Mice Lacking Tuberous Sclerosis 2 in Osteoblasts Develop Insulin Resistance with Increased Bone and Fat Mass. Ryan Riddle^{*1}, Julie Leslie², Douglas Digirolamo², Thomas Clemens². ¹Johns Hopkins University School of Medicine, USA, ²Johns Hopkins University, USA

Recent studies demonstrate that insulin receptor (IR) signaling in osteoblasts is required for osteoblast differentiation and for the regulation of global glucose metabolism in mice. To interrogate insulin-responsive pathways in osteoblasts responsible for these metabolic actions, we examined the role of *Tsc2*, which encodes a component of the tuberous sclerosis complex that regulates mTOR activity. Insulin stimulates mTOR activity by inactivating the Tsc1/Tsc2 complex, and thereby enhances protein synthesis, glucose utilization, and cell growth. Mice selectively lacking *Tsc2* in osteoblasts (Δ Tsc2) exhibited striking increases in trabecular bone (122% vs. controls at 12 wks). With age, the Δ Tsc2 mice developed metabolic abnormalities similar to those observed previously in mice lacking the IR in osteoblasts. Body weights of Δ Tsc2 mice were significantly higher than controls by 5 weeks of age and were accompanied by the development of hyperglycemia and low levels of serum insulin. Formal glucose and insulin tolerance tests confirmed that Δ Tsc2 mice were severely glucose intolerant and mildly insulin resistant. In vitro, calvarial osteoblasts rendered deficient for *Tsc2* had increased levels of phospho-S6 kinase, an indicator of mTOR activation, and differentiated poorly with reduced expression of *runx2* and *osterix* mRNA when compared to controls. Notably, Δ Tsc2 osteoblasts expressed 3-fold higher levels of osteoprotegerin mRNA, suggesting that defective osteoclastogenesis contributed to the dramatic increase in bone volume in the mutant mice. Δ Tsc2 osteoblasts expressed normal levels of IR but were refractory to insulin as evidenced by impaired insulin-stimulated Akt phosphorylation. The blunted insulin responsiveness was associated with decreased levels of IRS-1, elevated levels of markers of ER stress (Chop and Grp78) and increased phospho-JNK levels, changes compatible with known mechanisms for accelerating turnover of IRS-1. Together, our data suggest a model in which IR generated signals converge on *Tsc2* to ensure proper mTOR signaling, which in turn is required for normal osteoblast development and function. We speculate that this same pathway enables negative feedback regulation of insulin signaling in the osteoblast through *Tsc2*/mTOR mediated alterations in ER stress response pathways, which dampen insulin receptor signaling by triggering accelerated IRS-1 turnover.

Neuropeptide Y Receptor Signaling in Osteoblasts is Required for Normal Glucose Homeostasis in Mice. Nicola Lee¹, Daniela Sousa², Ronaldo Enriquez³, Amanda Sainsbury³, Herbert Herzog³, Paul Baldock^{*1}. ¹Garvan Institute of Medical Research, Australia, ²INEB - Instituto de Engenharia Biomedica, Portugal, ³Garvan Institute, Australia

The skeleton has recently emerged as a potential player in the control of whole-body glucose metabolism; however, the mechanism behind this regulatory axis has not been fully elucidated. Here we demonstrate that neuropeptide Y (NPY) receptor signalling in osteoblasts is required for normal glucose metabolism, in addition to bone formation. The osteoblastic NPY receptor (Y1R) was deleted from the osteoblast lineage by crossing Y1R floxed mice with collagen 1 α 1 3.6 Cre mice (Y1R KO_{OB}). In addition, the circulating Y1R ligand, peptide YY (PYY), was over expressed in osteoblasts by crossing collagen 1 α 1 3.6 Cre mice with Cre-inducible PYY transgenic mice, which drives PYY expression through a CMV promoter (PYY TG_{OB}). Mice were examined for glucose homeostasis at 13-14 weeks and culled at 18 weeks of age.

Mice lacking Y1 receptors solely in cells of the osteoblastic lineage displayed a high bone mass phenotype. Cancellous bone volume of the distal femoral metaphysis was greater in Y1R KO_{OB} due to significantly increased mineral apposition rate and bone formation rate. This was an uncoupled response, as the bone resorption marker, osteoclast surface, was reduced. Y1R KO_{OB} mice also displayed altered whole-body glucose metabolism. This was due to significantly decreased pancreatic insulin content, pancreas weight, and decreased insulin secretion leading to elevated glucose levels and reduced glucose tolerance, but with no effect on insulin induced glucose clearance.

Furthermore, increased activity of Y1R signalling induced by over-expression of its ligand, PYY in osteoblastic cells, in PYY TG_{OB} mice also led to impaired glucose tolerance. However, insulin secretion was elevated and insulin sensitivity was impaired. Expression of osteocalcin, ATF4, Esp and Foxo1 in whole bone extracts were unaltered in either model compared to respective wild type.

Together these data reveal a novel mechanism by which NPY receptor signalling in bone tissue is involved in the control of glucose and energy homeostasis. Maintenance of Y1R signalling activity in osteoblasts appears crucial to preservation of optimal glucose homeostasis.

Altering AP-1 Transcription via Δ FosB in the Hypothalamus Regulates Bone and Energy Homeostasis through the ARC and VMH Nuclei, Respectively. Kazusa Sato^{*1}, Glenn C Rowe², Min Yin¹, Hiroaki Saito¹, Sutada Lotinun¹, William Horne¹, Roland Baron³. ¹Harvard School of Dental Medicine, USA, ²Beth Israel Deaconess Medical Center, USA, ³Harvard Medical School, Endocrine Unit, Massachusetts General Hospital, & Harvard School of Dental Medicine, USA

Bone homeostasis and energy balance are regulated by endocrine and neural pathways that originate from the hypothalamus. Two nuclei in the mediobasal hypothalamus, the arcuate nucleus (ARC) and ventromedial hypothalamic nucleus (VMH), play a pivotal role in mediating these pathways.

Δ FosB is a naturally truncated form of the AP-1 transcription factor FosB. Overexpression of Δ FosB under the control of the enolase 2 promoter (ENO2), which drives expression in several tissues including bone, white and brown fat, and the brain including hypothalamus, results in increased bone mass and energy expenditure, this latter leading to decreased fat mass. We also have shown that targeted injections of adeno-associated virus (AAV) encoding Δ FosB and DNJunD, an artificial antagonist of AP-1 activity, to the mediobasal hypothalamus in mice phenocopied the observations in ENO2- Δ FosB mice.

To examine the role of ARC and VMH nuclei neurons in Δ FosB-mediated regulations of bone mass and energy balance, we performed chemical lesion of these two nuclei in ENO2- Δ FosB mice and control littermates by monosodium glutamate (MSG) treatment for ARC lesion or gold thioglucose (GTG) for VMH lesion.

MSG treatment induced an osteopenic phenotype in both Δ FosB and control mice. In addition, the increased bone mass in Δ FosB mice was cancelled by MSG treatment. On the other hand, GTG treatment had no effect on bone homeostasis in both Δ FosB and control mice.

Both MSG and GTG treatments progressively promoted obesity as expected. However, MSG-treated Δ FosB mice showed partial but significant suppression in weight and fat gain compared to MSG-treated control mice while GTG-treated Δ FosB mice gained weight and developed adiposity to the same extent as GTG-treated controls.

Consistent with this, increased energy expenditure and improved insulin sensitivity and glucose tolerance in Δ FosB mice were cancelled by GTG-treatment, not by MSG-treatment. GTG-treated Δ FosB mice had exacerbated hyperinsulinemia along with hypertrophic pancreatic islets while these deleterious changes were significantly suppressed in MSG-treated Δ FosB mice.

Overall, these results suggest that hypothalamic signaling downstream of Δ FosB affects bone and energy through two different neuronal circuits: it regulates bone remodeling through MSG-sensitive neurons in ARC nucleus, while mediating energy balance and glucose homeostasis through GTG-sensitive neurons in VMH nucleus.

Reduced Peripheral Leptin Signaling Drastically Decreases Bone Formation. Urszula Iwaniec^{*}, Carmen P. Wong, L. Bailey Lindenmaier, Kenneth Philbrick, Dawn Olson, Russell Turner. Oregon State University, USA

The skeletal abnormalities observed in leptin-deficient ob/ob mice are corrected by long duration central (hypothalamic) leptin gene therapy. However, this finding does not preclude an important role for peripheral leptin in regulation of bone metabolism. To determine the effects of loss of peripheral leptin signaling on bone formation and energy metabolism, we performed bone marrow transplantations where the bone marrow (BM) from wild type (WT) or leptin receptor-deficient db/db donor mice was used to reconstitute the hematopoietic and mesenchymal stem cell compartments in 8-week-old WT recipient mice. Four groups of mice (n=8/group) were studied: 1) untreated leptin receptor-deficient db/db, 2) untreated WT, 3) WT mice that received WT BM (WT to WT), and 4) WT mice that received db/db BM (db/db to WT). Four additional WT mice received BM from GFP donor mice (GFP to WT) to track the reconstitution and differentiation of donor-derived cells. Compared to WT (100%), db/db mice consumed significantly more food (215%), weighed more (226%), had higher blood glucose (325%), and higher white adipose tissue mass (1.762%). WT mice engrafted with db/db BM did not differ in energy homeostasis from untreated WT mice or WT mice engrafted with WT BM. The GFP tracking studies revealed that BM engraftment resulted in quantitative replacement of hematopoietic and mesenchymal lineage cells in spleen and bone marrow, respectively. In contrast, the gene for GFP was not detected in brain tissue. Compared to WT, db/db mice had significantly lower bone formation at the femoral endocortical diaphysis (20%) and cancellous sites in the femur (metaphysis, 31% and epiphysis, 30%) and lumbar vertebra (LV, 37%). This finding indicates that leptin signaling is required for normal bone formation. Bone formation rates in WT mice engrafted with WT BM did not differ from untreated WT mice (diaphysis, 75%; metaphysis, 107%; epiphysis, 103%; and LV5, 100%). In contrast, engraftment of WT mice with cells from db/db donor mice resulted in significantly lower bone formation rates compared to untreated WT mice at all sites examined (diaphysis, 14%; metaphysis, 25%; epiphysis, 25%; and LV, 33%). Bone formation rates in WT mice engrafted with db/db cells did not differ from the low rates observed in untreated db/db mice. In summary, these surprising findings indicate that peripheral leptin is predominantly responsible for the ability of the hormone to maintain bone formation in normal mice.

In vivo Fate Mapping identifies Mesenchymal Progenitor Cells. Danka Grcevic¹, SLAVICA PEJDA², DARIO REPIC³, Liping Wang³, Haitao Li³, Mark Kronenberg³, Peter Maye³, Douglas Adams³, David Rowe³, Hector Aguila³, Ivo Kalajzic³. ¹University of Zagreb, Croatia, ²University of Connecticut, USA, ³University of Connecticut Health Center, USA

Adult mesenchymal progenitor cells have enormous potential for use in regenerative medicine. However, the true identity of the progenitors in vivo and its progeny has not been precisely defined. We hypothesize that cells expressing smooth muscle α -actin promoter (α SMA) directed transgene represent mesenchymal progenitors of adult bone tissue. By combining complementary colors in combination with transgenes activating at mature stages of the lineage we confirmed the ability of isolated α SMA⁺ cells to progress from a progenitor to mature osteoblasts and adipocytes. In order to determine whether α SMA promoter can identify cells with progenitor activity in vivo, we generated α SMACreERT2 transgenic mice and we characterized its expression by crossing it with the Ai9 reporter transgenic line to generate α SMACreERT2/Ai9 (SMA9) mice. In vivo lineage tracing experiments using new bone formation model confirmed the osteogenic phenotype of α SMA⁺ cells. The labeling pattern of SMA9 cells defined a small population of cells present in primary spongiosa or within the periosteum two days after tamoxifen induction. No cells expressing SMA9 reporter were detected within the bone matrix. Interestingly, 17 days after the tamoxifen activation we found numerous osteoblast and osteocytes labeled by the transgene. Similarly, in fracture healing model α SMA⁺ cells served as a pool of fibrocartilage and skeletal progenitors. One week following injury we could observe the expansion of SMA9⁺ cells within bone marrow and periosteum. Interestingly, we detected also the presence of SMA9⁺ expressing cells in newly formed chondrogenic areas of the fracture callus, and a numerous areas of osteoblasts. We observed that the osteoblasts derived from SMA9 progenitor cells showed intense deposition of new bone, indicated by the tight correlation between calcein label (green) and tdTomato (red) positive cells. To track more specifically the population of SMA9⁺ cells into mature osteoblast we bred a bone specific transgene into the SMA9 mice. The expression of SMA9⁺ cells co-localized to Col2.3emd expressing mature osteoblasts and osteocytes. This finding was a direct evidence for terminal differentiation of SMA9⁺ cells into mature osteoblast lineage cells. Our findings provide a novel in vivo identification of defined population of mesenchymal progenitor cells with active role in bone remodeling and regeneration.

Nestin as a Marker for Bone Marrow Mesenchymal Stem Cells. Xiaoli Zhao^{*1}, Bing Yu¹, Lingling Xian², William Lu³, Mei Wan⁴, Xu Cao¹. ¹Johns Hopkins University, USA, ²Johns Hopkins university school of Medicine, USA, ³The University of Hong Kong, Hong Kong, ⁴Johns Hopkins University School of Medicine, USA

Markers are critical in study of stem cells. Lack of a unique marker has been the challenge in the characterization of bone marrow mesenchymal stem cells (MSCs). Murine bone marrow Sca-1+CD29+CD45-CD11b- cells are recognized MSCs and recruited during bone remodeling. Recent study reveals that nestin+ bone marrow cells contain all the bone-marrow CFU-F activity of MSCs and can self-renew and differentiate into osteoblasts. In this study, we demonstrate that bone marrow nestin+ cells are self-renewal and multi-potential MSCs. We first characterized the nature of nestin+ cells in comparison with Sca-1+CD29+CD45-CD11b- MSCs. GFP-labeled MSCs were isolated from GFP transgenic mice and Sca-1+CD29+CD45-CD11b- or nestin+ MSCs were sorted by fluorescence activated cell sorting (FACS). Further flow cytometry analysis revealed that Sca-1+CD29+CD45-CD11b- cells were 91 percent nestin-positive, and the sorted nestin+ cells were 97 percent Sca-1-positive, indicating that nestin is a marker of MSCs and represent the same population of Sca-1+CD29+CD45-CD11b- cells.

To assess the multilineage differentiation capacity, nestin+ MSCs were cultured in single cell suspensions for single colony forming. Individual and well-separated colonies were selected and individually expanded. Each clonal strain derived from a single CFU-F underwent osteogenic, adipogenic, and chondrogenic induction by different culture media. These clones were capable of osteogenesis, adipogenesis and chondrogenesis. To examine self-renewal of nestin+ MSCs in vivo, GFP+ clonal strains were injected individually into the femur cavity of 8-week-old Rag2^{-/-} mice. GFP+ cells from the injected bone were collected by FACS 8 weeks after injection and plated in culture. This procedure resulted in the generation of secondary CFU-Fs. Importantly, the colonies generated were positive for nestin. The clonal strains were then pelleted, resuspended in matrigel, and injected underneath the renal capsule of Rag2^{-/-} mice to generate heterotopic ossicles for assessing their osteogenic differentiation capacity in vivo. Complete ossicles, including bone, sinusoids, and hematopoietic components, were generated from individual clones. The lining cells on the bone surface and osteocytes in the bone matrix were GFP+, indicating that the donor cells induced osteogenesis. Collectively, our results demonstrate that nestin is a unique marker for Sca-1+CD29+CD45-CD11b- MSCs.

A Y Chromosome Gene, Uty, Defines Sexual Dimorphism in Skeletal Phenotype. KAZUKI INOUE^{*1}, Yuuki Imai¹, Shigeki Kato². ¹The University of Tokyo, Japan, ²University of Tokyo, Japan

Males have higher bone mass and larger skeletal size than females. Such gender-specific bone phenotype has considered to be generated by the actions of sex steroid hormones. However, an uncharacterized Y chromosome gene is assumed as a significant factor to form gender-specific bone phenotype from clinical observations of patients mutated in the GCY (Growth Controlling region on the Y chromosome).

To reveal the biological functions of Y chromosome gene in skeletal systems, we ablated mouse *Uty* (Ubiquitously transcribed tetratricopeptide repeat gene, Y chromosome) gene, whose human ortholog is located in the GCY. Using a Cre/loxP system and two step ES gene-targeting methods that are potent to low efficiency of homologous recombination in Y chromosome, successfully, *Uty* gene was genetically disrupted for the first time among the Y chromosome genes. *Uty* knockout mice (*Uty*^{XIL/-}) exhibited short stature with shortened trunk and long bones like wild-type (WT) female littermates, while no endocrine disturbance was detected. In *Uty*^{XIL/-}, the thickness of growth plates, especially at proliferative zone, was significantly reduced when compared with that of WT male littermates. As expected, primary cultured chondrocytes from *Uty*^{XIL/-} showed decreased proliferative ability with increased expression of *Col10a1*, a marker of hypertrophic chondrocytes. These results suggest that *Uty* regulates male skeletal length by controlling cartilage development. Since *Uty* bears a JmjC domain, we assumed *Uty* function as an epigenetic regulator. In a co-immunoprecipitation assay, *Uty* was found to associate with Runx2 and Hdac4, the key factors in chondrocytes differentiation. Consistently, *Uty* was potent to repress transcriptional activity of Runx2 in an OSE-luc assay. A ChIP assay showed that these factors were recruited to the Runx2 target gene (*Col10a1*) promoter. Moreover, recruitment of Hdac4 was reduced and several histone modifications of *Col10a1* promoter were altered in *Uty*^{XIL/-} chondrocytes.

Thus, these findings suggest that *Uty* is a negative regulator for Runx2 by recruiting a transcriptional co-repressor HDAC4, expressed at hypertrophic chondrocytes, and thereby facilitates cartilage development. Taken together, the present study has uncovered a molecular basis of gender-specific cartilage development.

Transcriptional Coregulator Jab1 Is Essential for Chondrocyte Differentiation in vivo. Dongxing Chen¹, Bojian Liang¹, Martina Panattoni², Keiko Tamai¹, Ruggero Pard², Brendan Lee³, Guang Zhou^{*1}. ¹Case Western Reserve University, USA, ²Scientific Institute San Raffaele, Italy, ³Baylor College of Medicine & Howard Hughes Medical Institute, USA

Evolutionarily conserved factor Jab1 plays critical roles in cell differentiation, proliferation, and apoptosis by modulating the activity of diverse transcription factors and regulating the output of various signaling pathways. However, Jab1 function in skeletogenesis is largely unknown. In this study, we utilized loxP/Cre system with *Col2a1*-Cre transgene and *Jab1*^{lox} allele to delineate the specific role of Jab1 in cartilage formation. *Col2a1-Cre;Jab1*^{lox/lox} mutants exhibited neonatal lethal chondrodysplasia with severe dwarfism. In E18.5 mutant embryos, all the skeletal elements developed via endochondral ossification were extremely small with severely disorganized chondrocyte columns. *Jab1*-null chondrocytes exhibited increased apoptosis and cell cycle defect. Interestingly, the chondrocytes immediate adjacent to hypertrophic chondrocytes, the presumptive pre-hypertrophic zone, were of abnormally large size and ectopically expressed Runx2, a positive regulator of chondrocyte maturation. Real-time RT-PCR analysis confirmed the increased expression of hypertrophic chondrocyte markers *Col10a1* and *Runx2* in *Jab1* mutants. Jab1 has been shown to directly interact with Runx3 and negatively regulate Runx3 function. Interestingly, in our preliminary study, Jab1 can also inhibit Runx2 transcriptional activity in a dose-dependent manner. Thus, in *Jab1* mutants, chondrocyte maturation is dysregulated likely in part due to up-regulated Runx2 expression. Additionally, our study showed that Jab1 is a novel inhibitor of BMP signaling in chondrocytes. BMP signaling regulates the critical Ihh-Pthrp feedback loop to control chondrocyte differentiation. In *Jab1*-null primary chondrocytes, gene expression profiling analysis revealed heightened expression of BMP targets, including *Ihh* and *Noggin*. The expression of BMP downstream effector, phospho-Smad1/5/8, was also upregulated in *Jab1*-null cartilage. Furthermore, *Jab1*-null primary chondrocytes exhibited an enhanced response to exogenous BMP treatment. Together, our novel study demonstrates that Jab1 is essential for proper cartilage formation in vivo, likely in part by repressing BMP signaling and Runx2 activity. Loss of Jab1 in chondrocytes leads to accelerated chondrocyte hypertrophy and enhanced BMP signaling. We are currently further analyzing the *Jab1* mutant mice to dissect the detailed mechanisms underlining the intricate interaction between Jab1, Runx2, and BMP signaling during chondrocyte differentiation.

Notch/Rbpj/Hes1 Signal in Chondrocytes Modulates the Terminal Stage of Endochondral Ossification during Skeletal Growth and Osteoarthritis Development. Yoko Hosaka^{*1}, Taku Saito¹, Shurei Sugita¹, Atsushi Fukai¹, Tomohiro Hikata², Haruhiko Akiyama³, Takashi Nakamura³, Kozo Nakamura⁴, Ung-Il Chung⁵, Hiroshi Kawaguchi⁶. ¹University of Tokyo, Graduate School of Medicine, Japan, ²Keio University School of Medicine, Japan, ³Kyoto University, Japan, ⁴The University of Tokyo, Japan, ⁵University of Tokyo Graduate Schools of Engineering & Medicine, Japan, ⁶University of Tokyo, Faculty of Medicine, Japan

Here we have examined the role of the Notch signaling pathway in chondrocytes during the endochondral ossification process that is essential for skeletal growth and osteoarthritis (OA) development. In cultures of mouse primary costal chondrocytes and chondrogenic ATDC5 cells, Notch1, 2, the transcriptional effector Rbpj, and the target transcription factor Hes1 were strongly expressed in their terminal differentiation stages during Mmp13 and Vegf expression, while Notch3, 4 and other target Hes/Hey members were little expressed throughout the differentiation stages. In the limb cartilage of mouse embryos and in the knee joint cartilage of a mouse experimental OA model with surgical induction of instability, intracellular domains (ICD) of Notch1, 2 were localized in the nucleus of highly differentiated chondrocytes in the hypertrophic zone and in the degraded cartilage, respectively, while they remained in the cytoplasm of less differentiated chondrocytes of the proliferative zone and undegraded cartilage. Rbpj and Hes1 were also co-expressed in the nucleus of highly differentiated chondrocytes, while other Notch ICDs and Hes/Hey members were not detected in either cartilage. We then created conditional knockout mice of Rbpj in chondroprogenitor cells (*Sox9-Cre;Rbpj^{fl/fl}*) and chondrocytes (*Col2a1-Cre;Rbpj^{fl/fl}*). Although the *Sox9-Cre;Rbpj^{fl/fl}* mice died shortly after birth, the embryos exhibited dwarfism with impaired matrix degradation and vascular invasion into the cartilage primordia due to decreases of Mmp13 and Vegf expression. When we created the experimental OA model in a *Col2a1-Cre;Rbpj^{fl/fl}* mouse line with partial Rbpj inactivation causing normal skeletal growth, the knee OA development was suppressed as compared to the *Rbpj^{fl/fl}* littermates, with prevention of the terminal stage of endochondral ossification, similar to the *Sox9-Cre;Rbpj^{fl/fl}* limb cartilage. Retroviral overexpression of Notch1-ICD or Notch2-ICD in ATDC5 cells caused enhancement of Alizarin red S and ALP stainings, as well as Mmp13, Vegf, and Hes1 expression. These effects were inhibited by a Notch inhibitor DAPT. Luciferase analyses revealed that the Hes1 transfection enhanced the *Mmp13* and *Vegf* promoter activity most potently among the Hes/Hey members. In conclusion, the Notch/Rbpj/Hes1 signal in chondrocytes modulates the terminal stage of endochondral ossification during skeletal growth and OA development, indicating it to be a possible therapeutic target of OA.

Disclosures: Yoko Hosaka, None.

Notch Inhibits Nuclear Factor of Activated T-Cells (NFAT) Transactivation in Primary Epiphyseal Chondrocytes In Vitro. Stefano Zanotti^{*}, Maria Monarca, Ernesto Canalis. St. Francis Hospital & Medical Center, USA

Notch proteins are transmembrane receptors that determine lineage specification between neighboring cells. In the canonical signaling pathway, activation of Notch receptors results in the cleavage, release and nuclear translocation of the Notch intracellular domain (NICD). In the nucleus, NICD interacts with C Promoter Binding Factor 1, Suppressor of Hairless and Lag-1 (CSL) to activate the transcription of target genes, such as *Hairy enhancer of split (Hes)* or *Hes related with YRPW motif (Hey)*. Conditional overexpression of NICD in cartilage impairs endochondral bone formation. However, the mechanisms involved have not been defined. Nuclear Factor of Activated T-Cells (NFAT)c1 to c4 are transcription factors that determine cell differentiation and function, and NFAT signaling is required for chondrogenic differentiation *in vitro*. *Nfatc2* null mice display lesions reminiscent of osteoarthritis, although this may be the consequence of B- and T-cell proliferation and dysregulated cytokine synthesis. We postulated that Notch could act in cartilage through the regulation of NFAT signaling. The mechanisms of Notch action were studied in primary epiphyseal chondrocytes harvested from the fore and hind limbs of 3 to 5 day old *Rosa^{Notch}* mice. In this model, delivery of Cre recombinase induces the excision of a STOP cassette flanked by *loxP* sequences, allowing expression of NICD under the control of the *Rosa26* promoter. Adenoviral vectors where the cytomegalovirus promoter directs the expression of Cre recombinase were used to induce Notch. Notch transactivated a reporter construct where 12 copies of a CSL consensus sequence control *Luciferase* expression. Accordingly, Notch induced the activity of fragments of the *Hes1*, *Hey1* and *Hey2* promoters and increased Hes1, Hey1 and Hey2 transcript levels, confirming the validity of the *Rosa^{Notch}* model to investigate the role of Notch signaling in cartilage. In agreement with the impaired chondrogenesis observed in Notch transgenic mice, overexpression of Notch in chondrocytes suppressed collagen type II $\alpha 1$ transcripts. Furthermore, Notch inhibited NFAT transactivation. Since NFAT is required for chondrogenesis, these results suggest that the effects of Notch on this process could be mediated by a downregulation of NFAT activity. In conclusion, Notch impairs chondrogenesis and suppresses NFAT transactivation in chondrocytes.

Disclosures: Stefano Zanotti, None.

C/EBP- β and RUNX2 Cooperatively Control Cartilage Degradation with MMP-13 as the Target and HIF-2 α as the Inducer in Chondrocytes. Makoto Hirata^{*1}, Fumitaka Kugimiyama², Atsushi Fukai¹, Taku Saito³, Akihiko Mabuchi¹, Bishwa Raj Sapkota¹, Toru Akune¹, Fumiko Yano⁴, Toshivuki Ikeda¹, Nao Nishida¹, Noriko Yoshimura⁵, Takumi Nakagawa¹, Kozo Nakamura⁴, Katsushi Tokunaga⁶, Ung-Il Chung⁷, Hiroshi Kawaguchi⁶. ¹University of Tokyo, Japan, ²Sensory & Motor System Medicine, University of Tokyo, Japan, ³University of Tokyo, Graduate School of Medicine, Japan, ⁴The University of Tokyo, Japan, ⁵22nd Century Medical & Research Center, University of Tokyo, Japan, ⁶University of Tokyo, Faculty of Medicine, Japan, ⁷University of Tokyo Graduate Schools of Engineering & Medicine, Japan

The endochondral ossification is a crucial process in normal skeletal growth and osteoarthritis (OA) development. Aiming at elucidation of the molecular mechanism underlying this process and identification of therapeutic targets for OA, we examined the signal network around CCAAT/enhancer-binding protein- β (C/EBP- β), a regulator of chondrocyte functions. Computational predictions and a C/EBP motif-reporter assay identified RUNX2 as the most potent transcriptional partner of C/EBP- β in chondrocytes. Both C/EBP- β and RUNX2 were co-expressed in the terminal differentiation stage of chondrocytes in several cell culture systems, in the mouse limb cartilage, and in the OA joint cartilage of mice and humans. To determine the involvement of C/EBP- β and RUNX2 in the endochondral ossification process, we generated their compound knockout mice: *Cebpb^{-/-};Runx2^{+/-}* and *Cebpb^{+/-};Runx2^{-/-}*, because *Runx2^{-/-}* mice died just after birth. The *Cebpb^{-/-};Runx2^{+/-}* mice showed more severe dwarfism than the *Cebpb^{-/-}* and *Runx2^{+/-}* littermates with impaired cartilage degradation but unaffected chondrocyte differentiation. Although *Cebpb^{+/-};Runx2^{+/-}* mice showed normal skeletal growth, they exhibited greater suppression of knee OA development in surgical and age-related OA models than their *Cebpb^{+/-}* and *Runx2^{+/-}* littermates. Histological analyses in the limb cartilage and the OA joint cartilage showed that the compound knockout caused a considerable decrease of matrix metalloproteinase-13 (MMP-13) among various factors related to endochondral ossification. In cultured chondrocytes, C/EBP- β and RUNX2 cooperatively enhanced endogenous expression and promoter activity of *MMP13* shown by real-time RT-PCR and luciferase assay. The specific and direct binding of C/EBP- β and RUNX2 as a protein complex to a C/EBP-binding motif and an OSE2 motif in the *MMP13* promoter was shown by EMSA and ChIP-reIP assay. Lastly, to identify the upstream mechanism, we performed a screening of transcription factors using a human *CEBPB* promoter fragment among putative factors regulating chondrocyte differentiation, and identified hypoxia-inducible factor-2 α (HIF-2 α) as the most potent and functional inducer of C/EBP- β expression in chondrocytes through specific binding to a hypoxia-responsive element. In conclusion, C/EBP- β and RUNX2, with MMP-13 as the target and HIF-2 α as the inducer, cooperatively control cartilage degradation. This molecular network in chondrocytes may represent a therapeutic target for OA.

Two Major microRNA Species in Chondrocytes, miR-140 and let-7 miRNAs, Regulate Endochondral Bone Growth through Distinct Mechanisms. Jennifer Inloes^{*}, Tatsuya Kobayashi. Massachusetts General Hospital, USA

microRNAs (miRNAs) regulate gene expression at the post-transcriptional level. In chondrocytes, a few hundred miRNAs are present at detectable levels. Global miRNA deficiency in mouse chondrocytes causes skeletal dysplasia with reduced chondrocyte proliferation and accelerated post-mitotic hypertrophic differentiation; however, the physiological roles of individual miRNAs in endochondral bone development remain largely unknown. The chondrocyte-specific miRNA, miR-140 (encoded by *Mir140*), and the let-7 miRNAs are some of the most abundantly expressed miRNAs in chondrocytes. To investigate the roles of these miRNAs, we generated *Mir140*-null mice and mice expressing *Lin28*, a protein that suppresses let-7 miRNA expression. *Mir140*-null mice exhibit mild longitudinal skeletal growth defects and shortened naso-occipital length due to impaired endochondral bone growth. *Mir140*-null chondrocytes show normal proliferation but also show a reduction in size of the columnar proliferating zone and an increase in size of the resting zone, suggesting that *Mir140* negatively regulates resting chondrocyte differentiation. *Lin28* overexpression in chondrocytes reduces most let-7 miRNAs with the exception of let-7c. Known let-7 target genes, including *Hmga2* and *Igf2bp2*, were upregulated. Mice overexpressing *Lin28* in chondrocytes show few gross growth defects, but their growth plate chondrocytes show significantly reduced proliferation, increased cell death, altered cell morphology, and disorganized extracellular matrix. *Mir140*-null and *Lin28* transgenic compound mutants show growth defects that are significantly more severe than those of single mutant mice, suggesting a synergistic regulation of endochondral bone growth by *Mir140* and let-7 miRNAs. The growth plate of compound mutants shows an increase in size of the resting zone, decreased cell proliferation, and shortening of the columnar zone, a phenotype containing features of both *Mir140*-null and *Lin28* transgenic mice. These results demonstrate that miR-140 and let-7 miRNAs cooperatively regulate endochondral bone growth through distinct pathways; miR-140 regulates cell differentiation, while let-7 miRNAs regulate cell proliferation and survival.

Disclosures: Jennifer Inloes, None.

Targeting the TGF- β /Smad Pathway in Neurofibromatosis Type 1 Skeletal Defects. Steven Rhodes^{*1}, Yongzheng He¹, Xiaohua Wu¹, Lisa Hong Chen¹, Ping Zhang², Shi Chen¹, Chang Jiang³, Hiroki Yokota³, Xianghong Peng¹, Khalid Mohammad¹, Theresa Guise¹, Feng-Chun Yang¹. ¹Indiana University, USA, ²Indiana University School of Medicine, USA, ³Indiana University Purdue University Indianapolis, USA

Neurofibromatosis type 1 (NF1) is a common genetic disorder that arises from mutations in the NF1 gene that encodes Neurofibromin, a negative regulator of Ras. In addition to the hallmark soft tissue tumors, NF1 patients experience skeletal pathologies including osteoporosis and pseudarthrosis of the tibia – non-union fractures that have no medical therapy and often require amputation. Here, we establish that transforming growth factor-beta1 (TGF- β 1), a critical cytokine for skeletal development and homeostasis, is overexpressed by *Nf1*^{+/+} osteoprogenitors resulting in pathological bone remodeling.

We found that TGF- β 1 was overexpressed by 2-3 fold in *Nf1*^{+/+} osteoprogenitors vs. WT controls, quantified at both the mRNA and protein level by RT-PCR and ELISA. Differentiation assays were also performed to assess the effects of TGF- β 1 on osteoclast and osteoblast development. We found that TGF- β 1 promoted osteoclast formation *in vitro* while inhibiting terminal osteoblast differentiation. Moreover, *Nf1*^{+/+} osteoprogenitors and osteoclasts were hyperresponsive to limiting doses of TGF- β 1, correlating with increased phosphorylation of Smad2 by western blot. Importantly, a pharmacologic TGF- β inhibitor, SD-208, blocked Smad phosphorylation and enhanced osteoblast differentiation in TGF- β treated osteoprogenitors *in vitro*.

As an *in vivo* proof of concept, SD-208 (60 mg/kg/day) was administered by gavage in an ovariectomy (OVX) model of NF1 associated osteoporosis to determine whether blocking TGF- β dependent Smad phosphorylation could restore bone mass in *Nf1*^{+/+} mice. BMD and trabecular microarchitecture were assessed by pDEXA and micro-CT. Static and dynamic bone histomorphometry were also performed. We found that *Nf1*^{+/+} OVX mice lost significantly more bone than both WT OVX mice and sham operated controls. SD-208 treatment restored bone mass and trabecular architecture in both WT and *Nf1*^{+/+} OVX mice as compared to vehicle treated controls. Intriguingly, the *Nf1*^{+/+} OVX mice exhibited a greater response to the SD-208 treatment as compared to WT OVX controls, suggesting that the TGF- β /Smad pathway may be a critical effector in the NF1 pathological bone remodeling process. Further study is warranted to investigate the potential clinical application of TGF- β inhibitors as a novel therapy for NF1 osseous defects such as osteoporosis, and particularly pseudarthrosis, where current treatments are lacking.

Plekhl1 is Essential for Bone Resorption in Mice and Regulates Cathepsin K Secretion through Linking Lysosomes to Microtubules in Osteoclasts. Shiqiao Ye^{*1}, Kai Liang², Yi-Ping Li³, Stavros Manolagas¹, Haibo Zhao¹. ¹University of Arkansas for Medical Sciences, USA, ²Department of Dermatology, University of Arkansas for Medical Sciences, USA, ³University of Alabama at Birmingham, USA

PLEKHM1 is the causative gene of osteopetrosis in *ia/ia* rats as well as a subset of patients with intermediate osteopetrosis. However, whether Plekhl1 is essential for bone homeostasis and resorption in mice and the molecular mechanisms of its action in osteoclasts (OCs) remain unknown. To address these issues and to facilitate further mechanistic studies, we have generated a Plekhl1 floxed mouse line in which exon 3 of the murine PLEKHM1 gene was flanked by two LoxP sites. To obtain Plekhl1 OC conditional knockout (cKO) mice we crossed floxed Plekhl1 and Cathepsin K-Cre (CTSK-Cre) transgenic mice, thereby deleting the Plekhl1 gene only in OCs. The progeny of Plekhl1^{+/+};CTSK-Cre and Plekhl1^{Flox/Flox};CTSK-Cre were designated Plekhl1 wild type (WT) and Plekhl1 OC cKO mice, respectively. Ablation of Plekhl1 protein expression in cKO OCs was confirmed by western blots. The development and tooth eruption of Plekhl1 cKO mice were normal, but the animals had increased bone mass at 1 and 2 months of age as assessed by longitudinal measurements of BMD by DEXA, as compared to WT mice. Impaired bone resorption in Plekhl1 cKO mice was reflected by a decreased serum Ctx-I level. While OC differentiation was indistinguishable between Plekhl1 WT and cKO bone marrow macrophage cultures, the resorptive capacity of OCs lacking Plekhl1 was compromised as revealed by a significant decrease in resorption pits formation and a diminished medium Ctx-I level. Moreover, double staining of CTSK and F-actin by immunofluorescence showed an inhibition of CTSK secretion into the resorption lacuna in Plekhl1-depleted OCs. Consistent with cell autonomous functions of Plekhl1 in OCs, the impaired bone resorption and CTSK secretion in Plekhl1-null OCs were normalized by retroviral expression of WT full-length but not the N-terminal half and the C-terminal half fragments of the protein. Furthermore, we have uncovered that the N-terminal localized RUN and PH1 domains of Plekhl1 mediate its interaction with LIS1, a critical molecule regulating microtubule dynamics and the function of cytoplasmic dynein, a microtubule-based motor complex. The extreme C-terminal region of Plekhl1 is responsible for lysosomal and the ruffled border targeting and the binding of Plekhl1 to Rab 7, a small GTPase regulating lysosome biogenesis and trafficking. Thus, Plekhl1 is a lysosomal adaptor protein linking

lysosomes to microtubules in OCs and is essential for OC bone resorption *in vivo* and *in vitro*.

Increased Osteoclast Formation and Bone Resorption in the Brtl Osteogenesis Imperfecta Mouse Occur through Marrow Mesenchymal Stromal Cell and Abnormal Matrix Dependent Mechanisms. Patricia Collin-Osdoby^{*1}, Linda Rothe¹, Matthew Kwong¹, Wayne Cabral², Rajeev Aurora³, Joan C. Marini⁴, Philip Osdoby¹. ¹Washington University in St. Louis, USA, ²NIH, NICHD, USA, ³St Louis University, USA, ⁴NIH NICHD, USA

Brtl mice, which contain a glycine substitution (G349C) in half of their type I collagen α 1(I) chains, provide a valuable model for investigation of the pathogenesis and treatment of moderately severe osteogenesis imperfecta. In addition to a smaller body size, reduced cortical and trabecular bone volumes, and matrix insufficiency, Brtl mice exhibit abundant osteoclasts (OCs), brittle bones, and an increased propensity to fracture. Bone sections from Brtl vs. WT mice have increased OC numbers, sizes, TRAP stain intensities, and associated *in vivo* bone resorption. The mechanisms responsible for stimulating OC formation and bone resorption in Brtl OI mice are not yet clear. Although RANKL and OPG mRNA and protein levels are increased in Brtl vs. WT bones and in mesenchymal stromal cells (MSCs) cultured from such bones, RANKL/OPG ratios are equivalent and therefore not a simple explanation for the increased OC formation and activity in Brtl mice. Moreover, RANKL-induced OC formation *in vitro* from pre-OC marrow cells is higher in Brtl vs. WT cultures. This suggests a greater RANKL sensitivity and/or an expanded OC precursor pool exists in Brtl marrow, in keeping with our finding of higher RANK mRNA levels in Brtl bones and greater numbers of CD11b⁺ myeloid precursors in Brtl marrow by FACS analysis. In mixed co-cultures of Brtl or WT marrow pre-OCs with Brtl or WT MSCs, OC formation was 2-fold greater only when Brtl MSCs were present and was independent of the pre-OC origin (Brtl or WT). Therefore, Brtl MSCs are both necessary and sufficient for driving enhanced osteoclastogenesis in co-cultures with marrow pre-OCs. RT-PCR microarray profiling revealed key cytokines and other signals that are altered in Brtl vs. WT MSCs and may mediate these actions. Furthermore, the abnormal collagenous OI bone matrix in Brtl mice appears particularly prone to OC degradation. The seeding of pre-OCs onto Brtl vs. WT isolated calvarial bone did not influence RANKL-induced OC formation, whereas Brtl bone markedly stimulated the activity of individual OCs and overall bone turnover. Overall, we conclude that increased formation and function of bone-resorbing OCs in Brtl OI mice is multifaceted and involves an expanded OC precursor pool, crucial MSC-derived regulatory signals that drive elevated osteoclastogenesis, and increased activation of OCs to resorb the abnormal collagenous OI matrix. Further elucidation of these pathways may lead to novel therapeutic approaches for OI.

The V-ATPase a3 Subunit Mutation R740S Results in Osteoclast Apoptosis Due to Uncoupled ATP Hydrolysis in Homozygous Mice. Noelle Ochotny^{*1}, Ann Flenniken², Celeste Owen³, Irina Voronov¹, Morris Manolson⁴, Jane Aubin⁵. ¹University of Toronto, Canada, ²Centre for Modeling Human Disease, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Canada, ³Centre for Modeling Human Disease, Samuel Lunenfeld Research Institute, Mt Sinai Hospital, Canada, ⁴University of Toronto, Canada, ⁵University of Toronto Faculty of Medicine, Canada

Osteoclast-mediated acidification via a vacuolar-type H⁺-ATPase (V-ATPase) is necessary for bone resorption. V-ATPases are proton pumps composed of 14 subunits, including the 'a' subunit. Of the 4 'a' isoforms in mammals, a3 is enriched in osteoclasts where it is essential for bone resorption. Humans with mutations to both a3 alleles are severely osteopetrotic and die within 6 years without treatment. The two mouse models for osteopetrosis that lack a3, *Tcirl*^{-/-} and *ocloc*, survive for 4-6 weeks. During a mouse genome-wide mutagenesis screen for dominant mutations affecting bone mineral density, we identified a mouse with an osteopetrotic phenotype carrying the dominant V-ATPase a3 missense mutation, R740S. While all osteoblast parameters appear normal, *Tcirl*^{R740S/R740S} pups have osteopetrotic features like increased trabecular bone, no marrow spaces and widening of growth plates. Despite normal size and weight at birth, whole mount staining of *Tcirl*^{R740S/R740S} pups reveal a poorly mineralized mandibular chondyle. By day 10, *Tcirl*^{R740S/R740S} pups can be distinguished from their WT littermates by a lack of incisor eruption, smaller size and weight. Transmission electron microscopy analysis of newborn *Tcirl*^{R740S/R740S} bones reveals abnormal looking osteoclasts with poorly developed ruffled borders, while 14 day old *Tcirl*^{R740S/R740S} pup long bones contain numerous osteoclasts with an abnormal apoptotic-like morphology. TUNEL staining confirms that most of the osteoclasts from 14 day old *Tcirl*^{R740S/R740S} pups undergo apoptosis. In contrast, osteoclasts from *Tcirl*^{-/-} and *ocloc* mice are normal in appearance and number, but fail to resorb. We attempted but failed to isolate primary osteoclasts from long bones of 4 day old *Tcirl*^{R740S/R740S} mice. We therefore generated osteoclasts *in vitro* from RANKL-MCSF treated spleen cells of 4 day old

Tcirl^{R740S/R740S} and WT pups. Osteoclasts from *Tcirl^{R740S/R740S}* pups express the $\alpha 3$ subunit as revealed by western blotting. Preliminary studies demonstrate that the *Tcirl^{R740S/R740S}* osteoclast membranes have similar rates of concanamycin-sensitive ATP hydrolysis to WT. Our data leads us to hypothesize that *Tcirl^{R740S/R740S}* osteoclasts undergo apoptosis due to depletion of cellular ATP levels caused by the uncoupling of V-ATPase-dependent ATP hydrolysis from proton translocation. We are measuring cellular ATP levels and proton pumping of osteoclast membranes to test this hypothesis.

Embryonic Loss of Cytochrome P450 Reductase in Mice Results in Antley-Bixler Syndrome-Like Craniofacial and Bone Mass Defects. Satya Panda¹, Anyonya Guntur², Rekha Kar³, Kejian Tang¹, Bettie Sue Masters¹. ¹UTHSCSA, USA, ²Maine medical center research institute, USA, ³The University of Texas Health Science Center, USA

Craniosynostosis and midface hypoplasia are among the most common dysmorphic features of patients harboring mutations in NADPH-cytochrome P450 oxidoreductase (CYPOR) and are similar to the phenotypes of Antley-Bixler syndrome patients. Patients with CYPOR deficiency, caused by mutations in the reductase (of which >40 have been reported), also present with ambiguous genitalia and abnormal steroidogenic profiles. CYPOR is the obligate electron donor for cytochromes P450, dehydrocholesterol reductase, heme oxygenase, squalene monooxygenase, and cytochrome b₅. These enzymes play various physiological roles, including endo- and xeno-biotic metabolism, cholesterol biosynthesis, and heme degradation. The complete knockout of CYPOR in mice leads to embryonic lethality. In order to probe the possible roles played by CYPOR during bone development, we have generated conditional knockout mice by cross breeding *Cyp^{lox/lox}* and Dermo 1 (Twist 2) Cre mice. Dermo 1 Cre recombinase is active from embryonic day of 9.5 and will delete the gene of interest in both chondrocytes and osteoblasts. Here we report the first mouse model showing craniofacial abnormalities upon deletion of CYPOR. Differential staining of CKO mice skulls using Alizarin red and Alcian blue show premature fusion of spheno-occipital synchondrosis (SOS) and anterior intraoccipital synchondrosis (AIS). Malocclusion was also noticed in a few adult knockout mice, leading to unusual growth of the lower incisors. Micro CT analysis of the tibia samples showed the deletion of CYPOR also caused a reduction in the bone mineral density compared to its age- and sex-matched littermate control sample without affecting the cortical bone thickness. Shorter long bones were also observed in these mice using hematoxylin and eosin staining of paraffin-embedded tissue sections. These results recapitulate the human CYPOR deficiency phenotype and offer an approach to study the sequelae of mutations in NADPH-cytochrome P450 reductase.

BMN 111, a CNP Analogue, Promotes Skeletal Growth and Rescues Dwarfism In Two Transgenic Mouse Models of Fgfr3-related Chondrodysplasia. Florence Lorget¹, Nabil Kaci², Jeff Peng¹, Catherine Benoist², Federico Di Rocco², Emilie Mugniery², Sherry Bullens¹, Stuart Bunting¹, Laurie Tsuruda¹, Charles O'Neill¹, Arnold Munnich², Laurence Legeai-Mallet². ¹BioMarin Pharmaceutical Inc, USA, ²INSERM U781 - Universite Paris Descartes, Hopital Necker, France

Although Fgfr3-related chondrodysplasia were identified more than 20 years ago, no corrective treatments are available and therapeutic interventions are limited to surgical procedures. Achondroplastic patients display a short stature with disproportionate shorter proximal bones, narrow trunk and macrocephaly. The severity of the phenotype ranges from mild (hypochondroplasia) to severe (achondroplasia) and lethal (thanatophoric dysplasia) depending on the point mutation. C-type natriuretic peptide (CNP) is considered to be a potential therapeutic agent because of its inhibition of Fgfr3 downstream signaling. Targeted in vivo overexpression of a CNP transgene or continuous infusion of native CNP were shown to rescue the impaired bone growth in a mouse model of achondroplasia. To overcome the short half-life of native CNP, BioMarin developed a CNP analogue, BMN111, with an increased half-life allowing daily subcutaneous administration. BMN111 pharmacological activity was characterized in two transgenic mouse models of Fgfr3-related chondrodysplasia. In the Fgfr3G380R mouse model(1), the transgene expression is restricted to the chondrocytes while it is ubiquitously expressed in the Fgfr3Y367C/+ mouse model(2). A more severe phenotype is observed with the Fgfr3Y367C/+ (shorter bones, pronounced prognathism and reduced lifespan). The mice received daily subcutaneous administrations of BMN111 from 6 days of age in the Fgfr3Y367C/+ mice and three weeks of age in the Fgfr3G380R mice, supporting both achondroplastic and hypochondroplastic pediatric populations. The Fgfr3Y367C/+ mice were treated for 10 days at dose levels up to 800 ug/kg. The Fgfr3G380R mice were treated for 5 weeks at dose levels up to 280 ug/kg. Overall, the treatment was well tolerated. A dose related increase in the axial and appendicular skeletons was measured in both models (~5-10% increase in the high dose groups). Normalization of bone age and growth plate architecture was observed in the Fgfr3Y367C/+ mice. Based on these data, BMN111 may be a potential therapeutic agent for achondroplasia and hypochondroplasia.

Inflammatory Markers and the Risk of Hip and Spine Fractures in Older Men: MrOS. Jane Cauley¹, Yona Keich Cloonan², Michelle Danielson², Kristine Ensrud³, Howard Fink⁴, Eric Orwoll⁵, Robert Boudreau². ¹University of Pittsburgh Graduate School of Public Health, USA, ²University of Pittsburgh, USA, ³Minneapolis VA Medical Center / University of Minnesota, USA, ⁴GRECC, Minneapolis VA Medical Center, USA, ⁵Oregon Health & Science University, USA

Cytokines play major roles in regulating bone remodeling in the bone microenvironment but their relationship to incident fractures in older men is uncertain. Using data from the Osteoporotic Fracture in Men Study (MrOS), we tested the hypothesis that men with higher levels of circulating cytokines at baseline will have a higher risk of fracture. We used a case-cohort design and measured cytokines in a random sample of 980 men and in 538 men with incident fractures including 98 clinical spine fractures and 97 hip fractures. Average follow up was 6.96 years. Levels of pro-inflammatory cytokines including interleukin (IL)-6, high sensitivity C-reactive protein (CRP), tumor necrosis factor (TNF- α), soluble receptors (SR) of IL-6 (IL-6SR) and TNF (TNF-SR1 and TNF-SR2); IL-10, an anti-inflammatory cytokine, was also measured. Cytokines and SR were measured in fasting frozen serum using ELISA. CRP assay was standardized according to the WHO International Reference Standard. Average inter-assay coefficients of variations ranged from 1.5 to 10.7%. Total hip BMD was measured by DXA. The risk of non-spine, hip and clinical spine fracture was compared across quartiles of cytokines (quartile 1=referent) using Cox proportional hazard models. Quartile cutoffs were determined based on the distributions in the random cohort. Tests for linear trend were performed. The average age of men was 73.8y (random cohort) and 75.3y (fracture cases); 92% were Caucasian. In multivariable adjusted models, the risk of hip and clinical spine fracture increased with increasing TNF- α , TNF-SR1, TNF-SR2 and IL-6. Men with the highest cytokines (Q4) had a 1.9-4.35 fold higher risk of hip and clinical spine fracture than men with the lowest cytokine (Q1), Table. Similar results were observed for all non-spine fractures but the magnitude of the association was lower (data not shown). There was no association between CRP and IL-6SR. Men with the highest IL-10 (Q4) had a 41% lower risk of hip fracture and a 64% lower risk of spine fracture compared to men with the lowest IL-10. We conclude that inflammation plays an important role in the etiology of fractures in older men.

Table: Multivariable* adjusted hazard ratio (95% CI) for hip and clinical spine fractures across quartiles (Q) of cytokine

Hip Fractures

Serum OPG and sRANKL Levels and Incident Hip Fracture in the Women's Health Initiative. Andrea LaCroix¹, Rebecca Jackson², Aaron Aragaki¹, Charles Kooperberg¹, David Duggan³. ¹Fred Hutchinson Cancer Research Center, USA, ²The Ohio State University, USA, ³Translational Genomics Research Institute, USA

The discovery of osteoprotegerin (OPG) in 1997 led quickly to the understanding that the OPG/RANKL/RANK System is central to the coupling of osteoclasts and osteoblasts in bone biology. However, large epidemiologic studies relating new generation, high sensitivity serum biomarkers in this pathway to future risk of hip fractures have not yet been reported. We conducted a nested case-control study within the Women's Health Initiative Observational Study. 400 incident hip fracture cases that occurred between baseline (1993-1998) and September 2005 were randomly selected and individually matched to randomly selected controls who reported no postmenopausal fractures at baseline and were free of hip fracture during follow-up. Case-control pairs were Caucasian and matched on age (+/-1yr), enrollment date (+/-365 days) and current hormone therapy use at baseline (exact). OPG and soluble RANKL (sRANKL) were measured by ELISA (Osteoprotegerin EIA, and ampli-sRANKL EIA, Biomedica distributed by American Laboratory Products Company, LTD; Salem, NH) at Ohio State University. Odds ratios for quartiles of each serum biomarker (defined by the control distribution) were computed from conditional logistic regression models adjusting for the matching variables, plate, and WHO FRAX score. No association was observed between sRANKL and hip fracture (p-trend=0.25) or the ratio of OPG/sRANKL (p-trend=0.27). OPG levels in the highest quartile were associated with a two-fold increased risk of hip fracture as shown in the table below. These results are consistent with a recent study showing an association of higher OPG levels (but not RANKL or OPG/RANKL levels) with height loss in men and postmenopausal women not using hormone therapy. We conclude that high serum OPG levels are associated with an increased risk of hip fracture in postmenopausal women.

Quartile (range)	OddsRatio (95% CI)	p-value for trend (1 df)
1 (< 4.0 pmol/L)		0.005
2 (4.0-5.0 pmol/L)	1.40 (0.89-2.19)	
3 (5.0-6.0 pmol/L)	1.24 (0.78-1.96)	
4 (> 6.0 pmol/L)	2.11 (1.32-3.37)

High Sensitive CRP Is an Independent Risk Factor for Fractures in Elderly Men: The MrOS Sweden Study. Sofia Moverare Skrtic¹, Anna-Lena Eriksson², Osten Ljunggren³, Magnus Karlsson⁴, Dan Mellstrom⁵, Claes Ohlsson⁶. ¹Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, ²University of Gothenburg, Sweden, ³Uppsala University Hospital, Sweden, ⁴Skane University Hospital Malmo, Lund University, Sweden, ⁵Sahlgrenska University Hospital, Sweden, ⁶Center for Bone Research At the Sahlgrenska Academy, Sweden

Background: Osteoporosis-related fractures constitute a major health concern not only in women but also in men. Chronic inflammatory diseases are associated with an enhanced fracture risk. However, it is still unclear whether low-grade inflammation as estimated by high sensitivity C-reactive protein (hs-CRP) is associated with an increased fracture risk in men.

