than one drug was recommended by the FLS, the following hierarchy was used to select the one drug: oral bisphosphonate > denosumab > zoledronate, then teriparatide or raloxifene or strontium or activated vitamin D or oestrogen therapy. Results: 50 FLS submitted data on 44,139 patient records. Overall, the mean age of patients was 73 years, and 78% were women. Eighteen percent had an index hip fracture, 3.8% spine fracture and 72.9% non-hip non-spine fracture. Nine FLSs had more than 50% missing treatment data. 40% of patients submitted were recommended a specific medication or referred to

another clinician. However, there was considerable variation between individual FLSs: the decision to treat (10% to 94%), the proportion referred to another clinician (0.3 to 69%) and the proportion recommended a parenteral therapy (0 to 33%). Neither the volume of patients or proportion of patients recommended therapy predicted type of therapy.Conclusions: This audit has demonstrated marked variation between FLSs in the decision to treat and the type of bone therapy recommended despite national recommendations. A better understanding of the contributory factors for this variation will inform quality improvement for FLSs to provide more effective and efficient secondary fracture prevention.

Cost-effectiveness Evaluation of a Screening Programme for Fracture Risk in UK Fredrik Borgström*[1], Emma Jonsson[1], Nick Harvey[2], Lee Shepstone[3], Elizabeth Lenaghan[3], Shane Clarke[4], Neil Gittoes[5], Ian Harvey[6], Richard Holland[3], Alison Heawood[7], Niamh Redmond[8], Amanda Howe[3], Tanya Marshall[10], Tim Peters[7], David Torgerson[11], Terence O'Neill[9], Eugene Mccloskey[12], Cyrus Cooper[2], John Kanis[12]. [1]Quantify Research, Sweden, [2]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [3]University of East Anglia, School of Medicine, United Kingdom, [4]University Hospitals Bristol BS2 8HW, United Kingdom, [5]University Hospital Birmingham, Endocrinology, United Kingdom, [6]University of East Anglia, School of Medicine, Health Policy and Practice, United Kingdom, [7]Bristol Medical School, University of Bristol, United Kingdom, [8]University of Bristol, United Kingdom, [9]University of Manchester, United Kingdom, [10]Norfolk and Norwich University Hospital, Department of Rheumatology, United Kingdom, [11]York University, York Trials Unit, United Kingdom, [12]University of Sheffield, United Kingdom

ObjectiveTo estimate the cost-effectiveness of screening for fracture risk in a UK primary care setting, based on a randomised controlled trial in women aged 70–85 comparing a screening programme using the FRAX risk assessment tool versus usual management of osteoporosis (the SCOOP study).Material and MethodsThe design of the SCOOP study is described elsewhere [1]. A health economic Markov model was used to predict the lifetime consequences in terms of costs and quality of life of the screening programme. The model was populated with drug, administration and screening intervention costs derived from SCOOP. Fracture costs, quality of life-weights and general population fracture risks and mortality were derived from the literature. Fracture risk reduction in the screening arm compared with the usual management arm were derived from SCOOP. Modelled fracture risk corresponded to the observed risk in SCOOP. The main outcome measures were quality-adjusted life years (QALY), costs and incremental cost/QALY.ResultsFracture-related costs were £551 lower/patient in the screening arm compared with the usual management arm (Table 1). Drug and intervention costs were £265 higher in the screening arm. In total, the screening arm saved costs (£286) and gained 0.015 QALYs/patient in comparison with usual management arm. Screening saved 9 hip fractures and 20 non-hip fractures over the remaining life-time (average 14 years) of 1,000 patients, compared with usual management.ConclusionThis analysis suggests that a screening programme of fracture risk in older women in the UK could gain quality of life and life years, and additionally, reduce fracture costs offsetting the cost of running the programme.References[1] Shepstone L, et al. A Randomised Controlled Trial of Screening in the Community to Reduce Fractures in Older Women: the SCOOP Study. Lancet. 2017 Dec 15.

Table 1. Cost-effectiveness results

	Usual management	Screening	Screening vs. usual management
Costs			
Hospitalisations	3,059	2,934	-125
Nursing home	6,056	5,645	-410
Outpatient	378	363	-15
Total morbidity cost	9,493	8,942	-551
Drugs	12	43	31
Treatment management	92	326	234
Total intervention cost	104	369	265
Total cost	9,596	9,310	-286
Effects

Understanding the Patient Experience and Challenges to Osteoporosis Care Delivered Virtually by Telemedicine Patricia Palcu*[1], Sarah Munce[2], Susan B. Jaglal[3], Sonya Allin[1], Arlene Silverstein[4], Sandra Kim[5]. [1]University of Toronto, Canada, [2]Toronto Rehabilitation Institute, University Health Network, Canada, [3]University of Toronto, Department of Physical Therapy, Canada, [4]Women's College Hospital, Canada, [5]University of Toronto, Women's College Hospital, Canada

Background: Evidence in support of telemedicine (TM) for chronic conditions in rural populations has been well described. There is limited research on the role of TM in the assessment and management of osteoporosis. In 2005, a multidisciplinary osteoporosis TM program, based on an existing outpatient program, was developed at Women's College Hospital, to provide specialized osteoporosis care to underserviced areas of Ontario, Canada. We previously reported the high-risk patient characteristics of those serviced by TM. These patients had a higher prevalence of fragility fractures, comorbidities, and need for allied health resources than those serviced by the outpatient clinic. Purpose: To understand the patient experience, and benefits and challenges associated with receiving osteoporosis care by TM. Methods: This study adopted a qualitative descriptive approach. Semi-structured interviews lasting an average of 30 minutes were conducted by telephone on 16 patients of the TM program. Descriptive themes were identified from interview notes; thematic analysis as described by Braun and Clarke will be applied to full transcripts. Results: The majority of participants were comfortable with virtual technology and perceived that quality of care was equivalent to being seen in-person. The main benefits expressed were the convenience and ease of timely care close to home, reduced burden of travel and costs, and improved sense of reassurance and confidence associated with being assessed by an osteoporosis expert. Patients seen by allied health team members by TM indicated increased confidence in self-management; however, many patients were dissatisfied by the coordination of referral to allied health members in the TM program (eg. physiotherapist and dietician). Some patients reported never hearing back on referred appointments to the allied health team. Another perceived challenge was the coordination of investigations such as lab and bone density tests. Many participants indicated interest in a self-management program designed specifically for osteoporosis. Conclusions: Our study contributes to an area of limited research on patient perspectives on osteoporosis care delivered by TM. We identified the need to improve our existing processes by better coordinating access to allied health team members and arrangements for investigations. Future research will involve developing and implementing self-management initiatives for osteoporosis patients receiving care by TM.

Knowledge Translation: Implementation of Recommendations for Fracture Prevention in Long-Term Care Alexandra Papaioannou*[1], George Ioannidis[1], Mary-Lou Van Der Horst[2], Caitlin Mcarthur[2], Loretta M. Hillier[2], Ravi Jain[3], Susan Jaglal[4], Jonathan D. Adachi[1], Lora Giangregorio[4]. [1]McMaster University, Canada, [2]Geriatric Education and Research In Aging Sciences (GERAS) Centre, Canada, [3]Osteoporosis Canada, Canada, [4]University of Toronto, Canada

Purpose: For long-term care (LTC) residents, fractures can have life-changing and debilitating consequences. Recommendations for preventing fractures in LTC were published in 2015, aiming to reduce immobility, pain, hospital transfers and improve quality of life of residents. However, there is much research demonstrating large gaps between the development of clinical guidelines and application to practice in LTC. Aligned with the Canadian Institute of Health Research Knowledge Translation (KT) model, we describe the KT activities developed by the Ontario Osteoporosis Strategy for LTC to mobilize the fracture prevention guidelines, and present key tools to support implementation.Methods: KT activities were guided by the Knowledge to Action Cycle, informed by a program of research that has identified that fractures are a significant source of morbidity in LTC, with significant gaps in fracture risk assessment and treatment. Our previous work identified barriers and facilitators to frature prevention efforts in LTC. Engagement with resident and family councils have highlighted thier knowledge needs for fracture prevention. Various interventions, including education, audit and feedback and team based action planning, were developed to address identified barriers and leverage facilitators to suppor the implementation of fracture prevention guidelines.Results: KT interventions have demonstrated improvements in prescribing of osteoporosis medication, calcium, and vitamin D. Clinical support tools include: an assessment algorithm for management, an order set for managing fracture risk, and a safe administration therapy tool. The Fracture Risk Scale was created for LTC to fill the knowledge/ do gap and address the identified barriers and facilitators to fracture risk assessment. The scale will be integrated into the Resident Assessment Instrument Minimum Data Set, a standardized assesment used in LTC. A series of videos instruct staff on safe resident movement to prevent falls and fractures. Knowledge tools for residents and family councils aim to increase awareness of fracture risk and prevention. All tools are available as part of an easily accessible on-line fracture prevention toolkit.Conclusion: Multifaceted approaches to knowledge translation (KT) can improve the uptake of clinical recommendations. The use of these tools may help close the gap betwen recommendations of clinical guidelines and application to clinical practice in LTC.

MON-0848

Hip Bone Loss Persists One Year Following an Intentional Weight Loss Intervention in Older Adults Kristen Beavers*[1], Michael Walkup[2], Walter Ambrosius[2], Leon Lenchik[2], Sue Shapses[3], Barbara Nicklas[2], Anthony Marsh[1], Jack Rejeski[1]. [1]Wake Forest University, United States, [2]Wake Forest School of Medicine, United States, [3]Rutgers University, United States

Purpose: To evaluate change in bone mineral density (BMD) and trabecular bone score (TBS) in the year following an 18 month weight loss intervention in older weight regainers (WR) or weight loss maintainers (WLM).Methods: Data come from a longitudinal, non-randomized comparison of 77 older adults (67±5 years, 69% women, 74% Caucasian) with obesity (BMI: 33.6±3.7 kg/m2) who lost weight during an 18 month diet and exercise intervention (randomization groups: weight loss, weight loss + aerobic training, weight loss + resistance training). We assessed baseline, 18, and 30 month total body mass; total hip, femoral neck, and lumbar spine BMD; and TBS data. WR (n=52) and WLM (n=25) categories were defined as a ≥ or < 2 kg weight gain from 18 to 30 months, respectively.Results: In models adjusted for randomization group, baseline outcome value, recruitment wave, age, race, and gender, WRs lost more total body mass than WLMs during the 18 month intervention period [WR: -11.5 (-15.5, -7.7) % vs WLM: -5.9 (-10.2, -1.5) %; group p<0.01]; however, by 30 months, total body mass was similarly reduced from baseline in both groups [WR: -5.2 (-9.1, -1.3) % vs WLM: -6.7 (-11.0, -2.4) %; group p=0.44]. Of bone outcomes, only total hip BMD was reduced during the 18 month intervention period, with similar reductions observed for WRs [-3.5 (-5.3, -1.6) %] and WLMs [-2.5 (-4.6,-0.4) %], group p=0.09. After further adjustment for total body mass lost during the intervention, a differential group effect (p<0.05) was observed for change in total hip BMD from 18 to 30 months, with a modest increase in WRs [0.9 (-0.2, 2.0) %] relative to WLMs [-1.1 (-2.7, 0.5) %]. By 30 months, WRs presented with half the loss in total hip BMD from baseline, compared to WLMs [WR: -2.4 (-4.0, -0.8) % vs WLM: -5.0 (-6.8, -3.1) %; group p<0.01]. Femoral neck and lumbar spine BMD were unchanged over the intervention and follow up periods. By 30 months, TBS was modestly reduced from baseline in WRs, but not differently from WLMs [WR: -2.5 (-5.1, -0.0) % vs WLM: -1.5 (-4.5, 1.5) %; group p=0.41]. Figure 1 presents (a) 18 to 30 month and (b) baseline to 30 month percent change in total body mass, BMD, and TBS. Conclusion: In the year following an intentional weight loss intervention in older adults with obesity, loss in total hip BMD was partially recovered with WR, while WLM was associated with continued BMD loss. Future work will address categorization of WR and WLM and predictors of hip BMD change.

Effective exercise for osteoporosis in the real world: Three year observations from The Bone Clinic Belinda Beck*[1], Lisa Weis[2]. [1]Griffith University, Australia, [2]The Bone Clinic, Australia

Introduction: Our recent work showed high intensity resistance and impact training (HiRIT) was safe and improved bone, muscle and function in postmenopausal women with low bone mass under strict RCT conditions. We then established a translational research Clinic to examine effectiveness, feasibility and acceptability of supervised HiRIT as a legitimate osteoporosis intervention in the 'real world' when delivered on a user-pays basis, with systematic longitudinal monitoring of bone, muscle, function, falls and fractures. The aim of the current work was to determine outcomes from the first 3 years of operation of the Clinic.Methods: Clinic clients undergo comprehensive testing for height, weight, lumbar spine (LS), total hip (TH) and femoral neck (FN) bone mineral density (BMD), lean and fat mass, kyphosis angle, back extensor strength (BES), functional performance, falls and fracture, at their baseline visit to the Clinic, and annually thereafter. Twice-weekly supervised HiRIT with balance training is undertaken on a voluntary basis. Compliance and injuries are recorded. Clients with >30% HiRIT compliance were included in the current analyses. In the absence of a control group in this real world sample, training effects were examined using one-sample T-tests of percent change in outcome measures.Results: We report outcomes from 121 Clinic clients (64.2±10.1yrs, 161.0±11.1cm, 60.8±14.8kg, LS T-score -2.39±0.94, FN T-score -2.37±0.65; average training compliance 85.1±29.8%, 6.7% men). Improvement was observed in every measured parameter and reached significance for LS (4.0±4.1%, P<0.0001), TH (1.5±3.4%, P<0.0001) and FN BMD (2.4±4.5%, P<0.0001), lean mass (1.8±4.1%, P<0.0001), functional reach (8.1±12.0%, P<0.0001), timed up and go (12.0±12.8%, P<0.0001), tandem walk (20.5±28.8%, P<0.0001), sit to stand (10.7±17.6%, P<0.0001), and BES (27.8±49.1%, P<0.0001). Previous 12 month falls decreased 45% (from 45 to 25, P<0.053) and fractures decreased 91.7% (from 24 to 2, P<0.0001). Twenty minor injuries were sustained in a combined total of 27,840 training sessions.Conclusions: Supervised, bone-targeted high intensity resistance and impact training is safe and reduces risk for osteoporotic fracture in postmenopausal women with low to very low bone mass in a 'real world' clinical setting. Ongoing monitoring of this unique translational dataset will provide insight into the long term feasibility of exercise as a first line intervention for osteoporosis.

Effect of high dose vitamin D on free 25(OH)D and ionised calcium in vitamin D-deficient postmenopausal women Simon Bowles*[1], Jennifer Walsh[1], Richard Jacques[1], Eastell Richard[1], Thomas Hill[2]. [1]University of Sheffield, United Kingdom, [2]Newcastle University, United Kingdom

Several studies have shown an increase in the rate of falls and fractures after high dose vitamin D supplementation, but the mechanism for the increase in falls is yet to be elucidated. Vitamin D and its metabolites are bound to proteins in the circulation: around 85-90% of 25-hydroxylated vitamin D (25(OH)D) is bound to vitamin D binding protein (DBP), 10-15% is bound to albumin, and less than 1% is in the free form. Administration of a large bolus dose of vitamin D (e.g. 500 000IU) may saturate the binding capacity of DBP, leading to high free 25(OH)D, vitamin D toxicity and falls. We tested the clinically important hypothesis that a disproportionate rise in free 25(OH)D and hypercalcaemia could cause the increase in falls and fractures after high dose vitamin D (cholecalciferol). We recruited 33 vitamin D deficient (25(OH)D <30nmol/l) post-menopausal women who

were randomized to a bolus dose of either 50 000IU, 150 000IU or 500 000IU of orally administered cholecalciferol. We also recruited 28 postmenopausal women who were vitamin D sufficient (25(OH)D >50nmol/l) as a concurrent control group. Participants attended five study visits, over a three-month period. We made a range of biochemical measurements, including 25(OH)D3, free 25(OH)D, parathyroid hormone (PTH) and ionized calcium. We assessed muscle strength and function with grip strength and a Short Physical Performance Battery (SPPB).25(OH)D3 and free 25(OH) increased in a dose-dependent manner at 1 week and remained significantly different between treatment groups at 4 weeks and 12 weeks after administration. Peak 25(OH)D3 was at 1 week for all doses (46.7nmol/l, 69.6nmol/l and 153.7nmol/l, respectively). Peak free 25(OH)D was at 1 week in the 500 000IU group (14.90pg/ml) and 4 weeks in the 50 000IU (4.00pg/ml) and 150 000IU (5.46pg/ml) groups. There were proportionally similar increases in 25(OH)D3 (x=7.09 (95% CI: 5.73, 8.88)) and free 25(OH)D (x=7.21 (95% CI: 6.34, 8.19)) at 1 week in the 500 000IU treatment group. There were no within-group changes over time and no between-group effects of vitamin D dose on serum ionized calcium, PTH, SPPB scores or grip strength at any timepoint.In conclusion, the large increase in 25(OH)D3 and free 25(OH)D in response to a high dose bolus of vitamin D is not associated with hypercalcaemia. A 500 000IU dose does not appear to have adverse effects in vitamin D deficient, but otherwise healthy postmenopausal women.
MON-0851

Effect of Home Exercise on Functional Performance, Posture, Quality of Life and Pain in Older Women with Vertebral Fractures: A Pilot Feasibility Trial Jenna C. Gibbs*[1], Jonathan D. Adachi[2], Maureen C. Ashe[3], Robert Bleakney[4], Angela M. Cheung[4], Keith D. Hill[5], David L. Kendler[3], Aliya Khan[2], Sandra Kim[6], Judi Laprade[4], Caitlin Mcarthur[7], Nicole Mittmann[8], Alexandra Papaioannou[2], Sadhana Prasad[2], Samuel C. Scherer[9], Lehana Thabane[2], John D. Wark[9], Lora M. Giangregorio[1]. [1]University of Waterloo, Canada, [2]McMaster University, Canada, [3]University of British Columbia, Canada, [4]University of Toronto, Canada, [5]Curtin University, Australia, [6]Women's College Hospital, Canada, [7]GERAS Centre for Aging Research, Canada, [8]Cancer Care Ontario, Canada, [9]University of Melbourne, Australia

Guidelines for osteoporosis management advocate for regular exercise to prevent falls and fractures, but there is limited evidence on the safety and efficacy of exercise in individuals at high risk of fracture. Purpose: We conducted a pilot randomized controlled trial to evaluate the feasibility of recruitment, retention and adherence to 12 months of home exercise compared to control among older women with vertebral fractures. Herein we present an exploratory analysis of the effect of the home exercise program on secondary outcomes, including functional performance, posture, quality of life and pain. Methods: Community-dwelling women aged 65 years and older with at least one radiographically-confirmed Genant Grade 2 vertebral compression fracture were recruited at seven sites in Canada and Australia. We randomized participants in a 1:1 ratio to a 12-month home exercise program (n=71) or equal attention control group (n=70), both delivered by a physical therapist over six home visits and monthly phone calls. The exercise program included progressive strength, posture, balance and endurance training and behavioral counseling. Adherence was defined as the completion of strength or balance exercises at least three days per each seven-day period in daily diaries. Functional performance tests, occiput-to-wall distance, health-related quality of life questionnaires and pain scales were performed at baseline and 12 months by a blinded research assistant. T-tests explored between-group mean differences (MD) in change from baseline in intention-to-treat (ITT) and per-protocol analyses. Results: There was a positive effect of exercise on five times sit-to-stand test time versus control (MD: -1.58 seconds, 95% CI: -3.09, -0.07, ITT; MD: -1.49 seconds, 95% CI: -3.12, 0.16,

per-protocol). There were no other significant between-group differences for functional mobility, balance, posture, quality of life and pain. Average adherence to the exercise program over months 1 to 11 was 73%; yet, adherence declined from 68% at month 6 to 59% at month 11. Conclusions: The effect of home exercise on functional leg muscle strength was consistent in direction and magnitude to the effects of exercise on mobility outcomes in other trials in individuals with vertebral fractures. Declining adherence to home exercise suggests that strategies to enhance long-term adherence or more supervision might be important in future exercise trials in older women with vertebral fractures.

Changes in Vascular Calcification and Bone Mineral Density in Calcium Supplement Users from the Canadian Multi-center Osteoporosis Study (CaMOS). Maggie Hulbert*[1], Rachel Holden[2]. [1]Queen's University, Canada, [2]Kingston General Hospital, Canada

Background: Calcium supplements are widely used to prevent osteoporosis and fragility fractures. Recently, epidemiological data has shown a concerning association between calcium supplement use and cardiovascular events. Calcium deposition in the vasculature has been proposed as an underlying mechanism. Objectives: To determine the association between calcium supplement use and change in the Framingham vascular calcification score and bone mineral density T-scores in participants of CaMOS. Methods: We identified post-menopausal women and older men (n=296) who had completed facilitated health history questionnaires and had lateral spine X-rays and DEXA bone mineral density scans at two time points with a 5 year interval. Abdominal aortic calcification (AAC) was assessed on lateral spine X-ray by the Framingham Method. The change in BMD T-scores at L1-L4 (lumbar), total hip, and femoral neck sites measured by DXA (Hologic, Inc.) was calculated during the same 5 year interval. The association between calcium supplement use and AAC change was assessed using t-tests and multi-variable logistic regression models. Results: AAC significantly increased over 5 years (mean increase 1.86, SD 3.238). AAC progression was significantly greater in calcium supplement users as compared to non-users (p=0.033), and female calcium supplement users had the most significant amount of AAC progression (mean 2.61 p=0.018). Amount (mg/day) of calcium supplement taken positively correlated to AAC progression (r=0.16, p= 0.006). In the multi-variable model, calcium supplement use and amount remained significantly associated with AAC progression after adjustment for age, hypertension, diabetes and smoking history in women only (r=2.16, p=0.032). Calcium supplement use was not associated with preservation of BMD at any site, and was associated with a significantly greater BMD loss at all three sites in men only. Conclusion: Calcium supplement users have significantly higher AAC progression over 5 years. This effect is seen most significantly in post-menopausal women. Calcium supplement users did not have any significant preservation of BMD. These results suggest that vascular calcification may contribute to the increased cardiovascular events observed in calcium supplement users, and that calcium supplement use may have a negative risk-benefit ratio.

MON-0853

3D analysis of the cortical and trabecular bone of elite female athletes involved in high- and low-impact sports Ludovic Humbert*[1], Luis Del Río[2], Antonia Lizarraga[3], Montserrat Bellver[4], Renaud Winzenrieth[1], Amineh Amani[2], Franchek Drobnic[3]. [1]Galgo Medical, Spain, [2]CETIR Centre Medic, Spain, [3]Football Club Barcelona, Spain, [4]Centro de alto Rendimiento, Spain

Purpose: To assess and compare the cortical and trabecular bone of the proximal femur of athletes involved in high-impact sports (football and volleyball) and low-impact sports (swimming, synchronised swimming and water polo) using DXA-derived 3D analysis. Methods: Elite female athletes from the football first team of FC Barcelona and from the Spanish national team of volleyball, swimming, synchronised swimming and water polo were included in this study. Hip DXA scans were performed at the Medical Services of FC Barcelona (Barcelona, Spain) using a Lunar iDXA scanner (GE Healthcare, Madison, WI). Areal BMD (aBMD) were calculated at total femur. The 3D-SHAPER software (v2.7, Galgo Medical, Barcelona, Spain) was used to provide 3D analysis of the cortical and trabecular bone from hip DXA scans. Trabecular volumetric BMD (vBMD) and cortical surface BMD (sBMD) were calculated at total femur. DXA and DXA-derived 3D measurements calculated for every groups were compared using Student's t-test.Results: The number and mean age (±SD) of the female athletes involved in this study was N=60, 22±4 years (football); N=26, 23±6 years (volleyball); N=18, 19±4 years (swimming); N=25, 21±5 years (synchronised swimming); and N=14, 24±4 years (water polo). No difference in aBMD, trabecular vBMD and cortical sBMD was found between athletes involved in high-impact sports (football and volleyball). Among the groups involved in low-impact sports, water polo athletes had 10% higher aBMD, trabecular vBMD and cortical sBMD (p<0.05 for all measurements), compared to swimmers. They showed 7% higher cortical sBMD (p<0.05), compared to synchronised swimmers, while no significant differences were found for aBMD and trabecular vBMD. Athletes involved in high-impact sports had higher aBMD (12% to 21%), trabecular vBMD (17% to 34%) and cortical sBMD (11% to 27%), compared to low-impact sports. Distribution of the mean differences in cortical sBMD between football and swimming athletes are shown in Figure 1.Conclusions: Athletes involved in high-impact sports exhibited higher densities in both cortical and trabecular compartments, compared to

low-impact sports. Interestingly, water polo athletes have higher cortical density compared with other swimming athletes which could be explained by higher workout.

Yoga-related bony spine injuries Melody Lee*, Mehrsheed Sinaki. Mayo Clinic, United States

Background: Yoga has gained great popularity in recent years, being touted as a safe and gentle form of exercise. However, injuries can occur despite the perceived benign nature of yoga. The purpose of this case series is to describe vertebral anterior wedging and compression fractures that were directly linked to the practice of yoga. Methods: The study population consisted of 25 patients who were treated in the musculoskeletal clinic of the physical medicine and rehabilitation department. All of the patients had identified yoga as the primary cause of their injury and pain. Their charts were reviewed and analyzed retrospectively. Results: All 25 patients had radiographically confirmed vertebral body anterior wedging (18 patients) and/or compression fractures (14 patients). Mean age: 64, height: 162.8cm, and weight: 62.4kg. Average T-score: -2.46. Patients were able to identify the poses that induced their injuries. The most commonly identified poses were: bridge pose in 13(52%), seated forward fold in 12(48%), and plow pose in 9(36%). Conclusion: To our knowledge, this is by far the largest case series of yoga-related vertebral anterior wedging and compression fractures to date. While yoga potentially has many health benefits, it still carries some risks. Patients who have osteopenia or osteoporosis may be at higher risk of compression fractures or deformities, particularly when perfoming extreme spinal flexion. Practitioners should address this when counseling patients on yoga as exercise.

MON-0855

Relationships between high sodium intake and trabecular bone score as well as fracture in postmenopausal women Kiyoko Nawata*[1], Mika Yamauchi[2], Masahiro Yamamoto[2], Toshitsugu Sugimoto[2]. [1]Health and Nutrition, The University of Shimane, Faculty of Nursing and Nutrition, Japan, [2]Internal Medicine 1, Shimane University Faculty of Medicine, Japan

Objective: Some earlier studies suggest that excessive dietary sodium (Na) intake is associated with a higher prevalence of osteoporosis. However, the role of high Na intake on bone fragility has not been yet fully elucidated. On the other hands, a decrease in trabecular bone score (TBS), which is an indicator of the cancellous bone microstructure, is recognized as a risk factor for fracture, independent of bone mineral density (BMD). Therefore, the present study investigated the influence of Na intake on TBS and Fx risk. Methods: The subjects were 213 healthy postmenopausal women who had undergone osteoporosis screening. Serum levels of PTH, 25-hydroxyvitamin D [25(OH)D], P1NP, CTX, urinary Ca (uCa) and Cr(uCr) were measured. The BMD of the lumbar (L) and femoral neck (FN) was measured using DXA, and TBS (L1-4) was calculated. Nutrient intake was calculated using a food frequency questionnaire. Results: The mean age of subjects was 63±8 years. The mean values of measured variables were: L-BMD 0.84±0.15g/cm2, FN-BMD 0.62±0.09g/cm2, and TBS 1.31±0.07. Na intake was 5211±1697mg. Vertebral (VFx) and non-vertebral (non-VFx) fractures were observed in 49 and 36 subjects, respectively. Na intake was not correlated with BMD, bone metabolic markers and uCa/uCr. In an analysis of TBS by quartile of Na intake, the highest Na intake group (highest Na) showed a value significantly lower than each other groups. While the presence or absence of VFx showed significant differences in TBS, no such difference was observed between the Na intake and VFx in quartile analyses. On the other hand, while the presence or absence of non-VFx did not show differences in TBS and Na intake, the proportion of the presence of non-VFx in the highest Na (7561±1035 mg) was significantly higher as compared with the other groups. Logistic regression analysis revealed that the highest Na was a significant risk factor for non-VFx even after adjustments for TBS, in addition to age, BMI, PTH, 25(OH)D, CTX, FN-BMD, uCa/uCr, other nutritional intake, and presence or absence of hypertension [odds ratio 3.01 (95%CI: 1.05-8.60), p<0.05]. Conclusion: Excessive Na intake may be associated with deteriorating cancellous bone microstructure in postmenopausal women. Excessive Na intake is also a risk factor

for non-VFx. However, the association between excessive Na intake and non-VFx was independent of the deterioration of the cancellous bone microstructure as well as BMD and urinary Ca excretion.

A Randomized Trial of Vitamin D Supplementation in Healthy Inner-city Children Christine Simpson*[1], Jane Zhang[2], Dirk Vanderschueren[3], Lei Fu[4], Teresita Pennestri[1], Roger Bouillon[3], David Cole[4], Thomas Carpenter[1]. [1]Yale University School of Medicine, United States, [2]VA Connecticut Healthcare System, United States, [3]Katholieke Universiteit Leuven, Belgium, [4]University of Toronto, Canada

Determinants of vitamin D (vitD) status in children include ethnic/genetic background and vitD binding protein (DBP) haplotype. We therefore performed a trial of vitD supplementation in 2-10 yr-old children of predominantly Hispanic background to determine effects of vitD dose and DBP haplotype on the response to supplementation. Subjects were randomized to receive low (2800 IU weekly) (LD) or higher dose (HD) vitamin D3 (7000 IU weekly) for 6 months (mos), and stratified to one of the 6 commonly occurring DBP haplotypes. Total 25-hydroxyvitamin D (T25-OHD) increased by 1 mo of supplementation, with a 31% increase in HD subjects (mean Δ=7.7 ng/mL) which differed from the 22% increase in LD subjects (mean Δ=4.7 ng/mL) (P=0.003). Increases differed slightly by DBP haplotype (P=0.034) with the least change occurring in the Gc1f/Gc1s (DETT) group. The difference in dose response persisted at 6 mos (Δ=10.4 ng/mL in HD, a 43% increase, vs. Δ=3.4 ng/mL in LD, a 17% increase; P=0.040). DBP haplotype effects were no longer evident (P=0.29) at 6 mos. Differences between doses were similar across all DBP haplotypes (interaction of dose and haplotype, P=0.26). 1,25-dihydroxyvitamin D (1,25D) increased after 1 and 6 mos (P<0.001). Change from baseline did not differ between dose groups at either 1 mo (P=0.13) or 6 mos (P=0.59). DBP haplotype did not affect 1,25D at either 1 mo (P=0.62) or by 6 mos (P=0.37). No significant change from baseline occurred in circulating DBP levels (measured only at 6 mos) in either treatment group (P=0.96), however calculated free (CF) 25-OHD at 6 mos increased by 13% and 40% in LD and HD groups respectively (P<0.001), changes comparable to those observed for T25-OHD. Circulating 25-OHD levels in healthy inner-city children can be enhanced by doses of vitamin D3 equivalent to 400 IU and 1000 IU daily without toxicity. T25-OHD levels increase by 1 mo of supplementation and dose differences are sustained at 6 mos. CF25-OHD levels increase comparably to T25-OHD. 1,25D levels increase within 1 mo of vitamin D3 supplementation and persist through 6 mos, suggesting a sustained substrate effect contributing to circulating levels of this metabolite. Although small changes may transiently occur across DBP haplotypes, vitD supplementation does not require targeting to a patient's specific DBP haplotype.
Low dose groups are shown in black and higher dose groups in gray. BL=baseline, mo=month. The 6 bars on the left of figure represent Total 25-OHD (left axis) and the 4 bars on the right represent Calculated Free 25-OHD (right axis). *p<0.05

MON-0857

Low T3 is Associated with Decreased Bone Turnover Rate in Exercising Women with Eumenorrhea and Amenorrhea Emily Southmayd*, Andrew Oneglia, Rebecca Mallinson, Nancy Williams, Mary Jane De Souza. The Pennsylvania State University, United States

INTRODUCTION: Energy and estrogen deficiency are detrimental to bone health in young exercising women, increasing the risk for impaired bone density and geometry. While bone formation and resorption have been reported in isolation as a result of menstrual dysfuction, such as amenorrhea, or acute energy deficiency via caloric restriction, the effect of energy and estrogen deficiency in isolation or in combination on bone turnover dynamics, which might have implications for fracture risk, have not been established. The purpose of this study was to assess the independent and interactive effects of energy and estrogen deficiency on bone formation, resorption, net bone balance, and bone turnover rate. METHODS: Exercising women age 18-30yr with amenorrea (estrogen deficient, E2D, n=48) or ovulatory eumenorrhic cycles (estrogen replete, E2R, n=31) were recruited. Menstrual status was assessed by self-reported history of menses corroborated with daily urinary measures of estrogen and progesterone metabolites for one menstrual cycle (if eumenorrheic) or one 28d monitoring period (if amenorrheic). Energy status was assessed via serum triiodothyronine (T3) concentration. Women were grouped as energy deficient (EnD, n=40) or energy replete (EnR, n=39) based on a median split of T3 concentrations (83.85 ng/dl cutoff). Bone turnover dynamics were assessed via serum measurements of P1NP and CTx. Bone formation (MoMf) and resorption (MoMr) scores were calculated relative to healthy, ovulatory reference data (MoMf=[P1NP]i/median[P1NP]ov ; MoMr=[CTx]i/median[CTx]ov). Bone balance (BB) and Bone Turnover Rate (BTR) were calculated (BB=MoMf/MoMr ; BTR=sqrt(MoMf2+MoMr2)). 2-way ANOVA was used to assess main and interactive effects of energy and estrogen status on P1NP (MoMf), CTx (MoMr), BB, and BTR. RESULTS: There was a main effect of energy status on bone formation (P1NP, MoMf, p=0.007) and BTR (p=0.023), such that women that were energy replete based on higher T3 concentrations had greater bone formation and faster bone turnover. There were no main effects of estrogen status on bone turnover dynamics, and there were no interactive effects of energy and estrogen status. CONCLUSION: Energy status drives indicators of bone turnover. Thus, adequate nutrition, which may also promote menstrual health, should be a priority to optimize bone health in exercising women. Bone turnover rate is a novel measurement that should be explored with respect to bone density and fracture risk.

Note: Slope of line represents bone balance (BB) and length of vector from origin to arrowhead represents bone turnover rate (BTR).
*Main effect of energy status on MoMf and BTR (p<0.023)

MON-0858

Supervised high intensity resistance and impact training does not cause vertebral crush fractures and improves thoracic kyphosis in postmenopausal women with low to very low bone mass: The LIFTMOR Trial Steven Watson*[1], Benjamin Weeks[1], Lisa Weis[2], Amy Harding[1], Sean Horan[1], Belinda Beck[1]. [1]School of Allied Health Sciences, Griffith University, Gold Coast, Australia, [2]The Bone Clinic, Brisbane, Queensland, Australia

Introduction: The recent LIFTMOR trial demonstrated that supervised high intensity resistance and impact training (HiRIT) improves BMD and functional performance in postmenopausal women with low to very low bone mass to a greater degree than other forms of exercise. Concerns have been raised, however, that such high intensity loading may increase the risk of vertebral crush fracture in this high risk population. The aim of the current work was to assess vertebral morphology and kyphosis for evidence of fracture before

and after 8 months of HiRIT in the LIFTMOR cohort.Methods: Postmenopausal women with low bone mass (T-score <-1.0) were recruited and randomized to either 8 months of twice-weekly, 30-minute, supervised HiRIT, or a home-based, low intensity exercise program (CON). At baseline and 8 months, lateral spine DXA scans were performed (Medix DR, Medilink, France) on which lateral vertebral assessments were conducted, based on the Genant method. Clinical kyphosis measures were also performed (degree of deformity from inclinometer [Plurimeter, AMTI, Australia] and kyphosis index [unitless] from Flexicurve [Flexible curve, Staedtler, Germany]), in both relaxed standing and standing tall postures. Changes in vertebral morphology and posture were tested using repeated measures ANOVA (ITT).Results: Fifty-one participants (64±4 years, 161.5±5.9cm, 63.6±10.4kg) were included in the analysis. At baseline, 17 participants (33%) had a vertebral deformity (CON=11; HiRIT=6), with wedge deformities being most common (n=12/18). No changes in vertebral morphology were observed following HiRIT. One new vertebral deformity was identified after CON. The HiRIT group exhibited greater improvement in degree of thoracic kyphosis in the standing tall position compared to CON (-6.7±8.2° vs -1.6±8.1°, p=0.031). In relaxed standing, both HiRIT and CON groups had within-group improvements in kyphosis degree (HiRIT: -6.0±6.9°, p<0.001; CON: -4.0±6.9°, p=0.005) and kyphosis index (HiRIT: -2.4±2.5, p<0.001; CON: -2.0±2.4, p<0.001), but no between-group difference could be detected.Conclusion: Contrary to concerns regarding the risk of crush fracture during heavy lifting in postmenopausal women with low bone mass, our supervised HiRIT program was not associated with changes in vertebral morphology. Indeed, HiRIT improved thoracic kyphosis. We thus conclude that supervised HiPRT not only improves BMD and posture, but is safe for postmenopausal women with low bone mass.

Kynurenine Regulates Osteogenesis in Aging Through miRNAs 29b-1-5p and 141-3p Khaled Hussein*[1], Ahmed Elmansi[1], Sudharsan Periyasamy-Thandavan[2], Galina Kondrikova[1], Wendy Bollag[3], Sadanand Fulzele[4], Xingming Shi[5], Meghan Mcgee-Lawrence[1], Mark Hamrick[1], Carlos Isales[5], William Hill[2]. [1]Department of Cellular Biology and Anatomy, Augusta University, United States, [2]Department of Cellular Biology and Anatomy, Augusta University, Georgia, [3]Department of Physiology, Augusta University, United States, [4]Department of Orthopedic Surgery, Medical College of Georgia, United States, [5]Department of Neuroscience and Regenerative Medicine, Augusta University, United States

We propose that age-related osteoporosis is in part due to increased levels of kynurenine (KYN), a Tryptophan (TRP) metabolite that goes up with aging and is generated by Indoleamine-(2,3)-dioxygenase as well as reactive oxygen species oxidation. miRNAs are small non-coding RNA molecules involved in post-transcriptional regulation of gene expression. Of interest, we identified miRNAs 29b-1-5p and 141-3p to target a number of osteogenic genes (Runx2, BMP-2, Col1) including stromal cell-derived factor-1 (SDF-1/CXCL12), and its receptor CXCR4, while increasing adipogenic markers such as c/BEP. We hypothesized that KYN increases both miRNAs 29b-1-5p and 141-3p leading to inhibition of osteogenic genes, including the SDF-1 axis, leading to reduced BMSC osteogenesis.We show that in BMSCS KYN increases both miRNAs in a dose-dependent fashion rapidly within 6 hours, then declining, and leads to a sustained significant reduction of both mRNA and protein levels of SDF-1 and CXCR4 over 48 hours in human and murine bone marrow mesenchymal stem cells. To test whether SDF-1 concentration is dependent on changes in miRNAs, we show that using antagomirs to miRNAs with KYN co-treatment rescued SDF-1 gene expression and protein levels. KYN is known to have a cytoplasmic receptor, the aryl hydrocarbon receptor (AhR), which translocates to the nucleus to regulate gene expression as part of a xenogen transcription complex. Using a AhR blocker CH223191 with KYN only partly rescued SDF-1 expression levels, suggesting that Kynurenine could be working through the AhR pathway and potentially another mechanism as well. We also show that miR-29b-1-5p also targets Hdac3, which plays a role in determining BMSCs osteogenic or adipogenic cell fate.KYN up-regulates age associated miRNAs, decreases SDF-1 levels, and inhibits osteogenic differentiation, while at the same time upregulating adipogenic pathways. This work suggests mechanisms linking KYN directly to age-associated changes in bone homeostasis and osteoporosis.

Exome sequencing and functional follow-up identifies KIF26B as a novel genetic determinant of familial osteoporosis Melissa M Formosa*[1], Robert Formosa[2], Herma C Van Der Linde[3], Juriaan R Metz[4], Gert Flik[4], Deepak Kumar Khajuria[5], David Karasik[5], M Carola Zillikens[6], Rob Willemsen[3], Andre G Uitterlinden[6], Tjakko J Van Ham[3], Fernando Rivadeneira[6], Annemieke Jmh Verkerk[6], Angela Xuereb-Anastasi[1]. [1]Department of Applied Biomedical Science, Faculty of Health Sciences, University of Malta, Msida, Malta, [2]Department of Medicine, Faculty of Medicine and Surgery, University of Malta, Msida, Malta, [3]Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, Netherlands, [4]Department of Animal Physiology, Institute for Water and Wetland Research, Faculty of Science, Radboud University Nijmegen, Nijmegen, Netherlands, [5]The Musculoskeletal Genetics Laboratory, Azrieli Faculty of Medicine, Bar-Ilan University, Safed 1311502, Israel, [6]Department of Internal Medicine, Erasmus University Medical Center, Rotterdam, Netherlands

Objective: Osteoporosis is a skeletal disease under strong genetic control. The aim of the study was to identify the genetic determinants of primary osteoporosis in a Maltese family and investigate the function of identified novel genes and variants. Methods: A 2-generation family of 12 recruited relatives (including 7 siblings) with ages ranging from 34-77 years was tested. Osteoporosis was defined using DXA scans of the lumbar spine (LS) and hip. The proband had a LS T-score of -4.0. Exome sequencing was performed on 6 well-phenotyped relatives and replication of shortlisted variants was sought in a case-control collection of Maltese postmenopausal women (n=1012). In vitro protein expression was analyzed by transfecting in COS-7 cells and western blotting, whereas consequences of gene knockdown was studied in a zebrafish model. BMD was assessed with micro-computed tomography; mineralization rate with Alizarin red staining of the whole fish skeleton; and resorption activity with TRAcP staining of regenerating scales. Results: Comprehensive exome variant filtering according to dominant inheritance identified in all affected individuals a novel nonsense variant p.Q287X (c.C859T) within the Kinesin family member 26B (KIF26B) gene. Screening of the variant identified two heterozygous carriers of the T allele (MAF=0.001) presenting with low LS BMD (average T-score: -2.3). The variant is located within a highly conserved region of the protein, upstream of the kinesin motor domain. In silico modeling predicted the T allele to result in nonsense mediated mRNA decay. Western blotting confirmed a complete absence of the protein in the presence of the T allele. As compared to wild-type (WT) fish matched for age and length, kif26b knockout fish had lower numbers of mineralized vertebrae until 1 month post fertilization (mpf). Notorious decrease in BMD (-23%, p=0.01) and bone volume/tissue volume (-40%; p=0.01) was observed at 3mpf. At 4mpf, knockout fish presented higher osteoclast activity in regenerating scales at 6-day (p=0.04) and 14-day (p=0.03) recovery set-points. Conclusion: Our findings postulate KIF26B as a novel factor playing a role in bone biology and susceptibility to familial osteoporosis. KIF26B is involved in intracellular transport and cell division, linked to Wnt5a-Ror signaling in morphogenesis, including limb development. Further elucidation of the underlying cellular processes may identify novel therapeutic targets for osteoporosis treatment.