Methods: To investigate the predictive role of hs-CRP, serum levels of hs-CRP were measured in elderly men (n = 2910, mean 75 years of age) included in the prospective population-based MrOS Sweden cohort, using ultrasensitive immunoturbidimetry. Fractures occurring after the baseline visit were validated (average follow-up at analyses 5.4 years). The incidence for having at least one validated fracture after baseline was 23.7/1000 person-years.

Results: In hazard regression analyses adjusted for age, weight and height, hs-CRP was related to fracture risk. Study participants were divided into tertile groups based on their serum levels of hs-CRP. Serum levels of hs-CRP were [<1.812], [≥ 1.812 , <2.760] and [≥ 2.760] mg/L in the lowest, medium and highest tertiles, respectively. The HR of fracture for the highest tertile of hs-CRP, compared with the lowest and the medium tertiles combined, was 1.54 (95% CI, 1.25-1.89). Femoral neck BMD was not associated with hs-CRP, and the predictive role of hs-CRP for fracture risk was essentially unchanged after adjustment for femoral neck BMD (HR 1.45, 95% CI 1.17-1.79). Exploratory sub-analyses of fracture type demonstrated that hs-CRP was clearly associated with clinical vertebral fractures (HR 1.73, 95% CI 1.20-2.48). The association with non-vertebral fractures was of borderline significance (HR 1.36, 95% CI 0.98-1.89).

Conclusions: We demonstrate, using a large prospective population-based study, that elderly men with high hs-CRP have increased risk of fractures. This was true also when vertebral fractures were studied separately. The association between hs-CRP and fractures was independent of BMD.

The Effects of Adiponectin and Leptin on Changes in Bone Mineral Density of the Hip. Kamil E. Barbour¹, Joseph M. Zmuda¹, Robert Boudreau¹, Elsa S. Strotmeyer¹, Mara J Horwitz², Rhobert W. Evans³, Alka M. Kanaya³, Tamara B. Harris⁴, and Jane A. Cauley¹ for the Health ABC study. ¹Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA. ²Division of Endocrinology and Metabolism at the University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA. ³Division of General Internal Medicine, University of California, San Francisco, California. ⁴Laboratory of Epidemiology, Demography, and Biometry, National Institute of Aging, Bethesda, Maryland

Leptin and adiponectin are hormones secreted by adipose cells that may impact bone mineral density (BMD) and modulate bone formation. Few studies have evaluated the longitudinal association of leptin and adiponectin with rates of BMD loss. To test the hypothesis that low leptin and high adiponectin levels are associated with a higher rate of BMD loss we studied 3,075 men and women, aged 70-79, from the Health Aging and Body Composition (Health ABC) study. Areal BMD (aBMD) of the hip was measured 5 times using dual energy x-ray absorptiometry (DXA) over a 10 year period. Random slope and intercept models accounted for within person correlation and multivariate models adjusted for age, race, BMI, weight change, diabetes, and baseline hip aBMD. Among women, the annualized rate of hip BMD loss in the highest tertile of adiponectin was -0.67% compared to -0.43% in the lowest tertile, p trend=0.019. In men, BMD loss was greatest in the high adiponectin group (tertile 3), however this association was not significant, p trend=0.148. After adjusting for weight change in women, the association between leptin and BMD loss was attenuated and no longer significant, p trend=0.134. Among men, leptin did not predict BMD loss in crude or adjusted models. Results suggest that adiponectin, but not leptin is a risk factor for bone loss in women. Future studies are needed to evaluate and explain the physiological basis underlying these associations. Identification of potential mediators in the causal pathway may better explain these findings.

Serum Cystatin C and Risk of Hip Fractures in Older Women. Kristine Ensrud¹, Neeta Parimi², Yelena Slinin³, Teresa Hillier⁴, Jane Cauley⁵, Michael Steffes⁶, Steven Cummings⁷. ¹Minneapolis VA Medical Center / University of Minnesota, USA, ²California Pacific Medical Center Research Institute, USA, ³University of Minnesota / VA Medical Center, USA, ⁴Kaiser Center for Health Research, USA, ⁵University of Pittsburgh Graduate School of Public Health, USA, ⁶University of Minnesota, USA, ⁷San Francisco Coordinating Center, USA

Serum cystatin C is a biomarker of renal function; higher levels indicate worse function. Previous studies have reported an increased risk of hip fracture among postmenopausal and older women with higher cystatin C, but it is uncertain whether the association persists after adjustment for BMD. To test the hypothesis that older women with higher cystatin C are at increased risk of hip fracture, we conducted a case-cohort analysis in the cohort of 7008 white women attending a Year 10 SOF examination that included 300 women with incident hip fracture and a random sample of 1170 women from the cohort. Cystatin C was measured using a particle-enhanced immunonephelometric assay (inter- and intra-assay CV 3.1% and 2.8%, respectively). Hip fractures (identified during an average follow-up 5.4 years) were confirmed with x-ray reports. Modified proportional hazards models were used to estimate the relative hazards (RH) of fracture across quartiles of cystatin C (cutpoints 0.84, 0.96, 1.11 mg/L). In models adjusted for age, site and body mass index, higher cystatin C was associated with an increased risk of hip fracture (p for trend 0.009) with women in Q4 having a 1.8-fold (95% CI 1.2-2.8) higher risk of hip fracture compared with those in Q1 (ref group) (Table). Additional adjustment for several potential confounders including health status, fall history, prior fracture, prevalent CVD, frailty status, and total hip BMD only slightly attenuated the association (p for trend 0.06); the risk of hip fracture was 1.6-fold higher (95% CI 1.1-2.6) in women in Q4 compared with those in Q1. In conclusion, older women with renal dysfunction as manifested by higher serum cystatin C have an increased risk of hip fracture independent of traditional risk factors including age, prior fracture, frailty status, body weight, and hip BMD.

Table. Association between Cystatin C and Risk of Hip Fracture

Hip Fracture	RH of Fracture (95% CI) by Quartile of Cystatin C				p for trend
	Q1	Q2	Q3	Q4	
Base model*	1.0 (ref)	1.5 (1.0-2.2)	1.4 (1.0-2.1)	1.8 (1.2-2.8)	0.009
Base + BMD	1.0 (ref)	1.5 (1.0-2.2)	1.4 (0.9-2.1)	1.8 (1.2-2.8)	0.01
Base + frailty status	1.0 (ref)	1.5 (1.0-2.2)	1.4 (0.9-2.0)	1.7 (1.1-2.5)	0.04
Final MV model†	1.0 (ref)	1.4 (0.9-2.1)	1.3 (0.9-2.0)	1.6 (1.1-2.6)	0.06

*model adjusted for age, site, and body mass index

†base model further adjusted for health status, fall history, prior fracture, prevalent CVD, frailty status, and total hip BMD

Clinical Characteristics of Women Who Fracture Despite Anti-Osteoporosis Medication. The Global Longitudinal Study of Osteoporosis in Women. Adolfo Diez-Perez^{*1}, Philip Sambrook², Juliet Compston³, Jonathan Adachi⁴, Frederick Hooven⁵, Nelson Watts⁶, Stuart Silverman⁷, Susan Greenspan⁸, Cyrus Cooper⁹, Steven Boonen¹⁰, Allison Wyman¹¹, Stephen Gehlbach¹². ¹Autonomous University of Barcelona, Spain, ²Royal North Shore Hospital, Australia, ³University of Cambridge School of Clinical Medicine, United Kingdom, ⁴St. Joseph's Hospital, Canada, ⁵University of Massachusetts Medical School, USA, ⁶University of Cincinnati Bone Health & Osteoporosis Center, USA, ⁷Cedars-Sinai/UCLA, USA, ⁸University of Pittsburgh, USA, ⁹University of Southampton, United Kingdom, ¹⁰Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ¹¹UMass Medical School, USA, ¹²University of Massachusetts, USA

Background: Little is known about the characteristics of women who fracture while on anti-osteoporosis medication (AOM). Using data from the Global Longitudinal Study of Osteoporosis in Women (GLOW), we analyzed the clinical characteristics of women who had an incident fracture after ≥ 1 year on AOM.

Methods: Among the 46,443 participants in GLOW at the end of year 2, we identified 6584 women on AOM at baseline, year 1, and year 2, with known fracture status at the end of year 2. We performed multivariable logistic regression to predict fracture at year 2, beginning with all of the variables significant on univariate analysis.

Results: 338 women (340 fractures) fractured while on AOM. Compared with women who did not fracture, women who fractured were older (median age 72 vs. 70), sicker (higher rates of chronic bronchitis or emphysema, osteoarthritis, stroke, Parkinson's disease, and diabetes), and at baseline had higher rates of previous fracture (after age 45), current cortisone use, and greater alcohol consumption. Rib (19%), wrist (18%), spine (18%), ankle (8.7%), hip (7.5%) and upper arm (7.2%) were the most common fractures. In multivariable analysis, age, prior stroke, Parkinson's disease, diabetes, prior fracture (wrist, spine, rib), current corticosteroid use and high alcohol intake were independent predictors of fracture on treatment (Table).

Conclusions: Comorbidities, prior fracture, corticosteroid use, and high alcohol consumption were associated with higher rates of fracture despite AOM. Women with these risk factors remain at high risk despite being on therapy.

Baseline characteristic	Odds ratio	95% CI	P-value
Age (per 10-year increase)	1.18	1.03-1.36	0.018
History of stroke	1.67	1.05-2.66	0.031
History of Parkinson's disease	2.86	1.06-7.74	0.038
History of diabetes	2.74	1.61-4.68	<0.001
Prior fracture			
Wrist	1.46	1.09-1.95	0.011
Spine	2.00	1.38-2.88	<0.001
Rib	2.08	1.49-2.90	<0.0001
Cortisone use (vs. never use)			0.006
Current	1.94	1.29-2.92	0.002
Past	1.15	0.87-1.51	0.32
Alcohol intake (>20 vs <20 drinks/week)	8.02	2.81-22.85	<0.0001

LLP2A-Alendronate, a Novel Compound That Directs Mesenchymal Stem Cells to Bone, Prevents Bone Losses Induced By Aging or Ovariectomy. Min Guan^{*1}, Nancy Lane², Ruiwu Liu³, Kit Lam³, Liping Meng³, Junjing Jia², Brian Panganiban⁴, Robert Ritchie⁴, Wei Yao². ¹Department of Internal Medicine, University of California at Davis Medical Center, USA, ²University of California, Davis Medical Center, USA, ³Department of Biochemistry & Molecular Medicine, University of California at Davis Medical Center, USA, ⁴Department of Materials Science & Engineering, University of California at Berkeley, USA

Aging reduces the number of mesenchymal stem cells (MSCs) in the bone marrow which leads to impairment of osteogenesis. However, if MSCs could be directed toward osteogenic differentiation, they could be a viable therapeutic option for bone regeneration. We have developed a method to direct the MSCs to the bone surface by attaching a synthetic high affinity and highly specific peptidomimetic ligand (LLP2A) against integrin $\alpha 4 \beta 1$ that expressed on the MSC surface, to a bisphosphonate (alendronate, Ale), that has high affinity for bone. We have previously reported that LLP2A-Ale increased MSCs migration and osteogenic differentiation *in vitro*. One single intravenous injection (i.v.) of LLP2A-Ale increased bone formation and trabecular bone mass in both xenotransplantation and immune competent mice. In

this report, we evaluated the efficacy of LLP2A-Ale on disease states, i.e., in preventing bone losses associated with age or estrogen deficiency (ovariectomized, OVX). Eight-week old C57/BL6 mice were sham-operated or OVX for two weeks. The mice were treated with one single i.v. injection of LLP2A-Ale (0.9nmol/mouse). PTH (1-34) (25 μ g/kg/d, 5x/week) was used as positive control. The mice were sacrificed at four or eight weeks after the treatments.

In sham-operated mice, the femoral trabecular bone volume (BV/TV) decreased by approximately 30% after 4-weeks and 45% after 8-weeks in PBS-treated mice. In contrast, BV/TV increased by approximately 10% after 4-weeks and 50% after 8-weeks in LLP2A-Ale treated mice. LLP2A-Ale treatment induced significantly higher mineral deposition and bone formation rate as compared to PBS-treated animals. After 6 weeks of estrogen deficiency, OVX mice treated with PBS experienced a 30% decrease in their vertebral trabecular bone mass. However, treatment with LLP2A-Ale partially prevented the trabecular bone loss that the BV/TV was 34% higher than the OVX but 14% lower than the Sham-treated group. LLP2A-Ale treatment increased osteoblast surface, and their activities (osteocalcin levels and mineral apposition rate).

The bone formation rate/bone surface was increased above the sham-treated mice with LLP2A-Ale treatment. The activation of bone formation by LLP2A-Ale was comparable to that of PTH-treated OVX mice in preventing trabecular bone loss in this acute estrogen deficiency model.

Our findings demonstrate that LLP2A-Ale augments bone formation and prevents bone losses associated with aging or estrogen deficiency.

Therapeutic RNAi targeting CKIP-1 for Promoting Bone Formation in an Aged Rat Model of Postmenopausal Osteoporosis. Baosheng GUO^{*1}, Baoting Zhang², Heng WU¹, Tao Tang³, Yixin HE⁴, Gang Li³, Leungkim HUNG¹, Fuchu HE⁵, Lingqiang ZHANG⁵, Ling QIN¹, Ge ZHANG¹. ¹Musculoskeletal Research Laboratory, Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Hong Kong, ²Prince of Wales Hospital, The Chinese University of Hong Kong, Hong Kong, ³The Chinese University of Hong Kong, Hong Kong, ⁴The Chinese University of Hong Kong, Hong Kong, ⁵State Key Laboratory of Proteomics, Beijing Proteome Research Center, Beijing Institute of Radiation Medicine, Beijing, China, China

Introduction: Currently, the only FDA-approved anabolic agent is PTH. However, dominant bone resorption after long-term using with PTH is a great concern. Casein kinase-2 interacting protein-1 (CKIP-1) gene is a newly discovered negative regulator gene of bone formation without activating bone resorption. Recently, we have identified a specific cross-species CKIP-1 siRNA sequence with high knock down efficiency. Further, a bone targeting siRNA delivery system i.e. (DSS)6-liposome) was successfully developed.

Hypothesis & objectives: Our hypothesis was that therapeutic RNAi targeting CKIP-1 might promote bone formation for reversing postmenopausal bone loss.

Methodology: Six-month-old female SD rats were either ovariectomized (OVX) or sham-operated (SHAM). At 9 months post surgery, the OVX and SHAM rats were injected intravenously with (DSS)6-liposome-CKIP-1 siRNA (siRNA group) or (DSS)6-liposome (OVX group) or vehicle (SHAM group) via tail vein every two weeks for 6 weeks. Before and during treatment, left proximal tibia was in vivo monitored by microCT every two weeks and registration analysis was also performed between week 0 and week 2, 4, 6. The rats were injected intraperitoneally with xylanol (25mg/kg) and calcein green (30mg/kg) at 10 and 3 days before sacrifice and left femur was subjected to histomorphometric analysis.

Results: In vivo microCT analysis demonstrated that the siRNA group showed a significantly increase in BMD, BV/TV and Tb.Th, at week 6 in relation to week 0, respectively. Further, the siRNA group showed higher in BMD, BV/TV and Tb.Th, respectively, when compared to that in OVX group at week 6 after treatment. Furthermore, the Tb.Th in the siRNA group reached the level in the SHAM group after 6-week treatment. Registration analysis between week 0 and other time point demonstrated that more newly formed was found in the siRNA group, compared to either OVX or SHAM groups (Fig. 1, 2). Histomorphometric analysis showed that MAR, BFR and Ob.S/BS in either distal or mid-shaft femur and Ps.Pm at mid-shaft femur in the siRNA group were all significantly higher than those in the OVX group at week 6, whereas no difference was found in Oc.S/BS between the OVX and siRNA groups (Fig. 3).

Conclusion: Therapeutic RNAi targeting CKIP-1 could exert anabolic action on bone in aged rat model of postmenopausal osteoporosis, without activating bone resorption, which indicated its translational potential for reversing established osteoporosis.

A Delivery System Specifically Approaching Bone Formation Surfaces To Facilitate Translating RNAi-based Anabolic Therapy. Ge Zhang^{*1}, Baosheng GUO², Heng Wu³, Tao Tang⁴, Baoting Zhang⁵, Leungkim Hung³, Fuchu He⁶, Lingqiang Zhang⁶, Ling Qin³. ¹Prince of Wales Hospital, Hong Kong, ²Prince of Wales Hospital, Hong Kong, ³Musculoskeletal Research Laboratory, Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Hong Kong SAR, China, Hong Kong, ⁴The Chinese University of Hong Kong, Hong Kong, ⁵Prince of Wales Hospital, The Chinese University of Hong Kong, Hong Kong, ⁶State Key Laboratory of Proteomics, Beijing Proteome Research Center, Beijing Institute of Radiation Medicine, Beijing, China, China

Impaired bone formation during bone disease is a great clinical challenge. One approach to treat this defect would be to silence bone formation-inhibitory genes by small interference RNAs (siRNAs) in osteogenic lineage cells that occupy the niche surrounding the bone formation surfaces. However, a bone-targeting delivery system for RNAi-based bone anabolic therapy is still lacking. Here, we developed a targeting system involving DOTAP-based cationic liposomes attached to six repetitive sequences of aspartate-serine-serine (DSS)6 for delivering siRNAs to specifically approach bone formation surfaces (Figure 1 and Figure 2). Using the system, we encapsulated an osteogenic siRNA targeting casein kinase-2 interacting protein-1 (CKIP-1), a protein that interacts with and augments the osteoblast-suppressing activity of the ubiquitin ligase Smurf1, which was identified by our joint group (Lu K, et al. Nature Cell Biology 2008). In vivo systemic delivery of CKIP-1 siRNA in rats using the (DSS)6-liposome system resulted in the siRNA's selective enrichment in osteogenic lineage cells (Figure 3-1 and Figure 3-2) and subsequent efficient depletion of CKIP-1. Histomorphometry and microCT analysis further demonstrated that this approach significantly promoted bone formation, enhanced the micro-architecture and increased bone mass in healthy rats. We also used the same approach in an osteoporotic rat model, and found it consistent with the effects seen in healthy rats, as evidenced by marked improvement in microarchitecture and bone mass (Figure 4). Collectively, these results demonstrate (DSS)6-liposome as a promising targeted delivery system, thus providing a potential solution to the bottleneck in translating RNAi-based bone anabolic therapies.

A Combined Fc-OPG/hPTH(1-34) Therapy to Restore Impaired Skeletal Growth and Bone Loss in a Mouse Model of IL-6 Dependent Juvenile Inflammatory Diseases. Andrea Del Fattore^{*1}, Marta Capannolo², Barbara Peruzzi², Alfredo Cappariello¹, Nadia Rucci², Fabrizio De Benedetti¹, Anna Teti². ¹Children Hospital Bambino Gesù, Italy, ²University of L'Aquila, Italy

Premature osteoporosis and stunted growth are common complications of juvenile chronic inflammatory diseases and have a significant impact on patients' quality of life. Presently no treatment regimens are available for these defects in childhood. To test a new therapeutic approach, growing mice overexpressing the pro-inflammatory cytokine IL-6 (TG) showing a generalized bone loss and stunted growth were used. Since TG mice present increased bone resorption and impaired bone formation, we hypothesized that a combined therapy with the antiresorptive modified osteoprotegerin, Fc-OPG, and the anabolic PTH could counteract their skeletal failure and improve growth. We therefore treated TG mice with Fc-OPG 0.25 mg/Kg once at the 4th day of life and with 80 µg/Kg hPTH(1-34) everyday from the 16th to the 30th day of age. Treated mice presented a complete rescue of growth, as showed by a body weight of 93% and a tibia length of 92% of WT ($p < 0.05$ vs TG vehicle), and of bone phenotype (BV/TV %; WT vehicle 6.38±2.46; TG vehicle 3.12±0.82; TG Fc-OPG/hPTH 5.24±0.66[#]; $p < 0.02$ vs TG vehicle), due to a normalization of osteoclast and osteoblast parameters. Restoring of normal bone turnover was confirmed by RT-PCR on femurs of Fc-OPG/hPTH-treated mice that showed normalization of TRAcP, ALP and RUNX2 expression compared to vehicle-treated TG mice, rescuing levels similar to WT mice. In vitro cultures from Fc-OPG/hPTH-treated mice confirmed the full rescue of osteoclast and osteoblast activity, reaching levels similar to those observed in cultures from WT mice. The phenotypic rescue of TG mice was due to the combined treatment, because TG mice treated once at the 4th day of life with Fc-OPG 0.25 mg/Kg alone showed an increase of body weight (WT vehicle 14.61±1.72 g; TG vehicle 7.64±0.7 g^{*}; TG Fc-OPG 10.4±1.12 g^{*}; $p < 0.05$ vs WT vehicle), tibia length and bone volume to intermediate levels between those observed in WT and in vehicle-treated TG mice. Similar partial improvement was observed treating TG mice with hPTH alone since the 16th day of life. In contrast, intermittent injections of hPTH since the 4th day of age caused distress of the mice with no effects on the somatic growth. In conclusion, our results identified the sequential treatment with Fc-OPG/hPTH as a treatment regimen to rescue the somatic growth and bone disorder in TG mice, thus providing the proof of principle for a new therapeutic approach to correct these defects in juvenile inflammatory diseases

The Impaired Anabolic Effect of PTH In the Absence of Endogenous FGF2 Is Partially Due to Reduced ATF4 Expression. Yurong Fei^{*1}, Liping Xiao¹, Thomas Doetschman², Douglas Coffin³, Marja Marie Hurley⁴. ¹University of Connecticut Health Center, USA, ²University of Arizona, USA, ³The University of Montana, USA, ⁴University of Connecticut Health Center School of Medicine, USA

Parathyroid hormone (PTH) is currently the only approved anabolic agent for osteoporosis pharmacotherapy in the USA. PTH increases FGF2 and FGF receptor expression in osteoblasts. Further, PTH treatment upregulates serum FGF2 associated with increased bone formation in osteoporotic patients. However, the ability of PTH to stimulate bone formation is impaired in *Fgf2*^{-/-} mice. These studies indicate that the anabolic action of PTH in bone formation requires FGF2.

Studies showed that intermittent FGF2 treatment positively regulates osteoblast differentiation and bone formation. However, its downstream targets are not fully defined. Activating transcription factor 4 (ATF4) was recently identified to be a downstream target of PTH signaling in osteoblasts and FGF2 is able to rapidly increase ATF4 mRNA and protein expression in osteoblasts. Furthermore, ATF4 expression is markedly reduced in *Fgf2*^{-/-} osteoblasts. Therefore, we hypothesize that the impaired anabolic effect of PTH in *Fgf2*^{-/-} mice is partially due to reduced ATF4 expression. To test this hypothesis, we examined the ability of PTH to increase ATF4 expression in vitro and in vivo. In vitro data showed that PTH induced a significant increase in ATF4 mRNA expression as early as 15min in *Fgf2*^{+/+} primary bone marrow stromal cells (BMSCs) but not in *Fgf2*^{-/-} BMSCs. In vivo data showed that treatment with hPTH (1-34) (40ug/kg/d) for 2 weeks increased lumbar vertebrae bone mineral density in *Fgf2*^{+/+} female mice (16.9% in 17-19ms, 13.8% in 21-23ms). In contrast there was a 4.7% increase in 17-19ms and a 2.1% decrease in 21-23ms *Fgf2*^{-/-} female mice. Interestingly, basal ATF4 mRNA expression was significantly lower in tibiae of *Fgf2*^{-/-} female mice (46% decrease) compared to *Fgf2*^{+/+} mice. hPTH treatment increased ATF4 mRNA by 15% (p=0.08) and 97% (p<0.05), respectively, in 17-19ms and in 21-23ms *Fgf2*^{+/+} compared to 51% (p<0.05) and 8% (p=0.57), respectively, in 17-19ms and in 21-23ms *Fgf2*^{-/-} mice. Immunohistochemistry of vertebrae showed less ATF4 staining in *Fgf2*^{-/-} tissue, and treatment with hPTH increased ATF4 staining in *Fgf2*^{+/+} but the increase was attenuated in *Fgf2*^{-/-} tissue.

The impaired anabolic response of PTH in *Fgf2*^{-/-} mice is consistent with our previous report. Reduced ATF4 expression may result in decreased osteoblast differentiation, and possibly contribute to the impaired stimulation of PTH on bone formation in *Fgf2*^{-/-} mice.

Efficacy of the Combination of Parathyroid Hormone plus Odanacatib or Alendronate, as compared to the Monotherapies in Estrogen-Deficient Rabbits. Brenda Pennypacker^{*1}, Guoxin Wu², Rachel Korn², Rana Samadfam³, Susan Y. Smith³, Le Thi Duong¹. ¹Merck Research Laboratories, USA, ²Merck & Co., Inc., USA, ³Charles River Laboratories, Canada

The cathepsin K inhibitor odanacatib (ODN) and alendronate (ALN) have been shown to effectively prevent bone loss in ovariectomized (OVX) rabbits. While ALN reduces bone remodeling, ODN preserves trabecular and cortical bone formation (BF) in this model. Intermittent administration of human parathyroid hormone 1-34 (PTH) is an approved anabolic agent for the treatment of osteoporosis. Here, we compare the potential additive effects on bone mass and remodeling in rabbits treated with ODN or ALN combined with PTH, or to the respective monotherapy. Adult (7 mo.) rabbits were Sham (N=20) or OVX'd (N=120) for 6-mo. prior to study start. OVX-rabbits were randomized by lumbar vertebrae 5-6 (LV) BMD into the following treatment groups: OVX-vehicle (Veh), PTH (15µg/kg, 5x/wk), ALN (100µg/kg, 2x/wk), ODN (~7µM·24hr, in food), PTH+ALN, and PTH+ODN. After 6 months of treatment, the combined regimens were switched to the respective antiresorptive for the 10 mo. study duration. In-life DXA LV5-6, urinary helical peptide (uHP) and serum bone specific alkaline phosphatase (sBSAP), were determined at 0, 6 and 10 mo. LV4 dynamic histomorphometry was performed based on dual tetracycline labeling at mo. 6, and calcein labeling prior to necropsy at 10 mo. Baseline LV BMD in OVX decreased by 9% (p<0.05) vs. Sham. After 6 mo. of treatment, Veh lost BMD/body weight (BW) by 16% (p<0.001) vs. Sham. PTH, ODN, and ALN increased LV BMD/BW (p<0.01) by 20%, 16%, 18%, respectively. Both PTH+ALN and PTH+ODN groups gained BMD/BW by 32% (p<0.001). uHP and BSAP were elevated in response to OVX. uHP was reduced in ODN (85%, p<0.05), PTH + ODN (69%, p=0.06), ALN (65%, p=0.07) and PTH+ALN (13%, NS) vs. Veh at 6 mo, but was increased 3-fold by PTH (p<0.001). BSAP was reduced by ALN (26%, p<0.05) at 3 mo. and remained elevated in OVX-rabbits treated with PTH at 6 mo (48%, p<0.001), ODN (14%, NS) or PTH+ODN (66%, p<0.001) vs. Veh. ALN alone or in combination with PTH significantly reduced LV mineralizing surface or bone formation rate in OVX-rabbits. Unlike ALN, the BF parameters in ODN and PTH+ODN were comparable to those in PTH and Veh. Taken together, this study demonstrates that ALN and ODN are additive to PTH in providing BMD gains, but ALN blunts BF in the trabecular LV of OVX-rabbits, whereas ODN does not. By preserving BF in this model, ODN in combination with PTH may provide better

long-term BMD gains compared to the PTH+ALN combo, or to the respective monotherapy.

Heart Failure is a Clinically and Densitometrically Independent and Novel Risk Factor for Major Osteoporotic Fractures: Population-Based Cohort Study of 45,509 Subjects. Sumit Majumdar^{*1}, Justin A. Ezekowitz¹, Lisa M. Lix², William Leslie³. ¹University of Alberta, Canada, ²University of Saskatchewan, Canada, ³University of Manitoba, Canada

OBJECTIVES: To determine if heart failure is associated with an increased risk of major osteoporotic fractures and whether this risk is independent of low bone mineral density (BMD).

METHODS: We conducted a population-based cohort study in Manitoba, Canada. We linked a clinical registry of all adults age 50 years and older who underwent initial BMD testing from 1998-2007 with provincial databases and followed them until 2009. We collected traditional osteoporosis risk factors, comorbidities, medications, and BMD results. Using validated diagnostic coding algorithms we identified heart failure during the 2-years before BMD test and major non-traumatic osteoporotic fractures (i.e., vertebrae, distal radius, humerus, hip) diagnosed after BMD test. Multivariable Cox proportional hazards models were used to determine if heart failure was independently associated with incidence of major fractures.

RESULTS: The cohort consisted of 45,509 adults of whom 1,841 (4%) had diagnosed heart failure. Subjects with heart failure were significantly (p<0.001) older (mean 74 vs 66 years), more likely to be men (17% vs 7%), had more previous major osteoporotic fractures (21% vs 13%) and had lower total hip BMD than those without heart failure (T-score -1.3[SD1.3] vs -0.9[SD1.2], p<0.001). There were 2,703 incident fractures over a median 5-years observation. Overall, 10% of heart failure subjects had incident major fractures compared with 5% of those without (FIGURE; age-sex adjusted hazard ratio[aHR] 1.64, 95%CI 1.45-1.86). Adjustment for osteoporosis risk factors, comorbidities, and medications attenuated but did not eliminate this association (aHR 1.33, 95%CI 1.11-1.60) as did further adjustment for total hip BMD (aHR 1.28, 95%CI 1.06-1.53).

CONCLUSIONS: Heart failure is associated with an almost 30% increase in major osteoporotic fractures and this is independent of traditional clinical risk factors and BMD. Subjects with heart failure represent a previously unrecognized but easily identified high-risk population that would benefit from increased screening and treatment for osteoporosis.

A Screening Programme for Identification of Vertebral Fractures Increases Bisphosphonate Prescribing and Reduces Fractures: Results of a Large RCT. Emma Clark*, Leigh Morrison, Miranda Cuming, Virginia Gould, Jon Tobias. University of Bristol, United Kingdom

Background: Osteoporotic vertebral fractures (VF) are common in the elderly and are associated with morbidity and mortality, but in particular an increased risk of further osteoporotic fractures. Medications are available to reduce this future fracture risk by approximately 50%. Yet despite this there are no national screening programmes to identify individuals with osteoporotic VFs in the community.

Aim: To investigate whether a primary care-based screening tool to identify postmenopausal women with osteoporotic VFs can appropriately increase prescription of medications for osteoporosis, leading to a reduction in fracture risk.

Methods: We performed a pragmatic individual patient-based randomised controlled trial (RCT) of 3200 women aged 65-80. Women were enrolled from 15 General Practices within the Bristol area of the UK with no exclusion criteria. In those randomised to the active group, a simple screening tool was carried out by a nurse in primary care to identify women at high risk of prevalent osteoporotic VFs. All women identified as high-risk on the basis of a pre-defined algorithm, developed from a previous cross sectional study performed in a similar population, were offered a diagnostic thoraco-lumbar radiograph at their local hospital. Radiographs were reported using standard NHS reporting with results sent back to each participant's General Practitioner. Those randomised to the control arm did not receive the screening tool or radiographs. Analysis was by intention-to-treat for the main outcome measure, which was self-reported prescription of medication for osteoporosis at 6 months (a random 5% sub-sample was verified against electronic GP records). Secondary outcome was self-reported incidence of new fractures.

Results: In the screening group prescription of osteoporosis medications was increased by 124% compared to the control arm (OR for prescription 2.24 at 6 months (95%CI 1.16 to 4.33). 64.3% of women prescribed bisphosphonates within 6 months of starting the study had been identified with definite or probable osteoporotic VF. Fracture incidence was also reduced in the screening versus control arm by 72% between 6 and 12-months follow-up (OR for new fracture 0.28, 95%CI 0.12 to 0.67).

Conclusion: Adoption of a simple screening tool for prevalent VF in older postmenopausal women in primary care not only increased bisphosphonate prescribing, but also reduced fracture incidence, suggesting such an approach is likely to be highly cost effective

Persistent Skeletal Exposure to Bone Morphogenetic Proteins is Detrimental and Causes Osteopenia. Ernesto Canalis*, Lisa Brunet², Kristen Parker³, Stefano Zanotti¹. ¹St. Francis Hospital & Medical Center, USA, ²University of California, USA, ³Saint Francis Hospital & Medical Center, USA

Bone morphogenetic proteins (BMPs) induce endochondral bone formation, but the role of BMPs in osteoblastogenesis has been challenged since they decrease Wnt signaling and activity. BMP activity is controlled by BMP antagonists. Noggin is a secreted specific BMP antagonist and its only function is to bind BMPs and prevent signaling. Therefore, *Noggin* inactivation results in persistent tissue exposure to BMPs. Studies from transgenics overexpressing noggin in the skeletal environment reveal that BMPs are required to maintain skeletal homeostasis; however, unregulated tissue exposure to BMPs may have detrimental effects on bone. Models of *Noggin* inactivation are ideal to test this possibility, but the global inactivation of *Noggin* results in serious developmental abnormalities and prenatal lethality. To study the consequences of *Noggin* inactivation in the postnatal skeleton and consequently the persistent skeletal exposure to BMPs, mice, where the *Noggin* allele was flanked by *loxP* sequences, were mated with mice expressing the Cre recombinase under the control of the osteocalcin promoter, and compared to littermate control mice. Calvarial *noggin* mRNA was decreased by 50 to 70% in *Noggin* conditional null mice. Bone mineral density, microcomputed tomography and histomorphometry revealed marked osteopenia in male and female *Noggin* conditional null mice. Trabecular bone volume was decreased by 40 to 50% due to a decrease in trabecular number, and connectivity density was decreased by 60 to 70%. The osteopenic phenotype was observed at 1 and 3 months of age, but subsided partially at 6 months possibly due to a decline in osteocalcin promoter activity. The osteopenia following *Noggin* inactivation was generalized and observed in femoral and vertebral trabecular bone, and was not compartment-specific since cortical thickness was decreased by nearly 30%. Histomorphometry revealed no changes in osteoblast number, but osteoclast number and eroded surface were increased in male *Noggin* conditional null mice. Although bone formation also increased, it was not sufficient to maintain trabecular structure and reverse the osteopenic phenotype. In conclusion, the conditional inactivation of *Noggin* in the skeleton causes marked osteopenia due to an increase in bone remodeling, indicating that persistent exposure of the skeleton to BMPs is detrimental. Consequently, therapies targeting BMP antagonists may not prove successful in the management of osteoporosis.

Brown Fat Regulates Bone Mass Through Modulation of Sympathetic Tone. Katherine Motyl*, Masanobu Kawai², Sheila Bornstein², Victoria Demambro¹, Leeann Louis³, Sutada Lotun⁴, Mark Horowitz⁵, Roland Baron⁶, Mary Boussein³, Clifford Rosen². ¹Maine Medical Center Research Institute, USA, ²Maine Medical Center, USA, ³Beth Israel Deaconess Medical Center, USA, ⁴Harvard School of Dental Medicine, USA, ⁵Yale University School of Medicine, USA, ⁶Harvard School of Medicine & of Dental Medicine, USA

Brown adipose tissue (BAT) is critical for energy homeostasis in rodents. Loss of BAT leads to lower body temperature but activates an alternative thermogenic program through the sympathetic nervous system (SNS) to white adipose tissue (WAT). Skeletal metabolism is under the control of the SNS, although it is uncertain whether BAT dysfunction affects bone mass through the SNS. In this study, we examined skeletal and metabolic changes in two mouse models: 1) the *Misty* mouse, a spontaneous mutant with altered BAT function and 2) *Ucp1*^{-/-} mice that have no functional BAT. At 12 wks, *Misty* have low body temperature and greater sympathetic tone. White adipocytes were more 'brown-like' in their appearance and several BAT lineage determination and fatty acid oxidation genes were up-regulated in WAT. Skeletal phenotyping revealed that 8 wk female *Misty* mice had significantly lower total areal bone mineral density (aBMD) ($p < 0.01$) and distal femoral trabecular bone volume (BV/TV) fraction ($p < 0.001$) compared to controls. By 16 wks *Misty* lost significantly more bone mass than controls ($p < 0.0001$) and this difference (64%) was associated with a reduced BFR/BV, increased osteoclast number and a greater eroded surface by histomorphometry compared to controls. Importantly, the low aBMD and the trabecular thickness, but not trabecular number, of *Misty* were rescued by treatment with a beta-blocker. Similarly, trabecular BV/TV in the distal femur was enhanced although not totally restored by the 8-wk beta-blocker treatment. To confirm the indirect effects of BAT dysfunction on bone were non-cell autonomous, we studied uncoupling protein 1 null (*Ucp1*^{-/-}) mice that require elevated temperatures to maintain thermoneutrality. These mice have increased energy expenditure, are lean and have 'brown-like' adipocytes in inguinal WAT. We found that *Ucp1*^{-/-} mice had very low aBMD of the femur and low BV/TV of the distal femur at 6 wks ($p < 0.001$). These differences were significantly accentuated at 16 wks such that trabecular BV/TV was reduced by 80% ($p < 0.0001$) compared to controls. This is the first report demonstrating that alterations in BAT function affect the rate of bone loss in mice. Further studies are required to define whether age-associated bone loss is linked with BAT dysfunction in humans and to determine whether responders to beta-blocker therapy, with respect to BMD and/or fracture risk, are those with the greatest resting sympathetic tone.

Unexpected Enhanced Response to Mechanical Loading of Mice Lacking Cx43 Exclusively in Osteocytes. Nicoletta Bivi*, Nathan Farlow², Lucas Brun³, Jeffrey Benson², Keith Condon², Alexander Robling¹, Teresita Bellido², Lilian Plotkin². ¹Indiana University, USA, ²Indiana University School of Medicine, USA, ³University of Rosario, Argentina

The osteocyte network is crucial for the response of bone to mechanical force. Within this network, connexin 43 (Cx43) mediates the communication of osteocytes and osteoblasts among themselves and with the extracellular milieu. Although Cx43 appears to be important for the response of osteocytic cells to mechanical stimulation *in vitro*, the contribution of Cx43 expression in osteocytes to mechanotransduction *in vivo* is not known. To this end, we examined the anabolic response to loading of mice lacking Cx43 in osteocytes (Cx43^{ΔOT}) generated by crossing Cx43^{fl/fl} mice with DMP1-8kb-Cre mice. Unlike the 10kb fragment that directs gene expression to osteocytes and some osteoblasts, the 8kb fragment of the DMP1 promoter targets gene expression only to osteocytes. Indeed, Cre recombinase mRNA was detected only in green fluorescent protein (GFP) positive cells (osteocytes) and not in GFP negative cells (osteoblasts) isolated from calvaria of DMP1-8kb-Cre mice crossed with DMP1-8kb-GFP mice. Immunohistochemistry confirmed lack of Cx43 expression only in osteocytes in Cx43^{ΔOT} bone sections. Moreover, Cx43 mRNA was reduced by 88% in osteocyte-enriched cortical bone of Cx43^{ΔOT} mice compared to control Cx43^{fl/fl} littermates. Right ulnae of control and Cx43^{ΔOT} mice were subjected to axial loading at equivalent low, medium, and high strain magnitudes during 1min/d for 3 consecutive days; left ulnae were used as non-loaded controls. Bone formation rate (BFR/BS) was quantified 14d later. Loading induced strain-dependent increases in periosteal BFR/BS of 1.4-, 1.8-, and 2.2-fold in control animals. To our surprise, loading induced a greater response in Cx43^{ΔOT} mice (2.5-, 4.3- and 4.9-fold), due to a combination of higher mineralizing surface covered by osteoblasts (MS/BS) and higher rate of mineral apposition by individual osteoblasts (MAR). These results suggest that the absence of Cx43 in osteocytes unleashes bone formation by periosteal osteoblasts and are consistent with previously reported higher basal periosteal bone formation in femora from Cx43^{ΔOT} mice. The apparent discrepancy with earlier evidence showing decreased endosteal BFR/BS induced by tibia loading in mice lacking Cx43 in both osteocytes and osteoblasts (col1-2.3kb) can be explained by the fact that, in the latter model, osteoblasts are unable to function optimally. We conclude that the intrinsic function of Cx43 in osteocytes is to restrain the response of osteoblasts to mechanical loading.

We studied 27 prospective population-based cohorts from more than 25 countries. Height and weight were measured at baseline and body mass index (BMI) was calculated as kg/m². Bone mineral density (BMD) was measured at the femoral neck by DXA. Fractures during follow up were collected by self-report and, in some cohorts, confirmed by radiography. An extension of Poisson regression was used to examine the relationship between BMI and fracture risk adjusted for age, BMD and time since baseline within each cohort. The results were merged and weighted according to the variance.

Baseline data on BMI were available in 296 736 women aged 20-105 years with an average of 62.7 years. Femoral neck BMD was measured in 74 394 women aged 67.0 years, who were followed for 368 000 person-years. The prevalence of obesity (BMI ≥ 30 kg/m²) was 18%. During overall follow-up of 1.4 million person-years, 18,336 osteoporotic fractures (4,509 hip fractures) occurred. A majority of fractures (85%) arose in non-obese women (Figure 1). The risk of osteoporotic and hip fracture decreased progressively with increasing BMI. Compared to a BMI of 26, the hazard ratios (HR, 95%CI) for osteoporotic fracture at a BMI of 35 or 40 were 0.89 (0.84-0.93) and 0.83 (0.77-0.90), respectively. Interestingly, when adjusted for BMD, the corresponding HRs were 1.14 (1.06-1.23) and 1.23 (1.10-1.39), respectively. The HR for hip fracture was also reduced at higher BMIs (0.75 [0.67-0.85] and 0.64 [0.53-0.78] at 35 and 40 vs. 26 kg/m²). When adjusted for BMD, the corresponding HRs were 1.09 (0.91-1.30) and 1.14 (0.86-1.50), respectively.

Our results demonstrate that at a population level, obesity is protective for fracture in women and this protection is mediated by effects on BMD. At a given BMD, obesity appears to be a weak risk factor for fracture.

Osteocytes Regulate Bone Microenvironment Through Gsa Signaling to Support Normal Hematopoiesis. Keertik Fulzele^{*1}, Daniela Krause², Kevin Barry³, Sutada Lotinun⁴, Roland Baron⁵, Lynda Bonewald⁶, Jian Feng⁷, Min Chen⁸, Lee Weinstein⁹, David Scadden¹⁰, Paola Divieti Pajevic¹¹.
¹Massachusetts General Hospital; Harvard Medical School, USA, ²Center of Regenerative Medicine, Massachusetts General Hospital & Harvard Medical School, USA, ³Massachusetts General Hospital & Harvard Medical School, USA, ⁴Harvard School of Dental Medicine, USA, ⁵Harvard School of Medicine & of Dental Medicine, USA, ⁶University of Missouri - Kansas City, USA, ⁷Texas A&M Health Science Center, USA, ⁸Metabolic Diseases Branch, NIDDK, NIH, USA, ⁹National Institute of Diabetes & Digestive & Kidney Diseases, USA, ¹⁰Center for Regenerative Medicine Massachusetts Gen, USA, ¹¹Massachusetts General Hospital Harvard Medical School, USA

Osteocytes, the most abundant and long living cells of bone, coordinate bone remodeling by regulating osteoblast and osteoclast activity, in part, via G-protein coupled receptor signaling. Osteoblasts and osteoclasts also control hematopoiesis primarily by influencing self-renewal, differentiation, and mobilization of hematopoietic stem cells in their endosteal bone niche. Here, we hypothesized that osteocytes may directly or indirectly regulate hematopoiesis through the stimulatory subunit of G-protein, Gsα, signaling. To test this, we engineered mice lacking Gsα in osteocytes (DMP1-GsαKO) using the Cre-loxP recombination technique. Consistent with the previously established role of osteocytes in regulation of bone remodeling, DMP1-GsαKO mice showed severe osteopenia with an 86% decrease in trabecular bone volume and a 40% decrease in cortical thickness (p<0.01, N=5) as revealed by micro-CT analysis of femurs from 21-week old mice. Histomorphometric analysis of femurs from 7-week old mice showed that the osteopenia in the KO mice was due to a dramatic 95% decrease in osteoblast numbers (p<0.001, N=6) whereas the number and activity of osteoclasts was unaffected. To determine if the Gsα-deficient osteocytes may influence hematopoiesis, we examined the hematopoietic profile. DMP1-GsαKO mice displayed hematopoietic abnormalities that resembled myelodysplastic disease (MPD) characterized by a dramatic and significant increase in leukocytes, neutrophils, and platelets in the peripheral blood (p < 0.001, N=8) and increased myeloid cells in bone marrow (BM) and spleen (p<0.01, N=6). Surprisingly, the number of hematopoietic colonies formed in-vitro from BM cells were not changed indicating the requirement of the bone microenvironment to induce MPD. Indeed, transplantation of BM from control to DMP1-GsαKO mice rapidly recapitulated the MPD whereas converse transplantation completely normalized the hematopoietic abnormality. Co-culture of osteocyte-enriched bone explants from DMP1-GsαKO mice with control BM cells significantly increased the number of hematopoietic colonies compared to control explants. Furthermore, considering that mice lacking Gsα in osteoblasts or in hematopoietic cells do not display MPD, MPD in DMP1-GsαKO mice is most likely a direct effect of Gsα-null osteocytes. In summary, our results present the first evidence for osteocyte-mediated regulation of hematopoiesis via Gsα-signaling-induced alteration of the BM microenvironment.

Conditional Knockout of IGF-I in Osteocytes Surprisingly Accelerates Fracture Repair. Matilda Sheng^{*1}, Xiaodong Zhou¹, Kin-Hing William Lau², Lynda Bonewald³, David Baylink¹.
¹Loma Linda University, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³University of Missouri - Kansas City, USA

Past studies indicate that the osteocyte is an important regulator of bone formation (BF) and that bone-derived IGF-I is essential for BF and regeneration. IGF-I is expressed in osteocytes as well as osteoblasts. The goal of this study was to determine the effect of osteocyte-derived IGF-I on the enhanced BF required for fracture repair. For this work, we generated mice with conditional knockout (KO) of IGF-I gene in osteocytes by crossing DMP1-Cre mice with the IGF-I loxp mice. Fractures were created on the tibia of 10 weeks-old males by 3 point bending. At 21 and 28 days post-fracture, the % increases in total bone density (P=.01 and .04), cortical mineral contents (P=.03 for each), sub-cortical mineral contents (P=.04 and P=.02), cortical bone area (P=.04 and P=.06), and cortical thickness (P=.01 for each) were greater each by 13-26% in the healing calluses of KO mice than wild-type (WT) calluses. The basal periosteal BF per bone surface was not different between the KO mice and WT mice (1.57.09 vs. 1.44.12, P>.05), indicating that this increased BF during fracture repair was not due to a different basal BF. There was a 85% decrease in % cartilage (P=.06) and >2 fold increase in the number of TRAP+ osteoclasts within the KO callus, suggesting that the endochondral bone in the KO callus had been remodeled more rapidly, resulting in accelerated bony bridging of the fracture gap, which was confirmed by x-ray and histology. The mRNA levels of the BF genes [cbfa1, BMP2, and osteocalcin] in the KO callus were also increased by 149% (P=.04), 73% (P=.04), and 150% (P=.09), respectively, than those in WT calluses. These results, together, support the conclusion that targeted deletion of IGF-I in osteocytes would result in an increase in bone callus remodeling with a balance shifted toward BF; the end result being an accelerated fracture healing including bridging. Importantly, because IGF-I is a potent BF stimulator in osteoblasts, our findings that the KO of

osteocyte-derived IGF-I not only did not impede, but actually accelerated, BF during the fracture healing process, suggest a novel inhibitory function of osteocyte-derived IGF-I in fracture repair. More importantly, in a separate study these KO mice exhibited an obliterated BF response to the mechanical loading challenge in vivo. Thus, the enhanced fracture repair in the absence of loading BF response challenges the generally accepted dogma that loading is essential for an optimal fracture healing.

Osteocyte Autophagy Declines with Age in Mice and Suppression of Autophagy Decreases Bone Mass. Haibo Zhao, Jinhu Xiong, Melda Onal, Priscilla Cazer, Robert Weinstein, Stavros Manolagas, Charles O'Brien*, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

Osteocyte viability is reduced in aged bone, but the mechanisms responsible are unclear. The viability of other long-lived cells is sustained by autophagy, an intracellular process in which organelles and proteins are delivered to lysosomes for degradation and reuse of their components. Specifically, genetic suppression of autophagy in long-lived cells leads to increased numbers of damaged mitochondria, oxidative stress, and cell death. Based on this, the accumulation of damaged cellular components that occurs with age has been attributed to decreased autophagy. To determine whether autophagy in osteocytes declines with age, we quantified the expression of several genes involved in autophagy in femoral cortical bone after digestion with collagenase to remove surface cells. In two different mouse strains (DBA/2 and C57BL/6), BNIP3 and LC3 mRNA levels were reduced in cortical bone from 20 month old mice compared with 6 month old mice. Based on this finding and evidence in other tissues that reduced autophagy leads to increased mitochondrial DNA, we compared mitochondrial mass by quantifying mitochondrial DNA, normalized to nuclear DNA, in cortical bone of young and old mice. We found that mitochondrial DNA was significantly higher in cortical bone from aged mice, consistent with the contention that autophagy in osteocytes declines with age. To directly address whether autophagy is functionally important in osteocytes, we deleted a conditional allele for ATG7, a gene that is essential for autophagy, from osteocytes using the DMP1-Cre transgene. Suppression of autophagy in osteocytes was confirmed by demonstrating that conversion of LC3 protein from form I (unlipidated) to form II (lipidated) was significantly reduced in cortical bone of conditional knockout (KO) mice. Similar to the results we obtained from aged mice, the reduction in autophagy in the conditional KO mice was associated with an increase in the levels of mitochondrial DNA isolated from cortical bone. Moreover, bone mineral density was significantly lower, compared to littermate controls, in the spines and femurs of both male and female conditional KO mice beginning at 4 months of age and continuing to at least 6 months of age without differences in body weight between genotypes. These results demonstrate that loss of autophagy in osteocytes leads to low bone mass and suggest that a decline in osteocyte autophagy with age contributes to the low bone mass associated with aging.

Sclerostin Deficiency does not Induce Bone Gain in Mice Lacking Osteocyte \hat{O} -catenin. Ming-Kang Chang*, Ina Kramer, Michaela Kneissel, Novartis Institutes for Biomedical Research, Switzerland

Wnt/ \hat{O} -catenin signaling controls bone homeostasis by impacting on the entire osteoblastic cell lineage and osteoclastic bone resorption. In consequence, mice lacking osteocyte \hat{O} -catenin (*Ctnnb1^{loxP/loxP};Dmp1-cre*) develop severe osteoporosis. Osteocytes secrete the bone formation inhibitor sclerostin encoded by *Sost*. Sclerostin is thought to act as a paracrine inhibitor of osteoblast Wnt/ \hat{O} -catenin signaling. However the final proof that sclerostin indeed targets this pathway in bone is lacking. Furthermore the possibility that sclerostin targets osteocytes in an autocrine manner cannot be excluded. To address these questions, we generated mice lacking both osteocyte \hat{O} -catenin and sclerostin (*Ctnnb1^{loxP/loxP};Dmp1-cre;Sost^{-/-}*). We previously reported that sclerostin deficiency did not prevent bone loss induced by the lack of osteocyte \hat{O} -catenin. To elucidate bone turnover in these mutant mice, we performed histomorphometry on the femur of 10-week-old male mice (wildtype, *Sost^{-/-}*, *Ctnnb1^{loxP/loxP};Dmp1-cre* = single KO, *Ctnnb1^{loxP/loxP};Dmp1-cre;Sost^{-/-}* = double KO). Endocortical bone forming surfaces were increased in *Sost^{-/-}* mice compared to wildtype controls (e.g. +40% mineralizing surface). However this was abolished in the osteocyte \hat{O} -catenin deficient background and double KO mice when compared to single KO mice. Endocortical bone resorption was non-significantly reduced in *Sost^{-/-}* animals (-64% osteoclast surface; -19% eroded surface), while single KO mice displayed increases (+72% and +189% respectively) as observed before. Bone resorption perimeters were comparable in single and double KO mice. Cancellous bone volume was increased in *Sost^{-/-}* mice (+56%), while it was decreased in single and double KO mice (-67% and -88% respectively). Bone formation parameters were increased in *Sost^{-/-}* mice (e.g. +175% osteoblast surface). As previously reported osteoblast parameters were non-significantly elevated on the few trabeculae of single KO mice. Double KO mice displayed a similar phenotype. Bone resorption was

elevated in double KO mice compared to other genotypes, however without reaching significance due to variability based on paucity of the bone template. The results demonstrate that bone turnover was overall comparable between *Ctnnb1^{loxP/loxP};Dmp1-cre* single and *Ctnnb1^{loxP/loxP};Dmp1-cre;Sost^{-/-}* double KO mice. The data indicate that sclerostin indeed targets \hat{O} -catenin dependant signaling in bone possibly in an autocrine fashion.

Increased RANKL Production by Osteocytes is a Major Mechanism Underlying the Bone Loss Induced by Unloading. Jinhu Xiong*, Melda Onal, Priscilla Cazer, Stavros Manolagas, Charles O'Brien, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

Osteocytes are thought to control the response of bone to changes in mechanical forces; and bone loss due to mechanical unloading has been attributed to both increased bone resorption and decreased bone formation. However, the mechanisms by which osteocytes may mediate these responses remains unclear. To determine whether osteocytes control bone resorption via production of RANKL, we crossed mice with a conditional allele for RANKL with DMP1-Cre mice, which express the Cre recombinase predominately in osteocytes. Mice lacking RANKL in osteocytes, hereafter referred to as RANKL conditional knock out (CKO) mice, displayed normal tooth eruption and were not grossly osteopetrotic. However, at 5 weeks of age RANKL CKO mice had a small but significant elevation of bone mass, compared with control littermates, and this difference increased with time so that at 6 months of age there was a 30% increase in bone mineral density (BMD). At this age, both RANKL mRNA in bone and osteoclast number were significantly reduced in RANKL CKO mice. These results demonstrate that osteocytes produce a significant amount of the RANKL present in bone and that they are an essential source of the RANKL that controls basal bone remodeling. Next, we examined whether RANKL produced by osteocytes contributes to the bone resorption induced by mechanical unloading. Six-month-old RANKL CKO mice and control littermates were either tail-suspended or left grounded for 3 weeks. Tail-suspension of control mice reduced femoral BMD by 12% ($p < 0.05$), while the grounded mice did not show any change in bone mass. In contrast, tail-suspension of the RANKL CKO mice reduced BMD by only 4%, which was significantly less than the effect of tail-suspension on control littermates ($p < 0.05$ by ANOVA). Moreover, unloaded control mice exhibited a significant decrease in femoral cortical thickness, compared to their grounded controls, as measured by microCT. In contrast, unloading had no effect on cortical thickness in the RANKL CKO mice. Consistent with this, unloading significantly elevated RANKL mRNA in the cortical bone of control, but not RANKL CKO, mice. Taken together, these results demonstrate that osteocytes produce RANKL, and that this production increases in response to mechanical unloading. Moreover, the increased RANKL production by osteocytes is a major contributor to the bone resorption and bone loss associated with mechanical unloading.

Sclerostin Stimulates Osteocyte Support of Osteoclast Activity by a RANKL-Dependent Pathway. Asiri Wijenayaka, Masakazu Kogawa, David Findlay, Gerald Atkins*, University of Adelaide, Australia

Sclerostin is a product of mature osteocytes embedded in mineralised bone and is a negative regulator of bone mass and osteoblast differentiation. Both animal (1) and human (2) studies employing a neutralising anti-sclerostin antibody have reported decreases in bone resorption parameters. Thus, while it is clear that sclerostin has an anti-anabolic role, it is also possible that sclerostin has direct catabolic activity. To test this we examined the effect of recombinant human sclerostin (rhSCL) on pro-osteoclastic gene expression in cultures of human primary immature osteoblasts and differentiated late-osteoblast/pre-osteocyte cultures. Sclerostin dose-dependently up-regulated expression of RANKL mRNA and down-regulated that of OPG mRNA, causing an increase in the RANKL:OPG mRNA ratio in late osteoblast/pre-osteocyte-like cultures, a phenotype we showed previously to be exquisitely sensitive to rhSCL(3). We also found that the RANKL:OPG mRNA ratio was increased in mouse osteocyte-like MLO-Y4 cells in response to rhSCL. To examine the functional effects of rhSCL on resulting pro-osteoclastic activity, MLO-Y4 cells plated onto a bone-like substrate were primed with rhSCL for 3 days and then either mouse splenocytes or human peripheral blood-derived mononuclear cells (PBMC) were added. Analysis of resorptive activity after 14 days revealed that rhSCL elevated osteoclast resorptive activity approximately 7-fold. The increased resorption was abolished by co-addition of recombinant OPG. SCL increased to a small extent the number of TRAP-positive multinucleated cells formed, and significantly increased the size of the cells formed. rhSCL had no effect on TRAP-positive cell formation from monocultures of either splenocytes or PBMC. rhSCL did not induce apoptosis of MLO-Y4 cells, as determined by caspase activity assays and nuclear morphology. Together, our findings suggest that sclerostin may have a catabolic action through promotion of osteoclast formation and activity by viable osteocytes, in a RANKL-dependent manner.

Deletion of the Rho-GEF Kalirin Leads to Bone Loss Due to Defects in the Function of Osteoblasts and Osteoclasts. Su Huang¹, Pierre Eleniste¹, Cameron Carter¹, Melissa Kacena², Matthew Allen², Angela Bruzzaniti¹.
¹Indiana University School of Dentistry, USA, ²Indiana University School of Medicine, USA

The guanine nucleotide exchange factors (GEFs) control to the activation of the Rho-GTPases and are known to play a critical role in cellular motility and cytoskeletal reorganization. Kalirin, a recently identified Rho-GEF belonging to the family of Dbl-homology proteins, has been shown to play a role in cytoskeletal remodeling and dendritic spine formation in neuronal cells, but its function in non-neuronal cells is largely unknown. We confirmed by Western blotting and real time PCR that Kalirin is expressed in human and mouse osteoclasts (OCs) and mouse osteoblasts (OBs). Given that cytoskeletal remodeling is critical for the function of bone cells, we examined the role of Kalirin in regulating OC and OB activity *in vitro*, and bone mass *in vivo*. Micro-CT analysis of the distal femurs of 14 week old female mice revealed a dramatic 45% decrease in bone volume/trabecular volume (BV/TV) in Kalirin KO mice, compared to littermate controls. Moreover, trabecular number and trabecular thickness was decreased by 38% and 26%, respectively. Histomorphometric analysis of bone sections stained for tartrate-resistant acid phosphatase (TRAP) also revealed an increase in OC surface/bone surface and OC number/bone surface, respectively, in Kalirin KO mice, suggesting that OC differentiation was accelerated *in vivo*. In support of this, increased levels of RANKL and decreased levels of OPG were detected in the serum of Kalirin KO mice. Next, OCs were generated from the bone marrow of WT and Kalirin KO mice by treatment with RANKL and M-CSF. We detected an increase in the number of TRAP-positive multinucleated OCs in cultures from Kalirin KO mice, compared with WT mice. Importantly, OCs lacking Kalirin also exhibited a 30% increase in bone resorbing activity on dentin. Next, we examined the role of Kalirin in OBs. Consistent with an increase in the ratio of RANKL/OPG in serum, we detected increased RANKL and decreased OPG levels in conditioned media from Kalirin KO calvarial OBs. Furthermore, ectopic expression of Kalirin in OBs led to an increase in the secretion of OPG. Taken together, our studies demonstrate that Kalirin is a novel regulator of bone mass. Moreover, Kalirin's effects on bone are due cell-autonomous defects in both OCs and OBs, which leads to an increase in OC number and activity and to dysregulation of the bone remodeling process.

Osteopetrosis in Mice with Knockout of Leucine-Rich Repeat Kinase 1 (Lrrk1) Gene. Robert Brommage¹, Jeff Liu¹, Peter Vogel¹, Thomas Wronski². ¹Lexicon Pharmaceuticals, USA, ²University of Florida, USA

As part of Lexicon Pharmaceuticals' Genome5000™ program, high-throughput DEXA scans were performed on 2995 knockout (KO) mouse lines. KO of Lrrk1 had the highest body vBMD value (T score = 7.0). LRRK1 is a serine/threonine kinase with GTPase activity and related to LRRK2, which has been implicated in Parkinson's disease. KO mice appear healthy through 79 weeks of age. Bone shape is normal with ~10% reductions in femur and tibia lengths. Bones contain extensive cancellous trabeculae with numerous osteoclasts. At 10 weeks of age, serum TRAP5b levels are elevated (6.2 ± 0.3 versus 3.8 ± 0.2 U/liter, P < 0.001). Retention of mineralized cartilage and primary spongiosa occur below the growth plates. At 70 weeks of age DEXA BMD values in male KO mice were elevated 65% for total body, 85% for femur and 2.9-fold for spine. KO mice had reduced serum levels of PINP, suggesting lower bone remodeling. KO mice respond normally to the anabolic actions of teriparatide, as 8 days of daily teriparatide treatment increased serum PINP levels greater than 4-fold in both WT and KO mice. By microCT, tibial cortical bone in male KO mice at 79 weeks of age has a normal diameter, but reduced marrow cavity area, resulting in elevated cortical thickness (P < 0.001) at both the midshaft (Δ = 22%) and tibia-fibula junction (Δ = 35%). Material BMD is increased by 3% (P = 0.002) in KO cortical bone, suggesting slight hypermineralization or reduced porosity. Analyses of trabecular bone in a 1.2 mm thick region of the mid vertebral body (away from the extensive primary spongiosa near the growth plates) showed severe osteopetrosis, as BV/TV increased from 8.5 ± 1.1 to 53.1 ± 3.9 percent. Female mice underwent sham or ovariectomy (OVX) surgery at 16 weeks of age, with DEXA BMD measurements at baseline and 12 weeks. At baseline, BMD values in KO mice were elevated by 40% in whole body, 64% in spine, and 65% in femur. OVX induced loss of BMD in sham controls but was without effect in KO mice (P < 0.01 for effect of genotype by two-factor ANOVA) at all three bone sites. Tibia cortical bone thickness was elevated 14% in KO mice. OVX decreased cortical thickness in WT mice (Δ = 7%, P = 0.04), but not in KO mice (Δ = 1%, P = 0.83). Disruption of the mouse Lrrk1 gene results in severe osteopetrosis from osteoclast dysfunction and protects against OVX-induced bone loss.

Estrogen Indirectly Suppresses Mesenchymal Cell Migration and Mineralization by Stimulating Sclerostin and Sostdc1 Expression in Osteoclasts. Kuniaki Ota^{*1}, Patrick Quint², Moustapha Kassem³, Jennifer Westendorp¹, Sundeep Khosla⁴, Merry Jo Oursler¹. ¹Mayo Clinic, USA, ²Mayo Clinic Rochester, USA, ³Odense University Hospital, Denmark, ⁴College of Medicine, Mayo Clinic, USA

Estrogen is a critical regulator of osteoblast differentiation and bone turnover. Reduced estrogen levels lead to postmenopausal osteoporosis. Osteoclast-mediated resorption and osteoblast-mediated bone formation are tightly coupled processes and the involvement and influences of estrogen on this coupling are unclear. In vitro studies have reported direct, but often contradictory, effects of estrogen on coupling of osteoclasts to osteoblasts during mesenchymal stem/stromal cell (MSC) recruitment and differentiation. We examined the influences of estrogen on coupling of osteoclasts to osteoblast lineage recruitment and differentiation using bone marrow-derived osteoclasts and hMSC-TERT cells. Estrogen had no direct effects on hMSC-TERT cell migration or mineralization. Conditioned media from mature osteoclasts enhanced hMSC-TERT cell migration and mineralization. Surprisingly, estrogen reduced osteoclast-driven hMSC migration and mineralization. We have published that osteoclasts secrete Wnt10b and BMP6 to promote mesenchymal cell mineralization. Estrogen did not alter expression of either coupling factor. We next determined if estrogen affects expression of Sclerostin, which suppresses Wnt signaling, and Sostdc1, which suppresses BMP signaling. Western blot analysis of osteoclast conditioned media revealed that estrogen stimulated Sclerostin secretion. Because no functional antibodies could be identified for Sostdc1, we employed QPCR analysis to examine gene expression. Estrogen treatment increased Sostdc1 gene expression in osteoclasts.

Next, osteoclasts were differentiated from bone marrow of Estrogen Receptor knock-in (NERKI) mice. NERKI osteoclasts have elevated levels of ER-beta and are unable to activate classical ER-alpha signaling. NERKI osteoclasts exhibited enhanced estrogen induction of Sclerostin and Sostdc1 compared to wildtype controls. These data indicate that either non-classical ER-alpha signaling and/or ER-beta signaling in osteoclasts regulates Sclerostin and Sostdc1 production to inhibit Wnt and BMP support of mesenchymal cells.

Critical Role of ATF4 in Regulating Osteoclast Differentiation and Bone Resorption. Huiling Cao^{*1}, Shibing Yu², Zhi Yao³, Deborah Galson¹, Yu Jiang⁴, Xiaoyan Zhang⁵, Jie Fan⁴, Binfeng Lu⁴, Youfei Guan⁵, Min Luo⁴, Yumei Lai⁴, Noriyoshi Kurihara⁶, Kenneth Patrene⁴, G. David Roodman⁷, Guozhi Xiao¹. ¹University of Pittsburgh School of Medicine, USA, ²University of Pittsburgh Medical Center, USA, ³Tianjin Medical University, China, ⁴University of Pittsburgh, USA, ⁵Peking University, China, ⁶Center for Bone Biology, University of Pittsburgh, USA, ⁷VA Pittsburgh Healthcare System (646), USA

Activating Transcription Factor 4 (ATF4) has a critical role in regulating osteoblast differentiation and bone formation. However, its direct role in osteoclasts differentiation has not been addressed yet. In order to define the role of ATF4 in osteoclasts, we deleted ATF4 expression in mice or targeted expression of ATF4 to the osteoclast lineage using the tartrate-resistant acid phosphatase (TRAP) promoter. Osteoclast differentiation was severely impaired in primary bone marrow monocyte (BMM) cultures and bones from *Atf4*^{-/-} mice. Coculture with wt osteoblasts or a high concentration of receptor activator of NF-kappaB ligand (RANKL) failed to restore the osteoclast differentiation defect in *Atf4*^{-/-} BMM cultures. Conversely, *Trap*-ATF4-tg mice display a severe osteopenia with dramatically increased osteoclastogenesis and bone resorption. We further demonstrated that ATF4 is a novel upstream activator of the critical transcription factor nuclear factor of activated T cells c1 (NFATc1) gene and is critical for RANKL activation of multiple MAPK pathways in osteoclast precursors. Further more, ATF4 is crucial for M-CSF induction of receptor activator of NF-kappaB (RANK) expression on BMMs, and lack of ATF4 caused a shift in osteoclast precursors to macrophages, thereby increasing macrophages. Finally, ATF4 is largely modulated by M-CSF signaling and the PI3K/AKT pathways in BMMs. These results for the first time demonstrate that ATF4 plays a critical direct osteoclast-intrinsic role in regulating osteoclast differentiation and suggest that it may be a therapeutic target for treating bone diseases associated with increased osteoclast activity.

Deletion of Dynamin-1 and Dynamin-2 in Osteoclasts Shows that Dynamins are Required for the Fusion of Osteoclast Precursors and for Bone Resorption in vivo. Shawn Ferguson¹, William Horne², Pietro De Camilli¹, Lynn Neff², Hiroaki Saito², Nah-Young Shin^{*3}, Roland Baron⁴. ¹Yale University School of Medicine, USA, ²Harvard School of Dental Medicine, USA, ³Harvard University, USA, ⁴Harvard School of Medicine & of Dental Medicine, USA

We have previously shown that the large GTPase dynamin (Dyn), which is best known for playing a critical role in endocytic membrane fission, also contributes to the regulation of podosomes and bone resorption. Here we found that all three classical Dyn isoforms, Dyn-1, -2 and -3, are expressed in osteoclasts (OCs). Interestingly, we observed that the expression of Dyn-2, the predominant isoform in OCs, is highly increased at the stage when OC precursors (OCPs) are fusing to form multinucleated cells (MNCs). To determine the role of dynamin in OC differentiation, we analyzed Dyn-deficient OCs derived from Dyn-1/Dyn-2 double floxed mice crossed with 4-hydroxy-tamoxifen-inducible Cre mice. The number of MNCs formed in vitro from M-CSF and RANKL-treated Dyn-1/Dyn-2-null bone marrow macrophages (BMMs) and the number of nuclei incorporated into MNCs were both decreased by ~65%, while the number of TRAP+ mononuclear OCPs in these cultures was increased by about 3-fold, suggesting that the fusion of OCPs was impaired in the absence of Dyn-1 and Dyn-2. To test this hypothesis, we developed a fusion assay mixing DiI (red)- and DiO (green)-labeled live BMMs in the presence of M-CSF and RANKL and determined the percentage of fused (yellow-orange) MNCs. The results confirmed that deletion of Dyn-1 and Dyn-2 reduced the fusion activity of OCPs by about half. The expression of OC differentiation markers, including cathepsin K, calcitonin receptor, integrin beta3 and TRAP, were all decreased in the Dyn-1/Dyn-2-null cells, as was the expression of the fusion-mediating membrane proteins DC-STAMP and E-cadherin, which are important for the generation of fusogenic OCPs. Dyn-1/Dyn-2-null OCs also showed significantly reduced in vitro bone resorption activity. In Dyn-deficient OCPs and OCs, a pronounced accumulation of endocytic clathrin coated pits labeled with F-actin and the Dyn-binding BAR domain protein endophilin, which was associated with a decreased internalization of DC-STAMP, a process required for the fusion of OCPs, were observed by confocal microscopy. These results suggest that dynamins are required for the fusion of OCPs, possibly through their role in endocytosis. Finally, we generated Dyn-1;Dyn-2;Cathepsin K-Cre mice and found a significant increase in bone density. Thus, Dyn-1 and Dyn-2, and possibly endocytosis, are critical for OCP fusion, in addition to dynamin's role in podosomes and bone resorption.

Contrasting Roles of Leukemia Inhibitory Factor (LIF) in Neonatal Bone Development and Adult Bone Remodeling Involve Region-Specific Regulation of Vascular Endothelial Growth Factor (VEGF). Ingrid J Poulton¹, Narelle E McGregor¹, Sueli Pompolo¹, Emma C Walker¹, Natalie Sims^{*2}. ¹St. Vincent's Institute of Medical Research, Australia, ²St. Vincent's Institute for Medical Research, Australia

Leukemia inhibitory factor (LIF) is expressed in pre-hypertrophic chondrocytes and osteoblasts, suggesting roles in bone development and remodeling. In this study, age- and region-specific analyses of LIF deficient (KO) mice reveal independent roles for LIF in osteoclast and osteoblast activity in these processes.

LIF KO neonates demonstrated many "giant" osteoclasts, as previously described. In 12 week old LIF KOs, osteoclast number was doubled, and osteoclast size increased by 30%. Surprisingly, this was only observed in those osteoclasts destroying mineralized growth plate cartilage (chondroclasts). Osteoclast number and size in the secondary spongiosa were not modified in LIF KO. Although osteoclast formation was normal in LIF KO remodeling bone, osteoblast surface, mineral appositional rate and bone formation rate were all significantly reduced (by 75%, 50% and 60% respectively) and marrow adipocyte volume was increased 3-fold. Consistent with this, LIF delayed adipocyte formation and stimulated mineralization by murine stromal cells and inhibited sclerostin expression.

To understand the region-specific role of LIF in osteoclast formation, we examined neonatal bone development. Chondrocyte proliferation and hypertrophy, vascularization and osteoclast invasion were timed identically in LIF KO and WT phalanges and metatarsals. However, once vascular invasion commenced, the vessels of LIF KO metatarsals were larger and more numerous than WT. Furthermore, in adult LIF KO bones, blood vessel area was significantly increased (3-fold) compared to WT littermates, but only immediately below the growth plate. To explore the control of vascularisation and osteoclast formation at the growth plate, LIF receptor (LIFR) was assessed by immunohistochemistry and was detected at very high levels in hypertrophic chondrocytes. Furthermore, in LIF KO bones, consistent with early reports of LIF inhibiting VEGF expression in retina and placenta, VEGF mRNA levels were significantly elevated (3-fold), and VEGF immunohistochemical staining was greater in LIF KO chondrocytes compared to WT littermates. In conclusion, LIF influences the skeleton in a region-specific manner. Chondrocytic LIF acts as a brake on VEGF production; in its absence, vascularization and osteoclast formation is enhanced in bone development and growth. LIF is not required for normal osteoclast

formation in bone remodeling however, but stimulates osteoblast formation at the expense of adipogenesis.

Autocrine/Paracrine Actions of Cyp27b1, VDR, and CaSR Signaling in the Regulation of Parathyroid Function: Studies of Parathyroid-Specific Knock-out Mice. Zhiqiang Cheng, Chialing Tu, Alfred Li, Michael You, Dolores Shoback, Daniel Bikle, Wenhan Chang*. University of California, San Francisco, USA

The Ca^{2+} -sensing receptor (CaSR) and vitamin D receptor (VDR) mediate critical suppression of PTH secretion by parathyroid cells (PTCs). The 1,25 (OH)₂ vitamin D (1,25D) produced by renal Cyp27B1 is thought to be the major source of ligand that achieves these suppressive actions in PTCs. The demonstration of CYP27B1 activity in PTCs, however, raises the question whether these cells also produce 1,25D to regulate PTH secretion directly. To address the source of 1,25D and the role of the VDR and CaSR in the control of PTC function, we generated mice with homozygous Cyp27B1 (Cyp-KO) or VDR (VDR-KO) gene KO targeted specifically to PTCs. We performed similar gene KO in the background of CaSR-Het mice (which lack one allele of the CaSR gene) to produce VDR-KO/CaSR-Het or Cyp-KO/CaSR-Het double KO mice. Serum Ca^{2+} , phosphate (Pi), and PTH levels in these mice and their control littermates (Cont), which carry floxed alleles (but no Cre), were compared. PTC glands (PTGs) were also isolated for PTH secretion assays to determine the Ca^{2+} -set-point ($[\text{Ca}^{2+}]$) inhibiting 50% of PTH secretion) and maximal PTH secretory response on a per-gland basis (PTH-Max) in an organ culture system. As shown (see Table), serum PTH levels were increased by $\approx 25\%$ in both VDR-KO and CaSR-Het mice and much more robustly ($\approx 100\%$) in the VDR-KO/CaSR-Het double KO (d-KO) mice, compared to Cont mice. PTH secretion from PTGs from CaSR-Het mice (but not VDR-KO mice) displayed a right-shift in the Ca^{2+} -set-point vs Cont (see Figure; Cont: 1.2 mM; CaSR-Het: 1.4 mM; and VDR-KO: 1.2 mM). However, mice with VDR KO (and intact CaSR alleles) showed a 30% increase in the PTH-Max vs Cont or CaSR-Het mice. In PTGs from VDR-KO/CaSR-Het mice, the Ca^{2+} -set-point was further right shifted to ≈ 1.6 mM along with a more profound increase in PTH-Max by $\approx 60\%$, indicating a synergistic effect of CaSR and VDR KO in expanding PTH pools and decreasing Ca^{2+} -sensitivity. Hypercalcemia and hypophosphatemia developed only in the CaSR-Het mice and not in VDR-KO mice, suggesting that VDR and CaSR signaling may have different effects on the patterns of PTH secretion (pulsatility, amplitude, duration) that have different effects on mineral metabolism. Importantly, Cyp-KO mice also showed increased PTH and serum $[\text{Ca}^{2+}]$ equivalent to VDR-KO (see Table), with similar increases in PTH-Max in vitro, supporting the idea that locally produced 1,25-D plays a critical role in regulating PTH function via the VDR in the PTC.

Conditional Deletion of the Parathyroid Hormone (PTH) Receptor 1 from Osteocytes Results in Decreased Bone Resorption and a Progressive Increase in Cancellous Bone Mass. Xiaolin Tu*, Rachel Edwards¹, Naomie Olivis¹, Jeffrey Benson¹, Carlo Galli², Gretel Pellegrini³, Nicoletta Bivi⁴, Lilian Plotkin¹, Teresita Bellido¹. ¹Indiana University School of Medicine, USA, ²Università Degli Studi Di Parma, Italy, ³seccion osteopatias medicas, Hospital de Clínicas Jose de San Martín, Argentina, ⁴Indiana University, USA

Some skeletal actions of PTH might be mediated by direct effects of the hormone on osteocytes. To explore the physiological role of the PTH receptor (PTHr1) in these cells, we generated conditional knockout mice (cKO) by mating PTHr1^{flx/flx} mice with DMP1-8kb-Cre mice. Cre mRNA was detected in green fluorescent protein (GFP) positive cells (osteocytes) but not in GFP negative cells (osteoblasts) isolated from DMP1-8kb-Cre mice crossed with DMP1-8kb-GFP mice. PTHr1 mRNA was reduced by 54% in lumbar vertebra and 73% in tibial diaphysis of cKO mice compared to control PTHr1^{flx/flx} littermates. cKO mice exhibited no gross skeletal abnormalities. BMD (DEXA) progressively increased in lumbar spine (5.3% to 14.8%), but not in the femur, in 2 to 8 month-old female cKO mice. Cancellous bone volume (BV/TV) and trabecular number and thickness (micro-CT) were increased in spine and distal femur, without changes in femoral cortical bone, at 4 months. At this age, the resorption marker CTX was 22% lower in plasma from cKO mice, whereas osteocalcin was similar to controls. The discrepancy with the reported reduced BMD without changes in BV/TV or CTX in PTHr1^{flx/flx};DMP1-10kb-CreERT2 mice might be due to the fact that the 10kb fragment directs gene expression to osteocytes and some osteoblasts, whereas the 8kb fragment only targets osteocytes. In tibial diaphysis (composed of cortical bone and enriched in osteocytes) the expression of RANKL and the Wnt target genes OPG, naked2, Cx43, Smad6 and BMP4 was lower in cKO mice. In contrast, in lumbar vertebra (mostly composed of cancellous bone), only RANKL was decreased resulting in a reduction in the RANKL/OPG ratio. This suggests that osteocytes are the main source of RANKL whereas OPG is also contributed by other osteoblastic cells relatively more abundant in cancellous versus cortical bone. Thus, removal of the PTHr1 only from osteocytes leads to a site specific reduction in the RANKL/OPG ratio resulting in increased cancellous but not cortical bone mass in the cKO mice. Reduced bone resorption induced by deletion of PTHr1 in osteocytes is consistent with earlier evidence that, conversely, osteocyte-specific activation of PTHr1 increases osteoclasts and bone resorption. We conclude that actions of the PTHr1 in osteocytes are required to maintain basal levels of Wnt signaling and RANKL, and that the primary effect of absence of the receptor in osteocytes is a reduction in osteoclast activity in cancellous bone.

PTH/PTHrP (PPR) Receptor Signaling in Osteocytes Regulate Bone Development in Temporal Manner. Vaibhav Saini*, Kevin Barry², Keertik Fulzele³, Jian Feng⁴, Paola Pajevic Divieti⁵. ¹Research Fellow, MGH, Harvard Medical School, USA, ²Massachusetts General Hospital, USA, ³Massachusetts General Hospital; Harvard Medical School, USA, ⁴Texas A&M Health Science Center, USA, ⁵MGH- Harvard Medical School, USA

Osteocytes, the terminally differentiated cells of the osteoblastic lineage, regulate bone remodeling by influencing osteoblast and osteoclast activities. Osteoblasts are targets for numerous systemic hormones, including parathyroid hormone (PTH), which acts through the PTH/PTHrP receptor (PPR). Clinically, PTH is the only available anabolic agent to treat osteoporosis. Recent evidence suggests that osteocytes may partially mediate the anabolic effects of PTH via PTH mediated suppression of the osteocyte-specific protein sclerostin, a potent Wnt signaling inhibitor. To understand the role of PPR signaling in osteocytes and to determine if osteocytes directly mediate the effects of PTH on bone, we generated mice with osteocyte-specific ablation of PPR (DMP1-PPRKO) using Cre-loxP recombination technique. Mice with floxed PPR alleles were mated with mice expressing Cre-recombinase driven by a 10Kb-DMP1 promoter which has been shown to be active in osteocytes. Littermates lacking Cre expression were used as controls for all experiments. Real-time PCR analysis of mRNA from osteocyte-enriched long bones showed a 70% reduction in PPR expression in the DMP1-PPRKO mice compared to controls, indicating successful PPR deletion. Alizarin-red/alcalin-blue staining of newborn pups' skeletal preparations showed no obvious patterning defects in the KO mice compared with controls. To assess PPR ablation in osteocytes in the context of aging, we performed dual-energy X-ray absorptiometry (DXA) at 8, 10, 12, and 24 weeks on KO and controls. Total body BMD (g/cm²) was comparable at 8 weeks of age. However, at 10, 12, and 24 weeks, DMP1-PPRKO mice showed a significantly higher BMD compared to controls. Moreover, microCT analysis at 14 weeks, revealed a significant increase in trabecular BV/TV%, trabecular number, cortical thickness and bone area (BA) in DMP1-PPRKO compared with controls. While osteoblasts are important for bone formation during growth (until 8-weeks of age), osteocytes are critical for remodeling in later life. Our results suggest an important role of PPR on osteocytes in bone homeostasis and bone remodeling and support a key role of PTH signaling via PPRs in osteocytes for proper bone modeling and remodeling. Taken

together, these data suggest that PPR signaling may regulate bone development in temporal and spatial manner.

The Calcium Sensing Receptor Synergizes with PTH in Modulating Bone Turnover. Yingben Xue¹, Yongjun Xiao², Jingning Liu³, Andrew Karaplis⁴, Martin Pollak⁵, Edward Brown⁶, Dengshun Miao⁷, David Goltzman⁸. ¹Calcium Research Lab, McGill University, Canada, ²the Centre for Bone & Periodontal Research, McGill University, Canada, ³Calcium Research Laboratory, McGill University Health Centre & Department of Medicine, Canada, ⁴McGill University, Can, ⁵Renal Division, Department of Medicine, Brigham & Women's Hospital, USA, ⁶Brigham & Women's Hospital, USA, ⁷Nanjing Medical University, Peoples Republic of China, ⁸McGill University Health Centre, Canada

Both parathyroid hormone (PTH) and the calcium sensing receptor (CaSR) may influence skeletal function, however the interaction of the two *in vivo* requires clarification. We infused human PTH (1-34) for 2 weeks into wild-type (WT) mice; into mice with genetic deletion of the gene encoding PTH (PTH^{-/-} mice); and into mice with genetic deletion of the genes encoding both PTH and the CaSR (PTH^{-/-}CaSR^{-/-} mice). We examined the effects biochemically, histologically and by skeletal imaging. The results showed that continuous PTH administration increased alkaline phosphatase positive area, osteoblast numbers and osteoclast numbers in cortical bone in all three genotypes. This increased turnover was associated with increased cortical porosity and loss of cortical bone volume and by a decrease in femoral bone mineral density (BMD). Relative to effects in PTH^{-/-} mice, however, PTH^{-/-}CaSR^{-/-} mice displayed reduced PTH-stimulated bone turnover in cortical bone, less marked PTH-induced reductions of cortical bone volume, decreased PTH-induced increases in cortical porosity and reduced PTH-induced reductions in femoral BMD. *Ex vivo* and *in vitro* studies demonstrated reductions of PTH-stimulated receptor activator of nuclear factor kappa B ligand (RANKL) and tartrate resistant acid phosphatase (TRACP) expression, and *in vitro* studies demonstrated reductions in PTH-stimulated osteoclastogenesis. In trabecular bone, continuous PTH also induced increased bone turnover, but this was associated with increases in trabecular bone volume and trabecular number. In PTH^{-/-}CaSR^{-/-} mice, PTH-stimulated bone turnover in trabecular bone was significantly lower and PTH-induced increases in genetic markers of osteoblast activity i.e., expression of the transcription factor Runx2 and of Nkx2, a marker of Wnt activity, were lower than in PTH^{-/-} mice. These studies show that following PTH infusion, genetic deletion of CaSR substantially impaired PTH-induced bone turnover, and bone loss in cortical bone, while also modestly impeding PTH-induced bone turnover and osteoblastic stimulation in trabecular bone. These results are consistent with a role for CaSR in differentially modulating both PTH-induced resorption and PTH-induced formation in discrete skeletal compartments.

Mammary-Specific Ablation of the Calcium-Sensing Receptor Gene Results in Alterations in Systemic Calcium Metabolism and Breast Calcium Transport During Lactation. Ramanaiah Mamillapalli¹, Joshua VanHouten², Pamela Dann², Laleh Ardeshirpour¹, Wenhan Chang³, Dolores Shoback⁴, Daniel Bikle⁵, John Wysolmerski². ¹Yale University, USA, ²Yale University School of Medicine, USA, ³University of California, San Francisco, USA, ⁴VA Medical Center, USA, ⁵Endocrine Research Unit, Division of Endocrinology UCSF, USA

The calcium-sensing receptor (CaSR) is expressed on mammary epithelial cells (MECs) during lactation. Pharmacological data suggested that activation of the CaSR on MECs inhibits the secretion of PTHrP into milk and the circulation, but stimulates the transport of calcium into milk. Global deletion of the CaSR results in severe hypercalcemia and early death. Therefore, in order to provide genetic support for the functions of the mammary gland CaSR, we ablated the CaSR gene specifically in MECs. Mice bearing a floxed CaSR gene (CaSR^{lox/lox}) were bred to mice expressing Cre recombinase driven by a milk protein gene (beta-lactoglobulin) promoter (BLG-Cre). In BLG-Cre/CaSR^{lox/lox} mice, the CaSR gene is disrupted only in MECs and only at the end of pregnancy. Deletion of the CaSR did not affect mammary alveolar development and BLG-Cre/CaSR^{lox/lox} mice lactated normally. Mammary CaSR mRNA levels were reduced from 60 to 95 percent in lactating BLG-Cre/CaSR^{lox/lox} mice. As expected, loss of the CaSR resulted in elevated levels of mammary gland PTHrP mRNA and milk PTHrP concentrations. Loss of the mammary CaSR also led to a reduction in milk calcium concentrations. Lactational bone loss by PIXImus was not accelerated in BLG-Cre/CaSR^{lox/lox} mice, but on microCT measurements, mineral density was decreased although bone volume was not. Loss of the mammary CaSR led to transient hypercalcemia. On day 2 of lactation, mean calcium levels in BLG-Cre/CaSR^{lox/lox} mice were 13.80.6 as compared to 10.70.3 in controls. However, on day 9 of lactation, circulating calcium concentrations were the same in each group. In contrast on day 9, urinary calcium excretion was 5 times higher in BLG-Cre/CaSR^{lox/lox} mice as compared to controls.

Since other sites of CaSR expression remain intact in these mice, the transient nature of the hypercalcemia is likely due to stimulation of the renal CaSR and compensatory hypercalciuria. These data demonstrate that the mammary CaSR regulates systemic calcium metabolism and calcium transport in MECs during lactation.

Skeletal Mineralization Defect of FGF23 Deficient Mice Is Mediated by Increased Osteopontin. Quan Yuan¹, Yan Jiang², Tadatoshi Sato¹, Reinhold Erben³, Beate Lanske¹. ¹Harvard School of Dental Medicine, USA, ²Peoples Republic of China, ³University of Veterinary Medicine, Austria

Excessive FGF23 has been identified as the pivotal phosphaturic factor leading to renal phosphate wasting, and the subsequent development of rickets and osteomalacia through impaired osteoblastic mineralization. Interestingly, Fgf23-ablated (Fgf23^{-/-}) mice also exhibit a skeletal phenotype characterized by a severe mineralization defect. The reason for this abnormality is largely unknown. Through *in situ* hybridization and immunohistochemical staining, we found that expression of osteopontin (Opn), an inhibitor of bone mineralization, was markedly increased in Fgf23^{-/-} bones. These results were confirmed by qPCR analyses of the cortical bone and ELISA measurement of serum Opn. To investigate whether the elevated levels of Opn are contributing to the bone mineralization defect of Fgf23^{-/-} mice, we generated Fgf23^{-/-}Opn^{-/-} double knockout mice (DKO), and compared their phenotype to the one of wild-type (WT), Fgf23^{-/-} and Opn^{-/-} single knockout mice. Biochemical analyses showed that the hypercalcemia and hyperphosphatemia observed in Fgf23^{-/-} mice remained unchanged in the DKO mice. However, additional ablation of Opn in Fgf23^{-/-} mice resulted in larger, heavier, and more active DKO mice when compared to Fgf23^{-/-} littermates. The length and radiopacity of the femora in the DKO mice were significantly increased. MicroCT analyses of femurs showed that cancellous bone volume in Fgf23^{-/-} mice was reduced compared with WT and Opn^{-/-} mice, but restored to the values found in Opn^{-/-} mice in DKO mice. Deletion of Opn also improved femoral trabecular number, trabecular thickness, and cortical thickness in Fgf23^{-/-} mice. In addition, the elevated serum CTX levels found in Fgf23^{-/-} mice were normalized in compound mutants. Opn^{-/-} mice showed lower CTX levels compared to those of WT. In summary, our results suggest that increased osteoblastic Opn expression is an important pathogenetic factor mediating the mineralization defect and the alterations in bone metabolism observed in Fgf23^{-/-} bones.

Age, Bone Mineral Density, and Spine Fracture Status for Predicting Fracture Risk. John Krege¹, Xiaohai Wan¹, Brian Lentle², Claudie Berger³, Lisa Langsetmo⁴, Jonathan Adachi⁵, Jerilynn Prior², Alan Tenenhouse³, Jacques Brown⁶, Nancy Kreiger⁷, Wojciech P. Olszynski⁸, Robert Josse⁹, David Goltzman¹⁰, CaMos Research Group¹⁰. ¹Eli Lilly & Company, USA, ²University of British Columbia, Canada, ³McGill University, Canada, ⁴Canadian Multicenter Osteoporosis Study, Canada, ⁵St. Joseph's Hospital, Canada, ⁶Laval University, Canada, ⁷University of Toronto, Canada, ⁸University of Saskatchewan, Canada, ⁹St. Michael's Hospital, University of Toronto, Canada, ¹⁰McGill University Health Centre, Canada

Using data from 2761 subjects from the Canadian Multicentre Osteoporosis Study (CaMos), we previously reported that the most predictive risk factors for incident fracture were age, BMD, and spine fracture status. A model considering these risk factors captured almost all of the predictive information provided by other models that included additional risk factors. The objective was to validate the previous analysis using data from subjects (1447 women, 517 men) whose spine radiograph assessments were not complete and were excluded from the previous analyses. CaMos is a prospective study following a randomly selected, population-based community cohort of non-institutionalized men and women. Prevalent and incident spine fractures were assessed by quantitative morphometry of lateral spine radiographs at baseline and 5 years. Incident nonvertebral fractures were determined by an annual, mailed questionnaire with validation; fragility fracture was defined as a fracture with minimal trauma, i.e. fall from a standing height or without trauma. The endpoint was 5-year risk of an osteoporotic fracture defined as morphometric vertebral fracture and/or a nonvertebral fragility fracture. The results in these 1964 subjects were similar to the published results for the 2761 subjects. A logistic regression model including age, femoral neck BMD, and spine fracture status (yes/no) revealed a gradient of risk/SD (GR/SD) of 1.88. This model captured almost all of the predictive information provided by a model with spine fracture status plus the WHO risk factors (GR/SD 1.92) and provided greater predictive information than a model considering the WHO risk factors alone (GR/SD 1.74). The five-year risk of incident fragility fracture in the women based on age, femoral neck T-score, and spine fracture status is shown (Table). Fracture risk was markedly impacted by spine fracture status at all ages and BMD, including those with younger age and higher BMD. We repeated all analyses for the overall population (N = 4725) and the results were very similar. The data confirm that morphometric spine fracture status along with age and BMD predicted

future fracture risk with greater simplicity and higher prognostic accuracy than consideration of more complex models including the WHO risk factors. Spine fracture status provides useful prognostic information regarding future fracture risk and an assessment of spine fracture status should be performed in patients at risk.

Recency and Duration of Glucocorticoid Use and Fracture Prediction: The Manitoba BMD Cohort. William Leslie^{*1}, Sumit Majumdar², Suzanne Morin³, Colleen Metge¹, Lisa Lix⁴. ¹University of Manitoba, Canada, ²University of Alberta, Canada, ³McGill University Health Centre, Canada, ⁴University of Saskatchewan, Canada

BACKGROUND: Glucocorticoid (GC) use, conventionally defined as any history of exposure to supra-physiologic doses for 90-days or more, is a major risk factor for osteoporosis and fracture and is included in the WHO fracture risk assessment (FRAX) algorithm. FRAX does not, however, distinguish between recent (versus remote) exposure or short-duration (versus prolonged) GC use, and such distinctions may be clinically important. **METHODS:** We identified all adults over age 40-years with baseline femoral neck (FN) DXA testing between April 1998 and March 2007 within a comprehensive clinical BMD database for Manitoba, Canada. Using linkages to a province-wide pharmacy network, we identified total dose (based on GC dispensed before BMD testing in the last 12-months and cumulatively since 1995) and stratified this by timing ("recent" if last 12-months versus "remote" if earlier) and duration (short [<90 days] versus prolonged [≥ 90 days]). Other relevant covariates, osteoporosis medications, and major fractures to March 2010 were obtained from a population-based administrative health data repository. Multivariable adjusted least squares mean (LSM) FN T-score was estimated according to patterns of GC use with ANCOVA. Time to fracture was estimated according to patterns of GC use after multivariable (including FN T-score) adjustment using Cox proportional hazards models. **RESULTS:** Among 52,070 subjects included in the analysis, prior GC was identified in 12,818 (see Table). GC users were slightly younger than nonusers (mean age 63 vs 64, $p < .001$) and more likely to be men (14% vs 6%, $p < .001$). Only recent GC use for ≥ 90 days was associated with a significant reduction in FN T-score (LSM -0.07 versus non-use, $p < .001$). Major osteoporotic fractures occurred in N=2,842 (566 hip fractures) subjects. Recent (but not remote) GC users were more likely to sustain major osteoporotic fracture than non-users (6.5% vs 5.3%, $p < .001$) or hip fractures (1.5% vs 1.0%, $p = .001$). Recent GC use ≥ 90 days showed a significant BMD-independent increase in major osteoporotic fracture risk (adjusted HR 1.25, $p = 0.003$) and hip fracture risk (adjusted HR 1.61, $p = 0.003$). Non-significant trends were seen for remote exposure and short duration GC use. **CONCLUSIONS:** We confirmed that prior GC use is a risk factor for reduced FN BMD and osteoporotic fractures. The largest and most consistent effect, however, was seen with recent and prolonged GC use. These findings may inform risk-prediction and permit physicians to take a more precise and useful GC history.

GC Use	N	LSM (95% CI)	HR (95% CI)	HR (95% CI)
		FN T-score	Major #	Hip #
Recent use <90 days	2644	+0.01 (-0.01 to +0.03)	1.16 (0.97-1.38)	1.26 (0.87-1.83)
Recent use ≥ 90 days	2896	-0.07 (-0.09 to -0.05)	1.25 (1.07-1.45)	1.61 (1.18-2.2.0)
Remote use <90 days	6453	+0.06 (+0.05 to +0.08)	1.14 (1.00-1.29)	0.98 (0.72-1.32)
Remote use ≥ 90 days	825	-0.01 (-0.04 to +0.01)	1.29 (0.99-1.69)	1.05 (0.54-2.03)

Bolded results are statistically significant. LSM=least squares mean (ANCOVA), HR=hazard ratio (Cox survival model). All results adjusted for sex, age, BMI, prior fracture, RA, COPD, substance abuse diagnosis, osteoporosis treatment. HRs also adjusted for FN T-score.

Table: Effect of prior GC use versus non-use on FN T-score and fracture outcomes.

Low Bone Turnover and Abnormal Collagen Crosslinking in Women with Atraumatic Fractures and Near- Normal BMD: A Disease Entity Different from Post-Menopausal Osteoporosis. Hartmut Malluche^{*1}, Daniel Porter², Marie-Claude Faugere¹, Hanna Mawad³, David Pienkowski². ¹University of Kentucky Medical Center, USA, ²University of Kentucky, USA, ³University of Kentucky, Division of Nephrology Bone & Mineral Metabolism, USA

Osteoporotic fractures normally occur with minimal or no-trauma and are associated with low bone mineral density (BMD); however, atraumatic fractures may also occur with near-normal BMD. This study addresses potential abnormalities in bone quality associated with atraumatic fractures in women who are non-osteoporotic by BMD criteria. Anterior iliac crest bone samples were obtained from 19 pre- or perimenopausal untreated Caucasian women with nonosteoporotic t-scores in this IRB approved study. Ten of these women sustained one or more low-trauma bone fractures. The other nine women were normal volunteers (no fractures, normal BMD). BMD was measured by DEXA. Fourier transform infrared (FTIR) spectroscopy and histomorphometry (static and dynamic bone parameters) were employed to quantify the material, microstructural, and turnover characteristics. Cancellous bone volume was in the normal range and not different between the groups. Lumbar t-scores were not different between the groups, while hip t-scores were greater in the fracture group vs. normal controls (Table). Bone turnover in the fracture group was lower, as shown by 66% lower activation frequency and 85% lower osteoblast numbers/bone perimeter. Additionally, women in the atraumatic fracture group had 10% more enzymatic collagen crosslinking. No differences were detected in the other measured parameters. The greater hip t-scores in the fracture group, compared to the non-fracture controls, demonstrate the limitations of BMD as a general metric of fracture resistance. The obvious explanation for this limitation is that neither bone turnover nor collagen crosslinking can be evaluated by BMD. Prior studies linked crosslinking abnormalities to decreased bone strength (1) and low bone turnover to increased fracture risk (2). The present findings agree with prior studies that showed either matrix (3) or turnover (4) abnormalities in women with atraumatic fractures. This study is novel in reporting both abnormalities concurrently. The data indicate that occurrence of atraumatic fractures in women with normal or near-normal BMD might be a different disease entity than what is conventionally considered "post-menopausal osteoporosis". 1. Is the Ability of FRAX to Predict Fractures Comparable in Obese and Non-obese Postmenopausal Women? Melissa Premaor^{*1}, Richard Parker², Li-Yung Lui³, Teresa Hillier⁴, Kristine Ensrud⁵, Jane Cauley⁶, Juliet Compston⁷. ¹Federal University of Santa Maria, Brazil, ²Department of Public Health & Primary Care, Institute of Public Health, University of Cambridge, United Kingdom, ³California Pacific Medical Center Research Institute, USA, ⁴Center for Health Research, Kaiser Permanente Northwest/Hawaii, USA, ⁵Minneapolis VA Medical Center / University of Minnesota, USA, ⁶University of Pittsburgh Graduate School of Public Health, USA, ⁷University of Cambridge School of Clinical Medicine, United Kingdom

There is increasing evidence that low trauma fractures in obese postmenopausal women contribute significantly to the overall fracture burden. FRAX-generated fracture probabilities in obese women are likely to be lower than in non-obese women because of higher bone mineral density (BMD) and body mass index (BMI); in addition, clinical risk factors for fracture in obese women may differ from those in the non-obese population. We compared the ability of FRAX to predict fractures in obese (BMI ≥ 30 kg/m²) and non-obese (BMI < 30 kg/m²) women in the Study of Osteoporotic Fractures (SOF) cohort. SOF is a prospective population-based study of 9704 Caucasian older postmenopausal women followed up for a mean(SD) of 12.8 (5.4) years. As FRAX generates 10-year probabilities, the follow-up was truncated to ten years. Data for FRAX clinical risk factors and femoral neck BMD were available in 6252 women. Incident fracture outcomes included hip fracture, major osteoporotic fracture (hip, clinical vertebral, wrist, or humerus), and any clinical fracture. Fracture probability was estimated using FRAX. Receiver operating characteristic (ROC) curve analysis was used to compare fracture prediction in obese and non-obese women.

18.5% women in the cohort were obese. Incident clinical fractures occurred during the follow-up period in 26.9% and 32.7% of obese and non-obese women respectively. FRAX-derived probabilities in women with incident hip and major osteoporotic fractures were significantly lower in obese than in non-obese women (without BMD; 5.8 vs 11.4% for hip and 17.6 vs 23.6% for major osteoporotic fracture $p < 0.0001$); with BMD: 7.1 vs 10.9% for hip and 18.2 vs 23.3% for major osteoporotic fracture $p < 0.0001$). ROC analysis showed no significant differences in the ability of FRAX models without or with BMD to predict fractures in obese and non-obese women (Table 1). In conclusion, FRAX-derived probabilities for both hip and major osteoporotic fractures are significantly lower in obese women than in non-obese women. The ability of FRAX to predict fracture in obese postmenopausal women is similar to that in non-obese women, although its relatively poor performance for non-vertebral fractures indicates that addition of unmeasured risk factors may improve prediction. Addition of BMD to FRAX risk factors enhanced hip fracture prediction more in obese than non-obese women, probably reflecting the differing effect on fracture probability of BMI in the model with and without BMD.

Table 1 Comparison of the area under the curve [AUC (95% CI)] from receiver operating characteristic curve (ROC) for the FRAX algorithm between obese and non-obese women

	Body mass index < 30 kg/m ²	Body mass index ≥ 30 kg/m ²	p
FRAX algorithm not including BMD			
Women with hip fractures	0.689 (0.665, 0.714)	0.656 (0.587, 0.725)	0.19
Women with major osteoporotic fracture (hip, clinical vertebral, wrist, and humerus)	0.630 (0.610, 0.650)	0.633 (0.587, 0.679)	0.13
Women with any clinical fracture (non-vertebral and clinical vertebral)	0.603 (0.586, 0.620)	0.586 (0.547, 0.624)	0.21
FRAX algorithm including BMD			
Women with hip fractures	0.734 (0.711, 0.757)	0.755 (0.698, 0.812)	0.48
Women with major osteoporotic fracture (hip, clinical vertebral, wrist, and humerus)	0.675 (0.656, 0.695)	0.696 (0.655, 0.737)	0.18

Baseline BMD T-score and Time to Fracture in Older Women: the Study of Osteoporotic Fractures. Margaret Gourlay^{*1}, Jason P. Fine¹, Chenxi Li¹, John S. Preisser¹, Ryan C. May¹, Li-Yung Lui², Kristine Ensrud³. ¹University of North Carolina, USA, ²California Pacific Medical Center Research Institute, USA, ³Minneapolis VA Medical Center / University of Minnesota, USA

Lower BMD predicts increased fracture risk, but the time to fracture has not been determined for different BMD T-score ranges. To estimate the time to hip or clinical vertebral fracture accounting for the competing risk of incident osteoporosis using WHO diagnostic criteria, we conducted competing risks analyses of 4914 women aged 67 years and older without osteoporosis or hip or clinical vertebral fracture at the Year 2 SOF Exam (baseline). Participants had DXA BMD measurements at the femoral neck and total hip at 2 to 5 visits in up to 15 years of follow-up. We estimated the time during which 2% of women suffered a hip or clinical vertebral fracture for

four baseline T-score ranges: normal BMD (T-score ≥ -1.00); mild (T-score -1.01 to -1.49), moderate (T-score -1.50 to -1.99) or advanced (T-score ≤ -2.00 to ≤ -2.49) osteopenia. Parametric cumulative incidence curves for the time to hip or clinical vertebral fracture were estimated from log logistic cumulative incidence models for interval censored data adjusting for age, BMI, estrogen use, any fracture after age 50, current smoking, oral glucocorticoid use and self-reported rheumatoid arthritis. Participants were censored for use of bisphosphonates, calcitonin or raloxifene, death or termination of study participation. Transitions from normal BMD (n=1252 women) and osteopenia (n=4163 women) were analyzed separately; 501 women who transitioned from normal BMD to osteopenia prior to incident osteoporosis, treatment, or hip or clinical vertebral fracture contributed to both analyses. Adjusting for covariates, estimated times for 2% of women to transition to hip or clinical vertebral fracture were: normal BMD, 22.21 years; mild osteopenia, 14.26 years; moderate osteopenia, 5.24 years; advanced osteopenia, 5.21 years (table). For women with baseline osteopenia, T-score group, age, BMI, any fracture after age 50, rheumatoid arthritis, and the interaction of age by rheumatoid arthritis were significant predictors of time to incident hip or clinical vertebral fracture (all $P < 0.04$). These results suggest that older women with normal BMD or mild osteopenia are unlikely to sustain hip or clinical vertebral fractures in the subsequent 10 years. However, for older women with moderate or advanced osteopenia at baseline, findings suggest that repeat BMD testing should be deferred no longer than 5 years to identify potential candidates for antifracture therapy before a hip or clinical vertebral fracture occurs.

Baseline T-score range	N	N(%) with incident hip or clinical vertebral fracture	Time between DXA exams for 2% of participants to transition to fracture	
			Unadjusted years (95% CI)	Adjusted* years (95% CI)
Normal BMD (T-score ≥ -1.00)	1252	9 (0.72%)	22.44 (5.60, 89.96)	22.21 (5.67, 87.00)
Mild osteopenia (T-score -1.01 to -1.49)	1369	17 (1.24%)	13.41 (8.05, 22.37)	14.26 (8.65, 23.50)
Moderate osteopenia (T-score -1.50 to -1.99)	1464	53 (3.62%)	4.39 (3.16, 6.08)	5.24 (3.82, 7.19)
Advanced osteopenia (T-score ≤ -2.00 to ≤ -2.49)	1330	46 (3.46%)	4.60 (3.27, 6.47)	5.21 (3.74, 7.26)

* adjusted for age, BMI, current estrogen use, any fracture after age 50 years, current smoking, oral glucocorticoid use, rheumatoid arthritis (N=4047 complete cases). For normal BMD group, time was conservatively estimated for lowest BMD in the normal range, results adjusted for continuous BMD and age only (N=1252 complete cases).

Height Loss Starting in Middle Age Predicts Increased Mortality in Elderly Men and Women. Saeko Fujiwara^{*1}, Naomi Masunari², Fumiyoshi Kasagi³, Toshitaka Nakamura⁴. ¹Radiation Effects Research Foundation, Japan, ²Faculty of Pharmacy, Iwaki Meisei University, Japan, ³Department of Epidemiology, Radiation Effects Research Foundation, Japan, ⁴University of Occupational & Environmental Health, Japan

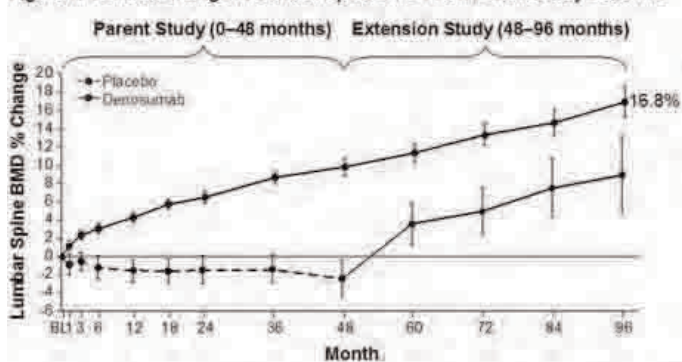

Objective: Our previous report demonstrated that height loss and vertebral deformity significantly and independently affected quality of life (QOL) in the elderly (Osteoporos Int. 2007;18:1493). The objective of this study was to determine mortality risk among Japanese elderly men and women with height loss starting in middle age, taking into account lifestyle and physical factors. **Methods:** From among a population-based community cohort, the Adult Health Study, 2,498 subjects (755 men and 1,743 women) aged 47 to 91 years old were enrolled in a prospective and longitudinal cohort study in Hiroshima, Japan. These individuals underwent physical examinations including BMD measurement as well as a questionnaire during the period 1994-95, and were followed for mortality status through 2003. Mortality risk was estimated using an age-stratified Cox proportional hazards model. In addition to sex, radiation dose, lifestyle and physical factors such as smoking status, alcohol intake, total cholesterol, blood pressure, and diagnosed diseases were included as adjustment factors for analysis of total mortality and mortality from each cause of death. **Results:** There were a total of 302 all-cause deaths, 46 coronary heart disease and stroke deaths, 58 respiratory deaths including 45 pneumonia deaths, and 132 cancer deaths during the follow-up period. Participants were followed for 20,787 person-years after baseline. Prevalent vertebral deformity and hip fracture were not associated with mortality risk. However, at least 2 cm of height loss starting in middle age showed significant association with all-cause mortality among the study participants (HR=1.76, 95% CI 1.31-2.38, $p=0.0002$), after adjustment was made for sex, atomic-bomb radiation exposure, and lifestyle and physical factors. Such a level of height loss was also significantly associated with coronary heart disease- and stroke-caused death (HR=3.35, 95% CI 1.63-6.86, $p=0.0010$) as well as respiratory-disease death (HR=2.52, 95% CI 1.25-5.22, $p=0.0130$), but not cancer death. **Conclusions:** Height loss starting in middle age predicted coronary heart disease- and stroke-caused death as well as respiratory-disease death although prevalent vertebral deformity was not associated with mortality risk.