MIR4697HG knockdown prevents ovariectomy-induced osteoporosis in mice Chanyuan Jin*, Yongsheng Zhou. Peking University School and Hospital of Stomatology, China

Osteoporosis is believed to have a strong correlation with reduced osteogenic potential of bone marrow mesenchymal stem cells (BMMSCs). However, the underlying mechanism of osteogenesis of BMMSCs remains elusive. Recent studies have found long non-coding RNAs (lncRNAs) play important roles in osteogenesis of BMMSCs. In this study, we found lncRNA MIR4697HG was upregulated in BMMSCs of osteoporotic mice (OVX) compared with control group. Additionally, we found MIR4697HG was downregulated during the osteogenic differentiation of BMMSCs. Moreover, we demonstrated that knockdown of MIR4697HG promoted osteogenic differentiation of BMMSCs in vitro and in vivo, whereas overexpression of MIR4697HG inhibited osteogenesis of BMMSCs in vitro and in vivo. Finally, we found bone loss was attenuated in OVX injected with MIR4697HG siRNA. Taken together, these results suggest MIR4697HG plays an important role in osteogenesis of BMMSCs and may have a potential use in treating osteoporosis.

Age related changes in bone microstructure, bone turnover markers, and serum pentosidine levels: HR-pQCT study in healthy Japanese men Narihiro Okazaki*, Ko Chiba, Mitsuru Doi, Kazuaki Yokota, Makoto Osaki. Department of Orthopaedic Surgery, Nagasaki University Hospital, Japan

Introduction: Many studies on osteoporosis have been conducted in women. However, its pathogenesis in men remains unclear. In this study, we analyzed age-related changes in the bone microstructure, bone turnover markers, and serum pentosidine levels cross-sectionally to investigate the pathogenesis of osteoporosis in men.Methods: A total of 78 Japanese

men (mean age 42 ± 14; range, 21-75 years) from the J-CaraT study (Japanese study of bone miCrostructure and minerAl density in a noRmAtive cohorT measured by HR-pQCT) in Nagasaki University were included as study subjects. The distal radius and tibia were scanned using high-resolution peripheral quantitative computed tomography (XtremeCT II; Scanco Medical, Switzerland) with a voxel size of 60.7 µm, and the volumetric bone mineral density (vBMD) and bone microstructure parameters were analyzed. The serum levels of tartrate-resistant acid phosphatase-5b (TRACP-5b), total procollagen type I N-terminal propeptide (P1NP), and pentosidine were also evaluated.Results: Age was negatively correlated with trabecular vBMD, bone volume fraction, and number (radius, r = -0.45, -0.47, and -0.36; tibia, -0.49, -0.49, and -0.29, respectively); positively correlated with cortical porosity (radius, r = 0.46; tibia, r = 0.30); but not correlated with cortical vBMD or cortical thickness. Furthermore, age was also negatively correlated with total P1NP levels (r = 0.55), positively correlated with pentosidine levels (r = 0.51), but not correlated with TRACP-5b levels.Conclusions: In men, the bone resorption markers did not change, whereas the bone formation markers decreased with age. Furthermore, pentosidine levels increased with age; the trabecular bone decreased and cortical porosity increased; however, the cortical thickness was relatively maintained.

Upregulated osteoclastogenesis and accelerated mineralization associated with perlecan deficiency were rescued by exogenous heparin treatment in vitro Ashutosh Parajuli*, Ping Li, Jerahme Martinez, Catherine Kirn-Safran, Liyun Wang. University of Delaware, United States

Perlecan/HSPG2, a large multifunctional heparin sulfate proteoglycan is found in basement membranes and the pericellular matrices of cartilage and bone [1]. Perlecan deficiency is also a risk factor of osteoporosis [1]. We found cortical hypermineralization [2], trabecular osteopenia [3] in perlecan deficient (Hypo) mice, upregulated osteoclastogenesis and accelerated mineralization of progenitor cells from the hypo bone marrow (Figs. A,B) [4]. The purpose of this study was to examine if exogenous treatment with Heparin (hyper-sulfated GAG) can rescue the above impairments associated with perlecan deficiency.Dot blot assay: Soluble protein were extracted from bone marrow. Perlecan content was determined using dot blot with anti-perlecan A7L6 antibody. Osteoclastogenesis assay: Freshly harvested marrow from long bones was cultured in media supplemented with M-CSF (25 ng/ml) for 2 days. The non-adherent cells were cultured 9 more days in media with M-CSF (25 ng/ml) & RANKL (20ng/ml) on dentin slices in 96-well plates, followed by TRAP staining. Osteogenesis mineralization assay: The adherent MSCs from fresh bone marrow were cultured in osteogenic media for 19 days and stained with 2% Alizarin red [2]. Mineralization was quantified. Heparin treatments: Both assays were carried out on WT and Hypo samples with 3 different concentrations of Heparin: 0, 20 and 200 µg/ml with at least three repeats.Dot blot showed significantly lower perlecan content (-30%) in Hypo bone marrow than WT (Fig. C), agreeing with the reduced perlecan gene expression in Hypo [5]. Similar to in vivo (Fig. A), the # of multinucleated TRAP+ osteoclasts was nearly doubled in Hypo without exogenous Heparin (Fig. D), while this significant difference (p < 0.05, Hypo vs. WT) was diminished with Heparin treatment at 20 and 200 µg/ml (Fig. D). Similarly, the higher mineralization seen in non-treated cultures (Hypo vs. WT, p <0.05) appeared to be diminished with Heparin treatment (Fig. E).Our results indicate that addition of Heparin can rescue the adverse effects of perlecan-deficiency on bone progenitor cells, by slowing down mineralization and osteoclastogenesis. This result, if translated in vivo, could help develop therapeutics to treat bone impairment/osteoporosis associated with perlecan deficiency.References: [1] Farach-Carson+ 2014, Matrix Biol. Atrophic Non-union Fracture is Caused by Severe Damage on Periosteal Mesenchymal Progenitors and Fibrosis Derived from Non-osseous Tissue.
Luqiang Wang*[1], Robert Tower[1], Abhishek Chandra[2], Yejia Zhang[1], Xiaowei Liu[1], Joel Boerckel[1], Xiaodong Guo[3], Jaimo Ahn[4], Ling Qin[1]. [1]Department of Orthopaedic Surgery, Perelman School of Medicine, University of Pennsylvania, United States, [2]Department of Physiology and Biomedical Engineering, Division of Geriatric Medicine & Gerontology, Mayo Clinic, United States, [3]Department of Orthopaedics, Union Hospital, Tongji Medical college, Huazhong University of science and Technology, China, [4]Orthopaedic Trauma and Fracture Reconstruction, Perelman School of Medicine, University of Pennsylvania, United States

Fractures represent a substantial economic burden to our society. The atrophic non-union of a fracture is especially challenging, as it often requires additional surgeries to overcome the lack of inherent biology in a regenerative healing process gone awry. Using a focal irradiator for rodents, we reproducibly created a nonsurgical atrophic non-union model in mice. 2-month-old male mice received radiation (8 Gy, day 1 and 3) at the mid-shaft of right tibiae (5 mm long) followed by bilateral, transverse tibial fractures on day 15. MicroCT and mechanical testing at day 57 (n=9) revealed that, in sharp contrast to bone healing in contralateral tibiae, fractures in irradiated tibiae did not show any bony bridging, resulting in 100% non-union. Histology at days 22, 29, 43, and 57 (n=6-9/time point) revealed that irradiated tibiae show less robust endochondral healing at the proximal side (region close to the knee) and a clear biologic non-union response on the distal side (region close to the ankle) with exclusive fibrotic cells and type I collagen matrix. These fibrotic cells did not stain for osteogenic (osterix and osteocalcin) and chondrogenic (Sox9 and type II collagen) markers, nor did they express VEGF. Thus, histology and microfil perfusion showed no vessel infiltration in this region. Characterization of tissues from clinical human atrophic non-union paralleled our mouse findings. Mechanistically, radiation blunted the injury response of periosteal mesenchymal progenitors at 3 days post fracture, resulting in a 67% reduction in their proliferation rate and an 83% reduction in periosteum thickness (n=6). In vitro, radiation hindered osteogenic differentiation of periosteal mesenchymal progenitors but did not affect hypoxia-induced chondrogenesis of these cells. Lineage tracing using mouse models that specifically labeled bone mesenchymal cells (Col2-Cre, aSMA-CreER, and Gli1-CreER in combination with Rosa-Td) revealed that non-union fibrotic cells did not originate from periosteal progenitors but from progenitors residing in non-osseous tissues. In addition, we surgically removed periosteum at either side or both sides of the mouse tibial fracture site and found that it eventually leads to atrophic non-union with fibrosis formation only at the surgery side(s). In summary, we demonstrate that atrophic non-union fracture is caused by severe damage to the periosteal mesenchymal progenitors with fibrosis formation that is derived from non-osseous tissue.

Bone mass of bariatric patients may recalibrate to new body weight Andrew Froehle*[1], Richard Sherwood[2], Richard Laughlin[3], Dana Duren[2]. [1]Wright State University, United States, [2]University of Missouri, United States, [3]University of Cincinnati, United States

Bariatric weight loss surgery is an effective treatment for reducing excess body weight (EBW). One common procedure, Roux-en-Y gastric bypass (RYGB), results in the loss of 60-80% of EBW in the first year following surgery, with concomitant benefits for metabolic health. Despite these benefits, the malabsorptive conditions generated by the procedure may have negative effects on the musculoskeletal system in the form of significant loss of bone mass. Bone loss in general is associated with negative long-term consequences, including osteopenia, osteoporosis and fractures. However, it is unclear whether post-RYGB bone loss represents a true deficit, or whether it is instead a recalibration of bone mass to a new, lower body weight. To address this question, we assessed bone health (areal bone density; aBMD) in women 5 years after RYGB weight loss surgery and compared them to a non-surgical female reference sample matched for current age and body mass index (BMI). The present study of women who underwent RYGB bariatric surgery found that, five years after surgery, bone density was slightly lower than a non-surgical reference sample matched for current age and BMI. The Bariatric and reference samples were similar for mean age, height, weight, BMI, waist circumference, ideal body weight, EBW, and body composition. The Bariatric sample had slightly lower median aBMD values compared to the controls in each body region examined, but none of these differences reached significance. Femoral neck and total hip T-scores within the osteopenic range occurred in 56% and 44% of Bariatric participants and 34% and 24% of controls, respectively. Post hoc sub-analysis of the Bariatric sample suggests that the key explanatory factors for post-surgical osteopenia, osteoporosis, and fracture risk were not the effects of the surgery itself on digestion or body composition, but rather vitamin D and menopause status prior to surgery. The results overall indicate that RYGB patients are at greater risk for osteopenia than their non-surgical counterparts, but that this risk may be related to pre-surgical hormonal and metabolic conditions more than the effects of the surgery itself. Such factors should be taken into consideration when planning post-surgical treatment and follow-up.

Evaluation of bone indices by DXA and HR-pQCT in newly diagnosed hyperthyroidism due to Graves' Disease and associations with disease severity. Diana Grove-Laugesen*[1], Klavs Würgler Hansen[2], Eva Ebbehoej[1], Torquil Watt[3], Lars Rejnmark[1]. [1]Aarhus University Hospital, Denmark, [2]Regionshospitalet Silkeborg, Denmark, [3]Rigshospitalet, Denmark

Hyperthyroidism increases bone turnover and decreases areal BMD. Risk of fracture is increased. High-resolution peripheral quantitative computed tomography (HR-pQCT) is a technique used to assess bone microarchitecture and volumetric BMD in vivo. The bone micro architectural changes in hyperthyroidism are sparsely described. A frequent cause of hyperthyroidism is Graves' Disease (GD) characterized by Thyrotropin receptor antibodies (TRAb) that correlates to the severity of the disease. We aimed to investigate the association between severity of hyperthyroidism and bone mineralization, bone geometry, and strength in the early state of hyperthyroidism due to GD.Methods. Eighty-six newly diagnosed adult patients with GD referred to our outpatient clinic were included. Patients were hyperthyroid and treated with antithyroid drug for less than 14 days. Areal BMD was assessed based on DXA scans of forearm, femoral neck, and lumbar spine. Lumbar spine trabecular bone score (TBS) was calculated. Based on HR-pQCT scans volumetric BMD and bone microarchitecture was assessed, and stiffness, failiure load, and cortical porosity were calculated. Morning blood samples were collected after 8 hours of fasting. In a multiple regression analysis, associations between severity of hyperthyroidism and bone indices were estimated adjusted for age, gender, BMI, level of vitamin D, and parathyroid hormone.Results. Patient characteristics were: female (86 %), age 39.4 years (interquartile range (IQR) 31.5-51.1), TRAb 9.2 iu/L (IQR 4.7-15.4), and triiodothyronine 15.6 pmol/L (IQR 7.9-14.3). TRAb was inversely associated with stiffness (-0.32 (CI 95%:-0.51;-0.13), p=0.001) and failure load (-0.14 (CI 95%: -0.022;-0.0051), p=0.002) in tibia. TRAb was associated with cortical porosity in tibia (0.02 (CI 95%:0.0037;0.036), p=0.017. There were no association with TRAb or thyroid hormones and areal or volumetric BMD, TBS, or indices of microarchitecture. Age was significantly associated with bone indices in all analysis.Conclusion. Despite abundant evidence of reduced BMD in hyperthyroidism we did not find association between areal or volumetric BMD and degree of hyperthyroidism in newly diagnosed patients with GD. However, we did find association between disease severity and increased cortical porosity and reduced stiffness and strength in tibia. These data suggests that cortical areas in weight bearing extremities are affected in early state of hyperthyroidism.

Bone Fragility after Spinal Cord Injury: Reductions in Stiffness and Bone Mineral at the Distal Femur and Proximal Tibia as a Function of Time.
Ifaz Haider*[1], Stacey Lobos[1], Narina Simonian[2], Thomas Schnitzer[2], W Brent Edwards[1]. [1]University of Calgary, Canada, [2]Northwestern University, United States

IntroductionSpinal cord injury (SCI) is associated with bone loss and skeletal fragility at the knee. Understanding the temporal patterns of bone loss after SCI may help develop more effective interventions. The purpose of this investigation was to expand on our previous research [1,2] and more thoroughly quantify temporal changes at the distal femur and proximal tibia in people after SCI. We used patient-specific finite element (FE) modelling to measure stiffness and computed tomography (CT) to measure changes in bone mineral. MethodsCT scans of the distal femur and proximal tibia were collected from 101 patients (ages 18-72 yrs, 80 males) with SCI between 1 month and 50 years prior to participation. We computed bone mineral density (vBMD), bone volume (BV) and bone mineral content (BMC) at integral, cortical, and trabecular compartments of the epiphyseal, metaphyseal, and diaphyseal regions. We also generated patient-specific FE models of the same three regions to estimate stiffness under axial compression (Kc) and torsion (Kt). Finally, we fit all measures as a function of time since injury using a single decaying exponential (1-DE) and a superposition of two decaying exponential functions (2-DE).ResultsBone mineral and stiffness decreased exponentially over time (R2 ≥ 0.47; Figure 1, TOP), but the more complex 2-DE model did not explain more variation than the 1-DE model (p ≥ 0.67). All measures reached steady-state by 3.5 years after SCI. After this time, patients had significantly decreased stiffness (40-85%; p < 0.005) and bone mineral (12-107%; p < 0.005), compared to recently injured patients (t ≤ 47 days; Figure 1, BOTTOM).DiscussionBone loss at the knee after SCI was rapid and profound, with rates of loss greatest immediately after injury. We observed significant reductions to both torsional and axial stiffness, suggesting that both failure modes may be clinically relevant. Changes over time were described by the 1-DE model, which predicts rapid loss within 3.5 year after SCI and negligible change after this time. It is plausible that moderate bone loss occurs after this period, as predicted by the 2-DE model, but the rate of loss is likely small with respect to patient-to-patient variation and could not be detected.References[1] Edwards et al. EFFECT OF TNF INHIBITORS ON BONE MICROARCHITECTURE IN PATIENTS WITH ANKYLOSING SPONDYLITIS: A LONGITUDINAL STUDY BASED ON HIGH-RESOLUTION PERIPHERAL QUANTITATIVE BASED (HRPQCT) Nisha Nigil Haroon*[1], Angela Cheung[2], Robert Inman[2]. [1]NOSM, Canada, [2]University of Toronto, Canada

Background: Ankylosing spondylitis (AS) is associated with high risk of fractures. BMD,bone microarchitecture and strength are negatively affected in AS.TNF inhibitors such as etanercept, adalimumab, golimumab and infliximab are the mainstay of treatment in AS.However no data is available on the effect of TNF inhibitors on bone microarchitecture and strength. This study aimed to assess the effect of TNF inhibitors on bone microarchitecture in patients with AS.Methods: AS was defined by Modified New York criteria. Areal BMD was measured by DXA. Volumetric BMD (vBMD) and bone microarchitecture were measured using highresolution peripheral quantitative CT (HRpQCT) at the radius and tibia at baseline and after one year of treatment with TNF inhibitors. Intake of calcium and vitamin D were optimized.Results: There were 31 subjects (58% men). Mean (+SD) age and BASDAI were 40+14 years and 4.1+ 2.1 respectively. Median duration of disease was 14 (IQ: 6.5-25.5) years.Mean duration of follow-up was 15 months. Areal BMD (n=22) at lumbar spine (1.053+0.235 vs. 1.049+ 0.202,p=0.89), total hip (0.944+ 0.152 vs. 0.912+0.164,p=0.5), and femoral neck (0.955+ 0.151 vs. 0.954+ 0.191,p=0.2) did not change significantly.HRpQCT (n=31) on follow-up demonstrated that total, trabecular and cortical volumetric BMD were unchanged at both radius and tibia. Also, HRpQCT based trabecular parameters such as trabecular number, thickness and separation, BV/TV and cortical parameters such as cortical porosity and thickness remained stable. FEA estimates of bone stiffness and stress tended to be lower at the radius on follow-up however these parameters were not significantly different at the tibia.Conclusions: This is the first study to document the changes in bone strength in AS patients with the use of TNF inhibitors. Treatment with TNF inhibitors might maintain bone microarchitecture at cortical and trabecular sites in patients with AS.

Bone Mass, Geometry and Strength in Postmenopausal Women with Type 1 Diabetes Viral Shah*, Prakriti Joshee, Rachel Sippl, Dana Carpenter, Wendy Kohrt, Janet Snell-Bergeon. University of Colorado Denver, United States

Purpose: Fracture risk is increased in patients with type 1 diabetes (T1D) and cannot be explained based on areal bone mineral density (aBMD) alone. Therefore, this study examined the association between T1D and volumetric bone density (vBMD), geometry and estimated bone strength at distal radius and tibia in postmenopausal women.Methods: 24 postmenopausal women with T1D (mean age: 60.9 years, years post menopause: 11.6, T1D duration: 41 years, HbA1c: 7.8%,) and 22 age, sex and BMI- frequency matched controls (mean age: 63.2, years post menopause: 16.9, HbA1c: 5.5%) were analyzed for vBMD, geometry and estimated strength at distal radius (4% and 33%) and distal tibia (4%, 38%, and 66%) using peripheral quantitative computed tomography (pQCT).Results: Prevalent fracture was higher among T1D patients compared to controls (79% vs 45%, p=0.02). Age, BMI, and use of hormone replacement therapy was similar between the groups. HbA1c and lean body mass was higher in T1D compared to controls (P<0.01). There was no difference in aBMD at lumbar spine, femoral neck and total hip, vitamin D levels, and bone

turnover markers (P1NP, CTX, OC) between the groups. However, aBMD at distal radius was lower in T1D patients (0.61±0.09 vs 0.66±0.08, P=0.01). After adjusting for age, race, menopause duration, BMI and bone length, only distal radius trabecular vBMD was lower among patients with T1D compared to controls (165.9±32.6 vs 196.8±32.4, p<0.01). There was no difference in vBMD, endosteal and periosteal circumference, cortical thickness and estimated strength between the groups. BMI was associated with higher vBMD and cortical thickness at tibia and higher HbA1c and albumin excretion rate was associated with lower trabecular vBMD at distal radius.Conclusion: Areal BMD and trabecular vBMD are lower at distal radius in postmenopausal women with T1D compared to postmenopausal women without diabetes. Bone mass, geometry and estimated strength are not different by diabetes status in postmenopausal women despite higher prevalence of fracture in postmenopausal women with T1D.

Longitudinal Analysis of the Association between Glycemic Control and Sclerostin in Male Patients with Type 2 Diabetes Reiko Watanabe*, Nobuyuki Tai, Junko Hirano, Yoshiyuki Ban, Daisuke Inoue, Ryo Okazaki. Teikyo University Chiba Medical Center, Japan

Background & Aim: Type 2 diabetes (T2DM) confers fracture risk. However, the mechanism is not completely understood. Serum levels of sclerositin (Scl), an inhibitor of bone formation, have been shown to be elevated in T2DM, but dependence of Scl levels on glycemic controls is still controversial. We previously reported that obesity, pioglitazone use and systemic inflammation were associated with decreased Trabecular Bone Score (TBS) in a cross-sectional study of 91 Japanese male subjects with T2DM. We present here one-year follow-up data of the same cohort, focusing on Scl. Particularly, we tested a hypothesis that impact of glycemic controls on Sclexpression by osteocytes would require a long period of time, at least longer than a few months sufficient for stabilizing HbA1c.Subject & Method: In this longitudinal study, we recruited 60 Japanese male subjects with T2DM (71.7± 27.3years old, duration: 12.6 ± 9.3years, BMI: 24.8 ± 3.8kg/m2) and measured bone mineral density (BMD), TBS, bone turnover markers, and Scl, inflammatory cytokines at baseline and after one year. Result: HbA1c and Scl levels at baseline were 7.14 ± 1.60%, 53.5 ± 19.5 pmol/L,respectively. Scl levels were significantly decreased (49.3 ± 23.0pmol/ml, p=0.024) and HbA1c levels tended to be decreased (6.77 ± 1.19%) after one year. There was no correlation between each other at either point, although Scl levels positively correlated with BMD as previously reported. Interestingly, however, percent changes in HbA1c significantly correlated with percent changes in Scl levels (r=0.429, p=0.001), probably because individual variations were canceled out in percent changes. And weighted mean (wm) HbA1c for 1 year showed a marginally significant correlation with post Scl levels. Moreover, in multivariate linear regression analysis, wmHbA1c was an independent determinant of post Scl levels besides BMD after adjustment for age and PTH. As for bone parameters, femoral neck BMD T-score was -0.82 ± 0.83(osteoporosis: 3.3%, osteopenia: 33.3%) and TBS was 1.345 ± 0.086 at baseline. And both remained virtually unchangedfor 1 year. We found that the negative correlation of high sensitivity (hs) CRP with TBS at baseline became clearer after 1 year. We also observed positive correlations of wmHbA1c with post TNF- α and hsCRP (p=0.297, r=0.021; r=0.369, p=0.004). Conclusion: The current study demonstrated for the first time that serum Scl levels depend on glycemic controls during a relatively long period of time in T2DM. It may reflect inflammation and other time-requiring processes causing gradually accumulating changes in osteocytes, but further studies will be necessary to establish regulatory mechanism of Scl and its role in bone metabolism in T2DM.

Improvement of the functional status after CT-guided radiofrequency sacroplasty (RFS) and cement sacroplasty (CSP) in patients with insufficiency fractures of the sacrum – a prospective randomised comparison of methods Reimer Andresen*[1], Sebastian Radmer[2], Julian Ramin Andresen[3], Mathias Wollny[4], Urs Nissen[5], Hans-Christof Schober[6]. [1]Institute of Diagnostic and Interventional Radiology/Neuroradiology, Westkuestenklinikum Heide, Academic Teaching Hospital of the Universities of Kiel, Luebeck and Hamburg, Heide, Germany, [2]Centre of Orthopaedics, Germany, [3]Sigmund Freud University, Medical School, Austria, [4]Medimbursement, Germany, [5]Department of Neurosurgery and Spine Surgery, Westkuestenklinikum Heide, Academic Teaching Hospital of the Universities of Kiel, Luebeck and Hamburg, Heide, Germany, [6]Department of Internal Medicine I, Municipal Hospital Suedstadt Rostock, Academic Teaching Hospital of the University of Rostock, Germany

Introduction:The objective of this study was a comparative analysis of RFS and CSP with regard to pain reduction, change in quality of life and possible complications.Material and method:In 100 patients with 32 unilateral and 68 bilateral non-dislocated insufficiency fractures, RFS or CSP was performed after random allocation in 50 patients each. For RFS, the spongious space in the fracture zone was extended using a flexible osteotome. The viscous PMMA, activated by radiofrequency, was then inserted into the fracture zone. Cement augmentation was performed discontinuously with instrumental guidance under CT monitoring. For CSP, the spongious space was extended analogously to RFS. The viscous PMMA was then inserted discontinuously using a pressure gauge. Cement leakages were detected by CT on the first postoperative day. Pain intensity was determined on a VAS before the intervention, on the second day, and 6, 12, 18 and 24 months after the intervention. The patients' self-sufficiency was assessed using the Hamburger-Barthel index. Additionally occurring complications were recorded and the patients were asked to state their satisfaction. Results:RFS and CSP were technically fully feasible in all patients. The average amount of PMMA inserted per fracture was 5.8 ml in the RFS- and 5.2 ml in the CSP group. A leakage was ruled out for the RFS group with 82 fractures treated, 7 leakages were found among 86 fractures treated in the CSP group, while none of the leakages were symptomatic. An interventionally related bleeding or infection was ruled out for all patients. The mean value for pain on the VAS before intervention was 8.8 in the RFS- and 8.7 in the CSP group. On the second postoperative day, there was a significant pain reduction (p<0.0005) with an average value of 2.4 for both groups. After 6 (12; 18; 24) months, these values were stable at 2.3 (2.2; 2.0; 2.3) for the RFS- and 2.4 (2.3; 2.2; 2.4) for the CSP group. The Hamburger-Barthel index increased significantly (p<0.001) from an average of 30 points before the intervention to 80 points on the fourth postoperative day and 70 points 24 months after the intervention. No differences were found between the two procedures with regard to pain reduction, improvement in functional status and satisfaction.Discussion:RFS and CSP are minimally invasive procedures that enable equally good and sustained pain reduction which leads to a marked improvement in the patients' self-sufficiency.

Abaloparatide Increases Bone Formation and Mass in Orchiectomized Male Rats with No Effect on Bone Resorption Heidi Chandler*[1], Daniel Brooks[2], Kenichi Nagano[3], Dorothy Hu[3], Mary Bouxsein[2], Roland Baron[3], Gary Hattersley[1], Beate Lanske[1]. [1]Radius Health Inc, United States, [2]Beth Israel Hospital, Harvard Medical School, United States, [3]Harvard School of Dental Medicine and Harvard Medical School, United States

Male osteoporosis can occur with advanced aging and hypogonadism, which can lead to lower bone formation and higher bone resorption resulting in bone loss and increased fracture risk. Abaloparatide (ABL), a selective PTH1 receptor agonist, increases bone mass and formation with minimal effects on bone resorption. Here we assessed the effects of ABL in orchiectomized (ORX) rats as a model of male osteoporosis. Male Sprague-Dawley rats underwent ORX or sham surgery at 4 months of age. After an 8-week bone depletion period, ORX rats were injected daily (s.c.) with vehicle (Veh) or ABL at 5 (ABL5) or 25 µg/kg/d (ABL25) (n=10/group) for 8 weeks. Sham controls received s.c. vehicle (n=10). Dual-energy X-ray absorptiometry showed that between the pre-treatment baseline (BL) and week 8 of treatment, whole body aBMD increased by 13.8% and 17.3% in the ABL5 and ABL25 groups, respectively, versus 6.3% in Veh controls (both P < 0.001 vs Veh). Lumbar spine aBMD increased by 24.5% and 29.1% in the ABL5 and ABL25 groups, versus 7.6% in Veh controls (both P < 0.001 vs Veh) during the 8 weeks treatment period. ABL5 had lower urine deoxypyridinoline (DPD) levels (-27%, p<0.05) than ORX-Veh rats. ABL25 presented trends for increases in serum osteocalcin levels (+38%) and similar urine DPD levels as ORX-Veh. Micro-CT analyses of distal femurs and vertebrae (L4) showed a significant increase in trabecular bone volume, trabecular number and thickness with a marked decrease in trabecular spacing at both skeletal sites when compared to vehicle (P<0.05 for all). Moreover, cortical thickness and cortical bone area fraction were both significantly higher in ABL25 than in ORX-Veh (p<0.05). Static and dynamic histomorphometry of vertebrae (L5) demonstrated a marked increase in bone formation rate, osteoblast number, and mineralizing surface compared to ORX-Veh. Interestingly, however, osteoclast number was not increased with ABL treatment confirming previous observations that ABL has less bone

resorbing activity in comparison to its effects on bone formation. Our findings suggest that ABL may have therapeutic benefits in men with osteoporosis.

A Bisphosphonate with Low HA-Binding Affinity Prevents Bone Loss after Estrogen Loss and Reverses Rapidly when Treatment Ceases Abigail Coffman*[1], Robert J. Majeska[1], Jelena Basta-Pljakic[1], Mark W. Lundy[2], Frank H. Ebetino[3], Mitchell B. Schaffler[1]. [1]City College of New York, United States, [2]Indiana University School of Medicine, United States, [3]University of Rochester, United States

PURPOSE: Bisphosphonate (BPs) are a mainstay of osteoporosis treatment; however, concerns about bone health due to over-suppression of remodeling remain.1,2 While the concept of a "drug holiday" to restore bone remodeling and improve bone quality seems reasonable, clinical BPs have long half-lives (>1 yr.) due to high hydroxyapatite (HA) binding affinity. This imposes a practical limit to effective drug holiday. Several BPs with low HA affinity (thus rapid biological clearance) and strong FPPS inhibition have not been pursued for clinical use, but offer potential advantages with regard to reversibility. In this study, we tested this concept using NE-580253, a BP with low HA affinity. METHODS: Young adult female C57Bl/6 mice (15 w.o., JAX, n=10/group,IACUC approved) were ovariectomized (OVX) and treated with either NE-58025 (NE-025, 200µg/kg daily,sc), Risedronate (RIS, 2.4 µg/kg4 3x/wk,sc) or PBS vehicle. NE-025 has much lower HA binding than RIS but comparable FPPS-inhibition.3 At 3 mo post-OVX+treatment, half the mice in each group were euthanized. For others, BP therapy was stopped and animals were sacrificed 1 mo later. Femurs were examined by µCT (6.7 µm voxel resolution). We focused on mid-diaphyseal cortex to provide a consistent anatomical location for comparison. Sham, baseline and age matched cage controls were also examined. Comparisons: ANOVA and post-hoc Tukey test; data shown as mean±SD. RESULTS: Total cross-sectional area (T.Ar) was unchanged in all groups. At 3 mo. marrow cavity area (Ma.Ar) in OVX mice increased and cortical thickness decreased by ~10% from baseline. Cortical bone loss was prevented by NE-025 or RIS. At 1 mo after ending treatment, Ma.Ar was unchanged in RIS mice; however, bone loss resumed in NE-025 mice and Ma.Ar was similar to OVX mice at 1 mo. DISCUSSION: Studies revealed that NE-025, a BP with low HA, suppressed OVX-induced cortical bone loss similar to RIS. However, NE-025 suppression of bone loss reversed rapidly after treatment ceased. NE-025 required daily dosing at high concentration to prevent bone loss. While no adverse effects were noted, these studies were of short duration and require follow up. Nevertheless, these proof-of-concept studies reveal that low HA affinity BPs can suppress bone loss and may prove useful as reversible anti-resorptive agents. Denosumab treatment improves health related quality of life in patients with osteoporosis Koji Fukuda*, Shinya Hayashi, Hanako Nishimoto, Yoshitada Sakai, Yasushi Miura, Ryosuke Kuroda, Tomoyuki Matsumoto, Koji Takayama, Shingo Hashimoto. Kobe University Graduate School of Medicine, Japan

Introduction: Improving quality of life (QOL) and prevention of bone fracture are fundamental goals of the treatment for osteoporosis. Several studies have reported the therapeutic benefit of increasing bone mass, via inhibition of bone resorption, in preventing fracture, improving low back pain and QOL among patients with osteoporosis. The purpose of our study was to clarify the therapeutic effect of denosumab treatment in improving the QOL of patients with osteoporosis.Methods: We evaluated 332 patients with osteoporosis over a 24-month period. All patients received a 60-mg dose of denosumab, subcutaneously, every 6 months. Bone mineral density (BMD) of the distal radius was assessed in all patients, with serum concentrations of calcium, phosphate, PINP, and TRACP5b measured in 152 patients. QOL was evaluated using self-reported pain (visual analogue scale) and the EQ-5D questionnaire.Results: Denosumab treatment produced a 3.4% increase, from baseline, in the BMD of the distal radius, at 24 months. Serum levels of TRACP5b and PINP were significantly lower at 6 months, with no effect on calcium and phosphate levels. The average VAS pain score decreased at 6 months, from a score of 3.5 at baseline to 2.7 at 6 months (p<0.001; Figure a). The average EQ-5D utility score increased from 0.57 at baseline to 0.61 at 6 months (p=0.007; Figure b). The correlation between BMD values and the EQ-5D utility score at all time-points of measurements are reported, with a positive significant correlation identified at all time-points, with the exception of 12 months.Conclusions: We demonstrated that denosumab treatment was effective in increasing the BMD of the distal radius and improved the health-related QOL, with the improvement in QOL being associated with increase in BMD. Our findings support the feasibility of using denosumab for the treatment of osteoporosis. Comparative studies against other osteoporosis treatments are needed to identify optimal treatment strategies for osteoporosis.

MON-0947

Multiple spontaneous vertebral fractures only 2 months after a missed dose of Denosumab Sonaina Imtiaz*, Tamara Vokes. University of Chicago, United States

Case Presentation:An 81 year old female presented with sudden onset of back pain and was found to have vertebral fractures at at L4, L3, L2, T12 and T11. She had been on denosumab every 6 months for 7 years during which her BMD increased by 14.3% at the lumbar spine and 11.6% at the total hip. At the time of her last denosumab dose, 8 months earlier her T-scores were -2.3 at the lumbar spine, -2.7 at the femoral neck and -2.0 at the total hip. In addition to denosumab she was taking Vitamin D3 5000 IU daily and 1000- 1200mg of calcium through diet and calcium supplements. She had a history of thyroid cancer post total thyroidectomy more than 60 years ago and was on stable dose of levothyroxine 100 mcg daily for years. She reported no recent weight changes and had not been on steroids. She had no prior history of any fractures and had not received bisphosphonates prior to initiating denosumab. At the time of her presentation with the new vertebral fractures, a marker of bone resorption, serum c-telopeptide (CTx) was remarkably elevated at 1909 pg/ml , serum calcium was elevated at 11.5 mg/dl (previously normal), with normal serum albumin of 4.3 mg/dl, and intact PTH of 25 pg/ml (nl 15- 75 pg/ml). 11 days after receiving the dose of denosumab CTx decreased to 601pg/ml, serum calcium decreased to 9.2 mg/dl and PTH increased to 167 pg/ml.DiscussionBone loss after discontinuation of denosumab has been well documented in the literature, as has the occurrence of the new vertebral fractures. Our case is interesting as it demonstrates that vertebral fractures can occur as early as 2 months after the missed dose. This finding should prompt a greater attention to educating patients and physicians prescribing this medication about the risks of discontinuing denosumab and the importance of timely administration. The other interesting finding in our case if the dramatic increase in bone resorption leading to hypercalcemia with return to normal only 11 days after the administration of the next dose of denosumab and even development of secondary hyperparathyroidism.

MON-0948

Assessing the Ability of Baseline Bone Turnover Markers to Predict the BMD Response for Denosumab Treatment in Patients with Osteoporosis: A Multicenter, Retrospective, Observational Study. Koji Ishikawa*[1], Takashi Nagai[1], Yusuke Oshita[2], Msayuki Miyagi[3], Gen Inoue[3], Takeshi Eguro[4], Kazuaki Handa[1], Tomoaki Toyone[1], Katsunori Inagaki[1]. [1]Department of Orthopaedic Surgery, Showa University School of Medicine, Japan, [2]Department of Orthopaedic SurgerShowa University Northern Yokohama Hospital, Japan, [3]Department of Orthopedic Surgery, Kitasato University, School of Medicine, Japan, [4]Department of Orthopaedic Surgery, Yamanashi Red Cross Hospital, Japan

INTRODUCTION: Several factors including bone turnover markers (BTMs) associated with BMD increase are reported with denosumab treatment. Although BTMs was affected by the prior treatment, there has been no systematic analysis to summarize these associations. The purpose of this study was to investigate the clinical determinants associated with BMD increase to denosumab treatment.METHODS: In total, 1822 patients with osteoporosis treatment were screened from multicenter database. 231 patients with denosumab treatment and complete 12 months follow-up were enrolled. Patients were eligible for the study if they were postmenopausal osteoporosis and BTMs (BAP and TRACP-5b) were evaluated at baseline. Of the initial cohort, 141 of 231 patients (61.0 %) were eligible for this study. To determine the response variables of BMD changes, we investigated the clinical determinants using univariate and multivariate analyses.Results: The LS BMD after 12 months of denosumab therapy showed a 7.0 ± 6.5 (%) increase. The effect of baseline data on LS BMD increase were evaluated by univariate analysis. Baseline ALP, BAP, and TRACP concentration were significantly associated with percent LS BMD response, and strongest with TRACP (r=0.41, P<0.01). In the multivariate regression analyses (which included age, BMI, baseline LS BMD), patients with higher baseline TRACP concentration were significantly more likely to have greater percent LS BMD increase (std β=0.436, P<0.001). To analyze the effect of prior treatment, we examined the relationship between LS BMD increase and BTMs in categorized by prior treatment subgroups. In Naïve group (N=82), positive correlations were observed between BTMs and LS BMD increase [(BAP: r=0.22, P<0.05), (TRACP: r=0.38, P<0.01)]. Interestingly, in Prior Bis group (N=23), positive correlations were observed only between BAP and LS BMD increase. In contrast, in Prior PTH group (N=36), positive correlations were observed only between TRACP and LS BMD increase. CONCLUSIONS: This study examined the relationship between various baseline determinants and LS BMD increase in response to denosumab treatment. Our results showed BTMs were a strong predictor of LS BMD increase. In addition, the present study is the first report to summarize that a bone turnover marker which we should mention at baseline was different according to the prior treatment. We recommend that physicians should keep these results in mind in clinical practice.

An Approach to Defining Bisphosphonate Exposure in Observational Studies Using Pharmacy Databases Monika Izano*[1], Romain Neugebauer [1], Bruce Ettinger[1], Rita Hui[2], Malini Chandra[1], Annette Adams[3], Fang Niu[2], Susan Ott[4], Joan Lo[1]. [1]Division of Research, Kaiser Permanente Northern California, United States, [2]Pharmacy Outcomes Research Group, Kaiser Permanente California, United States, [3]Department of Research & Evaluation, Kaiser Permanente Southern California, United States, [4]Department of Medicine, University of Washington, United States

Purpose: Assigning drug exposure is a necessary first step in examining oral bisphosphonate (BP) treatment in observational studies that use pharmacy data. One approach for assigning drug exposure in each quarter of follow-up is to determine whether drug was received for more than a specified portion of that period, referred to as the proportion of days covered (PDC). In this study we evaluated the extent to which the choice of PDC affects ongoing BP exposure assignment in a population of women who received long-term treatment. Methods: We identified 10,381 Kaiser Permanente Northern California female members who initiated oral BP treatment between 2002-2010 and who received 5 consecutive years of treatment. Women were subsequently followed each quarter for up to five additional years.

A woman was considered "on treatment" in each quarter if she received drug for more than a predetermined PDC based on pharmacy days' supply. Conversely, a woman was considered off treatment if she received drug for less than the PDC. We evaluated the extent to which the choice of three PDC cutoffs (≥0.5, ≥0.6, and ≥0.7) impacts the proportion of women classified as "continuously on" or "continuously off" BP treatment during follow-up. Women in the "continuously off treatment" group were off treatment in the first quarter of follow-up and were followed to see if they remained off treatment in subsequent quarters.Results: Under the 0.5, 0.6, and 0.7 PDC cutoffs, 48%, 43%, and 36%, respectively, were categorized as being continuously on treatment at year 2 of follow-up. Under these same PDC cutoffs, 18%, 14%, and 12% were categorized as continuously on treatment by the end of follow-up (Figure 1). Women who were categorized as continuously off treatment were highly likely to remain off therapy under the same 3 PDC cutoffs: 4%, 5%, 5% were classified as continuously off therapy at year 2 of follow-up, and 4% of women were classified as continuously off treatment by the end of follow-up.Conclusions: In a cohort of women with long-term BP exposure, using various PDC cutoffs somewhat altered the proportions of women considered continuously on, but not off treatment.

Denosumab therapy improved bone mineral density in Japanese geriatric osteoporotic patients previously treated with bisphosphonates Jiro Kato*, Shusuke Ota, Takanobu Doi, Daiki Yonezu, Yasuyoshi Okamoto, Yuji Joyo. Department of Orthopaedic Surgery, Shizuoka Medical Center, National Hospital Organization, Japan

BackgroundDenosumab (DMB), a human monoclonal antibody to receptor activator of nuclear factor kappa B ligand, was approved in 2013 in Japan for osteoporosis. DMB increased bone mineral density (BMD) by inhibition of bone resorption in postmenopausal women with osteoporosis.OBJECTIVE:The aim of this study was to compare the DMB-induced efficacy in BMD and bone turnover markers (BTM) between Japanese geriatric osteoporotic patients who were previously treated with or without bisphosphonates (BP).METHODS:A retrospective chart review was conducted of Japanese elderly osteoporotic patients who start DMB administration (60mg subcutaneously every 6 months) over 2 years. A total of 75 patients were identified (12 males and 63 females; mean age, 80.0±8.1 years) and were measured BMD of lumbar spine (L-BMD) and femoral neck (F-BMD) and BTMs (serum intact type I procollagen N-propeptide (P1NP), serum undercaroxylated osteocalcin (ucOC) and serum tartrate-resistant acid phosphatase-5b (TRACP5b)) every 6 months during the DMB treatments. We divided the patients into 2 groups; naïve group (defined as who were not previously treated for osteoporosis) and post-BP group (defined as who were previously treated with BP), and compare the DMB-induced change in BMD and BTMs.RESULTS: Percent change from baseline of L-BMD significantly increased at 6 months after the treatment in both groups (naïve group; 2.9±5.3%, post-BP group; 2.0±4.0%, P<0.01). F-BMD was delayed in increase at 18 months in both groups (naïve group; 3.2±8.3%, post-BP group; 3.0±4.5%, P<0.05). BTMs were significantly higher levels at baseline in the naïve group than in post-BP group (P<0.05). However, BTMs were significantly reduced at 6 months in naïve group (TRACP5b; 333±150 at 0 month and 285±139MU/dl at 6 month, P1NP; 111±56 and 40±22ng/ml, ucOC; 7.2±8.3 and 3.0±2.7ng/ml at 6 month, respectively, P<0.01) and maintain the suppressive effect until 24 months in both groups.CONCLUSION:DMB treatment was effective in increase of BMD and maintain of BTMs' suppression despite of pre-BP treatment.