Effects of Denosumab on Bone Mineral Density and Biochemical Markers of Bone Turnover: 8-Year Results of a Phase 2 Clinical Trial. Michael McClung¹, E. Michael Lewiecki², Michael A. Bolognese³, Munro Peacock⁴, Richard Weinstein⁵, Beiyang Ding⁶, Michelle L. Geller⁷, Andreas Grauer⁶, Rachel B. Wagman⁶, Paul Miller⁸. ¹Oregon Osteoporosis Center, USA, ²New Mexico Clinical Research & Osteoporosis Center, USA, ³Bethesda Health Research Center, USA, ⁴Indiana University Medical Center, USA, ⁵Diablo Clinical Research, Inc., USA, ⁶Amgen Inc., USA, ⁷Amgen Inc. & University of California Los Angeles, USA, ⁸Colorado Center for Bone Research, USA

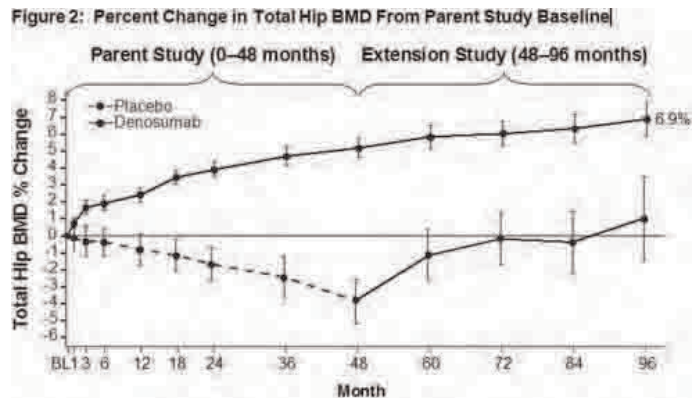

Denosumab (DmAb) is a fully human monoclonal antibody that inhibits RANKL, reduces bone resorption by osteoclasts, and reduces the risk of new vertebral, hip, and nonvertebral fractures at 3 years compared with placebo (Cummings *NEJM* 2009). With its unique mechanism of action, long-term experience with DmAb therapy is of clinical interest. Here we present the effects of 8 years of DmAb treatment on bone mineral density (BMD) and bone turnover markers (BTM) in a phase 2 study. In the phase 2 parent study, postmenopausal women with a BMD T-score between -1.8 and -4.0 (lumbar spine) and/or -1.8 and -3.5 (total hip or femoral neck) were randomized to receive placebo, alendronate (ALN), or 1 of 7 different doses of DmAb. After 2 years on study, subjects were reallocated to maintain, discontinue, or discontinue and reinitiate DmAb; discontinue ALN; or maintain placebo for an additional 2 years (Miller *Bone* 2008). In the extension phase of this study, all subjects received open-label DmAb 60 mg every 6 months (Q6M). Here our results focus on subjects who received DmAb treatment for 8 years and those who received placebo for 4 years followed by DmAb for 4 years. Of the 262 subjects who completed the parent study, 200 enrolled in the extension study and of these, 116 (58%) had completed the 4-year extension study at the time of the submission. For the 80 subjects who received 8 years of DmAb treatment, BMD at the lumbar spine and total hip increased on average by 16.8% and 6.9%, respectively, compared with their parent study baseline (Figures 1 and 2). For the 11 subjects in the previous placebo cohort, 4 years of DmAb treatment resulted in gains in BMD comparable with those observed during the first 4 years of 60 mg Q6M in the parent study. Reductions in CTX and BSAP were sustained over the course of continuous DmAb treatment. Reductions in these BTMs also were observed when the placebo group transitioned to DmAb treatment. The adverse event profile was overall similar to what has been reported previously. These data demonstrated that DmAb treatment for up to 8 years was associated with continued gains in BMD and persistent reduction in markers of bone turnover, and was well tolerated.

Effects of Denosumab on Radius BMD, Strength, and Wrist Fractures: Results From the Fracture Reduction Evaluation of Denosumab in Osteoporosis Every 6 Months (FREEDOM) Study. J Simon¹, C Recknor², A Moffet³, J Adachi⁴, E Franek⁵, EM Lewiecki⁶, CA Mautalen⁷, S Ragi⁸, GC Nicholson⁹, C Muschitz¹⁰, R Nuti¹¹, O T'Jerring¹², A Wang¹³, C Libanati¹³. ¹George Washington University, USA, ²United Osteoporosis Centers, USA, ³OB-GYN Associates of Mid Florida, USA, ⁴St. Joseph's Hospital, McMaster University, Canada, ⁵Central Clinical Hospital MSWiA, Poland, ⁶New Mexico Clinical Research & Osteoporosis Center & University of New Mexico School of Medicine, USA, ⁷Centro de Osteopatias Medicas, Argentina, ⁸CEDOES Centro de Diagnostico e Pesquisa, Brazil, ⁹Barwon Health, The Geelong Hospital, Australia, ¹⁰St. Vincent Hospital, Austria, ¹¹University of Siena, Italy, ¹²Karolinska Institutet Sodersjukhuset, Sweden, ¹³Amgen Inc., USA

Purpose: Denosumab (DmAb) is an approved therapy for postmenopausal women with osteoporosis at increased risk of fracture. DmAb increases cortical bone mineral density (BMD) and thickness, and reduces cortical porosity, contributing to improved bone strength. Here, we report the effects of DmAb in cortical and trabecular bone at the radius using DXA and QCT scans, and the wrist fracture reduction observed in the FREEDOM study.

Methods: Women received placebo (Pbo) or 60 mg DmAb every 6 months for 3 years. BMD, bone mineral content (BMC), and polar moment of inertia (PMI, a measure of bone strength) at the radius were assessed in a DXA substudy (N=209 Pbo, N=232 DmAb) or QCT substudy (N=79 Pbo, N=103 DmAb) at baseline and months 12, 24, and 36. The incidence of wrist fractures was evaluated for all FREEDOM subjects (N=3906 Pbo, N=3902 DmAb) and in a higher-risk subgroup for nonvertebral fractures (baseline femoral neck BMD T-score ≤ -2.5 ; N=1406 Pbo, N=1384 DmAb).

Results: DmAb significantly increased DXA BMD at all radius regions of interest (1/3, ultradistal, and total radius; Table) at 12, 24, and 36 months compared with Pbo and baseline (all $p < 0.05$). QCT BMD changes were consistent with DXA results. DmAb also significantly improved BMC and PMI compared with Pbo and baseline (proximal, distal, and ultradistal; all $p < 0.05$). At 36 months, all measurements decreased significantly from baseline in Pbo subjects (all $p < 0.05$). For the entire study population, the incidence of wrist fractures was 2.9% and 2.5% for the Pbo and DmAb subjects, respectively (hazard ratio: 0.84, $p = 0.21$). In the higher-risk subgroup, DmAb significantly reduced the relative risk by 40% (absolute risk reduction 1.6%; $p = 0.03$; Figure). The wrist fracture reduction could not be explained by fewer subjects reporting falls (7.4% Pbo, 7.2% DmAb; $p = 0.73$). Wrist fracture incidence in DmAb subjects at higher risk for fracture (baseline femoral neck BMD T-score ≤ -2.5) was similar to Pbo subjects with lower risk (baseline BMD femoral neck T-score > -2.5).

Conclusion: DmAb significantly improved DXA BMD and QCT BMD, BMC, and calculated strength compared with baseline and Pbo along the radius. In higher risk women, DmAb treatment significantly reduced the incidence of wrist fractures to the level observed in women with lower risk. The positive effects of DmAb on the cortical compartment may explain the beneficial wrist fracture outcomes in women at higher risk for nonvertebral fractures.

Efficacy of Five Years of Denosumab: A Novel "Virtual Twins" Method for Minimizing Bias in Extensions of Trials. Steven Cummings¹, Nadia Daizadeh², Eric Vittinghoff³, Cesar Libanati², Jacques P Brown⁴, Christian Roux⁵, Matthew Austin², Andreas Grauer², Socrates Papapoulos⁶, Henry G Bone⁷. ¹San Francisco Coordinating Center, USA, ²Amgen Inc., USA, ³University of California, San Francisco, USA, ⁴CHUC-CHUL Research Centre, Laval University, Canada, ⁵Paris Descartes University, France, ⁶Leiden University Medical Center, Netherlands, ⁷Michigan Bone & Mineral Clinic, USA

Purpose: In the 3 year FREEDOM trial, denosumab reduced the risk of new vertebral, hip, and nonvertebral fractures by 68%, 40%, and 20%, respectively (Cummings, NEJM, 2009). FREEDOM was extended to continue the evaluation of fracture rates with long-term denosumab treatment. However, only a self-selected portion of participants in FREEDOM continued into the extension and there is no equivalent placebo control group. To provide a reference group for the observed fracture rates during the extension, we used a novel "virtual twin" simulation method (Vittinghoff, Stat Med, 2010) to estimate expected fracture rates in a cohort of placebo controls with baseline characteristics that are identical to subjects who continued denosumab treatment into the extension.

Methods: During the first 2 years of the extension, all women in the long-term group received 60 mg denosumab every 6 months, reflecting 5 years of continuous denosumab exposure (N=2343). Linear, Poisson, and logistic prediction models were developed using actual FREEDOM data on bone mineral density, fracture history, body mass index, and age for subjects who received placebo during the 3 years of FREEDOM. These models were then used to calculate fracture outcomes for virtual twins of the denosumab-treated women during the extension. Inferences on the differences in fracture rates between long-term denosumab subjects and their virtual twins used bootstrapping.

Results: During FREEDOM, denosumab reduced the risk of new vertebral and nonvertebral fractures during each year of the trial compared with placebo (Figures 1 and 2). In the first 2 years of the extension, the observed fracture rates remained below the estimated fracture rates had the denosumab subjects who enrolled in the extension received placebo ("twins"). During years 4 and 5 of treatment, denosumab significantly reduced the estimated risk of new vertebral fractures by 36% (RR: 0.64; 95% CI: 0.43 to 0.93) and nonvertebral fractures by 51% (RR: 0.49; 95% CI: 0.35 to 0.65) compared with their placebo "twins."

Conclusion: Using a novel method that minimizes bias, the risk of new vertebral and nonvertebral fractures during the 4th and 5th years of continuous denosumab treatment in postmenopausal women with osteoporosis was significantly reduced compared with the estimated placebo rate over the same period.

The Transitory Increase in PTH Following Denosumab Administration is Associated With Reduced Intracortical Porosity: a Distinctive Attribute of Denosumab Therapy. Ego Seeman^{*1}, Cesar Libanati², Matt Austin², Roland Chapurlat³, Steven Boyd⁴, Roger Zebaze¹, David A. Hanley⁴, Jose R. Zanchetta⁵, Andreas Grauer², John P. Bilezikian⁶. ¹Austin Health, University of Melbourne, Australia, ²Amgen Inc., USA, ³INSERM UMR 1033, Université de Lyon, France, ⁴University of Calgary, Canada, ⁵Instituto de Investigaciones Metabolicas, Argentina, ⁶College of Physicians & Surgeons, Columbia University, USA

The benefit of an antiresorptive upon the material composition and structure of bone is largely determined by its direct and indirect effects on the volumes of bone resorbed and deposited by each bone remodeling unit (BMU), and by the number of BMUs inhibited in both the trabecular and cortical compartments. Denosumab (DMAb) rapidly reduces bone resorption by existing BMUs and markedly inhibits the birth rate of new BMUs during the initial months following administration. This acute remodeling reduction is accompanied by a transitory increase in circulating PTH which could increase osteoblast longevity and/or activity. We hypothesized that the direct effect of DMAb on resorption inhibition, and the possible indirect effect on bone formation mediated by an increase in PTH in the face of inhibited osteoclastic activity by the BMU, would reduce cortical porosity in women at risk for fracture.

Postmenopausal women (N=247) with a mean (SD) age of 60.6 (5.4) yrs and low BMD were randomly assigned in a double-blind, double-dummy trial to DMAb 60mg Q6M (N=83), alendronate (ALN) 70mg QW (N=82), or placebo (Pbo; N=82). PTH was measured at baseline (BL), wk 1, and mos 1, 3, 6, 6.25, 7, 9, and 12. An area under the curve (AUC) for PTH was derived from the change from BL for each subject. Porosity was evaluated in the compact-appearing cortex of the distal radius at BL and mo 12 by HR-pQCT. Associations between PTH AUC and change in porosity were evaluated.

Transitory increases in PTH were seen in the DMAb and ALN groups, but not Pbo (Fig 1). The increase in PTH was larger following DMAb than ALN ($P<0.05$) and was observed after each DMAb dose. At the radius by 12 mos, porosity increased in the Pbo group, increased less in the ALN group, and was reduced by DMAb (+5.2%, +2.9%, and -3.0%, respectively). In the Pbo and ALN groups, porosity increased with increasing PTH (Fig 2). With DMAb, porosity decreased as PTH increased. These relationships were maintained after adjusting for BL remodeling.

In conclusion, DMAb partly reverses microarchitectural deterioration; predominantly by directly reducing bone remodeling intensity, but perhaps also indirectly, by transiently increasing PTH, and so positively influencing BMU balance. The results describe a unique mechanism of DMAb action due to its direct effect to fully and rapidly inhibit osteoclastic activity at cortical and trabecular bone, and its indirect effect to increase PTH when osteoclastic resorption is fully inhibited.

Purpose: Denosumab (DMAb) is an approved therapy for the treatment of postmenopausal women with osteoporosis at increased risk for fracture. A favorable DMAb risk/benefit profile was demonstrated in the pivotal, 3-year FREEDOM trial. All women who completed FREEDOM were eligible to participate in an extension to investigate the safety and efficacy of DMAb treatment for up to 10 years. We previously reported that 5 years of DMAb treatment maintained bone turnover reduction, increased BMD, and was associated with low fracture rates. Here, we provide details on the yearly incidence of serious adverse events (SAEs) of infection and adverse events (AEs) of malignancy in FREEDOM and the extension.

Methods: Of the 6478 women who completed FREEDOM, 4550 (70%) enrolled in the extension, during which, all women receive 60 mg DMAb every 6 months and supplemental calcium and vitamin D daily. For the analyses reported here, women from the FREEDOM DMAb group received 2 more years of DMAb for a total of 5 years of exposure (long-term group; N=2343) and women from the FREEDOM placebo group received 2 years of DMAb exposure (cross-over group; N=2207). The analyses of AEs were descriptive and are reported as exposure-adjusted subject incidence rates.

Results: The year-to-year observed subject incidence rates of SAEs of infection (Table 1) and AEs of malignancy (Table 2) in the placebo group exhibited some variation during the 3 years of the FREEDOM trial. The yearly subject incidence rates in the first 2 years of the extension for the long-term and cross-over groups were similar to or lower than the observed yearly rates in the FREEDOM placebo group. This was also the case for individual SAEs of infection (by preferred term) including cellulitis or erysipelas (Table 1) and individual malignancies (by preferred term; Table 2). One case of oral osteomyelitis and one case of bone necrosis in the cross-over group were adjudicated as consistent with ONJ.

Conclusions: The year-to-year observed AE rates in placebo subjects provide a valuable indicator of the expected variation in untreated subjects and assist in the interpretation of safety results associated with therapy. Yearly incidences of SAEs of infection and AEs of malignancies did not increase over 5 years of continuous DMAB treatment of postmenopausal women with osteoporosis. The imbalances in SAEs of skin infections reported in the original FREEDOM study were not observed with DMAB treatment in the extension study.

Table 1. Yearly Incidence of Serious Adverse Events of Infections

		FREEDOM			Extension	
		Year 1 r (n)	Year 2 r (n)	Year 3 r (n)	Year 1 r (n)	Year 2 r (n)

Reduction in Incidence of Vertebral Fractures with Once Yearly Zoledronic Acid in Men with Osteoporosis. Steven Boonen¹, Jean-Marc Kaufman², Jean-Yves Reginster³, Rene Rizzoli⁴, Kurt Lippuner⁵, Dirk Vanderschueren⁶, Josef Hruska⁷, Oscar Antunez⁸, Philemon Papanastasiou⁷, Guoqin Su⁸, Eric Orwoll⁹. ¹Katholieke Universiteit Leuven, Belgium, ²University Hospital of Ghent, Belgium, ³University of Liege, Belgium, ⁴University Hospitals & Faculty of Medicine of Geneva, Switzerland, ⁵Osteoporosis Policlinic, University of Bern, Switzerland, ⁶Leuven University Hospital, Belgium, ⁷Novartis Pharma AG, Switzerland, ⁸Novartis Pharmaceuticals, USA, ⁹Oregon Health & Science University, USA

Introduction

Male osteoporosis and associated fracture risk have not been adequately studied and, to date, therapeutic trials in osteoporotic men have not included fracture endpoints. This 24-month multicentre, randomized, controlled trial investigated the efficacy and safety of annual intravenous zoledronic acid 5 mg (ZOL) in men with osteoporosis.

Methods

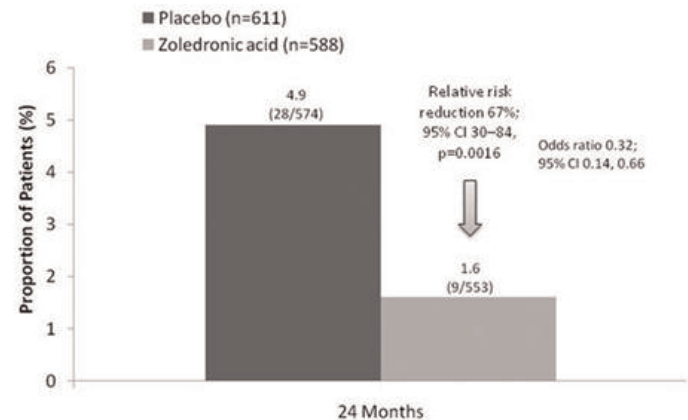

In total, 1199 men (range 50–85 years) with primary osteoporosis, or secondary osteoporosis due to hypogonadism, were randomized to receive once-yearly ZOL as a 15-min intravenous infusion or placebo (PBO). Patients also received daily calcium 1000–1500 mg and vitamin D 800–1200 IU. The primary endpoint was the proportion of patients with ≥ 1 new morphometric vertebral fracture over 24 months. Secondary endpoints included changes in biochemical markers of bone resorption and formation including β-CTX and PINP, change in height, and overall safety.

Results

At baseline, 32.1% of patients had ≥ 1 vertebral fractures. The proportion of patients with ≥ 1 new morphometric vertebral fracture over 24 months was significantly lower in the ZOL group (1.6%), compared with the PBO group (4.9%; odds ratio 0.32; 95% CI 0.14, 0.66 [relative risk reduction 67%; 95% CI 30–84, p=0.0016]) [Graph]. ZOL also reduced moderate–severe fractures by 63% compared with placebo. Over 24 months, ZOL showed significantly lower serum β-CTX and PINP levels relative to PBO (p<0.0001) at all post-baseline timepoints. With these markers, a significant between-treatment difference was achieved at Month 3 and maintained over the 24-month period. Men treated with ZOL for 24 months experienced less height loss than those treated with PBO (LSM –2.34 mm vs –4.49 mm, respectively; p=0.0020). ZOL was generally well-tolerated, with a similar incidence of serious adverse events between groups (ZOL, 25.2%; PBO, 25.3%).

Conclusion

Treatment with ZOL for a period of 24 months reduces the risk of new vertebral fractures in men with osteoporosis. This is the first clear demonstration of the efficacy and safety of bisphosphonate treatment for fracture risk reduction in men with osteoporosis.

Proportion of Patients with New Morphometric Vertebral Fractures at 24 months

PTH Receptor 1 Expression in Osteocytes Is Indispensable for the Anabolic Effect of Mechanical Loading in Mice. Xiaolin Tu^{*1}, Gretel Pellegrini², Carlo Galli³, Jeffrey Benson¹, Keith Condon¹, Nicoletta Bivi⁴, Lilian Plotkin¹, Alexander Robling⁴, Teresita Bellido¹. ¹Indiana University School of Medicine, USA, ²seccion osteopatias medicas, Hospital de Clínicas Jose de San Marti, Argentina, ³Universita Degli Studi Di Parma, Italy, ⁴Indiana University, USA

Osteocytes play an essential role in skeletal homeostasis by integrating the responses of bone to mechanical and hormonal stimuli. Both mechanical loading and activation of the PTH receptor 1 (PTH1R) in osteocytes promote new bone formation by downregulating the expression of sclerostin, the inhibitor of bone formation secreted by osteocytes, and thereby activating the Wnt pathway. To explore a potential crosstalk between PTH1R signaling and mechanotransduction, we examined the osteogenic response to loading of mice lacking the PTH1R specifically in osteocytes (cKO). Mice were generated by crossing PTH1R^{fl/fl} mice, in which the E1 exon of the PTH1R is flanked by loxP sites, with DMP1-8kb-Cre mice, which express Cre recombinase in osteocytes but not in osteoblasts. PTH1R mRNA was reduced in all bones examined, in particular by 73% in long bones of cKO mice compared to control PTH1R^{fl/fl} littermates. Female, 4 month-old cKO mice exhibited no significant changes in ulnae geometry or in material density. However, ex vivo loading induced 20% higher strains in cKO mice (1541.7µε/N) compared to controls (1229.1µε/N), indicating less resistance of cKO bones to mechanical force. Right ulnae from control and cKO mice were loaded at equal strains of low, medium, and high magnitude during 1min/day for 3 consecutive days and sacrificed 14 days later; left ulnae were non-loaded controls. Dynamic histomorphometric analysis revealed that basal periosteal bone formation rate (BFR) was similar in control and cKO mice. Loading caused a strain-dependent increase in BFR in controls (0.130.06; 0.180.13; and 0.380.15 µm³/µm²/day), resulting from an increase in both mineralizing surface covered by osteoblasts (MS/BS) as well as activity of individual osteoblasts (MAR). In contrast, loading-induced BFR was dramatically reduced in cKO mice by 23%, 44%, and 71% (0.100.05, 0.100.05, and 0.110.08 µm³/µm²/day) with minimal but significant changes induced only by medium and high strains. This effect resulted mainly from the lack of stimulation of MAR by loading at any strain magnitude. Loading-induced MS/BS was also reduced in the cKO mice, with significant increases induced only by medium and high strains. We conclude that signaling downstream of the PTH1R in osteocytes is required for the osteogenic response induced by mechanical force.

β-catenin Haploinsufficiency in Osteocytes Abolishes the Osteogenic Effect of Mechanical Loading In Vivo. Behzad Javaheri^{*1}, Mark Dallas¹, Hong Zhao¹, Lynda Bonewald¹, Mark Johnson². ¹University of Missouri - Kansas City, USA, ²University of Missouri, Kansas City Dental School, USA

Targeted deletion of β-catenin in osteoblasts and osteocytes results in a severely compromised and fragile skeleton. We have also shown that β-catenin signaling is activated by mechanical loading. To determine whether β-catenin signaling is required for the anabolic bone formation response to mechanical loading we used an osteocyte conditional knockout approach. As loading of the osteocyte β-catenin homozygous knockout was not possible due to the fragile skeleton and premature death of these mice, our approach was to conditionally delete a single allele of β-catenin in osteocytes by crossing β-catenin fl/fl mice with Dmp1-Cre mice. The haploinsufficient heterozygous mice have a modest reduction in bone mass and are perfectly viable. We examined load-induced new bone formation in these heterozygous mice compared to fl/fl littermates.

The right ulnae of 15 week-old female β-catenin osteocyte heterozygous knockout mice (n=3) (HET cKO) or β-catenin fl/fl controls (WT) (n=3) were subjected to in vivo loading on 3 days per week for 3 weeks (100 cycles, 2N, 2500µε). The left ulnae of these mice served as the non-loaded controls. Bone responses to loading were determined by dynamic histomorphometry, following calcein (5mg/kg) and alizarin complexone dihydrate (20mg/kg) injections on 10 and 3d prior to sacrifice, respectively. Right and left ulnae were analyzed by µCT and histomorphometry. The loaded right ulnae of the fl/fl control mice showed a 7.4% increase in cortical thickness compared to the unloaded left ulnae (p<0.05). In contrast, no increase in thickness was detected in the HET cKO mice. Histomorphometric analysis of the comparable region is shown in Table 1. There was a significant increase in endocortical (Ec) and periosteum (Ps) MAR and BFR/BS, BFR/BV and BFR/TV in WT mice (p<0.05). In contrast no significant increase was detected in HET cKO mice.

These data indicate that deleting a single copy of β-catenin in osteocytes is sufficient to inhibit new bone formation in response to anabolic levels of mechanical loading. This provides compelling evidence for a requirement for β-catenin signaling in regulating new bone formation in response to loading and suggests that a critical threshold level of β-catenin is needed for this response.

Treatment with Sclerostin Antibody Increases Bone Mass and Strength During Hindlimb Unloading. Jordan Spatz^{*1}, R Ellman¹, AM Cloutier², D Dwyer³, Marina Stolina⁴, HZ. Ke³, Mary Boussein⁵. ¹Harvard-MIT Division of Health Sciences & Technology (HST), USA, ²Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, USA, ³Amgen Inc., USA, ⁴Amgen Inc, USA, ⁵Beth Israel Deaconess Medical Center, USA

Sclerostin, a protein made by osteocytes, inhibits bone formation and plays a key role in mechanotransduction. We tested the ability of an anti-sclerostin antibody (Scl-AbIII) to prevent bone loss in adult female mice (C57Bl/6J, 12 wks of age) subjected to hindlimb unloading (HLU) for 21 days. Mice were assigned to one of four groups (n=8/group): 1) control, fully loaded + vehicle (CON-VEH), 2) control + Scl-AbIII (CON-SclAbIII), 3) HLU + vehicle (HLU-VEH), and 4) HLU + Scl-AbIII (HLU-SclAbIII). Mice were injected subcutaneously with either Scl-AbIII (25 mg/kg) or vehicle twice weekly. Scl-AbIII completely inhibited the trabecular and cortical bone deterioration due to disuse, with bone properties in HLU-SclAbIII being at or above values of fully loaded, VEH mice. Total body BMD decreased -5.3 2.8% in HLU-VEH, whereas it increased 4.4 2.8%, 16.3 4.8% and 30.7 4.6% in CON-VEH, HLU-SclAbIII and CON-SclAbIII, respectively, vs. baseline (p<0.0001). Trabecular bone volume (Tb.BV/TV %), assessed by µCT imaging of the distal femur, was lower in HLU-VEH vs CON-VEH (p<0.05), and was 2-3 fold higher in Scl-AbIII-groups vs VEH (p<0.001)(see Table). Midshaft femoral strength assessed by 3-pt bending and distal femoral trabecular strength assessed by micro-finite element analysis (µFEA) was significantly higher in Scl-AbIII vs VEH-groups in both loading conditions. Serum sclerostin was higher in HLU-VEH (134 16 pg/ml) compared to CON-VEH (116 22 pg/ml, p<0.05) at sacrifice. Serum osteocalcin was decreased by hindlimb suspension (98 22 ng/ml vs 149 54 ng/ml in HLU-VEH vs CON-VEH), and increased by SclAbIII treatment (133 22 ng/ml and 203 44 ng/ml in HLU-SCLAbIII, and CON-SCLAbIII), respectively. SclAbIII did not influence the muscle loss seen in HLU. Altogether, these results indicate increased serum sclerostin levels with unloading, and via its anabolic activity, demonstrated the ability of Scl-AbIII to abrogate disuse-induced bone deterioration. These data suggest that sclerostin antibody can increase bone mass by increasing bone formation in normal loaded or under-load bones, though it seems that sclerostin antibody is more effective in increasing bone mass in normally loaded bone than in under-loaded bones.

Table 1: µCT Parameters and Mechanical Strength Results

	CON-SclAbIII	CON-VEH	HLU-SclAbIII	HLU-VEH
Distal Femur				
Tb.BV/TV (%)	32.0 ± 4.9 ^{a,b}	10.3 ± 1.4 ^b	21.7 ± 4.0 ^a	8.0 ± 1.9
Tb.N (mm ⁻³)	4.32 ± 0.16 ^{a,b}	3.86 ± 0.14 ^b	4.05 ± 0.17 ^a	3.72 ± 0.23
Tb.Th (mm)	0.097 ± 0.008 ^{a,b}	0.053 ± 0.002 ^b	0.075 ± 0.006 ^a	0.047 ± 0.003
Femur Midshaft				
Ct.Thickness (mm)	0.21 ± 0.01 ^{a,b}	0.16 ± 0.01 ^b	0.17 ± 0.01 ^a	0.13 ± 0.01
3-point Bending Max Force (N)	18.6 ± 1.1 ^b	12.4 ± 0.9 ^b	15 ± 1.2 ^a	10 ± 0.8

a: p<0.05 SclAbIII vs VEH treatment within the CON or HLU;
b: p<0.05 HLU vs CON within the SclAbIII and VEH treatment groups.

Sclerostin Antibody Increased Bone Mass and Reduced Fractures in Osteogenesis Imperfecta Mice. Jean-Pierre Devogelaer¹, Catherine Behets², Patrick Ammann³, Michael Ominsky⁴, Christine Coppin², Daniel H Manicourt². ¹St. Luc University Hospital, Belgium, ²Université catholique de Louvain, Belgium, ³Division of Bone Diseases, Switzerland, ⁴Amgen, Incorporated, USA

Osteogenesis imperfecta (OI) type III is a severe genetic condition that results in poor bone quality and a high rate of fractures in children. Treatments to prevent these fractures are limited; therefore we tested the effects of a potential therapeutic agent, sclerostin neutralizing monoclonal antibody (Scl-Ab) on bone mass, bone strength and fracture reduction in oim/oim mice, a model of OI type III.

Twenty four 7-week-old OI and 24 wild/wild (WT) control mice were treated with either vehicle (PBS) or Scl-Ab at 25 mg/kg twice per week for 10 weeks. Skeletal fractures excluding rib fractures were detected using mammography X-ray. Bone biomechanical properties were assessed using a three points-bending test and axial compression of the tibia, respectively; ultimate load, elastic energy and plastic energy were determined. Peripheral quantitative computerized tomography (pQCT) was used to measure bone geometry and mineral density (BMD). Statistical analysis included parametric analysis of variance (ANOVA) followed by post hoc tests.

Scl-Ab reduced the number of fractures in OI mice by 56% (mean SD = 2.8 0.6 versus 6.3 1.5 in PBS; $p < 0.001$). In OI mouse tibia, Scl-Ab increased ultimate strength (midshaft: +30%, proximal: +98% versus PBS; all $p < 0.001$), stiffness (midshaft: +132%, proximal: +88% versus PBS; all $p < 0.01$) and plastic energy (midshaft: +125%, proximal: +260% versus PBS; all $p < 0.01$). These strength increases corresponded to significant increases in tibia BMD (midshaft: +30%, proximal: +50% versus PBS; $p = 0.02$ and 0.001 , respectively) and in tibia cortical thickness (midshaft: +40%, proximal: +75% versus PBS; all $p < 0.001$). Scl-Ab-therapy was also associated with significant increases in BMD and cortical thickness in both the humerus and lumbar vertebra, so that at the end of therapy, the strength, BMD and cortical thickness of bones of the OI skeleton were similar to those found in corresponding bones of PBS-treated WT control mice (Table). Scl-Ab-therapy also increased the strength, BMD and cortical thickness in tibia, humerus and vertebra of WT normal mice.

By increasing cancellous and cortical bone mass throughout the skeleton, Scl-Ab improved bone biomechanical properties and reduced the prevalence of bone fractures in OI mice. These results suggest that Scl-Ab might be a promising therapy for human type III OI.

Parameter	Site	OI mice		WT mice	
		Scl-Ab	PBS	Scl-Ab	PBS
Ultimate load (N)	Tibia midshaft	7.6 ± 0.6*	5.7 ± 0.3	19.7 ± 0.9*	10.7 ± 2.7
	Proximal tibia	23.6 ± 6.6*	11.9 ± 0.6	87.2 ± 14.1*	30.4 ± 7.8
Stiffness (N/mm)	Tibia midshaft	24.2 ± 2.3*	10.4 ± 1.5	48.7 ± 2.3*	33.1 ± 9.1
	Proximal tibia	179 ± 49*	95 ± 50	402 ± 23*	252 ± 38
Plastic energy (N*mm)	Tibia midshaft	0.9 ± 0.4*	0.4 ± 0.4	1.0 ± 0.3	1.1 ± 0.4
	Proximal tibia	1.8 ± 0.4*	0.5 ± 0.3	5.5 ± 1.3	4.7 ± 0.6
BMD (mg/cm ³)	Tibia midshaft	951 ± 88	740 ± 65	1045 ± 73	845 ± 35
	Proximal tibia	677 ± 76*	448 ± 91	872 ± 54*	643 ± 78
Cortical thickness (mm)	Tibia midshaft	0.25 ± 0.02	0.18 ± 0.03	0.39 ± 0.05	0.26 ± 0.01
	Proximal tibia	0.14 ± 0.03*	0.08 ± 0.01	0.21 ± 0.03*	0.15 ± 0.01

Osteocyte-derived IGF-I Functions as a Portion of the Circuitry For Normal Loading Activation Response in Osteoblasts: Data From the Osteocyte IGF-I Conditional Knockout Mouse. Matilda Sheng¹, Kin-Hing William Lau², Xiaodong Zhou¹, Lynda Bonewald³, David Baylink¹. ¹Loma Linda University, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³University of Missouri - Kansas City, USA

Earlier studies have demonstrated that the IGF-I and its signaling in osteoblasts are essential for the bone formation (BF) response to mechanical loading, and that osteocytes are the primary mechanoresponsive cells in the bone. This study sought to test the hypothesis that osteocyte-derived IGF-I plays a key role in mechanical stimulation of osteoblastic BF by determining the osteoblastic BF response to loading of a mutant mouse with a conditional knockout (KO) of the IGF-I gene in osteocytes, which was generated by crossing the DMP1-Cre transgenic mice with the IGF-I LoxP mice in which the IGF-I exon 4 is flanked by the LoxP site. Analyses by q-PCR and immunohistochemical staining for IGF-I confirmed that the deficient IGF-I expression was restricted to osteocytes. The tibia of the KO mice and wild-type (WT) littermates were subjected to 2 weeks of 4-point bending exercise. The loading force was 9.70.2 and 11.10.1 N for the KO and WT mice, respectively, at a frequency of 2 Hz

for 36 cycles to adjust for the ~11% difference in the bone size. This loading force is equivalent to a loading strain of 4153235 $\mu\epsilon$ in KO mice and 4671265 $\mu\epsilon$ in WT mice ($p > 0.05$). A number of pQCT parameters (total, cortical, subcortical, and trabecular bone mineral contents (BMCs) and bone area) of the loaded tibia were each increased by 35-66% in WT mice; whereas only 9-10% increase was detected in each of these parameters in the KO mice ($P < .001$ for each parameter). Bone histomorphometry revealed that increased BF surface and mineral apposition rate both contributed to the osteoblastic BF response to loading in WT mice. The changes in these parameters in KO mice were too small to be determined with confidence. A loading strain dosage study (Fig. 1) indicates that at each equivalent loading strain, the osteoblastic BF response in KO mice was significantly much less than that in WT controls, confirming that deletion of IGF-I in osteocytes drastically reduced the BF response to loading. In conclusion: 1) this study shows for the first time that osteocyte-derived IGF-I is an important positive regulator of osteoblastic BF to mechanical loading; 2) the 11% smaller cross section area and periosteal circumference in tibia of KO mice than WT mice could be explained by the impaired sensitivity of the KO mouse to mechanical loading, and 3) because osteocyte IGF-I is an important determinant of bone size, it follows that it is also important to determine the bone strength.

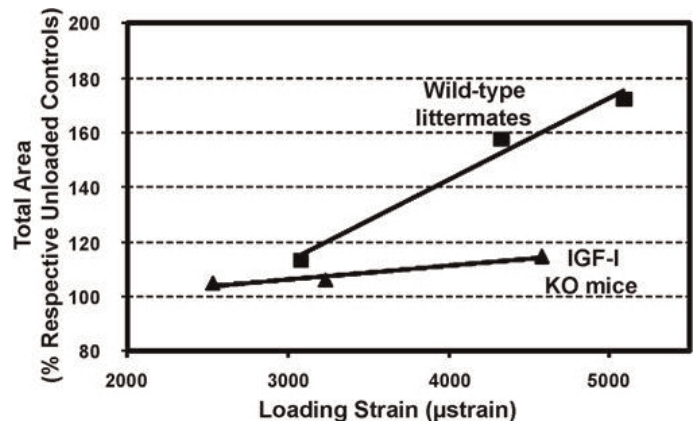

Figure 1. Loading strain dose response curves of osteocyte IGF-I conditional KO mice and WT mice.

Low Trabecular Bone Volume in α_2 C-Adrenoceptor Knockout Mice. Marilia Teixeira¹, Gisele Martins², Cristiane Costa³, Patrícia Brum⁴, Cecília Gouveia². ¹University of Sao Paulo, Brazil, ²Institute of Biomedical Science, Brazil, ³Institute of Biomedical Science, Brazil, ⁴School of Physical Education and Sport, Brazil

Evidence demonstrates that sympathetic nervous system (SNS) activation causes osteopenia via β_2 -adrenoceptor (β_2 -AR) signaling. In a recent study, we showed that female mice with chronic sympathetic hyperactivity due to double knockout of adrenoceptors that negatively regulate norepinephrine release, α_2 a-AR and α_2 c-AR (α_2 a/ α_2 c-AR KO), present an unexpected and generalized phenotype of high bone mass with decreased bone resorption and increased bone formation. These findings suggest that β_2 -AR is not the single adrenoceptor involved in bone turnover regulation and show that α_2 -AR signaling may also mediate the SNS actions in the skeleton. To further investigate the participation of the SNS and α_2 ARs in the regulation of bone mass, we are evaluating the bone phenotype of α_2 c-AR knockout mice (α_2 c-AR^{-/-}). A cohort of 120 day-old female congenic α_2 c-AR^{-/-} mice in a C57BL/6J background and their wild-type (WT) controls (n=7/group) were studied. Single knockout mice presented decreased retroperitoneal fat pad (40%, $p < 0.01$), decreased body length (4%, $p < 0.001$) and decreased femur length (4%, $p < 0.001$). Surprisingly, microtomography analysis of the distal metaphysis of the femur showed that α_2 c-AR^{-/-} mice present a 15% decrease in trabecular bone volume (BV/TV; $p < 0.01$). These findings suggest that α_2 a-AR, but not α_2 c-AR, may have a role in mediating the deleterious effects of the sympathetic activation in trabecular bone.

Bmp2 Gene in Osteoblasts Controls Bone Quantity and Quality by Regulating the Vascular Niche for Skeletal Stem Cells (SCCs) in both Periosteum and Trabeculae. Wuchen Yang^{*1}, Valentin David², Jeffry Nyman³, Marie Harris¹, Yong Cui¹, Jelica Gluhak-Heinrich¹, Ivo Kalajzic⁴, Barbara Kream⁴, David Rowe⁴, Alexander Lichtler⁴, Xiao-Dong Chen¹, Yuji Mishina⁵, Stephen Harris¹. ¹University of Texas Health Science Center At San Antonio, USA, ²UTHSC, USA, ³Vanderbilt University Medical Center, USA, ⁴University of Connecticut Health Center, USA, ⁵University of Michigan, USA

In vivo studies indicate that *BMP2* action in osteoblasts is much more complex and plays fundamental roles in both periosteal and trabecular function. The *Bmp2* gene now appears to control both quantity and quality of bone. We generated *BMP2* conditional floxed allele and removed the *Bmp2* gene from early osteoblasts postnatally (*Bmp2*-cKO^{ob} mouse model) using 3.6Col-Cre transgenic mice and from earlier preosteoblasts using the OsterixBAC-Tet-off-Cre model (*Bmp2*-cKO^{Sp7Cre}). The *Bmp2*-cKO^{ob} mice display progressive osteopenia that mimics bone ageing, including loss of bone (smaller bones and smaller cross-sectional diameter) and increased brittleness (post yield toughness in a mechanical test), and reduced vascular system (3D vascular profusion). The microvascular 3D mapping demonstrates a 50 to 70% reduction in blood vessels associated with the periosteum and trabeculae. By dynamic bone formation rate, *Bmp2*-cKO^{ob} and *Bmp2*-cKO^{Sp7Cre} mice show severely deteriorated capacity to appose mineral to the outside (periosteum) and inside (trabeculae) of the bone. We established that there was a 70% decrease in SSCs in a CFU-F bone marrow assay, and confirmed these results *in vivo* by showing reduced CD146+ and Sma-Cherry+ cells on the small blood vessels associated within the periosteal and the trabecular region. There is even fewer SSCs per length of microvessel (<12um). By histomorphometric analysis and *in situ* hybridization (Col1a1, Osterix, Osteocalcin and VegfA), we demonstrated that the osteoblasts of the *Bmp2*-cKO^{ob} do not mature to cuboidal matrix producing osteoblasts and cannot produce high level of the *Bmp2* induced gene VegfA, which is required for this *Bmp2* induced vascularization. We now demonstrate this late osteoblast differentiation defect is linked to the vascular niche and SSCs in both the periosteum and trabecular bone. This establishes a cycle between late osteoblast function and regulation of the SSCs through regulation of the vascular niche. With more limited studies with the *Bmp2*-cKO^{Sp7Cre} model, we have determined that the bones are all smaller or thinner, more brittle by mechanical loading tests, and have reduced blood vessels in both the periosteum and trabecular region. However, to our surprise, a dramatic increase in CD146+ cells on the fewer blood vessels was observed, suggesting that the SSCs may not be able to egress from their vascular niche when the *Bmp2* gene is deleted in this earlier stage in the osteoblast lineage.

Absence of NFATc2 Results In High Bone Mass and Impaired Hematopoiesis. Martina Rauner^{*1}, Wolfgang Bauer², Ivonne Habermann², Michael Haase³, Gerhard Ehninger², Lorenz Hofbauer⁴, Alexander Kiani². ¹Medical Faculty of the TU Dresden, Germany, ²Technical University Dresden, Department of Medicine I, Germany, ³Technical University of Dresden, Institute of Pathology, Germany, ⁴Dresden University Medical Center, Germany

Nuclear factor of activated T cells (NFAT) constitutes a family of transcription factors which are critically involved in T cell activation and modulation of bone remodeling. NFATc1 has been identified as the master transcription factor for osteoclasts and also suppresses osteoblast function. By contrast, the role of other NFAT members such as NFATc2 is poorly understood. Based on our observation that NFATc2 is highly expressed in hematopoietic stem cells and regulated during myeloid commitment in a lineage-specific manner, we hypothesized that NFATc2 is an essential regulator of both hematopoiesis and bone mass. To test this hypothesis, we characterized the haematological and skeletal phenotype of NFATc2^{-/-} mice. Besides a reduced number of blood platelets and total bone marrow cells, young NFATc2^{-/-} mice of less than 3 months did not show any hematologic abnormalities compared to wild-type (WT) mice. However, detailed assessment of old NFATc2^{-/-} mice older than 12 months revealed mild microcytic, hypochromic anemia, lymphocytosis (20%) and severe thrombocytopenia. The femora of old NFATc2^{-/-} mice showed a 46% reduction of bone marrow cells, wherein the megakaryocytic/erythroid lineage was most affected. Of note, the differentiation of myeloid progenitor cells as assessed by colony formation was intact. Strikingly, all NFATc2^{-/-} mice displayed an ossified bone marrow space with subsequent extramedullary hematopoiesis in the spleen. Bone histology revealed numerous osteoblasts and osteoclasts at the bone surface of the trabeculae in NFATc2^{-/-} mice, indicating a high bone turnover underlying osteosclerosis. *Ex vivo*, NFATc2^{-/-} osteoblasts displayed a 2.3-fold increased ALP activity (WT: 23.6 10.3 relative units; NFATc2^{-/-}: 54.3 14.2 relative units, *p* < 0.01) and produced twice as much mineralized matrix as WT cells (*p* < 0.05). Moreover, osteoclast differentiation, as determined by counting TRAP-positive, multinucleated cells, was diminished by 30% in NFATc2^{-/-} mice (*p* < 0.05). In conclusion, our data demonstrate that prolonged absence of NFATc2 enhances bone mass by stimulating osteoblastic functions and concurrently suppressing osteoclast

formation. Moreover, NFATc2 is critical in the maintenance of steady-state hematopoiesis in adult organisms. This indicates that NFATc2 is a central player in the intimate relationship of hematopoiesis and bone homeostasis within the bone/bone marrow microenvironment.

Interleukin-6 Receptor Signaling Links Hematopoietic and Anabolic Actions of PTH in Bone. Sun Wook Cho^{*1}, Flavia Pirihi¹, Megan Michalski¹, Matt Eber¹, Seo jin Oh¹, Thomas Wronski², Laurie McCauley³. ¹University of Michigan School of Dentistry, USA, ²University of Florida, USA, ³University of Michigan, School of Dentistry, USA

Intermittent administration of parathyroid hormone (PTH) increases bone mass by stimulating bone formation. Interleukin (IL)-6 is upregulated by PTH and is a critical mediator of PTH effects on hematopoietic cells. The purpose of this study was to determine the role of IL-6 signaling on hematopoietic and skeletal action of PTH. Intermittent PTH (PTH 1-34, 50 µg/kg/day) was administered to wildtype (WT) and IL-6 deficient (IL-6 KO) mice at two different ages (young 3~24day and adult 16~22week). There was a similar PTH mediated increase in bone area via histomorphometry (tibia and vertebrae), bone volume via microCT (femurs), and bone formation rates via dynamic histomorphometry in young and adult WT and KO mice. To investigate IL-6 compensatory mechanisms, protein levels of soluble IL-6 receptor (sIL-6r) were evaluated in 16-week-old WT and IL-6 KO mice after PTH administration (2 weeks). Under basal conditions, serum sIL-6r was significantly reduced in IL-6 KO vs. WT mice, however bone marrow sIL-6r was similar. Interestingly, treatment with PTH significantly increased bone marrow sIL-6r in both WT and IL-6 KO mice suggesting potential compensation. Hence, the sIL-6r transsignaling pathway was investigated *in vivo* using soluble glycoprotein 130 receptor (sgp130r) blocking. Young IL-6 KO mice were treated with vehicle, PTH, sgp130r or PTH plus sgp130r for 2weeks. PTH increased bone volume and trabecular number in IL-6 KO mice which was significantly attenuated when sgp130r was combined with PTH. Consistently, PTH increased serum PINP and sgp130 prevented the PINP increase. Since PTH in concert with fms-like tyrosine kinase-3 ligand (Flt-3L), expands hematopoietic cells in an IL-6 dependent manner, whether sIL-6r could replace these IL-6 actions was evaluated. In an *ex vivo* bone marrow expansion study, sgp130r inhibited the cell expansion response to PTH with Flt-3L. Additionally sIL-6r treatment resulted in earlier cell amplification, and in combination with PTH, sIL-6r expanded cells independently of Flt-3L. Collectively, PTH depends on IL-6 for its hematopoietic cell expansion, whereas IL-6 appears to be compensated for by sIL-6r in both hematopoietic cell expansion and the anabolic actions of PTH in bone. These findings link together IL-6 targeted signaling in the bone and marrow microenvironments toward a better mechanistic understanding of PTH anabolic actions.

Circulating Human Lineage Negative/Osteoblast Progenitor Cells Support Hematopoiesis in Tk-Rag Mice. Pilar Peris^{*1}, Robert Jilka², Sundeep Khosla³, Ulrike Moedder³. ¹Hospital Clinic of Barcelona, Spain, ²University of Arkansas for Medical Sciences, USA, ³College of Medicine, Mayo Clinic, USA

Hematopoietic stem cells (HSC) are multi-potent cells that generate a lifelong supply of all blood cell types. HSC self-renewal is regulated, in part, by cells of the osteoblast lineage within the hematopoietic niche. We have previously identified osteoblast-like (lineage negative/alkaline phosphatase positive [lin-/AP+] cells) in peripheral blood in humans. Here, we tested for the ability of these lin-/AP+ cells to support hematopoiesis *in vivo*. To do so, we first bred mice expressing thymidine kinase (tk) under the control of the Col3.6 promoter into an immuno-compromised (Rag) background, designated tk-Rag mice. Daily treatment of 4-week-old male tk-Rag mice (*n* = 32) with ganciclovir (300µg/d) resulted in the ablation of osteoblast progenitors from cancellous bone and subsequent loss of hematopoiesis, as measured by the number of bone marrow erythroid precursors (Ter119+) using flow cytometry. Human bone marrow-derived mesenchymal stem cells (Clonetic) or *ex vivo* expanded peripheral blood lin-/AP+ cells (~10⁵ cells each) were infused locally into both femoral bone marrow cavities of tk-Rag mice; control tk-Rag mice received saline infusions (*N* = 6-11 per group). The infusion of the cells was performed after an initial treatment period with ganciclovir of 18 days to insure that a complete depletion of osteoblasts and hematopoietic cells had occurred. The ganciclovir treatment was continued throughout the entire experiment and all the mice were euthanized 12 days following cell (or saline) infusion. Ganciclovir caused a significant (7.4-fold, *P* < 0.001) reduction of Ter119+ cells in the bone marrow of ganciclovir-treated tk-Rag mice compared to tk-Rag control mice given saline injections. Infusion of MSCs into ganciclovir-treated mice resulted in an (3.3-fold, *P* = 0.08) increase in Ter119+ cells compared to mice treated with ganciclovir but not receiving any cells. Similarly, infusion of lin-/AP+ cells into ganciclovir-treated mice resulted in a significant (2.7-fold, *P* < 0.001) increase in Ter119+ cells compared to mice not receiving any cell infusion. This study thus demonstrates that human peripheral blood lin-/AP+ cells have the capacity to support and maintain hematopoiesis in mice and are as potent as bone marrow MSCs in this experimental model. Further studies are aiming to

determine whether the infused cells home to the hematopoietic niche itself and how long they reside there.

Hematopoietic Stem Cells Give Rise to Osteo-chondrogenic Cells During Fracture Repair. Meenal Mehrotra*, Jonathan D McGuirt, Christopher R Williams, Makio Ogawa, Amanda C LaRue. Research Services, Ralph H Johnson VAMC & Medical University of South Carolina, USA

There are approximately 6.5 million fractures in the United States per year which represents a substantial cause of morbidity, missed work and medical cost. About 5-10% of these fractures result in delayed union or non-union, meaning that the bone does not heal in a timely manner or does not heal at all. Bone healing is unique in that, once a fracture is sustained, the injured bone has the capacity to remodel and regenerate its original structure and integrity. Remodeling of skeletal bone requires the recruitment and proliferation of stem cells with the capacity to differentiate to functional osteoblasts that deposit and mineralize extracellular bone matrix. Given the close association of bone and bone marrow, it has been suggested that bone marrow may serve as a source of these progenitors. Bone marrow is thought to contain two types of stem cells, mesenchymal stem cells (MSCs) and hematopoietic stem cells (HSCs). To test the ability of HSCs to give rise to osteo-chondrogenic cells, we used a single HSC transplantation paradigm in conjunction with a tibial fracture model. For transplantation, mice were lethally irradiated and transplanted with a clonal population of cells derived from a single enhanced green fluorescent protein positive (EGFP+) HSC. After confirming multilineage engraftment, non-stabilized fracture was created through tibial mid-diaphysis. To confirm fracture remodeling, micro-computed tomography images of tibia were taken two months post non-stabilized fracture. These images and morphometric analysis show the presence of a large fracture callus and bone remodeling. Longitudinal paraffin sections were then examined at 7 days, 2 weeks and 2 months after fracture. A large number of EGFP+ hypertrophic chondrocytes, osteoblasts and osteocytes were identified in and around the fracture callus. The morphology of the callus was confirmed by staining serial sections with Massons Trichrome stain. The cells in the callus were further characterized by co-localization of EGFP expression and Runx-2 or osteocalcin expression. A majority of the cells stained positive for Runx-2 or osteocalcin and were also EGFP+ demonstrating their origin from the HSC. These data demonstrate that HSCs can differentiate into hypertrophic chondrocytes, osteoblasts and osteocytes and contribute to fracture healing. Together, these findings strongly support the concept that HSCs can generate bone cells and suggest therapeutic potentials of HSCs in fracture repair.

Transdifferentiation of Hematopoietic Stem Cells into Mesenchymal Stem Cells for Use in Bone Regeneration. Xianmei Meng*, Amanda Neises¹, Kin-Hing William Lau², David Baylink¹, Xiaobing Zhang¹. ¹Loma Linda University, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA

Mesenchymal stem cells (MSCs) from marrow or adipose tissues have been demonstrated in animal and preclinical studies to have important potential in regenerative medicine applications such as bone fracture healing and critical-sized bone formation. However, the procedures to harvest MSCs are invasive and often do not produce enough MSCs for use in clinical treatment. Thus, we have sought for alternative approaches for transdifferentiation of readily available cells, such as blood cells, into MSCs. Recently, reprogramming factors used in generating induced pluripotent stem cells have also found to be able to convert one cell type to another. We hypothesized that some of these reprogramming factors may also promote transdifferentiation of CD34⁺ hematopoietic stem cells into MSCs. To test this hypothesis, we cloned OCT4, SOX2, MYC and KLF4 into a lentiviral vector and transduced human cord blood CD34⁺ cells with these reprogramming factors in various combinations. One day after transduction, CD34⁺ cells were seeded into 6-well plates that were pre-coated with MEF feeder cells and cultured in DMEM/10% FBS. After several attempts, we have identified the combination of OCT4+MYC as the best condition to transdifferentiate CD34⁺ cells into MSC-like cells in 1 week, with an efficiency of up to 5%. Cells were further cultured in well plates without feeder support and passaged every 2-3 days. Flow cytometry analysis at 2-3 weeks after transduction showed that 80-95% cells expressed MSC markers CD29, CD44, CD73, CD90, CD105 and CD166. 20-30% cells also expressed CD271, a marker used for purification of MSCs from marrow and adipose tissue. Expression of hematopoietic markers like CD14, CD34 and CD45 was not detectable. Our data suggest that the blood-turned cells manifest MSC phenotype. These cells expanded robustly for more than 1 month, with generation time of 30-40 hours. Functional test of these cells in preliminary in vitro studies showed that these MSCs can be induced to differentiate into osteoblasts, adipocytes and chondrocytes when cultured in corresponding differentiation media for 3 weeks. In conclusion, we have, for the first time, developed an effective and convenient approach to transdifferentiate hematopoietic stem cells into MSCs. This new development is exciting because it may facilitate and expand the therapeutic applications of MSCs for the regeneration of bone as well as other tissues.