Osteoporosis Treatment Rate Following Hip Fracture in a Community Hospital Farhan Tariq*[1], Moin Khan[1], Madiha Tauqir [1], Paul Zalzal[1], Sacha Dubois[2], Rafik El Werfalli[1], Simona Abid [1], Bradley Weening[1], Mark Ginty [1], Hajar Abu Alrob[1], Aliya Khan[1]. [1]McMaster University, Canada, [2]Lakehead University, Canada

Introduction:Hip fractures are associated with significant morbidity and mortality and increase future fracture risk (1). A significant care gap exists with low treatment rates post

hip fracture (1). Meta- analyses evaluated models of care and confirmed their effectiveness in reducing the care gap (2,3).An Orthogeriatric team (OGT) was developed at Halton Healthcare Services in 1992 designed to enable early ambulation, evaluate skeletal health and implement effective therapy for osteoporosis. Study Objectives:Evaluate the effectiveness of the OGT in initiating osteoporosis therapy predischarge in comparison to the usual care by the hospitalist.Methods:A retrospective chart review of all patients over the age of 59 admitted with a hip fracture to HHS from 1 January 2016 to February 1, 2017 was undertaken. Patients with a history of cancer were excluded. A standardized audit form was used to extract patient dataResults and Discussion:196 patients were admitted to HHS following a hip fracture during the study period.The majority of the hip fractures occurred at the femoral neck (43.7%) or intertrochanteric site(35.5%) with 6 atypical femoral fractures (AFF) All AFF patients had been on amino-bisphosphonates (ABP) duration (7yrs- 20yrs). One AFF patient was on ABP for 10 years followed denosumab for 3 years.Of the 196 patients, 134 were seen by the OGT (68.3%)Therapy rates for osteoporosis prior to discharge were 73.1% (98/134) – 21 were referred to the complex osteoporosis clinic for further evaluation (renal osteodystrophy, parathyroid disease or other metabolic bone disease). Definitive therapy was initiated in the complex osteoporosis clinic in all of these patients within 3 months of discharge increasing the treatment rate to 88.8% within 3 months of the hip fracture.62 patients were seen by the hospitalist (31.6%) 1 patient was treated with an ABP predischarge – Two patients had low vitamin D levels and started supplementation. Treatment rates predischarge were 3/62 (4.8%).AFF were uncommon (6/196) at 3% of all hip fractures seen and ABP use was noted in all patients. All AFF patients had thigh or groin pain prior to developing the AFF.Conclusion:OGT intervention was associated with high treatment rates for the underlying osteoporosis of 73.2% pre discharge and 88.8% at 3 months post discharge. Usual care was associated with a low rate of treatment of 4.8% of patients predischarge. Impending AFF may be identified with early imaging of the full femurs in patients on antiresorptive therapy in the presence of thigh or groin pain(4). This study demonstrates the benefit of an OGT in implementing treatment for osteoporosis.References:1 - Khan A, et al. Osteoporosis in menopause. Improvement of anti-osteoporosis medication after multimodal intervention in patients with hip fracture: prospective multicenter study Deog-Yoon Kim*[1], Hyoung Moo P[2], Yong-Chan Ha[3]. [1]Kyung Hee University Hospital, Republic of Korea, [2]Grace Women's Hospital, Republic of Korea, [3]Chung-Ang University, Republic of Korea

Purpose: Previously, from 2008 to 2011, the authors conducted a retrospective cohort study in Jeju Island, where it was found that hip fracture occurred in 945 patients who were over 50 years of age. Among these 945 patients, 344 patients (36.4%) had their bone mineral density tested and 218 patients (23.1%) received osteoporosis medication. The purpose of this study was to determine whether a patient's education program could improve osteoporosis management after hip fracture using the data of this previous study for comparative purpose. Methods: From November 1, 2014 to September 30, 2015, 190 patients with hip fracture who were over 50 years of age who were admitted for hip fractures at six hospitals were enrolled in the present study. During the hopitalization periods, patients underwent education sessions and provided brochures. Patients were evaluated the rate of diagnosis and treatment of osteoporosis at six months after discharge and were followed-up for at least a year.Results: Of 222 hip fractures, 190 patients (37 in men and 153 womens) were enrolled at the six hospitals in 2015. Dual-energy X-ray absorptiometry (DXA) was performed on 115 patients (60.5%) and 92 patients (48.4%) were prescribed medication for osteoporosis at time of discharge. Anti-osteoporosis medication was maintained in 43.7% of patients at 6 months follow-up and 40.2% of patients at 12 months follow-up. Conclusion: This interventional multicenter study demonstrates that patients education program in patients with hip fracture can improve anti-osteoporosis medication and well maintained up to 12 months follow-up.

A retrospective review of initial bisphosphonate infusion in an inpatient vs. outpatient setting for bisphosphonate naïve patients. Rose Kreikemeier*, Eric Rush , Lisa Halbur, Heather Gosnell. Childrens Hospital & Medical Center, United States

BACKGROUND:The purpose of this study was to evaluate the safety and convenience of initial bisphosphonate infusion therapy in inpatient and outpatient settings for patients with low bone mineral density.METHODS:All data were collected from retrospective chart reviews of heterogeneous groups of patients. Abnormal findings prior to the infusion and side effects during the infusion were documented. Patients were contacted following the infusion to discuss post-infusion adverse events.RESULTS:The majority of both outpatients (80%, n=44) and inpatients (50%, n=27) did not experience any adverse events related to the infusion. Some patients reported minor adverse events that were expected. Only one of the inpatients had a severe adverse event (SAE) after the infusion.CONCLUSIONS:For patients at low risk for severe reactions to treatment, the infusion center appears to be a safe and

possibly more convenient treatment setting for both the patient and the hospital, although more expensive for the patient at our institution.

MON-0954

Local Osteo-Enhancement Procedure Increases Femoral Raw Trabecular Bone Score (rTBS) at 5-7 Year Follow-up in Osteoporotic Patients Christophe Lelong*[1], John Stroncek[2], James Howe[2], Bryan Huber[3], Ronald Hill[2], Didier Hans[4]. [1]Medimaps Group Plan-les-Ouates, Switzerland, [2]AgNovos Healthcare, United States, [3]Copley Hospital, United States, [4]Lausanne University Hospital, Switzerland

Osteoporosis is characterized by low bone mass and deterioration of bone microarchitecture leading to increased fracture risk. Trabecular bone scoring (TBS) is correlated with changes in bone microarchitecture and is independent of bone mineral density [Silva BC et al, J. Bone Miner. Res. 2014;29:518]. The AGN1 local osteo-enhancement procedure (LOEP) is a novel, minimally invasive approach intended to strengthen the femur by addressing local osteoporotic bone loss. A triphasic calcium sulfate/calcium phosphate implant material (AGN1) is injected into the proximal femur to be resorbed and replaced with new bone. The purpose of this IRB approved study was to evaluate long-term effects of AGN1 femoral LOEP on hip microarchitecture using TBS. An IRB-approved clinical study enrolled 12 post-menopausal osteoporotic women (mean age 71, range: 59-86 years). The left proximal femur was treated with AGN1 LOEP and the right was the untreated control. Ten patients were available for imaging at 5-7 year follow-up. TRIP software v1.0 (Medimaps) used to analyze the texture of AP x-rays computes a raw TBS (rTBS), similar to the TBS iNsight computes, but with parameters adapted to x-rays. The ellipse-shaped region of interest included the trabecular space from the lateral subtrochanteric region to the femoral neck (Figure 1). There was no significant difference at baseline between treated and control femoral neck aBMD or rTBS. At 5-7 years, AGN1 was completely resorbed and femoral neck aBMD had increased 57.4% in treated compared to control femurs (0.828 ± 0.125 vs. 0.526 ± 0.039 g/cm2; $p < 0.001$). Similarly, rTBS was 48.6% greater in treated compared to control femurs (0.398 ± 0.067 vs. 0.268 ± 0.067; $p < 0.001$) and each individual patient had a higher treated compared to control rTBS. AGN1 LOEP improved femoral neck aBMD with a concomitant increase in femoral rTBS suggesting improved trabecular microarchitecture of the proximal femur. These differences between treated and control femurs suggest that AGN1 LOEP treatment results in bone less prone to fracture and supports performing further analyses during additional clinical use of AGN1 LOEP to reduce osteoporotic hip fracture risk.

Global Development of Bone Health TeleECHO to Improve the Care of Patients with Skeletal Diseases E. Michael Lewiecki*[1], Rachelle Rochelle[2], Matthew F. Bouchonville Ii[2], Avery Jackson[3], Anne Lake[4], John Carey[5], Zhanna Belaya[6], Varta Babalyan[7], Diana Wiluzanski[8]. [1]New Mexico Clinical Research & Osteoporosis Center, United States, [2]UNM Health Sciences Center, United States, [3]Michigan Neurosurgical Institute, United States, [4]Wake Forest University, United States, [5]NUI Galway, Ireland, [6]National Centre for Endocrinology, Russian Federation, [7]Armenian Osteoporosis Association, Armenia, [8]Centroseo - Densitometria Osea, Uruguay

Background. Bone Health TeleECHO (Extension for Community Healthcare Outcomes) was established at the University of New Mexico Health Sciences Center (UNM HSC) through collaboration of the ECHO Institute and the Osteoporosis Foundation of New Mexico. It is a strategy for improving the level of knowledge of healthcare professionals in the care of patients with skeletal diseases. The ECHO model of learning uses videoconferencing to link participants located anywhere there is an electronic connection. Interactive case-based discussions recapitulate familiar learning strategies of postgraduate medical training programs. Since the launch of the first Bone Health TeleECHO, additional programs have been started in other US states and other countries.Purpose. To report progress and challenges in the worldwide development of Bone Health TeleECHO.Methods. Registration of UNM HSC Bone Health TeleECHO participants is processed at the ECHO Institute. Demographic information is collected and participation is logged for each session attended. Other Bone Health TeleECHO programs collect data independently through a variety of methods. Sharing of ECHO experiences occurs through web-based postings, personal communications, quarterly collaborative teleconferences, and periodic live ECHO congresses. Results. The proof-of-concept Bone Health TeleECHO program at UNM HSC was launched on October 5, 2015. Weekly (excluding holidays) videoconferences have been held since that time. Other Bone Health TeleECHO programs are based at locations that include Grand Blanc, Michigan; Washington, DC; Galway, Ireland; and Moscow, Russia. More are anticipated. Challenges for initiating and maintaining these include funding, staffing, recruitment of participants, and bureaucratic barriers.Summary. Bone Health TeleECHO uses state-of-the-art communication technologies to connect participants to a collegial learning environment to advance their level of knowledge, with the goal of making them better equipped to manage patients with bone diseases. It offers educational opportunities with minimal disruption to office routines and relieves professional isolation that commonly occurs in a wide range of practice settings. Through replication and innovation in many global locations, Bone Health TeleECHO leverages scarce resources and expands capacity to provide better bone health care for more patients closer to home, with greater convenience and lower cost than referral to a specialty center.

The Effects of Bisphosphonate at the Nanoscale: Effects on Bone Collagen, Mineral Strain and Collagen-Mineral Interaction Shaocheng Ma*[1], En Lin Goh[2], Angelo Karunaratne[3], Crispin Wiles[4], Yong Wu[4], Oliver Boughton[5], Tabitha Tay[4], John Churchwell[6], Rajarshi Bhattacharya[7], Nick Terrill[8], Justin Cobb[9], Ulrich Hansen[8], Richard Abel[8]. [1]MEng, United Kingdom, [2]BSc, United Kingdom, [3]PhD, MEng, Sri Lanka, [4]MSc, United Kingdom, [5]MBBS, MRCS, BSc, United Kingdom, [6]PhD, MSc, United Kingdom, [7]MBBS, MRCSEd, MRCSGlas, MSc, FRCS, United Kingdom, [8]PhD, United Kingdom, [9]MBBS, MRCS, FRCS, United Kingdom

Introduction Osteoporosis is a metabolic bone disorder characterized by the loss of bone mass. This condition affects 200 million individuals worldwide. Bisphosphonates (BPs) are potent anti-resorptive agents used as the first-line treatment of osteoporosis. In order to further understand the effect of BP on bone mechanical properties, especially at the nano-scale level, the present study aims to investigate and compare the mechanical behaviour of the collagen-mineral matrix under tensile loading between the BP treated bone and controls, using synchrotron small angle X-ray scattering (SAXS) and wide angle X-ray diffraction (WAXD) techniques.MethodsSample PreparationThe tissue samples from patients treated with BP were compared with patients who had not received any treatment for bone osteoporotic disease. Non-fractured cadaveric femoral from individuals with no history of bone metabolic disease were also used as controls. Trabecular bone specimens were sectioned out from a tensile region in each femoral head using a diamond blade cutting saw. The dimension of the rectangular specimens was 12mm in length, 2.8mm in width and 1mm in thickness. In-Situ Tensile TestingThe specimens' SAXS and WAXD spectra were collected while the specimens underwent tensile loading. All specimens were scanned in real-time during tensile testing at 2.5 second intervals. SAXS and WAXD spectra were then used to resolve the structural properties of the collagen fibrils and mineral platelets at the nanoscale. ResultsThe bisphosphonate therapy group exhibited the lowest yield stress point across all

groups, followed by the fracture control and non-fracture control groups, all of which were statistically significant. Correspondingly, the bisphosphonate therapy group demonstrated the lowest fibril and mineral strain, followed by the fracture and non-fracture control groups (Figure 1). Discussion and ConclusionThe present study showed the reduced elasticity and deformability within the collagen-mineral matrix at the nanoscale level in BP treated and untreated fracture groups. Osteoporotic bone has a lower ratio of cross-linked fibrils and mineral content compared to healthy bone. Cross-linking of collagen fibrils provides the viscoelasticity necessary for effective stress distribution. Thus, the structural changes that occur in the organic matrix as part of the osteoporotic process reduce elasticity, increasing risk of fracture.
Figure 1. Overall mechanical characteristics. (a) Overall normalised stress-strain curves are shown for the non-fracture control (NFC), fracture control (FC) and bisphosphonate therapy (BP) groups. (b) Overall fibril-tissue strain curves are shown for the NFC, FC and BP groups. (c) Overall mineral-tissue strain curves are shown for the NFC, FC and BP groups. The shaded area represents the 95% confidence intervals for each group.

A multicenter, randomized, open label, parallel group study to evaluate the efficacy of loxoprofen on acute-phase reactions in Japanese primary osteoporosis patients treated with zoledronic acid Akinori Sakai*[1], Satoshi Ikeda[2], Hidehiro Matsumoto[3], Nobukazu Okimoto[4], Kunitaka Menuki[1], Tomohiro Kobayashi[5], Toru Yoshioka[5], Toru Ishikura[6], Saeko Fujiwara[7]. [1]Department of Orthopedic surgery, School of Medicine, University of Occupational and Environmental Health, Fukuoka, Japan, [2]Department of Orthopedic Surgery, Ken-Ai Memorial Hospital, Japan, [3]Department of Orthopedic Surgery, Sanzai Hospital, Japan, [4]Okimoto Clinic, Japan, [5]Department of Orthopedic surgery, Shimura Hospital, Japan, [6]Department of Orthopedics, Youmeikai Obase Hospital, Japan, [7]Faculty of Pharmacy, Yasuda Women's University, Japan

Background/Purpose: The bisphosphonate zoledronic acid (ZOL) significantly increases bone mineral density and suppresses the incidence of fractures. However, ZOL causes acute-phase responses (APRs) like other bisphosphonates.A very recent 2-year phase III study (ZOledroNate treatment in Efficacy to osteoporosis; ZONE study) carried out in Japan has shown that the incidence rate of drug-related adverse events (AEs) within 3 days after administration of ZOL was 57.4% and that of placebo was 11.7%, whereas APRs were reported in 31.6% of patients treated with ZOL in the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly Pivotal Fracture Trial (HORIZON-PFT). These results indicate that the incidence of APRs is higher in the Japanese populations, compared to other populations. And a sub-analysis of the HORIZON-PFT showed that the incidences of pyrexia and arthralgia in the Chinese population were higher than those in the multinational population, of which 14.2% were Asians. The highest risk of developing APRs was reported even in the non-Japanese Asians and Pacific Islanders.These results indicate that the incidence of APRs is higher in the Asian populations, including Japanese, compared to non-Asian populations. Previous studies have shown that APRs can be managed by treating patients with antipyretic and anti-inflammatory drugs such as acetaminophen and ibuprofen. Methods: A total of 400 patients aged 60 or older were randomly allocated to a ZOL plus loxoprofen group (Z+L group) or ZOL group (Z group) on a 1:1 basis. After the treatment, patients were observed for 7 days, during which patients will record APRs for the first 3 days, and body temperature and drugs taken for 7 days. Primary endpoints are incidence of APRs and increase in body temperature, and secondary endpoints are relationship between prior treatment for osteoporosis in the past 3 years versus incidence of APRs, and that versus a change in body temperature.Results: APRs occurred at a rate of 34.4% in the Z+L group and 47.8% in the Z group (p =0.0109). And the incidence of APRs in patients with prior history of treatment with bisphosphonate is lower than that in naïve patients.Conclusion: Higher incidence of APRs was observed after zoledronic acid infusion in Japanese patients. However, the incidence of APRs decreased treating with loxoprofen after the zoledronic acid infusion, and less occurrence in patients with prior bisphosphonate use. The majority of APRs was also mild, and appeared to be transient.

Anti-sclerostin Antibodies for the Treatment of Osteoporosis: A Systematic Review and Meta-analysis Xerxes Pundole*, Maria Lopez-Olivo, Maria Suarez-Almazor, Huifang Lu. Department of General Internal Medicine, Section of Rheumatology and Clinical Immunology, The University of Texas MD Anderson Cancer Center, United States

Background: Anti-sclerostin antibodies are newer humanized monoclonal antibodies that inhibit sclerostin, with a dual effect on bone, resulting in increased bone formation and reduced bone resorption. We conducted this systematic review and meta-analysis of randomized controlled trials to evaluate the benefits and harms of anti-sclerostin antibodies in the treatment of postmenopausal osteoporosis.Methods: A comprehensive search was conducted in electronic databases of MEDLINE, EMBASE, Web of Science, PubMed, The Cochrane Library, clinical trials registries, and web sites of regulatory agencies until March 26th 2018. Study selection, quality assessment and data collection were done independently by two reviewers. We assessed changes in bone mineral density (BMD), incidence of fractures, and adverse events. We primarily evaluated romosozumab 210 mg every month and blosozumab 270 mg every 2 weeks compared to placebo, other doses and comparisons to other therapies were considered secondary. Results: We included seven studies with 12,745 patients. Six of the included studies evaluated the anti-sclerostin antibody romosozumab and one study evaluated blosozumab. In general, all included trials had a low risk of bias. At 12 months, romosozumab 210 mg every month resulted in significant increases in BMD at the lumbar spine (weighted mean difference (WMD) 12.95; 95% confidence interval (CI) 10.24-15.65), femoral neck (WMD 4.21; 95% CI, 3.32-5.10), and total hip (WMD 4.37; 95% CI, 3.27-5.47) compared to placebo. Similar results were seen at 12 months with blosozumab 270 mg every two weeks at the lumbar spine (WMD 19.30; 95% CI, 16.65-21.95), femoral neck (WMD 5.70; 95% CI, 4.04-7.36), and total hip (WMD 7.40; 95% CI 5.46-9.34) compared to placebo. Romosozumab resulted in lower risk of new or worsening vertebral fractures (risk ratio (RR) 0.29; 95% CI 0.17-0.49), and major osteoporotic fractures (RR 0.60; 95% CI 0.40-0.90) compared with placebo or in comparison to alendronate at 12 months. There were no significant differences in adverse events in patients receiving romosozumab or blosozumab compared to placebo within the 12 month follow-up period.Conclusion: Romosozumab and blosozumab resulted in significant increases in BMD in postmenopausal women with

osteoporosis. Romosozumab also reduced new or worsening fractures and major osteoporotic fractures in comparison to other therapies. Both anti-sclerostin antibodies were generally well tolerated.

Effectiveness of Intravenous Ibandronate on Bone Mineral Density in Patient with Osteoporosis Treated with Oral Bisphosphonate Low-responders -MOVEMENT Study- Hiroshi Hagino*[1], Akinori Sakai[2], Satoshi Ikeda [3], Yasuo Imanishi[4], Hiroshi Tsurukami[5], Satoru Nakajo [6], Naohisa Miyakoshi [7]. [1]Tottori University, Japan, [2]University of Occupational and Environmental Health, Japan, [3]Ken-Ai Memorial Hospital, Japan, [4]Osaka City University Graduate School of Medicine, Japan, [5]Tsurukami Clinic of Orthopedics and Rheumatology, Japan, [6]Nakajou Orthopaedic Clinic, Japan, [7]Akita University Graduate School of Medicine, Japan

ObjectiveBisphosphonates (BPs) have favorable efficacy in increasing bone mineral density (BMD). In some patients, however, increase in BMD may be poor, presumably in part due to interindividual variability in the bioavailability of oral BPs. We evaluated the effectiveness of intravenous (IV) ibandronate (IBN) on BMD in primary osteoporotic patients with no increase in lumbar spine BMD despite oral BPs therapy for 1–3 years. MethodsThe MOVEMENT Study (the effect of MOnthly IBN iV injected on the low-responders to pre-Existing oral BP treatMEnt for to osteoporosis patieNts) is multicenter, interventional, prospective study. This study has two treatment groups as patients treated with IV IBN monthly and oral BPs. Since the dosage form differed between the treatment groups, patients were not randomized to treatment but were allowed to select their preferred dosage form (ie, intravenous or oral), for better patient accrual and prevention of dropouts due to assignment to an undesired dosage form. Patients aged 50 years or older with osteoporosis with no increase in lumbar spine BMD despite oral BPs therapy (with adherence 75% or above) for 1–3 years were eligible. In the IV IBN group, patients received IV IBN monthly. In the BPs group, patients either continued their oral BPs or were switched to another oral BPs.The primary effectiveness endpoint was the percent change in lumbar spine BMD from baseline to 12 months of IV IBN group, and the treatment period was 1-year. The safety endpoint was adverse event and calcium-related laboratory data. ResultsOf 381 patients enrolled from August 2015 to March 2017, 240 and 141 patients treated with IV IBN and oral BPs, respectively. Baseline characteristics were similar between the groups (IV IBN vs BPs: mean age, 74.8±7.6 vs 74.4±7.8 years; female, 95.8% vs 97.2%; and proportion with prior fractures, 44.1% vs 52.5%, respectively). Data from 271 patients (IV IBN, n=164; oral BPs, n=107) who completed the dual-energy X-ray absorptiometry assessment by December 2017 had been locked and tabulated. Positive change has been observed in the interim tabulation of lumber spine BMD in the IV IBN group.No new concerns on safety profiles in both groups were found. ConclusionSwitching to IV IBN (ie, a change in administration route) was suggested to be effective in low-responders to oral BPs. These results support the treatment as one of the new strategy that is expected to be beneficial for BMD as well as for treatment adherence.

A fracture liaison in an orthopaedic office did not improve adherence to treatment for patients with osteoporosis Patricia Seuffert*[1], Carlos A. Sagebein[2], Dorene O' Hara[2]. [1]University Orthopaedic Associates, LLC, United States, [2]UOA, LLC, United States

Introduction: A fracture liaison service has been shown as the most effective intervention for secondary fracture prevention and osteoporosis management. In our orthopaedic practice, we have employed a dedicated fracture liaison to increase patient adherence by arranging for same day DXA scanning at the time of initial evaluation and an endocrinology consult within 14 days. Furthermore, we identified a cohort of patients with osteoporosis or fragility fracture that agreed to endocrinology consultation and adherence to treatment at the time of their initial diagnosis. Our hypothesis was that the patients who specifically agreed to treatment would show a significantly higher adherence rate for treatment. Methods: A total of 443 office patients underwent a DXA scan in our office in 2017. From this group, 42 patients consented to see an endocrinologist within 2 weeks as arranged by the fracture liaison. Patient follow-up continued during the year and adherence to osteoporosis therapy was assessed. Basic demographic data, incidence of fractures and T scores were collected for all patients. For the 42 patients, treatment recommendations and patient decisions regarding treatment were also collected. All data between groups were compared using Student's T test, with a p level of 0.05 considered significant. Results: Of the 443 patients studied in 2017, there were 72 males and 371 females. For the subset of 42 patients studied, there were 8 males and 34 females. Overall, the males were significantly older than the females (72.75

+/- 8.60 vs 69.44 +/- 9.03, p = 0 0085). T scores for the 443 patients were not significantly different overall, -2.11 +/- 1.02 for males, and -2.30 +/- 1.26 for females. Of these patients, 29 did consult with a physician for osteoporosis treatment. Data for the 42 patients is summarized in table 1. Ultimately, only 23 of these patients were adherent with medication treatment recommendations. Reasons stated for non-adherence included planned dental work, apprehension about the medication, advice from friends, and dementia. Conclusion: Despite the implementation of a dedicated fracture liaison, same day in office DXA screening and prompt endocrinology referral, our orthopaedic practice initiative was unsuccessful in optimal patient adherence to osteoporosis treatment. There continues to be significant barriers to treatment despite improved commitment and management of osteoporotic patients in an orthopaedic office.

Table 1 – Referral Group Medication Adherence

Number	Percent	Details
29	74%	Completed referral consultation
29	74%	Medication ordered
11	26%	Did not complete referral consultation
23 of 29	79%	Patients referred, saw physician, taking medication
23 of 42	55%	Those in referral group overall, taking medication

Teriparatide improves healing of medication-related osteonecrosis of the jaw: a placebo-controlled, randomized trial Ie-Wen Sim*[1], Gelsomina Borromeo[2], John Seymour[3], Peter Ebeling[4]. [1]Melbourne Medical School, University of Melbourne, Australia, [2]Eastern Health Clinical School, Monash University, Australia, [3]Department of Haematology, Peter MacCallum Cancer Centre, Australia, [4]Department of Medicine, Monash University, Australia

Medication-related osteonecrosis of the jaw (MRONJ) is an infrequent, but potentially debilitating, condition associated with antiresorptive therapy. Whereas MRONJ incidence can be reduced by optimising oral health, management of established cases remains challenging.We conducted a prospective double-blind, placebo-controlled, randomised trial (ACTRN12612000950864) investigating the efficacy of 8 weeks teriparatide (20µg/day) treatment in 34 participants, with a total of 47 MRONJ lesions. Ten participants had multiple lesions. Most participants had at least moderate severity MRONJ, with 61.8% being stage 2 or 3, ie exposed bone associated with infection and/or complications such as fistulae or fracture. Participants were followed up for 12 months, with primary outcomes including the clinical and radiological resolution of MRONJ lesions. The Oral Health Impact Profile-14 (OHIP-14) questionnaire was used to assess quality of life. Baseline characteristics were similar between groups, with the mean time from MRONJ diagnosis being 12 months. Antiresorptive therapy was indicated for treatment of skeletal-related events in the setting of malignancy in the majority of participants (79.4%).In the teriparatide arm, P1NP increased by 47% (p < 0.001) and fluoride-PET tracer uptake increased by 24% (p = 0.008). 10 of 22 (45.4%) MRONJ lesions in the teriparatide group resolved by 52 weeks compared with 8 of 24 (33.3%) lesions in the placebo group, with a greater rate of resolution of MRONJ sites with teriparatide (OR = 0.15 vs OR 0.40, p = 0.013) (Figure). Bone mineral density and OHIP-14 scores were similar between groups. The incidence of adverse events was low and balanced between groups. Adverse events were mild in severity, including nausea, anorexia and musculoskeletal pain.Therefore, teriparatide improves the rate of resolution of established MRONJ lesions, and represents an efficacious and safe treatment for MRONJ.

Sex and Diet Specific Differences In Bone Mass of 4 Mouse Strains: Can Mice Tell Us What to Eat for Bone Health? Rihana Bokhari*, Peter Schneider, William Barrington, Alyssa Falck, Alexis Mitchell, Shannon Huggins, Diarra Williams, Larry Suva, David Threadgill, Dana Gaddy. Texas A&M University, United States

Diet-induced obesity increases the risk of metabolic disorders and chronic conditions, yet little is known regarding the effects of diet on the skeleton. This study investigated how genetic differences in mice influence skeletal responses to several diets. Starting at 4 wks of age, males and females of 4 genetically distinct inbred mouse strains (A/J (A), C57BL/6J (B6), FVB/NJ (FVB), and NOD/ShiLtJ (NOD) were fed one of 4 diets (Japanese, ketogenic, Mediterranean, and standard mouse chow) ad libitum for 6 months. The diets closely recapitulate human diets, matching macronutrient ratio, fiber content, types of ingredients and fatty acid ratios. At sacrifice tibias were analyzed by microCT. No change was observed in daily activity level across diet within any strain, but sex differences across diets were observed. B6 male mice had at 50-70% greater ($p<0.05$) BV/TV than females on all diets. However, A female mice had 35% greater BV/TV than males, but only on the Mediterranean diet. Dietary differences in BV/TV in males were only observed in B6 mice, where BV/TV was 30-40% greater ($p<0.05$) on the Japanese and Mediterranean diets compared to the standard chow diet. In females, BV/TV was significantly greater (85-90%) in B6 and A mice on the Mediterranean diet compared to those on standard diet. In FVB females, BV/TV was significantly lower (33%; $p<0.05$) on the Japanese diet; no significant differences in BV/TV were observed in NOD females on any diet. Interestingly, both sexes of B6 mice also demonstrated a significant increase in body weight as well as both lean and fat body mass. Collectively, the Mediterranean diet consistently and significantly increased BV/TV, as did the Japanese diet, whereas the ketogenic diet did not increase BV/TV in any strain compared to standard diet. B6 mice of either sex are the most sensitive to dietary changes. Skeletons of NOD mice are the least sensitive to dietary changes, despite the Mediterranean diet inducing significant increases in overall body weight, lean and fat mass. These data indicate that although some strains are more sensitive to dietary interventions, the skeletal response is not uniform between the sexes, demonstrating that care is required in diet selection. Indeed, if similar genetic- and sex-dependent dietary responses exist in humans, then a personalized, or "precision dietetics," approach to dietary recommendations may yield better health outcomes than the traditional one-size-fits-all approach.

Immune system, bone and fat axis: the role of LIGHT/TNFSF14 Giacomina Brunetti*[1], Graziana Colaianni[2], Sara Bortolotti[2], Giuseppina Storlino[2], Adriana Di Benedetto[3], Maria Felicia Faienza[4], Carl Ware[5], Silvia Colucci[1], Maria Grano[2]. [1]Department of Basic and Medical Sciences, Neurosciences and Sense Organs, Section of Human Anatomy and Histology, University of Bari, Italy, [2]Department of Emergency and Organ Transplantation, Section of Human Anatomy and Histology, University of Bari, Italy, [3]Department of Clinical and Experimental Medicine, University of Foggia, Foggia, Italy, [4]Department of Biomedical Sciences and Human Oncology, Section of Pediatrics University of Bari, Bari, Italy, [5]Infectious and Inflammatory Disease Center, Sanford Burnham Prebys Medical Discovery Institute, La Jolla, CA, United States

LIGHT/TNFS14 is a cytokine produced by immune cells. We demonstrated its role in regulating basal and pathological bone remodeling whereas other authors showed its pro-adipogenic role. Based on the cross-talk among immune system, bone and fat, here we investigated whether LIGHT could be a new linker of this interaction. In Tnfsf14-/- mice (KO), in which we proved the reduced trabecular bone, we firstly detected a reduced expression of PPARγ and PCG1alpha, key pro-adipogenic transcription factors, in bone marrow cell extracts. Consistently we detected a lower weight of visceral and inguinal white adipose (iWAT) tissues respect to the WT, suggesting an impairment of adipocyte precursors. Moreover, in the iWAT of KO mice, we detected a lower number of brown adipocytes and lower mRNA levels of Wnt10b, involved in browning response, respect to WT, indicating that LIGHT-deficiency alters the adipose phenotype in addition to the bone one. These effects are mediated by immune cells, indeed, by using Rag-/Tnfsf14-mice lacking mature B/T-cells and LIGHT expression, the levels of PPARγ and PCG1alpha in bone marrow extracts and the number of brown adipocytes in iWAT are rescued respect to KO mice. Consistently, obese children showed higher levels of LIGHT in sera compared to sex and age-matched controls (520 ± 265 ng/ml vs 240 ± 156, $p<0.01$ ng/ml; n=30/group). These findings indicate LIGHT as new linker in immune system/bone/fat cross-talk and a potential target in obesity.

Deletion of CXCL12 in Osteoblasts and Osteocytes Results in Lower Trabecular Bone Volume Chao Liu*, Pamela Cabahug, Shahar Qureshi, Olivia Patton, Cinyee Cai, Alesha Castillo. New York University, United States

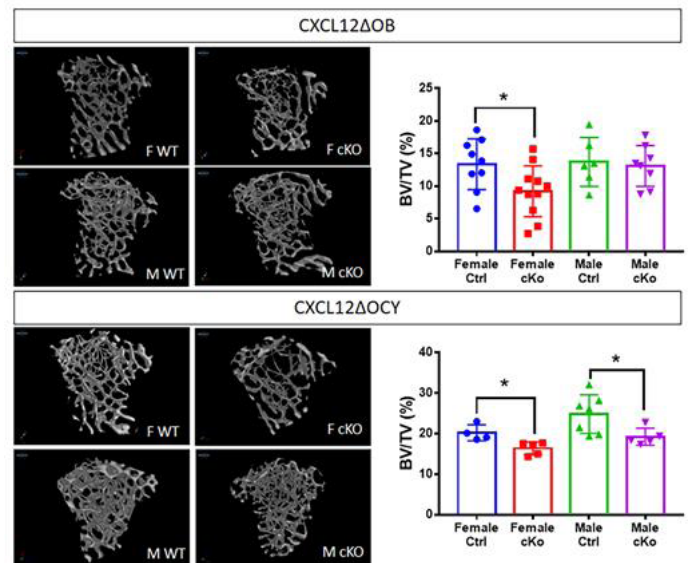
The CXC Motif Chemokine Ligand 12 (CXCL12) is a cytokine expressed in stromal cells [1]. Though it has been shown to be secreted by osteocytes (OCYs) and is a potential control mechanism for bone remodeling[2], whether CXCL12 regulates bone quality and quantity is unclear. Based on the role of CXCL12 in stem cell recruitment and osteogenic differentiation [3], we hypothesized that its deletion in mature osteoblasts (OBs) and OCYs would alter bone structure and whole bone mechanical strength.Adult mice (16-week-old) with a CXCL12 conditional knockout (cKO) in OBs, and consequently OCYs, (CX-CL12ΔOB) and OCYs only (CXCL12ΔOCY) were generated by crossing CXCL12 floxed mice with 2.3 kb Col1a1-Cre transgenic mice or 10kb DMP-1 Cre transgenic mice. CXCL12 deletion was confirmed by qRT-PCR, Western blot and IHC. MicroCT imaging (6 μm voxel) was used to analyze trabecular (Tb) bone structure under the proximal tibial growth plate. Cortical (Ct) bone structure was assessed at mid-length. Biomechanical properties of the femur were measured by 3-point bending.CXCL12ΔOB and CXCL12ΔOCY mice exhibited reduced CXCL12 mRNA (-400%) and protein (-30%). CXCL12 deletion did not affect animal weight. CXCL12ΔOB mice exhibited significantly reduced Tb BV/TV (-31%), Tb.Th (-14%), and resulted in a decreasing trend in Tb.N in female, but not male, mice. CXCL12ΔOCY mice exhibited significantly reduced Tb BV/TV in females (-19%) and males (-23%.). Tb.N was lower in CXCL12ΔOCY females (-19%), but not males, while Tb.Th was reduced in males (-10%) but not females. Ct geometry and bone strength were unaffected by CXCL12 deletion.Considering the high turnover rate of trabecular bone, a reduction in trabecular bone volume in cKO mice under homeostatic conditions suggests that osteoblast- and osteocyte-specific CXCL12 expression plays a role in bone remodeling. This corresponds with previously published work showing that CXCL12 regulates osteogenic differentiation [3]. Though highly expressed in OCYs, DMP-1 is also expressed in stem cells, OBs, and cells in other organs [4], which could cause disparate responses from our two CXCL12 cKO models. Sex-based differences in Tb microarchitecture in both models were unexpected, and additional work is required to examine potential cross-talk between hormonal and CXCL12 signaling.[1]Nagasawa, T. et al., PNAS, 1996 [2]Leucht, P. et al., JOR, 2013 [3]Shahnazari, M. et al., FASEB, 2013 [4] Terasawa, M. et al., 2004.


Figure 1. Trabecular structure in CXCL12ΔOB and CXCL12ΔOCY mice. 3D volumes were reconstructed from microCT images and assessed for bone volume (BV/TV) in a VOI of 1.5 mm under the proximal tibial growth plate. *P < 0.05.

Intra-articular Parathyroid Hormone (1-34) Improved Knee function in Aging-related Osteoarthritis without Affecting Subchondral Bone Chung-Hwan Chen*[1], Ling-Hua Chang[1], Sung-Yen Lin[1], Lin Kang[2], Yi-Shan Lin[1], Shun-Cheng Wu[1], Je-Ken Chang[1], Mei-Ling Ho[1], Shih-Tse Chen[3]. [1]Kaohsiung Medical University, Taiwan, [2]National Cheng Kung University, Taiwan, [3]National Taiwan University Hospital Hsin-Chu Branch, Taiwan

Osteoarthritis (OA) is prevalent in geriatrics and incurable. Intra-articular parathyroid hormone (1-34) improved OA in papain-induced OA model. Subcutaneous PTH (1-34) is a potent agent for osteoporosis treatment and high dose of subcutaneous PTH (1-34) can alleviate OA progression. Thus, we examined the roles of PTH treatment on aging-related OA. The purposes of this study were to study whether PTH can alleviate OA progression

in an aging-related knee OA in Dunkin Hartley (DH) strain guinea pigs. Specifically we set out to determine (1) whether PTH improves knee function; (2) PTH can alleviate OA progression in histological study; and (3) the effects of PTH is related to subchondral bone change or not. Fifteen 6-month-old male guinea pigs were divided into the 9M group (n=7) and the 9M+PTH group (n=8) and twelve 7-month-old male guinea pigs were divided into the 11M group (n=6) and the 11M+PTH group (n=6). The treatment right knees were intra-articular injected with 40μl of 10nM PTH (1-34) or vehicle once weekly for 3 months until 9 month-old at both 9M and the 9M+PTH groups and till 10 month-old at both 11M and the 11M+PTH groups. Another eight 6-month-old guinea pigs and 7-month-old guinea pigs were served as young control groups, 6M and 7M respectively. The time of the guinea pigs can withstand in the treadmill were evaluated before sacrifice. The bone mass of tibia plateaus were analysis by μCT and histological study. PTH (1-34) increased the endurance in the treadmill test and GAG stain. In addition, PTH (1-34) decreased OARSI score and chondrocyte apoptosis rate. In μCT, there was no difference in subchondral plate bone density and trabecular bone volume at metaphysis between control and treatment group both at 9 and 11 months. In this study, we further found PTH (1-34) could improve aging-related OA in guinea pig in histology by increasing GAG and decreasing OARSI score and knee function by increasing the endurance in the treadmill test. Subchondral bone plays a crucial role in the initiation and progression of OA. Previous study showed subcutaneous PTH (1-34) improved knee OA via improving subchondral and metaphyseal bone mass. In this study, we demonstrated low dose intra-articular injection PTH (1-34) improved spontaneous OA via direct cartilage effect rather than subchondral and metaphyseal bone effect.

Bariatric Surgery in mice leads to decreased bone mass over time Katrien Corbeels*, Lieve Verlinden, Matthias Lannoo, Ann Mertens, Christophe Matthys, Annemieke Verstuyf, Ann Meulemans, Geert Carmeliet, Bart Van Der Schueren. KU Leuven, Department of Chronic Diseases, Metabolism & Ageing (CHROMETA), Clinical and Experimental Endocrinology, Leuven, Belgium

BackgroundBariatric surgery has proven to be a valuable treatment option for morbid obesity. However, Sleeve gastrectomy (SG) and Roux-en-Y Gastric Bypass (RYGB) can lead to impaired intestinal absorption of calcium and vitamin D, which may challenge calcium homeostasis and contribute to bone loss. To better understand the alterations in calcium homeostasis and bone metabolism, mouse models of bariatric surgery are used.MethodsC-57Bl/6J mice were fed a high-fat diet (60 kcal% fat) for 14 weeks. Subsequently, sham or bariatric surgery was performed and the diet was switched to a standard diet (5 kcal% fat). Calcium and bone homeostasis was assessed 2 and 8 weeks after surgery. Data are expressed as mean ± SEM.ResultsMicro-CT analysis at 2 weeks after surgery showed no bone loss in SG or RYGB, compared to sham-operated mice. However, 8 weeks after surgery, strong cortical thinning and loss of trabecular bone mass was observed after both SG (0.129 ± 0.003 μm; 2.61 ± 0.29%) and RYGB (0.112 ± 0.004 μm; 2.94 ± 0.42%) compared to sham (0.162 ± 0.003 μm; p<0.0001; 5.22 ± 0.27%; p<0.0001). Examination of dynamic histological parameters of the tibia after 8 weeks, showed a manifest increase in bone formation rate for both SG (0.043 ± 0.010%; p<0.001) and RYGB (0.045 ± 0.004%; p<0.001) compared to sham (0.005 ± 0.002%) Consistently, serum osteocalcin levels were significantly increased 8 weeks after SG (35.4 ± 3.0 ng/ml; p<0.01) and especially after RYGB (60.5 ± 5.4 ng/ml; p<0.0001), compared to sham (22.9 ± 2.1 ng/ml), whereas serum levels for C-terminal telopeptide (CTX) showed no differences between groups. Unexpectedly, no differences in serum levels of parathyroid hormone (PTH) at 2 and 8 weeks or 1,25(OH)2vitaminD3 levels at 8 weeks were found. Nonetheless, gene expression of the calcium transporter calbindin D9K, showed a trend to be increased in jejunum (p=0.08) and kidneys (p=0.05) after RYGB compared to sham. Moreover, after SG, fractional calcium clearance was decreased (p<0.05) compared to sham.ConclusionAfter SG and RYGB, bone mass decreased over time, accentuating the long-term implications of bariatric surgeries. Likely, bone resorption increased early after bariatric surgery and was followed by increased bone formation, which was however, not sufficient to restore bone mass. The unchanged PTH levels further indicate that other mechanisms contribute to bone loss after bariatric surgery.