A Novel Syndrome Characterized By Intermittent Hypercalcemia, Hypercalciuria, Elevated Serum Calcitriol And Undetectable 24,25-Dihydroxyvitamin D Concentrations, Nephrolithiasis, Osteoporosis, And Mutations In The CYP24A1 (25-Hydroxyvitamin D/1, 25-Dihydroxyvitamin D 24-Hydroxylase) Gene. Peter Tebben¹, Dawn Milliner², Ronald Horst³, Rajiv Kumar⁴. ¹Mercy Health, USA, ²Mayo Clinic, USA, ³Heartland Assays, Inc., USA, ⁴Mayo Clinic College of Medicine, USA

We describe a novel syndrome in a 44-year-old Caucasian male characterized by intermittent hypercalcemia, hypercalciuria, elevated serum 1,25-dihydroxyvitamin D, undetectable serum 24, 25-dihydroxyvitamin D, nephrolithiasis, and reduced bone mineral density. In 2005, the patient developed left renal colic and a stone was removed with laser lithotripsy. Analysis of stone fragments revealed calcium oxalate. A new calculus was noted in the left kidney in 2008. This increased in size over a period of two years from 4 mm to 6 mm. Bone densitometry of the lumbar spine revealed low BMD (Z score lumbar spine of -3.1). Laboratory investigations performed on several occasions over 12 months are shown in table 1.

Angiotensin converting enzyme concentrations were normal. Monoclonal proteins in the serum and urine were negative. Fungal serologies were nonreactive. A CT of the chest showed a 2X6 millimeter calcified nodule in the right major fissure. CT of the abdomen showed multiple small bilateral renal cysts suggestive of an early or mild form of polycystic kidney disease. A 6 mm stone was noted in the mid left kidney. We obtained DNA for sequencing of the 25-hydroxyvitamin D 1 α -hydroxylase (Cyp27b1) and 25-hydroxyvitamin D or 1, 25-dihydroxyvitamin D 24-hydroxylase (Cyp24a1) genes. The sequence of the Cyp27b1 gene was normal without evidence of duplication. The sequence of the Cyp24a1 gene showed 2 intron-exon splice junction abnormalities that would result in altered 25-hydroxyvitamin D/1, 25-dihydroxyvitamin D 24-hydroxylase expression.

Family history revealed an unaffected mother (father was deceased) and three children (two daughters and one son) among whom a 3-1/2-year-old daughter exhibited similar phenotypic features with elevated serum 1, 25-dihydroxyvitamin D concentrations, hypercalciuria, nephrocalcinosis and renal cysts.

Conclusions: Elevated 1, 25-dihydroxyvitamin D and undetectable 24,25-dihydroxyvitamin D concentrations in a patient with intermittent hypercalcemia, hypercalciuria, nephrolithiasis and renal cysts were associated with splice-junction abnormalities of the 25-hydroxyvitamin D/1, 25-dihydroxyvitamin D 24-hydroxylase (Cyp24a1) gene. The data suggests that in humans, 25-hydroxyvitamin D/1, 25-dihydroxyvitamin D 24-hydroxylase activity regulates 1, 25-dihydroxyvitamin D concentrations, and abnormalities in the Cyp24a1 gene can result in a clinically important phenotype.

Hajdu-Cheney Syndrome: Serum Biomarker Profiling, Bone Radiography and Histopathology, and Germline Mutation Analysis Indicate Complex Dysregulation of Skeletal Cells from Gain-of-Function Truncation of NOTCH2. Michael P. Whyte*, Marina Stolina², William H. McAlister³, Deborah Wenkert⁴, Deborah V. Novack⁵, Xiafang Zhang⁶, Angela R. Nenner⁴, Denise C. Dwyer⁷, Vivienne T. Lim⁴, Nelson Watts⁸, David L. Lacey⁷, Steven Mumm¹. ¹Shriners Hospital for Children & Washington University School of Medicine, St. Louis, USA, ²Amgen Inc, USA, ³Department of Pediatric Radiology at the Mallinckrodt Institute of Radiology, St. Louis Childrens Hospital at the Washington University School of Medicine, St. Louis, USA, ⁴Shriners Hospital for Children, St. Louis, USA, ⁵Washington University in St. Louis School of Medicine, USA, ⁶Washington University in St. Louis School of Medicine, St. Louis, USA, ⁷Amgen Inc., USA, ⁸University of Cincinnati Bone Health & Osteoporosis Center, USA

Hajdu-Cheney syndrome (HCS) is the rare, autosomal dominant disorder that features acroosteolysis together with generalized osteoporosis presenting in childhood. The skeletal abnormalities advance with aging (Figure). Notch refers in humans to four, single-pass, transmembrane receptors that share multiple ligands and function

ubiquitously in cell differentiation and apoptosis. This year, two research groups discovered that heterozygous, truncating mutation within the final coding exon of *NOTCH2* causes HCS (Nat. Genet. 43:303,306 2011). The mutant mRNA would evade nonsense mediated decay, disrupt a carboxy-terminal proteolytic recognition sequence thereby preventing ubiquitination, and consequently activate Notch signaling.

Here, we confirm in six sporadic instances of HCS and in five affected individuals from two HCS families that heterozygous truncating mutation in exon 34 of *NOTCH2* causes HCS. Mutations for our patient cohort include one unique nonsense mutation, five unique small (one or two base pairs) deletions or insertions, and two small (one or two base pairs) deletions shared with previous reported cases. Our patients' radiographs demonstrated a complex skeletal disease including compromise of fracture repair. Bone histopathology of one child and two adults with HCS showed increased cortical porosity and decreased trabecular bone mass and connectivity, but without obvious changes in osteoclasts or osteoblasts. In a distal phalanx, there was absence of bone without inflammation, necrosis, or fibrovascular changes. Biomarker profiling of four HCS patients suggested multifactorial dysregulation of bone cells with markedly diminished serum levels of sclerostin, serotonin, and vegf (and usually dickkopf1 and TGF β), and significantly increased levels of prostaglandin E₂.

Heterozygous truncating mutation in the carboxy-terminal exon of *NOTCH2* causes HCS by Notch activation and seems to disrupt the skeleton by a complex pathogenesis involving the LRP5/WNT, TGF β , and other signaling pathways.

This 46-year-old woman with HCS has remarkable acro-osteolysis of the distal and middle phalanges (arrows).

Paget's Disease-causing Mutations in Sequestosome-1 Impair Autophagic Protein Degradation. Eman Azzam, Miep Helfrich, Lynne Hocking*. University of Aberdeen, United Kingdom

Paget's disease of bone (PDB) is characterised by focal lesions of increased bone turnover, driven by overactive osteoclasts. Mutations affecting Sequestosome-1 (SQSTM1/p62) ubiquitin-associated domain have been identified in individuals with PDB, which impair binding to ubiquitylated proteins targeted for degradation. We have previously shown elevated abundance of p62, ubiquitin, proteasomal subunits and LC3 (marker of autophagic protein degradation) in osteoclasts from Pagetic biopsies, suggesting generalised defects in protein degradation occur. The aim of this study was to examine the effect of PDB-causing mutations on p62 degradation.

HEK293 cell lines stably expressing exogenous p62 (wildtype or mutant P392L, E396X or G425R) were generated using the FlpIn System (Invitrogen). Exogenous p62 is under the control of a CMV promoter such that differences in protein abundance cannot be due to transcriptional upregulation. These cell lines also express endogenous p62, thereby approximating heterozygous mutations. Cells were examined under normal growth conditions, and following amino acid starvation to induce autophagy, or bafilomycin treatment to inhibit autophagy. Lysates were western blotted for exogenous p62 and GAPDH. Protein abundance was measured using LiCOR Odyssey and results expressed relative to GAPDH, normalised to the wildtype p62 cell line.

Exogenous p62 abundance was increased for all mutants compared with wildtype under normal growth conditions, suggesting p62 degradation is impaired by PDB mutations. Upon amino acid starvation, mutant exogenous p62 still exhibited increased abundance compared with wildtype. When autophagy was inhibited, the difference between wildtype and mutant exogenous p62 was lost, suggesting that pharmacological inhibition of autophagy prevents degradation of wildtype p62 to a similar extent as the presence of PDB-causing mutations.

We have shown that autophagic protein degradation is impaired by PDB-causing SQSTM1 mutations. Dissection of protein degradation dynamics (autophagic and proteasomal) will provide important insights into the regulation of osteoclast function by protein degradation pathways, and into the influence of SQSTM1 mutations on these.

Disclosures: Lynne Hocking, None.

Mutations of SQSTM1 Cause Dysregulation of the Autophagy Pathway in Osteoclast Precursors and Are Responsible for Development of Intranuclear Inclusions in Paget's Disease. Anna Daroszevska¹, Robert Van't Hof¹, Lorraine Rose¹, Ken Rose¹, Rob Layfield², Stuart Ralston^{*1}. ¹University of Edinburgh, United Kingdom, ²University of Nottingham, United Kingdom

Osteoclasts in patients with Paget's disease of bone (PDB) characteristically contain nuclear inclusion bodies. These were originally thought to be paramyxovirus nucleocapsids, but their true identity is unknown and previous investigators have noted that the Pagetic inclusions differ morphologically from those found in subacute sclerosing panencephalitis the archetypal slow virus disease caused by measles virus infection. On the other hand, intracellular inclusions have long been recognized to be a feature of human neurodegenerative disorders such as Alzheimer's disease and Parkinson's disease which are thought to be caused in part by defects in degradation of abnormal protein aggregates by the proteasome and autophagy. In order to clarify the nature of the intranuclear inclusions in PDB we generated a mouse model of the disease in which the P392L mutation of SQSTM1 (P394L in the mouse) was created by gene targeting. The P394L mutant mice developed a bone disorder with remarkable similarity to PDB characterized by the development of focal osteolytic and osteosclerotic bone lesions characterised by high bone turnover and woven bone. Osteoclasts within the lesions were larger than normal and contained intranuclear inclusion bodies almost identical to those observed in human PDB. The inclusions consisted of multiple microcylindrical structures approximately 12 nm in diameter arranged in a paracrystalline array as in human PDB. To determine if this might be associated with abnormalities in the autophagy pathway we measured expression of marker genes for this process including SQSTM1, the microtubule associated protein 1 light chain 3 gene (LC3) and the autophagy related gene 5 (ATG5) using real-time PCR. There was a significant increase in SQSTM1, LC3 and ATG5 expression in osteoclast precursors from P394L mutant mice when compared with wild type littermates ($p < 0.02$). Interestingly, no difference in expression of these genes was observed in macrophages indicating that the abnormalities observed were specific to osteoclasts. We went onto perform Western blotting for LC3-II (a marker of autophagosome formation) and found that levels were significantly higher in P394L mutant osteoclasts as compared to wild type controls ($p < 0.001$), consistent with dysregulation of the autophagy pathway. We conclude that the nuclear inclusions observed in human PDB and in the model described here most probably represent abnormal protein aggregates related to dysregulation of autophagy system, rather than viral particles, confirming the importance of genetics as opposed to persistent viral infection as the cause of this disorder.

Mutations in *SERPINF1* cause Osteogenesis Imperfecta Type VI. Erica Homan^{*1}, Ingo Grafe², Frank Rauch³, Caressa Lietman¹, Jennifer Doll⁴, Brian Dawson¹, Terry Bertin¹, Dobrawa Napierala⁵, Roy Morello⁶, Richard Gibbs¹, Lisa White¹, Rika Miki⁷, Daniel Cohn⁷, Susan Crawford⁴, Rose Travers⁸, Francis Glorieux⁹, Brendan Lee¹⁰. ¹Baylor College of Medicine, USA, ²Department of Molecular & Human Genetics, Baylor College of Medicine, USA, ³Shriners Hospital for Children, St. Louis, Canada, ⁴NorthShore University Health System Research Institute, USA, ⁵University of Alabama at Birmingham School of Dentistry, USA, ⁶University of Arkansas for Medical Sciences, USA, ⁷University of California, Los Angeles, USA, ⁸Shriners Hospital for Children, Canada, ⁹Shriners Hospital for Children & McGill University, Canada, ¹⁰Baylor College of Medicine & Howard Hughes Medical Institute, USA

Osteogenesis Imperfecta (OI) is a spectrum of genetic disorders characterized by low bone mass and fragility. It is caused by dominant mutations affecting the synthesis and/or structure of type I procollagen or by recessively inherited mutations in genes responsible for the post-translational processing/trafficking of type I procollagen. In all but one class of OI, the histopathological and clinical features cannot predict the causative gene or functional defect among affected individuals. However, recessive OI type VI is characterized by a pathognomonic increase in the amount of unmineralized osteoid, thereby suggesting a distinct disease mechanism. OI type VI is of unknown etiology and identifying the disease gene will add to our understanding of matrix mineralization and identify potential therapies.

To identify the gene region, homozygosity mapping was carried out using the genomic DNA of 3 members of a consanguineous French Canadian family. A single region of homozygosity was shared by all three of these related OI VI patients defined by the markers rs8074026 and rs1362761. Next generation sequencing of one patient from this family identified homozygosity for a stop mutation in exon 4 (g.4130C>T, p.R99X) of serpin peptidase inhibitor, clade F, member 1 (*SERPINF1*) which was confirmed by Sanger sequencing in all affected family members. The stop codon mutation was predicted to result in nonsense mediated decay (NMD) of the *SERPINF1* transcript and realtime RT-PCR of patient fibroblasts confirmed that this is the case. Sanger sequencing the 8 exons of *SERPINF1* in 10 unrelated patients identified additional mutations. Interestingly, the g.4130C>T mutation was identified in additional patients of French Canadian origin, suggesting the presence of a founder allele in the population. *SERPINF1* encodes the 50kDa secreted protein, Pigment Epithelium-derived Factor (PEDF). Serum PEDF levels were undetectable in OI type VI patients in contrast to classical OI patients (caused by mutations affecting type I collagen) in whom PEDF serum levels were comparable to normal controls.

These data suggest that mutations in *SERPINF1* resulting in loss of PEDF cause OI type VI. This provides an avenue for proper OI diagnosis of patients, where PEDF could be measured in serum for confirmation. In addition, PEDF is a secreted protein, suggesting therapy with recombinant PEDF could be used as a potential therapy for OI type VI patients.

Aim: While genetic factors appear to confer susceptibility to the risk of fracture, no large-scale GWAS meta-analysis consortia have been undertaken to identify the common variants associated with fracture within the framework of the Genetic Factors of Osteoporosis (GEFOS) consortium. We therefore sought the largest GWAS meta-analysis to date to identify the common genetic variants associated with fracture. **Methods:** We broadly defined fracture, as fracture of any bone occurring in individuals 18 years and older, confirmed through medical, radiological and/or questionnaire reports regardless of trauma type. This definition maximizes the case sample size, since common variants generally confer small risks for common disease. The GWAS discovery meta-analysis comprised 13 GWAS cohorts (n=53,016, of which, 9,185 were fracture cases). Additive association with fracture risk was tested for ~2.5 million imputed SNPs (HapMap CEU release 22, build 36) employing logistic regression models adjusted for gender, age, height, weight and population stratification when applicable. Results were meta-analyzed using inverse variance fixed-effects using METAL. Genome-wide significance (GWS) was set at $P < 5 \times 10^{-8}$ while suggestive significance at $P < 5 \times 10^{-6}$. Results: The strongest signal included six SNPs associated at GWS (lowest $P = 1.7 \times 10^{-10}$, odds ratio = 1.13, 95% CI: 1.09 - 1.17) and maps to the novel 18p11 locus recently identified as a BMD locus by our parallel GEFOS BMD effort. This locus contains a gene coding for a protein of unknown function (C18orf19) with no other clear candidate gene on the vicinity. Other suggestive signals included a known variant in *LRP5* ($P = 3.1 \times 10^{-6}$) and novel signals mapping in or near *MDH2* ($P = 4.8 \times 10^{-6}$), *RGS9* ($P = 4.8 \times 10^{-6}$), *FAM20C* ($P = 2.3 \times 10^{-6}$) and *MYO3B* ($P = 9.0 \times 10^{-7}$). Interestingly, mutations in *FAM20C* cause Rayne syndrome which presents with intracranial calcification, generalized osteosclerosis and enhanced periosteal bone formation. These variants will undergo further replication through GWAS and de-novo genotyping in > 80,000 individuals (~30,000 cases). **Conclusion:** In this first large-scale GWAS meta-analysis assessing fracture risk we confirmed the BMD locus on chromosome 18p11 as associated with fracture, albeit with modest effect size, and highlighted other loci in or near genes,

some known to cause skeletal monogenetic disorders. These findings help to understand the genetic basis of fracture susceptibility.

Activation of Notch Signaling in Bone Cells Causes Osteoma and Osteosarcoma. Janning Tao¹*, Shan Chen¹, Ming-ming Jiang¹, Yangjin Bae¹, Terry Bertin¹, Francis Gannon¹, Lisa Wang¹, Lawrence Donehower¹, Brendan Lee². ¹Baylor College of Medicine, USA, ²Baylor College of Medicine & Howard Hughes Medical Institute, USA

Human osteosarcoma (OS) is the most common primary bone cancer, comprising approximately 20% of all bone tumors and about 5% of pediatric tumors overall. Most OS occurs sporadically and our understanding of its molecular basis is still limited. Recently, we found that human and p53^{-/-} mouse osteosarcoma tumor samples show evidence of upregulated Notch signaling. Moreover, chemical or genetic inhibition of Notch signaling decreased tumor growth in a xenograft mouse model of human osteosarcoma. Notch signaling plays an important role in the developmental processes and tissue homeostasis. Altered Notch signaling has been associated with several cancers in which the data suggest that Notch can act both as an oncogene and tumor suppressor depending on its expression level and timing. To generate a mouse osteosarcoma model and examine the role of Notch signaling in bone tumorigenesis, we utilized a bitransgenic mouse model that constitutively expressed a single copy of Notch NICD in osteoblasts. The resulting bitransgenic Notch gain-of-function (GOF) mice developed osteosclerosis at age of two months. Histomorphometric and molecular analysis of cavarial and long bones indicated that Notch could stimulate proliferation of immature osteoblasts while inhibiting their differentiation into mature osteoblasts. This gain of function phenotype was reminiscent of osteoblastic tumors. Indeed, aging studies of these GOF mice showed that they spontaneously developed osteoma/OS lesions with 100% penetrance at a mean of 9.5 months. To explore a genetic interaction of Notch and p53 pathways in the pathogenesis of OS, the GOF mice were bred with p53-conditional mice. We found that p53-null GOF mice have increased significantly tumorigenic potential, as mice develop osteosarcomas at a mean of 5 months. This result suggests that the genetic interaction of Notch and p53 plays a critical role in OS development. Together, our data support that p53-Notch interaction may be a dominant mechanism in OS pathogenesis.

Hedgehog Signaling Modulates Osteoclast Formation and Bone Metastasis. Michelle Hurchla¹*, Emanuela Heller², Kyu-Sang Jeong², Marcos Vidal³, Jochen Schneider⁴, Leah Goldberg², Hongju Deng², Mary C. Hornick², Julie Prior², David Piwnica-Worms², Fanxin Long², Ross Cagen³, Katherine Weilbaecher². ¹Washington University in St. Louis, USA, ²Washington University in St. Louis School of Medicine, USA, ³Mount Sinai School of Medicine, USA, ⁴Washu, USA, ⁵Washington University School of Medicine, USA

Using a novel whole animal drosophila-based cancer metastasis drug screen, we identified inhibitors of the Hedgehog (Hh) regulator Smoothened (SMO), as powerful anti-metastatic compounds. The Hh pathway plays a critical role in tumor development and cancer progression in addition to being necessary for proper embryonic bone development and osteoblast differentiation. We hypothesized that Hh antagonism could inhibit bone metastasis through direct effects on both tumors and host cells within the bone microenvironment. Evaluation of the SMO antagonist cyclopamine in adult non-tumor bearing mice resulted in increased trabecular bone volume and decreased osteoclastic bone resorption. In vitro, both cyclopamine and Cre-mediated deletion of Smoothened inhibited osteoclastogenesis, suggesting direct regulation of osteoclast (OC) activity by Hh. Furthermore, mice with enhanced Hh signaling due to heterozygous loss of the Hh inhibitory receptor Patched (Ptc^{+/+}) showed increased cell autonomous OC function in vivo and in vitro. OC activation is critical to tumor-associated bone loss and tumor growth in bone. Pharmacologic inhibition of Hh with cyclopamine decreased bone and lung metastases and decreased bone tumor burden following intra-arterial or intra-tibial inoculation of 4T1 murine breast cancer cells. 4T1 breast cancer cells have an intact Hh signaling pathway and cyclopamine was directly toxic to 4T1 in vitro. To evaluate the contribution of Hh signaling in tumor-associated stromal cells, we examined Ptc^{+/+} mice, with enhanced Hh signaling in host cells. Ptc^{+/+} mice had increased tumor burden in the bone following intra-arterial inoculation with osteolytic B16 melanoma cells, suggesting that increased Hh activation in host cells promotes tumor growth. Bone marrow transplantation experiments demonstrated that Hh activation in both hematopoietic and non-hematopoietic cells contribute to tumor growth. Together these data suggest a novel role for Hh signaling in the regulation of OC activity and that inhibition of the Hh pathway can reduce tumor burden in bone through direct effects on tumor cells, osteoclasts and stromal cells within the bone microenvironment, making Hh a promising therapeutic target for bone metastases.

New Players in the Tumor Bone Vicious Cycle: Myeloid Derived Suppressor Cells Enhance Bone Tumor Growth in Osteopetrotic PLCγ2^{-/-} Mice. Aude-Helene CAPIETTO¹*, SEOKHO KIM², Roberta Faccio². ¹Washington University School of Medicine, USA, ²Washington University in St Louis School of Medicine, USA

We have recently shown that PLCγ2^{-/-} mice are more susceptible to tumor growth in bone compared to WT immunocompetent mice, despite a decrease in osteoclast (OC) number and function. PLCγ2 expression is confined to cells of hematopoietic origin, including all myeloid-derived cells but not T-cells. Surprisingly, we find that increased bone tumor growth in PLCγ2^{-/-} mice is accompanied by reduced anti-tumor CD8⁺ T cell responses. Since one of immune-evasion mechanism of tumor development is to recruit CD11b+Gr-1⁺ myeloid derived suppressor cells (MDSC), we then hypothesized that this immature myeloid population could be responsible for inhibiting CD8⁺ T cells, thus promoting the tumor outgrowth in bone of OC-deficient PLCγ2^{-/-} mice. Supporting this hypothesis, increased tumor size following B16 melanoma and Lewis Lung Carcinoma tumor inoculation in PLCγ2^{-/-} mice is associated with a 2-fold increase in the percentage of MDSC compared to WT mice both in spleen and at the tumor site (p<0.01). In addition to their higher number, MDSC isolated from tumor-bearing PLCγ2^{-/-} mice present a more immature phenotype with a lower expression of F4/80, CD11c and B7.2 markers. Importantly, PLCγ2^{-/-} MDSC are more efficient than WT in suppressing antigen-specific CD8⁺ T cell proliferation, via increased ROS and NO production. To further confirm the relevance of MDSC in tumor growth, MDSC isolated from tumor-bearing PLCγ2^{-/-} or WT mice were injected into subcutaneous tumor bearing WT mice. Animals receiving PLCγ2^{-/-} MDSC displayed an increased tumor burden compared to mice receiving WT-MDSC. This increase in tumor growth was accompanied by a greater expansion of MDSC in the spleen (WT mice+WT-MDSC: 8.20.8%, WT mice +PLCγ2^{-/-} MDSC: 16.71.4%, p<0.001). As downregulation of β-catenin is associated with MDSC development and mobilization, we analyzed its expression in PLCγ2^{-/-} MDSC and found reduced β-catenin levels both in vitro and in vivo. Thus, PLCγ2 regulates MDSC expansion and migration from bone marrow to spleen and at tumor sites, possibly via the Wnt pathway, and modulates their capacity to suppress CD8⁺ T cell activation. In conclusion, suppression of anti-tumor T cell responses by MDSC can lead to increased tumor growth in bone, even in mice with defective OC. Thus, the vicious cycle of tumor growth in bone, in which tumor cells and OC stimulate each other, should be expanded to include MDSC as important positive regulators of tumor growth, independent of OC.

Parathyroid Hormone-related Peptide (PTHrP) Up-regulates Myeloid-Derived Suppressor Cells (MDSC) in the Bone Marrow, Contributing to Prostate Cancer Growth and Angiogenesis. Serk In Park¹*, William Sadler¹, Amy Koh¹, Fabiana Soki¹, Laurie McCauley². ¹University of Michigan, USA, ²University of Michigan, School of Dentistry, USA

The tumor microenvironment consists of primary tumor cells mixed with multiple types of stroma, in which a significant fraction originates from the bone marrow. Among those bone marrow-derived cells, CD11b⁺Gr1⁺ cells (MDSCs) correlate with tumor progression. MDSCs compromise the T cell-mediated host immune response, and serve as a predominant source of pro-tumorigenic factors such as matrix metalloproteinases (MMP). However, regulation of MDSCs in their organ of origin (i. e. bone marrow) by distant solid tumors remains unclear. PTHrP is functionally homologous with PTH, and is expressed by solid tumors including prostate cancer (PCa) that has a strong affinity for bone. This study addressed the hypothesis that PCa-derived PTHrP regulates MDSCs in the bone marrow, contributing to tumor growth and angiogenesis. Two PCa cell lines, PC-3 (expressing high basal PTHrP) and Ace-1 (expressing undetectable PTHrP), were used. PTHrP gene expression was targeted via shRNA in PC-3 cells (resulting in PTHrP^{hi} and PTHrP^{Lo} PC-3 clones), whereas PTHrP was overexpressed in Ace-1 cells (resulting in Ace-1^{PTHrP} and Ace-1^{pcDNA}). Stable clones were selected and grown subcutaneously in male athymic mice. As PTHrP is a known mitogen, low-PTHrP expressing tumors were grown for a longer period, resulting in tumors of similar size between groups. Tumor tissues were then analyzed by flow cytometry, immunostaining and quantitative PCR. PCa-derived PTHrP levels correlated with MDSC recruitment in the tumor tissue and also with tumor microvessel density, potentially mediated by MDSC-derived MMP-9 expression, but not by tumor-derived VEGF. In addition, administration of recombinant PTHrP (1-34) to mice carrying Ace-1^{pcDNA} tumors expanded MDSCs both in both the tumor tissue and in bone marrow, with increased angiogenesis. Furthermore, MDSCs were sorted out by flow cytometry from the bone marrow of Ace-1^{PTHrP} or Ace-1^{pcDNA} tumor-bearing mice, followed by co-injection with tumor cells. Interestingly, tumors co-injected with MDSCs from mice bearing PTHrP-expressing tumors were significantly larger than the tumors co-injected with MDSCs from non-PTHrP tumor mice. In summary, PCa-derived PTHrP circulates to expand and potentiate MDSCs in the bone marrow, which then return to the tumor tissue contributing to tumor angiogenesis and growth. These data suggest that tumors positively regulate the bone marrow microenvironment via PTHrP expression to promote tumor angiogenesis and immune suppression.

The Heparin Binding Domain of PRELP: a New Therapeutic Approach for the Treatment of Breast Cancer Induced Bone Metastases. Nadia Rucci¹, Mattia Capulli², Barbara Peruzzi², Anna Rufo², Marta Capannolo³, Barbara Peruzzi¹, Dick Heinegard⁴, Anna Teti¹. ¹University of L'Aquila, Italy, ²Department of Experimental Medicine, University of L'Aquila, Italy, ³Department of Experimental Medicine University of L'Aquila, Italy, ⁴Lund University, Sweden

hbdPRELP, a peptide corresponding to the heparin binding domain of the matrix protein PRELP, inhibits osteoclastogenesis by impairing NF- κ B transcriptional activity. Hence, we hypothesized a potential application of hbdPRELP for the management of bone loss diseases. We observed that hbdPRELP counteracted bone loss in ovariectomized (OVX) mice treated with daily injections of 10 mg/kg starting both three days or 5 weeks after OVX. Potency was similar to that of alendronate and the effect specifically impaired osteoclast number and activity. hbdPRELP treatment was well tolerated also at high doses and in prolonged treatments. Balb/c nu/nu mice were then intracardially injected with the human breast cancer cell line MDA-MB-231, stably transfected with the firefly luciferase (MDA-LUC) to monitor tumor progression by bioluminescence. In a preventive protocol, mice were treated with 3.7 and 15 mg/kg hbdPRELP, 5 days/week, starting the day after tumor cell injection. Compared to controls, in hbdPRELP treated mice we found a dose dependent decrease of mortality (85% vehicle vs 36% hbdPRELP, $P=0.03$) and incidence of bone metastases (55% vehicle vs 18% hbdPRELP, $P=0.04$), together with a decrease of the bone resorption marker CTX (vehicle 31.55.1 vs hbdPRELP 18.81.7 ng/ml, $P=0.005$). Of note, in these experiments hbdPRELP also reduced visceral metastasis size. We next applied a curative protocol treating animals after the appearance of metastases and observed a 40% reduction of bone metastasis size. When MDA-LUC cells were directly injected into the tibia, hbdPRELP did not alter tumor take and osteolytic lesion incidence, while it decreased osteolytic area (vehicle 6.60.14, hbdPRELP 2.70.05, arbitrary units, $P=0.03$), osteoclast surface (vehicle 163.9 vs hbdPRELP 3.30.4, $P=0.049$) and osteoclast number per bone surface (vehicle 10.42.1 vs hbdPRELP 3.0.9, $P=0.05$), suggesting that the decreased incidence was determined by the reduced homing ability of circulating tumor cells induced by hbdPRELP. MDA-LUC cells were also orthotopically injected into the mammary fat pad. Treatment with hbdPRELP reduced tumor volume, evaluated up to 23 days after cell injection (vehicle 2.10.1 vs hbdPRELP 1.30.3 cm³, $P=0.04$). Taken together, these pre-clinical data indicate a translational application of hbdPRELP in the treatment of osteoporosis and metastatic disease of breast cancer, with the expectation that its endogenous nature could minimize drug therapy side effects.

ER stress Signaling Molecule XBP1s Regulates Bone Marrow Stromal Cells in Multiple Myeloma Bone Disease. Guoshuang Xu¹, Kai Liu¹, Judy Anderson¹, Suzanne Lentzsch¹, G. David Roodman², Hong-Jiao Ouyang¹. ¹University of Pittsburgh, USA, ²VA Pittsburgh Healthcare System (646), USA

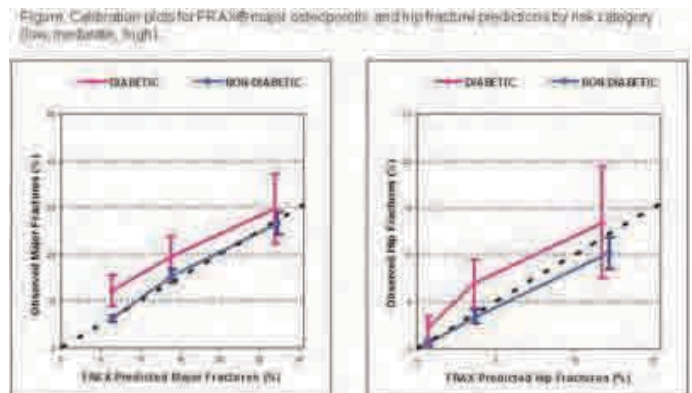

Multiple myeloma (MM) is one of the most frequent cancers that affect skeleton and induces osteolytic lesions. Complex cell-cell interactions among MM tumor cells and their microenvironment are essential for tumor growth, survival and MM-induced osteolytic lesions. Bone marrow stromal cells (BMSCs) are considered a key player in the microenvironmental support of MM cell growth and bone destruction. In order to disrupt the protective effects of BMSCs on MM cell growth and osteoclast (OCL) formation, it is essential to achieve a thorough understanding of the molecular changes in BMSCs induced by MM cells in MMBD. Spliced form of x-box binding protein-1 (XBP1s) is a major proximal effector of the ER stress/unfolded protein response (UPR) signaling. It is highly expressed in MM cells and plays an indispensable role in survival and growth of MM cells. However, it remains completely unknown if XBP1s plays a role in regulating MM microenvironment support to MM cell growth and OCL formation. Our results demonstrated that XBP1s was induced in BMSCs from MM patients compared with the healthy donors. TNF α , a major inflammatory cytokine secreted by MM cells, also induced XBP1s mRNA splicing and protein expression in normal donors' BMSCs. Overexpression of XBP1s in normal BMSCs enhanced both baseline and TNF α -induced the protein levels of adhesion molecule VCAM-1 as well as secretion of osteoclastogenic cytokines IL-6 and RANKL. Consequently, overexpression of XBP1s in BMSCs increased their support of MM cell growth and OCL formation. Conversely, deficiency of XBP1 in normal donors' BMSCs displayed a range of effects on BMSCs opposite to that of overexpression of XBP1s. Further, knockdown of XBP1 in MM patients' BMSCs greatly compromised their hypersensitivity to TNF α as to VCAM-1 protein expression and IL-6 and RANKL secretion. Consequently, knockdown of XBP1 in MM patients' BMSCs reversed their enhanced capacity to support MM cell growth to a level that was comparable to that of normal donors. Further, knockdown of XBP1 in murine BMSCs significantly reduced their support of OCL formation. Taken together, our results, for the first time, demonstrate that XBP1s is a pathogenic factor underlying BMSCs supports of MM cell growth and OCL formation. These results imply a great therapeutic potential of targeting the XBP1 signaling to disrupt the BMSCs support of MM cell growth and bone resorption as a means to treat MM bone disease.

FRAX® Underestimates Fracture Risk in Patients with Diabetes. Lora Giangregorio¹, William Leslie², Lisa Lix³, Helena Johansson⁴, Anders Oden⁵, Eugene McCloskey⁶, John Kanis⁷. ¹University of Waterloo, Canada, ²University of Manitoba, Canada, ³University of Saskatchewan, Canada, ⁴Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, ⁵Chalmers University of Technology, Sweden, ⁶University of Sheffield, United Kingdom, ⁷University of Sheffield, Belgium

OBJECTIVE: To determine whether diabetes is a risk factor for incident hip or major osteoporotic fractures independent of FRAX®. **METHODS:** Men and women with diabetes (N=3,518) and non-diabetics (N=36,085) age ≥ 50 y at the time of BMD testing (1987-2008) were identified in a large clinical database from Manitoba, Canada. FRAX probabilities were calculated and fracture outcomes to 2008 were established via linkage with a population-based data repository. Diagnosed diabetes prior to BMD testing was from a validated algorithm. Multivariable Cox proportional hazards models were used to determine if diabetes was associated with incident hip fractures or major osteoporotic fractures after controlling for FRAX risk factors, and after controlling for derived FRAX probabilities. Fracture probabilities from FRAX were categorized as low (<10%), moderate (10-20%), or high (>20%), and observed 10 y fracture risk was estimated using the Kaplan-Meier method. **RESULTS:** Mean probabilities were similar between groups for major fractures (diabetic 11.17.2 vs. non-diabetic 10.97.3, $p=0.116$) and hip fractures (diabetic 2.94.4 vs. non-diabetic 2.84.4, $p=0.400$). After controlling for age, sex, medication use, BMD and FRAX risk factors, diabetes was a significant predictor of subsequent major osteoporotic fracture (HR 1.61 [95% CI: 1.42-1.83]). Similar results were seen after adjusting for FRAX probability directly (HR 1.59 [95% CI: 1.40-1.79]). No diabetes interactions were observed with age, sex or femoral neck WHO category. Age (but not sex or femoral neck WHO category) modified the effect of diabetes on hip fracture risk (p -interaction $p=0.002$) with diabetes a stronger predictor of hip fracture in those age <65 y after adjustment for hip fracture probability (HR 5.34 [95% CI: 3.14-9.08], $p<0.001$) than in those ≥ 65 (HR 2.06 [HR 1.59-2.6], $p<0.001$). Higher mortality from diabetes attenuated but did not eliminate the excess fracture risk. FRAX underestimated observed major osteoporotic and hip fracture outcomes in diabetics (adjusted for competing mortality), but was well calibrated for non-diabetics (Figure). **CONCLUSIONS:** Diabetes confers an increased risk of fracture that is independent of FRAX derived with BMD. The current study suggests that diabetes might be considered for inclusion in future iterations of FRAX.

Reduced Fracture Risk After Kidney Transplant With Early Corticosteroid Withdrawal Regimens: An Analysis of the United States Renal Data System. Lucas Nikkel¹, Sumit Mohan¹, Chiyuan Zhang², Donald McMahon³, David Cohen¹, Lloyd Ratner¹, Geoffrey Dube¹, Bekir Tanriover¹, Christopher Hollenbeak⁴, Stephanie Boutroy¹, Mary Leonard⁵, Elizabeth Shane³, Thomas Nickolas¹. ¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Columbia University College of Physicians & Surgeons, USA, ⁴Penn State Hershey College of Medicine, USA, ⁵Children's Hospital of Philadelphia, USA

Corticosteroid (CS) based immunosuppression (CSBI) after kidney transplant (KTx) is associated with rapid bone loss and fractures (Fx). Early CS withdrawal (ECSW) protocols are being implemented at KTx centers across the United States, and more than 30% of KTx recipients are now managed with ECSW. In contrast to CSBI, ECSW does not cause rapid spine or hip bone loss. However, the impact of ECSW on Fx risk has not been assessed. We hypothesized that ECSW would be associated with fewer Fx than CSBI.

Using the United States Renal Data System, 92,699 adults who had a KTx between January 1, 2000 and December 31, 2006 were identified. CS use was determined from UNOS immunosuppression forms completed at time of KTx in an intent-to-treat analysis. First Fx events requiring hospitalization were identified from discharge ICD-9 codes after KTx. Continuous covariates (age, BMI, HLA mismatches) were compared with Students t tests and categorical covariates were compared with χ^2 analysis. Time to first Fx after KTx was modeled by the Kaplan-Meier method and Cox proportional hazards.

Patients on ECSW differed slightly but significantly from CSBI patients in age (50 vs 48 years; $p<0.001$), gender (62% vs 60% male, $p<0.001$), race/ethnicity (69% vs 67% white; $p<0.001$), BMI (27.1 vs 26.6 kg/m², $p<0.001$), donor (48% vs 39% live donor; $p<0.001$), and prior transplant (4% vs 16%; $p<0.001$). Fx rates were similar pre-KTx. Median (IQR) follow-up was 1428 (784-2042) days. Fx associated with hospital admissions post-KTx were more common among patients initiating CSBI than ECSW (total incidence 3.3% vs 1.8%, $p<0.001$). After KTx, 2890 Fx hospitalizations were observed during follow-up (362620 person-yr). There were 6.3 Fx per 1000 patients/year for ECSW and 8.2 Fx per 1000 patients/year with CSBI. On multivariate analysis, ECSW reduced Fx risk by 28% (HR 0.72; $p<0.001$). Fx risk increased with older age, pre-transplant Fx, female gender, low BMI, pre-transplant diabetes, prior transplant, and pre-transplant dialysis. ECSW and Asian or Black race were associated with reduced Fx risk. Lower Fx incidence with ECSW versus CSBI was significant by 29 months post-KTx (Figure 1).

After KTx, ECSW is associated with a 28% lower Fx rate associated with hospitalization compared to CSBI. As most Fx are treated as outpatients, these results likely underestimate the fracture burden. Prospective studies are needed to quantify the effects of ECSW on all-fracture incidence after KTx.

Bone Resorption and Bone Mineral Density Across the Menopausal Transition in the Study of Women Across the Nation (SWAN). Beth Prairie*¹, Leslie Mevn², Kristine Ruppert², Yinjuan Lian³, Carolyn Crandall⁴, Gail Greendale⁴, Joel Finkelstein⁵, Mary Fran Sowers⁶, Jane Cauley⁷. ¹University of Pittsburgh, Magee-Womens Hospital, USA, ²University of Pittsburgh, USA, ³University of Pittsburgh, USA, ⁴University of California, Los Angeles, USA, ⁵Massachusetts General Hospital, USA, ⁶University of Michigan, USA, ⁷University of Pittsburgh Graduate School of Public Health, USA

Evidence suggests that N-telopeptide of Type I collagen (NTx) is a sensitive marker of bone resorption in women, and that NTx is very sensitive to changes in the hormonal milieu. To evaluate the association and diagnostic value of NTx for changes in bone mineral density (BMD) in women across the menopausal transition, we studied 2,359 multi-ethnic women, aged 42-53 years, enrolled in SWAN. Women were pre- or peri-menopausal at enrollment and attended up to 8 annual follow-up clinical visits. At each visit, BMD of the total hip and total spine were measured by dual-energy x-ray absorptiometry (DXA) and urinary cross-linked NTx/creatinine ratio was assayed. Generalized linear mixed models were used to evaluate the longitudinal relationship of baseline and time-varying NTx with annual BMD measurements. The correlation between annual NTx measurements with BMD and percent change in BMD was assessed using Spearman's correlation coefficient (r). The area under receiver operating characteristic curves (AUC) and likelihood ratios (LR) were calculated to assess the utility of NTx for detecting an annual BMD loss of 5% or more. Data were censored when a participant had a hysterectomy, bilateral oophorectomy, started hormone or other antiresorptive therapy. The mean baseline age was 45.8 \pm 2.7 years. Half of the women were White, 28% African American, 11% Chinese, and 11% Japanese. Both NTx and BMD measurements were available for 11,273 visits. Higher NTx values (baseline and time-varying) were associated with

lower total hip and total spine BMD ($P<0.0001$), even after adjustment for time, study site, race, menopausal status, body mass index, follicle-stimulating hormone, and baseline age, activity, and osteocalcin. There was a significant negative correlation between NTx and both BMD measures: total hip ($r = -0.158$), and total spine ($r = -0.236$), as well as percent annual change in BMD: total hip ($r = -0.165$), and total spine ($r = -0.237$). The AUCs for a 5% loss of total hip and total spine BMD were 0.698 and 0.708 (Figure 1). Table 1 shows the LR for ranges of NTx values in detecting a 5% total spine and hip BMD loss. The overall negative predictive value of NTx for a 5% loss of BMD at total hip and total spine is 97.4% and 94.9%, respectively. With an NTx >60 (90% percentile of NTx), a woman is twice as likely to have lost 5% BMD in the past year as not. Urinary NTx may be a useful clinical tool in the future for predicting women at higher risk for decreased BMD.

Table 1. Likelihood ratios for NTx predicting a 5% loss in total hip or total spine

NTx Value	No. (Proportion) of Women with 5% Total Hip BMD loss (N=221)	No. (Proportion) of Women with <5% Total Hip BMD loss (N=8175)	Likelihood Ratio	No. (Proportion) of Women with 5% Total Spine BMD loss (N=433)	No. (Proportion) of Women with <5% Total Spine BMD loss (N=7925)	Likelihood Ratio
70+	36 (0.158)	440 (0.054)	2.93	80 (0.185)	390 (0.048)	3.78
60-69.99	25 (0.118)	409 (0.050)	2.35	57 (0.132)	374 (0.047)	2.79
50-59.99	40 (0.181)	701 (0.086)	2.11	64 (0.148)	671 (0.085)	1.75
40-49.99	42 (0.190)	1456 (0.178)	1.07	90 (0.208)	1401 (0.177)	1.18
<40	78 (0.353)	5167 (0.632)	0.56	142 (0.328)	5069 (0.642)	0.51

Trajectories of Femoral Neck Strength Over the Menopause Transition. Shinya Ishii¹, Jane Cauley², Carolyn Crandall¹, Mei-Hua Huang³, Michelle Danielson⁴, Gail Greendale¹, Arun Karlamangla¹. ¹University of California, Los Angeles, USA, ²University of Pittsburgh Graduate School of Public Health, USA, ³UCLA, USA, ⁴University of Pittsburgh, USA

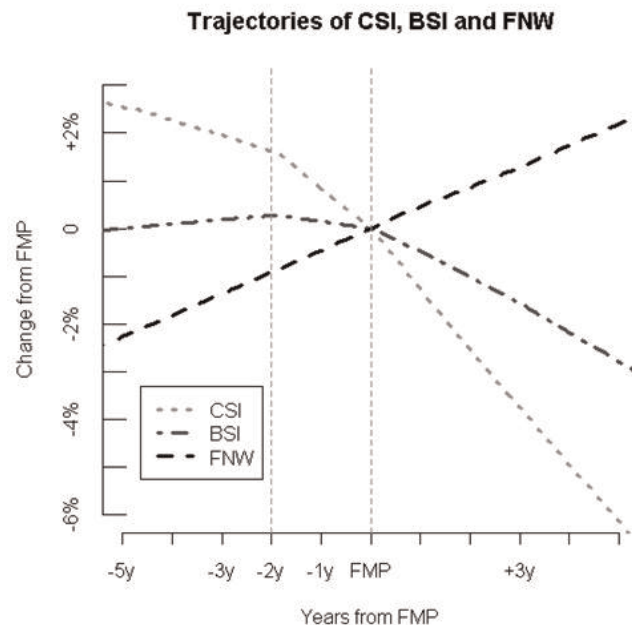

Composite indices of femoral neck strength, which integrate dual energy x-ray absorptiometry (DXA) derived areal bone mineral density (aBMD) and bone size with body size, have been shown to be inversely associated with hip fracture risk. Our objective was to describe longitudinal trajectories of the strength indices across the menopausal transition and determine major influences on trans-menopausal declines in strength.

We analyzed data from 921 women (Caucasian 406, African American 254, Chinese 126 and Japanese 135) in the Study of Women's Health across the Nation (SWAN) who had ≥ 3 hip DXA scans and had reliable final menstrual period (FMP) dates. Participants were pre- or early peri-menopausal, ages 42-53 at baseline, and were followed for 9.11.8 years. Composite indices of femoral neck strength in different failure modes were created from repeated DXA-based observations of aBMD, femoral neck width (FNW), and femoral neck axis length (FNAL), as $aBMD \cdot FNW / \text{weight}$ for compression strength index (CSI), $aBMD \cdot FNW^2 / (FNAL \cdot \text{weight})$ for bending strength index (BSI) and $aBMD \cdot FNW \cdot FNAL / (\text{height} \cdot \text{weight})$ for impact strength index (ISI). Based on examination of LOESS plots as a function of time from FMP, we fit piecewise linear mixed effects models to the repeated measurements, with two knots at FMP -2 years and FMP for all three indices. We adjusted for age at FMP, body mass index (BMI), race/ethnicity, smoking status, physical activity, and medication use.

FNW increased linearly at 0.1 mm/year throughout the study period. CSI and ISI declined slightly prior to FMP -2 year but decline accelerated thereafter. BSI increased slightly prior to FMP -2 years, plateaued, then began to decline after the FMP (Figure). Mean decline over the 10 years (5 preceding and 5 following FMP) was 7.7% in both CSI and ISI, and 3.4% in BSI. Women with higher BMI had slower declines in CSI and ISI, but not in BSI. Japanese women had slower increase in FNW and faster declines in CSI and BSI.

Despite increases in bone size to compensate for declines in bone density, femoral neck strength declines significantly during the menopausal transition, with rapid declines commencing two years before the FMP. The rates of decline are modified by BMI and race/ethnicity.

Young and Elderly Women Matched for Areal BMD by DXA at the Radius Have Profound Differences in Cortical Porosity, but Not Trabecular Microstructure. Kristy Nicks¹, Shreyasee Amin¹, Elizabeth Atkinson¹, Byron Riggs¹, L. Joseph Melton¹, Sundeep Khosla². ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA

Previous studies using DXA have demonstrated that age is a major predictor of bone fragility and fracture risk independent of areal BMD (aBMD). Thus, for the same aBMD, a 70-yr-old woman has >10-fold the risk of fragility fracture as a 30-yr-old (Hui et al, JCI 1988). While this BMD-independent effect of age has been attributed to poorer bone "quality" in elders, the structural basis for this effect remains unclear. Since high resolution peripheral quantitative computed tomography (HRpQCT) can assess trabecular and cortical microarchitecture, we matched young and elderly women for aBMD at the radius and then evaluated for differences in trabecular or cortical microstructural parameters by HRpQCT. From an age-stratified, random sample of community adults, we selected from women not currently on osteoporosis treatment who had DXA and HRpQCT scans at the radius (n = 155), to match 44 women <50 yrs (mean age, 41 yrs) with 44 women ≥ 50 yrs or over (mean, 62 yrs) by radius aBMD from DXA (mean SEM, young, 0.69 0.01 g/cm²; elderly, 0.69 0.01 g/cm²; p = 0.71). HR-pQCT (Xtreme CT, Scanco; voxel size, 82 μ m) provided trabecular (bone volume/tissue volume [BV/TV], trabecular number [TbN], thickness [TbTh], and separation [TbSp]) and cortical microstructure (cortical thickness [CtTh], cortical pore volume [CtPoV], and percent cortical porosity [CtPo]). In young and elderly women matched for DXA aBMD, trabecular BV/TV and was not statistically different (Figure panel A), with similar findings for TbN, TbTh and TbSp (data not shown). Interestingly, while CtTh was similar in young and elderly women (panel B), both CtPoV and CtPo were significantly higher (by 125%) in older as compared with younger women (panels C and D). Since both groups were matched on DXA aBMD, these differences in CtPoV and CtPo clearly were not captured by aBMD. Collectively, our findings indicate that young and elderly women matched for DXA aBMD, at least at an appendicular site represented by the radius, have identical trabecular microarchitecture but clearly different cortical microstructure, with a marked increase in CtPoV and CtPo. Further studies are needed to define the extent to which this deterioration in cortical microstructure contributes to the BMD-independent effect of age on bone fragility and fracture risk at the radius as well as other sites of osteoporotic fractures, such as the spine and hip.

Differences in Hip Geometry Between Older Men With and Without Hip Fracture. Laura Yerges-Armstrong¹, Marc Hochberg², William Hawkes¹, Lisa Reider³, Thomas Beck⁴, Denise Orwig⁵, Jay Magaziner¹. ¹University of Maryland, USA, ²University of Maryland School of Medicine, USA, ³School of Public Health At Johns Hopkins, USA, ⁴Quantum Medical Metrics, LLC, USA, ⁵University of Maryland, Baltimore, USA

While bone mineral density (BMD) is an important risk factor for hip fracture, measures of proximal femur shape and structure have also been associated with hip fracture risk. However, most prior studies have been performed in women. This analysis was conducted to compare hip structural geometry parameters from the contralateral proximal femur in male hip fracture cases to male controls. Cases were older men (age ≥ 65 years) who were enrolled in the Baltimore Hip Study (BHS)-7, a prospective cohort study of hip fracture outcomes in community dwelling elders, and underwent dual energy x-ray absorptiometry (DXA) of the contralateral femoral head within 2 weeks of hospitalization for repair of hip fracture. Controls were men enrolled in the Baltimore Male Osteoporosis Study (MOST), a prospective cohort study of men age 65 and older from the Baltimore metropolitan area recruited without regard to their skeletal health. DXA scans were analyzed using the hip structural

PTH(1-84) Replacement Therapy in Hypoparathyroidism (HypoPT): a Randomized Controlled Trial on Pharmacokinetics and Dynamic effects Following 24 Weeks of treatment. Tanja Sikjaer*, Lars Reinmark, Lars Rolighed, Leif Mosekilde, Aarhus University Hospital, Denmark

In HypoPT, lack of PTH necessitates treatment with calcium and vitamin D analogues in order to avoid hypocalcemia. To study if replacement with the missing hormone possesses advantages, we randomized 62 patients with HypoPT to 24-wks with a daily SC injection in the thigh of PTH(1-84) 100 µg or similar placebo, as add to conventional therapy. At end of study, we performed a 24h biochemical monitoring on 39 patients (22 on PTH) in order to assess effects on diurnal variations in calcium-phosphate homeostasis. Following injection, blood samples were obtained at 0.25, 0.5, 1.0, 1.5, 2, 3, 4, 5, 6, 7, 8, 10, 12, 16, 20, 24h and urine was collected for the time intervals: 0-2, 2-4, 4-8, 8-16, and 16-24h.

Overall, during the 24-wks of therapy patients on PTH reduced their daily dose of calcium and active vitamin D significantly by 75% and 73%, respectively. Plasma PTH levels rose immediately, reaching a peak level of median 246 (interquartile range (IQR): 181–396) pg/ml at the first time point of measurement (15 min after injection). Thereafter, PTH levels decreased gradually reaching pre-dosing levels after app. 16h, with a plasma $t_{1/2}$ of 4.7 (IQR 4.0–5.8)h. PTH caused significant changes in the diurnal rhythms of plasma ionized calcium and 1,25(OH)₂D levels (Figure), with rising levels reaching a peak app. 8h following the injection. 4 to 12h following injection, asymptomatic hypercalcemia (>1.32 mmol/l) was present in 41% of PTH treated patients. Despite hypercalcemia, renal excretion of calcium was significantly lower 4-8h following injection in the PTH- compared with the placebo-group, and 24h urinary calcium did not differ between groups. Renal excretion rates of magnesium was significantly lower in the PTH- compared with the placebo-group throughout the 24h of study causing a decreased total (24h) magnesium loss in the PTH- (4.7, IQR: 4.1–6.7 mmol/d) compared with the placebo- (5.7; IQR: 4.0–7.7 mmol/d, $p < 0.05$) group. PTH caused lower phosphate levels, although treatment did not affect diurnal rhythms of plasma phosphate- or magnesium- levels, or the calcium-phosphate product.

In conclusion, a fixed dose of 100 µg/d PTH(1-84) may be too high, as transient hypercalcemia developed in some patients. However, PTH decreased urinary calcium losses in the hour following injection and magnesium losses throughout the study period. Accordingly, PTH may possess advantages compared with conventional treatment if administered in doses adapted to the patient's needs.

analysis (HSA) program (Beck et. al; Inv. Radiol 1990) to compute geometry parameters at the narrow neck and intertrochanteric regions. Statistical analyses testing for differences between men with and without fracture were adjusted for participant's age. HSA data were available for 41 cases and 688 controls. Unadjusted values for selected HSA parameters are presented in Table 1. Compared to controls, men with hip fracture had a 24.4% higher buckling ratio ($p < 0.0001$) at the narrow neck region and a 24.3% higher buckling ratio at the intertrochanteric region ($p < 0.0001$) compared to controls. In addition, there was a 9.9% smaller narrow neck cross-sectional area ($p = 0.001$) and 7.7% smaller intertrochanteric cross-sectional area ($p = 0.02$) observed in men with hip fracture compared to controls. These results demonstrate that hip geometry parameters in the contralateral proximal femur that are markers for decreased bone strength (higher buckling ratio and smaller cross sectional area) are associated with hip fracture in older men.

Treatment of Hypoparathyroidism with PTH(1-84) is Safe and Effective For Up to 4 Years. Natalie Cusano*¹, Mishaela Rubin², Donald McMahon¹, Rebecca Ives³, Jim Sliney Jr³, John Bilezikian¹. ¹Columbia University College of Physicians & Surgeons, USA, ²Columbia University, USA, ³Columbia University Medical Center, USA

Hypoparathyroidism (HypoPT) is a rare disorder characterized by low serum calcium and PTH levels. Standard treatment is oral calcium and vitamin D but maintaining normal serum calcium levels can be a therapeutic challenge. We previously described our 2-yr experience with PTH(1-84) in 30 HypoPT subjects. Calcium (Ca) and calcitriol supplementation requirements fell, while BMD of the lumbar spine (LS) increased and of the distal one third distal radius (DR) decreased. In view of the chronic nature of HypoPT, information about longer term effects of PTH(1-84) treatment on calciotropic parameters and BMD is needed. This report, for the first time, provides information on the use of PTH(1-84) in HypoPT for 48 months.