High Dose Calcitriol Induces Vascular Calcification in Non-CKD Rats Corey Forster*[1], Kimberly Laverty[1], Cynthia Pruss[1], Mandy Turner[1], Rachel Holden[2], Michael Adams[1]. [1]Queen's University Department of Biomedical and Molecular Sciences, Canada, [2]Queen's University Department of Medicine, Canada

Premature mortality in chronic kidney disease (CKD) patients is linked to the progression of cardiovascular disease (CVD). In CKD, marked reductions in the kidneys' ability to excrete excess phosphate and calcium results in extra-osseous mineral deposition, particularly vascular calcification (VC), causing a significant decline in vascular health. Regulation of circulating calcium and phosphate is dependent, in part, on 1,25-dihydroxyvitamin D3 (calcitriol), as well as the signalling molecules parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF-23). Calcitriol, the active form of vitamin D, is made primarily in the kidneys. In CKD, calcitriol production declines generating secondary hyperparathyroidism, a condition which is managed by administering calcitriol or other vitamin D mimetics. However, activation of vitamin D receptors can also lead directly and/or indirectly to the de-

velopment of VC. This study was designed to assess the temporal basis of calcitriol-induced VC in the absence of CKD, as the complex CKD phenotype can confound the profile of VC pathophysiology in the adenine-induced CKD model. The study, in male Sprague-Dawley rats, aged 15-16 weeks, was approved by the Queen's Animal Care Committee in accordance with the guidelines from the Canadian Council on Animal Care. After acclimation, rats were randomly sorted into either a subcutaneous (n=8) or an intraperitoneal injection group (n=5). Of these rats, one group received 1.0% dietary phosphate (n=10) while a second group received a 0.5% phosphate diet (n=3). After 72 hours on their diets, calcitriol was administered daily (0.5 or 1μg/kg dose) for 8 days. Daily blood samples were taken to monitor changes in biomarker profiles. At the end of the treatments, all animals were sacrificed and tissues were collected to determine vascular mineral content, serum hormone levels and vascular histology. Animals who received 8 doses, regardless or injection method, dose, or dietary phosphate all developed VC. The development of VC was associated with hypercalcemia, however, elevations in serum phosphate did not occur in these animals. Animals who received fewer than 8 doses did not develop VC, but were found to be hypercalcemic. The mechanisms responsible for the development of VC have not been fully elucidated. Characterizing calcitriol-induced VC in the absence of CKD will enable insight into the mechanisms involved as well as provide the basis for improved therapeutic strategies.

Treatment with LpPLA2 inhibitor reduces osteopenic bone loss in diabetic and hypercholesterolemic pig model. Theresa Freeman*. Thomas Jefferson University, United States

Diabetes mellitus type 2 (DM II) affects 18.2 million Americans and can cause several chronic and morbid adverse effects on patient health. Further complication occurs when this disease is accompanied with high cholesterol. Diabetes and high cholesterol results in the oxidation of the low density lipoprotein (LDL) on "bad" cholesterol. Oxidized LDL is the hydrolyzed by lipoprotein-associated phospholipase A2 (Lp-PLA2) to produce lysophosphatidylcholine (LysoPC) and oxidized nonesterified fatty acids. Lp-PLA2 is associated with coronary heart disease. Interestingly vascular calcification is inversely related to bone loss. Inhibition of Lp-PLA2 reduces vascular calcification in a diabetic and hypercholesterolemic (DM-HC) pig model so the aim of our study was to determine if treatment with an Lp-PLA2 inhibitor would also rescue the bone loss observed in this model.Male Yorkshire domestic farm pigs were induced to develop diabetes with a single intravenous injection of 125 mg kg–1 of streptozotocin and fed a hyperlipidemic diet to achieve hypercholesterolemia. One month after DM-HC induction, one group was orally with Lp-PLA2 inhibitor darapladib. After 28 weeks, the pigs were sacrificed and whole knee joints were collected according to IACUC approved procedures. MicroCT, histology and immunohistochemistry were performed.Bone loss was observed in the microCT analysis of trabecular bone of the femur from the DM-HC pigs when compared to non-diabetic, normal chow fed control pigs. Treatment with the Lp-PLA2 inhibitor, darapladib significantly reduced the amount of bone loss. Histology showed abnormal pathology in the bone marrow surrounding the trabeculae, and this was also reduced in the treated pigs. TUNEL analysis of the histology sections revealed increased apoptosis in the trabecular osteoblasts was decreased in the treated pigs. In vitro, in the presence of LysoPC osteogenesis resulted in decreased alizarin red staining.Taken together these results show DM-HC has an osteopenic effect on trabecular bone which may be rescued to some extent by treatment Lp-PLA2 inhibitor. An increase in LysoPC can slow bone mineralization, increase osteoblast apoptosis and alter the bone marrow niche. Chronic diabetes is known to cause multiorgan failure via microvascular and macrovascular damage and may possibly exacerbate this problem. Our laboratory has launched an extensive series of experiments to delineate the potential cellular mechanism for these phenomena.

MON-1008

Combined Caloric and Dietary Protein Restriction Has a Synergistic Negative Impact on Bone Mass Ke-Hong Ding*[1], Tianyang Guo[1], Jianrui Xu[1], Qing Zhong[1], Wendy Bollag[1,2], Meghan Mcgee-Lawrence[1], William Hill[1,2], Xing-Ming Shi[1], Mohammed Elsalanty[3], Sadanand Fulzele[1], Beom-Jun Kim[4], Mark Hamrick[1], Carlos Isales[1]. [1]Medical College of Georgia, United States, [2]Charlie Norwood VA Medical Center, United States, [3]School of Dental Medicine, United States, [4]University of Ulsan College of Medicine, Republic of Korea

Both caloric restriction (CR) and dietary protein restriction (PR) have health benefits including lifespan extension in animal models. However, there is concern that dietary restrictions may lead to bone and muscle loss in the elderly. We recently published that selective amino acid supplementation, particularly with aromatic amino acids (phenylalanine, tyrosine and tryptophan; PTT) prevents bone loss in mice fed a PR diet. Previous studies however have not examined the impact of a combined CR and PR diet on bone health. This dietary combination occurs regularly in the institutionalized elderly patient resulting in frailty. The present IACUC-approved study compared the effects of restricted (8%) vs. standard (18%) dietary protein with or without added caloric restriction (25% total caloric intake reduction) and selected amino acid supplementation on bone mass. To test this, we fed mice (6-month-old male C57BL/6 mice N=8/group) specified diets for eight weeks. Bone was analyzed by densitometry (DXA) and serum markers of bone turnover (PYD). Histology and microCT studies are ongoing. Groups were: (1) standard dietary protein (PS); (2) 18% dietary pro-

tein + CR (PS+CR); (3) restricted (8%) protein (PR); (4) PR+CR; (5) PR+CR+amino acids PTT. All data are presented as Mean±SD below. We found that CR, but not PR, resulted in decreased body weight: (31.8+3.2 PS vs. 26.9+1.5 PS+CR, p<0.002, and 32.2+2.9 PR vs. 24.2+1.9 g PR+CR, p<0.0001; grams). Neither CR nor PR itself decreased total BMD: 0.055+0.002 PS vs. 0.055+0.001 PS+CR vs. 0.055+0.001 PR, g/cm^2). However, the combination of CR and PR resulted in a significant drop in total BMD: 0.055+0.002 PS vs. 0.053+0.002 PR+CR; p<0.0027; g/cm2). In contrast, the addition of aromatic amino acids to the PR+CR group prevented the drop in total BMD: 0.053+0.002 PR+CR vs. 0.054+0.001 PR+CR+PTT, g/cm^2). Markers of bone breakdown (PYD) were highest in mice on a low protein diet; the combination of CR and PR suppressed resorption activity, but PTT restored resorption activity (1.72+0.23 PS vs. 2.10+0.28 PR vs. 1.55+0.41 PR+CR vs. 2.17+0.39 PR+CR+PTT; p<0.01 PS vs. PR; p<0.007 PR vs PR+CR; p<0.008 PR+CR vs PR+CR+PTT; nmol/L). Taken together these data suggest that the combination of CR+PR has a detrimental effect on bone health by suppressing bone turnover, but selective amino acid supplementation can prevent the negative impact CR and PR have on bone health.

MON-1009

Repurposing PDE5 Inhibitors for Osteoporosis – Erecting Bone Se-Min Kim*, Li Sun, Lubna Munshi, Tony Yuen, Mone Zaidi. Icahn School of Medicine at Mount Sinai, United States

Purpose Nitric oxide (NO) plays an important role in skeletal homeostasis. NO-cGMP-PKG pathway mediate anabolic effects of mechanical stimuli and estradiol.In vivo studies using direct NO donor and soluble guanylate cyclase demonstrated therapeutic potential for osteoporosis. However, the role of cGMP-specific phosphodiesterase (PDE) in skeletal health is not clear. In this study, we hypothesize that widely used cGMP specific PDE5 inhibitors – tadalafil and vardenafil – have anabolic skeletal effect.Methods 14-week-old C57BL/6 mice were treated with DMSO (vehicle), tadalafil (48 µg/day), or vardenafil (240 µg/day) intraperitoneally for 6 weeks. This dose corresponds to 10 mg tadalafil and vardenafil in human. aBMD was measured using DXA (Piximus, Lunar-GE). Microtomography (Desktop CT40, SCANCO) and dynamic histomorphometry (Zeiss Observer) were performed. Affymetrix gene chip array was carried out to examine the expression of cGMP-specific PDE5, PDE6 and PDE9 in non-transformed mineralizing osteoblasts, human CD14+ cells, and osteoclasts. Comparisons used 1-way ANOVA with Bonferroni's correction or 2-tailed Student's t-tests. Results aBMD at all sites was significantly increased in tadalafil- and vardenafil-treated mice compared with vehicle-treated group. vBMD was also significantly increased in drug-treated mice, especially with tadalafil (~4 fold). Vardenafil-treated mice showed modest vBMD gain. Dynamic histomorphometry demonstrated increased mineralizing surface (MS) and bone formation rate (BFR) in both groups, while osteoclast surface was decreased in tadalafil-treated mice only. Microarray data showed selective expression of PDE5A in non-transformed human osteoblasts. PDE6D, but not PDE6A, the main subunit of holoenzyme PDE6, was expressed in osteoblasts and osteoclasts. Conclusions Our findings suggest that blocking cGMP-specific PDE5 have anabolic effect in bone. The additional bone gain in tadalafil over vardenafil could be the result of additional anti-osteoclastic effects. Since we did not find PDE5 expression in osteoclasts, we postulate that the specificity of PDE inhibition of tadalafil (PDE5 and PDE11) and vardenafil (PDE5 and PDE6) may explain the finding. Furthermore, widely expressed PDE6D, unlike the other PDE6 subunits, regulates prenylated-protein, and may play a role in osteoclast activation independent of the NO-cGMP-PKG pathway.

Apolipoprotein A-I Prevents Osteoporosis and Promotes Osteogenesis of Mesenchymal Stem Cells via STAT3 and CXCL6/8 Yu-Chuan Liu*, Jean Lu. Genomic Research Center, Academia Sinica, Taiwan

ObjectivesBone integrity is maintained by continuous remodeling, which consists of bone formation by osteoblasts and bone resorption by osteoclasts. Osteoporosis, a severe public issue, resulting from bone resorption predominates over bone formation. Currently, most of osteoporosis treatments function by suppressing bone resorption; on the contrary, fewer drugs are designed to promote bone formation. In addition, these treatments may have several side effects, like increasing risks in cancer or cardiovascular disease. Therefore, we want to identify potential new drug for osteoporosis.MethodsWe utilized high throughput screening in human bone-marrow mesenchymal stem cells with 12380 human open reading frame (ORF) clones and identified novel regulators in promoting osteogenesis by means of increasing alkaline phosphatase activity and matrix mineralization. Moreover, we also performed ovariectomy surgery to define the function of candidate genes in mouse osteoporotic model.ResultsBy gain-of-function screen, we demonstrated that apolipoprotein A-I (ApoA-I), the major protein component of high-density lipoprotein (HDL), could promote osteogenesis of mesenchymal stem cells. Overexpression ApoA-I in the transgenic mice could prevent bone loss in ovariectomy-induced osteoporosis through increasing osteoblast numbers and decreasing osteoclast numbers concurrently, while ApoA-I induced by bromodomain inhibitor I-BET151 in ovariectomized mice could also cure bone loss as well. Interestingly, two chemokines, chemokine (C-X-C motif) ligand (CXCL) 6, and 8 are significantly enhanced by ApoA-I through STAT3 activation. In addition, the inhibition in STAT3 activation or CXCL6/CXCL8 expression blocked ApoA-I-mediated osteogenesis, while

overexpression of CXCL6 promoted osteogenesis.Summary & ConclusionOur results indicate that ApoA-I promotes osteogenesis as a positive regulator in bone formation and offer anabolic and catabolic effect on bone remodeling through increasing osteoblast numbers and decreasing osteoclast numbers simultaneously. Importantly, ApoA-I was reported to block tumor formation and treat cardiovascular diseases. Thus, our findings may support ApoA-I as a potential target to prevent or treat osteoporosis with fewer side effects in the future.

Butyrate Mediates The Bone Anabolic Activity Of The Probiotic L. rhamnosus GG Via A Regulatory T Cell Mediated Pathway Abdul Malik Tyagi*, Mingcan Yu, Trevor M. Darby, Chiara Vaccaro, Jau-Yi Li, Joshua A. Owens, Emory Hsu, Jonathan Adams, Rheinallt M. Jones , Roberto Pacifici. Emory University, United States

Probiotics are defined as viable microorganisms that confer health benefits. The most common genus of bacteria with probiotic activities are lactobacilli. Lactobacilli prevent ovariectomy induced bone loss by decreasing bone resorption, but the effects of probiotics in eugonadic conditions and their mechanism of action are largely unknown. To investigate this, 10-week-old conventionally raised (Conv.R) mice were treated for 4 weeks with vehicle or the probiotic L. rhamnosus GG (LGG) at a dose of 1 X 109 total bacteria 5 times/week. In vivo and in vitro µCT measurements revealed that LGG markedly increased bone volume (BV/TV) by stimulating bone formation. By contrast, LGG was ineffective in germ-free mice, demonstrating that LGG acted in cooperation with the gut microbiota. LGG produces lactate, which expands clostridia, a genus which produces bone active short-chain fatty acids (SCFAs). Accordingly, LGG supplementation increased intestinal and serum levels of the main SCFA butyrate. Attesting to the mechanistic role of butyrate, direct feeding of butyrate increased BV/TV and bone formation as potently as LGG. Neither LGG nor butyrate affected bone resorption. SCFAs are potent inducers of regulatory T cells (Tregs). Accordingly, both LGG and butyrate increased the differentiation of naive CD4+ T cells into Tregs in the bone marrow (BM). In turn, Tregs induced the release of the osteogenic Wnt ligand Wnt10b by BM CD8+ T cells. Wnt10b caused the activation of Wnt signaling in osteoblastic cells, leading to increased bone formation. Attesting to the relevance of Wnt10b, LGG and butyrate were ineffective in mice lacking CD8+ T cells production of Wnt10b. Demonstrating the role of Tregs, blockade of Treg expansion in two established in vivo models prevented the bone anabolic activity of LGG and butyrate. Mechanistically, LGG and butyrate increased Treg TGFβ expression, which activates SMAD signaling in CD8+ T cells. Moreover, Tregs activated NFAT signaling and blocked AP-1 activation in BM CD8+ cells, thus favoring the binding of NFAT/SMAD dimers to a critical NFAT/SMAD-activated promoter site that stimulates Wnt10b gene expression in CD8+ T cells. In summary, the probiotic LGG is a potent bone anabolic agent that stimulates bone formation via a butyrate/Treg/Wnt10b dependent pathway. Nutritional supplementation with butyrate may provide a novel therapeutic strategy for increasing bone mass and preventing osteoporosis.

Influence of a 17β-hydroxysteroid dehydrogenase type 2 (17β-HSD2) selective inhibition on ovariectomy induced bone loss in Wistar rats Sebastian T. Müller*[1], Sophie Pählig[1], Ahmed Merabet[2], Chris Van Koppen[3], Sandrine Marchais-Oberwinkler[2], Rolf W. Hartmann[3], Oliver Zierau[1], Günter Vollmer[1]. [1]Technische Universität Dresden, Molecular Cell Physiology and Endocrinology, Institute for Zoology, Dresden, Germany, [2]Institute for Pharmaceutical Chemistry, Philipps University Marburg, 35032 Marburg, Germany, [3]Pharmaceutical and Medicinal Chemistry, Saarland University, Campus E8.1, 66123 Saarbrücken, Germany

Osteoporosis is a major healthcare factor with an important socio-economical impact. Direct costs of osteoporosis related fractures increase up to ~76.7 billion Euros in Europe in 2050. Estrogens, most notably estradiol (E2), play a major role in bone health. Therefore, postmenopausal women are a high-risk group because of their hypoestrogenemia. Hormone replacement therapy (HRT) is the "Gold Standard" for bone protection. However, side effects (e.g. increased risk of breast cancer or thrombosis) are controversially debated. Other currently available therapies like bisphosphonates or selective estrogen receptor modulators (SERMs) show a reasonable efficacy, but all have limitations and side-effects. Consequently, additional therapeutic approaches to treat osteoporosis are needed.The 17βHydroxysteroid dehydrogenase type 2 (17βHSD2) is expressed in a variety of tissues (e.g bone) and catalyzes the oxidation of E2 into the less potent estron (E1). Inhibition of 17βHSD2 should ideally increase E2 levels in tissues expressing the enzyme but impact on systemic E2 levels.Currently, only one animal experimental study about 17βHSD2 inhibition and bone protection is available. However, the inhibitor used in this study was less potent and more limited in bioavailability than the inhibitor available to us. Within our study, we test for the first time the 17βHSD2 inhibition in the rat model of ovariectomy induced bone loss. In order to identify bone sparing effects, we analyzed several bone parameters (e.g. BV/TV, Tb.N., Tb.Th. and, Tb.Sp. based on µCT and histology of the tibia). To evaluate the safety of a 17βHSD2 inhibition we analyzed uterine parameters on tissue, protein and mRNA level. Regarding bone, three out of four µCT parameters (BV/TV, Tb.N. and, Tb.Sp.) showed a significant bone

Monday Posters

protective effect by 17βHSD2 inhibition compared to the ovx control. No significant effects could be observed for the other bone parameters. For the uterus no significant estrogenicity caused by the 17βHSD2 inhibition could be observed. As a proof of principle evaluation, our data indicates that 17βHSD2 inhibition might be a new and promising approach to prevent osteoporosis.

Bilateral Distal Femoral Epiphyseal Defect Models for Safety Testing: A 5-Week Rat Bone Healing Study Luis Fernando Negro Silva*[1], Julius Haruna[1], Pritpal Malhi[1], Simon Authier[1], Yannick Trudel[2], Raluca Kubaszky[1], Michel Assad[2]. [1]Citoxlab North America, Canada, [2]AccelLAB Inc., Canada

Low trauma fractures represent clinical complications from our aging society. Most fractural injuries are known to occur in long bones with inevitable consequences such as pseudoarthrosis and relatively high non-union rates. In the last 20 years, substantial efforts in the field of biomechanical and biomaterials research have been devoted to the development of synthetic osteoconductive graft substitutes for tissue engineering in presence (or not) of drug-eluting therapeutic agents with osteoinductive and antimicrobial properties to respectively improve bone healing and prevent iatrogenic infections. In toxicology, the rat is the most frequently selected rodent model to investigate drug safety, but scarce data is available relative to the use of this murine species in orthopedic models. Following an IACUC-approved protocol from an AAALAC-accredited institution, eighteen (18) female Sprague-Dawley rats were used to evaluate if 2-mm critical-size defects in distal femoral condyles were adequate for toxicology evaluation of drugs with potential impact on bone remodeling. Under anesthesia, both hindlimbs were prepped and draped in sterile fashion. Then, bilateral cylindrical defects of 2x5mm (DxL) were created in distal femoral condyles. Per-op and terminal digital radiography was performed on all femurs. Then, at 5 weeks post-op, all femoral defect sites were harvested, decalcified, and embedded in paraffin. Central longitudinal histological sections were then taken from the bone defect site and prepared for microscopic examination following H&E and Goldner's Trichrome staining. Histopathology scoring was performed on the quality of new bone formation, while the extent of new bone formation was quantified by histomorphometry (Table 1). Regardless of treatment, all defect sections demonstrated significant bone remodeling characterized by the repair of the cortical bone and an ingrowth of bony trabeculae consisting of a mixture of woven and lamellar bone. These results demonstrate that creating a 2-mm long-bone defect enables evaluation of potential drug effects on bone healing in toxicology. In contrast, a 2-mm femoral epiphyseal defect will not be considered a critical-size defect in the rat long bone, but larger defects (ex. ≥ 3mm) may further be explored for this purpose. When this is met, this murine femoral defect model may then represent a promising one to evaluate the superiority of new bone substitutes with osteoconductivity and osteoinductivity properties.

Table 1: Quantification of bone ingrowth

Prevention of spaceflight-induced Osteoarthritis: a potential dietary countermeasure Elizabeth Blaber*, Ann-Sofie Schreurs. NASA USRA, United States

Current treatments against spaceflight-induced bone loss provided to Astronauts are not without limitations. Most of the current treatments against osteoporosis are anti-resorptive, but few act to prevent resorption and increase bone formation simultaneously. Spaceflight is a combination of multiple factors including microgravity, in addition to space radiation. Therefore, we conducted studies to determine if our potential dietary countermeasure could prevent simulated spaceflight (simulated microgravity and radiation combined) bone loss. Mice were exposed to gamma (TBI, 137Cs, 2 Gy), simulated microgravity (using the hindlimb unloading system, HU) or TBI+HU. While we observed bone loss in mice fed the control diet due to both treatments (TBI=14%, HU=20%), and a worse effect with combined treatments (TBI+HU=25%), mice fed the countermeasure diet did not sustain significant bone loss relative to untreated controls. The countermeasure prevented microarchitectural decrements in both appendicular bone (tibia) and axial bone (vertebrae). In parallel, space-flown mice exhibited a novel and severe disruption of the epiphyseal boundary, resulting in

endochondral ossification of the femoral head and perforation of articular cartilage by bone. This suggests that spaceflight in microgravity may cause rapid induction of an aging-like phenotype with signs of osteoarthritic disease in the hip joint. Taken together, femurs from mice exposed to spaceflight onset of an accelerated aging-like phenotype with signs of osteoarthritic disease shown by disruption of the epiphyseal boundary and endochondral ossification. We plan to determine if the countermeasure also prevents the OA phenotype observed in the mice exposed to simulated spaceflight (HU+IR).

Anatomic Deconvolution of Vascular and Osteoanabolic Responses in Osseointegration Kathleen Turajane*[1], Ed Purdue[1], Gang Ji[1], Ugur Ayturk[1], Matthew Greenblatt[2], Xu Yang[1], Mathias Bostrom[1]. [1]Hospital for Special Surgery, United States, [2]Weill Cornell Medical College, United States

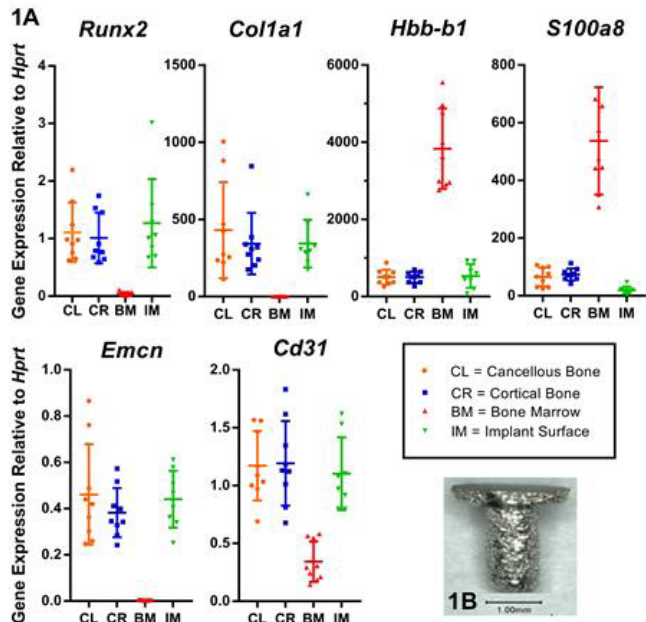
Purpose: The number of total joint replacements (TJRs) performed in the United States is over 1 million per year. Cementless TJRs provide better long-term fixation than conventional cemented implants. Higher failure rates in total knee replacement caused by implant loosening due to deficient osseointegration between bone and implant remains a major clinical problem. To address this problem, we need a better understanding of the molecular mechanisms of osseointegration. Here, we have performed gene expression analysis of tissues in different anatomic subdomains at the bone-implant interface in our mouse model of tibial implant osseointegration (Yang et al., 2015).Method: A titanium implant (Fig 1B) was inserted into the right proximal tibia of 16-week female mice. At 1 week post-surgery, the implant (with attached tissue) was removed from the tibia. Then, the tibia was centrifuged to isolate bone marrow. Cancellous bone was separated from the cortical bone using a 1mm biopsy punch. Bone and implant samples were homogenized separately (Kelly et al., 2014). Following total RNA extraction, samples were evaluated for RNA yield and quality. Subsequently, transcripts associated with osteoblasts (Runx2 and Col1a1), bone marrow cells (Hbb-b1 for erythrocytes and S100a8 for immune cells), and endothelial cells (Emcn and Cd31) were examined with real-time RT-PCR.Results: The RNA integrity assessment confirmed the feasibility of obtaining high quality RNA from the implant-bone interface for mRNA expression analysis. The real-time PCR analyses revealed that our approach was successful in separating bone marrow from the bone and implant (Fig 1A). Importantly, the abundance of osteoblast-associated genes (Runx2 and Col1a1) transcripts on the implant surface suggested the presence of osteoblasts. Intriguingly, the enrichment of endothelial cell markers in multiple anatomic regions demonstrated that active angiogenesis occurs in both bone and the implant interface simultaneously.Conclusion: We have developed a reproducible method to evaluate important subanatomical locations of osseointegration. Preliminary gene expression analyses support the involvement of angiogenesis and osteoblast activity directly at the bone-implant interface in total knee replacements. These findings demonstrated that our mouse implant model will be a viable platform for studying the molecular mechanisms of implant osseointegration.


Figure 1A: The real-time RT-PCR analysis of transcripts associated with osteoblasts (*Runx2, Col1a1*), red blood cells and marrow cells (*Hbb-b1, S100a8*), and endothelial cells (*Emcn, Cd31*) in cancellous bone (CL), cortical bone (CR), bone marrow (BM), and bone implant surface (IM). Measurement of lipid metabolites in a mouse model of breast cancer using imaging mass spectrometry shows specific signals linked to CYP27B1 gene ablation Mengdi Xing *[1], Jiarong Li[1], Ethan Yang [2], Pierre Chaurand [2], Richard Kremer[1]. [1]RI MUHC, Canada, [2]University Montreal, Canada

Vitamin D is known as an essential regulator of bone metabolism through the regulation of calcium and phosphate homeostasis. However, it has become clear that vitamin D and its active metabolite 1,25(OH)2D have many extra skeletal actions such as the regulation of glycemic control and lipid metabolism. The most abundant circulating form of vitamin D, 25(OH)D, is converted to its metabolically active form 1,25(OH)2D in both kidney and extrarenal tissues such as breast by the enzyme 1-α-hydroxylase, which is encoded by gene CYP27B1. Previous study in our group has shown that vitamin D can control fat distribution, and fat accumulation in breast promotes breast cancer. Thus, a PyMT mouse model of breast cancer has been established with the conditional knockout of CYP27B1 that could locally inhibit the production of 1,25(OH)2D in breast. The purpose of this study is to investigate the effect of locally produced 1,25(OH)2D in mammary glands on breast tumor progression by comparing the lipid profile and phospholipid expression in breast tumor tissues with/without 1,25(OH)2D production by imaging mass spectrometry (IMS).A PyMT mice model has been used with the conditionally knockout of CYP27B1, which produces knockout breast tumor (without 1,25(OH)2D production) and wild type breast tumor (with 1,25(OH)2D production). Tumors were collected at different time points, which are hyperplasia (32-34 days), adenoma (7 weeks), and late stage (11 weeks) respectively (n=8 at each time point). Lipid profiles and images were compared across cohorts and time points. Serial sections were cut and stained to validate histology and align with IMS results and to ensure tissue quality.Segmentation of the IMS results allowed to accurately define the different histologies present with the tumors (hyperplasia, tumors, and adipose stroma) at the various time points. Interestingly, several lipid signals (for example, m/z 942.8, m/z 650.83, m/z 884.1, etc) absent (or expressed in lower abundance) in hyperplasia and adenoma stages have been found differently expressed in late stage tumorous tissues. However, the relative abundance of these appeared significantly higher in KO tumorous tissue. In contrast, there are lipid signals (such as m/z 1071.4) have been found abundant in hyperplasia and down regulated with tumor progression.Our study suggests a mechanistic link between vitamin D activation in breast tissue, lipid signals and tumor progression.

Argentina, Argentina, [3]Cátedra de Nutrición. Facultad de Farmacia y Bioquímica – UBA, Argentina

The galactooligosaccharides (GOS) are bioactive carbohydrates present in human milk. GOS could incorporated in dairy products, such as yogurt, from enzymatic action of ß-galactosidase on the milk lactose. Its consumption changes the gut microbiota composition which release several metabolites that could improve calcium absorption (CaAbs) and bone health. We evaluated the prebiotic effect on CaAbs of a yogurt containing GOS during normal growth. Male weaning Wistar rats (n=10 per group) received during 30 days AIN´93-G control diet (CD) or diet based on the yogurt containing GOS (ED), and calcium (Ca) and protein according to AIN´93-G. Food consumption was evaluated three times per week; body weight (BW) and faecal Lactobacilli (LB) colonies weekly; CaAbs during the last 3 days of the experience and caecal pH and short-chain fatty acid (SCFAs) at the end of the study. Result as mean±SD. No differences in food consumption and BW were found (16.6±2.7 vs. 16.4±0.6 g and 229±13 vs. 214±5 g, respectively). ED compared to CD group showed an increased in faecal LB colonies (p

Engineering Dual-Specific M-CSF Antagonists That Inhibit c-FMS And αvβ3 Integrin As Anti Resorptive Compounds Yuval Zur*[1], Lior Rosenfeld[1], Gali Guterman-Ram[2], Niv Papo[1], Noam Levaot[2]. [1]Department of Biotechnology Engineering and the National Institute of Biotechnology in the Negev, Ben-Gurion University of the Negev, Beer-Sheva, Israel, [2]Department of Physiology and Cell Biology, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Excessive and uncontrolled bone resorption by osteoclasts is a hallmark of many bone diseases, including osteoporosis. Therefore, controlled and specific inhibition of osteoclast activity is a desired outcome in treatments of bone diseases. Osteoclast differentiation and function are coordinated by cell surface receptors, including c-FMS and αvβ3 integrin, which cross talk with each other to drive signals that are essential for osteoclast functions. Using functional FACS-based screening assays of random mutagenesis M-CSF libraries against c-FMS and αvβ3 integrin, we engineered dual-specific M-CSF mutants with high affinity to both receptors. We showed by SPR and cell surface binding assays that the engineered dual-specific M-CSF proteins can bind both αvβ3 integrin and c-FMS receptors, leading to antagonism of immediate signaling events (c-FMS and Akt phosphorylation) and downstream biochemical events regulating osteoclast differentiation. Moreover, the dual-specific mutants had enhanced osteoclast inhibitory capabilities compared to inhibitors that target only one of the pathways, thereby highlighting the effects of the dual functionality that we engineered into these proteins. In the presence of the dual-specific inhibitors osteoclasts were unable to form a solid actin belt and were not able to differentiate properly in a dose dependent manner. Finally, we show that injection of the bispecific c-FMS and αvβ3 integrin proteins significantly inhibited bone resorption by osteoclasts in ovariectomized mice providing proof of concept for their utilization as anti resorptive drugs.

[1]Clinical Genetics, Center for Molecular Medicine, Karolinska Institutet, Sweden, [2]Children's Hospital, University of Helsinki and Helsinki University Hospital, Finland, [3]CHU Sainte Justine Research Centre, University of Montr, Canada, [4]Genetic Health Service New Zealand (Northern Hub), New Zealand, [5]Clinical Genetics Unit, Instituto da Criança HC-FMUSP and Instituto de Biociências- Universidade de São Paulo, Brazil, [6]University of Oklahoma Health Sciences Center, United States, [7]Medical Genetics and Neurodevelopmental Pediatrics, St Vincent Children's Hospital, Indianapolis, United States, [8]GeneDx, United States, [9]Department of Anatomy and Cell Biology, McGill University, Montreal, Canada, [10]Children's Hospital, University of Helsinki and Helsinki University Hospital, Finland, [11]Department of pediatrics, University of Montreal, Canada

Spondylometaphyseal dysplasias (SMD) comprise a group of genetically and phenotypically heterogeneous bone dysplasias that affect the growth plates and the spine. Metaphyseal fractures, so called "corner fractures", are typical features in a type of SMD. The most striking feature in SMD is irregular metaphyses and the presence of atypical "corner fractures". Only recently, mutations in the FN1 gene, encoding fibronectin (FN), were found in a fraction of individuals with this novel form of SMD. Fibronectin is an important extracellular matrix component for bone and cartilage development, but less is known about the role of FN in bone strength. So far, only ten patients in seven families with FN1 mutation-related SMD have been described, and the complete genetic and phenotypic spectrum of the disease needs more deeply characterization.In our ongoing research on genetic determinants of skeletal dysplasias we identified 5 new patients with SMD with "corner fractures" caused by five novel missense mutations in FN1. The study was approved by Institutional Ethics Boards and participants provided written informed consent. Clinical and radiographic evaluations were part of the clinical care. Genomic DNA was extracted from peripheral blood using standard procedures. Whole-exome sequencing or whole-genome sequencing was used to identify cause of disease in four patients, while targeted Sanger sequencing was applied in one case.The obvious metaphyseal bone changes and "corner fracture" appearances were the most extensive clinical feature in these patients. In addition, low trauma bilateral femoral fractures in one patient represent a novel finding in SMD with "corner fractures". Osteopenia and increased serum N-telopeptide suggesting increased bone turnover were noted in some patients. All individuals had cysteine mutations, disrupting disulphide bonds in the fibronectin type-I assembly domain (NM_212482.2: p.Cys213Tyr, p.Cys123Tyr, p.Cys169Tyr, p.Cys231Trp and p.Cys258Tyr).These novel findings extend the clinical spectrum and genotype of SMD with "corner fractures" and indicate metaphyseal fractures as a hallmark for diagnosis of FN1-related SMD. The high frequency of methaphyseal "corner fractures" in all patients with FN1 mutations indicates altered bone tissue, causing decreased bone strength especially during childhood. This emphasizes the importance of FN not only in bone formation, but possibly also in maintenance of bone strength and fracture resistance.

Quality Of Life is Not Impaired In Patients With Isolated Craniofacial Fibrous Dysplasia Marlous Rotman*, Natasha Appelman-Dijkstra, Stijn Genders, Sander Dijkstra, Neveen Hamdy. LUMC, Netherlands

In craniofacial fibrous dysplasia (CFD) quality of life may be impaired due to pain, disfigurement and dysfunction caused by cranial nerve entrapment, but data on predictive factors affecting quality of life (QoL) are scarce in these patients. In this study we used the Short Form-36 (SF-36) questionnaire to evaluate QoL in 97 out of 138 eligible FD/MAS pa-

tients. Twenty-two patients had CFD: 9 had isolated CFD,13 had CFD associated with other skeletal localizations. Seventy-five patients had no CFD: 50 with monostotic FD (MFD) and 25 with polyostotic FD/McCune Albright syndrome (PFD/MAS).Data on age, gender, age at diagnosis of FD, clinical characteristics, relevant serum biochemistry and Skeletal Burden Scores (SBS) were retrieved from medical records.The SF-36 questionnaire was completed by predominantly female patients (68%). Mean age of respondents at FD diagnosis was 27.0 (0-77 years), and mean SBS was 11.6 (range 0.1-64.7). CFD patients (64% female) had a mean age at FD diagnosis of 22.8 years (0-60 years), a mean total SBS of 6.2 (range 0.1-64.7) and a mean skull SBS of 19.5 (range 2.5-75.0). Patients with isolated CFD had a lower skull SBS than those with CFD/PFD/MAS (mean 15.0 vs. 25.6). Main clinical features in CFD patients were facial deformity (48%), headache (27%), vision loss (12%) and nerve entrapment (9%). Patients with isolated CFD, who had the least complaints and the lower skull SBS, reported no impairment in any QoL domain compared to MFD and PFD/MAS patients and to the more severe and symptomatic CFD associated with PFD/MAS, who had the most bodily pain and impairment in several other SF-36 domains including physical and social function. Our data suggest that aspects of QoL as evaluated by the SF-36 appear to be unaffected in patients with isolated CFD. In contrast we show that several aspects of QoL are severely impaired when CFD is associated with PFD/MAS.

High prevalence of enthesopathies in patients with X-Linked Hypophosphatemia Axelle Salcion *[1], Louis Lassalle[2], Valérie Merzoug[3], Alessia Usardi[4], Anya Rothenbuhler[4], Peter Kamenicky[5], Christian Roux[6], Agnès Linglart[7], Karine Briot[6]. [1]French Reference Center for Genetic Bone Diseases, Cochin Hospital, AssistancePublique- Hôpitaux de Paris, Paris, France, [2]Department of Radiology, Cochin Hospital, AssistancePublique- Hôpitaux de Paris, France, [3]Kremlin Bicêtre, France, [4]Department of Pediatric Endocrinology, Reference Center for Rare Disorders of Calcium and Phosphate, Kremlin Bicêtre Hospital Assistance, France, [5]Department of Endocrinology, Kremlin Bicetre Hospital, Assistance, France, [6]Department of Rheumatology, French Reference Center for Genetic Bone Diseases, Cochin Hospital, AssistancePublique- Hôpitaux de Paris, France, [7]Department of Pediatric Endocrinology, Reference Center for Rare Disorders of Calcium and Phosphate, France

X-linked hypophosphatemia (XLH) is a rare genetic disease characterized by impaired renal phosphate reabsorption which leads vitamin D resistant rickets in children. In adulthood, the burden of disease is related to musculoskeletal symptoms due to osteomalacia, osteoarthritis, and muscle weakness but also ossifications of entheses (enthesopathies), this latter feature being a strong determinant of alteration in quality of life in this population. These enthesopathies localized to the spine, peripheral joints and Achilles tendons are responsible for chronic pain, joint limitations, stiffness and disability. In the literature, these ossifications may be referred to enthesopathies or osteophytes with a different anatomical structure involved. The aim of this study was to describe the prevalence and the type of ossifications (enthesophytes and osteophytes) in a large cohort of adult patients with XLH. This retrospective study was conducted in adult patients followed in the rheumatology department, part of the French Reference Center for Rare Disorders of Calcium and Phosphate Metabolism. Full body X-rays were performed using the EOS® low-dose radiation system between June 2011 and December 2017. X-rays were interpreted independently by two trained physicians specialized in rare bone diseases.Eighty one patients were included in this study (68% women, mean age 42.4 ± 13.6 years). Sixty-three (78%) patients had been treated during childhood with phosphate and/or vitamin D analogs. At the time of the study, 41 (50.6%) were still receiving on phosphate supplements and/or vitamin D analogs, and 65 (80%) suffered from pain of multifactorial origin. 58 (72%) enthesopathies of spine, pelvis and heels. 44 (63%) had spine enthesopathies with a mean of 4.1±2.6 per patient, mostly found in the cervical spine (82%) or in the lumbar spine (62%). 86% of patients had thin ossifications (similar to syndesmophyte observed in spondyloarthritis), 61% had coarse ossifications (hyperostosis-like disease), and 50% had an association of both. Calcanei were visible on 52 radiographs, showing coarse ossifications in 22 cases (42%). Overall, 90% of patients had hip osteophytes with a narrowed hip joint space in 65%. We did not observe any peri-articular and spinal enthesopathies in patients under 30 years of age.This study showed that 72% of adult patients with XLH have at least one enthesopathy of spine, pelvis and heels. We did not observe any enthesopathies in subjects below 30 years old. In most cases this enthesopathy is similar to a syndesmophyte, usually observed in SpA. Aware that this disease can be long misunderstood and finally diagnosed in adulthood, attention must be paid to ossification of the entheses. The mechanisms of formation of these enthesopathies remain to be determined.

Homozygous Calcium-sensing Receptor Polymorphism R544Q Presents as Hypocalcemic Hypoparathyroidism Lucie Canaff*[1], Branca M. Cavaco[2], Alexis Nolin-Lapalme[1], Margarida Vieira[2], Tiago Silva[2], Ana Saramago[2], Rita Domingues[2], Valeriano Leite[2], Geoffrey N. Hendy[1]. [1]Metabolic Disorders and Complications, McGill University Health Centre Research Institute, Canada, [2]Instituto Português de Oncologia de Lisboa Francisco Gentil, Portugal

Background:Autosomal dominant hypocalcemia type 1 is caused by heterozygous activating mutations in the calcium-sensing receptor gene (CASR). Whether polymorphisms that are benign in the heterozygous state pathologically alter receptor function in the homozygous state is not known. Purpose: To identify the genetic defect in an adolescent female with a past history of surgery for bilateral cataracts and seizures. The patient has hypocalcemia, hyperphosphatemia and low serum parathyroid hormone (PTH) levels. The parents of the proband are healthy. Methods: Mutation testing of PTH, GNA11, GCM2 and CASR genes was done on leukocyte DNA of family members. Functional analysis in transfected cells was conducted on the gene variant identified. Public single-nucleotide polymorphism (SNP) databases were interrogated for the presence of the variant allele. Results: No mutations were identified in PTH, GNA11 and GCM2 genes in the proband. However, a germline homozygous variant (c.1631G>A; p.R544Q) in exon 6 of the CASR gene was identified. Both parents are heterozygous for the variant. The variant allele frequency was near 0.1 % in SNP databases. By in vitro functional analysis the variant was significantly more potent in stimulating both the Ca2+i and ERK/MAPK signaling pathways than wild-type CaSR when transfected alone (p<0.05) but not when transfected together with wild-type CaSR. The overactivity of the mutant CaSR is due to loss of a critical structural cation-π interaction. Conclusions: The patient's hypoparathyroidism is due to homozygosity of a variant in the CASR that normally has weak or no phenotypic expression in heterozygosity. Although rare, this has important implications for genetic counseling and clinical management.

Cardiopulmonary Outcomes in Adults with Osteogenesis Imperfecta Sobiah Khan*[1], Erin Carter[1], Robert Sandhaus[2], Cathleen Raggio[1]. [1]Hospital for Special Surgery, United States, [2]National Jewish Health, United States

Introduction:OI is a type I collagen deficiency resulting in disordered connective tissue. Respiratory insufficiency is the leading cause of death in people with OI. It has been suggested that decreased pulmonary function may be an intrinsic component of OI, rather than a secondary effect of scoliosis.Hypothesis:Reduced pulmonary function in individuals with OI is intrinsic to the connective tissue disorder, not curve magnitude.Results:14 individuals with a diagnosis of OI were enrolled in this IRB-approved prospective study. Anteroposterior radiographs were evaluated for scoliosis (curve >10°). If more than one curve was present, the largest curve was used for analysis. Pulmonary function was defined by FEV1/FVC ratio, with restrictive disease defined as FEV1/FVC >80%, while obstructive disease was defined as FEV1/FVC <70%. Chest CTs were qualitatively evaluated for evidence of lung disease. Echocardiograms and EKG were obtained to assess cardiac health. QOL was evaluated via SF-36. Individuals that complained of disordered sleep underwent polysomnography. Bivariate correlation analysis was performed, using Spearman's rho correlation coefficient as well as point-biserial correlation analysis (p<0.05).71% of participants were female. Mean age was 35±15 years. 36% had OI Type 3, 36% Type 4, and 29% Type 1. 57% presented with scoliosis. 14% had cardiac comorbidities and 7% pulmonary comorbidities. Abnormalities (parenchyma scarring, glass-ground opacities, air trapping) were seen on 23% of chest CTs. 50% EKGs showed abnormal results (tachycardia or non-specific wave abnormalities). 93% had trace mitral, tricuspid, or aortic regurgitation. Correlation between curve magnitude and pulmonary function was weak (R=0.1154) and not statistically significant (p=0.308).Conclusions:Pulmonary function is weakly correlated with curve magnitude. Therefore, decreased pulmonary function is likely an intrinsic factor of OI. We suggest that there be a reevaluation of clinical practice in evaluating cardiopulmonary health in individuals diagnosed with OI. We recommend that at least baseline echocardiograms and EKGs be obtained for all adults diagnosed with OI.
Figure 1 Weak and non-significant correlation between scoliosis curve magnitude and FEV1/FVC (r=0.1154; p=0.308).

MON-1063

Asymmetric metaphyseal dysplasia due to COL2A1 mutation with mosaicism Lisa Cruz-Aviles, Md*[1], Thomas O. Carpenter, Md[1], Allen E. Bale, Md[2], Cemre Robinson, Md[1]. [1]Yale University School of Medicine, Department of Pediatrics, Section of Endocrinology, United States, [2]Department of Genetics, Yale School of Medicine, United States

Background: Heterozygous mutations in COL2A1 cause skeletal dysplasia syndromes involving epiphyses of the long bones and vertebral bodies. The phenotypic spectrum ranges from mild skeletal abnormalities in utero to lethal dwarfism, without clear phenotype-genotype correlation. We describe the clinical, radiological and molecular features in a patient with striking asymmetrical metaphyseal dysplasia due to a mosaic COL2A1 mutation. Case: This now-10-year-old girl presented at birth with skeletal asymmetry, with right arm and leg shorter than the left, and disproportionately short legs with the right femur being the most severely affected limb segment. Epiphyseal fraying of long bones and dysplastic metaphyses (Fig. 1a, arrowhead) and leg-length discrepancy (Fig. 1b, arrow) were present. Other prominent clinical findings included mild craniofacial asymmetry, facial muscle hypotonia, asymmetric chest wall, bilateral clinodactyly, and short stature, but no ocular findings. Family history was unremarkable. A right femoral/tibial lengthening procedure performed at age 3 provided near-approximation of leg-length symmetry, but asymmetry recurred by age 8. Coincidentally, she developed central precocious puberty around age 7. Whole exome sequencing revealed a pathogenic missense variant in exon 24 of COL2A1 c.G1537A:p.G513S. A reference to alternative allele ratio of 36:17 suggested mosaicism. Conclusions: We describe a non-lethal collagenopathy due to a mosaic glycine substitution in COL2A1, presenting as an asymmetrical metaphyseal dysplasia. Though rare, asymmetric limb shortening with marked metaphyseal dysplasia has been reported with other mutations in COL2A1. The identified G->S variant in our patient has not been observed in the general healthy population, but has been reported in a sporadic patient with lethal hypochondrogenesis1 and is predicted to have a severe phenotype. This mutation, which is likely somatic in view of both the mosaicism and the non-lethality, may explain the asymmetrical feature of the skeletal dysplasia. This case highlights the consideration of COL2A1 mutation analysis in the clinical setting of asymmetric limb skeletal dysplasias. 1. Mortier GR, Weis M, Nuytinck L, et al. Report of five novel and one recurrent COL2A1 mutations with analysis of genotype-phenotype correlation in patients with a lethal type II collagen disorder. Multiple Endocrine Neoplasia, type 4 - a Novel CDKN1B Mutation with High Penetrance of Primary Hyperparathyroidism Anja Lisbeth Frederiksen*[1], Maria Rossing[2], Anne Pernille Hermann[3], Charlotte Ejersted[4], Morten Frost[5]. [1]Dept.of Cinical Genetics, Odense University Hospital, Denmark, [2]Center of Genomic Medicin, Copenhagen University Hospital, Denmark, [3]Dept. of Endocrinology M, Odense University Hospital, Denmark, [4]Department of Endocrinology M, Odense University Hospital, Denmark, [5]Steno Diabetes Centre, Odense, Dept. of Endocrinology M and KMEB, Odense University Hospital, Denmark

Background: Mutations in CDKN1B have recently been associated with Multiple Endocrine Neoplasia, type 4 (MEN4). The MEN syndromes are characterized by tumors in two or more endocrine organs including parathyroid, pituitary, adrenocortical glandels or gastro-enteropancreatic neuroendocrine and carcinoid tumors. These present with a dominant pattern of inheritance with heterogeneous phenotypes. Similar to MEN1, caused by mutations in the tumor supressor gene MEN1, MEN4 appear to present with hypercalcemia. There are however, only few cases reported on CDKN1B an the clinical phenotype including penetrance and genotype/phenotype associations remains to be further illuminated.We report at novel variant in CDKN1B identified in a 38 years old woman who presented with Mb.Cushing. Further, we describe the clinical, biochemical and radiological findings in 12 mutation-positive family member including the pathological findings of five tumors.Methods: Genetic screening of CDKN1B was performed on DNA from whole blood.(MiSeq, Illumina, CA, USA) to an average depth of at least 100X. We assessed the family history of the proband and predictive genetic testing of family members.Clinical assessment of mutation positive subjects included physical examination, biochemical evaluation, MRI of cerebrum, CT scans of thorax and abdomen. In addition, we studied "loss-of-heterozygosity" (LOH) of CDKN1B in tumor tissues on DNA extraced from paraffin embedded (FFPE) tumor samples analyzed on OncoScan assay (Affymetrix, CA, USA).Results: Genetic screening of the proband idenfified a novel heterozygous pathogenic frame-shift variant in CDKN1B (c.121_122delTT, p.Leu41Asnfs*83). The mutation segregated with the MEN4 associated diseases in two generations including two branches of the family. All 13 carriers had hypercalcemia (age of debut: 29-69 years), 12 had primary hyperparathyroidism (PHPT). The proband had Mb.Cushing with an ACTH-producing pituitary tumor while three carriers had non-functioning pituitary adenoma, and one had carcionoid tumor in pancreas. Two of five tumors had LOH.Conclusion: We present a novel CDKN1B and the clincial phenotypes in, to the best of our knowlegde, the largest family of patients with MEN4 reported. There was a high penetrance of asymptomatic hypercalcemia and PHPT, and a high proportion of pituitary adenomas while additional ME4 associated diseases were less frequent. The present case delineates the knowlegde about MEN4.

Palovarotene Reduces New Heterotopic Ossification in Fibrodysplasia Ossificans Progressiva (FOP) Frederick S. Kaplan*[1], Edward C. Hsiao[2], Geneviève Baujat[3], Richard Keen[4], Carmen De Cunto[5], Maja Di Rocco[6], Matthew A. Brown[7], Mona M. Al Mukaddam[8], Donna R. Grogan[9], Robert J. Pignolo[10]. [1]Perelman School of Medicine, The University of Pennsylvania, United States, [2]Division of Endocrinology and Metabolism, University of California, San Francisco, United States, [3]Groupe Hospitalier Necker Enfants Malades, France, [4]Royal National Orthopaedic Hospital, Brockely Hill, United Kingdom, [5]Affiliation Department of Pediatrics/Hospital Italiano de Buenos Aires, Argentina, [6]Unit of Rare Diseases, Department of Pediatrics, Gaslini Institue, Italy, [7]Institute of Health and Biomedical Innovation, Queensland University of Technology, Australia, [8]The University of Pennsylvania, Center for Research in FOP and Related Disorders, United States, [9]Clementia Pharmaceuticals Inc., United States, [10]Mayo Clinic College Of Medicine, Division of Geriatric Medicine & Gerontology, United States

FOP is a rare, severely disabling disease characterized by episodic flare-ups and accumulation of heterotopic ossification (HO) that leads to restricted movement, physical disability, and early death. This preliminary analysis evaluated the ability of three palovarotene (PVO) dosing regimens to prevent HO following a flare-up using data from two Phase 2 interventional studies and one natural history study (NHS).The volume of new HO was assessed by CT of the flare-up body site at baseline and 12 weeks post-baseline. Regimens included: PVO 10 mg for 2 weeks followed by 5 mg for 4 weeks (10/5 mg [45 flare-ups/27 subjects/ages 9-44yrs]); PVO 20 mg for 4 weeks followed by 10 mg for 8 weeks or longer (20/10 mg [12 flare-ups/10 subjects/7-18yrs]); or chronic PVO 5 mg daily with increased dosing during a flare-up to 20 mg for 4 weeks followed by 10 mg for 8 weeks or longer (chronic/flare-up [27 flare-ups/18 subjects/13-46yrs]). These were compared to a pooled population of placebo-treated (9 flare-ups/9 subjects/9-53yrs) and untreated flare-ups (49 flare-ups/38 subjects/4-39yrs) from the NHS. All flare-ups were assessed using pre-specified imaging procedures by a central imaging laboratory blinded to treatment or study. The average difference in the volume of new HO at Week 12 between the chronic/flare-up regimen and placebo/untreated flare-ups was -7,798 mm3 (95% CI = -17,383 mm3, -1,764 mm3; p=0.007; ANOVA with BCa bootstrap), representing a 94% reduction in new HO (see figure).The adverse event profile was similar across the PVO groups; the majority were mild or moderate mucocutaneous events. Three subjects had four serious adverse events possibly related to treatment. No subject required dose reduction with PVO 10/5 mg. Nine of 28 subjects (32%) who received PVO 20/10 mg for at least one flare-up had at least one dose reduction; the majority (75%) during the 20-mg dose. No subject discontinued the study due to adverse events. These data demonstrated a statistically significant decrease in new HO volume with the chronic/flare-up palovarotene regimen as compared to the placebo/ untreated control, and support further evaluation of this regimen in the ongoing Phase 3 MOVE study. Palovarotene was tolerated at the doses administered.Acknowledgments: the authors wish to thank the FOP patient community and the clinical research teams for their participation and support of this study.

MON-1067

Melorheostosis: a case series of different imaging phenotypes Anupam Kotwal*[1], Bart Clarke[1], Jane Matsumoto[2]. [1]Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Mayo Clinic, United States, [2]Department of Radiology, Mayo Clinic, United States

Background: Melorheostosis is a rare sclerosing bone dysplasia that affects both cortical bone and adjacent soft tissue structures in a sclerotomal distribution. The exact etiology remains unknown, with possible causes being somatic LEMD3 mutations, BMP/TGF-ß pathway, or non-genetic causes. Histopathology studies have shown increased osteoid formation in a disorganized manner, and increased angiogenesis in the affected bones. Methods: Here we describe 4 cases of melorhestosis with differing radiological features. All the patients presented with pain in the affected area prior to diagnosis.Results: The 1st case is of 43 year old male whose plain radiography showed extensive hyperostosis of the left tibia shaft in the classic "flowing candle wax" pattern of melorheostosis. Bone scan demonstrated multifocal increased uptake in left tibia, left radius and lumbar spine. Management included stripping of the periosteum from the left tibia, intravenous zoledronic acid until he developed ONJ, calcitonin nasal spray, external beam radiation to tibia, but without much improvement in pain over the years. This was managed subsequently with opioids and physical therapy. The 2nd case is of a 39 year old female diagnosed with monostotic classic "flowing candle wax" cortical hyperostosis in an L3-L4 sclerotomal distribution. The 3rd case is of a 56 year old female with melorheostosis since childhood who subsequently developed postmenopausal osteoporosis. Plain radiography showed "osteopathia striata-like" hyperostosis and bone scan showed increased uptake in the left tibia, left fibula and talar dome. She received 6 infusions of zoledronic acid yearly for osteoporosis which also improved pain from melorheostosis. The 4th case is of a 22 year old female, diagnosed to have inactivating LEMD3 mutation and felt to have an overlap syndrome of melorheostosis and osteopoikilosis involving left knee, left foot and ankle. Biochemical bone and mineral parameters were normal. Left lower extremity pain due to syringomyelia was managed with gabapentin.Conclusions: Melorheostosis may present as mixed or atypical osseous involvement as opposed to the classically described "dripping candle wax" appearance of hyperostosis. The morbidity of melorheostosis appears to be mostly due to pain, contractures, limitation of joint motion, limb length discrepancies, and osseous deformities. Multidisciplinary care utilizing medical, surgical and rehabilitative techniques with an individualized approach provides the best outcomes for these patients. In recent years, bisphosphonates have demonstrated reduction in pain. Better characterization of genetic and developmental factors predisposing to this condition may lead to development of targeted therapy for this condition, as well as more commonly encountered skeletal abnormalities.

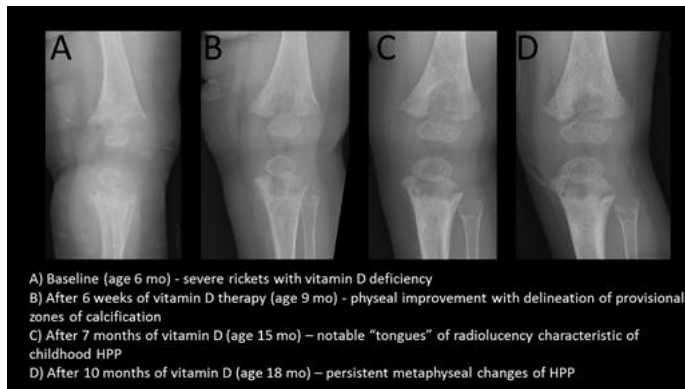
MON-1068

Vitamin D Deficiency Rickets Complicating Severe Childhood Hypophosphatasia: Response to Sequential Therapy with Vitamin D then Asfotase Alfa Elizabeth L. Lin*[1], Gary S. Gottesman[2], William H. Mcalister[3], Steven Mumm[1], Michael P. Whyte[2]. [1]Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine, United States, [2]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, United States, [3]Mallinckrodt Institute of Radiology, Washington University School of Medicine at St. Louis Children's Hospital, United States

Hypophosphatasia (HPP) is an inborn-error-of-metabolism that involves skeletal disease in the perinatal, infantile, severe and mild childhood, and adult forms. HPP is caused by loss-of-function mutation(s) in the ALPL gene that encodes the cell-surface tissue non-specific isoenzyme of alkaline phosphatase (TNSALP). Extracellular accumulation of inorganic pyrophosphate, an inhibitor of mineralization, often leads to rickets or osteomalacia. Severe childhood HPP also features muscle weakness, limb pain, and a waddling gait. Studies of mineral homeostasis show hypophosphatasemia, often hyperphosphatemia, and sometimes mild hypercalcemia with normal or suppressed circulating PTH. A 6-month-old girl presented with failure-to-thrive. Biochemical investigation was notable for 25(OH)D of 8 ng/mL (Nl: 30 - 100), calcium 10.1 mg/dL (Nl: 8.5 - 10.1), phosphorus 6.4 mg/dl (Nl: 2.5 - 4.9), PTH 21 pg/mL (Nl 14-72), and serum ALP of 55 U/L (Nl: 124-341). She could not roll or sit. Radiographs revealed metaphyseal fraying consistent with rickets. Thus, she started vitamin D 1000 IU p.o. daily. We first evaluated her at age 9 months, after 6 weeks of vitamin D, when she could now roll and sit. There was thoraco-lumbar kyphosis. 25(OH)D was 86 ng/mL, but ALP remained at 55 U/L (Nl: 91 - 388). Radiograph review showed marked improvement in her rickets [Figure]. Vitamin D supplementation continued at 600 IU daily. At age 15 months, she started walking. At age 18 months, her kyphosis had resolved yet her waddling gait persisted with a positive Gower's sign. Serum 25(OH)D was 55 ng/mL. Follow-up radiographs now showed "tongues" of radiolucency characteristic of pediatric HPP. Mutation analysis of ALPL revealed biallelic missense mutations. Due to persisting skeletal disease and muscle weakness, she started asfotase alfa enzyme replacement therapy with follow-up planned in 3-months. Thus, our patient highlights the importance of identifying and treating vitamin D deficiency prior to further assessing and managing severe childhood HPP. Sequential treatment with vitamin D resolved the most common type of rickets, and established a baseline for monitoring asfotase alfa therapy.

A) Baseline (age 6 mo) - severe rickets with vitamin D deficiency
B) After 6 weeks of vitamin D therapy (age 9 mo) - physeal improvement with delineation of provisional zones of calcification
C) After 7 months of vitamin D (age 15 mo) – notable "tongues" of radiolucency characteristic of childhood HPP
D) After 10 months of vitamin D (age 18 mo) – persistent metaphyseal changes of HPP


*Disclosures: **Elizabeth L. Lin,** None*

MON-1069

Early Diagnosis of Gaucher Disease with Focus in Bone Affection (BIG Project)Argentinian Experience Beatriz Oliveri*[1], Diana Gonzalez[2], Paula Rozenfeld[3], Camilo Lis[4], Omar Riemersma[4], Martin Kot[4]. [1]Laboratorio de Osteoporosis y Enfermedades Metabólicas Óseas. Instituto de inmunología, Genética y Metabolismo (INIGEM) CONICET-UBA Hospital de Clínicas., Argentina, [2]Mautalen, Salud e Investigación, Argentina, [3]IIFP, Universidad Nacional de La Plata, CONICET, Facultad de Ciencias Exactas, Departamento de Ciencias Biológicas, Argentina, [4]Shire, Argentina

Gaucher disease (GD, OMIM#230800) the most frequent lysosomal disease, is caused by a deficient activity of glucocerebrosidase (GCase) that leads to excessive storage of glucocerebroside in the liver, spleen, bone and bone marrow. The clinical suspicion of GD is traditionally associated to hepato/splenomegaly and cytopenias and available algorithms for the diagnosis are based on those signs and employed more frequently by hematologists. However bone symptoms have been recognized in 30 % of patients at the time of diagnosis, isolated or associated with other hemathological alterations. Notably, due to a lack of awareness, long diagnostic delays are described leading to serious complications. Early diagnosis and enzyme replacement therapy (ERT) are extremely important for reversing splenomegaly and citopenias, and preventing irreversible skeleton damage.Purpose: to enhance early GD diagnosis in patients whose first manifestations are bone symptoms we designed a program of medical educational meetings in GD and proposed a novel screening algorithm for GD with focus in bone affection.The algorithm was based on the following consulting diseases: 1- osteomyelitis of unknown ethiology and Perthes disease in patients below 18 years old (yo) 2- recurrent fragility Fx, bone pain, AVN, hip arthroplasty (of uncertain ethiology) in patients below 50 yo. 3-Low bone density (Z score < - 2.0) and bone pain without known causality associated with abnormal ferritin levels and/or platelet count. The first step in the screening is by assaying in dried blood filter paper (DBS). Pathological results must be confirmed by measuring GCase in leukocytes. Results: From April 2017 this project has been presented in 7 hospitals of different argentinian provinces in meetings ad hoc with an overall attendance of 250 physicians with different related specialities and in two Bone Metabolism Meetings (2016 and 2017) (with 300 attendants). Until today 26 samples had been submitted (ages from 1 to 47 y) originated in: bone crisis (n= 8), AVN (n=2), recurrent fractures (n=8), bone pain (n=2), a painful bone lesion (n=1), and visceromegalies or cytopenias(n= 5). DBS was pathological in three patients, and the diagnosis of GD was confirmed in two of them. Conclusion: These results encourage to continue in implementing the educational program designed to improve the awareness in GD facilitating the early diagnoses and treatment to avoid morbidity and complications.

Cone-Beam Computed Tomography of Osteogenesis Imperfecta Types III and IV: Three-Dimensional Evaluation of Craniofacial Features and Upper Airways Natalie Reznikov*, Didem Dagdeviren, Faleh Tamimi, Francis Glorieux, Frank Rauch, Jean-Marc Retrouvey. McGill University, Canada

Osteogenesis Imperfecta (OI) is a rare genetic disease of connective tissues resulting in fractures and bone deformities. The more severe forms of OI (OI types III and IV) often affect the craniofacial skeleton but these craniofacial manifestations have not been investigated with three-dimensional (3D) imaging. In the present study, we obtained 3D craniofacial measurements by cone-beam computed tomography (CBCT) in a cohort of 41 individuals (age 11 to 35 years; 28 females) with OI type III (N = 13) or IV (N = 28). Angular and linear craniofacial measurements, facial proportions and airways assessments were compared between the type III and type IV groups, and in relation to reference data for the general population. The results showed that craniofacial deformities varied widely and overlapped between OI type III and IV with regard to most of the measured parameters. Many of the aberrant craniofacial features were associated with an increased cranial base angle. The max-

illa was retrognathic and was a significant contributor to the observed malocclusion. The total face height was significantly reduced due to counter-clockwise rotation of the mandible. Both maxilla and mandible were narrower, and together with an increased bi-temporal width, produced the characteristic triangular face appearance. Face asymmetry was common, and cranial asymmetry was often severe. Craniofacial deformities in OI patients were not associated with reduced patency of the upper airways. In conclusion, a combination of several parameters, in particular cranial base angle, cranial asymmetry and the 3D position of the maxilla and mandible should be used to assess the severity of craniofacial involvement in OI and be collectively considered for treatment planning in neurologic, orthodontic, and otorhinolaryngologic practice.

MON-1072

A Novel Case of Human Osteopetrosis Associated with Glanzmann's Thrombasthenia Due to a Homozygous Pathogenic Mutation in ITGB3 Jennifer Sarhis Avigdor*, Gary M Kupfer, Allen Bale, Thomas O Carpenter. Yale University School of Medicine, United States

Osteopetrosis, a sclerotic disorder of bone, is due to mutations in a variety of genes critical for osteoclast differentiation, recruitment, or function. We describe a novel case of osteopetrosis and Glanzmann's thrombasthenia caused by a homozygous pathogenic mutation in ITGB3, encoding a member of the integrin family. Although described in murine models, there are no reported cases of osteopetrosis and Glanzmann's thrombasthenia in humans caused by ITGB3 mutations. A 2-month old infant presented with respiratory failure due to pulmonary hemorrhage and petechiae. MRI suggested a left subdural hematoma, and radiographs identified "bone in bone" appearance of the ulnae and phalanges of the hands and feet. Serum calcium, magnesium, phosphorus, PTH and alkaline phosphatase were normal (see table). Serum 25-OHD level was low, and creatine kinase BB isoezyme fraction was elevated (6%, nl: 0). Serum CTX was 809 pg/mL (low-normal for this age) and P1NP was 1010 ug/dL (high normal for young children). Areal BMD of the lumbar spine (0.252 g/cm2) was >2 SDs above mean for age (Kalkwarf H, JBMR 28:206, 2013). Decreased hemoglobin content, hematocrit and platelet count as well as a prolonged prothrombin time were evident. Whole exome sequencing revealed a homozygous missense mutation of the ITGB3 gene (Asp145Tyr; G->T), which alters the function of the encoded protein (Loftus J, Science 249:915, 1990). αVβ3 integrin, a member of the cell adhesion receptor family, mediates an interaction between osteoclasts and the extracellular bone matrix, allowing for resorption. Integrin αIIβ3, located on platelet membranes, is critical for clot formation, and mediates platelet adherence to fibrinogen. Defective integrin disrupts osteoclast and platelet function in β3 knockout mice; mutations in this subunit have not been described in human osteopetrosis (McHugh K, J Clin Invest 105:433, 2000). At age 17 months the patient is healthy with intact hearing and vision, although has been hospitalized twice for observation of bleeding incidents. Platelet count has normalized since initial presentation. Computed tomography scanning performed at 6-month intervals has shown normal caliber of the optic foramina and persistent, but mild diffuse sclerosis of the skull base. Bone marrow aspirate is normal. Continued monitoring will be important in order to establish the long-term course of this novel form of osteopetrosis, which appears to present with a relatively mild phenotype in infancy.

	Patient	Reference Range
Calcium (mg/dl)	10.4	8.8-10.2
Magnesium (mg/dl)	1.9	1.7-2.6
Phosphorus (mg/dl)	5.6	3.0-7.5
PTH (pg/ml)	23	10-69
Alkaline Phosphatase (U/L)	197	80-380
25-OHD (ng/mL)	19	20-50
CK-BB (%)	6	0
CTX (pg/ml)	809	500-3,000
P1NP (ug/dl)	1010	277-824
Hemoglobin (g/dl)	7.1	13-20
Hematocrit (%)	20.9	37-60
Platelet (x1000 U/L)	96	140-165
PT (seconds)	12.4	10.1-12.1

Complications in patients with autosomal dominant hypocalcemia compared with non-surgical hypoparathyroidism Line Underbjerg*[1], Tanja Sikjaer[1], Lars Rejnmark[2]. [1]MD, PhD, Denmark, [2]Professor, senior consultant, Denmark

Only few data are available on biochemical markers and complications in terms of cardiovascular findings, bone indices and quality of life (QoL) in autosomal dominant hypocalcemia (ADH). We aimed to assess the biochemistry and complications in patients with genetically verified ADH (N=20) compared to age- and gender-matched patients with non-surgical hypoparathyroidism (Ns-HypoPT) (N=20).Patients had an average age of 44 years (75% females). Significantly fewer patients with ADH received treatment with alfacalcidol (p=0.04), however daily doses of calcium supplements did not differ between groups (p=0.16). Biochemical findings showed no difference in levels of ionized calcium, phosphate, magnesium or creatinine (pall>0.05). Prevalence of renal impairment did not differ between groups with none having an GFR<30 mL/min. TSH levels were lower in patients with ADH (p=0.03), even though no differences were seen in the number of thyroid hormone supplement users (p=0.61). Renal calcium excretion did not differ between groups, and no correlations were seen between urinary calcium (mmol/24h) and total daily calcium intake.Cardiovascular findings, showed no difference in ambulatory or 24-hour blood pressure measurements. Assessing arterial stiffness in terms of pulse wave velocity (PWV) showed no difference between group in crude analyses, however, after adjustment for mean arterial pressure, BMI, age and gender, patients with ADH had a significantly higher PWV compared with Ns-HypoPT (p<0.01).Bone indices showed no difference in Z-scores as measured by DXA. Using QCT-scans, patients with ADH had a lower cortical vBMD at the total hip (p=0.04) and at the trochanter (p=0.02). No differences were seen in cortical parameters using HRpQCT.QoL was measured using SF-36v5 and WHO-5 Well-Being Index, showed a similar QoL between groups.In conclusion, for most of studied indices, patients with ADH did not differ from patients with Ns-HypoPT, including urinary calcium which wasn't increased in ADH compared with Ns-HypoPT. However, ADH was associated with an increased arterial stiffness and a lower vBMD. Further studies should aim to investigate whether ADH is associated with increased risk of fractures and cardiovascular diseases.

MON-1074

Identification and Molecular Analysis of a Potential Disease-causing Mutation in ZMAT2 in Congenital Radioulnar Synostosis Takako Suzuki*[1], Yukio Nakamura[1], Tatsuya Kobayashi[2], Hiroyuki Kato[1]. [1]Shinshu University School of Medicine, Japan, [2]Endocrine Unit, Massachusetts General Hospital and Harvard Medical Schoo, United States

Background: Congenital radioulnar synostosis (RUS) is a skeletal disorder resulting in fusion of the radius and ulna. Since the etiology of RUS is largely unknown, treatment options are limited. Elucidation of pathophysiology of RUS is needed for development of better treatment.Methods: We collected DNA samples of 10 trios (an affected patient and his or her biological parents) and performed whole exome-sequencing (WES). We identified mutations in several candidate genes including the zinc finger matrin-type 2 gene (ZMAT2) in a patient. The WES identified the following potential disease-causing de novo heterozygous missense mutation in a patient; human hg19 chr5:g.140084124T>A, c.424T>A, p.

F142I. The patient was born in the year 2000 and had bilateral RUS. His left and right arms were surgically treated at the ages of 5 and 6, respectively.Results: To date, there has been no report of mutations in the ZMAT2 gene that is evolutionarily conserved. The homology of ZMAT2 at the amino acid level is 100% between humans and mice, and 91% between humans and zebrafish. We first cloned the human and zebrafish orthologs of ZMAT2 cDNA and introduced the potential allelic mutation. We performed whole-mount in situ hybridization (ISH) in zebrafish. ISH showed specific expression of ZMAT2 in pectoral fins, which correspond to human upper limbs, and in craniofacial regions. ZMAT2 knockdown in zebrafish caused defects in pectoral fins and dorso-ventral patterning, which are likely caused by inhibitory effects of bone morphogenetic protein (BMP) action. These abnormalities were partially rescued by bmp2b RNA overexpression. In addition, the skeletal defects caused by ZMAT2 knockdown was rescued by simultaneous overexpression of ZMAT2, whereas the mutant ZMAT2 overexpression did not rescue the dorso-ventral patterning defect. Furthermore, ZMAT2 inhibited Bmp2 signaling as demonstrated by the downregulation of alkaline phosphatase activities in mouse C3H/10T1/2 cells treated with Bmp2. These findings suggest that ZMAT2 regulates skeletal development via BMP signaling. Importantly, we demonstrate that the ZMAT2 mutation, associated with RUS, leads to a loss or reduction of its biological activity in zebrafish.Conclusion: We identified ZMAT2 of which mutation potentially plays a causal role in RUS through deregulation of BMP signaling. Our zebrafish studies will provide insights into the mechanism by which ZMAT2 regulates limb and fin patterning in vertebrates.

Follow-up After Discontinuation of Bisphosphonate Treatment in Osteogenesis Imperfecta When Skeletal Maturity is Complete Pamela Trejo*[1], Telma Palomo[2], Francis Glorieux[2], Frank Rauch[2]. [1]Clinica Alemana Santiago, Chile, [2]Shriners Hospital for Children Canada, Canada

Little is known about the follow up in osteogenesis imperfecta (OI) during adulthood. We performed a retrospective chart review of patients with OI caused by an identified collagen mutation, who received bisphosphonate treatment for at least 2 years while growing until they reached final height, and had at least 2 years of follow up after treatment discontinuation. Fifty-five patients were identified, (26 males); 30 had a mutation in COL1A1, and 25 in COL1A2; 19 were classified as OI type I, 12 as OI type III and 24 as OI type IV. We found that the number of long bone fractures decreased from a mean of 0.7 (SD 1.1; range 0 to 6) in the last two years of treatment, to a mean of 0.3 (SD 0.8; range 0 to 4) in the last two years of follow up, p = 0.01. Vertebral deformities were evaluated in 32 patients with available x-rays of the spine at the time they stopped bisphosphonate treatment and at the last follow up, with a median time in between x-rays of 3.0 years (range 0.8 - 13.9), the percentage of compressed vertebrae went from 7.1% (range 0.0% to 92.9%) to 3.6% (range 0.0% to 90.9%; p = 0.938), the severity of fractures (spine deformity index) remained stable at a median of 0.1 (ranges 0.0 to 1.9 and 0.0 to 1.8; p = 0.493).In a subgroup of 31 individuals with BMD measurements at discontinuing treatment and after 2 and 5 years, areal BMD at the lumbar spine remained stable from 0.791 g/cm2 (SD 0.094) to 0.813 g/cm2 (SD 0.102) after two years and 0.814 g/cm2 (SD 0.090) after five years (p = 0.188). But a decrease in the lumbar spine areal BMD z score was observed from -1.8 (SD 1.1) to -2.0 (SD 1.1) at 2 years and -2.2 (SD 0.9) at 5 years, p = 0.028. Trabecular density at the distal radius (4% site) remained without significant changes from 188.2 mg/cm3 (SD 103.0), to 164.1 mg/cm3 (SD 77.9) and 168.7 mg/cm3 (SD 97.2) at 2 and 5 years respectively, p = 0.468. Cortical density at the proximal radius (65% site) increased from 1,133.0 mg/cm3 (SD 69.8) to 1,162.3 mg/cm3 (SD 58.2) at 2 years and 1,172.5 mg/cm3 (SD 45.9) at 5 years, p < 0.01. In conclusion in patients with OI after discontinuation of bisphosphonate treatment lumbar spine BMD and trabecular BMD remained stable, and cortical BMD increased after 2 and 5 years, which correlated with a decrease in long bone fractures and stability of spine deformities. However, the decrease in lumbar spine BMD z scores should continue to be monitored regularly in such patients in case re-treatment would be considered.

Lifelong Hyperphosphatasemia Without Low Plasma Pyridoxal 5′-Phosphate In A Healthy Boy With Uniquely Aberrant Bone Alkaline Phosphatase Yet Normal ALPL Gene Structure Michael P. Whyte*[1], Nina S. Ma[2], Gary S. Gottesman[1], Pamela S. Smith[3], Vinieth N. Bijanki[1], Steven Mumm[4], Per Magnusson[5]. [1]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, United States, [2]Division of Endocrinology, Boston Children's Hospital, United States, [3]Division of Pediatric Endocrinology and Diabetes, Washington University School of Medicine, United States, [4]Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine at Barnes-Jewish Hospital, United States, [5]Department of Clinical Chemistry, Linköping University, Sweden

Alkaline phosphatase (ALP) refers to a family of homodimeric phosphohydrolases routinely assayed in the clinical and research laboratory using non-physiological conditions, including alkaline pH. In humans, three genes encode tissue-specific ALPs, whereas a fourth (ALPL) encodes the tissue non-specific ALP isoenzyme (TNSALP) expressed richly in bone

and liver. TNSALP has five putative N-linked glycosylation sites, and post-translational modifications account for the different physicochemical properties among the TNSALPs. In health, the skeleton liberates three bone ALP (BAP) isoforms into the circulation (B/I, B1, and B2), and a fourth BAP isoform (B1x) can circulate in chronic kidney disease. We report an extensively studied 7-year-old healthy boy with lifelong enigmatic hyperphosphatasemia (recent ALP activity 1088 U/L, reference interval 196-449 U/L) featuring serum BAP elevated 2- to 3-fold the upper reference limit in both the routine MicroVueTM and Ostase® assays. Renal function and skeletal assessments were unremarkable except for elevated PINP and CTX. Our HPLC, electrophoretic, heat inactivation, inhibition, and polyethylene glycol precipitation findings confirmed high circulating levels of all three BAP isoforms, but no macro-ALP in his blood. His BAP profile on HPLC was different compared with other high circulating BAP conditions (e.g., Paget's bone disease, skeletal metastases, chronic kidney disease). Most remarkably, B/I had ~ 23-fold higher activity compared to healthy age-matched children. Despite his marked hyperphosphatasemia, plasma pyridoxal 5′-phosphate (PLP), a natural substrate for TNSALP, was not decreased, suggesting compromised catalytic activity of his BAP endogenously. In both non-consanguineous parents, total ALP was normal but BAP was twice the upper limit of normal in the commercial assays, suggesting a genetic disorder, yet ALPL sequencing of the patient was negative. In the inborn error hypophosphatasia (HPP), circulating TNSALP activity including BAP is decreased, and plasma PLP is consequently elevated. In extremely rare "pseudo-HPP" featuring severe rickets, circulating TNSALP activity is normal or increased but plasma PLP is elevated. Both HPP and pseudo-HPP involve ALPL mutations that directly impair TNSALP activity endogenously. Our patient, lacking an ALPL mutation, perhaps has a defect of a gene involved in post-translational modification of TNSALP, and could be considered the first example of "pseudo-pseudo-HPP".

Controlling Periodontitis Prevents Medication-related Osteonecrosis of the Jaw-like Lesions in Rice Rats (Oryzomys palustris) Evelyn Castillo*[1], Abel Abraham[1], Jessica Jiron[1], Jonathan Messer[1], Joshua Yarrow[2], Donald Kimmel[1], Jose Aguirre[1]. [1]University of Florida, United States, [2]Malcom Randall VAMC; University of Florida, United States

Medication-related osteonecrosis of the jaw (MRONJ) is a potentially serious adverse event seen in patients taking powerful anti-resorptive (pAR) agents. Multiple recent pre-clinical experiments indicate that combined local factors [e.g., periodontitis (PD)] and systemic factors (e.g., pARs, etc.) are required to cause MRONJ. Although various means have been proposed to minimize risk of MRONJ in pAR patients, few prospective preclinical studies have focused on this issue. Rice rats (Oryzomys palustris) consuming standard (STD) rat chow develop a high prevalence of spontaneous maxillary (Mx) localized PD lesions characterized by food impaction. These lesions appear to evolve into MRONJ when these rats are also treated with a pAR (e.g., zoledronic acid [ZOL]). We hypothesize that preventing localized PD lesions by feeding rats a diet free of insoluble fiber, or controlling PD lesions with periodic mechanical cleaning will reduce MRONJ.4-wk old rats were randomized into five groups (N=15) that received: 1) STD+vehicle (VEH; saline IV q4wks); 2) STD+ZOL (80µg/kg IV q4wks); 3) high soluble fiber (HSF) diet (7.5% inulin and 10% fructo-oligosaccharides to replace insoluble fiber)+VEH; 4) HSF+ZOL; and 5) STD+ZOL+biweekly mechanical cleaning (STD+ZOL+CL).Biweekly oral exams were conducted between ages 4-22 weeks with binocular loupes (4X). At each exam, oral condition was scored using an integral 0-4 severity scale (0=normal; 4=marked gingival recession with exposed bone [MRONJ-like lesion]). Any impacted materials were removed with a #23 dental explorer in STD+ZOL+-CL rats. At the end of study, rats were euthanized, high resolution photographs of the four jaw quadrants were obtained and graded 0-4. Oral tissues were processed for MicroCT and histopathologic assessment.40% of STD+VEH rats developed low severity focal PD lesions (1-1.5), but there were no PD lesions in any HSF+VEH rats. 25% of STD+ZOL rats had high severity (3-4. MRONJ-like) lesions. In contrast, no HSF+ZOL or STD+ZOL+CL rats developed MRONJ. In vivo oral exam data concurred with the post mortem oral analyses. Our ongoing data suggest that controlling the initiation or progression of focal PD by diet or periodic mechanical cleaning prevents development of MRONJ in rats treated with ZOL. The HSF diet is a practical method to prevent PD in rice rats. The cleaning data provide direct evidence to support current guidelines concerning maintenance of good oral hygiene in pAR patients.

Pyrophosphate regulators, ANK and ENPP1, regulate cementogenesis and extracellular matrix protein expression Emily Chu*[1], Atsuhiro Nagasaki[1], Michael Chavez[2], Daniel Leigh[1], Tammy Vo[1], Alyssa Coulter[1], Vivek Thumbigere-Math[3], Demetrios Braddock[4], Martha Somerman[1], Brian Foster[2]. [1]NIAMS/NIH, United States, [2]College of Dentistry, The Ohio State University, United States, [3]University of Maryland School of Dentistry, United States, [4]Yale School of Medicine, United States

Purpose: Regulation of pyrophosphate (PPi), a mineralization inhibitor, is critical for development of bones and teeth. Progressive ankylosis protein (ANK) and ectonucleotide

pyrophosphatase/phosphodiesterase-1 (ENPP1) increase PPi levels; ANK or ENPP1 loss results in ectopic calcifications and a striking hypercementosis phenotype in humans and mice. ENPP1 mutations are associated with generalized arterial calcification of infancy (GACI). Crosstalk between PPi regulators and SIBLING (small integrin-binding ligand- N-linked glycoprotein) members, e.g. osteopontin (OPN), dentin matrix protein (DMP1) has been proposed, however, specific mechanisms remain elusive. We propose that ANK and ENPP1 have critical, non-redundant roles in modulating PPi via different signaling pathways and downstream genes/proteins.Methods: Exfoliated primary teeth from individuals with GACI were analyzed by micro-computed tomography (microCT) and histology. Mandibles from wild-type (WT), Ank, Enpp1, and double knockout mice (dKO) were evaluated by microCT, histology, immunohistochemistry (IHC), tartrate resistant acid phosphatase (TRAP), and qPCR. Efficacy of an Enpp1-fusion protein (ENPP1-Fc) was assessed in Enpp1 KO mice. Results: GACI individuals demonstrated hypercementosis similar to Enpp1 KO mice (4 fold higher versus controls). Compared to WTs, with higher values in dKOs, increased acellular cementum width/volume (3-5 fold) were found in 60dpn Ank, Enpp1 KOs and dKOs. Ank KO cellular cementum volume was 30% higher compared to WTs. DKOs exhibited a 10% increase in cementum mineral density versus WTs and morphological characteristics of both single KOs. TRAP staining showed a trend toward increased osteoclast numbers in KOs and dKOs, and dKOs featured a further 15% decrease in alveolar bone volume compared to WTs. Distinct differences in gene/protein expression within periodontium of Ank, Enpp1 KOs and dKOs were detected, including 3-5 fold Spp1/OPN and Dmp1/DMP1 increases in Enpp1 KOs and dKOs absent in Ank KOs. Hypercementosis was attenuated in Enpp1 KO mice injected with ENPP1-Fc.Conclusions: Hypercementosis in GACI individuals validates clinical relevance of PPi regulators in dentoalveolar tissues. In alveolar bone and cementum, ANK and ENPP1 appear to have additive roles, possibly involving SIBLING regulation. Systemic ENPP1 manipulation altered cementum apposition, suggesting that factors decreasing local PPi levels are potential targets for periodontal therapies.

Health Burden of Hypophosphatasia in Adults: Results from a Self-Reported Study in the United Kingdom Sara Jenkins-Jones*[1], Laura Scott[1], Robert Desborough[2], Ioannis Tomazos[3], Richard Eastell[2]. [1]Global Epidemiology and Medical Statistics, Pharmatelligence, United Kingdom, [2]University of Sheffield, United Kingdom, [3]Alexion Pharmaceuticals, Inc., United States

Background: Hypophosphatasia (HPP) is a rare, systemic, metabolic disease characterized by poor skeletal mineralization, muscular weakness and ambulatory difficulties due to tissue-nonspecific alkaline phosphatase deficiency. Diagnosis of adults with HPP is challenging owing to broad manifestations, which can result in delayed diagnosis, misdiagnosis and inappropriate treatment. To evaluate the disease burden, we interviewed adults with HPP who visited a metabolic bone clinic in Sheffield, UK.Methods: In semi-structured, face-to-face interviews carried out by a specialist registrar between December 2016 and December 2017, in total, 28 consenting adults with HPP were asked to report their experience of HPP, including history of symptoms and healthcare resources used.Results: Of the 28 patients, 18 (64%) were female. Twenty-seven patients reported age at occurrence of their first HPP symptom: two (7%) experienced initial symptoms between 0–7 years of age, five (19%) between 8–18 years, 15 (56%) between 19–40 years and five (19%) between 41–70 years. Mean (median, interquartile range [IQR]) age at initial symptom presentation was 31.8 (32.5, 19.3–40.0) years. All patients reported being diagnosed between 19–40 years of age (n=12, 43%) or 41–70 years (n=16, 57%). Mean (median, IQR) age at diagnosis was 43.8 (44.0, 36.5–51.3) years. Mean (median, IQR) delay in diagnosis was 13.4 (10.0, 1.0–20.0) years. The main initial clinical symptoms reported by patients were musculoskeletal (MSK) conditions or pain (n=11, 39%), dental problems (n=7, 25%) and fractures (n=8, 29%). Patients reported experiencing the following over the course of their disease: MSK pain (n=20, 71%), weakness (n=9, 32%), dental problems (n=12, 43%) and mobility difficulties (n=7, 25%). Twenty patients (71 %) reported ≥ 1 fracture and 14 patients (50%) reported mental health problems (with 10 patients [36%] reporting symptoms of depression) . Before HPP diagnosis, patients reported multiple (mean 15.3, median 8.0, IQR 3.8–19.5) outpatient contacts with different secondary care specialties, mainly radiology (82%), accident and emergency (46%) and metabolic bone clinics (46%). Mean (median, IQR) number of diagnostic tests reported was 6.9 (6.0, 4.0–8.5).Conclusion: Although our findings may be affected by incomplete recall, these data suggest a substantial delay in diagnosis for adults with HPP, even though their clinical history conveys high disease burden and healthcare resource use.