18 HypoPT subjects [age 49 ± 13 yr, 4 men and 14 women (6 postmenopausal), serum Ca 8.3 ± 0.8 mg/dl, PTH 3.0 ± 5.4 pg/ml, T-scores at LS, +1.2 ± 2.2, femoral neck (FN), +0.28 ± 1.4, total hip (TH), +0.55 ± 1.4, and distal radius (DR), -0.14 ± 0.97] were treated with PTH(1-84) 100 µg qod for 4 years (3 switched to 100 µg q3d and 3 to 100 µg qd after 1 yr). Biochemistries and BMD were measured q 6 months. Treatment with PTH(1-84) reduced supplemental Ca requirements by 36% (3011 ± 2275 to 1929 ± 1193 mg/d from baseline to 48 months; $p < 0.01$). Calcitriol requirements fell (0.6 ± 0.7 to 0.4 ± 0.5 µg/d; $p = NS$), with 3 subjects able to stop all calcitriol. Serum Ca remained stable (8.3 ± 0.2 to 8.5 ± 0.2 mg/dl; $p = NS$). Urinary Ca fell from 277 ± 26 mg/d to 181 ± 28 at 12 months ($p = 0.007$), remaining lower throughout the remaining years (at 48 months, 222 ± 27 mg/d). Phosphorus levels fell from 4.4 ± 0.2 to 4.0 ± 0.2 mg/dl ($p < 0.0001$). BMD increased at the LS by 2.4 ± 1.2% at 12 months ($p = 0.05$); by 4.1 ± 1.2% at 24 months ($p = 0.002$); and by 6.0 ± 1.2% at 48 months ($p < 0.0001$). FN and TH BMD remained unchanged throughout while DR BMD fell slightly (-1.8 ± 0.8%) over the first 24 months ($p = 0.03$), not changing further at 48 months (-2.1 ± 0.9%; $p = NS$ from 24 months). There were only 3 transient episodes of mild hypercalcemia in 3 subjects over 4 years.

The data show that PTH(1-84) treatment of HypoPT for up to 4 years maintains serum Ca while reducing supplemental Ca and calcitriol requirements and urinary Ca excretion. LS BMD continued to increase while the initial small decline in DR did not progress. These data provide support for the safety and efficacy of PTH in HypoPT for up to 4 years.

Parathyroidectomy Improves Abnormal Cardiovascular Indices in Mild Primary Hyperparathyroidism. Marcella Walker^{*1}, Tatjana Rundek², Shunichi Homma¹, Marco DiTullio¹, James A. Lee¹, Chiu-Yuan Zhang¹, Donald J. McMahon¹, Ralph L. Sacco¹, Shonni J. Silverberg¹. ¹Columbia University, USA, ²University of Miami, USA

We have reported that mild primary hyperparathyroidism (PHPT) is associated with subclinical cardiovascular (CV) abnormalities, including increased carotid intima-media thickness (IMT), maximal carotid plaque thickness (MCPT) and carotid stiffness. To assess whether CV abnormalities are reversible with parathyroidectomy (PTX), patients (n=44, 80% female, 627 yrs, calcium 10.5 ± 0.1 mg/dl, PTH 977 pg/ml) had carotid ultrasound and echocardiograms at baseline, 1 and 2 yrs post-PTX (mixed model analysis; Table data mean ± SE). Blood pressure was normal at baseline (123/74/1) and did not change after PTX. BMI did not decline and only 1 patient initiated BP or cholesterol lowering medication. In the 2nd post-PTX yr, elevated carotid IMT declined from 12 mo values (p<0.05) and increased carotid stiffness decreased into the normal range (p=0.056 vs. baseline). Neither MCPT nor carotid plaque number regressed. Cardiac structure and function were normal at baseline. After PTX, left ventricular mass index (LVMI) and cardiac calcifications (myocardial and mitral annular) did not change. Measures of diastolic function either worsened within the normal range (intraventricular relaxation time [IVRT], tissue Doppler e' [e']), or were unchanged (deceleration time (DT), early to late mitral annular velocity [E/A]). In patients who were abnormal at baseline, certain CV indices improved significantly by 2 years after PTX. Elevated IMT, present in 73% at baseline, declined although it did not normalize (0.9970.096 to 0.9700.068 mm; p<0.03). Increased carotid stiffness, present in 40% at baseline, tended to decrease (9.03.4 to 6.41.9; p=0.058), and became normal in 8 of 17 patients. Diastolic dysfunction normalized in those with abnormal E/A (25% of patients; 0.670.06 to 0.830.15; p<0.005) and elevated IVRT (18% of patients; 11411 to 9912 msec; p<0.05). LVMI did not improve. In summary, in a cohort of PHPT patients with subclinical CV disease, the CV response to PTX was modest. However, those with abnormal carotid indices or diastolic dysfunction before PTX had clear improvement in, and in many cases normalization of those abnormalities after surgery. While the effect of these changes on CV events is unknown, the documented improvement in CV indices after PTX, particularly in those with baseline abnormalities, suggests that CV evaluation should be included in the assessment of patients with PHPT who otherwise do not meet criteria for PTX.

Administration of Oral Bisphosphonates Prior to the Diagnosis of Breast Cancer is Associated with a Reduction in the Development of Skeletal Metastases Independent of Stage of Disease at Diagnosis. Richard Kremer^{*1}, Ari N. Meguerditchian², Bruno Gagnon², Lyne Nadeau², Nancy Mayo². ¹McGill University, Royal Victoria Hospital, Canada, ²McGill University Health Center, Canada

Bisphosphonates are widely used for the treatment of osteoporosis. Their strong anti-bone resorbing effect has triggered their use in osteolytic bone disease and in particular for osteolytic lesions of metastatic breast cancer.

An earlier study indicates that intravenous administration of Pamidronate, an amino-bisphosphonate highly effective in the treatment of malignancy-associated hypercalcemia, significantly delays the progression of adverse skeletal events in breast cancer patients with established bone metastases. Pamidronate is approved for the treatment of metastatic breast cancer to bone since 1996. In another study the bisphosphonate Clodronate, given immediately after tumour removal, was found to be effective in preventing skeletal metastasis in a group of high risk breast cancer patients.

The effect of bisphosphonates is not restricted to inhibition of osteolysis but seems to reduce the tumour burden in bone in animal models of metastatic breast cancer. As the efficacy of bisphosphonates in skeletal metastasis is now established, it remains to be determined if these agents can be used widely in the prevention of skeletal metastasis, even before the breast cancer occurs.

The aim of this study was therefore to determine whether bisphosphonate use prior to a diagnosis of breast cancer could prevent development of bone metastases.

A cohort study comprising 21,664 women with breast cancer was carried out using health administrative data. Of these women, 77% were Stage 0 or 1 and 10.2% (n=2221) used a bisphosphonate in the 2 year period prior to diagnosis. The most common bisphosphonate was alendronate (66%), followed by risedronate (23%) and etidronate (11%). The modal age was 50 to 64 years; the median (maximum) follow-up time was 5 (10) years. Of the women with no pre-breast cancer bisphosphonate use (n=19,443), 6.5% developed bone metastases compared with 4% of women with pre-breast cancer bisphosphonate use (n=2,221). The unadjusted hazard ratio (HR) was 0.70 (95% CI: 0.57-0.87); adjusted for age, socioeconomic status, comorbidities, and stage, the HR was 0.78 (95% CI: 0.63-0.98). These results indicate the strong potential for bisphosphonates to be protective for the development of bone metastases when administered prior to the diagnosis of breast cancer independent of stage of disease at diagnosis. The study supports the Paget's seed and soil hypothesis that reducing bone turnover deters the establishment of cancer cells in bones.

Hypogonadism in Men (HIM) and Hypogonadism with Estrogen Removal (HER): Effects of Androgens and Estrogens on Bone Resorption in Young Adult Men. Joel Finkelstein^{*1}, Hang Lee¹, Elaine Yu¹, Sherri-Ann Burnett-Bowie¹, J. Carl Pallais¹, Benjamin Leder². ¹Massachusetts General Hospital, USA, ²Massachusetts General Hospital/Harvard Medical School, USA

Both androgen and estrogen deficiency contribute to the increase in bone resorption in severely hypogonadal men. Methods: To determine the roles of androgens and estrogens on bone resorption across the physiologic range of testosterone (T) levels, we recruited 2 cohorts of healthy men aged 20-50. All men received goserelin acetate (Zoladex[®], AstraZeneca LP, 3.6 mg q4wk) to suppress endogenous T and estradiol (E). In addition, men in Cohort 1 (T/E+, n=198) were randomized to treatment with 1 of 5 doses of a T gel (AndroGel[®], Abbott) daily for 16 weeks (G1-placebo; G2-1.25g; G3-2.5g; G4-5g; G5-10g). Men in Cohort 2 (T/E-, n=200) were randomized to the same T doses plus all men received anastrozole (Arimidex[®], AstraZeneca LP, 1 mg/d) to block conversion of T to E. Serum T, E, and CTX levels were measured every 4 weeks. Changes in CTX within the T/E- cohort were determined to assess T effects (i.e. G1 of T/E- cohort vs G2, G3, G4, and G5). If T has an independent effect on bone resorption, CTX should increase more as the T dose is reduced in the T/E- cohort because T levels will differ while all groups have similar (and low) E levels. Changes in CTX between groups receiving the same T dose in the T/E+ and T/E- cohorts were determined to assess E effects (i.e. G1 of T/E+ vs G1 of T/E-, G2 of T/E+ vs G2 of T/E-, etc). If E has an independent effect on bone resorption, changes in CTX should differ at each dose between the T/E+ and T/E- cohorts because T levels are matched while E levels are discordant (except in G1 where T and E are low in both cohorts). Results: Mean serum T and E levels and the change in CTX are shown in the Figure. Mean T levels in G1-G5 were 44, 185, 327, 458, and 790 ng/dL with T/E+ and 40, 198, 374, 478, and 827 ng/dL with T/E-. Within the T/E- cohort, CTX increased more in G1 than in G4 or G5 (P=0.03 and P=0.004) whereas changes in CTX were similar in G1, G2, and G3 indicating that a substantial decline in T is needed to increase CTX when E production is blocked. CTX increased more in G2, G3, G4, and G5 (P<0.05) in men treated with T plus an aromatase blocker than in men treated with T alone, indicating that even a modest fall in E levels (e.g. from 8 to 1 pg/ml in G2) is sufficient to increase bone resorption when T levels are matched. Conclusions: Both androgens and estrogens regulate bone resorption in adult men. However, the skeleton in adult men appears to be more sensitive to a decline in estrogens than to a fall in androgens.

Serum Sclerostin Levels Across a Wide Range of Bone Turnover. Maria Yavropoulou*¹, Antoon Van Lierop², Neveen Hamdy², Socrates Papapoulos². ¹Aristotle University of Thessaloniki, Greece, ²Leiden University Medical Center, The Netherlands

Background: Evidence has been accumulating on the role of osteocytes, as players in the regulation of bone remodeling. One of the main products of these ubiquitous cells, sclerostin, regulates bone formation through inhibition of the Wnt signaling pathway. Circulating sclerostin levels have been evaluated in healthy individuals, but data are scarce regarding different ranges of bone turnover. To address this issue we evaluated serum sclerostin levels in patients with Paget's disease of bone (PD) with predominantly increased bone resorption at different stages of disease activity, and in patients with prostate cancer (PC) metastatic to the skeleton with predominantly increased bone formation at different levels of skeletal involvement. **Patients and Methods:** Sclerostin levels were measured in 94 patients with PD, 28 patients with PC and 77 healthy individuals. Patients with PD and PC had bone scintigraphy to establish the extent of skeletal involvement. Bone turnover was evaluated by measuring serum levels of procollagen type I amino-terminal propeptide (PINP) in all individuals studied and β -carboxy-terminal cross-linking telopeptide of type I collagen (β -CTX) only in patients. None of the patients had renal or liver dysfunction, vitamin D deficiency, or other diseases known to affect bone metabolism. **Results:** The population studied had a wide age range (20 -88 years) and a wide range of bone turnover with serum PINP ranging from 8.4 to 1872 ng/ml and β -CTX ranging from 50 to 3120 pg/ml. Patients with PD and with PC had significantly higher serum sclerostin levels (53.58 \pm 22.4 pg/ml and 57.55 \pm 24.7 pg/ml, respectively) compared to healthy controls (40 \pm 12.8 pg/ml) ($p < 0.001$). Serum sclerostin levels significantly correlated with age ($r = 0.238$, $p < 0.001$) and with PINP ($r = 0.295$, $p < 0.001$), but not with β -CTX ($r = 0.094$, $p = 0.303$) across the wide range of bone turnover. **Discussion:** Circulating sclerostin levels are significantly increased in patients with increased bone turnover, regardless of underlying disease pathology, whether predominantly increased bone resorption as in Paget's disease or predominantly increased bone formation as in metastatic prostate cancer. Sclerostin levels also significantly correlate with bone formation but not resorption markers across a wide range of bone turnover.

Non-collagenous Proteins Influence Bone Mineral Size, Shape and Orientation: A SAXS Study. Atharva Poundarik*¹, Caren Gundberg², Deepak Vashishth³. ¹Rensselaer Polytechnic University, USA, ²Yale University School of Medicine, USA, ³Rensselaer Polytechnic Institute, USA

Bone is a complex hierarchical composite. The organization of bone contributes significantly to toughening its matrix. Recently, non-collagenous proteins (NCPs) have come to light as structural elements in bone's extracellular matrix. Besides, it has been studied that NCPs including osteocalcin (OC) and osteopontin (OPN) regulate the process of mineralization and crystal growth [1, 2]. We hypothesize that their deletion from the matrix is likely to alter crystal formation and growth, and hence modify mineral organization at the ultra-structural level. To this end, we investigate using small angle x-ray scattering (SAXS), the mineral characteristics of knock-out (KO) mice which are deficient in either OC, OPN or both OC and OPN.

SAXS spectra of cortical bone samples of WT, OC-/-, OPN-/- and OC-OPN-/- (double KO) (n=3 each) were acquired (Bruker Nanostar) at a specimen-detector distance of 65.5cm. For each acquisition point, intensity (I), scattering vector (q) and polar angle (θ) data was extracted. Crystal thickness and shape were determined by the computation of two invariants - Porod's constant and the area under the q^{-1} vs. q plot. I vs. q plots were used to analyze orientation of crystals within the plane of the sample.

Crystal thickness of WT group (1.8960.110nm) was greater than OC-/- (1.7770.152nm) and OC-OPN-/- (1.7700.118nm) groups ($p < 0.05$). There was no significant difference observed between the WT and OPN-/- (1.8400.102nm) groups. Shape analyses revealed that crystals of OC-/- and OC-OPN-/- mice were more plate-like as compared to WT mice, whereas OPN-/- mice crystals were more rod-like. Finally, crystals of the OC-OPN-/- mice were less aligned along the collagen fibrils than those of WT ($p < 0.001$), OC-/- ($p = 0.01$) and OPN-/- ($p = 0.002$).

We conclude that OC is a stronger regulator of mineral crystal size and shape, and OPN behaves as a compensatory molecule in the absence of OC. This is evident from OC-OPN-/- mice, where characteristics seen in OC-/- mice are heavily accentuated. NCPs also appear to facilitate orientation of crystals along the long axis of collagen and their absence results in poor crystal alignment. Thus the absence of NCPs may alter the organizational hierarchy of bone at higher scales reducing toughness [4].

Exercise When Young Provides Lifelong Benefit to Cortical Bone Structure and Strength in Men. Sara Mantila Roosa*, Andrea Hurd, Robyn Fuchs, Stuart Warden. Indiana University, USA

Exercise induces the greatest bone gains during growth; however, the persistence of these effects is unknown in the aged skeleton. Previous work suggests exercise-induced gains in bone mass are lost with age; however, exercise during growth primarily influences bone structure rather than mass to increase bone strength. The current study explored whether exercise-induced gains in bone structure and strength accrued when young persist lifelong in men. Former Major League Baseball (MLB) pitchers and catchers (n=81, age 31-85 yrs) were recruited as former exercisers/throwers and compared to control subjects (n=44, age 30-86 yrs). Former MLB players are unique as: 1) unilateral upper extremity loading associated with throwing enables the contralateral side to serve as an internal control; 2) throwing athletes have large dominant-to-nondominant (D-to-ND) differences in midshaft humeral properties, and; 3) former MLB pitchers and catchers were consistently exposed to extreme loading, reducing variations in exercise levels between generations. Peripheral quantitative computed tomography (pQCT) was used to assess the D and ND midshaft humeri, and D-to-ND percent differences were plotted against age. Regression lines for former throwers and controls were assessed for convergence, which represented the age when exercise benefits were predicted to be lost. Exercise when young induced significant skeletal benefits, with recently retired (30-yr-old) throwers having 30% D-to-ND difference in cortical BMC (Ct.BMC), cortical area (Ct.Ar) and total area (Tt.Ar), and 61% D-to-ND difference in estimated ability to resist torsion (polar moment of inertia, I_p). However, the Ct.BMC and Ct.Ar benefits of exercise were lost with age as former thrower and control regression lines converged by 83 yrs. In contrast, D-to-ND differences in Tt.Ar and periosteal perimeter (Ps.Pm) were maintained, with regression lines not converging until 168 yrs. The maintenance of exercise benefits on bone structure, despite loss of mass benefits, contributed to regression lines for D-to-ND difference in I_p not converging until 112 yrs. On average, 80-yr-old former throwers maintained a D-to-ND difference for I_p of >2.5 times that observed due to habitual loading associated with arm dominance in controls. These data indicate that exercise when young has lifelong benefits on cortical bone structure and strength, independent of benefits on bone mass.

Osteocyte Apoptosis is Required for Production of Pro-Osteoclastogenic Signals Following Bone Fatigue in vivo. Oran Kennedy*¹, Daniel Leong², Herb Sun³, Robert Majeska⁴, Mitchell Schaffler⁵. ¹The City College of New York, USA, ²City College New York, USA, ³Mount Sinai School of Medicine, USA, ⁴City College of New York, USA, ⁵City College of New York, USA

Introduction: Osteocyte apoptosis is spatially, temporally and functionally linked to replacement of microdamaged bone via remodeling. The precise molecular mechanisms linking osteocyte death to osteoclastogenesis are unknown. Osteocytes have two potential pathways to recruit osteoclasts to damage sites, one is via apoptotic debris transport or alternatively by production of osteoclastogenic signaling molecules. Transport of debris through the canalicular system is physically problematic. In contrast, cells near microdamage have been shown to upregulate osteoclastogenic signaling molecules. We tested the hypothesis that inhibition of apoptosis blocks expression of pro-osteoclastogenic signaling by cells near microdamage in bone.

Methods: A pan-caspase inhibitor, Q-VD-OPh (QVD) was used to inhibit apoptosis in rats. Two groups were subject to ulnar fatigue loading, and two groups were non-loaded. One fatigued group received 20 mg/kg/day QVD (FAT/QVD) and the other received a corresponding dose of vehicle (FAT/VEH). Two remaining non-loaded groups received identical dosing (CON/QVD and CON/VEH) serving as independent controls. Outcomes were evaluated at 3 and 7 days post-fatigue. These represent pre-resorptive phases in the remodeling response to microdamage. Tissue was harvested at the mid-ulna, a unique site which has a negligible marrow cavity. This combined with removal of the periosteum results in an osteocyte enriched system. RNA was isolated and extracted from this segment and cDNA synthesized. Transcripts were evaluated by qPCR and gene expression analyzed in the main regulatory pathways associated with control of bone resorption: RANKL/OPG/M-CSF. Immunohistochemistry (IHC) assays were also used to confirm gene expression data and to provide spatial information on the origin of these signals relative to damage sites in situ.

Results and Discussion: RANKL/OPG ratio, a primary indicator of osteoclastogenesis, was increased in FAT/VEH group 6-fold at 3d and 18-fold at 7d, M-CSF was unchanged in all groups. In contrast, when osteocyte apoptosis was prevented, despite the presence of the similar damage levels expression of pro-osteoclastogenic signals was absent. IHC data confirmed these findings with apoptosis inhibition preventing expression of signaling factors.

Conclusion: Following fatigue loading, the robust expression of pro-resorptive signaling molecules by resident osteocytes is completely abrogated when apoptosis is inhibited.

The Adaptive Response of Cancellous Bone to In Vivo Loading Is Diminished in Adulthood: A Longitudinal Study. Bettina Willie^{*1}, Annette Birkhold¹, Marta Aido², Tobias Thiele¹, Alexander Schill¹, Russell Main³, Georg Duda¹. ¹Charite- Universitätsmedizin Berlin, Germany, ²Charite- Universitätsmedizin Berlin, Deu, ³Purdue University, USA

Bone can adapt to mechanical stimuli to attain an optimized structure. With aging there may be a reduced adaptive response of cancellous bone to normal mechanical loading, resulting in low bone mass and microarchitectural deterioration. It is unclear how early this reduction in mechanosensitivity manifests. We hypothesize that a reduced adaptive response to mechanical loading may already be present in adulthood. We performed in vivo cyclic compressive loading of the left tibia in female postpubescent adolescent (10wk old) and adult (26wk old) C57Bl/6 mice, with the right limb as an internal control. A peak load of -11N was applied at 4Hz for 216 cycles/day, 5days/week for 2 weeks. This load magnitude engendered peak strains of 1200 µε on the medial tibial midshaft for both ages. Longitudinal microcomputed tomography at 10.5µm voxel resolution was performed at Day 0, 5, 10, and 15 (n=6/age) of the experiment. Additional mice were also loaded and only imaged at Day 15 (n=4/age). Sham loaded control mice were also only imaged at Day 15 (n= 3/age). Cancellous bone volume fraction (BV/TV), tissue mineral density (TMD, mg HA/cm³), trabecular thickness (TbTh, µm) and separation (TbSp, µm) were assessed in the proximal tibial metaphysis. An ANOVA of the inter-limb difference was used to assess within-subject (scan day) and between-subject (age) effects, and interactions. BV/TV, TbTh, and TMD were greater in the loaded relative to control limbs in both age groups. The inter-limb difference in BV/TV, TbTh, and TMD were significantly influenced by scan day (Table 1). Age significantly affected the response to loading. In adolescent mice, the inter-limb difference in BV/TV and TMD were due to load-induced increases in the loaded limb. In contrast, in adult mice the inter-limb difference was due to decreased BV/TV and TMD in the non-loaded control limbs, which were similar to sham loaded limbs at day 15, while applied load maintained bone mass in the loaded limb during the study. In conclusion, in vivo loading enhanced bone mass, density and architecture in adolescent mice and maintained bone mass in adult mice. These data suggest that the adaptive response of cancellous bone to mechanical loading is reduced in adulthood, but that loading may still be beneficial to maintain bone mass in individuals of advanced age.

Bone Mineral Density (BMD) of Individual Trabeculae in Human Trabecular Bone. Ji Wang^{*1}, Bin Zhou¹, X.Tony Shi¹, Xiaowei Liu², X. Guo¹. ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA

Recently developed individual trabeculae segmentation (ITS)-based morphological analyses have demonstrated the importance of trabecular type (plate vs. rod) in determining the mechanical properties of trabecular (Tb) bone. However, tissue mineralization in individual trabeculae of different types and orientations has not yet been investigated. In this study, we developed a novel technique which measures tissue mineral density of each individual trabecula (Tb.TMD). We first hypothesized that distribution of Tb.TMD varies between different Tb types and orientations; second, volumetric BMD (vBMD) categorized by Tb types and orientations has implications in apparent mechanical properties of human Tb bone.

22 Tb bone cylinders from human proximal tibiae were imaged by µCT at 15 µm resolution (Scanco VivaCT40). A calibration phantom was used to convert

attenuation data to hydroxyapatite (HA) densities. Tb microstructure was first segmented into individual plates and rods with their orientations determined, and the Tb.TMD was calculated for each trabecula (Fig. 1A). Mean Tb.TMD of all trabecular plates (pTb.TMD) and rods (rTb.TMD) were examined, as well as those of different orientations. The axial vBMD (axBMD) was defined as the vBMD of both trabecular plates and rods along the axial direction. Elastic moduli and yield strengths were determined from (1) direct mechanical testing and (2) µCT image-based finite element analysis using heterogeneous tissue modulus.

Results suggested that Tb plates were 0.7% more mineralized than rods (p<0.001, Fig.1B). Furthermore, Tb.TMD varied significantly in Tb plates with different orientations (p<0.001): transverse>oblique>longitudinal (Fig.1C). In contrast, Tb.TMD was uniform in rods with different orientations (Fig.1D). aXBMD showed stronger correlation with experimental yield strength (r²>0.90) and elastic modulus (r²>0.86) than the overall vBMD (r²>0.79). The ITS-based vBMD categorized by Tb types and orientations correlated equally as well as the ITS-based morphological parameters with the measured or calculated yield strength and elastic modulus.

The ITS-based Tb.TMD assessment reveals the type and orientation-associated heterogeneous mineralization distribution in Tb bone. Interestingly, Tb plates, particularly transverse plates, are most highly mineralized. Furthermore, this novel technique provides unique measures for both tissue mineralization and Tb microstructure that are critical determinants of bone strength.

How Vitamin D Deficiency Affects the Nature of Fracture Propagation in Human Bone. Bioern Busse^{*1}, Hrishikesh Bale², Elizabeth Zimmermann¹, Brian Panganiban², Holly Barth², Alessandra Carriero², Michael Hahn³, Joel Ager², Michael Amling³, Robert Ritchie². ¹University of California, Berkeley, USA, ²University of California - Berkeley, Lawrence Berkeley National Laboratory, USA, ³University Medical Center Hamburg-Eppendorf, Germany

Vitamin D deficiency unquestionably increases fracture risk in human bone. However, osseous changes in structure, collagen and/or mineralization with hypovitaminosis D and their corresponding effect on fracture risk are complex to interpret. Because cracks in human bone grow diversified, bone fracture can be described as a combination of intrinsic mechanisms acting on small length scales (mineral and collagen characteristics) resisting initiation of cracks and extrinsic mechanisms resisting the growth of cracks acting on coarser length scales (crack propagation). To address this issue, we carried out a study focusing on 2-D *in situ* fracture tests in an environmental scanning electron microscope to evaluate crack initiation and growth toughness. 3-D *ex situ* examination of crack paths and bone structure using synchrotron x-ray computed tomography was used to determine how changes in microarchitectural features with disease correlated with the extrinsic crack-growth toughness; changes to the mineral and collagen were evaluated using UV Raman spectroscopy and Fourier Transform Infrared Spectroscopy and correlated to changes in the intrinsic initiation toughness. Cortical iliac crest bone samples with a 25 (OH)D concentration below 10 µg/l were compared to 15 normal cases with a 25(OH)D level above 25 µg/l. Histomorphometric assessment of osteoid indices confirmed osteomalacia in cases with low 25(OH)D concentration; being absent in cases with levels above 25 µg/l. Cortical structure indices in vitamin D deficient bone demonstrated significantly increased cortical porosity, mean osteon diameter and osteocyte lacunar volume accompanied by significantly decreased cortical thickness. The osteon density remained unchanged in osteomalacic bone in comparison to the

normal cases. These structural features correlated with significantly decreased crack growth toughness, while alterations to the collagenous environment in osteomalacic bone correlated with significantly decreased crack initiation values. In conclusion, this study demonstrated that Vitamin D deficiency is not solely a matter of decreased mineralized bone volume due to hyperostoidosis but that changed characteristics on the bone tissue level may lead to losses in bone toughening mechanisms as well. These findings strongly support that well-balanced 25(OH)D is essential to avoid detrimental crack propagation as in osteomalacia, which compromises the bone's structural integrity and its resistance to fracture.

Targeted Disruption of the Glucocorticoid Receptor in Adipocytes Results in, an Osteosclerotic Phenotype, Increased Fat Mass and Growth Retardation in Mice. Yaqing Zhang¹, Jinwen Tu¹, Julian Kelly¹, Tara Brennan-Speranza¹, Alexander Rauch², Colin Dunstan³, Jan Tuckermann², Markus Seibel⁴, Dr. Hong Zhou^{*4}. ¹Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ²Tissue specific Hormone Action, Leibniz Institute for Age Research, Fritz Lipmann Institute, Germany, ³University of Sydney, Australia, ⁴Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia

Background: The mechanisms by which glucocorticoids (GCs) exert their receptor-mediated effects on bone and fat cells are poorly understood. In the present study we aimed to elucidate the role of the glucocorticoid receptor (GR) in adipocytes, and its interaction with bone, through characterisation of an adipocyte GR-deficient mouse line.

Methods: GR^{flox/flox} mice were crossed with Fabp4-Cre mice to generate GR^{Fabp4Cre} mice, in which the cre recombinase is under the control of the mouse fatty acid binding protein 4 (Fabp4) promoter. Cre-negative GR^{flox/flox} mice served as denote wild type (WT) controls. Mice were analysed for post-natal skeletal changes (by whole body bone and cartilage staining), body composition (by DEXA; Piximus) and bone volume (by micro-CT).

Results: GR^{Fabp4Cre} and their WT littermates had a similar phenotype at birth, with normal skeletal size and regular bone and cartilage staining. Both groups developed normally until day 6, when GR^{Fabp4Cre} mice started to display a pleiotropic phenotype with significant growth retardation, pronounced alopecia followed by premature death within 2 weeks after birth. On day 10, skeletal size and body weight were significantly reduced in GR^{Fabp4Cre} mice when compared to WT littermates ($p < 0.05$). Analysis of body composition revealed a significant increase in total body fat mass and a significant decrease in total body lean mass in GR^{Fabp4Cre} mice compared to WT littermates ($p < 0.05$ for both). In contrast, trabecular bone volume was significantly increased in Fabp4-GRko mice ($p < 0.05$). Despite delayed secondary calcification (Figure, arrows), GR knock-out in adipocytes significantly increased tibial BV/TV, compared to WT mice ($p < 0.05$ compared to WT littermates). In addition, calvaria bone density was increased in GR^{Fabp4Cre} mice (Figure), indicating that both endochondral and intramembranous bone formation are altered by adipocyte specific GR knock-out mice.

In summary, our results suggest that adipocytic glucocorticoid signalling through the GR plays an important role in the post-natal development and growth of mice with profound skeletal effect.

ER α -deletion from Osteoblast Progenitors Abolishes the Protective Effect of Estrogens on Cortical Bone Mass in Both Female and Male Mice. Srividhya Iyer^{*}, Shoshana Bartell, Aaron Warren, Li Han, Marta Martin-Millan, Elena Ambrogini, Jinhu Xiong, Robert Weinstein, Robert Jilka, Charles O'Brien, Maria Almeida, Stavros Manolagas. Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

The accelerated cancellous bone loss caused by menopause results predominantly from trabecular perforation and loss of connectivity. This phase is followed a few years later by a phase of slower bone loss that primarily affects cortical sites; this later stage occurs in both women and men and is associated with a decrease in osteoblast number and bone formation rate. Deletion of the estrogen receptor (ER) α in cells of the osteoclast lineage increases osteoclastogenesis, abrogates the effects of estrogens on osteoclast apoptosis, and causes loss of cancellous bone; but it does not affect cortical bone in females and has no effect in either cancellous or cortical bone in males. Here, we have tested the hypothesis that actions of estrogens on osteoblasts must be responsible for their protective effects on the cortical compartment in either sex. To this end, we deleted a conditional ER α allele in early precursors of the mesenchymal lineage of the appendicular skeleton, using a Prx1-Cre transgene. Cortical thickness in the femurs of 2 month old ER α -flox;Prx1-Cre was decreased in both females and males; while cancellous bone volume was unaffected. In contrast to ER α -flox littermate control mice, ER α -flox;Prx1-Cre mice did not lose bone following ovariectomy at 7 weeks of age. Further, we sought to elucidate the contribution of the effects of estrogens on mature osteoblasts, as opposed to progenitors, by deleting the conditional ER α allele in osteoblasts expressing collagen1 (ER α -flox;2.3kbCol1a1-Cre mice). In difference to the ER α -flox;Prx1-Cre mice, the ER α -flox; 2.3kbCol1a1-Cre mice had no changes of BMD up to 6 months of age as compared to controls, but they did exhibit a 2-fold increase in osteoblast apoptosis. These results demonstrate that ER α expressed in osteoblast progenitors is indispensable for the protective effects of estrogens on cortical bone in both male and female mice. Moreover, they strongly suggest that shortening the lifespan of mature osteoblasts in and of itself may not lead

to discernable loss of bone mass unless it is accompanied by decreased osteoblastogenesis (as in the setting of aging) and/or increased osteoclastic bone resorption (as in the acute phase of estrogen deficiency). Albeit, loss of estrogen action in osteoclasts is sufficient for loss of bone in the cancellous compartment because complete perforation of trabeculae by osteoclastic resorption precludes subsequent refilling of the cavities by the bone-forming osteoblasts.

MKP-1 in Canonical 1,25(OH)₂D₃-signaling and Skeletal Homeostasis. Alfred Griffin*, Keith Kirkwood. Medical University of South Carolina, USA

Vitamin D₃ and its most active form 1,25(OH)₂D₃ are well known to stimulate osteoclastogenesis through stromal cell induction of the receptor activator of nuclear factor kappaB (NF-kappaB) ligand (RANKL). Mitogen activating protein kinase phosphatase-1 (MKP-1) is a phosphatase classically known to negatively regulate the innate immune response through dephosphorylation of p38, ERK, and JNK activity. Here we describe a new, novel function of MKP-1 in permitting genomic 1,25(OH)₂D₃ signaling and downstream osteoclastogenesis through RANKL and an altered skeletal phenotype in developing MKP-1^{-/-} mice. Initially, qRT-PCR and immunoblot analysis comparing BMSCs revealed that 1,25(OH)₂D₃-induced VDR, CYP24a1 and RANKL mRNA expression and protein were significantly attenuated or absent in MKP-1^{-/-} BMSCs. When stable RANKL-BAC reporter UAMS-32 stromal cells containing the entire RANKL gene with 120kb of 5' flanking region including 5 validated VDREs were treated with MKP-1 siRNA or control siRNA, we found MKP-1 siRNA treated UAMS-32 stromal cells had a 4.79-fold decrease in RANKL reporter activation and a 3.22-fold decrease in VDR mRNA induction in the same cell line. BMSCs from tibias and femurs of MKP-1^{-/-} mice treated with 1,25(OH)₂D₃ and co-cultured with RAW 264.7 cells had a 91% decrease in osteoclastogenesis (TRAP+, ≥3 nuclei) compared with WT co-cultures (p<.0001). Immunoblot analysis from cellular fractions of WT and MKP-1^{-/-} BMSCs stimulated with 10⁻⁷M 1,25(OH)₂D₃ for 1 hr revealed that RXRα nuclear import was impaired in MKP-1^{-/-} BMSCs, while VDR import was not affected. To address skeletal changes due to loss of MKP-1, DXA and plasma analysis were performed on 4- and 12-week old mice. DXA analysis revealed that the 4- and 12-week MKP-1^{-/-} skeleton had a significant decrease (8.6% reduction) in BMD, and a 22.6% decrease in BMC. Plasma results from age and sex matched mice showed significant decreases in bsALP and TRAcP enzyme activity along with a concurrent 3-fold elevation in PTH serum levels in both male and female 4-week old MKP-1^{-/-} mice (p<.05). These results reveal an unexpected and highly novel role for MKP-1 in permitting canonical 1,25(OH)₂D₃ signaling via RXRα nuclear import and downstream osteoclastogenesis through stromal cell RANKL expression. While the skeletal and plasma phenotype of MKP-1^{-/-} mice may be partly due to a defect in vitamin D signaling, it also clear that MKP-1's role in skeletal biology is not limited to these findings.

The VDR Interacts Directly with Mediators of Hedgehog Signaling: Implications for the Development of Alopecia in VDR Null Mice. Francesca Gori*¹, Hilary Luderer¹, Eric Zhu², Marie Demay². ¹Massachusetts General Hospital, USA, ²Massachusetts General Hospital & Harvard Medical School, USA

Vitamin D receptor (VDR) knockout mice develop alopecia due to impaired regeneration of hair follicles after the morphogenic period. Postnatally, the hair follicle goes through cycles of proliferation (anagen), apoptosis (catagen) and quiescence (telogen). Initiation of anagen, which leads to follicle regeneration, is dependent upon activation of the canonical Wnt and hedgehog signaling pathways. In vitro investigations demonstrate that VDR ablation impairs canonical Wnt signaling in primary keratinocytes. Activation of hedgehog signaling in vivo induces hair growth in VDR null mice. Studies were undertaken to determine the effect of VDR ablation on the hedgehog signaling pathway in keratinocytes. Primary keratinocytes were cultured under proliferative conditions. RNA was isolated to evaluate the expression of genes involved in hedgehog and Wnt signaling. Gli1 expression was found to be repressed 3.9±0.6 fold in keratinocytes of VDR null mice relative to wildtype mice and the expression of the classic Wnt target gene, c-Myc was repressed 2.7±0.1 fold. Shh mRNA was not detected in proliferating primary keratinocyte cultures. To determine whether the VDR was required for activation of hedgehog signaling at the onset of anagen, 18 day old mice were subjected to depilation to initiate a new hair cycle. In contrast to wildtype mice, where a 70±18 fold increase in Shh, a 5.8±1.5 fold induction of Gli1 and a 3.7±0.3 fold induction in Patched mRNA was observed after 3 days, no induction of these genes was observed in the skin of VDR null mice. Consistent with these findings ISH demonstrated induction of Shh and Gli1 expression in the region of the hair follicle below the sebaceous gland by 3 days post depilation in wildtype, but not VDR null mice. To determine if the unliganded VDR was able to interact directly with regulatory regions of the Shh and Gli1 genes, chromatin immunoprecipitation analyses were performed. These studies demonstrated interactions of the VDR with DNA sequences in both these genes. Furthermore, transient transfection of the VDR into keratinocytes of VDR null mice resulted in a 2.0±0.3 fold increase in Gli1 expression. Thus, these

studies demonstrate that the VDR is required for induction of hedgehog signaling at the onset of the anagen phase of the hair cycle and implicate absence of VDR-mediated hedgehog signaling in the development of alopecia in the VDR null mice.

Bone Formation in Mice Deficient for the Vitamin D-24-hydroxylase Gene, Cyp24a1. Abdallah Hussein^{*1}, Alice Arabian², Rene St-Arnaud³. ¹Shriners Hospital & McGill University, Canada, ²Shriners Hospital for Children, Canada, ³Shriners Hospital for Children & McGill University, Canada

Vitamin D is a key regulator of bone homeostasis. The enzyme CYP24A1 initiates the C24-oxidation pathway that leads to degradation of the hormonal form of vitamin D, but is also responsible for the synthesis of 24,25-(OH)₂D. The putative biological activity of 24,25-(OH)₂D remains unclear. Previous studies showed an increase in the circulating levels of this metabolite following a fracture in chicks. Our laboratory has engineered a mouse model deficient for the Cyp24a1 gene in order to study any putative role of 24,25-(OH)₂D. We set out to study the role of 24,25-(OH)₂D in endochondral and intramembranous bone formation in fracture repair using this mouse model. Methods: wild-type and mutant Cyp24a1-deficient mice were subjected to two different surgical procedures. To mimic endochondral ossification, we performed intramedullary nailing of the tibia followed by an induced fracture. To evaluate intramembranous ossification, we applied distraction osteogenesis to mouse tibia using a mini Ilizarov external fixator apparatus. Histomorphometric parameters and gene expression differences in fracture repair and bone formation between the mutant mice and the wild-type controls were measured using micro computed tomography, histology and reverse-transcription quantitative PCR (RT-qPCR), respectively. Results: quantitative histomorphometric results showed a delay in endochondral fracture repair in the mutant mice calluses as compared to the wild-type mice calluses. In this model, gene expression of type X collagen in the callus was reduced in the Cyp24a1 mutant mice. These significant differences were fully rescued by treating the mutant mice with exogenous 24,25-(OH)₂D. In the intramembranous bone formation model, we found a trend towards reduced bone formation in the gap created by the distraction process in the Cyp24a1 mutant mice as compared to wild-type littermates, but the differences did not reach statistical significance. Conclusion: our results support a role for 24,25-(OH)₂D in fracture repair which is more dominant in endochondral ossification. Although our results did not reach statistical significance in the predominantly intramembranous ossification model, the observed trend suggests a role in this bone formation process as well. Further study of the role of 24,25-(OH)₂D in bone healing has the potential to support novel approaches in accelerating bone formation and fracture repair.

The Role of Vitamin D Receptor in Motor Function. Sadaoki Sakai^{*1}, KOICHI ENDO², Keisuke Tanaka³, Masahiko Mihara³. ¹Chugai Pharmaceutical Co., Ltd., Japan, ²Chugai Pharmaceutical Co., Ltd., Japan, ³CHUGAI PHARMACEUTICAL CO., LTD, Japan

The purpose of osteoporosis treatment is to reduce bone fracture. In achieving this purpose, an anti-osteoporotic medicine should ideally not only improve bone mineral density (BMD) and bone strength but also aid in preventing falls and maintaining locomotive ability. Active vitamin D₃ improves BMD and bone strength. Moreover, some studies have found that vitamin D₃ decreases the risk of falls. However, we have very little knowledge about the relationship between active vitamin D₃ and peripheral nerve function, which is known to decline with age. In this study we used vitamin D receptor knockout (VDR KO) mice to investigate the effect of VDR signaling on motor function. Wild type (WT) and VDR KO mice were trained on a rotarod five times a week (15 rpm, 5 min, 3 times/day) for 4 weeks, and locomotive performance was then measured by an accelerating rotarod test. Four-week training led to an increased duration on the rotarod in the WT mice but not in the VDR KO mice, suggesting that VDR signaling is essential for the improvement of motor function. Histological observations of sciatic nerve cross sections revealed that the axon diameter was smaller in VDR KO mice than in WT mice. Additionally, the distribution of acetylcholine receptor on the extensor digitorum longus was not as broad and the pattern of distribution was simpler in the VDR KO mice. Furthermore, active vitamin D dose-dependently upregulated mRNA expression of insulin-like growth factor-I (IGF-I) and myelin basic protein (MBP) in Schwann cells isolated from neonatal rats. In conclusion, VDR signaling plays a critical role in upregulating motor function in the rotarod training model. Stimulation with active vitamin D increased mRNA expression of IGF-I and MBP in Schwann cells in vitro. IGF-I broadens acetylcholine receptor distribution and increases the production of lipids that are included in the myelin sheaths, and the amounts of serum IGF-I and amounts of MBP in the sciatic nerve decrease with age. These results suggest that active vitamin D may improve motor function via the induction of IGF-I and MBP from peripheral Schwann cells.

NLRP3 Inflammasome is a Major Regulator of Bone Resorption. Sheri Bonar¹, Matthew McGeough², Marcus Watkins¹, Susan Grimston¹, Susannah Brydges², James Mueller², Carla Pena², Roberto Civitelli¹, Hal Hoffman², Gabriel Mbalaviele¹. ¹Washington University in St. Louis School of Medicine, USA, ²University of California, San Diego, USA

The Nod Leucine rich Repeat with a Pyrin domain 3 (NLRP3) inflammasome is an intracellular protein complex responsible for the maturation of IL-1 β family members into their active forms, and for proteolytic inactivation of poly(ADP-ribose) polymerase 1 (PARP1), a negative regulator of osteoclast (OC) development. Recent studies indicate NLRP3 is involved in low grade aseptic inflammation in metabolic diseases. NLRP3 senses cues triggered by crystalline particulates or degradation products of endogenous extracellular matrix as danger associated molecular patterns (DAMPs). Since mineral and organic bone degradation products can traffic through bone resorbing OC, we first tested whether hydroxyapatite crystals (HA) activate NLRP3 in OC lineage in vitro. Exposure of LPS-stimulated bone marrow macrophages to HA increased the processing of pro-IL-1 β to IL-1 β by 10-fold (ELISA) and PARP1 inactivation (immunoblot analysis) in NLRP3-, time-, concentration- and particle size- dependent manner. Since NLRP3 activating mutations cause skeletal malformations and low bone mass in patients with neonatal onset multisystemic inflammatory disease, we studied knock-in mice globally expressing a constitutively active NLRP3 allele. At age P14 (maximal lifespan), mutant mice were significantly smaller and osteopenic (whole body DXA) relative to WT mice. Accordingly, μ CT analysis of mutant femurs revealed rarefied and fragmented trabeculae, significantly decreased cortical bone volume and thickness, and larger bone marrow cavity relative to WT bones. Reduced hypertrophic zone in the growth plate and increased TRAP⁺ OC on the endosteal surfaces were observed on histology of mutant mice, associated with >10-fold higher serum CTX-1 levels, a marker of bone resorption. At the cellular level, the number of OC developing from unfractionated bone marrow cells in the presence of M-CSF and RANKL was 3-4-fold higher in mutants compared to WT cells; and FACS analysis revealed 3-fold higher number of CD11b⁺ OC precursors in marrow of mutant mice relative to WT mice. In summary, NLRP3 activation by bone relevant DAMPs stimulates cytokine maturation, and in mice constitutive NLRP3 activation dramatically increases bone resorption resulting in very low bone mass. Thus, NLRP3 is a major regulator of bone resorption, perhaps mediating pro-inflammatory signals originating from the bone matrix during normal bone remodeling.

PTH Induces Hemopoietic Stem Cell Expansion Through T Cell Produced Wnt10b. Jau-Yi Li¹, Brahmachetna Bedi¹, Hesham Tawfeek¹, Jonathan Adams¹, Timothy F. Lane², Tatsuya Kobayashi³, M. Neale Weitzmann¹, Henry Kronenberg³, Roberto Pacifici¹. ¹Emory University School of Medicine, USA, ²University of California, Los Angeles, USA, ³Massachusetts General Hospital, USA

Activation of Wnt signaling in stromal cells (SCs) is required for PTH to expand hemopoietic stem cells (HSCs). Since PTH induces T cell production of Wnt10b, a Wnt ligand critical for PTH action in bone, we investigated the role of T cell produced Wnt10b in PTH induced HSC expansion. PTH treatment (PTH 1-34, 80 μ g/kg SQ daily for 4 weeks) increased by 2 fold the number of HSCs (Lin-Sca-1+c-Kit⁺ cells) in WT mice but not in Wnt10b^{-/-}, T cell deficient TCR α ^{-/-}, or PPRT cells ^{-/-} mice, a strain lacking PTH receptor 1 (PPR) signaling in T cells. PTH increased Wnt10b production by T cells from control but not PPRT cells ^{-/-} mice by 4 fold. PTH also increased SC expression of Jagged1 (a Notch ligand critical for HSC expansion) in WT but not TCR α ^{-/-}, PPRT cells ^{-/-}, and Wnt10b^{-/-} mice. Adoptive transfer of WT but not Wnt10b^{-/-} or PPRT cells ^{-/-} T cells into TCR α ^{-/-} mice restored PTH mediated expansion of HSCs and SC Jagged1 expression. Thus, PPR mediated T cell produced Wnt10b is required for PTH to expand HSCs through upregulation of Jagged1 in SCs. Next, we measured survival rates in lethally irradiated WT mice transplanted with sub-optimal numbers of bone marrow (BM) cells. PTH treatment of recipient mice in the first 4 weeks after transplantation of WT BM increased survival from ~20 % to ~80%. PTH however did not increase survival of mice transplanted with BM from TCR α ^{-/-}, PPRT cells ^{-/-}, and Wnt10b^{-/-} mice. Confirming the relevance of T cell produced Wnt10b in vivo, PTH treatment of donor WT mice, but not TCR α ^{-/-}, PPRT cells ^{-/-}, and Wnt10b^{-/-} mice, increased survival of untreated WT recipients by 4 fold. Finally, to assess if T cells enhance HSC engraftment a competitive transplant experiment was conducted in which CD45.2⁺ WT mice, TCR α ^{-/-} mice and TCR α ^{-/-} mice previously reconstituted with WT T cells were treated with PTH for 4 weeks. Their BM was then mixed with BM from untreated CD45.1⁺ WT mice (1:2 ratio), and transplanted into lethally irradiated untreated WT CD45.1⁺ recipients. Analysis of CD45.2⁺ cells at 4 weeks demonstrated that PTH treatment improved by 2 fold the expansion of CD45.2 monocytes, granulocytes and B cells in WT and reconstituted TCR α ^{-/-} recipient mice, but not T cell deficient TCR α ^{-/-} mice. In summary, activation of PTHR1 in T cells and the resulting production of Wnt10b and stimulation of Notch signaling are required for PTH to stimulate HSC expansion and engraftment and improve survival after BM transplantation.

The Novel Osteoinductive Wnt Regulator NELL-1 Potently Antagonizes BMP2-induced Adipogenesis and Augments BMP2-induced Osteogenesis. Jia Shen¹, Ronald Siu², Sheng Pang³, Janette Zara⁴, Jinny Kwak⁵, Xinli Zhang², Aaron James², Michael Chiang⁵, Richard Ngo⁵, Weiming Li⁶, Min Lee⁷, Kang Ting², Chia Soo³. ¹University of California, Los Angeles, California, USA, ²University of California, Los Angeles, USA, ³Department of Orthopaedic Surgery, University of California, Los Angeles, USA, ⁴UCLA, USA, ⁵School of Dentistry/Section of Orthodontics, University of California, Los Angeles, USA, ⁶First Clinical Hospital, Harbin Medical University Department of Orthopaedics, China, ⁷Division of Advanced Prosthodontics, Biomaterials & Hospital Dentistry, University of California, Los Angeles, USA

NELL-1, a novel Runx2-regulated growth factor with critical roles in osteogenesis, demonstrated synergy with bone morphogenetic protein-2 (BMP2) in repair of calvarial and femoral defects. BMP2 is a major osteoinducer used clinically in spinal fusion and treatment of skeletal defects; unfortunately the supraphysiological dosages required clinically has resulted in numerous adverse effects. In previous work, we found that high doses (>300 μ g/ml) of BMP2 induced adipogenesis and cyst-like bone void formation. In this study, we asked whether NELL-1 could ameliorate these side effects and significantly improve BMP2-based skeletal repair.

To accomplish this goal, we applied BMP2 in a rat femoral segmental defect (FSD) model with and without co-treatment of NELL-1 and evaluated healing at 2 and 8 weeks post operation. Furthermore, we treated murine M2-10B4 cells with BMP2 or in combination with NELL-1 in vitro to gain mechanistic insight in support of our *in vivo* findings.

With BMP2 monotherapy, massive expansion of PPAR γ -positive cells was observed at 2 weeks, which progressed to terminally differentiated adipocytes and adipose-filled cyst-like bone voids by 8 weeks. Interestingly, the combination of NELL-1 with BMP2 preferentially accelerated the osteogenic differentiation of these cells at the expense of proliferation and adipogenesis, completely abolishing heterotopic, cyst-like bone formation and resulting in more organized and mature bone (Fig.1,2). Canonical Wnt signaling is known to enhance osteogenesis and conversely suppress adipogenesis. Interestingly, NELL-1 stimulated canonical Wnt pathway activity *in vivo* and *in vitro*, as supported by increased nuclear localization of β -catenin with NELL-1 treated FSDs and M2-10B4 cells (Fig.3). Importantly, the ability of NELL-1 to bias cells induced toward osteogenic differentiation by BMP2 was Wnt-dependent, as treatment with two different canonical Wnt inhibitors eliminated the anti-adipogenic and pro-osteogenic effects of NELL-1 (Fig.4).

To our knowledge, this was the first demonstration of an adjunctive treatment that could both improve BMP2-mediated bone healing and simultaneously alleviate its associated adverse effects, which could potentially increase the clinical safety and efficacy of current BMP2 orthopedic applications. Furthermore, understanding the role of NELL-1 and Wnt in the balance between bone and adipose tissue formation will be valuable for osteoporosis and other disorders of bone homeostasis.

Mx2-Wnt Signaling Inhibits and Dkk1 Promotes The Endothelial-Mesenchymal Transition In Primary Aortic Endothelial Cells. Su-Li Cheng^{*1}, Dwight Towler². ¹Washington University in St. Louis School of Medicine, USA, ²Washington University in St. Louis, USA

Endothelial cells (ECs) can undergo an endothelial-mesenchymal transition (EnMT) during cardiovascular development. Canonical Wnt/beta-catenin activity helps drive EnMT necessary for heart valve morphogenesis. EnMT also occurs in pathological conditions that contribute to cardiac fibrosis and ectopic ossification. We've previously demonstrated that Wnt/beta-catenin signals play an important role in the arteriosclerotic calcification and fibrosis that arises with diabetes. Increasing Wnt activity in vascular mesenchymal cells with Wnt7b or Mx2 increases osteogenic differentiation and matrix fibrosis via paracrine signals that are inhibited by the LRP receptor antagonist, Dkk1. We wish to test if canonical Wnt signaling exerted similar actions on aortic ECs, potentially contributing to calcification and fibrosis via EnMT. Thus, we transduced primary bovine aortic ECs (BAECs) with retroviruses expressing Mx2, Wnt7b, Dkk1, or LacZ (control). To our surprise, expression of either Mx2 or Wnt7b promoted the "cobblestone pavement" cell shape of well-differentiated ECs, with upregulation of EC phenotypic markers such as claudin 5. These effects were phenocopied by 20 ng/ml Wnt3a treatment. Moreover, when cultured under conditions that promote mineralization of mesenchymal cells, Mx2 and Wnt7b suppressed calcium deposition and collagenous matrix production. Conversely, transduction of ECs with the SFG-Dkk1 suppressed claudin 5, PECAM, VE-cadherin, Tie1 and Tie2. Myofibroblast and osteoblastic markers such as SM22, Osx, Runx2, type I collagen and alkaline phosphatase were upregulated. Dkk1 expression induces cell shape change, converting the cuboidal monolayer into a spindle shaped cell multilayer, and inhibited endothelial tube formation in matrigel. Moreover, Dkk1 enhanced matrix mineralization of BAECs cultured under osteogenic conditions– the inverse of the Dkk1 response elicited in cultured mesenchymal cells. Pulse-chase experiments of DiI-Ac-LDL tagged BAECs confirmed that Dkk1 enhanced EnMT, viz. the trans-differentiation of cuboidal ECs into spindle shaped mesenchymal cells. Thus, EC Mx2-Wnt signaling stabilizes the endothelial phenotype, while Dkk1 enhances the EnMT in differentiated BAECs. Endothelial response to Mx2, Wnt7b, and Dkk1 are the inverse of those responses elaborated by mesenchymal cells, potentially providing a mechanism that finely couples angiogenic with osteo/fibrogenic requirements during tissue injury and repair.