MON-1108

Activation of the RANKL/OPG pathway is central to the pathophysiology of fibrous dysplasia and is associated with disease burden and pain Luis Fernandez De Castro Diaz*[1], Andrea B Burke[1], Howard Wang[1], Pablo Florenzano[1], Jeffrey Tsai[2], Kristen Pan[1], Bhattacharyya Nisan[1], Alison M Boyce[1], Rachel I Gafni[1], Alfredo Molinolo[2], Pamela G Robey[2], Michael Collins[2]. [1]Section on Skeletal Disorders and Mineral Homeostasis, National Institute of Dental and Craniofacial Research, National Institutes of Health, United States, [2]National Institutes of Health, United States, [3]University of California, San Diego, United States

Fibrous dysplasia of bone (FD) is a debilitating, often painful, mosaic disease caused by mutations of GNAS. The constitutive activation of the GNAS transcript, Gαs, leads to an uncontrolled proliferation of bone marrow stromal cells (BMSCs), generating fibrotic tissue and abnormal immature bone that replaces marrow-resident hematopoietic cells and adipocytes. Increased FD BMSC RANKL expression has been previously demonstrated, suggesting a role for FD BMSCs in mediating lesion expansion. Treatment with denosumab, a RANKL neutralizing antibody, has been shown to decrease FD-associated pain. However, activation of the RANKL/OPG pathway is not fully characterized in FD. Methods: Serum levels of RANKL, OPG and inactive RANKL-OPG complexes in FD patients and healthy volunteers (HVs) were measured. Skeletal burden score (a validated measure of FD burden), and the presence or absence of pain was determined at the time of blood collection. FD tissue sections were assessed by immunohistochemistry for RANK, RANKL, and Ki67. BMSCs from FD lesions and HVs were cultured, and media levels of secreted RANKL and OPG were measured. FD-induced osteoclastogenesis was assessed by co-culturing FD and HV BMSCs with HV peripheral monocytes. Results: FD patients showed a 30-fold increase in serum RANKL compared to HVs, however there were no differences in OPG levels between the 2 groups. The serum RANKL/OPG ratio was 20-fold higher in FD patients than in HVs, however no differences in levels of serum RANKL-OPG complex were observed. RANKL, OPG and the RANKL/OPG ratio were positively correlated with skeletal disease burden. Serum levels of OPG, but not RANKL, were higher in patients reporting bone pain (p=0.053), resulting in a lower RANKL/OPG ratio in these patients. FD tissue showed RANKL+ Ki67+ fibroblastic cells co-localized to RANK+ multinucleated giant cells. RANKL levels were high in media from FD BMSC cultures, and undetectable in HV cultures. Less OPG was detected in FD BMSC cultures than in HV cultures. FD, but not HV BMSCs, induced cell fusion when co-cultured with peripheral monocytes. Conclusions: These data are consistent with the role of RANKL as a driver in FD-induced osteoclastogenesis. OPG serum levels correlate with FD burden, but on average are similar between FD and HV sera, and lower in FD BMSC cultures.

MON-1109

When bone collagen cross-linking fails: how abnormal collagen post-translational chemistry and cross-linking causes bone fragility in Bruck sydrome caused by PLOD2 mutations. Charlotte Gistelinck*, Maryann Weis, Jyoti Rai, Peter H. Byers , David R. Eyre. University of Washington, United States

Bruck syndrome (BS) is a congenital disorder characterized by joint flexion contractures, skeletal dysplasia and increased bone fragility, showing strong clinical overlap with Osteogenesis Imperfecta (OI). On a genetic level, BS is caused by biallelic mutations in either the FKBP10 or the PLOD2 gene. PLOD2 encodes the lysyl hydroxylase 2 (LH2) enzyme which is responsible for the hydroxylation of lysyl residues in fibrillar collagen telopeptides. This modification is essential for allowing collagens to form stable intermolecular cross-links in the extracellular-matrix. Bone collagen has a unique pattern of cross-linking that is required for bone strength, resistance to microdamage and crack propagation and also a normal ordered pattern of mineral nanocrystals in the collagen fibrils.To date, no direct studies of human bone from BS caused by PLOD2 mutations have been reported. We present here results from a case of BS in a 4-year-old Caucasian patient, caused by compound heterozygous mutations in PLOD2. Bone tissue was collected during surgery, and bone collagen was biochemically characterized using SDS-PAGE, cross-link analysis and peptide mass-spectrometry. The patient's bone showed diminished hydroxylation of type I collagen telopeptide lysines, while hydroxylation at helical sites was unaltered. Consequently, mature trivalent cross-links, which depend on the presence of telopeptide hydroxylysines, were shown to be greatly reduced. Mass-spectrometry identified abundant allysine aldol dimeric cross-links in the patient's bone, which are not normally present in bone but are a feature skin collagen. SDS-PAGE further illustrated a skin-like migration pattern of the patient's extracted bone collagen, with more prevalent b-dimers and g-trimers. Type II collagen cross-linked peptides from the patient's urine were also analyzed. In contrast to bone type I collagen, the results showed a normal telopeptide lysine hydroxylation of cartilage type II collagen. Taken together these findings shed light on the complex mechanisms that control the unique posttranslational chemistry and cross-linking of bone collagen, and that when defective can cause a brittle bone disorder.

MON-1110

Inhibition of tyrosine kinase receptor C-ROS-1 as a novel treatment for patients with TWIST haploinsufficiency induced craniosynostosis Esther Camp*[1], Peter Anderson[2], Andrew Zannettino[3], Stan Gronthos[1]. [1]Mesenchymal Stem Cell Laboratory, Adelaide Medical School, Faculty of Health and Medical Sciences, The University of Adelaide, Australia, [2]Australian Craniofacial Unit Women's & Children's Hospital, Australia, [3]Myeloma Research Laboratory, Adelaide Medical School, Faculty of Health and Medical Sciences, The University of Adelaide, Australia

The c-ros-oncogene 1 (C-ROS-1) gene encodes a receptor, which belongs to the seven-less subfamily of tyrosine kinase insulin receptors and is conserved among vertebrates [1,2]. We have, for the first time, identified C-ROS-1 expression in human bone marrow derived mesenchymal stem cells (BMSC) and cranial bone cells. Knock-down of C-ROS-1 in human BMSC and cranial bone cells resulted in a decreased capacity for osteogenic differentiation in vitro [3]. Expression of C-ROS-1 is upregulated during osteogenic differentiation, but is suppressed by the basic helix loop helix transcription factor, Twist-1 (TWIST) [3]. TWIST is important in skeletal and cranial development, where Twist-1 mutant heterozygote mice display abnormal craniofacial and skeletal structures. These abnormalities are replicated in a human childhood disorder known as Saethre–Chotzen syndrome (SCS) which is caused by a mutation in the TWIST gene. In both mice and humans, Twist-1 happloinsuficient results in the premature bony bridging between apposed skull plates in the cranium due to excessive intramembranous and endochondral ossification, leading to craniosynostosis. TWIST happloinsufficient human and mouse cranial bone cells express higher levels of C-ROS-1 when compared to wild type cells. Knock-down of C-ROS-1 transcript using siRNA, or inhibition of C-ROS-1 function using the drug Crizotinib in Twist-1 haploinsufficient cranial cells resulted in a decreased capacity for osteogenic differentiation. Furthermore, treatment of Twist-1 mouse cranial bone explants cultures with Crizotinib induced a decrease in mineral deposition compared to untreated cranial explants. We have identified C-ROS-1 as a possible novel target in the treatment of SCS. Currently, the only treatment option available is major invasive cranial surgery. This procedure is potentially life-threatening and traumatic for the children and their families, requiring substantial hospitalization and resources. The development of new approaches with therapeutic agents to prevent or minimize fusion could have a profound impact on an affected child's management resulting in reduced cranial surgery. Identifying Molecular Pathways in Autosomal Recessive Hypophosphatemic Rickets Type 2 (ARHR2) by Mapping Genetic Changes Associated with ENPP1 Loss of Function Nathan Maulding*[1], Kristin Zimmerman[2], Dillon Kavanagh[2], Mark Horowitz[2], Thomas Carpenter[2], Demetrios Braddock[2]. [1]Yale University, United States, [2]Yale, United States

Humans with homozygous loss of function (LOF) mutations in ENPP1 develop Autosomal Recessive Hypophosphatemic Rickets Type 2 (ARHR2), a rare disease clinically indistinguishable from X-linked Hypophosphatemia (XLH), a hypophosphatemic rickets induced by mutations in the neutral endopeptidase PHEX. Characteristic findings in both humans with PHEX and ENPP1 mutations include elevated FGF23, hypophosphatemia secondary to increased urinary phosphate loss, and rickets. Impaired growth, fractures of the long bones, and skeletal deformities occur in both ARHR2 and XLH. The histologic hallmark of both human conditions is osteomalacia responsive to phosphate replacement therapy. In contrast, while mice with PHEX mutations closely parallel the human phenotype, mice with ENPP1 mutations primarily demonstrate low bone mineral density and increased bone fragility more characteristic of an osteopenic phenotype.To map genetic pathways associated with ENPP1 LOF, we performed RNAseq and qPCR in liver, kidney and cortical bone from lower limbs of 10 and 23 wk old ENPP1asj/asj mice, which are characterized by an inactivating mutation near the enzymatic active site. Genetic changes were correlated with uCT and biomechanical parameters. The expression of the Wnt signaling components LRP6 (-2.2 fold, P=0.021), Wnt5a (-2.8 fold, P=0.044), and ß-catenin (-2.3 fold, P=00069) are decreased in the bones of ENPP1asj/asj mice, while expression of two inhibitors of Wnt signaling – SFRP1 , a soluble decoy produced in liver (+2.1 fold, P=0.037) and WIF1, a soluble decoy produced in kidney (+11.7 fold, P=0.0173) – are both increased. Bone expression of osteoblastic markers (osteocalcin, osterix, and bone sialoprotein) were decreased in ENPP1asj/asj mice (-2.5 to -1.8 fold, P<0.02). Finally, genetic evidence of increased bone resorption via decreased OPG in bone (-3.3 fold, P=0.0067) is also present in ENPP1asj/asj mice. uCT and biomechanical findings in ENPP1asj/asj mice demonstrated decreased cortical and trabecular bone mineral density and increased bone fragility. The constellation of findings suggests that ENPP1 LOF uncouples bone turnover via downregulating anabolic Wnt pathway activation while promoting bone resorption by increasing osteoclastic activity through decreased OPG. The pathways associated with ENPP1 LOF suggest mechanisms of osteopenia induced by ENPP1 loss and demonstrates ENPP1's role in balancing bone formation and resorption to maintain bone mineral density.

Continuous infusion of PTHrP(7-36) Inverse Agonist Ameliorates the Delay in Endochondral Bone Formation in a Mouse Model of Jansen's Metaphyseal Chondrodysplasia Shigeki Nishimori*[1], Hiroshi Noda[1], Ernestina Schipani[2], Jun Guo[1], Thomas Gardella[1], Harald Jueppner[1]. [1]Massachusetts General Hospital, United States, [2]University of Michigan, United States

Background: Jansen's metaphyseal chondrodysplasia (JMC) is a rare genetic disease caused by heterozygous activating mutations in the parathyroid hormone receptor-1 (PTHR1). The mutations cause a delay in endochondral bone formation, which leads to short stature and limb deformities. Currently, there is no effective treatment option. PTH(7-34) and PTHrP(7-36) analogs containing a D-tryptophan-12 substitution function as inverse agonists at mutant PTHR1s of JMC, such as PTHR1-H223R, and thus suppress their basal signaling activities in cell-based cAMP assays. Furthermore, transgenic mice expressing the H223R mutation under control of the Col2-promoter (C2-HR mice: Schipani, PNAS 1997) show delayed hypertrophic differentiation of growth plate chondrocytes. Here, we report the effects of a PTHrP-based inverse agonist (IA) in this mouse model of JMC.Methods: Heterozygous C2-HR males were mated with WT females. From day 6 of pregnancy, these females were infused with either IA or vehicle via Alzet mini pump at 0.25 mL/hour (0.4 nmol of IA/hour). The pups were sacrificed at birth for analyses. Residual IA in the pumps exhibited the same potency as the initial peptide, as determined by cAMP bioassay using HEK293/GloSensor/PTR1-H223R stable cells, confirming peptide stability.Results: Body weight, long bone length and long bone growth plates were not different between WT and C2-HR pups, either treated with IA or vehicle (WT: veh. and IA, n=6; C2-HR: veh., n=7; IA, n=4). Sternal growth plates of C2-HR mice exhibited the previously observed delay in endochondral bone formation. The distance between the two areas expressing Col10a1 was significantly reduced in C2-HR pups compared to WT pups (292±10 vs. 366±8 µm; p=0.001). The length of the areas expressing osteopontin was significantly shorter in C2-HR pups than in WT pups (219±9 vs. 303±4 µm; p=0.0006). Treatment with IA significantly expanded the areas of Col10a1 expression in C2-HR pups (292±10 vs. 388±25 µm; p=0.001), but not in WT pups (366±8 vs. 414±41 µm; p=0.08). Furthermore, IA treatment increased the area of osteopontin expression in C2-HR (219±9 vs. 337±36 µm; p=0.01), but not in WT pups (303±4 vs. 366±46 µm; p=0.15).Conclusion: Our studies suggest that a PTHrP(7-36)-based inverse agonist can access the growth plates and at least partially reverse the delay in endochondral bone formation that is caused by the constitutively active PTHR1-H223R allele of JMC.

X-Linked Hypophosphatemia: PHEX 3'UTR c.*231A>G Causes a Uniquely Mild Phenotype Including Three Large American Kindreds (A Retrospective, Case-Control Study) Pamela S. Smith*[1], Gary S. Gottesman[2], Fan Zhang[2], William H. Mcalister[3], Fiona Cook[4], Valerie Wollberg[2], Margaret Huskey[5], Steven Mumm[5], Michael P. Whyte[2]. [1]Division of Pediatric Endocrinology and Diabetes, Washington University School of Medicine, United States, [2]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, United States, [3]Mallinckrodt Institute of Radiology, Washington University School of Medicine at St. Louis Children's Hospital, United States, [4]Division of Endocrinology, Brody School of Medicine, United States, [5]Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine at Barnes-Jewish Hospital, United States

X-linked hypophosphatemia (XLH) accounts for ~ 80% of heritable hypophosphatemic rickets. Over 330 causal PHEX mutations lead to increased circulating FGF23 levels with significant renal phosphate wasting. In 2014, we reported 6 seemingly sporadic, mildly affected children and their mothers who carried the PHEX 3'UTR c.*231A>G (UTR) mutation. UTR is not listed as a normal gene variant in ExAC, gnomAD, or ClinVar. Subsequent investigation revealed three large American kindreds and additional individuals harboring this defect. The three kindreds comprised, thus far, 13, 9, and 6 members who were UTR mutation-positive. Thus, we conducted a retrospective, age/sex-matched, case-control study to delineate the phenotype of 30 UTR subjects (UTRs) versus 30 classic XLH patients (XLHs). Clinical and biochemical data were assessed using the two-sample T-test and Fischer's exact test. For the UTRs and XLHs, the mean ages were 23.4 years, with each group including 17 children (2-17 years) and 13 adults (23-63 years). There were 10 women and 3 girls in each group. UTRs versus XLHs mean (SD) fasting serum phosphorus was 3.0 (0.5) vs. 2.5 (0.7), FGF23 was 158 (61) vs. 278 (93), and TmP/GFR was 2.5 (0.5) vs. 1.9 (0.7); Ps < 0.01 (Table). Mean (SD) height Z-scores of UTRs versus XLHs were -1.03 (1.0) and -2.07 (1.4); p=0.003, whereas mean differences of arm span Z-scores and height Z-scores (AHD) were 0.1 (0.6) and 0.7 (1.0), respectively (p=0.014). Thus, UTRs were more proportionate than XLHs. The AHD of male UTRs versus male XLHs was 0.2 (0.5) and 0.8 (0.9); p=0.026. No significant difference for AHD was found between female UTRs and female XLHs (p=0.238). Notably, 43% of UTRs versus 90% of XLHs had received standard of care therapy (SOC). No female UTRs but 85% of female XLHs had received SOC. Also, 24% of male UTRs and 94% of male XLHs had received SOC (Ps < 0.0001). Thus, individuals, especially females, with UTR compared to classic XLH are mildly affected and are frequently of normal height, more proportionate, and have a better biochemical profile, even untreated. While UTR males have mild features of XLH, females have often-unrecognized subtle signs, such as genu varum/valgum, dental abnormalities, etc. UTRs with minor features may not require medical therapy, thereby avoiding potential complications. However, a correct diagnosis is important for understanding the inheritance pattern, sex-dependent expression of the UTR phenotype, and counseling for this population.

Novel c.G630A TCIRG1 Mutation Causes Aberrant Splicing Resulting in Unusually Mild Form of Osteopetrosis Ralph Zirngibl*[1], Andrew Wang[1], Yeqi Yao[1], Morris Manolson[1], Joerg Krueger[2], Roberto Mendoza-Londono[2], Irina Voronov[1]. [1]University of Toronto, Canada, [2]Hospital for Sick Children, Canada

Infant malignant autosomal recessive osteopetrosis (ARO) is a severe genetic bone disease characterized by high bone density. This disease is caused by mutations that affect formation or function of osteoclasts, the bone resorbing cells. Mutations in the a3 subunit of the vacuolar type H+-ATPase (encoded by TCIRG1 gene) are responsible for almost 50% of all ARO cases. We identified a novel TCIRG1 mutation (c.G630A) responsible for an unusually mild form of the disease.To characterize this mutation, osteoclasts were differentiated using the peripheral blood monocytes from the patient (homozygous for the mutation, c.G630A/c.G630A), unaffected male sibling (non-carrier, +/+), unaffected female sibling (carrier, heterozygous for the mutation, +/c.G630A), and unaffected parent (carrier, heterozygous for the mutation, +/c.G630A). Osteoclast formation (tartrate resistant acid phosphatase (TRAP) staining), bone resorbing function (Osteologicä plates), TCIRG1 protein and mRNA expression levels were assessed.The c.G630A mutation did not affect osteoclast differentiation; however, the resorption of the bone-like substrate was decreased in the patient compared to the unaffected controls. Both TCIRG1 protein and full-length TCIRG1 mRNA expression levels were also diminished in the patient's sample. Next, we tested for exon skipping. We analyzed the TCIRG1 sequence between exons 4 and 8 and detected deletions of exons 5 (ΔE5), ΔE6, ΔE7, and ΔE5-6 (sequencing of the PCR products confirmed the results). These deletions were only detected in c.G630A/c.G630A and +/c.G630A samples, but not in +/+ controls.The ΔE5-6 maintains the reading frame and is predicted to generate a 85 kDa protein. Exons 5-6 encode an uncharacterized portion of cytoplasmic N-terminal domain of a3, the domain not involved in proton translocation. To investigate the effect of ΔE5-6 on V-ATPase function, we transformed yeast with full-length Vph1p, the yeast ortholog of a3, or Vph1p with a truncation mimicking human ΔE5-6. Both proteins were expressed; however, ΔE5-6-Vph1p transfected yeast failed to grow on Zn2+-containing plates, a growth assay dependent on V-ATPase-mediated vacuolar acidification. In conclusion, our results so far suggest that mild ARO phenotype observed in the patient was due to the residual full-length protein expression, since the ΔE5-6 truncated protein does not appear to be functional.

Development and characterization of a hypophosphatasia (HPP) tooth and muscle phenotype in sheep to model disease in an index HPP patient Diarra Williams*[1], Shannon Huggins[1], Alexis Mitchell[1], Alyssa Falck[1], Jane Pryor[1], Cassandra Skenandore[1], Grant Read[1], Hays Boyd[1], Sierra Long[1], Brian Foster[2], Mark Westhusin[1], Charles Long[1], Larry Suva[1], Dana Gaddy[1]. [1]Texas A&M University, United States, [2]Ohio State University, United States

Hypophosphatasia (HPP) is a rare inherited disorder of mineral metabolism that affects the development of bones and teeth. The disease is the result of mutations in the tissue-non-specific alkaline phosphatase (TNSALP) gene (ALPL) often accompanied by a highly variable clinical presentation. Our identification of an index patient later confirmed as a compound heterozygote with an Alanine -> Threonine (c.346 G>A) mutation in exon 5 and an Isoleucine -> Methionine (c.1077 C>G) mutation in exon 10 of ALPL led us to initiate efforts to develop a model in which to understand the biology of the myasthenia and premature teeth loss in this patient. The patient experienced rhizomelia, waddling gait, and premature tooth loss that was associated with a significantly decreased alkaline phosphatase activity at 2 years of age (29 U/L (age-adjusted); NR 1-3 yrs. 125 U/L), normal serum calcium and high normal phosphate levels. MicroCT examination of prematurely erupted teeth demonstrated marked hypomineralized dentin and evidence of bone resorption. Since sheep and humans are diphiodont (two sets of teeth), including primary and secondary sets and mice are monophyodont (one set of teeth), we developed a novel sheep platform to model the tooth, muscle and bone pathophysiology of HPP. Using CRISPR/Cas9 the index patient ALPL gene mutations in exon 5 and exon 10 of the ALPL gene were introduced individually into the sheep genome. Compared to wild-type (WT) controls mutant HPP sheep have significantly reduced serum alkaline phosphatase activity. The exon 10 sheep have decreased tail vertebral bone size, enhanced metaphyseal flaring consistent with the mineralization deficits observed in human HPP as well as an altered gait and force distribution during locomotion. Oral radiographs and computed tomography revealed thin dentin and wide pulp chambers in incisors, and radiolucency of jaws in HPP vs. WT sheep at 2 months and 7 months of age. Skeletal muscle biopsies (2 months) identified aberrant fiber size and mitochondrial cristae structure in exon 10 HPP vs. WT sheep. Since there is still much to learn regarding HPP pathophysiology, we hypothesize that the HPP sheep presented here provide a unique opportunity to address fundamental HPP questions regarding muscle, bone and tooth development that this index patient and others currently struggle to manage.

Continued development of hiPSCs as an in vivo platform for exploring heritable disorders of the human skeleton Xiaonan Xin*, Kronenberg Mark, Alexander Lichtler, David Rowe. School of Dental Medicine, University of Connecticut Health, United States

Induced pleuripotent stem cells derived from human subjects (hiPSCs) provide the opportunity to study gene mutations that impact osteoblasts and chondrocytes at a level that cannot be achieved with primary cells or mouse models. Specifically, the heterogeneity of disease severity of the same gene mutation in different subjects is a consequence of the genetic background of the individual, and that important effect can only be modeled in hiPSCs. We have previously demonstrated that progenitor cells derived from embryoid bodies and grown in an endothelial growth medium under a low oxygen environment produce cryohistologically recognizable human cartilage and bone in a mouse calvarial defect. Furthermore the RNA profile of laser captured tissue sections shows the expected gene expression pattern of cartilage and osseous tissues. This platform can demonstrate that CRISPR/Cas correction of a COL1A1 mutation of a subject with type III OI reverses the mutant phenotype, in which adipocytic tissue predominates, back to production of cartilage and bone. However an unanticipated feature of the cartilage and bone from all donors is the lack of osteoclast remodeling of the bone and hypertrophic cartilage matrix, and the absence of bone marrow spaces. Thus the model does not replicate the indirect effects of a type I collagen mutation on the myeloid/osteoclast lineage. Postulating that the human RANKL lacks sufficient interaction with mouse RANK in vivo to initiate osteoclast invasion, we utilized a previously described strategy to convert the extracellular domain of RANKL from human to mouse. The CRISPR/Cas strategy worked exceptionally well converting exon 5 in both alleles from human to mouse. When implanted in the calvarial defect, more mineralized osseous tissue formed and contained osteoclasts within bone marrow islands. In an unrelated experiment, we observed that human outgrowth cells from the human implant tissue can be retransplanted into a second mouse. In this case only a bone matrix without cartilage is formed, replicating the in vivo outcome of human bone marrow stromal cells, including a human bone matrix that is not remodeled by mouse osteoclasts. These advances in manipulating hiPSCs to replicate the characteristics of chondrocytes and osteoblasts in a mouse transplantation platform will hasten their application for studying heritable disease in their native genetic background and developing cell therapies utilizing mutation-corrected progenitor cells.

Clinical characteristics and pathogenic gene mutations identification of Paget's disease of bone in Chinese population Hua Yue*, Zhenlin Zhang. Metabolic Bone Disease and Genetic Research Unit, Department of Osteoporosis and Bone Diseases, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, China

INTRODUCTION: Paget's disease of bone (PDB) is characterized by highly localized areas of increased bone resorption and disorganized bone remodeling. It is common in western descent. However, it is rare in Chinese. Genetic factors play an important role in the pathogenesis of the disease [1]. The purpose of the study was to characterize the clinical features and identify genetic mutations in Chinese PDB patients. METHODS: 37 clinically diagnosed PDB patients (two were father and son, the rest were sporadic) and 250 healthy donors were recruited. The clinical features were characterized and the whole-exome sequencing (WES) was carried out in patients to detect gene mutation and then confirmed in donors by Sanger sequencing. PolyPhen-2 and CADD analyses were performed to predict the damaging effect of the mutation. Mutant protein structure was constructed as well. RESULTS: The father and son were early-onset (onset age <30 years). The onset age of sporadic PDB patients (53.2±19.1 years) was younger than that of western patients. One of them was PDB combined with giant cell tumor (GC), had even earlier onset age (23 years) with mild symptoms. The most common lesion sites were the pelvis, femur, and skull. Most patients had high serum alkaline phosphatase (ALP) level and intravenous bisphosphonates was effective to relieve bone pain and reduce ALP level. Vitamin D receptor (VDR) gene mutation was identified in a 25-year-old male, who harbored a heterozygous G-to-A transversion at position 424 in exon 4 (c.G424A), which resulted in a glutamate-to-lysine (GAG >AAG) substitution at codon 142 (E142K). No SQSTM1 gene mutation was detected in all 37 patients, which was different from the western patients. VDRE142K was predicted to be damaging with PolyPhen-2 score of 1 and CADD score of 37. Meanwhile, the amino acid residues at p.142 is highly conserved across 9 different biological species. By constructing the mutant protein structure, it was found that the mutation site located in the VDR protein DNA binding region, and which would significantly enhance DNA interaction. DISCUSSION: Vitamin D regulates osteoclast function by binding to VDR [2]. Therefore, VDR dysfunction directly affects the osteoclasts status. CONCLUSION: Our study described the clinical features and reported that VDR gene mutation contributes to the pathogenesis of PDB in Chinese patients.REFERENCES1.Albagha OM. Genetics of Paget's disease of bone Bonekey Rep. 4: 756, 2015.2.Shibata T, Shira-Ishi A, Sato T, et al. Prospective Associations of Sarcopenic obesity and dynapenic obesity with joint replacement over 13 years in Community-dwelling Older Adults Saliu Balogun*[1], David Scott[2], Stephen Graves[3], Michelle Lorimer[4], Flavia Cicuttini[5], Graeme Jones[1], Dawn Aitken[1]. [1]Menzies Institute for Medical Research, University of Tasmania, Australia, [2]Department of Medicine, School of Clinical Sciences at Monash Health, Faculty of Medicine, Nursing and Health Sciences, & Peninsula Clinical School, Central Clinical School, Monash University, Australia, [3]Australian Orthopaedic Association, University of Melbourne, Parkville, Australia, [4]South Australian Health and Medical Research Institute (SAHMRI), Australia, [5]Department of Epidemiology and Preventive Medicine, Monash University, Australia

Purpose: This study aims to determine whether older adults with low muscle mass (sarcopenia) or strength (dynapenia), in the presence of obesity, have an increased risk of total knee and hip replacement surgery over 13 years.Methods: 995 community-dwelling older adults (51% women; mean age 62.8±7.4 years) were studied at baseline and multiple time points over 13 years. The incidence of knee and hip joint replacement was determined by data linkage to the Orthopaedic Association National Joint Replacement Registry. Total body fat mass and appendicular lean mass were measured using dual energy X-ray absorptiometry (DXA). Lower-limb muscle strength was assessed using dynamometer. Sarcopenic obesity and dynapenic obesity were defined as the lowest sex-specific tertiles for appendicular lean mass (adjusted for height and total body fat mass) or lower-limb strength, respectively, and the highest sex-specific tertile for total body fat mass. Competing risk regression models were used to estimate the sub-distribution hazard ratio (SHR) for knee and hip joint replacement over 13 years in unadjusted and adjusted analysis.Results: Over 13 years of follow-up, 74 (7.4%) participants had a knee replacement and 63 (6.4%) had a hip replacement. The risk of having a knee replacement was significantly higher in participants who were dynapenic obese (SHR=5.46, 95% CI 2.50, 11.94), dynapenic non-obese (SHR=4.09, 95% CI: 1.93, 8.69), and non-dynapenic obese (SHR=3.92, 95% CI: 1.86, 8.26) compared to those without dynapenia or obesity. However, dynapenic obesity did not lead to a significantly greater risk of knee replacement compared to having dynapenia or obesity alone. The risk of having a knee replacement was significantly higher only in participants who were non-sarcopenic obese (SHR=2.28, 95% CI: 1.26, 4.13) compared to those without sarcopenia or obesity. There was no evidence for an association between sarcopenic or dynapenic obesity and hip joint replacement (all P>0.05).Conclusions: In the presence of obesity, dynapenia but not sarcopenia increased the risk of knee joint replacement. Notably, the combination of low muscle strength and obesity did not lead to a significantly greater risk of knee replacement compared to having these conditions on their own. This finding suggests that combining muscle and fat assessments to predict the future risk of joint replacement is no better than each individual condition on its own.

MON-1139

Secular Trends in Mortality Due to Falls and Hip Fracture in the US Jane Cauley*, Kendra Jean Bobby, Elsa Strotmeyer, Jeanine Buchanich. University of Pittsburgh, United States

Declines in hip fracture incidence rates in the US from 2002-2012 have stopped with rates for 2013-2015 higher than expected (Lewiecky EM. Osteo Int 2017). To test whether secular changes in mortality from hip fractures or falls follow similar patterns, we used the Mortality Informatics and Research Analytics (MOIRA) database, a repository and retrieval system for US death data from the National Center for Health Statistics(NCHS) developed at the University of Pittsburgh. The MOIRA database contains individual demographic information plus the underlying and contributory cause of death for 120 million+ decedents. Age -adjusted death rates for falls from 1962 to 2014 (ICD-9th revision: 880-888; ICD 10th revision, W00-W19 (1999 on) and hip fractures from 1990-2015 (ICD 9th revision: 820. xy; ICD-10: S72.xy) were calculated. The NCHS comparability ratio of 0.84 was used for interpreting trends in fall mortality from the ICD-9 to ICD-10. No comparability ratio was available for the hip fracture mortality. Fall deaths were counted as underlying cause. Hip fractures were counted as either the contributing or underlying cause of death. Pathologic hip fractures (733.14) were excluded. We restricted our analysis to age groups 50+. Joinpoint regression was used to detect significant changes in trends. Fall death rates show a continued decline from 1962-1981; plateau in mortality rates 1981-1996 and a continued increase in fall death rates from 2000-2014, all changes in trends were significant at p<0.05, (Figure 1). Patterns were similar in men and women with fall death rates higher in men than women. Examination of age-specific fall death rates show the steepest increase in those age 85+. Hip fracture death rates have declined from 1989- 2015, Figure 2, p<0.05. The slight increase in death rates from 1998 to 2001 is likely an artifact of the ICD revision change. Consistent with previous literature, age adjusted hip fracture mortality rates were higher in men than women from 1999-2005. However more recently, a different pattern emerged from 2010-2015 where hip fracture mortality rates were higher in women than men. Understanding the factors contributing to the increase in fall death rates and the differential pattern overtime by sex in hip fracture mortality is critical with the concurrent population increase of the oldest old cohorts.

A new CT based approach to quantify adipose tissue in paraspinal muscle

Klaus Engelke*[1], Oleg Museyko[2], Daniel Günzel [1], Andreas Meier[3], Jean-Denis Laredo[4]. [1]Inst. of Medical Physics, University of Erlangen-Nuremberg, Germany, [2]Inst. of Medical Physics, Univ. of Erlangen, Germany, [3]Inst. of Informatics, University of Erlangen-Nuremberg, Germany, [4]Radiologie Ostéo-Articulaire, Hôpital Lariboisière, AP-HP, CNRS UMR 7052, France

Introduction: Adipose tissue infiltration in paraspinal muscle decreases muscle quality and may be associated with back pain, structural abnormalities of the lumbar spine and perhaps even vertebral fracture. Here a new approach for segmentation and determination of adipose tissue infiltration of paraspinal muscle using CT images is presented Methods: Accurate muscle segmentation in CT images is difficult due to low soft tissue contrast. We developed a new approach primarily aiming at high precision at the expense of accuracy of muscle volume. Based on a global VOI and three orthogonal clipping planes the result-ingsegmentation captured about 80-90% of the paraspinal muscle at the expense of the outer

parts. The clipping planes were determined automatically based on a vertebral coordinate system (VCS) and a number of landmarks such as the ends of the transverse processes, the center of the VCS and the width of the vertebral body. The resulting segmentation, implemented in the Medical Image Analysis Framework (MIAF), was compared with a manual segmentation of an expert radiologist, which served as gold standard. Within the segmented paraspinal muscle VOI, pure adipose tissue was automatically determined using a threshold obtained from subcutaneous adipose tissue. The remaining muscle tissue was further divided into 5 compartments according to the CT-value. A low muscle density indicated a higher portion of adipose tissue. Pure muscle was defined as a muscle density > 25 HU determined from young elite athlets. Automated and manual segmentations were compared in 13 elderly osteoporotic subjects. Results: The figure shows results of the automated segmentation of the paraspinal muscle compared to the radiological gold standard segmetnation. The correlation of relative % volume of pure adipose tissue and of muscle between the automated and the manual segmentation was very high (r2 >0.97). Intra- and interoperator reanalysis precision errors were below 2%. Conclusion: The new segmentation approach showed excellent precision, which is highly important in longitudinal studies. The compromise on muscle volume accuracy seems justified as % adipose and muscle volume obtained from the automated approach correlated extremely high with the gold standard technique. Thus the method provides an excellent basis for further research in the field of vertebral fractures.

Neither Sarcopenia, Body Composition Parameters, nor Salivary Cortisol Circadian Rhythm are Associated to Increased Risk of Falls in Women 50 to 80 Years. The OsteoLaus Cohort Elena Gonzalez Rodriguez*[1,2], Didier Hans[1], Georgios Papadakis[3], Peter Vollenweider[4], Martin Preisig[5], Gerard Waeber[4], Pedro-Manuel Marques-Vidal[4], Olivier Lamy[1,6]. [1]Center of Bone Diseases, Rheumatology Unit, Bone and Joint Department, CHUV, Switzerland, [2]Endocrinology, Diabetology and Metabolism Unit, Internal Medicine Department, CHUV, Switzerland, [3]Endocrinology, Diabetology and Metabolism Unit, Internal Medicine Department, CHUV, Switzerland, [4]Internal Medicine Unit, Internal Medicine Department, CHUV, Switzerland, [5]Epidemiology and Psychopathology Research Unit, Psychiatric Department, CHUV, Switzerland, [6]Internal Medicine Unit, Internal Medicine Department, CHUV, Switzerland

Introduction: Muscle weakness is an important risk factor for falls. There are increasingly efforts to identify measurable parameters related to muscle weakness that could be clinically relevant. Sarcopenia is defined as the loss of muscle mass and function, and is associated with aging, but its link to risk of falls has not been consistently found. Muscle weakness and sarcopenia are present in hypercortisolism. We wanted to determine whether these parameters were associated to an increased risk of falls the previous year.Material and Methods: Cross-sectional study including 815 women >50 years (mean age 63.2±7.7) from the OsteoLaus cohort. Included participants had: lean mass body composition assessment by DXA, salivary cortisol circadian rhythm measures (awakening, 30 minutes thereafter, 11 AM and 8 PM) and measurement of handgrip. All participants were asked whether their sustained a fall on the previous year.Results: 227 participants (27.9%) reported at least one fall, without differences in the in the 3 tertiles of age (25.6%, 31.4% and 26.6% for participants 54.9±2.6, 62.6±2.2, and 72.1±4.2 years respectively).Gynoid region lean mass, but no other lean mass measures, was inversely associated to 8 PM salivary cortisol values after adjustment to BMI (p=0.025), and to BMI and age (p=0.052).Handgrip was inversely associated to both 11AM and 8 PM salivary cortisol values (p= 0.010 and 0.014), without influence of BMI. After adjustment to age and BMI, only association to salivary cortisol at 8 PM was significant (p=0.041).There was no significant association between any body composition parameter, salivary circadian cortisol value, handgrip measure or sarcopenia diagnosis according to EWGSOP criteria (ALMI < 5.5 kg/m2 and muscle strength < 20 kg), and prevalence of falls in the previous year, either in the whole participants cohort or in the oldest tertile.Conclusions: In our cohort of healthy post-menopausal women 50 to 80 years old, neither body lean mass measures nor muscle function (handgrip), or any of their

determinants (age, BMI or increased nadir salivary cortisol) were associated to increased risk of falls.

MON-1142

Dysmobility syndrome is associated with prevalent morphometric vertebral fracture in older adults: The Korean Urban-Rural Elderly (KURE) study
Namki Hong*, Chang Oh Kim, Yoosik Youm, Jin-Young Choi, Hyeon Chang Kim, Yumie Rhee. Yonsei University College of Medicine, Republic of Korea

The term "dysmobility syndrome" was coined to encompass the comprehensive risk factors affecting fractures. However, data on the association of dysmobility syndrome and its components with prevalent morphometric vertebral fracture (VF) in elderly persons are limited. In this prospective cohort study, a total of 1369 community-dwelling elderly subjects (mean age, 71.6 years; women, 66%) were analyzed. Dysmobility syndrome was defined as the presence of ≥3 of the following 6 factors: falls in the preceding year, low grip strength (<30 kg in men, <20 kg in women), osteoporosis (T-score ≤-2.5 at any site in the lumbar spine, femoral neck, or total proximal femur), low timed get-up-and-go performance (12 s or longer), low lean mass (appendicular skeletal muscle mass/height2 <7.0 kg/m2 in men and <5.7 kg/m2 in women in bioimpedance analysis), and high fat mass (>30% for men and >40% for women). VF was defined as a ≥25% reduction in the height of vertebral bodies assessed using plain radiographs. Non-VF was assessed using interviewer-assisted questionnaires. The prevalence of dysmobility syndrome was 20% (n = 273). Subjects with dysmobility syndrome were older (73.5 vs. 71.1 years), malnourished (35% vs. 17%), and physically inactive (30% vs. 18%) and had more hospitalizations during the preceding year (17% vs. 10%, p <0.001 for all). The prevalence of VF and any fracture composite of VF and non-VF was 16% and 25%, respectively, increasing from subjects with 0 dysmobility components to those with ≥5 (VF, 10-35%; any fracture, 16-45%, p for trend <0.001 for all). Dysmobility syndrome and its components were associated with elevated odds of VF (crude odds ratio [OR] 2.14, p <0.001; adjusted OR [aOR] 1.43, p = 0.047) or any fracture (OR 2.05, p <0.001; aOR 1.39, p=0.037); however, the association with non-VF (OR 1.16, p=0.048; aOR 1.29, p=0.217) was attenuated after adjustment for covariates. When subjects were stratified by bone mineral density levels, the relative odds of VF and non-VF increased in a stepwise fashion as the number of dysmobility syndrome increased in both osteoporosis group (VF, aOR 2.3 to 5.1; non-VF, aOR 4.9 to 6.7) and osteopenia group (VF, aOR 1.7 to 2.4; non-VF, aOR 3.9 to 6.8). In conclusion, dysmobility syndrome and its components were associated with elevated odds of morphometric vertebral fracture, independent of age and covariate, suggesting potential clinical utility of this concept in identifying persons with a high fracture risk.

Alteration in Skeletal Muscle Mass in Women with Primary Aldosteronism
Mi Kyung Kwak*[1], Jae Hyeon Kim[2], So Jeong Park[3], Seong Hee Ahn[4], Hyeonmok Kim[5], Yoon Young Cho[6], Sunghwan Suh[7], Beom-Jun Kim[8], Kee-Ho Song[9], Seung Hun Lee[8], Jung-Min Koh[8]. [1]Division of Endocrinology and Metabolism, Asan Medical Center, University of Ulsan College of Medicine, Republic of Korea, [2]Division of Endocrinology and Metabolism, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Republic of Korea, [3]Asan Institute for Life Sciences, Republic of Korea, [4]Department of Endocrinology, Inha University School of Medicine, Republic of Korea, [5]Division of Endocrinology and Metabolism, Department of Internal Medicine, Seoul Medical Center, Republic of Korea, [6]Division of Endocrinology and Metabolism, Department of Medicine, Gyeongsang National University School of Medicine, Republic of Korea, [7]Division of Endocrinology and Metabolism, Department of Medicine, Dong-A University Medical Center, Dong-A University School of Medicine, Republic of Korea, [8]Division of Endocrinology and Metabolism, Department of Medicine, Asan Medical Center, University of Ulsan College of Medicine, Republic of Korea, [9]Division of Endocrinology and Metabolism, Department of Medicine, Konkuk University Medical Center, Konkuk University School of Medicine, Republic of Korea

Purpose: Despite the potential detrimental effects of aldosterone excess on skeletal muscle, whether aldosterone excess in primary aldosteronism (PA) affects skeletal muscle mass is unknown. Our objective was to understand the effects of the aldosterone level on skeletal muscle mass in patients with PA.Methods: We compared skeletal muscle mass and fat mass (FM) between 62 patients with PA (29 women and 33 men) and 247 controls (76 women and 171 men) with nonfunctioning adrenal incidentaloma (NFAI). Medical records were reviewed, and we measured body coposition parameters using bioelectrical impedance analysis and serum aldosterone levels.Results: After adjusting for confounding factors, plasma aldosterone levels were inversely correlated with appendicular skeletal muscle mass (ASM) (β = -0.194, P = 0.017) and appendicular skeletal muscle index (ASMI) (β = -0.208, P = 0.009) in all women, but not men. ASMI was significantly lower by 4.6% (P = 0.034) in women with PA compared with those with NFAI, but not men. In women, the odds for lower skeletal muscle mass with the plasma aldosterone concentration (PAC) were 1.17-fold higher (P = 0.030), and with the presence of PA were 10.90-fold higher with marginal significance (P = 0.066) after adjustment for potential confounders.Conclusions: This study showed that women with PA had lower skeletal muscle mass, and suggested that aldosterone excess also has adverse effects on skeletal muscle metabolism.