Vascular Tissues Are a Primary Source of BMP2 Expression during Bone Formation Induced by Distraction Osteogenesis. Hidehiko Matsubara¹, Daniel Hogan², Douglas Mortlock³, Elise Morgan⁴, Thomas Einhorn⁵, Louis Gerstenfeld^{*1}. ¹Boston University School of Medicine, USA, ²Boston University College of Engineering, USA, ³Vanderbilt University School of Medicine, USA, ⁴Boston University, USA, ⁵Boston Medical Center, USA

Skeletal development after injury or surgery is co-dependent on vascularization. While this co-dependency is often thought of in terms of the skeletal tissue's need for appropriate nutrition and oxygen, vascular morphogenesis provides the structural template around which Haversian and trabecular units of bone are formed, suggesting therefore that there are molecular mechanism that tightly coordinate skeletal and vascular tissue morphogenesis. Prior studies showed that bone regeneration during distraction osteogenesis (DO) was dependent on vascular tissue formation and that inhibition of vessel formation inhibited the expression of BMP2. A combination of micro-computed tomography analysis of vascular and skeletal tissues, histological analysis using transgenic mice containing ~239 kilobase BAC transgene in which beta-galactosidase has been inserted into the coding region of BMP2, and qRT-PCR analysis were used to determine the cellular origins of BMP2 during DO. The results showed within both the surrounding musculature and regenerating bone that BMP2 expression was induced in both smooth muscle and vascular endothelial cells lining arteries and veins but not in lymphatic vessels. Within the region of developing bone, BMP2 was expressed by hypertrophic chondrocytes and osteocytes. Separate peaks of BMP2 mRNA expression were induced in muscular tissues and the distraction gap, and each peak corresponded with a peak of expression of endothelial cell marker genes and vessel formation and remodeling. Earlier peaks of expression of these genes were always seen in the musculature preceding those in the bone. Interestingly peaks of DKK and Sost expression were also observed in both tissue compartments and these occurred slightly later than the BMP2 peaks suggesting that these morphogens are also produced during vascular tissue formation. These results suggest that during post natal bone regeneration vascular tissues in surrounding musculature and within the developing bone are the predominant source of BMP2 in the developmental environment and suggest that BMP2 carries out functional roles in both vascular and skeletal regeneration.

TGF β Inducible Early Gene-1 Plays a Critical Role in Mediating Estrogen and Canonical Wnt Signaling in the Growing Mouse Skeleton. John Hawse^{*1}, Muzaffer Cicek², Kevin Pite³, Sarah Grygo⁴, Kenneth Peters⁴, Nalini Rajamannan⁵, Urszula Iwaniec⁶, Russell Turner⁶, Merry Jo Oursler², Thomas Spelsberg², Malayannan Subramaniam². ¹Mayo Clinic College of Medicine, USA, ²Mayo Clinic, USA, ³University of Minnesota, USA, ⁴Mayo Clinic College of Medicine, USA, ⁵Northwestern University Medical School, USA, ⁶Oregon State University, USA

TGF β Inducible Early Gene-1 (TIEG) knockout (KO) mice display a gender specific osteopenic phenotype characterized by low bone mineral density, bone mineral content and overall loss of bone strength in female mice. We therefore speculated that loss of TIEG expression may impair the actions of estrogen on bone balance in female mice. In order to test this hypothesis, we performed sham or ovariectomy (OVX) surgeries on one month old WT and KO mice supplemented with placebo or 17-beta estradiol (E2) pellets at a dose of 0.063 ug/day. DXA, pQCT and μ CT analyses were conducted on all mice at 2 months of age. Analysis of whole body skeleton, tibias, femurs and L5 vertebrae revealed that WT mice lost significantly more bone following OVX than TIEG KO mice. Furthermore, the bone anabolic actions of E2 were approximately halved in the KO animals suggesting an important role for TIEG in mediating E2 signaling in the mouse skeleton. In order to begin to understand the molecular mechanisms responsible for these observations, we performed gene expression studies on the cortical shells of long bones isolated from these mice. A dramatic increase in the expression levels of bone marker genes such as Runx2, osterix, alkaline-phosphatase, osteocalcin and bone sialoprotein were observed following E2 administration in WT mice. In parallel with the bone phenotype, these increases in gene expression were significantly reduced in TIEG KO mice. Additionally, the expression levels of a number of Wnt pathway genes were also determined to be differentially regulated between these two genotypes. Of particular interest, the levels of sclerostin (SOST) were elevated by 12-fold in KO mice relative to WT controls suggesting that loss of TIEG expression alters canonical Wnt signaling. To determine if Wnt signaling is significantly affected in KO mice, we crossed these animals with the TOPGAL reporter mouse. Histochemical analysis of the L5 vertebrae revealed a 2-fold decrease in β -gal staining in KO animals compared to WT littermates. As an extension of these studies, we have also shown that TIEG mediates beta-catenin nuclear translocation and serves as a co-activator on TCF/Lef enhancer elements in osteoblasts. Taken together, these data clearly implicate a role for TIEG in mediating E2 and Wnt signaling in the mouse skeleton and suggest that defects in these pathways may be responsible for the gender specific osteopenic phenotype observed in TIEG KO mice.

Targeted Disruption of TGFBI in Mice Reveals Novel Role for this Gene in Regulating Peak Bone Size. Hongrun Yu^{*1}, Heather Watts², Anil Kapoor², Yongliang Zhao³, Jon Wergedal², Subburaman Mohan². ¹JLP Memorial VA Med Ctr, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³Center for Radiological Research, USA

Transforming growth factor beta-induced (TGFBI) protein, also known as betaig-h3, is an extracellular matrix (ECM) protein strongly induced by TGF- β , and structurally unrelated to similar TGF- β Inducible Early Gene-1 (TIEG1). TGFBI contains domains and motifs that interact with integrins and other ECMs to mediate cell adhesion and migration. It is highly expressed in bone, cartilages, and skin. Based on previous findings that TGFBI inhibits osteoblast differentiation in vitro, we tested the hypothesis in this study that TGFBI is a negative regulator of bone formation. Heterozygous mice with targeted deletions of exons 4-6 of TGFBI were crossed to generate homozygous knockout (KO) mice and wild type (WT) littermates. Skeletal phenotypes were analyzed by PIXImus, micro-CT and histomorphometry. Bone mineral density (BMD) as measured by PIXImus in total body, femur, tibia and vertebra was decreased by 8%, 19%, 15% and 15% (all $P < 0.01$), respectively, in KO mice compared to WT mice at 4 weeks of age. Lack-of-TGFBI induced skeletal deficits were seen in both genders, and were sustained up to a study period of 12 weeks of age. Micro-CT measurements revealed 25% and 15% decreases in total volume at the tibial diaphyseal and metaphyseal regions, respectively, indicating a reduction in bone size. Because TGFBI KO mice exhibited reduced body weight, we also adjusted for body and bone size, and found that body weight adjusted tibia bone mineral content (BMC) as well as bone length adjusted tibial bone size were reduced by 10% and 19%, respectively, in the KO mice compared to WT mice at 12 weeks of age. Micro-CT measurements of tibial metaphysis revealed no significant differences in trabecular bone parameters between KO and WT mice at 12 weeks of age. Histomorphometric analysis revealed an 11% reduction in total area at the femoral midshaft of KO mice, consistent with a reduced bone size. Accordingly, periosteal bone formation rate adjusted for bone surface was reduced by 25% in KO mice compared to WT mice. In contrast, bone formation rate at the endosteum was not significantly affected. Based on these results, we conclude: 1) Lack-of-TGFBI reduces peak bone size by affecting periosteal bone formation. 2) On the contrary to the known inhibitory effects of TGFBI on osteoblast differentiation based on in vitro studies, our in vivo studies using targeted disruption of TGFBI demonstrate a positive regulatory effect of TGFBI on periosteal bone formation.

BMP3 Suppresses Osteoblast Differentiation of Bone Marrow Stromal Cells via Interaction with Acvr2b. Shoichiro Kokabu^{*1}, Laura Gamer¹, Karen Cox¹, Kunikazu Tsuji², Regina Raz³, Aris Economides³, Takenobu Katagiri⁴, Vicki Rosen¹. ¹Harvard School of Dental Medicine, USA, ²Tokyo Medical & Dental University, Japan, ³Regeneron Pharmaceuticals, Inc., USA, ⁴Saitama Medical University Research Center for Genomic Medicine, Japan

Bone morphogenetic proteins (BMPs) were identified as signals that induce ectopic bone formation through effects on skeletal progenitor cells present in adult animals. Enhancing BMP signaling increases bone formation in a variety of settings that target bone repair; however, a physiological role for BMP signaling in the maintenance of adult bone mass remains to be determined. Here we focus on BMP3 because targeted disruption of BMP3 in mice results in increased trabecular bone formation (Daluiski A et al., 2001) while transgenic over-expression of BMP3 in skeletal cells leads to delayed mineral deposition during endochondral ossification and spontaneous fracture (Gamer LW et al., 2009). These data are consistent with BMP3 having an inhibitory role in osteoblast function. To define the pathway by which BMP3 affects osteoblast function, we created mice carrying a lacZ knock-in allele to the Bmp3 locus and used them to examine the expression of BMP3 in the postnatal skeleton. We find that osteoblasts and osteocytes are the source of BMP3 present in adult bone, and show that periosteal osteoprogenitors and bone marrow stromal cells (BMSC) do not express BMP3. Based on the distribution of Acvr2b, the BMP3 receptor, we hypothesize that BMP3, produced by mature bone cells acts to reduce BMP signaling in bone marrow stromal osteoprogenitors. In support of this hypothesis we show that loss of BMP3 increases CFU-OB in BMSC cultures, while increased levels of BMP3 reduce CFU-OB. We also determine that knockdown of endogenous Acvr2b in BMSC diminishes the suppressive effect of BMP3 on osteoblast differentiation. The importance of Acvr2b as a mediator of BMP3 action is confirmed by data showing that mutations in either BMP3 or Acvr2b that prevent the BMP3/ Acvr2b interaction result in the loss of BMP3 mediated osteoblast inhibition. Taken together, these data confirm that BMP3 regulates trabecular bone formation by inhibiting the osteoblast differentiation of BMSC and support the idea that endogenous BMPs have a physiological role in regulating adult bone mass.

TGF- β Type II Receptor Signaling Plays An Essential Role in Knee Development. Tieshi Li¹, Lara Longobardi¹, Froilan Granero-Molto¹, Timothy Myers², Douglas Mortlock³, Anna Spagnoli¹. ¹University of North Carolina at Chapel Hill, USA, ²University of North Carolina, USA, ³Vanderbilt University Medical Center, USA

We have previously reported that TGF- β type II receptor (*Tgfr2*) signaling is essential for joint morphogenesis. *Tgfr2*^{PRX-1KO} mouse, in which the *Tgfr2* is conditionally inactivated in developing limbs, lacks interphalangeal joints (Spagnoli A et al, J Cell Biol, 2007). To further investigate the function of Tgfr2 signaling in knee development, we evaluated the knee phenotype of the *Tgfr2*^{PRX-1KO} mouse. At E14.5 the *Tgfr2*^{PRX-1KO} showed segmentation of the knee skeletal elements but joint space was narrower compared with the space found in the *Tgfr2*^{lox/lox} control mouse. At E16.5 the *Tgfr2*^{PRX-1KO} mouse lacked the formation of the menisci and the patella. At P0, the knee of the *Tgfr2*^{PRX-1KO} mouse showed a dramatic phenotype characterized by a lack of posterior/anterior cruciate ligaments, synovial capsule, menisci, patella and showed abnormal shapes of the tibial plateau and femoral condyles. The space between the segmented tibia and femur was filled with disorganized cellular elements. In our lab we have also generated a Tgfr2- β -Gal-GFP-BAC transgenic mouse containing β -galactosidase (β -Gal) as an imaginable reporter for Tgfr2 expression under the control of endogenous (within 195.8kb) Tgfr2 gene regulatory sequences including the promoter. Using the Tgfr2- β -Gal-GFP-BAC transgenic mouse, we found that within the knee, Tgfr2 expression started at E13.5. At E14.5, we found that Tgfr2 was highly and specifically expressed in both the knee dorsal and ventral sides and in some restricted cells in the center of the joint. At E16.5 expression became related to well identifiable components of the joint. Consistently, at P0, Tgfr2 expression was localized specifically at the superficial sides of the menisci, patella, the tendons, along with synoviocytes, the capsule, and in restricted areas of the articular cartilage. The expression pattern of Tgfr2 is consistent with TGF β 2 expression and detection of phosphorylated Smad2 by immunohistochemistry in E14.5, E16.5 and P1 knees. Within the developing knees, we found a co-localization of Tgfr2-Lac-Z activity with joint marker genes such as Jagged1, Noggin, GDF5 and Notch1. At E14.5, the lack of Tgfr2 signaling in the knee of the *Tgfr2*^{PRX-1KO} mouse was associated with a decrease of Jagged1, Noggin, GDF5, Notch1 and phosphorylated Smad2. Our findings indicate that Tgfr2 expressing cells in the knee provide a signaling niche for the developing of the critical joint elements.

Anti TGF- β Antibody Attenuates Increased Bone Turnover in Rodent Models of High Turnover Chronic Kidney Disease-Mineral Bone Disorder (CKD-MBD). Shiguang Liu^{*}, Wenping Song, Joseph Boulanger, Wen Tang, Christina Bracken, Sue Ryan, Robert Fogle, Yves Sabbagh, Susan Schiavi. Genzyme Corporation, USA

Altered bone turnover is a key pathologic feature of CKD-MBD. TGF- β 1 plays an important role in regulating bone turnover and has been shown to be an important mediator of the anabolic effect of PTH on bone. TGF- β 1 expression is increased in bone biopsies from individuals with high bone turnover raising the possibility that it may contribute to the pathogenesis of renal osteodystrophy. Our data also demonstrated that TGF- β 1 expression is increased in bones from a CKD-MBD mouse model. To assess the relevance of elevated TGF- β 1 on the pathogenesis of high-turnover disorder in CKD-MBD, we administered a neutralizing anti-TGF- β antibody (1D11) to three independent rodent models of CKD-MBD: Jck mice, adenine-treated, and 5/6 nephrectomized rats. 1D11 treatment significantly attenuated the increase in serum osteocalcin levels in all 3 models and was associated with trends toward decreased serum type I collagen C-telopeptides (CTX) levels. μ CT analysis confirmed improvements in bone morphology in both adenine-induced and 5/6 nephrectomized rat models. To explore the potential efficacy of 1D11, we expanded characterization of its effects in jck mice as this genetic model of CKD-MBD has been shown to exhibit progressive changes in serum biochemistry, bone and vasculature mimicking human CKD-MBD. 1D11 was injected IP (0.5, 2 or 5 mg/kg) 3 times a week for 7 weeks. Bone histomorphometric analysis indicated that 1D11 significantly suppressed the elevated bone turnover in a dose-dependent manner. Importantly, in this model, 1D11 treatment did not significantly improve kidney function or reduce serum PTH levels indicating that the effect of 1D11 on bone may be independent of changes in renal or parathyroid function. 1D11 had no significant effect on the increased expression of osteoclast gene markers (Trap5, Ctsk, and Rank) but resulted in a significant increase in Sost mRNA expression consistent with an effect on the osteoblast/osteocyte lineage. Taken together, our data demonstrate that a neutralizing anti-TGF- β antibody can attenuate high turnover bone disease, providing further support for a pathological role of TGF- β in CKD-MBD.

TGF- β -dependent Regulation of Sclerostin during Mechanical Loading. Jacqueline Nguyen^{*}, Simon Tang, Dan Nguyen, Tamara Alliston. University of California, San Francisco, USA

The mechanical stimulation of exercise induces bone formation and maintains bone health. Though several molecules required for load-induced bone formation have recently been identified, many questions remain. Motivated in part by the observation that loading of rat tibiae increases TGF β 1 mRNA expression, we hypothesized that TGF β signaling participates in load-induced bone formation. Since TGF β can be regulated post-transcriptionally, we assessed the effect of *in vivo* loading on the activities of downstream TGF β effectors, called Smad2/3, using transgenic mice that express a Smad2/3 responsive promoter-luciferase reporter construct. We applied cyclic axial load of approximately 10 times the mouse body weight to the right tibia of Smad2/3-luciferase mice at 1 Hz for 600 cycles once a day and used the unloaded contralateral tibia as control. A 5-day loading regimen of *in vivo* mechanical stimulation induces a 14% increase in cortical thickness ($p < 0.05$). Within 5 hours of one load application, Smad2/3 activity was increased 20% ($p < 0.05$), showing that load increases a rapid activation of Smad2/3 activity. To determine if this correlation between load-induced bone formation and Smad2/3 activation is causal, we applied mechanical load to DNT β R11 mice, which express a dominant negative TGF β type II receptor under control of the osteocalcin promoter, and wild-type (WT) littermates. Unlike WT mice, DNT β R11 mice do not respond to mechanical load with increased bone deposition. Using immunohistochemistry, we next investigated whether this TGF β loss of function mutation is sufficient to impair the load-sensitive regulation of Sclerostin, a protein implicated in the control of load-induced bone formation. Consistent with previous reports, mechanical loading over 5 days caused a downregulation of Sclerostin expression in WT tibial cortical bone. However, mechanical load did not alter Sclerostin expression levels in DNT β R11 bone ($p < 0.05$). *In vitro* studies further document the regulation of SOST expression by TGF β . Together, these data reveal a novel pathway that participates in load-induced bone formation. Specifically, mechanical load activates TGF- β signaling in a Smad2/3 dependent manner to induce bone formation through a pathway that intersects with SOST. The molecular basis of this interaction remains under investigation.

A New Role for the TGF β R11-MCP-5 Axis as a Key Regulator in the Interplay between the Articular Cartilage and the Forming Bone during Limb Development. Lara Longobardi¹, Tieshi Li², Timothy Myers³, Froilan Granero-Molto¹, yun van³, ying li³, Anna Spagnoli¹. ¹University of North Carolina at Chapel Hill, USA, ²UNC, USA, ³UNC-CH, USA

In our previous studies we found that within the developing joint interzone a down-regulation of the cytokine MCP-5 is required for normal joint development (Longobardi L. et al. ASBMR 2010, OR#1116). The Tgfr2PRX-1KO mouse generated in our lab which lacks Tgfr2 in developing limbs, shows an aberrant up-regulation of MCP-5 in the interzone and fails joint development and chondrocyte hypertrophy. Genetically modified mice lacking joint development (noggin-KO, gdf5-KO) exhibit inappropriate skeletal morphogenesis, indicating that the developing joint is an essential regulator of skeletal element development. A derangement of the interplay between the articular cartilage and the subchondral bone is found in arthritic joints. Aberrant expressions of MCP-1 (MCP-5 human homologue) and its unique receptor CCR2 are found in arthritic joints. In the present studies we evaluated using *ex vivo* and *in vivo* approaches the effects of MCP-5 embryonic manipulations to the growth plate and ossification center development. In the *ex-vivo* approach, using a micro-injector unit and glycol-chitosan nanoparticles for sustained protein release, either MCP-5 protein or MC-21 antibody (against CCR2) were injected into the developing joints of dissected E13.5 WT or Tbr2PRX-1KO limbs respectively, that were cultured for 2 days. In the *in-vivo* approach, pregnant females potentially generating Tbr2PRX-1KO, were treated with RS504393 (CCR2 inhibitor) starting at E11.5 (4mg/Kg/day, PO). At E18.5 mice were sacrificed. Release of MCP-5 into developing WT joints abolished Ihh spatial distribution within the developing growth plate and decreased Col10 expression. Blockage of the CCR2 signaling in Tbr2PRX-1KO and WT mice either *ex-vivo* or *in-vivo*, led to a rescue of the Tbr2PRX-1KO growth plate phenotype restoring Ihh, Col10 and Col1 expression patterns; in the WT determined an increase in Col10 by hypertrophic chondrocytes and Col1 in the ossification center. Our data indicate that a correct spatial distribution of MCP-5 in the interzone and adjacent developing bone is crucial for the progression of growth plate chondrocytes to hypertrophy and the correct ossification of the mineralization center. Our findings, by providing evidence for a new role for MCP-5/TGF β R11 signaling as a key regulator in the interplay between articular cartilage and developing bone, open novel prospective for their function in adult joint-skeletal homeostasis and for the prevention and treatment of arthritis.

Precise 3D Localisation of a Cortical Thinning Defect Associated With Femoral Neck Fracture in Life. Kenneth Poole^{*1}, Graham Treece¹, Paul Mayhew¹, Martin Horak², Jan Stepan³, Andrew H Gee¹. ¹University of Cambridge, United Kingdom, ²Bulovka Hospital, Czech Republic, ³Charles University, Czech Republic

Thinning of the proximal femoral cortex with ageing and osteoporosis is considered a cause of fracture and a modifiable target for bone active treatment. We applied a novel 3D cortical thickness mapping technique to ordinary clinical CT scans in order to discover whether femoral cortical bone in patients with an acute hip fracture was thinner than femoral cortical bone from community dwelling controls without fracture. The technique allowed us to pinpoint systematic differences and visualise the magnitude of the differences with a colour map displayed on an average femur model.

In a case-control study, we analysed Siemens CT scans from 75 women volunteers with acute fracture and 75 age-matched controls from the Prague Study of Hip Joint in Trauma. We classified the fracture location as femoral neck or trochanteric before creating cortical thickness maps of the unfractured contralateral hip. After non-rigid registration to an average femur shape and statistical parametric mapping, we were able to pinpoint statistically significant foci of cortical thinning associated with each fracture type.

The cortex was approximately 10% thinner in fracture cases than controls throughout the femur. More remarkably, there were several distinct foci of statistically significant ($p < 0.02$) thinning of up to 30% which coincided anatomically with stereotypical fracture sites (femoral neck or trochanteric, fig. 1). The focal thinning of the head-neck junction associated with femoral neck fracture (fig. 1a) also coincided with the focus of peak tensile stress in Cristofolini's cadaveric and FE models of spontaneous femoral neck fracture (J Biomech 2007). Taken alongside the 3D density analyses of the whole hip of Li et al (Bone 2009), our results suggest that the DXA 'femoral neck' box ROI could eventually be replaced by more specific, fracture-critical ROIs in risk estimation, diagnostic and treatment strategies.

Patterns of Prevalent and Incident Vertebral Fracture in the Spine: Differentiating Prevalent Fracture from Deformity. Thomas Fuerst^{*1}, Gabriele von Ingersleben², Chun Wu², Souhila Ounadjela², Pierre Colombel², Jan Szechinski³, Karina Hufert³, Harry Genant⁴. ¹Synarc, Inc., USA, ²Synarc Inc, USA, ³Synarc Inc, Germany, ⁴UCSF/Synarc, USA

Vertebral fracture is a hallmark of osteoporosis signifying both presence of disease and increased risk of future fracture. As such, accurate assessment of prevalent vertebral fracture is critical to clinical practice as well as clinical research. Previous reports have documented the difficulty of differential diagnosis of vertebral fracture

versus deformities of other etiology. We investigated the spatial pattern of prevalent and incident vertebral fracture as a means to assess the validity of prevalent fracture assessment.

Postmenopausal women ($n=7,848$) >60 years old with osteoporosis (spine or hip T-score < -2.5) participating in a clinical trial had spine radiographs at screening and annual follow-up visits. Prevalent and incident vertebral fracture was assessed centrally using the Genant Semiquantitative method. The number of prevalent vertebral fractures at each vertebral level T4 to L4 was determined in total and by each fracture severity. The percentage of fractures at each level was calculated. In a similar fashion incident vertebral fractures over the 3 years of follow-up were counted and summarized.

In total 2,662 prevalent vertebral fractures were identified (80% mild, 17% moderate, 3% severe) compared with 509 incident fractures (42% mild, 38% moderate, 20% severe) found in 373 women. A similar distribution of fracture was seen throughout the spine for both prevalent and incident fracture except in the mid thoracic region (T7-T8) where the rate of prevalent fractures increased to double the rate of incident fractures. Broken down by fracture severity, the patterns were the same with most of the mid-thoracic disagreement explained by differences in the rate of mild fractures.

These data suggest a tendency to over call mild prevalent vertebral fracture in the mid-thoracic region of the spine. This is likely due to chronic stress-induced remodeling with subchondral microfractures or degenerative remodeling at this apex of thoracic curvature. These processes may cause gradual wedging of the vertebral body that mimics mild prevalent fractures. Accurate assessment of prevalent fractures requires careful assessment of these vertebrae for radiographic features indicative of fracture such as endplate bowing or buckling, distinguishing them from non-fracture deformities (Jiang et al, Osteoporosis Int 2004).

CT Methods That Use Thresholding Throw Out the Baby with the Bath Water. Ego Seeman^{*1}, Roger Zebaze¹, Ali Ghasem-Zadeh¹, Aloys Mbala². ¹Austin Health, University of Melbourne, Australia, ²Strax Corp, Australia

Methods using thresholding to separate cortical and trabecular bone binarize voxels into cortical or trabecular bone based on predefined density thresholds. This introduces errors in assessment of bone structure and its changes during ageing and therapy. Cortices that are thin and porous are discarded because they are below the threshold that nominally defines 'cortical' bone. Regions with high porosity are excluded so porosity is underestimated. At the cortical-trabecular interface, fragmentation of cortices (trabecularization) overestimates trabecular bone density in old age and so underestimates age-related decline in trabecular density. Thresholding also fails to 'see' and so quantify porosity due to small pores (i.e., < 82 microns). Most pores are <100 microns (haversian canals, blue areas in image). Only 10% are >100 microns (white areas). We report that the increase in porosity across age due pores >82 microns is only ~15%. When pores <82 microns are included, porosity increases across age by ~70%.

Segmentation without thresholding overcomes these limitations and allows measurement of tissue mineral density in vivo. Bisphosphonate treatment produces a right shift in the frequency distribution curve reflecting an increase in the proportion of voxels containing predominantly bone and a decrease in proportion of voxels occupied by void (figure). In patients receiving BPs, 55% of the bone is mineralized at 70-95% (yellow voxels), in age-matched untreated peers, mineralization is normally distributed, only 23% of the bone mineralized at 70-95% range. The higher cortical area is due to filling of intracortical pores as voxels within cortex adjacent to marrow fill with bone. The change at the voxel level precedes changes in other morphological parameters and is detected with this new method.

External Validation of the Garvan Nomograms For Predicting Absolute Fracture Risk: the Tromsø Study. Luai A. Ahmed¹, Nguyen Nguyen², Ashild Bjørnerem³, Ragnar M. Joakimsen³, Lone Jørgensen¹, Dana Bliuc², Jacqueline Center², John Eisman², Tuan Nguyen², Nina Emaus⁴. ¹Department of Health & Care Sciences, Faculty of Health Sciences, University of Tromsø, Norway, ²Garvan Institute of Medical Research, Australia, ³Department of Clinical Medicine, Faculty of Health Sciences, University of Tromsø, Norway, ⁴University of Tromsø, 9037 Tromsø, Norway

Absolute risk or individualized prognosis is considered a preferred approach for assessing fracture risk and making treatment decision for an individual. We have developed a prognostic model that uses age, bone mineral density, prior fracture, and fall for predicting absolute risk of fracture (Garvan nomograms). The present study was designed to validate and evaluate the performance of the Garvan nomograms for predicting 10-year risk of fragility fracture in a Norwegian cohort of men and women.

This prospective cohort study in Tromsø, Norway, included 1614 women and 1314 men (aged 60 years plus). Information on the clinical risk factors were collected in the fifth Tromsø survey in 2001. During 8 years follow-up from 2001 to 2009, the incidence of fragility fracture was ascertained by computerized search in the radiographic archives. Non-hip non-vertebral (NHNV) fractures occurred in 350 women and 114 men and 92 women and 49 men suffered a hip fracture. Predicted 10-year probabilities of NHNV and hip fractures were determined using Garvan's models with and without BMD. The concordance between observed and predicted incidence of fracture was used as a measure of fit. Reclassification analysis was used to compare the performance of models.

The overall incidence (per 1000 person-years) of NHNV and hip fracture during the follow-up was 34.6 and 9.1 in women, respectively; and 12.3 and 5.4 in men, respectively. In both sexes, the predicted 10-year probability of fractures in the fracture group was consistently higher than the non-fracture group for all models. For hip fracture, the predicted probabilities of fracture in the fracture group was 2.8 (women) to 3.1 times (men) higher than those in the non-fracture group. There was a close agreement between predicted and actual risk of fracture in both men and women. However, among those in the highest quartile of risk, the model over-estimated the risk of fracture (Figure). Models with BMD + clinical risk factors performed better than models with body weight + clinical risk factors in terms of correct classification of fracture and non-fracture cases in their risk.

In conclusion, the Garvan nomograms are valid and reasonably accurate in identifying individuals at high risk of fracture. Although the nomograms over-predicted the risk of fracture in high risk individuals, its predictive ability at the individual level can potentially be useful in clinical practice.

Concordance between the predicted and observed risk of non-hip non-vertebral (NHNV) fracture (upper panel) and hip fracture (lower panel) in the Tromsø Study cohort, according to the Garvan nomogram. Quartile cutoffs for the predicted 10-year risk (%) of NHNV fracture in women were: 12.8, 19.3 and 30.6 for model with BMD (M1), and 14.7, 20.0 and 29.8 for model with weight (M2). Corresponding features in men were 6.2, 10.1 and 16.9 for M1, and 6.8, 10.2, 16.5 for M2. Quartile cutoffs for the predicted 10-year risk of hip fracture in women were: 1.8, 4.0 and 10.3 for M1 and 2.4, 4.4 and 10.3 for M2. In men, 0.5, 1.3 and 3.2 for M1, and 1.2, 2.1 and 4.3 for M2.

Predicted and observed fracture risk in the Tromsø Study according to the Garvan nomogram.

A Long Femur Scan Field does not Substantially Alter Proximal Femur BMD measurements by DXA. Neil Binkley³, Fergus McKiernan¹, Richard Berg², James Linneman², Jane Hocking¹, Susan Cournoyer¹. ¹Marshfield Clinic, USA, ²Biomedical Informatics, Marshfield Clinic Research Foundation, USA, ³University of Wisconsin, Madison, USA

We postulated that a longer DXA femur scan field might be useful for the detection of atypical, subtrochanteric femur fractures. Before implementing this strategy it is necessary to demonstrate that this would not alter BMD measurements made at important diagnostic and monitoring proximal femur sites. 30 adult subjects underwent triplicate measures of FN and TH BMD by DXA using a conventional (i.e., short) and a longer femur scan field after randomization to either a long-short-long or a short-long-short scan field measurement sequence. Simple estimates of the standard deviation between paired long-long and paired short-short scan field BMD studies were 0.011 G/cm² for mean FN and 0.007 G/cm² for mean TH. The difference in mean FN BMD measured from a conventional (i.e., short) versus a long femur scan field was 0.008 G/cm² 0.002 (p=.002). The difference in mean TH BMD measured from a conventional (i.e., short) versus a long femur scan field was 0.004 G/cm² 0.002 (p=.079). Differences in measured BMD between the two scan field lengths were small and less than the precision error inherent in DXA testing. A longer proximal femur scan field does not substantially alter BMD measurements made at the FN or the TH and might be useful in clinical practice as a means of surveillance for the detection of atypical, subtrochanteric femur fractures.

Postmenopausal Women with Vertebral and Non-vertebral Fragility Fractures Have Marked Differences in Tibial Microarchitecture. Emily Stein¹, Thomas Nickolas², Adi Cohen², Donald McMahon¹, Xiaowei Liu¹, Mafo Kamanda-Kosseh³, Jeri Nieves⁴, Felicia Cosman⁴, X Guo³, Elizabeth Shane¹. ¹Columbia University College of Physicians & Surgeons, USA, ²Columbia University Medical Center, USA, ³Columbia University, USA, ⁴Helen Hayes Hospital, USA

Abnormal skeletal microarchitecture predisposes postmenopausal women to fragility fractures. Whether microarchitecture differs between women with vertebral (VFX) and non-vertebral fractures (NVFX) is unknown. We hypothesized that the

pattern of microarchitectural deterioration would be similar in women with VFX and NVFX, but more severe in VFX.

Women with a history of postmenopausal low trauma VFX (n=27), NVFX (n=70), and controls (C; n=120) with no fractures and normal spine x-rays had aBMD of the lumbar spine, total hip, femoral neck, 1/3 radius and ultradistal radius (UDR) measured by DXA. Trabecular (Tb) and cortical (Ct) volumetric BMD and microarchitecture were measured by high resolution peripheral computed tomography (HRpQCT, voxel size ~82 µm) of the distal radius (RAD) and tibia (TIB).

Mean age of subjects was 68.7yrs, 75% were Caucasian. The most common NVFX were wrist (39%) and ankle (26%). Groups were similar with respect to age, race, years since menopause and BMI. Mean T-scores were >-2.5 at all sites and aBMD did not differ from C at any site except the UDR (VFX 9% lower, p<0.02; NVFX 5% lower, p<0.04). In contrast, there were substantial microarchitectural differences among the groups (Table). Compared to C, VFX had smaller Ct and larger Tb area, lower total, Ct and Tb density, lower Ct thickness, lower Tb number and thickness at both radius and tibia. Tb separation and network heterogeneity were greater only at the tibia. NVFX had smaller Ct and larger Tb area, lower total and Tb density at both sites. Tb number was lower, and Tb separation and heterogeneity were substantially greater than C at the radius but did not differ from C at the tibia. Tb thickness was lower only at the tibia. There were no significant differences between VFX and NVFX at the radius. However, at the tibia, VFX had worse Ct and Tb microarchitecture than NVFX, specifically a trend toward lower Ct area, and significantly lower total and Tb density, Ct thickness, Tb number and greater Tb separation and heterogeneity.

In summary, Ct and Tb microarchitecture were substantially worse in women with VFX and NVFX compared to C. At the radius, microarchitectural differences between VFX and NVFX, albeit sizable, were not statistically significant. However, at the tibia, Ct and Tb abnormalities were significantly greater in VFX than NVFX. We conclude that women with VFX have more severe microarchitectural deterioration than those with NVFX, particularly at the tibia.

Effects of Bazedoxifene/Conjugated Estrogens on Bone Mineral Density and Bone Turnover Markers in Postmenopausal Women: A Double-Blind, Randomized, Placebo- and Active-controlled Phase 3 Study. J. Christopher Gallagher¹, Robert Lindsay², Kaijie Pan³, Sebastian Mirkin³, Arkadi Chines³. ¹Creighton University Medical Center, USA, ²Helen Hayes Hospital, USA, ³Pfizer Inc, USA

Bazedoxifene (BZA) combined with conjugated estrogens (CE) is a tissue selective estrogen complex (TSEC) that has been shown to be effective for the treatment of menopausal symptoms and prevention of osteoporosis while ensuring endometrial safety in women with a uterus. In this randomized, double-blind, placebo (PBO)-controlled phase 3 study (Selective Estrogens, Menopause, And Response to Therapy [SMART]-5) of nonhysterectomized postmenopausal women, the 2 primary endpoints were the mean percent change from baseline in lumbar spine bone mineral density (BMD) and the incidence of endometrial hyperplasia (results reported separately). Of 1,843 subjects who were randomized and received ≥1 dose of study drug, 590 (mean age standard deviation [SD], 52.9 y 3.4 y; mean years since last menstrual period SD, 2.5 y 1.5 y) participated in the osteoporosis study. Subjects were randomly assigned to daily oral doses of BZA 20 mg/CE 0.45 mg (n = 135), BZA 20 mg/CE 0.625 mg (n = 154), BZA 20 mg (n = 73), medroxyprogesterone acetate (MPA) 1.5 mg/CE 0.45 mg (n = 70), or PBO (n = 158); mean lumbar spine BMD T-scores at baseline were -0.91, -0.91, -0.82, -0.77, and -0.95, respectively. The mean percent changes from baseline in BMD at the lumbar spine at 12 months are shown below (Table). Significant improvements in BMD were also seen with BZA 20 mg/CE 0.45 mg, BZA 20 mg/CE 0.625 mg, BZA 20 mg, and MPA 1.5 mg/CE 0.45 mg at the total hip, femoral neck, and femoral trochanter versus PBO (Table; P < 0.01 for all). In addition, serum osteocalcin and C-telopeptide levels were significantly reduced with both BZA/CE doses compared with placebo (P < 0.001 for each) and BZA alone (P < 0.01 for each; Table). Both BZA/CE doses were associated with a favorable endometrial safety profile. In conclusion, BZA 20 mg/CE 0.45 or 0.625 mg showed significant improvements in BMD as well as significant reductions in bone turnover markers at 12 months while protecting the endometrium.

Table. Percent Change From Baseline at 12 Months (SMART-5)

	BZA 20 mg/ CE 0.45 mg (n = 135)	BZA 20 mg/ CE 0.625 mg (n = 154)	BZA 20 mg (n = 73)	MPA 1.5 mg/ CE 0.45 mg (n = 70)	Placebo (n = 158)

Results of the ORACAL Trial: A Phase 3 Randomized Trial of the Safety and Efficacy of Orally Administered Recombinant Salmon Calcitonin Tablets in Postmenopausal Women with Osteoporosis. Neil Binkley¹, Michael Bolognese², James Gilligan³, David Krause³. ¹University of Wisconsin, USA, ²Bethesda Health Research, USA, ³Tarsa Therapeutics, USA

BACKGROUND: An oral preparation of recombinant salmon calcitonin (oral rsCT) has previously been shown to be orally bioavailable, safe, and to suppress CTx in short term use. **METHODS:** In this Phase 3, multinational, three-armed, double-blind, double-dummy study, women were randomized 4:3:2 to receive daily 200 µg oral rsCT tablets plus nasal placebo, oral placebo and 200 IU commercially available synthetic nasal salmon calcitonin (nasal ssCT), or placebo-placebo for 48 weeks. All doses were administered at bedtime. Calcium and vitamin D (1000mg/800IU) were provided to subjects for daily use. Major inclusion criteria included vitamin D replete postmenopausal women age ≥ 45 years, with a bone mineral density (BMD) T score ≤ -2.5 at the lumbar spine (LS), femoral neck or total hip, or ≤ 2.0 with a prior vertebral fracture. Replicate DXA scans were obtained at baseline, weeks 24 and 48, and read centrally. The primary efficacy variable was the % change in LS-BMD over 48 weeks in the modified intent-to-treat (mITT) population. Biomarkers of bone resorption (CTx, NTx) and formation (P1NP) were also assessed. **RESULTS:** 565 subjects were enrolled in 6 countries; 411 were in the mITT population and contributed efficacy data, 549 contributed safety data. The mean age was 66.5y and mean LS T score -2.84. The increase in LS BMD are shown in TABLE:

Although powered to show non-inferiority, oral rsCT was superior to nasal ssCT (delta 0.77% [95% CI: 0.09, 1.45], p=0.026). Conclusions for the per-protocol population were similar (delta 1.05% [95% CI: 0.32, 1.78], p=.005). Consistent with the change in BMD, fasting CTx at the exit visit decreased by 29.9%, 11.4% and 11.8% in the oral, nasal, and placebo arms (oral rsCT vs. nasal ssCT: p < 0.001). Tolerability was similar among the groups; the most common adverse events (AEs) in each group were GI; few serious AEs occurred. Most AEs were mild or moderate in severity. Few fractures occurred. **CONCLUSIONS:** After 48 weeks of treatment subjects receiving oral rsCT tablets had an improvement in LS-BMD which was superior to that of subjects receiving nasal ssCT. The efficacy data (i.e., bone turnover markers and BMD) were robust and internally consistent. The safety and tolerability profiles were similar. Oral rsCT has potential to provide an additional oral treatment option for postmenopausal women with osteoporosis.

	N	% Increase LS BMD (SD)	Change From Baseline
Oral rsCT	189	1.53 (3.17)	p < 0.001
Nasal ssCT	140	0.76 (2.91)	p = 0.014
Placebo	82	0.47 (3.21)	p = ns

Effects of the Cathepsin K Inhibitor, ONO-5334, on BMD as Measured by 3D QCT in the Hip and the Spine After 2 Years of Treatment. Klaus Engelke¹, Shinichi Nagase², Thomas Fuerst³, Richard Eastell⁴, Harry Genant⁵, Maria Small², Tomohiro Kuwayama², Steve Deacon². ¹Synarc Inc, Germany, ²Ono Pharma UK Ltd, United Kingdom, ³Synarc, Inc., USA, ⁴University of Sheffield, United Kingdom, ⁵UCSF/Synarc, USA

Purpose: To evaluate the efficacy of the Cathepsin K inhibitor, ONO-5334 in a randomized, double-blind, parallel-group study using quantitative computed tomography (QCT).

Methods: 285 post-menopausal female subjects (age: 55-75) with osteoporosis (with no fragility fractures) or osteopenia (with a fragility vertebral fracture) were equally randomized to five study arms: three doses of ONO-5334 (50mg bd, 100 or 300mg qd), placebo (PBO) or alendronate (ALN, 70mg qw). Calcium and vitamin D were given to all subjects. 3D QCT scans of the spine (L1 and L2) and of the proximal femur were taken at baseline after 1 (Y1) and after 2 years (Y2). QCT (exploratory endpoint) analysis was performed for those patients who provided informed consent for this assessment, with MIAF (Medical Image Analysis Framework) in various integral, cortical and trabecular volumes of interest. 120 subjects had baseline and 2 year follow-up femur scans, 118 subjects had baseline and follow-up spine scans.

Results: Percentage BMD changes in total vertebral body of L1 plus L2 and total femur after 12 and 24 months relative to baseline are shown in the table. Vertebral and total femur volume did not change in any treatment. BMD continued to increase in Y2. For 300mg qd ONO-5334 the additional BMD increase between Y1 and Y2 for total, trabecular and cortical BMD in the spine was 68%, 83% and 30%, of the BMD increase observed between BL and Y1. In the femur, results for the neck were very similar to those of the total femur but in the trochanter integral %BMD changes were slightly higher for the ONO-5334 and ALN groups. In all hip regions, trabecular % BMD changes were higher for ONO-5334 50mg, 300mg and ALN groups. Cortical thickness of the hip did not change significantly in any group. For 300mg qd ONO-5334 trabecular and cortical BMD in the femur linearly increased over the two years, total BMD also continued to increase in Y2 but at a slightly lower rate compared to Y1.

Conclusions: After two years of treatment ONO-5334 50 mg bd and 300 mg qd demonstrated similar increases from baseline that were consistently superior to 100 mg qd, mirroring the results seen after one year. Response to ONO-5334 was roughly equivalent to ALN at the spine and at least as great at all compartments in the hip. Moreover, ONO-5334 trended toward larger gains in year 2 compared to ALN. ONO-5334 showed persistent gains over two years in QCT BMD at two important fracture sites with minimal attenuation of effects in the second year of therapy.

Table: Percentage change from baseline in volumetric BMD \pm SD

Controlled Trial of Two Interventions to Increase Osteoporosis Treatment in Patients with "Incidentally" Detected Vertebral Fractures on Chest Radiographs (NCT00388908). Sumit Majumdar^{*1}, Finlay A. McAlister¹, Jeffrey A. Johnson¹, Debbie Bellerose¹, Kerry Siminoski¹, David Hanley², Quazi Ibrahim¹, Douglas A. Lier¹, Robert G. Lambert¹, Anthony S. Russell¹, Brian H. Rowe¹. ¹University of Alberta, Canada, ²University of Calgary, Canada

BACKGROUND: Most vertebral compression fractures (VCF) are not clinically recognized, investigated, or treated. We conducted a controlled trial in older patients with VCF reported on chest radiographs taken for other reasons and compared usual care (control) with interventions directed at physicians (opinion-leader endorsed evidence summaries and reminders) or physicians+patients (activation with leaflets and telephone counseling).

METHODS: Patients 60 years of age and older discharged home from local Emergency Departments who had VCF reported and were not treated for osteoporosis were allocated to control or physician intervention using alternate-week time series. After 3-months, untreated controls were crossed-over to the physician+patient intervention. Allocation was concealed. Analyses were intent-to-treat. Primary outcome was starting prescription osteoporosis treatment within 3-months. Secondary outcomes were bone mineral density (BMD) testing and the composite endpoint of BMD testing or treatment.

RESULTS: 1315 consecutive patients were screened, 1075 were excluded, and 240 allocated to control (n=123) or physician intervention (n=117). Groups were similar at baseline (average 74 years, 45% female, 50% had previous fractures). Compared with controls, the physician intervention significantly increased osteoporosis treatment (20 [17%] vs 2 [2%], p<0.001), BMD testing (51 [44%] vs 5 [4%], p<0.001), and the composite of BMD testing or treatment (57 [49%] vs 7 [6%], p<0.001; FIGURE). 3-months after untreated controls (n=121) were crossed over to the physician+patient intervention, rates of new osteoporosis treatment, BMD testing,

and composite endpoints were 22%, 56%, and 65%. The physician+patient intervention significantly increased BMD testing or osteoporosis treatment another 16% compared with physician intervention alone (65% vs 49%, p=0.01).

CONCLUSIONS: Even when VCF are reported on chest radiographs, osteoporosis testing or treatment is rarely initiated. An opinion-leader based intervention targeting physicians substantially improved rates of BMD testing and osteoporosis treatment compared to usual care. Somewhat better management was achieved by adding patient activation to the physician intervention.

The 25(OH)D Level Associated With A Favorable Bisphosphonate Response Is >33ng/ml. Amanda Carmel^{*1}, Albert Shieh¹, Richard Bockman². ¹Weill Cornell Medical College, USA, ²Hospital for Special Surgery, Weill Medical College, USA

Background: The results of clinical trials are not always reproduced in the real world setting. The Fracture Intervention Trial with alendronate reported significant increases in hip bone mineral density (BMD) in 97.5% of patients, and a 12% rate of incident fracture. BMD was subsequently shown to be maintained for 10 years. In nearly all drug trials in osteoporosis, supplement use is imposed. Several studies that estimated vitamin D intake suggested that clinical response to bisphosphonates could in part be dependent on circulating vitamin D. This study examined the association between serum 25 hydroxy vitamin D [25(OH)D] level and bisphosphonate response using a composite definition of response. **Methods:** Postmenopausal women with low BMD being treated with > 18 months of bisphosphonates who had at least two dual energy x-ray absorptiometry (DEXA) scans separated by 18-60 months were identified from two ambulatory practices in New York City. Patients were excluded if they had a history of chronic steroid use, metabolic bone disease, or were not compliant with bisphosphonate therapy. Patients were categorized as bisphosphonate non-responders if they had a T score < -3 that persisted between DEXA scans, a > 3% decrease in BMD, or an incident fracture on bisphosphonate therapy, criteria based on the Eurofors trial. Demographic and clinical data including mean 25(OH)D levels between scans were obtained. Mean 25(OH)D levels were compared between responders and non-responders and multiple logistic regression analysis was performed to identify factors associated with non-response. **Results:** A total of 210 patients (mean age 65) with low bone mass (mean femoral neck T-score = -2.0) were included. The mean Charlson comorbidity index was low. Mean duration of bisphosphonate treatment was 63 months. The majority of the patients were Caucasian (83%), approximately half were treated with alendronate, a quarter with risedronate, and ~18% received intravenous zoledronate. Only 99 of 210 patients (47%) had a favorable response to bisphosphonates. Patients with a mean 25(OH)D \geq 33 ng/ml had a 4.5 fold greater odds of bisphosphonate response (estimated OR 4.5, P<0.0001). 25(OH)D level (as a continuous variable) was significantly associated with response to bisphosphonates - 1ng/ml decrease in 25(OH)D was associated with ~ 5% decrease in odds of responding (OR=0.95, 95% CI=[0.92, 0.98], P=0.0007). **Conclusions:** The current study is the first to identify a threshold level of 25(OH)D that defines improved outcome to bisphosphonate therapy such that patients with a mean 25(OH)D \geq 33 ng/ml had a substantially greater likelihood of responding to bisphosphonates. This threshold value of \geq 33 ng/ml for 25(OH)D is higher than the level considered adequate by the Institute of Medicine report for the general population, arguing that higher levels may be required for specific therapeutic outcomes.

Early Detection of Lateral Cortical Lesions in Atypical Subtrochanteric Fracture Using Dual Energy X-ray Absorptiometry (DXA) Hip Images. Kyu Hyun Yang^{*1}, Sungjun Kim², Young-Kyun Lee³, HanKook Yoon⁴, Chang-Wug Oh⁵, Hyeung Keun Song¹. ¹Gangnam Severance Hospital, South Korea, ²Yonsei University College of Medicine Gangnam Severance Hospital, South Korea, ³Seoul National University Bundang Hospital, South Korea, ⁴National Health Insurance Corporation Ilsan Hospital, South Korea, ⁵Kyungpook National University Hospital, South Korea

Purpose: To assess whether DXA hip images, which have been used to measure and monitor the bone mineral density, can be used to depict changes on the lateral cortex of the proximal femur in the patients who take bisphosphonate before atypical subtrochanteric fracture occurs. **Methods:** We retrospectively reviewed the medical records of forty-seven women who sustained atypical subtrochanteric fractures and their latest 52 DXA hip images, which were taken before the fracture, were analyzed. Thirty-three ipsilateral DXA hip images and 19 contralateral ones were available. Mean time of bisphosphonate administration was 5.9 years. Forty one patients took alendronate for prevention or treatment of osteoporosis. **Results:** Among 33 ipsilateral DXA images, diffuse lateral cortical thickening was found in 10 cases and positive focal changes in the lateral cortices were identified in 20 cases. Positive focal changes were external periosteal callus (6 cases), internal medullary callus (11 cases) and combined external-internal lesions (3 cases). Three images were negative. Two of them didn't include the fracture level in DXA hip examination. Mean time gap between positive DXA and ipsilateral fracture was 14.3 months. Hip pain was complained in 14 cases (42%). Mean T score of the total hip BMD was -1.2. The lateral cortical changes of 19 contralateral DXA hip images were as follows: two positive focal changes, 9 diffuse cortical thickening, and 8 negative findings. Detection rate of the focal positive findings on the ipsilateral DXA is significantly higher than on the contra-lateral one ($P<0.001$). **Conclusion:** Vigilance for the aforementioned 4 lateral cortical changes during serial DXA monitoring could help identifying the cortical stress lesions in asymptomatic long-term bisphosphonate users to prevent progression to complete subtrochanteric fracture.

Breastfeeding in Infancy and Bone Mass in British Children at 10 and 16 Years of Age. Alexa Gallagher^{*1}, Jihong Liu¹, Jon Tobias², Jim Hussey¹, Charlotte Atkinson², Susan Steck¹. ¹University of South Carolina, USA, ²University of Bristol, United Kingdom

Introduction: Little is known about the role that infant feeding plays on bone health in later childhood. We sought to examine this relationship using data from the Avon Longitudinal Study of Parents and Children (ALSPAC).

Methods: We assessed the relationship between bone measurements taken by total body DXA scans at age 10 [2356 boys, 2415 girls] and infant feeding practice [breastfeeding initiation and duration, as well as feeding type (breast milk only, breast milk and formula, formula only) at 5 months of age]. Analysis of covariance was used to adjust for age at the time of the scan, lean mass, fat mass, height, season of birth, gestational age, birth weight, maternal smoking during pregnancy, maternal education, age at introduction to solid foods, calcium intake at age 11, and physical activity at age 10. Due to significant interactions between sex and the breastfeeding variables at the 0.05 level, results were presented for boys and girls separately. To confirm our findings, the analysis was repeated using total body DXA scans [1425 boys, 1592 girls] taken at age 16.

Results: At age 10, ever breastfed boys had lower bone mineral density (BMD) [β -5.25, $p=0.02$] than never breastfed boys. A similar, but partially attenuated relationship was observed at age 16 [β -4.06, $p=0.40$]. At age 10, each additional month of breastfeeding in boys was associated with a 0.68 g/cm^2 [$p=0.02$] decrease in BMD [age 16: β -0.64, $p=0.31$]. Lastly, compared to boys fed only formula at 5 months, boys fed only breast milk [β -6.50, $p=0.01$] or breast milk and formula [β -4.81, $p=0.03$] had lower BMD at age 10. By age 16, similar, but partially attenuated results were again observed with boys fed only breast milk [β -6.28, $p=0.26$] or breast milk and formula [β -3.19, $p=0.52$] having lower BMD than those fed only formula. In girls, differences were observed only for type of feeding at 5 months. At ages 10 and 16, girls fed only breast milk at 5 months of age had lower BMD [age 10: β -3.83, $p=0.06$; age 16: β -10.07, $p<0.01$] than those who had been fed breast milk and formula.

Conclusion: In late childhood (age 10), boys who were breastfed had lower bone mass than their formula fed counterparts. Partial attenuation of these deficits was evident by late adolescence (age 16). Deficits seen in the bone mass of girls fed only breast milk for 5 months continued to be seen into late adolescence.

Lumbar Spine Bone Mineral Density Is Enhanced in Breast Fed Infants Receiving 800 or 1200 IU of Vitamin D Daily from 4 to 20 Weeks of Age. Sina Gallo^{*1}, Celia Rodd¹, Catherine Vanstone¹, Sherry Agellon¹, Mary L'Abbe², Ali Khamessan³, Hope Weiler¹. ¹McGill University, Canada, ²University of Toronto, Canada, ³EURO-PHARM INERNAIONAL CANADA INC, Canada

In North America, it is recommended that all breastfed infants be supplemented with 400 IU of vitamin D daily beginning at birth. This recommendation is to prevent deficiency and bone diseases such as rickets. Whether higher doses than the current standard of care would result in optimal bone mineral accrual has not been explored. The primary objective of this study was to determine whether 800 or 1200 IU daily supplementation of vitamin D given to breastfed infants would support higher bone after 8 and 20 weeks compared to 400 IU/day. Healthy, term breastfed infants ($n=116$) from the Montreal area (NCT00381914 clinicaltrials.gov) were randomized to one of 3 study groups of vitamin D3 (400, 800 or 1200 IU) daily beginning between 4-6 weeks of age. This analysis includes all data up to 20 weeks of supplementation, ~6 months of age. At each time point, whole body and lumbar spine (L1-4) bone BMC were measured using dual-energy x-ray absorptiometry (QDR 4500A, Hologic Inc.). Areal BMD for lumbar spine was also examined. Differences were tested using repeated measures ANOVA (by ITT) accounting for within-subject serial correlations as well as baseline parameters. Age did not differ among groups at each time point ($p=0.995$). Treatment dosage interacted with time ($p<0.05$) without main effects. Targeted estimate statements identified differences in comparison to the 400 IU group at 8 and 20 weeks for spine BMD only. Mean values by time and treatment are given below. This data provides promising evidence to suggest that additional vitamin D may be superior for bone growth. Continued evaluation to one year of age will better establish treatment effects on bone development.