Leisure-time aerobic physical activity and vitamin D concentrations in U.S. older adults Carlos Orces*[1], Daniella Orces[2]. [1]Laredo Medical Center, United States, [2]Southwestern University, United States

Purpose: Although leisure-time physical activity (LTPA) has been associated with increased 25(OH)D levels, previous studies among older adults have reported conflicting results between the duration or intensity of LTPA and 25(OH)D levels. Thus, this study aimed to examine the relationship between self-reported moderate and vigorous LTPA and 25(OH)D and 25(OHD3 concentrations among U.S. older adults.Methods: The present anaysis was based on participants aged 60 years and older in the The National Health and Nutrition Examination Survey 2007-2012. According to the 2008 physical activity guidelines for Americans, three levels of physical activity were created: 1) participants who engaged in ≥ 150 min/week of moderate activity, or ≥ 75 min/week of vigorous activity, or ≥ 150 min/week of an equivalent combination were defined as physically active; 2) insufficiently active were considered those who reported some physical activity, but no enough to meet the active definition (> 0 to < 150 min/week); 3) inactive if they reported no physical activity. Similarly, metabolic equivalent task (MET) scores per minutes/week were calculated. Those with < 750 MET-min/week or ≥ 750 MET-min/week were defined as insufficiently or sufficiently active, respectively. General linear models adujsted for potential confounders were created to examine mean 25(OH)D and 25(OH)3 across physical activity levels. Results: A total of 4,764 adults with a mean age of 69,7 (SE 0.1) years comprised the study sample, representing an estimate 46 millon U.S older adults during the study period. Overall, 57.5%, 14.8%, and 27.7% of participants were defined as physically inactive, insufficiently active, and physically active, respectively. The mean 25(OH)D and 25(OH)D3 concentrations were 75.0 (SE 0.9) and 68.8 (SE 0.9) nmol/L, respectively. As shown in Table 1, after controlling for confounders, those considered physically active had 9.9 and 9.0 nmol/L higher concentrations of 25(OH)D and 25(OH)3 than those physically inactive, respectively. Similarly, participants defined as physically active according to the intensity of LTPA had 10.4 and 9.8 higher mean 25(OH)D and 25(OH)D3 levels than their pysically inactive counterparts, respectively.Conclusion: Recreational physical activity is significantly associated with higher 25(OH)D concentrations in older adults. Despite this evidence, a considerable proportion of U.S. older adults are physically inactive.

Table 1. Association between leisure-time physical activity and 25(OH)D and 25(OH)₃ concentrations (nmol/L) among U.S. older adults

Physical activity	25(OH)D				25(OH)D₃			
Minutes/week	Model 1	Model 2			Model 1	Model 2		
Inactive (reference)	70.8 (1.0)	71.5 (0.9)			65.2 (0.9)	66.0 (0.9)		
Insufficiently active	76.7 (1.8)*	76.2 (1.6)			68.1 (1.6)	67.6 (1.6)		
Sufficiently active	82.7 (1.6)**	81.4 (1.4)**			76.3 (1.7)**	75.0 (1.7)**		
MET-min/week	Model 1	Model 2			Model 1	Model 2		
Inactive (reference)	70.8 (1.0)	71.5 (0.9)			65.2 (0.9)	66.0 (0.9)		
Insufficiently active	77.8 (1.5)	77.1 (1.3)*			69.4 (1.4)*	68.7 (1.3)		
Sufficiently active	83.2 (1.9)	81.9 (1.7)**			77.1 (2.1)**	75.8 (2.0)**

Alterations in Body Composition and Appendicular Lean Mass Assessed Using Whole-Body Dual-Energy X-ray Absorptiometry in BRCA Carriers Undergoing Prophylactic Salpingo-oophorectomy Jeevitha Srighanthan*[1], Joan Murphy[2], Joanne Kotsopoulos[3], Gabrielle E. V. Ene[1], Marcus Q. Bernardini[1], Queenie Wong[1], Diana Yau[1], Paula Harvey[3], Steven Narod[3], Barry Rosen[1], Amy Finch[4], Angela M. Cheung[1]. [1]University Health Network, Canada, [2]Trillium Health Partners, Canada, [3]Women's College Hospital, Canada, [4]Sunnybrook Hospital, Canada

Purpose: Prophylactic salpingo-oophorectomy (removal of the fallopian tubes and ovaries) is uniformly recommended to BRCA1/2 carriers at age 35 or once childbearing is complete. However, such surgically-induced menopause can induce bone and muscle loss, among other side effects. The long-term effect of this surgery on body composition is unknown. We compared differences in whole body composition and appendicular lean mass among women undergoing prophylactic salpingo-oophrectomy (PSO) as compared to non-oophorectomized women.Methods: This pilot one-year study examines musculo-skeletal outcomes among pre-menopausal women with a BRCA1/2 mutation undergoing PSO compared to pre-menopausal non-oophorectomized non-carrier women. Participants undergo a whole body dual-energy x-ray absorptiometry (DXA) scan at baseline (prior to surgery) and one year following PSO (or equivalent time frame for non-oophorectomized women). Percent changes in body mass index (BMI), whole body bone mineral density (BMD), bone mineral content, total mass, total lean mass, total fat mass, and percent fat mass from baseline to one-year were obtained from DXA scans using standard analysis protocols, as well as appendicular lean mass index (ALM/height2), lean mass index (LM/height2), and fat mass index (FM/height2). Differences between groups were statistically assessed using t-tests.Results: To date, 22 PSO BRCA carriers and 13 non-oophorectomized non-carriers have completed their one-year visit. Mean age of PSO BRCA carriers and non-oophorectomized women was 42.41 (SD 5.24) and 45.86 (SD 3.99) years, respectively. PSO BRCA carriers had a mean BMI of 26.19 (SD 4.10), as compared to a mean BMI of 26.64 (SD 3.01) in non-oophorectomized women. Participants were mostly Caucasian (83%). The table below demonstrates changes in bone, muscle and fat parameters for PSO BRCA carriers and non-carriers.Conclusions: Our preliminary findings demonstrate significant decreases in whole body BMD one-year after PSO when compared to non-oophorectomized women. Elevated percent fat mass among PSO patients also demonstrates a trend towards signif-icance. Other muscle and fat parameters were not significantly different between groups, however almost all outcomes were numerically poorer among PSO BRCA carriers. Further research with larger sample sizes and longer follow-up durations are required to understand the effects of this preventive surgery on musculoskeletal health.

One-Year Percent Change in BMI & Body Composition

	PSO BRCA carriers (n=22) % change (SD)	Non-oophorectomized non-carriers (n=13) % change (SD)	p-value
BMI (kg/m²)	0.11 (4.40)	0.30 (3.12)	0.89
Whole Body BMD (g/cm²)	-2.16 (2.68)	-0.10 (2.07)	0.024*
Bone Mineral Content (g)	-2.47 (3.78)	-1.33 (3.16)	0.37
Fat Mass (g)	3.48 (11.29)	-1.00 (7.74)	0.22
Percent Fat Mass	3.26 (7.50)	-0.36 (3.97)	0.072
Total Mass (g)	-0.0010 (4.68)	-0.76 (4.47)	0.64
Total Lean Mass (g)	-1.74 (3.26)	-0.67 (3.29)	0.36
Lean Mass Index (LMI) (kg/m²)	-1.73 (3.45)	-0.65 (3.49)	0.38
Appendicular Lean Mass Index (ALMI) (kg/m2)	-2.46 (5.12)	-1.72 (5.82)	0.70

Falls are the most frequent provocative factor for subsequent clinical fractures during 1-year follow-up in patients with a recent clinicl fracture evaluated and treated according to current osteoporosis guideline at a Fracture Liaison Service Lisanne Vranken*[1,2], Caroline E Wyers[1,2], Robert Y Van Der Velde[1,2], Irma Ja De Bruin[1,2], Heinrich Mj Janzing[4], Sjoerd Kaarsemaker[5], Piet Pm Geusens[3,4], Joop Pw Van Den Bergh[1,2,3]. [1]VieCuri Medical Center, Department of Internal Medicine, Netherlands, [2]Maastricht UMC+, NUTRIM School for Nutrition and Translational Research in Metabolism, Department of Internal Medicine, Netherlands, [3]Hasselt University, Netherlands, [4]VieCuri Medical Center, Department of Surgery, Netherlands, [5]VieCuri Medical Center, Department of Orthopaedic Surgery, Netherlands

Purpose: Our aim was to investigate the association between falls and fractures (fx) and to identify predictors for these adverse events in patients aged 50-90yrs with a recent clinical fx who were evaluated and treated according to current osteoporosis guidelines at a Fracture Liaison Service (FLS).Methods: Prospective observational cohort study in 486 consecutive FLS patients willing and able to participate. Patients with skull fx, high-energetic trauma or peri-prosthetic fx, osteomyelitis, metastasis, Paget's disease or multiple myeloma were excluded. Baseline assessment included evaluation of comorbidities and medication, BMD measurement and lateral spine imaging by DXA, and physical performance tests (chair stand test (CST), timed-up-and-go test and 6-minutes walking test (6-MWT)). At 1-year, self-re-ported falls using a weekly report and radiologically confirmed subsequent clincal fx were evaluated. Participants were categorized as non-faller or faller (subdivided in once and re-current fallers). Logistic regression analyses were adjusted for age, gender, height, weight, baseline fx type and time between baseline fx and fx risk evaluation.Results: Of 468 partic-ipants (72% women, mean age 65yrs, 34% treated with anti-osteoporosis drugs), 182 (39%) fell at least once, 98 (21%) fell once and 84 (18%) recurrently. Subsequent fx were observed in 20 (4%) participants, 4 in non-fallers (2%) and 16 in fallers (9%) (OR:6.9 95%CI:2.3-21.0). Thus, 80% of all subsequent fx occurred after a fall. Most subsequent fx in fallers (69%) occurred after the first fall. After adjustments, at least one fall was associated with a fall in the past year (OR:2.5 95%CI:1.7-3.9), low CST score (OR:3.4 95%CI:1.2-10.1), 6-MWT <450m (OR:1.6 95%CI:1.0-2.6) and depression (OR:3.1 95%CI:1.2-7.8). A single fall was associated with a fall in the past year (OR:2.90 95%CI:1.76-4.78) and recurrent falls with a fall in the past year (OR:2.04 95%CI:1.19-3.50), low CST score (OR:6.1 95%CI:1.8-21.1), arthritis (OR:3.82 95%CI:1.2-12.1) and depression (OR:5.3 95%CI:1.9-14.6).Con-clusions: In patients with a recent clinical fx who were evaluated and treated according to current osteoporosis guidelines at the FLS, 39% fell at least once and 4% sustained a sub-sequent clinical fx during 1-year follow-up. Of all subsequent fx, 80% occurred after a fall, indicating that fall risk evaluation and prevention are important for immediate secondary fx prevention in addition to anti-osteoporosis treatment.

Evidence for a direct role of Erythropoietin in the Regulation of FGF23 in Humans Kelly Roszko*, Sydney Brown, Ying Pang, Thanh Huynh, Karel Pacak, Michael Collins. NIDCR, NIH, United States

FGF23 increases urinary phosphate excretion, and decreases blood phosphate and 1,25-dihydroxyvitamin D. Posttranslational regulation of FGF23 involves glycosylation by the galactosyl transferase GALNT3. Glycosylation prevents degradation of intact FGF23 into biologically inactive C- and N-terminal fragments by a proprotein convertase, proba-bly furin. Posttranslational regulation is poorly understood, but recent, although conflicting, evidence suggests a role of the hypoxia/iron/erythropoietin (EPO) pathway. The prepon-derance of the data suggests that activation of the hypoxia pathway leads to increased tran-scription and translation of FGF23, with some models showing increased posttranslational processing to C- and N-terminal fragments with maintenance of euphosphatemia, but others

showing increased intact FGF23 and hypophosphatemia. To better understand this aspect of FGF23 physiology, we studied eight patients with a rare syndrome of paragangliomas and somatastatinomas caused by somatic, gain-of-function mutations in HIF2a that result in increased tumor-derived EPO levels with polycythemia. Intact and C-terminal FGF23 levels were assessed in relationship to blood phosphate, iron, and EPO levels in eight patients with HIF2α mutations and compared to matched controls.HIF2a patients had markedly elevated and highly correlated EPO and C-terminal FGF23 levels. Iron levels were normal and not correlated with EPO and/or FGF23.While more study is needed to better understand the cellular and molecular mechanisms underlying the observed phenomenon, these data represent the clearest evidence to date in humans for a direct role of EPO in FGF23 transcriptional, translational and posttranslational regulation. Normal blood phosphate and intact FGF23 levels in the setting of C-terminal FGF23 levels up to 20 times above normal demonstrate that posttranslational modification and processing is an exquisitely regulated process.

Gene expression changes are associated with severe bone loss and delayed fracture healing in paraplegic rats Mariana Butezloff*[1], Kelly Astolpho[1], Vitor Correlo[2], Rui Reis[2], João Paulo Ximenez[1], João Paulo Issa[1], Raquel Assed Silva[1], Antonio Carlos Shimano[1], José Batista Volpon[1], Ariane Zamarioli[1]. [1]University of Sao Paulo, Brazil, [2]University of Minho, Portugal

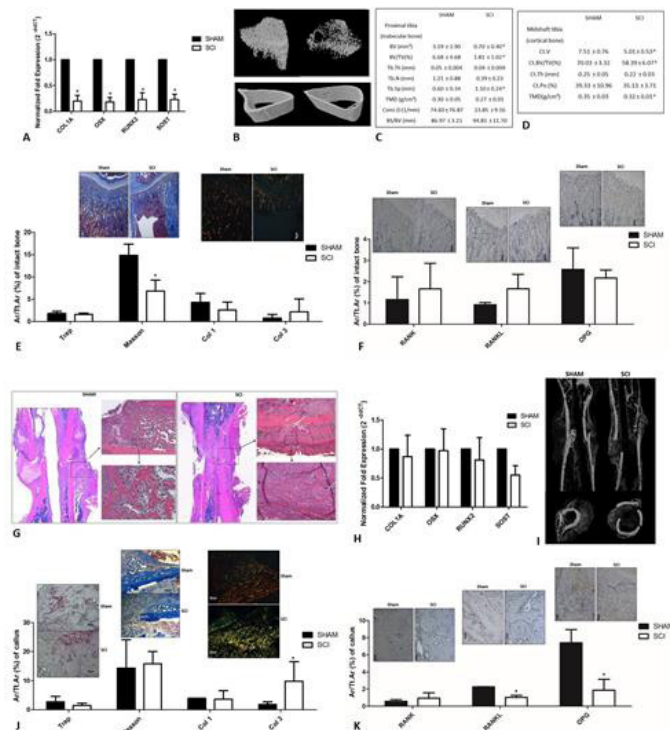
Spinal cord injury (SCI) is well known to induce severe bone loss thus increasing fracture risk. Bone fracture healing in SCI individuals can be either normal or impaired, whence such impairment may be either accelerated or delayed. The aim of this study was to investigate SCI-induced bone loss and the callus formation in rats sustaining a bone fracture. Thirty six-week-male Wistar rats were divided into two experimental groups: (1) CON: control rats with bone fracture; (2) SCI: SCI rats with bone fracture. SCI was performed as previously described (1). Ten days after SCI, the femoral diaphysis was fractured by a closed method (2). Immediately after fracturing the bone, an incision was made parallel in the proximal extremity of the femur and a 1-mm-diameter Kirschner wire was introduced into the medullary canal in order to stabilize the bone fragments. Bone callus formation was observed for 14 days post-fracture. At the end of the experiment, animals were euthanized, femurs and tibias were harvested and analyzed by morphometric measurements, μCT, DXA, mechanical test, histomorphometry, immunohistochemistry and gene expression at the femoral bone callus and intact tibia. Gene expression in non-fractured bones was downregulated by SCI, resulting in several phenotic changes related to severe bone loss (Fig 1A-F). Our data showed that SCI decreased bone mass in 21%, length in 6%, shaft perimeter in 14%, bone mineral density in 43% and severe microarchitecture deterioration at both trabecular and cortical bone (i.e. reduction in bone volume, trabeculae volume, number, thickness, density and connectivity, decrease in cortical volume and density and, increase in trabeculae separation), resulting in lesser mechanical strength (45% reduction in maximal load and 50% in stiffness). Although no difference was seen in gene expression at bone callus, SCI impaired fracture healing by reducing its density (-41% in BMD) and formation (decrease in newly formed trabeculae number and thickness, associated with increased porosity). Our histological data evidenced the healing delay in SCI rats by showing callus mainly formed by an unorganized non-bony structure and with an impairment in bone resorption regulation due to decreased OPG expression. As a result, bone callus was weaker in the SCI rats than in control (44% reduction in torque and 62% in failure angle). In conclusion, SCI resulted in severe deleterious changes in bone metabolism, delaying fracture callus formation.


Figure 1. (A-F) analysis at the non-fractured tibia; (A) gene expression was downregulated by SCI; (B) μCT images showing trabecular and cortical loss in SCI rats; (C) μCT data of trabecular bone; (D) μCT data of cortical bone; (E) histomorphometry: resorption area (TRAP staining, 100x), newly formed bone (Masson staining, 50x) and types 1 and 3 collagen deposition (50x); (F) immunohistochemistry showing the expression of RANK, RANKL and OPG (200x). (G-K) analysis at the fractured femurs; (G) Histological slides stained with HE (12.5x, 50x and 200x); (H) gene expression of qPCR; (I) μCT images of bone callus; (J) histomorphometry: resorption area (TRAP staining, 100x), newly formed bone (Masson staining, 50x) and types 1 and 3 collagen deposition (50x) and; (K) immunohistochemistry (RANK, RANKL and OPG, 200x). Age and Gender Effects on Architectural, Biomechanical and Muscle Performance in C57BL/6 Mice Hammad Mumtaz*, Julian Vallejo, Mark Dallas, Nuria Lara-Castillo, Joanna Scott, Michael Wacker, Mark Johnson, Thiagarajan Ganesh. University of Missouri Kansas City, United States

The biomechanical performance with aging of femur, ulna and tibia were determined in C57BL/6 mice. Three groups of mice 6, 12, and 22 mo old female (n=5-7 per age) and male (n=6-7 per age) were analyzed using microCT and three point bending. We calculated the ultimate load to failure (UL), elastic stiffness (K), modulus of elasticity (E) and the moment of inertia about bending axis (MOI) for each bone. Linear regression models with robust standard errors were used to determine differences in the all parameters with age in each bone and sex. MicroCT scans of all the bones were analyzed to determine cortical BV/TV, trabecular BV/TV and cortical bone area (B.Ar) and tested for correlation with the biomechanical parameters. EDL and Soleus contractile properties were determined ex vivo. The significance level was set to p < 0.05.In femur and tibia, UL was significantly reduced at 22 mo compared to 6 mo in both sexes. In male femur and tibia, K reduced significantly from 6 to 12 mo and 22 mo of age. In female tibia K was significantly lower at 22 months. In ulna, K increased significantly at 22 mo in females, but did not change in males. In both male and female femurs E was reduced significantly at 22 mo. In female ulna, E increased significantly at 12 and 22 mo of age, while no change was detected in male ulna. Female femur showed significant increase in MOI at the age of 12 mo, while no change was observed in males. MOI was reduced significantly in male tibia from 6 to 12 mo and 22 mo of age with no change detected in females.MicroCT analysis showed that cortical BV/TV is significantly correlated with UL and K of male and female femur, E of female femur, and K of female ulna. Trabecular BV/TV is significantly correlated with UL and K of male femur, UL of male tibia, and MOI of female femur. B.Ar was significantly correlated with MOI of male femur, with K and UL of both male and female femurs, and with UL of male tibia and ulna. On average, EDL and Soleus weight to body weight and maximum force reduced across aging. EDL contractile properties were positively correlated with B.Ar in females only. Soleus contractile properties showed no correlations with structural properties.In conclusion, aging effects on the skeleton need to be evaluated in a site-specific fashion and global conclusions extrapolated from one bone to another may not be valid. Significant differences between sexes occur acro

Quantifying Bone Marrow Adiposity Using T1-weighted Magnetic Resonance Images in Children With Typical Development and in Children With Cerebral Palsy Chuan Zhang*[1], Freeman Miller[2], Christopher Modlesky[1]. [1]University of Georgia, United States, [2]AI duPont Hospital for Children, United States

Background: Bone marrow contains mesenchymal stem cells which have the potential to promote both osteogenesis and adipogenesis at the expense of one another. Thus, quantifying adipose tissue in bone marrow may shed new light on bone growth and development status. Chemical shift magnetic resonance imaging (MRI) has been suggested to have good accuracy in assessing bone marrow adipose tissue (BMAT) in vivo. Some studies have also used standard T1-weighted magnetic resonance images to assess BMAT, but the accuracy has not been determined in children. The aim of this study was to determine whether a method using T1-weighted images provides an accurate estimate of BMAT in children who are typically developing, or in those with elevated BMAT infiltration, such as children with cerebral palsy (CP).Methods: Fifteen ambulatory children with spastic CP and 15 typically developing children (age range 4-11 y; 11 boys and 4 girls/group) participated in the study. Axial images (0.5 cm thick with 0.5 cm spacing) were collected from the tibia using an MRI scanner (GE, 1.5 T, Milwaukee, WI) and two different protocols. The first protocol (fast spin echo, TR = 650, TE = 14, FOV = 12, NEX = 3, BW = 15.63, frequency = 512, phase = 256) yielded standard T1-weighted images. The second protocol (IDEAL: fast-spin-echo, TR = 600, TE = min full, FOV = 12, NEX = 2, BW = 31.25, frequency = 320, phase = 224) yielded fat and water images. Images representing the mid-third of the tibia (i.e., midtibia) were processed. Bone marrow volume was determined using the standard T1-weighted images. BMAT volume was determined using the standard T1-weighted images (BMATVT1) and the fat and water images (BMATVIDEAL). BMAT fraction was calculated as the ratio of BMATVT1 to bone marrow volume (BMATFT1) and as the ratio of BMATVIDEAL to bone marrow volume (BMATFIDEAL). Results: BMATVT1 and BMATVIDEAL were highly correlated (r > 0.99, p < 0.001) and BMATFT1 and BMATFIDEAL were moderately correlated (r > 0.7, p < 0.01) in both groups of children. There were no group differences in BMATVT1 or BMATVIDEAL (both p < 0.05). BMATF IDEAL was higher in children with CP than in typically developing children (p < 0.05), but there was no significant group difference in BMATFT1 (p > 0.05). Conclusion: Standard T1-weighted magnetic resonance images can produce estimates of BMAT volume similar to estimates from chemical shift imaging in children. However, they are less sensitive to variation in AT concentration in the bone marrow.

Late adulthood skeletal muscle weakness and atrophy in osteoporotic OPG null mice Dounia Hamoudi*[1], Laetitia Marcadet[1], Louis-Benedict Landry[2], Antoine Boulanger-Piette[1], Francoise Morin[3], Anteneh Agraw[4], Jérôme Frenette[5]. [1]PhD student, Canada, [2]Trainee, Canada, [3]Professional Research, Canada, [4]PhD, Canada, [5]Professor, Canada

Bone and muscle are tightly coupled under normal conditions forming the functional muscle-bone unit. Cumulative evidence supports the existence of bidirectional muscle-bone molecular interactions. Osteoprotegerin (OPG) is a soluble decoy receptor and a key regulator of bone homeostasis and the lack of OPG causes an early onset osteoporosis in mice and human. In addition to bone cells, stimulated muscle cells can secrete OPG but, the role of OPG on muscle physiopathology remains poorly understood. Methods: Muscle function was evaluated in OPG null mice (OPG -/-), a model of juvenile Paget disease, and age-matched C57BL/6J (C57) mice were used as controls. To access the functional performances, four-limb grip strength and 12-h voluntary activity in open field, recorded using a video tracking system, were measured at 1, 3 and 5-month-old in OPG-/- and C57 mice. Ex vivo contractile properties followed by immunohistological staining were then performed on the fast-twitch extensor digitorum longus (EDL) muscles. Three-point bending tests, at the femur mid-diaphysis, were completed to confirm that OPG -/- mice were osteoporotic. Results: Contractile properties of EDL muscles and functional performances showed that OPG deletion did not affect muscle function and integrity in 1 and 3-month-old mice. Interestingly, 5-month-old OPG -/- and C57 mice had similar locomotor activity in open field but absolute (P0; g) and specific force production (sP0; N/cm2) of EDL muscles and normalized grip strength (gF/g) were significantly diminished in OPG-/- mice. Moreover, muscle mass and myofiber area were significantly smaller in OPG -/- compared to C57 mice at 5 months of age. Conclusion: Functional and contractile properties showed that the absence of OPG did not affect muscle function of young mice but caused, regardless of locomotor activity, muscle atrophy and weakness later in life.

Heterozygous ZNF687 P937R mutation underlies giant cell tumors arising from Paget's disease of bone also in non-Caucasian patients Fernando Gianfrancesco*[1], Giuseppina Divisato[1], Deborah J Veis[2,3], Yasmine Abbes[1], Federica Scotto Di Carlo[1], Teresa Esposito[1,4], Michael P Whyte[5,6]. [1]Institute of Genetics and Biophysics, National Research Council of Italy, Italy, [2]Division of Bone and Mineral Diseases, Department of Internal Medicine, Washington University School of Medicine at Barnes-Jewish Hospital, United States, [3]Department of Pathology, Washington University School of Medicine at Barnes-Jewish Hospital, United States, [4]IRCCS INM Neuromed, Italy, [5]Department of Internal Medicine, and Department of Pathology, Washington University School of Medicine at Barnes-Jewish Hospital, United States, [6]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, United States

Giant cell tumor of bone (GCTB) is a rare but severe complication of Paget's disease of bone (PDB). It typically occurs in polyostotic PDB. The prognosis for GCTB/PDB is poor, with ~ fifty percent of patients surviving 5 years. Recently, a founder germline mutation P937R in the ZNF687 gene was identified to underlie GCTB/PDB (all of 15 cases), but the study population was exclusively of Italian descent, all sharing the same haplotype. GCTB/PDB patients of different ethnic origin(s) were not studied. To fill this information gap, we performed mutation analysis of ZNF687 using DNA we extracted from a paraffin-embedded tumor of a deceased 45-yr-old black American woman with polyostotic PDB, neurofibromatosis type I, and remarkable extraskeletal osteoclastomas (JCEM 82: 3826-34, 1997). She had widespread PDB (skull, clavicles, ribs, pelvis, femurs and tibias) and developed two large extraskeletal tumors at the right iliac crest (15x10 cm) and left paraspinal (6x6 cm) regions as well as five smaller masses in the abdomen and pelvis. The ZNF687 P937R mutation was found in her osteoclastomas, but she did not have the ancestral haplotype that characterizes the Italian GCTB/PDB patients.We also explored the specificity of this ZNF687 mutation for GCTB/PDB, identifying a different ZNF687 mutation (R331W) in 1/28 pagetic osteosarcomas and the P937R mutation in 1/8 pagetic undifferentiated sarcomas; while no ZNF687 mutations were detected in other PDB neoplastic transformations (1 fibrosarcoma and 1 chondrosarcoma).Therefore, our results indicate that GCTB/PDB pathogenesis is globally caused by mutation in the ZNF687 gene that is involved in the DNA damage machinery to detect and repair lesions by homologous recombination. Conversely, the non-pagetic GCTB is due to alterations in the H3F3A gene, resulting in disrupted methylation of the H3.3 histone tail. Although the etiologies and pathological mechanisms are different, they give rise to histologically similar tumors, and misdiagnosis sometimes occurs. Thus, we report that combined analysis of ZNF687 and H3F3A mutations allows one to distinguish pagetic and conventional GCTBs, respectively. In fact, we identified the H3F3A mutation in a GCTB biopsy of a pagetic patient published as GCTB/PDB (Ann Rheum Dis 51: 1335-37, 1992), demonstrating here that a conventional GCTB can accompany PDB.

Ultra-Fast Na18F Whole Body Dynamic Using Digital PET/CT in a Preclinical Phase I Study Maria Menendez*, Richard Moore, Katherine Binzel, Zhang Jun, Rebecca Jackson, Michael Knopp. The Ohio State University, United States

Na18F enables in vivo assessment of bone physiology and pathophysiology as well as its biodistribution. Whole Body (WB) Dynamic (DYN) PET imaging enables the acquisition of real time spatio-temporal activity concentration of the whole skeleton tracer uptake. DYN PET acquisitions have been primarily performed in single-bed axial field-of-views (FOVs). There is an important unmet clinical need to translate static single FOV PET into DYN WB PET. The aim of this study was to assess the ultra-fast Na18F WB DYN protocol feasibility using digital PET/CT (dPET/CT) for systemic bone imaging in a healthy canine model, and to compare it with the single bed dynamic.Twelve healthy, adult male Beagles (weight (kg) mean ±SD; 15±1.54) were scanned. Two different doses of 3 mCi and 50 μCi Na18F were administered at different days. For the single FOV, imaging was initiated at the time of injection, covered 1 bed position covering the pelvis and knees, acquiring 120 seconds/bed position, lasting 30 minutes. Ultra-fast WB DYN imaging was initiated at the time of injection, covered 10 bed positions, acquiring 12 seconds/bed position for 6 consecutive WB runs, lasting 12 minutes. All imaging was performed on a digital photon counting PET/CT system. PET listmode data were reconstructed using a 576x576 matrix, producing a 1mm3 isometric voxel size; using point spread function and Gaussian filtering. Three iterations with three subsets were used for reconstructions. Standardized uptake values (SUVmean) were assessed in the following regions of interest (ROI) including distal femur, wrist, tarsal joint, first lumbar vertebra, and liver. Blinded experienced reviewers evaluated dynamic acquisitions via visual assessment of image quality.Ultra-fast WB DYN acquisitions were shown to be feasible and resulting in excellent image quality as scored during blinded review (Fig.1). Qualitatively and quantitative assessment provided detailed insight into skeleton perfusion and bio-distribution characteristics. Quantitative outcome measurements were highly consistent among ROIs in all subjects. Ultra-fast Na18F WB DYN using a dPET/CT showed a 10x reduction in acquisition time (120 to 12 seconds per bed), in addition to increasing the FOV from 1 bed (16.4 cm) to 10 beds (? 100 cm including overlap), allowing for whole skeleton assessment. The use of this methodology in a healthy dog provided feasi-

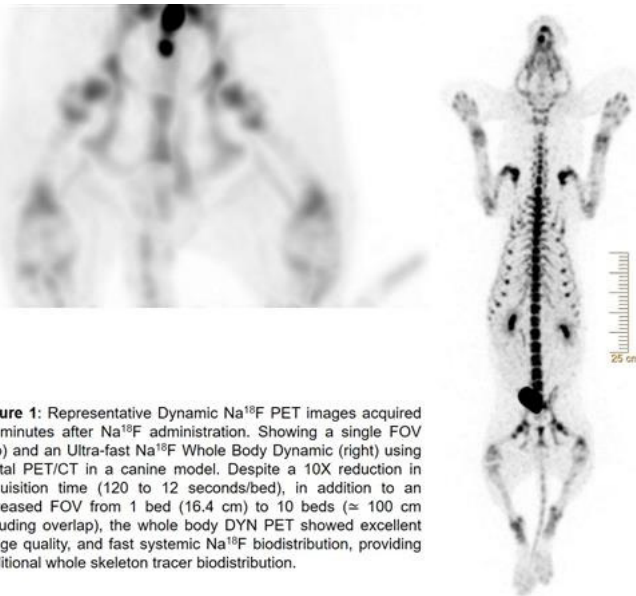
bility to increase Na18F dPET/CT diagnostic capabilities by providing a real time ultra-fast Na18F WB DYN PET, in addition to the WB static PET/CT acquired a posteriori in a standard dPET/CT examination. The Na18F dPET/CT canine imaging is a capable translational model that may advance bone imaging by providing a sensitive tool to visualize and quantify bone pathophysiology on both specific organs as well as at a systemic (whole-body) level.


Figure 1: Representative Dynamic Na[18]F PET images acquired 12 minutes after Na[18]F administration. Showing a single FOV (top) and an Ultra-fast Na[18]F Whole Body Dynamic (right) using digital PET/CT in a canine model. Despite a 10X reduction in acquisition time (120 to 12 seconds/bed), in addition to an increased FOV from 1 bed (16.4 cm) to 10 beds (≈ 100 cm including overlap), the whole body DYN PET showed excellent image quality, and fast systemic Na[18]F biodistribution, providing additional whole skeleton tracer biodistribution.

Heat Increases IGF-I Uptake in Growth Plate and Perichondrium Measured by in vivo Multiphoton Imaging Maria A Serrat*, Gabriela Ion, Dominic Thomas. Marshall University School of Medicine, United States

Introduction: Research into the molecular regulation of bone elongation has led to development of promising drug therapies for many growth plate disorders. However, delivering therapeutics to avascular cartilage remains a significant challenge. We previously combined a limb heating model with the growth-stimulating drug IGF-I to demonstrate that low dose IGF-I augments bone-lengthening effects of targeted, intermittent heat in mice. Here, we use in vivo multiphoton microscopy to directly measure uptake of IGF-I in growth plate and surrounding perichondrium at temperatures within a physiological range of healthy human knees. We tested the hypothesis that heat increases uptake of IGF-I in cartilage using fluorescently labeled, biologically active IGF-I measured in and around proximal tibial growth plates of live mice.Methods: Procedures were approved by our IACUC. 5-week old male and female C57BL/6 mice (N=9) were obtained from an in-house breeding colony. Purified human IGF-I (PeproTech) was conjugated with Alexa Fluor 488 (Life Technologies) and assessed for biological activity following our published protocols. The hindlimb was cooled (22C) or warmed (36C) and fluorescent IGF-I (~6 μg/g body wt) was visualized in the proximal tibial growth plate and perichondrium by multiphoton imaging at consistent depths and times as we have previously described. Data were collected in standardized regions. Statistical analysis was performed using independent samples t-tests in SPSS.Results: Warm temperature increased uptake of fluorescently labeled IGF-I in growth plate and perichondrium within 60 min after injection (Fig. 1). There was >1.5 times more IGF-I in the superficial perichondrium at 36C relative to 22C (t=1.8, p<0.05), and more than twice as much at the deepest edge of the perichondrium immediately adjacent to the growth plate (t=2.12, p<0.05), as well as in the growth plate itself (t=2.05, p<0.05). These data complement our prior results showing that IGF-I enhances bone lengthening effects of targeted heat, likely by increasing its uptake in the growth plate.Conclusion: These data support the hypothesis that heat increases IGF-I uptake in the proximal tibial growth plate and perichondrium of young mice. Our results using physiological knee temperatures suggest that mild limb heating could be a novel, noninvasive approach for modulating and targeting delivery of therapeutics such as IGF-I to enhance bone elongation in impaired growth plates of children.
Fig 1. Heat increases IGF-I uptake in growth plate and surrounding perichondrium. Error bar plot (left) shows IGF-I fluorescence in regions of growth plate and perichondrium measured in 25μm optical sections from superficial to deep 60 minutes after injection. Images (right) show IGF-I accumulation in deepest edge of the perichondrium (top panel) and 25μm below in the growth plate (bottom panel). Growth plate is between arrowheads. Metaphyseal bone is at the bottom. There was over twice as much IGF-I in the perichondrium and growth plate in these regions at 36C compared to 22C. Mean ± 1 SE plotted; *p< 0.05, denotes significant increase at 36C by independent samples t-test.

Differentiated Osteocytes Synthesize Taurine Which Reduces Sclerostin Expression and Prevents Osteocyte Cell Death Matt Prideaux*, Yukiko Kitase, Morris Kimble, Thomas O'Connell, Lynda Bonewald. Indiana University, United States

Taurine is a ubiquitous metabolite, known to be important in a number of metabolic processes. It has been shown that taurine protects against bone loss in osteoporotic rats. Taurine is synthesized by the liver, whereas the major source is absorbed through the diet. An untargeted NMR-based metabolomics approach was used on IDG-SW3 cells taken at days representing the early osteoblast (day 4), osteoid osteocyte (day 9), mineralizing osteocyte (day 18) and mature osteocyte (day 28). While performing metabolomic analysis, a two-fold elevation of taurine was observed in differentiating cells, peaking at 1 mM at day 18 and remaining elevated at day 28 (p<0.001). Interestingly, methionine consumption increased with cell differentiation, with a commensurate production of taurine only within the cell lysate but not in the media. The mRNA expression of Cysteine Dioxygenase (Cdo1), the rate-limiting enzyme of the taurine biosynthesis pathway, was highly expressed in these cells and increased greater than two-fold at day 18 compared to day 4 of differentiation (p<0.001). Similarly, Cdo1 mRNA expression was 6.5 fold higher in osteocyte-enriched bone chips compared to osteoblasts taken from the long bones of C57Bl6 mice (p<0.001). To determine if taurine may have an autocrine function in osteocytes, exogenous taurine (1-50 mM) was tested on day 28 IDG-SW3 cells. Taurine dose-dependently inhibited Sost mRNA expression by 60-70% in IDG-SW3 cells after 24 hrs (p<0.01), suggesting a potential mechanism for the beneficial effects of taurine on bone. As osteocytes are long lived cells subjected to the effects of aging and generation of elevated reactive oxygen species (ROS), the MLO-Y4 osteocyte-like cells were pretreated with taurine before exposure to H2O2. Taurine at 1-50 mM reduced H2O2 induced cell death by 30-60% (p<0.001). These studies show that osteocytes, like liver, have the capacity to synthesize taurine, but unlike liver, do not secrete taurine. Some of the beneficial effects of exogenous taurine on bone may be mediated through osteocytes. The synthesis of taurine by these cells may serve a protective function by preserving cell viability when exposed to elevated levels of ROS and utilized by osteocytes to survive under the demanding conditions within the lacuno-canalicular environment.

A Novel Mouse Model to Elucidate the Role of Gdf5 in Postnatal Joints Steven Pregizer*[1], Vicki Rosen[2]. [1]Boston Children's Hospital, United States, [2]Harvard School of Dental Medicine, United States

Growth and Differentiation Factor 5 (Gdf5) is expressed in all developing joints and plays a key role in joint morphogenesis. There is also a strong genetic association between Gdf5 and osteoarthritis (OA); however, it is unclear if the influence of Gdf5 in OA is due to altered joint development or to a specific role for Gdf5 in the maturation and/or subsequent maintenance of joints in postnatal life. To address this fundamental question, we developed a novel mouse model that allows us both to monitor Gdf5 expression and to inactivate Gdf5 in postnatal joints. First, we obtained embryonic stem (ES) cells containing a targeted "knockout first" Gdf5 allele from the International Knockout Mouse Consortium repository. This allele contains a gene-trapping reporter cassette expressing LacZ instead of Gdf5, thus rendering the allele non-functional, yet useful for monitoring transcriptional activity of the locus. Next, we established a mouse line harboring this allele via microinjection of the ES cells into blastocysts and propagation of the resulting founder chimeras. Animals with a single copy of the modified allele (Gdf5LacZ/+) had a joint-restricted pattern of LacZ expression during embryogenesis, perfectly recapitulating that of the native Gdf5 allele. Interestingly, LacZ expression persisted in articular cartilage until birth, but diminished rapidly thereafter. Animals with two copies of the modified allele (Gdf5LacZ/LacZ) had shortened skeletal elements, missing joints in the wrists, ankles, and digits, missing or hypoplastic fibulas, and

dysmorphic knees lacking cruciate ligaments, perfectly recapitulating the limb phenotype of homozygous Gdf5-null mice. Next, we derived from these mice a conditional Gdf5 mouse line by outcrossing to a Flp-expressing strain. From this intercross we obtained progeny in which the LacZ reporter was excised from the germline, owing to a pair of FRT sites flanking the reporter cassette. Animals with two copies of the derived allele (Gdf5flox/flox) exhibited no overt differences in limb length compared to wild-type littermates; moreover, the fibula and cruciate ligaments were present, indicating restoration of Gdf5 expression to the allele. Importantly, a pair of loxP sites flanking a critical exon can recombine in the presence of Cre, excising the exon and disrupting Gdf5 expression. This novel mouse model provides temporal control over Gdf5 levels and can be used to provide a framework for understanding how changes in Gdf5 availability correlate with joint homeostasis and the development of OA.

Bone is a major contributor of plasma FGF23 elevation in a model of chronic kidney disease in wildtype mice and mice lacking the extra-large G protein α-subunit (XLαs) Julia Matthias*[1], Lauren Shumate[1], Antonius Plagge[2], Harald Jüppner[1], Qing He[1], Murat Bastepe[1]. [1]Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, United States, [2]Institute of Translational Medicine, University of Liverpool, United Kingdom

FGF23 is a phosphaturic hormone, whose levels rise in renal failure to maintain normal phosphate levels and prevent soft tissue mineralization. The FGF23 elevation contributes greatly to the morbidity and mortality in patients with chronic kidney disease (CKD). Mechanisms causing kidney injury-induced FGF23 elevation are poorly defined. Inflammatory mediators, which are systemically increased in CKD, can induce FGF23 expression, and bone marrow (BM) has recently been shown to contribute significantly to FGF23 production in acute kidney injury or upon bleeding. The origin of FGF23 in CKD remains uncertain. We have found that the extra-large G protein α-subunit (XLαs), which is expressed in bone, mediates FGF23 synthesis in early postnatal life.To investigate whether XLαs is involved in FGF23 synthesis in CKD, we fed XLαs knockout (XLKO) and wildtype (WT) littermates a 0.2% adenine-containing diet. This led to the expected renal tubulopathy, as confirmed by histological analyses. Plasma C-terminal FGF23 levels were 136±102 and 273±116 pg/ml at baseline in XLKO and WT mice, respectively, and rose significantly one week after starting the diet in both groups (2,444±2,387 and 1,950±637 pg/ml, respectively). At 6 weeks, FGF23 levels were markedly elevated, with higher levels in XLKO than WT (96,000 vs. 22,000 pg/ml; p<0.01). XLKO mice also showed higher BUN levels at 6 weeks (96.6±30.6 vs. 57.5±22.6 mg/dl; p<0.01), indicating more pronounced kidney impairment. Analysis of inflammation markers in bone and BM revealed a tendency of IL-1β mRNA levels to rise in XLKO but not WT mice (bone: 1.7±0.8-fold; p=0.10; BM: 1.8 ±0.9-fold; p=0.06), suggesting greater inflammation in XLKO. Interestingly, XLKO bones displayed higher HIF1α mRNA levels than WT bones at baseline (1.4±0.2-fold; p=0.01). Regardless of the genotype, FGF23 mRNA levels rose in both bone and BM, but the bone levels were 203±152 or 42±55.1 times higher than BM levels at baseline and at 6 weeks, respectively. Moreover, a direct relationship was observed between plasma FGF23 and bone FGF23 mRNA levels (r=0.9; p<0.00001), while no significant correlation could be detected between plasma FGF23 and BM FGF23 mRNA levels (r=0.32; p=0.13).Our findings suggest that XLαs ablation increases susceptibility to adenine-induced renal failure, and that bone, rather than BM, is an important contributor to plasma FGF23 levels in this CKD model.

Associations of Joint Trajectories of Appendicular Lean Mass and Grip Strength with Risk of Non-Spine Fractures Rodrigo Valderrabano*[1], Neeta Parimi[2], Peggy M. Cawthon[2], Jennifer S. Lee[3,4], Joy Y. Wu[3], Andrew R Hoffman[3,4], Marcia L. Stefanick[5]. [1]Division of Endocrinology, University of Miami Miller School of Medicine, Miami, FL, United States, [2]California Pacific Medical Center, San Francisco, CA and Department Epidemiology and Biostatistics, UCSF, SF, United States, [3]Division of Endocrinology, Stanford University School of Medicine, Stanford, CA, United States, [4]Palo Alto Veteran Affairs Health Care System, Palo Alto, CA, United States, [5]Stanford University School of Medicine, Stanford, CA, United States

Muscle strength and appendicular lean mass (ALM) are interrelated and may jointly influence fracture risk. Patterns of change in muscle strength and mass may be important. We hypothesized that combined trajectories of change in grip strength (GS) and ALM/ht2 would be associated with fractures independent of values at the beginning or end of the change period.The Osteoporotic Fractures in Men (MrOS) study prospectively evaluated men ages 65 years or older with grip strength by hand dynamometry and ALM/ht2 by DXA at up to four visits from 2000-2009 and subsequently adjudicated incident fractures after 2009. We analyzed 3501 men after excluding those missing covariate or DXA data. Group based trajectory models identified 3 trajectory groups for both ALM/ht2 and grip strength, which declined at roughly parallel rates within measures. Groups were classified as "high", "intermediate" and "low" based on their starting and ending values, which reflected relative performance levels. The nine combined trajectories represented different musculoskeletal phenotypes (i.e. Low ALM/ht2 / High GS) and were used as predictors. The (Intermediate

ALM/ht2 / Intermediate grip strength) group served as the referent. Cox proportional-hazards models estimated the hazards ratio (HR) and 95% confidence interval (CI) of subsequent non-spine fracture (after the trajectory period). We adjusted for: age, BMD, race, study site, and potential confounders, and then subsequently adjusted for the last visit value for ALM/ht2 or grip strength.569 first incident non-spine fractures occurred during follow up. Men in the low ALM/ht2/ high GS group had reduced risk of non-spine fracture (HR 0.48; 95% CI 0.26-0.90) relative to the referent group (Table). This association remained after adjustment for LV ALM (HR 0.48; 95% CI 0.25-0.90) but was attenuated after consideration of LV GS (HR 0.61; 95% CI 0.32-1.16) and no longer significant. None of the other trajectory groups were associated with fracture risk.Combined trajectories in strength and lean mass were not robustly associated with fracture risk. However, older men with consistently high grip strength and low lean mass had reduced fracture risk, which was in part explained by higher grip strength value at the last visit. The reason for the association with reduced fracture in this group is not clear. Our findings do not support using these trajectories over single measurements of musculoskeletal parameters for fracture risk stratification.

Table. Association of Combined ALM and Grip Strength Trajectories with Risk of Non-Spine Fracture (HR [95% CI])

		Grip trajectory		
		Low	Intermediate	High
ALM/ht² trajectory	Low	0.99 (0.75-1.31)	1.08 (0.84-1.38)	**0.48 (0.26-0.90)**
	Intermediate	1.28 (0.96-1.71)	Referent	0.97 (0.73-1.30)
	High	1.11 (0.60-2.10)	1.21 (0.80-1.83)	1.23 (0.80-1.90)

*age, race and study enrollment site, total hip BMD, BMI, alcoholic drinks, osteoporosis medications, activity score, fall history, fracture after age 50, self-rated health
ALM: appendicular lean mass, Grip: Grip Strength by hand dynamometry, CI: confidence intervals

Qsox1 is a novel genetic determinant of bone size in mice Basel Al-Barghouthi*[1,2], Gina Calabrese[1], Larry Mesner[1], Kevin Nguyen[1], Mary Bouxsein[3], Daniel Brooks[3], Mark Horowitz[4], Clifford Rosen[5], Steve Tommasini[6], Petr Simecek[7], Gary Churchill[7], Cheryl Ackert-Bicknell[8], Daniel Pomp[9], Charles Farber[1,10]. [1]Center for Public Health Genomics, University of Virginia, Charlottesville, VA 22911, United States, [2]Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA 22911, United States, [3]Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, Department of Orthopedic Surgery, Harvard Medical School, Boston, MA 02215, United States, [4]Department of Orthopaedics and Rehabilitation, Yale School of Medicine, New Haven, CT 06520, United States, [5]Maine Medical Center Research Institute, 81 Research Drive, Scarborough, ME 04074, United States, [6]Department of Orthopaedics and Rehabilitation, Yale School of Medicine, New Haven, CT 06520, United States, [7]The Jackson Laboratory, Bar Harbor, Maine 06409, United States, [8]Center for Musculoskeletal Research and Department of Orthopaedics & Rehabilitation, University of Rochester Medical Center, Rochester, NY, 14627, United States, [9]Department of Genetics, University of North Carolina Medical School, Chapel Hill, NC 27599, United States, [10]Departments of Pubic Health Sciences and Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA 22911, United States

Osteoporosis is a complex disease of reduced bone strength and increased risk of fracture. Many characteristics of bone contribute to its strength; however, other than bone mineral density (BMD), which has been interrogated using genome-wide association studies (GWAS) in humans, we know little of the genetics of other strength-related traits such as bone size. To identify novel genetic factors affecting bone size, we used a powerful new murine resource, the Diversity Outbred (DO). The DO is an outbred population derived from eight genetically diverse inbred founder strains. We measured femoral size (femoral length (FL) and medial-lateral (ML)/anterior-posterior (AP) femoral widths) in a cohort of 12-16 week-old DO mice of both sexes (N=602). A significant (LOD=9.5; permutation P<0.05) quantitative trait locus (QTL) affecting ML was identified on Chr1@155Mbp. The QTL mapped to a confidence interval of ~2.8 Mbp and explained 6.6% of the variance in ML. We replicated the ML QTL in an independent cohort of 12 week-old DO mice of both sexes (N=312). To identify the gene(s) responsible, we queried the locus for non-synonymous mutations and expression QTLs (eQTLs). We imputed a complete list of variants from whole genome sequences of DO founder strains within the DO cohort and performed single variant association tests. None of the most significant variants were non-synonymous. We next identified eQTL for all genes in proximity of the ML QTL using tibial RNA-seq profiles from 192 DO mice. Of the 14 genes with eQTL, Quiescin Sulfhydryl Oxidase 1 (Qsox1) was the only one in which the ML QTL and eQTL founder haplotype effects were concordant, with the WSB/EiJ founder haplotype being associated with increased ML and decreased Qsox1

levels. QSOX1 is a secreted catalyst of disulfide bond formation that has not been previously linked to the regulation of bone size. Using CRISPR/Cas9, we generated five Qsox1 mutant lines with mutations ranging from a 1 bp frameshift to a ~1300 bp deletion encompassing the first exon of Qsox1. QSOX1 activity in serum was abolished in mutant mice from all lines. Across the five lines, we observed significantly (P<4.1 x 10-6) increased ML as a function of the number of Qsox1 mutant alleles. These data identify Qsox1 as a genetic determinant of bone size and highlight the power of the DO for the genetic analysis of complex traits.

Deletion of the auxiliary α2δ1 voltage sensitive calcium channel subunit regulates adipogenesis Christian S. Wright*, Xin Yi, Madison M. Kelly, Karan Sharma, William R. Thompson. Department of Physical Therapy, School of Health and Rehabilitation Sciences, Indiana University, United States

Bone loss, due to disuse or the consequences of aging, is accompanied by increased bone marrow adiposity, further impairing bone quality. Given bone marrow progenitors contribute to bone and fat formation, understanding the signaling events which control mesenchymal stem cell (MSC) fate can inform the design of interventions to enhance bone quality. Calcium influx is the first measurable response of bone cells to mechanical stimuli, which is tightly regulated by voltage sensitive calcium channels (VSCCs). Inhibition of VSCCs impairs osteogenesis, decreasing bone formation and mechanosensitivity, and stimulates adipogenesis. In addition to the pore-forming (α1) subunit, VSCC complexes contain auxiliary subunits like α2δ1. α2δ1 regulates the gating kinetics of the channel pore and facilitates trafficking of the channel pore to the cell membrane. We hypothesized that the α2δ1 subunit is necessary for the regulation of MSC fate lineage by influencing VSCC activity. Mice (C57BL/6) with global deletion of Cacna2d1, the gene encoding α2δ1, displayed increased whole-body adiposity longitudinally (p=0.0038) with a 22% increase in whole body fat (compared to WT) at 9 weeks of age by DXA. qPCR of RNA from whole tibiae showed a 4-fold increase in adiponectin (APN, p=0.0111) and a 2-fold increase in PPARγ (p=0.0259) expression. To determine whether the adipogenic phenotype was a result of increased MSC adipogenesis, primary murine MSCs were exposed to adipogenic media following siRNA knockdown of α2δ1. Knockdown of α2δ1 increased the expression of adipogenic markers APN, PPARγ, and perilipin by Western blotting, suggesting the α2δ1 subunit of VSCCs influences MSC fate. Furthermore, exposure of primary MSCs to adipogenic media decreased α2δ1 expression (-30%, p<0.05) while exposure to osteogenic media increased α2δ1 expression (+20%, p=0.055) by Western blotting. Coupled with our previous work showing α2δ1 regulates bone cell mechanosensitivity, these data suggest that α2δ1 is upregulated during osteogenic differentiation, potentially enhancing mechanosensitive responses; a feature not present in cells of adipogenic lineage. As the α2δ1 subunit is the exclusive binding site for the antiepileptic and neuropathic pain drug Gabapentin (GBP), where chronic use is associated with increased fracture risk and decreased bone quantity, these data provide mechanistic insights into how GBP may influence bone development.

Risk of Osteoarthritis by Bone Mineral Density Status in US and Korean Older Adults: NHANES 2005-2010 & 2013-2014 and KNHANES 2008-2011 Han-Saem Park*, Seung-Hee Kim, Clara Yongjoo Park. Dept of Food and Nutrition, Chonnam National University, Republic of Korea

The association between bone mineral density (BMD) and osteoarthritis (OA) has been investigated in small studies, but the results are inconclusive. We examined the risk of OA by BMD status using two nationally representative databases of the US and Korea, the National Health and Nutrition Examination Survey (NHANES) and Korea NHANES (KNHANES), respectively. Postmenopausal women ≥40 years and men ≥50 years participating in NHANES (n=4,551 and 4,244, respectively) and men and women ≥50 years of KNHANES (n=2,824 and 3,357, respectively) with data on BMD, self-reported OA and covariates were included. Participants consuming osteoporosis medications were excluded in both populations. BMD was assessed by DXA. Bone measures were classified according to T-score following the WHO guidelines for osteoporosis or in tertiles. Femur T-scores were used to determine osteoporosis for NHANES subjects. Of KNHANES participants, the number of subjects with both OA and osteoporosis, which was determined by the lowest T-score of the hip, spine, or femur, were few, thereby the risk of OA was assessed by BMD tertiles in this population. Logistic regression was performed to calculate odds ratio (OR). In US post-menopausal women, those with osteoporosis had a 72% greater risk for OA compared to those with healthy bones (95% CI: 1.158-2.552; p=0.03). A similar trend was found in males [OR: 1.61 (95%CI: 1.005-2.568); p=0.092]. In Koreans, risk of self-reported OA was not associated with BMD in men, but women in the lowest tertile for lumbar spine BMD or whole body BMD had lower ORs for OA compared to those in the highest tertile [0.51 (95% CI: 0.37-0.71) and 0.59 (95% CI: 0.43-0.82), respectively; both p<0.01], and a similar trend was observed with femoral neck BMD [OR: 0.69 (95% CI: 0.48-0.99); p=0.07]. The risk of OA was associated with BMD in both US and Korean women when assessed with nationally representative samples, though the direction was opposite. US post-menopausal women with osteoporosis have higher risk of OA, whereas Korean women with lower BMD had lower risk of OA.

Zika virus infection perturbs osteoblast function Bram Van Der Eerden*[1], Noreen Mumtaz[2], Marijke Schreuders-Koedam[1], Marion Koopmans[2], Barry Rockx[2], Johannes Van Leeuwen[1]. [1]Erasmus MC, Internal Medicine, Netherlands, [2]Erasmus MC, Viroscience, Netherlands

Zika virus (ZIKV) infection is typically characterized by a mild self-limiting disease presenting with fever, rash, myalgia and arthralgia. Virus-induced arthralgia due to perturbed osteoblast function has been described for other arboviruses. In case of ZIKV infection, the role of osteoblasts in ZIKV pathogenesis and bone-related pathology remains unknown. Here, we study the effect of ZIKV infection on osteoblast differentiation, and function by quantifying activity and gene expression of key biomarkers, using human bone marrow derived mesenchymal stem cells (MSCs) from 2 independent male healthy donors. We found that MSCs were highly susceptible to ZIKV infection. The Tissue Culture Infection Dose (TCID50) exceeded 10 million particles within 48 h post-infection, which remained above 10 thousand in up to 20 days of culture. While infection did not cause a cytopathic effect, a delay in MSC-derived osteoblast differentiation and function was observed as compared to uninfected controls. Gene expression of the key osteoblast transcription factor RUNX2 was 30-50% reduced (p<0.05) in MSC-derived osteoblasts at day 7 of differentiation. Alkaline phosphatase (ALP) mRNA was 40% reduced (p<0.05) at day 7 of osteoblast differentiation as well, which corresponded with 30% less ALP activity (p<0.05) at day 11 of culture. Finally, osteoblast mineralization measured by a calcium deposition assay, was severely affected as evidenced by 60-80% reduced calcium incorporation at day 18 and 21 of culture (p<0.05). All effects observed were similar between the 2 donors. In conclusion, we have developed and characterized a new in vitro model to study the pathogenesis of ZIKV-induced arthralgia. This will help to identify possible new targets for developing therapeutic and preventive measures against the skeletal consequences of ZIKV infections.

Role of fibrillin-1 fragments in bone resorption Muthu Lakshmi Muthu*, Kerstin Tiedemann, Svetlana Komarova, Dieter Reinhardt. McGill University, Canada

Marfan syndrome, caused by mutations in the fibrillin-1 gene, is a common type-I fibrillinopathy characterized by severe skeletal complications, including osteopenia and long bone overgrowth. How fibrillin-1 mutations lead to the skeletal problems is poorly understood. N-terminal sub-fragments of fibrillin-1 were identified as strong inhibitors of osteoclastogenesis in cell culture and in healthy animals. To identify potent osteoclast inhibitory sub-fragments of fibrillin-1, we produced several smaller fibrillin-1 N-terminal fragments. The purified proteins were tested for their function in osteoclastogenesis using primary osteoclasts. We observed reduced numbers and size of the differentiated osteoclasts. We plan to examine if these fibrillin-1 fragments exhibit sufficient anti-resorptive activity in a Marfan syndrome mouse model (Fbn1mgR/mgR). To understand the baseline bone parameters, we analyzed bones of Fbn1mgR/mgR mice at 4, 8, 12 and 16 weeks after birth. Compared to wild type littermates, young Fbn1mgR/mgR mice showed a trend of increased long bone length, increased body length and decreased bone mineral density which becomes significant at later time points. In osteoclastogenesis experiments, we found no significant difference in osteoclast number between the two groups. The expression of receptor activator of nuclear factor kappa-B ligand (RANKL) and osteoprotegerin (OPG) was increased in Fbn1mgR/mgR mice of both sexes, however the RANKL/OPG ratio was affected differently – it was higher in Fbn1mgR/mgR males compared to wild type, but lower in females. In conclusion, we have identified small fibrillin-1 fragments that exhibit osteoclast-inhibitory activity. Bone phenotype development in Fbn1mgR/mgR mice suggests that treatment with these fibrillin-1 fragments can be started at 4 week old animals.

Fluid flow shear stress alters interactions of osteoclasts to migratory tumor cells Yao Fan*[1], Aydin Jalali[1], Andy Chen[1], Bai-Yan Li[2], Ping Zhang[3], Hiroki Yokota[1]. [1]Indiana University, United States, [2]Harbin Medical University, United States, [3]Tianjin Medical University, China

Osteoclasts are multinucleated cells responsible for dissolving and absorbing mineralized bone tissue. Since bone loss in many diseases is linked to enhanced bone-resorbing activity, suppression of osteoclast activity is one of the primary therapeutic strategies, especially for patients with osteoporosis and osteolytic bone metastasis. While many lines of evidence demonstrate the effect of mechanical stimulation to mechano-sensing osteocytes, its effect to osteoclasts is not fully characterized. In this study, we addressed a question: does fluid flow shear stress to osteoclasts affect their interactions with migratory tumor cells in the bone microenvironment? It is reported that tumor-osteocyte interactions are affected by fluid flow-driven shear stress. Our hypothesis is that osteoclasts are sensitive to fluid flow shear stress, and they alter the migratory and proliferative behaviors of adjacent tumor cells. Using monolayer cultures and 3-dimensional spheroids, tumor cell lines (clones from MDA-MB-231 human breast cancer cells, and 4T1 mammary tumor cells) were cultured in the conditioned medium isolated from RAW264.7 osteoclast cells (CM), and fluid flow-treated

conditioned medium (FFCM; oscillatory fluid flow with 0.8 Pa shear stress at 1 Hz for 1 h). We conducted a tumor spheroid assay for evaluating proliferation of tumor cells, as well as a wound healing assay for examining their migratory capability. Furthermore, we evaluated expression of Snail, a transcription factor involved in epithelial-to-mesenchymal transition, as well as Src, a proto-oncogene tyrosine kinase. The results revealed that CM and FFCM induced opposing effects on cellular migration, proliferation, and expression of Snail and Src. While CM stimulated migration and upregulated Snail and Src, FFCM inhibited migration and downregulated Snail and Src. This study demonstrates the critical role of mechanical stimulation in tumor-osteoclast interactions. In response to mechanical stimulation, osteoclasts alter their influence to tumor cells and fluid flow-treated osteoclasts contribute to altering tumor cells less migratory in the bone microenvironment. Further analysis is needed to evaluate effects of mechanical stimulation, including other types of bone cells such as bone-forming osteoblasts and mechano-sensing osteocytes, and determine the risks and benefits of mechanical loading to bone.

Including Iodine based IV-Contrast Enhanced CT-Images into Screening Techniques for Osteoporosis Wolfram Timm*[1], J. Keenan Brown[2], Reimer Andresen[3]. [1]Mindways Software, Inc., Kiel, Germany, [2]Mindways Software, Inc., Austin, TX, United States, [3]Institute of Diagnostic and Interventional Radiology/Neuroradiology, Westkuestenklinikum Heide, Academic Teaching Hospital of the Universities of Kiel, Luebeck and Hamburg, Heide, Germany

Calibrated, phantomless asynchronous QCT makes feasible no-dose screening for osteoporosis from existing CT images acquired without IV contrast. Here we report results from studies including both native and IV-contrast enhanced CT-images and multiple methods for predicting native bone mineral density from contrast enhanced CT scans. Within clinical routine, 47 patients underwent native as well as IV-contrast (Imeron 350, Bracco Imaging Deutschland GmbH, Konstanz, Germany) enhanced CT scans (GE Revolution EVO, Waukesha, WI, USA) over three vertebrae, resulting in 141 native, arterial and portal phase estimates of bone mineral density (CliniQCT, Mindways Software, Inc., Austin, TX, USA) as well as iodine content calculated from aortical blood using a basis material composition scheme. In both arterial and portal phases, simple subtraction of the respective mean biases was compared to linear predictive models as well as non-linear Generalized Additive Models (GAM), with and without including the aortic iodine content into the models, resulting in eight different techniques of prediction. Two alternative thresholds, 80 and 110mg/cm3 were applied to identify the group of patients to screen for osteoporosis and to generate reference classifications based on the native BMD data. Within all pairings of classifiers, a significant difference was found with respect to the arterial phase of the GAM models compared to the simple subtraction of the bias and the linear prediction respectively, while all other pairings in both phases were not significantly different. For the threshold 80mg/cm3, sensitivity and specificity for the GAM models were 97% and 96% (arterial phase), 94% and 100% (portal phase), while for the threshold of 110mg/cm3 the GAM models showed 98% and 88% (arterial phase) as well as 97% and 85% (portal phase) in sensitivity and specificity. On the same data, Generalized Additive Models were identified elsewhere as the technique associated with the lowest residual error during prediction of native BMD data. The IV-contrast enabled classification schemes provide a universal screening technique. A clinical context might benefit from a threshold of 80mg/cm3, while an emphasis on early detection of fracture risk might favor a threshold of 110mg/cm3. The results require confirmation on an independent test data set and need to cover different CT brands before they can be used in a clinical context for screening.

ROC-Analysis: Classification Threshold 110 mg/cm3

Differences in Bone Mineral Density and Trabecular Bone Score in Hip Fracture Patients with Type 2 Diabetes Linsey Gani*, Thomas King, K. Reddy Saripalli , Karen Fernandes, Carmen Kam, Le Roy Chong. Changi General Hospital, Singapore

Purpose: The risk of fragility fracture is higher in type 2 diabetes (DM) patients, despite higher bone mineral density (BMD) readings. Trabecular Bone Score (TBS) has been shown to improve fracture risk predictions in diabetes patients, however studies within the South East Asian population have been limited. We aimed to measure BMD and TBS in patients with fragility fracture to assess for differences in those with and without type 2 DM. Methods: We conducted a retrospective analysis of all subjects admitted with low trauma hip fracture to a regional hospital in Singapore over a 6 month period. All BMD scans were performed on a single densitometer (Hologic QDR Discovery Wi,USA) and BMD files were analysed with the TBS iNsight software programme (Med-Imaps, France). Electronic patient records were reviewed; laboratory results and anthropomorphic data from the time of DXA were collected. Subjects were classified as having diabetes according to the WHO 2011 criteria, or current treatment by oral antidiabetic drugs or insulin. Results: There were 288 fragility hip fracture admissions from January to July 2017, and 227 had BMD performed. Of these 227 patients, 73 (32%) had type 2 DM and median DM duration was 11 (1-12) years. 7 (9.6%) were diet controlled, 65 (89%) were taking oral antidiabetic drugs and 12 (16.4%) were taking insulin. There was no difference in age or body mass index (BMI) between DM and non-DM patients (79 vs 79 years; 22.3 vs 21.4 Kg/m2, p=0.247), and mean HbA1c was (7.3 vs 5.9%, p<0.001). There was a greater prevalence of chronic kidney disease (CKD) in the DM vs non-DM group (45.2% vs 32.5% of subjects with eGFR <60ml/min, p=0.022). BMD was significantly higher in the DM than the non-DM group (T-score L-spine -1.4 vs -2.1, p=0.001; femoral neck -3.0 vs -3.2, p=0.034), and mean TBS was similar (1.25 vs 1.23, p=0.255). Spearman correlation between duration of diabetes and TBS was 0.17, p=0.153. In a multivariable regression, after adjusting for age, gender, BMI , CKD and race, only higher BMD in L-spine was significantly associated with DM. Conclusion: In a population with hip fracture, type 2 DM is independently associated with higher L-spine BMD after adjustment for age, gender, weight and eGFR. There was no significant difference in TBS between DM and non-DM patients. Further studies are needed to determine the relationship between DM, BMD, TBS and fractures

The effect of screening of high fracture risk and subsequent treatment on osteoporotic fractures: a systematic review and meta-analysis Thomas Merlijn*[1], Karin Swart[1], Coen Netelenbos[2], Petra Elders[1]. [1]Department of General Practice and Elderly Care Medicine, VU University Medical Center, Netherlands, [2]Department of Internal Medicine, Endocrine Section, VU University Medical Center, Netherlands

Objective: To study whether screening of high fracture risk and subsequent treatment in primary care can reduce osteoporotic fractures in comparison to usual care. Method: We performed a systematic literature search in Pubmed and Embase to identify all randomized trials that compared screening on high fracture risk with usual care. Only studies with verified fractures as outcome were selected. Furthermore, the Salt Osteoporosis Study (SOS) was selected, of which the results are to be published. Two reviewers independently considered the relevance and eligibility of the studies. The risk of bias of the selected articles was assessed with the Cochrane Collaboration's Risk of Bias Tool. Aggregate data were pooled using random effect models. Results: In addition to the SOS we identified two studies that met our criteria, the ROSE and SCOOP study. The design and strategy of the three studies was similar: a primary care population of older women (mean age 70-75), preselection of high fracture risk with a questionnaire followed by bone densitometry in the women with increased risk in the intervention group. There were small differences in risk selection and treatment thresholds, but all studies used FRAX in risk selection or in treatment thresholds. In all studies there was dilution: in the intervention group 13-25% had a treatment indication and 11-17% started anti-osteoporotic drugs. All three studies had low risk for bias except from the fact that the nature of the studies made blinding impossible, this increased the risk of contamination in the control group leading to a reduction of the contrast. Follow-up was complete in 94-100% of the participants. The heterogeneity between the three studies was low (I2 =0%). The pooled data (figure 1) indicated a significant effect on all osteoporotic fractures (HR=0.91 95%CI=0.81 to 1.00), the main osteoporotic fractures (HR=0.91, 95%CI=0.84 to 0.99, ROSE and SOS only) and hip fractures (HR=0.80, 95%CI=0.71 to 0.91). Conclusion: This meta-analysis of three large trials demonstrated that in older women in primary care preselection of high fracture risk followed by bone densitometry and subsequent treatment is effective in reducing all osteoporotic fractures, main osteoporotic, and hip fractures. Taking into account the dilution of the treatment effect in the intervention group and the contamination of the control group, we conclude that the effect on osteoporotic fracture reduction is substantial, especially on hip fractures reduction.

Time-dependent enhancement of osteoblast mineral deposition by green and black tea polyphenols originates during mineralization and not the differentiation phase William Gittings*, Michael D. Mcalpine, Adam J. Macneil, Wendy E. Ward. Brock University, Canada

There is growing interest in characterizing the effect of dietary bioactives that promote positive outcomes in musculoskeletal health, and the investigation of their interaction with tissue maintenance during aging as well as chronic inflammatory signalling. Previous results from our lab and others have demonstrated that whole tea preparations and their constituent polyphenols augment mineral deposition in osteoblasts in vitro. These findings are generally consistent with the beneficial effects of tea consumption on bone outcomes (i.e., BMD) in preclinical rodent models and associations reported in observational human studies. The objective of this study was to examine the effect(s) of green and black tea treatment in osteoblasts throughout the cell lifespan to describe the timing of modulation to cell function in a systematic fashion. SaOS-2 cells were cultured under standard conditions (37ºC, 5% CO2) and control (CC) responses were compared to three tea treatment conditions, including; tea treatment during differentiation only (TC), during mineralization only (CT), or throughout both phases of the cell lifecycle (TT). Tea treatment consisted of supplementing the control cell media with freshly prepared green or black tea at a standardized polyphenol content (1 µg/ml) determined using Folin-Ciocalteau's reagent (gallic acid equivalents). End-point mineral deposition quantified using Alizarin red staining at Day 3, 5, and 7 of mineralization determined that tea treatments during differentiation only (TC) did not enhance mineralization above control (CC) levels. In contrast, when green or black tea treatment occurred during mineralization (CT, TT), there was significant enhancement of nodule formation in both tea types at Day 3 (to ~1.4 of control values) and Day 5 (to ~2.0 of control values)(n=6, P < 0.05); a time-dependent effect which dissipated by Day 7 for both tea types. Transcriptional analysis using RT-qPCR of the principal mechanisms that regulate mineralization via the inorganic pyrophosphate (PPi) to phosphate (Pi) ratio (I.e., TNAP, ENPP1, ANKH, PHOSPHO1) did not explain the observed differences with green or black tea treatment. Our preliminary results suggest that a time-dependent enhancement of SaOS-2 mineral deposition by tea polyphenols occurs independent of modulation during the differentiation phase, and current investigation of post-translational mechanisms will accompany the primary findings.

Microglial Progranulin Promotes Age-Related Bone Loss in Female Mice Liping Wang*[1], Jiasheng Zhang[2], Eric Huang[2], Robert Nissenson[1]. [1]San Francisco VA Medical Center, United States, [2]University of California San Francisco, United States

Progranulin (PGRN) is best known as a glial factor that is deficient in a subset of patients with frontotemporal dementia. PGRN has also been identified as an adipokine that regulates glucose metabolism as well as a factor that affects bone. We recently found that global deletion of PGRN in female (F) (but not male (M)) mice was protective against age-related bone loss, implicating PGRN as a negative regulator of bone in aging females. In the present study, we hypothesized that PGRN expression by adipocytes is responsible for these negative skeletal effects. To test this notion, we characterized the bones of mice that were generated by specifically deleting PGRN expression in adipocytes using adiponectin-Cre. We found that deleting PGRN in adipocytes did not result in a change in distal femoral fractional bone volume (BV/TV, %) at 3 mo (M: WT vs. KO: 21% vs. 20%; F: 7.5% vs. 6.8%) or 6 mo (M: WT vs. KO: 17% vs.15%; F: 3.7% vs. 3.7%), but slightly decreased lean mass and body weight and significantly decreased mRNA encoding adipocyte marker genes Pparg (2.9-fold, p<0.05) and Emr1 (2-fold, p<0.05) in white adipose tissue of 3 mo male mice only. These data indicate that adipocyte-derived PGRN serves as a regulator of adipocyte metabolism, but does not account for the female skeletal effects of PGRN. We then asked whether microglial production of PGRN would inhibit bone formation since microglial PGRN contributes to the cognitive effects of PGRN. We studied the bones of female mice in which expression of the PGRN gene was deleted in microglial cells using Cx3cr1-Cre. µCT assessment of the L4 vertebra showed that deletion of PGRN in microglial cells led to a 27% (p<0.05) increase in BV/TV at 9 mo and a 86 % (p<0.01) increase at 16 mo. The increase in BV/TV was associated with a significant increase in trabecular number (9 vs. 16 mo: 23%, p<0.05 vs. 58%, p<0.01) and a significant decrease in trabecular separation (9 vs. 16 mo: 20%, p<0.05 vs. 38%, p<0.001). These changes are similar to those seen in global PGRN knockout mice, suggesting that microglial PGRN negatively regulates bone mass in aging females. However, Cx3cr1-cre is also expressed in peripheral macrophages and further work will be necessary to determine if macrophage-derived PGRN contributes to the bone phenotype. We speculate that PGRN acts by modulating the central mechanisms that control bone mass. Therapies aimed at blocking these mechanisms may prevent female age-related bone loss.

An oral PTH 1-34 formulation with a pharmacokinetic profile optimized for the treatment of osteoporosis Gregory Burshtien*[1], Hillel Galitzer[1], Ariel Rothner[1], Phillip Schwartz[1], Eric Lang[2], Roger Garceau[2], Jonathan C.Y. Tang[3], William D. Fraser[3], Yoseph Caraco[4]. [1]Entera Bio Ltd., Israel, [2]Entera Bio Ltd., United States, [3]University of East Anglia, United Kingdom, [4]Hadassah Clinical Research Center, Israel

An orally administered PTH 1-34 may be a novel treatment of Osteoporosis. It is well established that the duration of the drug exposure is critical in determining the balance between the anabolic and catabolic effects of PTH. In comparison to the commercially available PTH injections, we present clinical results of a novel oral PTH 1-34 formulation, characterized by a shorter systemic exposure, which is expected to be not only a more convenient treatment but may even have an improved anabolic effect.Methods:A Phase I, open label crossover study to assess the safety and PK of oral PTH 1-34 in ten healthy male adult volunteers was conducted. The PK profile of 1.5 mg oral PTH 1-34 was compared to that of the SC Forteo® injection. PTH 1-34 plasma levels were analyzed by immunoassay (IDS;UK).Results:The PK profile of oral PTH 1-34 was characterized by a rapid absorption and elimination. The average maximal plasma concentration (Cmax), time to maximal exposure (Tmax), systemic exposure (AUC) and elimination half-life of the oral drug VS. Forteo injection were 481pg/mL, 14.4 min, 190 pg*hour/mL, 16.5min VS. 207 pg/ml, 17.5 min, 197 pg*hour/mL and 36.2min. The duration of the systemic exposure above the upper limit of the endogenous PTH level was about 1 hr for the oral PTH 1-34 and about 2 hrs for Forteo. Significantly higher increase in serum calcium concentrations was observed following the SC injection, including 3 cases of transient hypercalcemia.Discussion:It is recognized that continuous administration of PTH primarily contributes to bone resorption, whereas intermittent administration promotes bone formation. It has been reported that the optimal duration of PTH exposure to promote the anabolic effect is 1 hr, as was achieved with the oral PTH 1-34 formulation. With this unique PK profile, characterized by a shorter duration of systemic drug exposure in comparison to the existing commercially available injectable formulations, we may anticipate that the oral PTH 1-34 formulation will provide not only better compliance, but also greater efficacy and a potentially improved safety profile in the treatment of osteoporosis. Additional clinical studies in patients with osteoporosis are required to confirm this hypothesis.

Patient Engagement in Clinical Guidelines Development: Input from > 1000 Members of the Canadian Osteoporosis Patient Network Larry Funnel*[1], Marija Djekic-Ivankovic[2], Rachel Chepesiuk[1], Lora Giangregorio[3], Isabel Braganca Rodrigues[3], Rowena Ridout[4], Sidney Feldman[4], Sandra Kim[4], Heather Mcdonald-Blumer[4], Gregory Kline[5], Wendy E Ward[6], Nancy Santesso[7], William D Leslie[8], Suzanne N Morin[9]. [1]Osteoporosis Canada, Canada, [2]Research Institute of the McGill University Health Center, Canada, [3]University of Waterloo, Canada, [4]University of Toronto, Canada, [5]University of Calgary, Canada, [6]Brock University, Canada, [7]McMaster University, Canada, [8]University of Manitoba, Canada, [9]McGill University, Canada

PURPOSE:Engagement of patients is essential in the development of high quality and relevant guidelines for the management of osteoporosis. Osteoporosis Canada (OC) is updating its national clinical practice guidelines using the GRADE approach, and is ensuring active patient involvement throughout the entire process.METHODS:Using electronic mail, we contacted 6937 members of the Canadian Osteoporosis Patient Network (COPN) to provide input in the selection of clinical questions and relevant outcomes via a self-administered on-line survey. Questions were developed by a working group that included clinicians, patients and researchers.Closed-ended questions were analyzed using descriptive statistics, and content analysis was conducted for the open-ended question. RESULTS:A total of 1108 individuals (16% participation rate) completed the survey (97% were women, 86% stated they lived with osteoporosis and most reported they were knowledgeable [61%] or very knowledgeable [24%] about osteoporosis). Most considered it to be very important to have recommendations on pharmacotherapy (83%), exercise (74%), nutrition (68%), fall prevention (68%), and how to discuss risks and benefits of medications (65%). Respondents stated that preventing fractures, preserving quality of life and ability to perform daily activities, preventing admission to long term care and fracture-related death, and avoiding serious harms from medications were very important outcomes (average scores ≥ 4.7 on a 5-point Likert scale). Discussion with a physician (51%) or other healthcare professional (41%), or access to material posted on the OC website (41%), were determined to be critical in ensuring a good understanding of the risks and consequences of fractures. Seven keys issues emerged from the content analysis of the open-ended question (498 respondents with 960 references): "Provide up to three questions you would like to see addressed in the next Guidelines" (Table). In addition to the key issues mentioned in the closed-ended questions, pain management following fractures and alternative therapies for prevention or treatment of osteoporosis were also identified as important questions to address (48 references).CONCLUSIONS:This survey has identified issues important to people living with osteoporosis that will inform the search strategy for knowledge syntheses, and the development of OC clinical guidelines recommendations.

Osteoporosis Treatment In Patients With Atypical Femur Fractures Denise Van De Laarschot*[1], Malachi Mckenna[2], M Carola Zillikens[1]. [1]Erasmus Medical Centre, Netherlands, [2]St. Vincent's University Hospital, Ireland

Atypical femur fractures (AFFs) are related to the use of bisphosphonates and often show delayed or non-healing. After an AFF, bisphosphonates are usually discontinued. It is unclear if certain osteoporosis drugs can promote AFF healing, while there is no guideline on how patients with high risk of fragility fractures should be treated after an AFF. We performed a systematic literature review to evaluate the effect of teriparatide, raloxifene and denosumab both on healing and occurrence of AFF in order to advice on treatment after AFF. We considered complete and incomplete forms separately. Our search retrieved 910 references and we reviewed 46 papers. The effect of teriparatide in AFF patients was described in 28 case reports, 7 retrospective cohorts and 3 prospective trials; the latter included 3 retrospective cohort studies on incomplete, 3 on complete and one on combined AFF. Although use of teriparatide showed a favorable trend towards shorter time to bone union after surgery in some studies, non-healing AFFs and development of contralateral AFFs occurred even after 11 months of teriparatide. With denosumab, 2 cases of AFF were reported in the Freedom extension study. Additionally, 8 cases of AFF were documented on denosumab, of which 6 cases were preceded by long-term bisphosphonate use. Additionally, 14 AFF cases are reported when denosumab was prescribed for treatment of metastatic bone disease. Nine patients were reported with continued use of denosumab after the AFF, of which 2 patients had delayed healing, one a second complete AFF, and one recurrent bilateral incomplete AFFs whilst on denosumab. Eight patients used raloxifene before the occurrence of AFF, including one case of AFF after only one year of raloxifene without prior bisphosphonates. No data are available on the outcome of raloxifene treatment started after the occurrence of AFF. In conclusion, all current antiresorptive drugs appear to be associated with AFF, and teriparatide does not seem to prevent AFF nor ensure fracture healing. These results need to be interpreted with caution due to heterogeneity of the reported studies and due to a lack of prospective, adequately powered, controlled trials. Based on these findings, we have for-

mulated treatment advise for patients who have sustained an AFF that considers the healing of both complete and incomplete forms, risk of worsening or new AFFs, and prevention of fragility fractures in those with high fracture risk due to osteoporosis.

Macromolecular Dexamethasone Prodrug Ameliorates Neuroinflammation and Prevents Bone Loss Associated with Traumatic Brain Injury Gang Zhao*[1], Xin Wei[1], Rongguo Ren[1], Zhifeng Zhao[1], Yuanyuan Sun[1], Ningrong Chen[1], Dexuan Kong[2], Dong Wang[1]. [1]University of Nebraska Medical Center, United States, [2]China Pharmaceutical University, China

Traumatic brain injury (TBI) is a leading cause of death and disability, particularly among young adults. In addition to neurologic damage and disfunction, TBI has also been found to induce bone loss in patients and animal models. The TBI associated osteopenia not only affects the patients' quality life but also can be life threatening. The combination of balance disorder and osteopenia will put the TBI patients at a higher risk of fall and bone fracture. Neurologic injury from TBI is largely attributed to the deleterious effects of the direct mechanical impact as well as secondary cerebral swelling and edema, which will increase intracranial pressure, leading to ischemic injuries. While glucocorticoids (GC) have been used extensively in treating TBI, the clinical outcome has been controversial. To further improve the therapeutic efficacy and safety of the GC therapy, we proposed to use a macromolecular dexamethasone prodrug (P-Dex) to treat TBI.Mice (C57BL/6, 9 weeks old, female) were randomly assigned to 3 groups (10/group, P-Dex, saline and healthy control). TBI was induced by controlled cortical impact (CCI) with 2.5 mm depth at 5.25 m/s. Mice from each group were sacrificed at 6 weeks post TBI. Brains were harvested to evaluate P-Dex' therapeutic efficacy on TBI. IRDye® 800CW labeled P-Dex were administrated to evaluate P-Dex' biodistribution at 1, 3 and 7 days post i.v. administration. Tibias and lumbar vertebrae (L5) were harvested for evaluation of bone quality.Optical imaging results suggested that P-Dex targeted to the injured cortex with sustained presence for up to 7 days. Immunohistochemistry results indicated that P-Dex had inhibited the activation of microglia with reduced lipid peroxidation. Brain edema in P-Dex treated group was also reduced as evident by the inhibition of Aquaporin 4 expression. Fluoro-Jade C staining indicated P-Dex could preserve neurons from degeneration after injury. Micro-CT analysis of tibias and L5 vertebrae confirmed the post TBI trabecular bone loss at 6 weeks. BV/TV in saline group was reduced to ~75% in proximal tibia and ~85% in L5 lumbar vertebrae of the healthy mice. BV/TV of the P-Dex group showed no statistically significant difference from the healthy mice but was significantly higher than saline group.Based upon these preliminary findings, we believe P-Dex treatment may attenuate brain injury induced by TBI and systemically preserved the skeletal quality of the mice with TBI.
Representative micro-CT images and quantitative analysis of the L5 Lumbar vertebrae and tibia of TBI mice from different groups. * P < 0.05; ** P < 0.01; *** P < 0.001.

Background & aim:Maintenance of skeletal muscle in older age is critical to reducing frailty and the risk of falls and fractures. Nutrition has established importance for muscle health in general, however, the relationship between specific micronutrients intake and sarcopenia has not been well established in older adults. The objective of this study was to assess the relationship between daily nutritional intake and sarcopenia.Methods:A total of 2426 Iranian adults aged ≥60 years, participating in the stage II of Bushehr Elderly Health (BEH) program, a population-based prospective cohort study; were included in this study. According to European Working Group on Sarcopenia in Older People (EWGSOP) definition, a person who had low muscle mass as well as low muscle strength and/or low physical performance (usual walking speed) was identified as having sarcopenia.Skeletal muscle mass index (SMI) less than < 7.0 kg/m2 and <5.4 kg/m2 were considered as low muscle mass among men and women, respectively Low muscle strength was defined as grip strength <26kg for men and <18kg for women, respectively, and a usual walking speed ≤0.8m/s was defined as low physical performance for both genders. Body composition was measured by the dual x-ray absorptiometry (DXA) method.Dietary nutrient intakes were estimated from a 24-hour recall method. Daily nutrients intake based on the consumption of each food item was calculated.Multivariate regression was used to investigate the association of sarcopenia with tertiles of daily nutrients intake groups.Results:Participants with sarcopenia consumed less dietary intakes of total calories, protein, and carbohydrates (P<0.001). Also, sarcopenia showed a strong inverse association with minerals such as Calcium, Iron, Magnesium, Phosphorus, Potassium, Zinc and vitamins (A, E, C, Biotin, B2, B3 and B6). When the odds ratios for sarcopenia according to daily nutrients intake tertile were analyzed, the risk for sarcopenia decreased as daily minerals and vitamins intake increased from the first to the third tertile, even after correction for confounding variables. Participates in the higher trertiles of daily protein intake, carbohydrate and total calories showed the significantly decreased risk of sarcopenia [OR=0.641(0.519-0.791); P for trend =0.002] , [OR=0.731(0.593-0.901); P for trend =0.010] [OR=0.780(0.633-0.9631); P for trend =0.05], respectively. The associations remained statistically significant after adjustment for age, sex, BMI, physical activity and smoking.Conclusions:Our results suggest a strong inverse association between daily nutrients intake and sarcopenia in older Iranian adults.