	Treatments		
	400 IU/day (n=38)	800 IU/day (n=39)	1200 IU/day (n=39)
Baseline	0.247 \pm 0.026	0.233 \pm 0.027	0.235 \pm 0.026
8 weeks	0.232 \pm 0.007	0.256 \pm 0.008*	0.246 \pm 0.008
20 weeks	0.256 \pm 0.035	0.266 \pm 0.035	0.279 \pm 0.035*

* $p<0.05$ vs. 400 IU/day treatment

Estimated mean lumbar spine (L1-4) BMD SE (g/cm²) at baseline, 8 and 20 weeks of supplementation

An Investigation Of Relationships Between Fracture Risk, Total Body DXA And Tibial pQCT Reveals Independent Influences Of Areal And Cortical BMD in Adolescence: Is There a Case For Combining DXA And pQCT In Assessing Fracture Risk?. Adrian Sayers*, Chau Jacky, Kate Tilling, Jon Tobias, University of Bristol, United Kingdom

Introduction: Areal bone mineral density (aBMD) as measured by total body DXA has previously been found to be related to fracture risk in children, particularly when adjusted for body size, possibly reflecting an influence of true volumetric bone density. Cortical BMD is likely to contribute to aBMD, and can be directly measured by pQCT. However, whether DXA and pQCT evaluate equivalent determinants of fracture risk is unknown. To address this question we examined whether, in the Avon Longitudinal Study of Parents and Children, areal and cortical BMD, as measured by total body DXA and pQCT respectively, are independently related with fracture risk.

Methods: Total body DXA and mid-tibial pQCT were linked to fracture history in the preceding three years in 2849 boys and girls mean 15.5 years of age. Fracture risk was investigated using multivariable logistic regression. Relative risk and absolute risk differences were calculated for minimally adjusted (age) and more fully adjusted models (height, fat and lean mass).

Results: In adjusted models aBMD and cortical BMD were both inversely associated with fracture risk: 25.3% reduction in odds of fracture per SD increase in aBMD ($b=0.747$ [95%CI: 0.636, 0.878], $p=0.0004$, $r^2=0.047$); 24.1% reduction in odds of fracture per SD increase in cortical BMD ($b=0.759$ [95%CI: 0.660, 0.874], $p=0.0001$, $r^2=0.048$). In a combined model, although individual associations were marginally attenuated, SD increases in aBMD and cortical BMD were still associated with 19.8% and 20% reductions in odds of fracture respectively ($b_{aBMD}=0.802$, [95%CI: 0.678, 0.949], $p=0.010$ / $b_{cBMD}=0.8$ [95%CI: 0.691, 0.926], $p=0.0029$, $r^2=0.051$). Finally, the absolute risk reduction between lower and upper quartiles of aBMD (-4.5%) and cortical BMD (-4.3%), was significantly improved when both were used in combination (-6.6%) $p<0.001$.

Conclusions: Whereas fracture risk in adolescence is related to both aBMD and cortical BMD, the inclusion of cortical BMD into a DXA based model of risk significantly improves fracture risk prediction, implying that these factors act in part independently. Further studies are justified to examine the utility of combined use of DXA and pQCT to evaluate fracture risk not only in adolescents, but also in older populations.

Variants in *WNT16* are Strongly Associated with Total Body Mineralization in Children of Different Ethnic Background and with Total Body BMD of Elderly Adults. Carolina Medina-Gomez*¹, Karol Estrada², Denise Hepp³, Lizbeth Herrera², Rodinde Bloot², Mette Offerhaus², Ling Oei², Albert Hofman⁴, Vincent Jaddoe³, Paul Eilers⁵, Andre G Uitterlinden², Fernando Rivadeneira². ¹Erasmus Medical Center, The Netherlands, ²Department of Internal Medicine, Erasmus Medical Center, Netherlands, ³The Generation R Study Group, Erasmus Medical Center, Netherlands, ⁴Department of Epidemiology, Erasmus Medical Center, Netherlands, ⁵Department of Biostatistics, Erasmus Medical Center, Netherlands

Aim: Bone Mineral Density (BMD), the major parameter to assess skeletal health is a highly heritable trait. In children, the rapid skeletal changes with growth makes it difficult interpreting BMD. Area-adjusted BMC (aBMC) has been proposed as a measure of mineral content fully independent of skeletal size and so suitable for pediatric studies. We ran a genome-wide association study (GWAS) on aBMC to identify common genetic determinants of bone accrual in children of diverse ethnic background; and replicated findings in 3 studies of Northern European individuals age > 45 years. **Methods:** Subjects are part of the *Generation R* study, a multiethnic birth cohort in Rotterdam, The Netherlands; we included 2,196 children (mean age=6.2, SD=0.28 years) with total body DXA measurements (GE-Lunar iDXA) and GWAS data (Illumina 660K). aBMC was calculated from BMC regressed on total body region area. Replication was pursued in adults from the Rotterdam Study I (RS-I; n=2436), II (RS-II; n=749), and III (RS-III; n=668) with total body BMD and GWAS data (age range 45-95). Analyses were adjusted for age, sex, weight and 20 (children) or 4 (adults) genomic principal components, using PLINK and results meta-analyzed with METAL. A $P<5\times 10^{-8}$ was considered genome-wide significant (GWS). **Results:** Genomic inflation factors were close to unity indicating stratification was controlled. We identified in children a GWS signal ($\beta=0.19$, $P=1.1\times 10^{-8}$) for a SNP mapping to *7q31* near the *WNT16* gene. The association was replicated in all adult studies RS-I ($P=6.3\times 10^{-5}$), RS-II ($P=5.2\times 10^{-4}$) and RS-III ($P=0.02$). The summary effect in the meta-analysis was highly significant ($P=1.1\times 10^{-15}$). **Conclusion:** We robustly show that *WNT16* exerts an effect on bone mineralization in children of different ethnicities and influences total body BMD variation in adulthood. *WNT16* has been shown to be highly expressed in the perichondrium and periosteum of developing long bones, in line with our results suggesting a role of Wnt factors on bone formation throughout life. These early effects of *WNT16* are likely to be influencing the development of peak bone mass and impacting the risk of osteoporosis in later life.

Racial and Ethnic Disparity in Fracture Risk among Pediatric Populations in the United States. Tishya Wren*¹, John Shepherd², Heidi Kalkwarf³, Babette Zemel⁴, Joan Lappe⁵, Sharon Oberfield⁶, Karen Winer⁷, Vicente Gilsanz¹. ¹Children's Hospital Los Angeles, USA, ²University of California, San Francisco, USA, ³Cincinnati Children's Hospital Medical Center, USA, ⁴Children's Hospital of Philadelphia, USA, ⁵Creighton University Osteoporosis Research Center, USA, ⁶Columbia University Medical Center, USA, ⁷National Institutes of Health, NICHD, USA

Fracture risk is substantially higher in elderly subjects of European descent when compared to other racial/ethnic groups. However, few studies have examined whether similar discrepancies exist in younger subjects. The purpose of this prospective multi-center study was to examine risk factors for fracture in a diverse cohort of healthy, normally developing children in the United States. The study subjects were 1,470 healthy boys and girls of different population ancestry groups, ages 6 to 16 years, who were followed longitudinally for 6 years in the multi-center Bone Mineral Density in Childhood Study (BMDCS). Subjects underwent annual examinations in which height, weight, body mass index (BMI), Tanner stage of sexual development, calcium intake, physical activity levels, and DXA measures of the whole body, lumbar spine, hip, and forearm were obtained. Fracture information was also obtained at each annual visit, and risk factors for fracture were examined using the Cox proportional hazard model.

Overall, 14% of subjects (212/1470) reported a fracture during the 6-year follow-up period, with 2% (36/1470) reporting multiple fracture incidents. The overall fracture incidence was 3.4 fractures per person-year. Most fractures occurred in the upper extremity (166/257, 65%) and during sports or similar activities (185/257, 72%). As expected, the fracture rate was higher for males (131/726, 18%) than for females (81/744, 11%) ($P<0.001$), but unexpectedly fracture rates were also higher for white subjects compared with all other population ancestry groups ($P<0.001$) (Table 1). In multivariable analysis, being white ($HR=2.7$, $P<0.001$) and male ($HR=1.6$, 95% $P<0.001$) were the strongest risk factors for fracture (Table 2). Younger age, more advanced Tanner stage, lower body fat percentage, and greater sports participation were also significant risk factors for fracture. DXA Z-scores and calcium intake did not influence fracture risk.

These results provide compelling evidence that population ancestry is a major determinant of fracture risk in U.S. children. Healthy boys and girls of European descent had 270% greater fracture risk than healthy children of other backgrounds including Hispanics, African Americans, and Asians. In comparison, the difference in fracture risk between boys and girls was 160%. Additional research is needed to identify the phenotypes underlying the greater susceptibility to fractures of the developing skeleton in white children.

Table 2: Risk factors for fracture using the Cox proportional hazard model

	HR	95% CI	P
White	2.75	2.00, 3.77	<0.001
Male	1.57	1.08, 2.27	0.02
Age (yr)	0.88	0.80, 0.95	0.002
Tanner	1.23	1.04, 1.46	0.02
Body fat (%)	0.96	0.94, 0.99	0.005
Sports (days/wk)	1.08	1.00, 1.17	0.03

Changes in the Genetic Architecture of Bone Health during Childhood. Dana L. Duren^{*1}, Richard J. Sherwood², Miryoung Lee², Maja Seselj³, Thomas Dyer⁴, Shelley Cole⁴, Roger M. Siervogel³, Stefan A. Czerwinski³, John Blangero⁴, Bradford Towne². ¹Lifespan Health Research Center, Department of Community Health, Wright State University; Department of Orthopaedic Surgery, Wright State University, USA, ²Lifespan Health Research Center, Department of Community Health, Wright State University; Department of Pediatrics, Wright State University, USA, ³Lifespan Health Research Center, Department of Community Health, Wright State University, USA, ⁴Texas Biomedical Research Institute, USA

Skeletal growth and development are directed by both genetic and environmental influences. The environmental envelope surrounding the developing skeleton will change as a child is exposed to novel experiences (diet, exercise, etc.). Likewise, the genetic influences on the growth and development of the pediatric skeleton can change over the course of childhood. We examined the genetic underpinnings of measures of bone health (cortical thickness and biomechanical properties) in three cross-sectional samples of genotyped children participating in the Fels Longitudinal Study representing distinct stages of childhood development: ages 3, 12 and 18 years (n = 359, 442, and 279, respectively). All analyses were conducted using a maximum-likelihood variance decomposition approach in SOLAR with age, sex, and skeletal age as covariates. Quantitative genetic analysis revealed significant heritability of bone measures in each of the three age groups. Heritabilities ranged from 0.47 (section modulus in the 12 year olds) to 0.82 (total cortical bone thickness in the 18 year olds). Suggestive linkages were identified for QTL on chromosomes 6q, 17q and 22p in the 3 year olds; on chromosomes 2p, 6p, 11p and 22p in the 12 year olds; and on chromosomes 1p, 6q, 7q, and 14q in the 18 year olds. A number of these genomic regions contain previously identified candidate genes for bone-related phenotypes (e. g., BMD, osteoporosis), while others include plausible candidate genes that have not previously been identified by population-level linkage or association approaches. Our results demonstrate that pediatric bone health is influenced by genes throughout childhood, and although some genomic regions appear to consistently influence bone health across ages each developmental stage is also characterized by genetic factors that are unique to that time period.

sFrp4 Differentially Regulates Trabecular and Cortical Bone Mass via Canonical Wnt and Ror2-BMP-Sclerostin Signaling, Respectively. Hiroaki Saito^{*1}, Eric Hesse², Kei Yamana³, Riku Kiviranta⁴, Lynn Neff⁵, Nicolas Solban⁶, William Horne¹, Roland Baron⁷. ¹Harvard School of Dental Medicine, USA, ²Harvard Schools of Medicine & Dental Medicine, USA, ³Teijin Pharma Limited, Japan, ⁴Medical Biochemistry & Genetics & Turku PET Centre, University of Turku, Finland, ⁵Harvard School of Dental Medicine, Oral Medicine, Infection & Immunity, USA, ⁶Accelaron Pharma, USA, ⁷Harvard School of Medicine & of Dental Medicine, USA

Osteoporosis often results from defective osteoblast (OB) function, with Wnt and BMP signaling playing central roles. Secreted Frizzled Related Protein 4 (sFrp4) is a Wnt decoy receptor that represses Wnt signaling. To determine the role of sFrp4 in bone, we established *Sfrp4*-deficient mice. Expectedly, *Sfrp4*^{-/-} and *Sfrp4*^{+/-} mice presented an increased trabecular bone mass (TBV) due to increased OB-dependent bone formation (MAR and BFR). To investigate whether this phenotype resulted from increased canonical Wnt-activity, *Sfrp4*^{+/-} mice were crossed with mice overexpressing the canonical Wnt inhibitor *Dkk1* targeted to OBs (*Dkk1*^{Tg}) and with *Dkk1*^{-/-} mice. *Dkk1*-overexpression in *Sfrp4*^{+/-} mice normalized the increased TBV and *Dkk1*-deficiency aggravated it. In vitro studies revealed an increase in activated

β -catenin in *Sfrp4*^{-/-} OBs and a dose-dependent repression of the Wnt3a-induced TopFlash reporter gene activation by exogenous sFrp4, demonstrating that *Sfrp4*-deletion causes a canonical Wnt-induced increase in TBV. Unexpectedly, cortical bone thickness (CBT) was reduced in *Sfrp4*^{+/-} mice due to a decrease in periosteal and endosteal MAR, which was not affected by gain or loss of *Dkk1* function. Thus, deletion of *Sfrp4* decreases CBT in a canonical Wnt-independent manner. Acting as a Wnt decoy receptor, sFrp4 also regulates the non-canonical Wnt pathway. Indeed, *Sfrp4*^{-/-} OBs demonstrated an increased level of total and phospho-JNK1/2/3. Furthermore, exogenous sFrp4 abolished the Wnt5a-induced activation of the non-canonical Wnt-specific Ror2-luc reporter gene assay, suggesting that in the absence of sFrp4, non-canonical Wnt activity is increased. Further in vitro analysis revealed a non-canonical Wnt-mediated activation of BMP signaling with an increase of p-Smads in *Sfrp4*^{-/-} OBs and an increased expression of the BMP target gene *Id2* in cortical but not in trabecular bone of *Sfrp4*^{+/-} mice. In turn, activation of BMP signaling increased the expression of the canonical Wnt inhibitor Sclerostin (Sost) specifically in the cortex of *Sfrp4*^{+/-} mice and injection of the BMP inhibitor RAP-661 fully reversed the thin cortical bone in *Sfrp4*^{+/-} mice. In conclusion, *Sfrp4*-deficiency 1/ activates canonical Wnt, causing an increase in TBV and 2/ activates non-canonical Wnt, resulting in increased BMP activity and Sost expression thereby reducing cortical bone formation. Thus, non-canonical Wnt signaling activates BMP signaling, exerting a negative effect on cortical bone in mice.

Conditional Ca²⁺-Sensing Receptor Knockouts in Mature Osteoblasts and Osteocytes Reveal Critical Roles for this Molecule in Maintenance of Bone Mass and Fracture Healing. Wenhan Chang¹, Zhiqiang Cheng¹, Tsui Hua Chen¹, Nathan Liang², Michael You², Alfred Li², Chialing Tu¹, Christian Santa Maria², Dolores Shoback^{*3}. ¹University of California, San Francisco, USA, ²VA Medical Center, San Francisco, USA, ³VA Medical Center, USA

Extracellular Ca²⁺ receptors (CaSRs), which detect changes in extracellular [Ca²⁺] in parathyroid cells, are also expressed in osteoblasts (OBs) and osteocytes (OCs). Conditional knockout of the CaSR in OBs early in differentiation produce severe growth retardation, underdeveloped bones, and early death of the mice (by 4-5 weeks of age). This prevents the assessment of the role of CaSRs at later stages of cell differentiation and in fracture healing in adult animals. To address these questions, we generated mice with homozygous CaSR KO targeted to mature OBs [osteocalcin (OCN)-CaSR-KO] or to OCs [dentin matrix protein (DMP)-CaSR-KO] by breeding floxed CaSR mice with mice expressing Cre recombinase (Cre) under the control of an OCN or DMP promoter, respectively. OCN-CaSR-KO and DMP-CaSR-KO mice developed normally to adulthood. Trabecular (Tb) bones in distal femurs from these mice and control mice (Cont) at 3 months of age were analyzed by micro-computed tomography (μ CT) for bone mineral content (BMC) and structural parameters. BMC as indicated by the Tb bone volume/tissue volume ratio (Tb.BV/TV) was decreased by $\approx 25\%$ in both OCN-CaSR-KO and DMP-CaSR-KO mice in both genders (Table 1), when compared to Cont mice. This was accompanied by decreased Tb connectivity density (CD), number (Tb.N), and thickness (Tb.Th) and increased Tb spacing (Tb.Sp) (Table 1). These data suggest that CaSRs in mature OBs and/or OCs play critical roles in maintaining bone mass in adult animals. To assess the role of CaSRs in fracture healing, we performed mid-shaft tibial fractures on 3-month-old male OCN-CaSR-KO and Cont mice and examined fracture calluses 4 weeks later by histomorphometry and gene expression profiling. In calluses from KO mice, we observed a decreased bone fraction (BV/TV) by $\approx 25\%$, accompanied by a decreased Tb.N and an increased Tb.SP without a change in Tb.Th (Table 2). Double fluorescence-labeled bone sections showed marked decreases in mineralizing surface (MS/BS) and bone formation rates (BFR/BS) in OCN-CaSR-KO vs Cont calluses. Quantitative PCR of RNA extracted from calluses showed decreased expression of early and late osteogenic markers (type I collagen, osteopontin, OCN, DMP, and sclerostin) by 50-75% in KO vs Cont mice, indicating delayed bone cell differentiation. Our data together support a critical role for the CaSR in maintaining bone mass and responding to challenges to skeletal homeostasis in both physiological and pathological states.

In vivo Multiphoton Imaging of Mesenchymal Stem Cell-Mediated Skeletal Repair. Chunlan Huang, Ming Xue, Xinping Zhang*. University of Rochester Medical Center, USA

Mesenchymal stem cells (MSCs) have demonstrated enormous potential in repair of skeletal defect. Understanding stem cell interactions with their microenvironment is critically important for development of material-based approaches to control stem cell behavior for enhanced repair and regeneration. Current studies to elucidate the mechanisms of interactions of MSCs in a complex in vivo bone healing environment are limited due to the lack of technology and an appropriate animal model that permits dynamic and high-resolution analysis. To overcome this, we have recently established a chronic cranial defect window chamber model in mouse, which permits in vivo real time analyses of cellular recruitment, cell-matrix interactions and vascular ingrowth during skeletal repair. Utilizing multiphoton-laser scanning microscopy (MPLSM) as the imaging platform, we are able to obtain high resolution images to simultaneously visualize extracellular/bone matrix via second harmonic generation (SHG), bone forming cells via fluorescence labeling, and vascular network via intravenously perfusion of dextran-conjugated fluorophore in a dynamic and real-time fashion. Skeletal defect can be further reconstructed in a three-dimensional format, enabling quantitative and qualitative characterization of extracellular matrix synthesis and neovascularization at the cellular level. Using this model, we examined the collagen matrix synthesis, remodeling and neovascularization over a time course of 1 month following implantation of a collagen gel plug encapsulated with bone marrow derived MSCs at the site of the cranial defect. Our data revealed a distinctive pattern of collagen compaction and remodeling by MSCs, which resulted in the formation of a porous matrix template that allows ingrowth of the newly formed blood vessels. In summary, establishment of a multiphoton based image modality in an in vivo cranial defect window chamber model enables high resolution assessment of the interactions of MSCs with fibrous matrix and neovascularization at cellular and subcellular level. With the possibility of using various transgenic animal models, this approach could open up research opportunities to study detailed molecular and cellular mechanisms underlying MSC-based bone repair and regeneration, further offering an experimental testing modality for therapeutic strategies.

N-cadherin Interferes with LRP5/6-PTH Receptor Association. Leila Revollo*, Valerie Salazar, Jin Norris, Gabriel Mbalaviele, Roberto Civitelli. Washington University in St. Louis School of Medicine, USA

Recent data indicate that the anabolic effect of PTH is in part mediated by an interaction between PTH receptor (PTH1R) and low-density lipoprotein receptor-related protein 6 (LRP6). Others have shown that N-cadherin interacts with LRP5/6 via axin, resulting in negative regulation of canonical Wnt/ β -catenin signaling. Since we find that the bone anabolic effect resulting from Wnt signaling activation is also dependent on N-cadherin, we hypothesized that N-cadherin may modulate bone cell response to PTH through LRP5/6 signaling. We studied this interaction in vivo and in vitro, using mice with a selective deletion of the N-cadherin gene (Cdh2) in osteoblasts, driven by the 2.3kb Col1 α 1 promoter (Cdh2flox/flox; Col1 α 1-Cre: cKO). Mice were injected with a single dose of PTH1-34 [40ug/kg], and protein preparations were obtained from tibias of cKO and wild type (WT) mice at different time-points. We observed a progressive up-regulation of β -catenin abundance reaching maximal levels 120 min after PTH1-34 injection in WT, while full effect was obtained in cKO after only 60 min. However, abundance of GSK3 α/β and p-GSK3 β did not change in cKO and WT mice. By contrast, p-ERK1/2 was up-regulated in N-cadherin WT mice after a single dose of PTH1-34, and it remained elevated in cKO mice for a longer time. These data suggest non-canonical mechanisms of β -catenin up-regulation in response to PTH. We then used bone marrow stromal cells (BMSC) from cKO and WT mice to further test LRP5/6-PTH interactions. Intriguingly, LRP5 abundance was significantly higher in cKO relative to WT BMSC, corroborating increased LRP5 mRNA and protein in bone lysates from cKO mice. Furthermore, LRP5/6 co-immunoprecipitated with N-Cadherin and PTH1R in MC3T3-E1 mouse calvarial cells. Preliminary studies suggest that PTH increases LRP5/6-N-Cadherin and decreases LRP6-PTH1R association. Surface membrane biotinylation of MC3T3-E1 cells revealed increased levels of N-cadherin at the plasma membrane 30 and 60 min after exposure to PTH1-34. In summary our results provide evidence that the response to PTH may be modulated by N-Cadherin through interference with LRP5/6 abundance at the plasma membrane.

BMP Type II Receptors Further Stimulate Constitutively Activated Mutant ALK2 found in Fibrodysplasia Ossificans Progressiva. Satoshi Ohte*¹, Hiroki Sasanuma², Masashi Shin¹, Katsumi Yoneyama², Seiya Suzuki², Toru Fukuda³, Shoichiro Kokabu⁴, Takenobu Katagiri². ¹Saitama Medical University, Japan, ²Saitama Medical University Research Center for Genomic Medicine, Japan, ³Keio University School of Medicine, Japan, ⁴Harvard School of Dental Medicine, USA

Bone morphogenetic proteins (BMPs) induce heterotopic bone formation in skeletal muscle. Intracellular signaling of BMPs is activated by binding to type I and type II transmembrane serine/threonine kinase receptors. In the ternary complex, type II receptor phosphorylates an intracellular domain of the type I receptor, and then the activated type I receptor phosphorylates Smad1/5. Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant congenital disorder characterized by progressive heterotopic endochondral bone formation in skeletal muscle. Muscle injury induces acute heterotopic bone formation in FOP. Several mutations in the intracellular domain of ALK2, a BMP type I receptor, have been found in typical and atypical patients with FOP. We found that not only a typical mutation but also other atypical mutations moderately activated phosphorylation of Smad1/5 and a BMP specific Id1-luc reporter. We examined effects of BMP type II receptors on ALK2 because the expression level of BMPR-II was increased at the site induced muscle regeneration in vivo. In the absence of BMPs, co-transfection of Actr-IIB or BMPR-II with one of mutant ALK2 strongly induced phosphorylation of Smad1/5 and ALP activity in C2C12 cells. Wild-type BMPR-II, but not a kinase activity-deficient BMPR-II, phosphorylated ALK2. That was higher in wild-type ALK2 than that in a typical FOP mutant ALK2. Interestingly, the kinase activity-deficient BMPR-II still stimulated biological activities of some types of FOP mutant ALK2, suggesting that a novel mechanism in addition to phosphorylation is involved in the activation of ALK2 by BMPR-II. Taken together, these results suggest that moderately activated mutant ALK2 are further stimulated by BMP type II receptors in FOP. Inhibitors of BMP type II receptors as well as that of ALK2 may aid in the establishment of novel treatments to prevent heterotopic ossification in FOP.

In Vivo Effect of Bone-Specific EphB4 Overexpression in Mice on Subchondral Bone and Cartilage during Osteoarthritis. Gladys Valverde-Franco*¹, Mohit Kapoor¹, David Hum¹, Koichi Matsuo², Bertrand Lussier³, Jean-Pierre Pelletier¹, Johanne Martel-Pelletier¹. ¹Osteoarthritis Research Unit, University of Montreal Hospital Research Centre (CRCHUM), Canada, ²School of Medicine, Keio University, Japan, ³University of Montreal, Faculty of Veterinary Medicine, Clinical Sciences, Canada

Background: In humans, evidence suggests subchondral bone to be an active component of the osteoarthritis (OA) process. Some members of the ephrin system, including the receptor EphB4 and its specific ligand, ephrin-B2, were found to be involved in bone biology. Recently, our group¹ showed that in vitro ephrin-B2 activation of the EphB4 receptor inhibits the resorptive activity of human OA subchondral bone osteoblasts. We further investigated, in mice, the in vivo effect of bone-specific EphB4 overexpression on OA development.

Methods: Morphological evaluation of the mouse skeleton was performed at postnatal day 5 (P5) with alizarin red/alcan blue staining and, in adults, radiographically. On the OA induced knee, histology (OARSI grading), cartilage collagen meshwork disorganization grading (sirius red staining), and micro-computed tomography scans (microCT) were performed on the medial compartment.

Results: Homozygous conditional type I collagen EphB4 overexpressing mice and wild type (WT) were used. Morphometric analysis and skeletal staining at P5 showed no obvious phenotypic difference in bone development between EphB4 and WT mice. Although 10-week-old WT and EphB4 mice had similar body size and bone length, EphB4 mice demonstrated increased bone density. OA was induced, using the partial medial meniscectomy (DMM) model, in the 10-week-old mice. Eight and 12 weeks after surgery, histology revealed EphB4 mice had significantly less articular alterations than WT in both medial condyle and tibia at 8 (4.90.1 vs. 3.10.4, p<0.008; 3.40.3 vs. 2.10.3, p<0.0009, respectively) and 12 weeks (3.40.3 vs. 2.40.30, p<0.04; 4.50.3 vs. 3.30.4, p<0.04) post-surgery. Evaluation of collagen fibril revealed significantly higher levels of disorganization in WT mice compared with EphB4 mice in the tibia at 8 (2.40.4 vs. 1.10.2, p<0.0007) and 12 weeks (2.30.2 vs. 1.10.1, p<0.0003) post-surgery. In addition, microCT of the medial tibia performed 12 weeks after surgery demonstrated a decrease in sclerotic subchondral bone in EphB4 compared with WT mice.

Conclusion: This study is the first to provide in vivo evidence that bone-specific EphB4 receptor overexpression exerts a protective effect on structural changes that occur in OA articular cartilage and subchondral bone. These data also support the notion that this system could be targeted as a specific therapeutic approach for OA.

Functional Redundancy of GSK-3 α and GSK-3 β to Control Chondrocyte Differentiation through Phosphorylation of RelA/NF- κ B p65. Shozo Itoh^{*1}, Taku Saito², Makoto Hirata³, Masahiro Ushita³, Toshiyuki Ikeda⁴, Kozo Nakamura¹, Ung-Il Chung⁵, Hiroshi Kawaguchi⁶. ¹The University of Tokyo, Japan, ²University of Tokyo, Graduate School of Medicine, Japan, ³University of Tokyo, Japan, ⁴Information Technology Services, Inc., Japan, ⁵University of Tokyo Graduate Schools of Engineering & Medicine, Japan, ⁶University of Tokyo, Faculty of Medicine, Japan

Several principal signals in chondrocytes are mediated by glycogen synthase kinase-3 (GSK-3). Here we examined individual roles of the two mammalian isoforms, GSK-3 α and GSK-3 β , in chondrocyte differentiation and skeletal development. Both isoforms were largely unphosphorylated and active in the early differentiation stages during SOX9, type II collagen (COL2A1), and aggrecan expression in cultured chondrogenic ATDC5 cells and in the mouse limb cartilage. Although *Gsk3a*^{-/-} mice and *Gsk3b*^{+/-} mice showed normal skeletal development, their compound *Gsk3a*^{-/-};*Gsk3b*^{+/-} mice exhibited dwarfism with impairment of early chondrocyte differentiation without affecting the later differentiation or proliferation. Gain- and loss-of-function analyses using cultures of ATDC5 cells and primary chondrocytes from the knockout mice with overexpression of GSK-3 isoforms and their siRNAs revealed that GSK-3 α and GSK-3 β induced early chondrocyte differentiation with functional redundancy in a cell-autonomous fashion. This was independent of the canonical Wnt signaling, since none of the transcriptional activity (TOPflash), protein level, nor subcellular localization of β -catenin was altered by the *Gsk3* genotypes. Instead, computational predictions followed by *SOX9* and *COL2A1* promoter assays identified RelA (NF- κ B p65) as a key phosphorylation target of GSK-3, and further analyses by mutagenesis in the 12 putative phosphorylation sites of RelA revealed that the Thr254-phosphorylation was essential for GSK-3 to induce chondrocyte differentiation. The gain- and loss-of-function analyses above showed that GSK-3 α and GSK-3 β caused the Thr254-phosphorylation in early differentiation stages without affecting the RelA protein level, subcellular localization, I κ B phosphorylation, or IKK level. The Cre-mediated deletion of RelA in the *Rela*tm chondrocyte culture caused suppression of the early differentiation markers, which was restored by the RelA overexpression, but not by the Thr254 mutant or the GSK-3 overexpression. Lastly, we created conditional knockout mice of *Rela* in undifferentiated limb mesenchyme (*Prx1*-Cre;*Rela*tm) and in cartilage (*Col2a1*-Cre;*Rela*tm), and confirmed that both mouse models exhibited dwarfism with impairment of early chondrocyte differentiation, similar to the *Gsk3a*^{-/-};*Gsk3b*^{+/-} mice. In conclusion, the redundant functions of GSK-3 α and GSK-3 β through phosphorylation of RelA at Thr254 play a crucial role in early stages of chondrocyte differentiation.

Runx2 Regulates Axin2 Modulation of Mesenchymal Stem Cell Fate in Cranial Sutures. Meghan McGee-Lawrence^{*1}, Amel Dudakovic¹, David Razidlo¹, Wei Hsu², Jane Lian³, Jennifer Westendorf¹. ¹Mayo Clinic, USA, ²URMC, USA, ³University of Massachusetts Medical School, USA

Runx2 and Axin2 are key regulators of skeletal development. Deletion of either gene causes craniofacial phenotypes in mice: Runx2^{+/-} mice develop cleidocranial dysplasia (CCD), whereas Axin2^{-/-} mice develop craniosynostosis. We discovered that Axin2 and Runx2 molecularly interact in ChIP, EMSA, and transcription assays, suggesting a direct relationship between these two factors in vivo. To determine if Axin2 and Runx2 are components of the same molecular pathway, we crossed Runx2^{+/-} and Axin2^{-/-} mice to generate Axin2^{-/-};Runx2^{+/-} mice. Axin2 deficiency reduced skull length and increased skull width, whereas Runx2^{+/-} mice were normal. Axin2^{-/-};Runx2^{+/-} mice skull dimensions fell between those of the single mutants, suggesting Runx2 is essential for enhanced calvarial bone formation in Axin2^{-/-} mice. Consistent with this hypothesis, bone marrow stromal cells (BMSC) from Axin2^{-/-} mice expressed mature osteoblast markers (e.g., osteocalcin) at high levels, whereas BMSC from Axin2^{-/-};Runx2^{+/-} mice had expression levels similar to wildtypes when cultured under osteogenic conditions.

Surprisingly, Axin2 deficiency did not rescue, but rather exacerbated the CCD phenotype of the Runx2^{+/-} mice as fontanel size increased two-fold in Axin2^{-/-};Runx2^{+/-} as compared to Runx2^{+/-} mice. MicroCT revealed that the endocranial layer of the posterior frontal (PF) suture failed to ossify in the double mutants. We performed mRNA and miR microarrays with calvarial RNA and found genes related to cartilage development (e.g., Aggrecan, Sox9 and miR140) were upregulated in Axin2^{-/-};Runx2^{+/-} mice, whereas genes related to blood vessel morphogenesis (e.g., Slit2) were downregulated. Histomorphometry of the PF suture revealed cartilaginous and fibrous tissues but no calcified bone in the enlarged fontanel of the double mutants.

In conclusion, Axin2 expression modulates mesenchymal stem cell fate. In the endocranial layer of the PF suture, decreasing Axin2 expression triggers formation of cartilage that is subsequently vascularized and ossified. Axin2^{-/-} mice rapidly close the PF suture due to enhanced Wnt signaling that accelerates endochondral ossification. Our data suggest that Runx2 regulates this process, since Runx2 haploinsufficiency on

the Axin2^{-/-} background increased chondrogenesis but decreased ossification in the PF suture. Downregulation of blood vessel gene expression likely reflects impaired vascularization of this cartilage, leading to defective calvarial ossification.

PTHrP Regulates the Modeling of Cortical Bone and Ligament and Tendon Insertion Sites During Linear Growth. Joshua VanHouten^{*1}, Randy L. Johnson², Guoying Liang³, Arthur Broadus¹. ¹Yale University School of Medicine, USA, ²M.D. Anderson Cancer Center, USA, ³Yale University, USA

PTHrP is widely expressed in the fibrous periosteum (PO) and in tendon and ligament insertion sites (entheses). In most such sites, PTHrP is mechanically-induced and is temporally associated with subadjacent osteoclast (OC) and/or osteoblast (Ob) populations. We tested here the working hypothesis that PTHrP might regulate the modeling of cortical bone and/or entheses by conditionally deleting PTHrP using scleraxis sequences (Scx-Cre); Scx is a bHLH transcription factor that is expressed in the fascia and connective tissues that bind bone and muscle together and to each other. A PTHrP-lacZ null allele enabled lacZ to speak for PTHrP gene expression in both KO and CT mice.

The Scx-KO mice display two types of abnormalities, one involving entheses and the other cortical size and shape. Of the enthesis abnormalities, the medial collateral ligament (MCL) insertion is particularly informative. The MCL inserts into the proximal tibial metaphysis below the growth plate, so that it must migrate during linear growth. PTHrP is load-driven and highly expressed at this site, and the migration is mediated by OCs at the migrating edge and Obs at the trailing edge. In the Scx-KO mice, these bone cell populations do not form, migration fails, and the MCL site is converted into a massive traction tuberosity that distorts the entire proximal tibia. Similar traction abnormalities are seen at the origins or insertions of the lateral triceps, pronator teres, and tibialis posterior, all muscles that are heavily engaged in the mouse because it walks on pronated and flexed limbs. Each of these sites is concordant as regards lacZ expression in PTHrP-lacZ and Scx-Cre/R26R mice.

All adult Scx-KO long bones are foreshortened (e.g., KO vs CT humeri 11.7 0.3 vs 10.4 0.4 mm, n=7, M SD, p<0.001). The bones are also squat, with an increase in moment of inertia (KO vs CT humeri 0.29 0.02 vs 0.23 0.01 mm⁴, M SEM, n=3, <0.05) but normal cortical thickness (0.22 0.01 vs 0.21 0.01, pNS). The PO in the metaphyses of some of these bones are concordant as regards lacZ expression in PTHrP-lacZ and Scx-Cre/R26R mice, suggesting that PTHrP regulation of cortical modeling may be responsible for this phenotype.

These data provide the first genetic evidence that PTHrP regulates the formation and function of membranous bone cell populations at the surface of long bones. These functions reflect the use of PTHrP as a tool by which mechanical forces sculpt cortical bone.

Deficiency of EED, a Critical Component of the Polycomb Repressor Complex 2, Causes Cell Death Due to Competitive Inhibition of HIF1 α by aryl Hydrocarbon Receptor in Chondrocytes. Erinn Rankin¹, Jennifer Inloes², Huafeng Xie³, Stuart Orkin³, Ernestina Schipani⁴, Tatsuya Kobayashi^{*2}. ¹MGH, USA, ²Massachusetts General Hospital, USA, ³Children's Hospital Boston & Dana-Farber Cancer Institute, USA, ⁴Indiana University School of Medicine, USA

Chromatin structure, regulated largely through histone tail modifications, controls gene expression by changing accessibility of transcription factors. This mechanism ensures robustness of gene expression patterns and cells' phenotypes. Polycomb repressive complex 2 (PRC2), whose core components include EZH1/2, EED and SUZ12, catalyzes tri-methylation of lysine 27 of histone 3 (H3K27me3) and silences chromatin. PRC2 binds to and regulates genomic loci containing key differentiation-related genes in ES cells and plays an essential role in ES cell pluripotency. However, the physiological role of PRC2 in somatic cells, let alone skeletal cells, remains unclear. To investigate the role of PRC2 in mouse skeletal development, we ablated the EED gene in chondrocytes. EED conditional knockout (cKO) mice were born and survived postnatally, but developed growth retardation and kyphosis, and the mice usually died before weaning. EED cKO growth plates showed a dramatic decrease in cell proliferation and increase in cell death, reminiscent of growth plates missing hypoxia-inducible factor 1 alpha (HIF1A), but showed normal cell differentiation patterns. We found that HIF-inducible genes, including *Pgk1* and *Bnip3* were downregulated in EED cKO chondrocytes. We found that HIF-inducible genes, including *Pgk1* and *Bnip3*, were downregulated in EED cKO chondrocytes. Downregulation of HIF1 activity was confirmed in primary chondrocytes using a reporter assay. In addition to known PRC2 target-genes including *Bmp4* and *Left1*, we found upregulation of aryl hydrocarbon receptor (AHR) in EED cKO chondrocytes. We found increased expression in EED cKO chondrocytes of AHR target genes, including *Cyp1b1*. Upregulation of AHR activity in EED cKO chondrocytes was confirmed using an AHR reporter assay. The aryl hydrocarbon receptor nuclear translocator, ARNT, binds both HIF's and AHR. Chromatin immunoprecipitation revealed increased ARNT binding to the *Cyp1b1* promoter and decreased binding to

HIF target genes, suggesting that HIF activity was, at least in part, competitively inhibited in EED cKO chondrocytes by AHR. The AHR gene was not associated with H3K27me3, and therefore the upregulation of AHR is likely an indirect consequence of deregulated gene expression caused by the loss of PRC2 function. These results demonstrate the critical role of PRC2 function in chondrocyte proliferation and survival, and provide evidence for the reciprocal regulation of HIF's and AHR *in vivo*.

The Transcription Factor Arid5B Is a Novel Partner of Sox9 in Endochondral Bone Formation. Rikako Takashima^{*1}, Kenji Hata¹, Makoto Wakabayashi¹, Masako Nakanishi¹, Koichiro Ono¹, Katsuhiko Amano¹, Robert Whitson², Yoshinobu Maeda¹, Riko Nishimura¹, Toshiyuki Yoneda¹. ¹Osaka University Graduate School of Dentistry, Japan, ²Beckman Research Institute of City of Hope, USA

The transcription factor Sox9 plays an essential role in chondrocyte differentiation. Mutations of Sox9 gene in human cause severe chondrodysplasia and chondrocyte specific Sox9-deficient mice exhibited profound skeletal malformations. Furthermore, Sox9 overexpression in the pluripotent mesenchymal C3H10T1/2 cells up-regulates chondrocyte phenotypic genes including Col2a1. However, introduction of Sox9 in some mesenchymal cells such as NIH3T3 cells failed to induce chondrogenesis, suggesting that C3H10T1/2 cells express a transcription factor (s) which is required for Sox9-dependent chondrogenesis. Based on this hypothesis, Solexa sequencing was performed to compare gene expression profiles between C3H10T1/2 and NIH3T3. As a result we found the transcription factor Arid5b (AT-rich interactive domain 5b) is highly expressed in C3H10T1/2 cells. Whole mount *in situ* hybridization demonstrated a discernible expression of Arid5b mRNA in the developing limbs where Col2a1 and Sox9 were specifically localized. More importantly, Arid5b deficient mice (Arid5b^{-/-}) showed pronounced growth retardation at birth and postnatal stage. Arid5b^{-/-} mice also exhibited shortened limbs with decreased width of proliferating chondrocytes. These data suggest that Arid5b is critical for chondrogenesis.

We next further verified the functional role of Arid5b in chondrocyte differentiation. Overexpression of Arid5b in C3H10T1/2 cells using adenovirus system enhanced Sox9-induced Col2a1 mRNA expression, although Arid5b had no effect on Sox9 expression. Of interest, transcriptional activity of Sox9 on Col2a1 gene promoter activity was markedly up-regulated by Arid5b. Pull-down and two-hybrid analyses showed that Arid5b physically associated with Sox9. Direct binding of Arid5b to the AT-rich motif (CATAT) present in the Col2a1 gene promoter was shown by DNAP and ChIP experiments and the mutation of this element caused the reduction of Sox9-induced Col2a1 promoter activity. Moreover, overexpression of dominant-negative mutant (DN) Arid5b inhibited BMP2-induced chondrocyte differentiation of mouse embryo limb bud cells. Consistently, DN-Arid5b transgenic mice driven by the Prx-1 gene promoter showed delayed endochondral ossification and reduced Col2a1 mRNA expression. In conclusion, our results suggest that Arid5b promotes chondrocyte differentiation as a transcriptional partner of Sox9 and provide further insights into the molecular mechanism by which Sox9 regulates chondrogenesis.

Disclosures: Rikako Takashima, None.

Direct Role of Nkx3.2 to Promote the Primary Chondrocytic Differentiation. Yoshitaka Kawato^{*1}, Makoto Hirao², Kosuke Ebina¹, Hiroki Oze¹, Shoichi Kaneshiro¹, Kenrin Shi¹, Akira Myoui³, Hideki Yoshikawa¹, Jun Hashimoto⁴. ¹Osaka University Graduate School of Medicine, Japan, ²Department of Orthopaedics, National Hospital Organization Osaka Minami Medical Center, Japan, ³Osaka University Hospital, Japan, ⁴Center of Immune Diseases, National Hospital Organization Osaka Minami Medical Center, Japan

Nkx3.2 is known to be a novel transcriptional factor to repress Runx2 function, leading to down-regulation of hypertrophy of chondrocyte. Spondylo-megaepiphyseal-metaphyseal dysplasia (SMMD) is a skeletal dysplasia, which shows metaphyseal dysplasia, markedly defective ossification of vertebral body centres, and enlarged epiphyses. SMMD is caused by homozygous inactivating mutations in the NKX3.2. The phenotypes observed in SMMD patients are very similar to that of Nkx3.2 knockout mice. On the other hand, it is also pointed out that Nkx3.2 has a tight relationship with Sox9 in a positive regulatory system initiated by Shh. Then, we hypothesized that Nkx3.2 might have a direct and positive role for primary chondrocytic differentiation. C3H10T1/2 cells were cultured with 300ng/mL of BMP2 to induce endochondral ossification. Overexpression of WT-Nkx3.2 up-regulated the expression of chondrogenic marker genes, such as Col2a1, Aggrecan, Comp, Col11a2, Col10a1, and Sox9, furthermore glycosaminoglycan (GAG) production was also promoted. On the other hand, down-regulation of Nkx3.2 using RNAi system strongly inhibited these genes expression and GAG production. Interestingly, Nkx3.2 affected on such chondrogenic events before the effect on Sox9 gene expression was observed. This phenomenon led us to consider that Nkx3.2 might also have a direct role to promote early chondrocytic differentiation independently of Sox9. To elucidate this hypothesis, we checked whether Nkx3.2 binds to the enhancer

elements of chondrogenic marker genes, Col2a1, Aggrecan, and Col11a2, using luciferase reporter assay and ChIP assay. WT-Nkx3.2 up-regulated the activity of 48bp-Col2a1 enhancer element about 10 fold compared to MOCK both in C3H10T1/2 and N1511 cells. And the activity was clearly stimulated in a dose dependent manner. ChIP assay revealed that Nkx3.2 directly binds to Col2a1, Aggrecan, and Col11a2 enhancer elements. Taken together, it is suggested that Nkx3.2 also has a direct role to promote early chondrocytic differentiation.

Disclosures: Yoshitaka Kawato, None.

OC-STAMP and DC-STAMP are both essential for cell-cell fusion in osteoclasts and foreign body giant cells. Kazuhiro Chiba¹, Hiroya Miyamoto^{*2}, Takeshi Miyamoto³, Yoshiaki Toyama¹, Hideo Morioka¹. ¹Department of Orthopedics, University of Keio, Japan, ²University of Keio, Japan, ³Keio University School of Medicine, Japan

Osteoclasts are unique cells to resorb bone and play a role in regulating bone homeostasis. Osteoclast multi-nucleation by cell-cell fusion plays a role in regulating osteoclast resorbing activity and physiological bone mass, and that we tried to clarify the molecular mechanism of osteoclast cell-cell fusion. We identified osteoclast stimulatory transmembrane protein (OC-STAMP) by a subtractive microarray screen between M-CSF induced mono-nuclear macrophages and M-CSF plus RANKL induced multi-nuclear osteoclasts. We generated OC-STAMP-deficient (KO) mice and found that osteoclasts cell-cell fusion was completely abrogated in OC-STAMP KO mice. OC-STAMP KO mono-nuclear osteoclasts demonstrated normal expression of TRAP, NFATc1 and CathepsinK, indicating that OC-STAMP is specifically required for cell-cell fusion rather than differentiation of osteoclasts. Foreign body giant cells (FBGCs) are also multi-nuclear macrophages induced by cell-cell fusion of mono-nuclear cells. FBGCs are formed in response to foreign body reaction at the site of implantation, and are reportedly cause a loosening of implanted materials. OC-STAMP KO mice also completely failed to form multi-nuclear FBGCs. Thus, OC-STAMP is also essential for cell-cell fusion in FBGCs. OC-STAMP expression in osteoclasts depended on NFATc1 in the presence of M-CSF plus RANKL. While, in FBGCs, OC-STAMP expression was regulated by STAT6 under IL4 signal. DC-STAMP is required for cell-cell fusion in osteoclasts and FBGCs, and DC-STAMP KO mice also exhibited complete abrogation of cell-cell fusion in both cells. The expression of DC-STAMP in OC-STAMP-KO cells, and OC-STAMP expression in DC-STAMP-KO cells were both comparable to WT osteoclasts and FBGCs, suggesting that OC-STAMP and DC-STAMP are both required for cell-cell fusion of macrophage lineage cells. We also generated OC-STAMP-Tg mouse, in which OC-STAMP expression is driven under an actin promoter, and crossed with OC-STAMP-KO mouse to generate OC-STAMP-KO/Tg mouse. OC-STAMP over-expression in OC-STAMP-KO mice restored the inhibited cell-cell fusion in osteoclasts and FBGCs. OC-STAMP KO mono-nuclear osteoclasts showed significant reduction of bone resorbing activity, and OC-STAMP KO mice exhibited increased bone mass. Thus our data inform a molecular understanding of cell-cell fusion in osteoclasts and FBGCs, and thus OC-STAMP can be a therapeutic target for osteoporosis and implant failure.

Notch-RBP-J Signaling Predominantly Suppresses TNF- α Induced Osteoclastogenesis and Inflammatory Bone Resorption. Baohong Zhao^{*1}, Shannon Grimes², Xiaoyu Hu¹, Lionel Ivashkin¹. ¹Hospital for Special Surgery, USA, ²Hospital for Special Surgery, USA

TNF- α plays a key role in the pathogenesis of inflammatory osteoclastogenesis and bone resorption. Mechanisms that regulate the direct osteoclastogenic properties of TNF- α to limit pathological inflammatory bone resorption are mostly unknown. In this study, we found that deletion of RBP-J, the master transcription factor in Notch signaling, in bone marrow macrophages resulted in dramatic induction of osteoclastogenesis by TNF- α in the absence of exogenous RANKL. TNF- α -induced mouse osteoclasts derived from RBP-J deficient cells formed actin rings and resorbed dentin slices *in vitro*. Similar results were obtained using TNF- α -treated human osteoclast precursors in which RBP-J expression was knocked down using RNA interference. RBP-J deficiency had a much milder augmenting effect on RANKL-induced osteoclastogenesis. Mechanistically, RBP-J deficiency resulted in dramatically increased TNF- α -induced NFATc1 expression and RNA Pol II occupancy at the NFATc1 gene locus. RBP-J suppressed NFATc1 induction by attenuating c-Fos activation and suppressing induction of Blimp1, thereby preventing downregulation of transcriptional repressor IRF-8 that blocks osteoclast differentiation. Mice with a myeloid-specific deletion of RBP-J (*Rbpj^{fl/fl}LysMcre*) did not exhibit a bone phenotype under physiological conditions. However, *Rbpj^{fl/fl}LysMcre* mice showed dramatically increased osteoclast formation, severe bone destruction and increased serum TRAP levels relative to littermate controls in a TNF- α -induced model of inflammatory bone resorption. Strikingly, further deletion of RBP-J in myeloid compartment in *Rank^{-/-}* mice (*Rank^{-/-};Rbpj^{fl/fl}LysMcre* mice) enabled TNF- α to effectively induce osteoclast formation and bone resorption *in vivo*, indicating that RBP-J deficiency allowed TNF- α -induced osteoclastogenesis and bone resorption to proceed independently of RANKL. Importantly, a gain of function approach to activate RBP-J in mice with

myeloid-specific constitutive expression of Notch intracellular domain NICD1 (*Rosa^{Notch1}+/+*; *LysMcre*) significantly prevented inflammatory arthritic bone resorption in an antibody-induced arthritis model. These findings identify a key role for Notch-RBP-J signaling in restraining inflammatory TNF- α -induced osteoclastogenesis and bone resorption and provide mechanisms by which RBP-J suppresses NFATc1 induction. Notch-RBP-J signaling plays a more prominent role in inhibiting osteoclastogenesis in inflammatory settings than under physiological conditions.

Dual Specificity Phosphatase 1 Limits Inflammatory Osteolysis. Youridies Vattakuzhi^{*1}, Sonya Abraham², Adel Ersek², Dany P. B. Perocheau², Richard O. Williams², Andy R. Clark², Nicole Horwood². ¹Kennedy Institute of Rheumatology/Imperial College, GBR, ²Kennedy Institute of Rheumatology, United Kingdom

Dual specificity phosphatase 1 (DUSP1) dephosphorylates and inactivates p38 mitogen-activated protein kinase (MAPK). It is upregulated by various pro-inflammatory stimuli and is essential for constraining p38 MAPK signalling and expression of p38-dependent genes such as tumor necrosis factor α (TNF α). p38 MAPK plays a central role in both differentiation and activation of osteoclasts (OCL). TNF α , a potent activator of p38 MAPK, is known to activate OCL, causing bone resorption in inflammatory diseases like rheumatoid arthritis. The aim of this study was to investigate whether DUSP1 may function as a negative regulator of inflammatory osteolysis.

Bone marrow cells of *Dusp1*^{+/+} and *Dusp1*^{-/-} mice were harvested for *in vitro* OCL assays. OCL formation and activity were analysed by evaluating tartrate resistant acid phosphatase (TRAP) staining and by measuring the resorption area on dentine. Expression of DUSP1 was measured in mouse bone marrow derived OCL precursors after RANKL (receptor activator of nuclear factor κ B ligand) stimulation. RANKL induced DUSP1 gene expression, and *in vitro* differentiation and activation of OCL were enhanced in the absence of DUSP1. This enhanced activation was particularly striking in the presence of low concentrations of TNF α and RANKL.

Dusp1^{+/+} and *Dusp1*^{-/-} mice were immunized with type II chicken collagen to induce chronic arthritis. Development of disease and bone resorption of the affected paws were assessed by histological examination, TRAP staining and micro-CT analysis. Compared to *Dusp1*^{+/+} mice, *Dusp1*^{-/-} mice showed earlier development and more severe disease, characterised by increased numbers of OCL and bone loss in affected joints.

These observations demonstrate that DUSP1 plays an important role in limiting OCL differentiation and activation by regulating the p38 MAPK pathway in OCLs under inflammatory conditions both *in vitro* and in an *in vivo* model of chronic arthritis.

Further highlighting the role of DUSP1 in OCL activation we observed that a *Dusp1*^{-/-} mouse strain with mixed (129Sv and C57BL/6) genetic background developed spontaneous inflammation of their toes, with neutrophilic infiltration, fibrosis, and dramatic osteolytic destruction of distal phalanges.

We speculate that DUSP1 negatively regulates OCL activation in humans, and that variations in its expression or function may play a role in diseases characterised by inflammatory osteolysis.

Deletion of β -catenin in Osteoclast Precursors and their Progeny Increases Osteoclastogenesis and Induces Cortical Bone Loss. Marta Martin Millan^{*1}, Maria Carmen Gonzalez-Martín², Shoshana Bartel³, Maria Jose Almeida³, Marian Ros⁴, Jesus Gonzalez MacUas⁵. ¹Instituto de Formacion e Investigacion Marques Valdecilla, Esp, ²Instituto de Biomedicina y Biotecnología de Cantabria, Spain, ³University of Arkansas for Medical Sciences, USA, ⁴Instituto de Biomedicina y Biotecnología de Cantabria, Spain, ⁵Instituto de Formacion e Investigacion Marques Valdecilla, University of Cantabria, Spain

It is well established that activation of Wnt/ β -catenin in cells of the osteoblast lineage leads to an increase in bone mass through a dual mechanism: Increased osteoblastogenesis and decreased osteoclastogenesis. It remains unclear, however, whether a cell autonomous effect of β -catenin on osteoclasts is involved in bone mass regulation. To this end, we first examined *in vitro* the effects of Wnt3a recombinant protein on bone marrow (BM)-derived osteoclasts. Wnt3a increased the protein levels of β -catenin and induced osteoclast apoptosis, as assayed by caspase 3 activity. Moreover, Wnt3a attenuated M-CSF and RANKL-induced osteoclast formation, as determined by enumeration of TRAP positive cells. The Wnt3a-induced increase in β -catenin levels, as well as the pro-apoptotic effect on osteoclasts was abrogated by DKK1, indicating that the canonical Wnt signaling is required for the pro-apoptotic effect of Wnt3a. To examine the role of β -catenin on osteoclasts *in vivo*, we generated mice in which β -catenin was selectively deleted from cells of the monocyte/macrophage lineage. To this end β -catenin-floxed mice (*Catnb*^{fl/fl}) were crossed with the *LysM*:Cre deleter line (hereafter Δ Catnb;*LysM*). Δ Catnb;*LysM* mice were born at the expected Mendelian ratios and had the same body weight than their littermate

controls. β -catenin mRNA level in macrophages and osteoclasts from Δ Catnb;*LysM* mice was 70% decreased as compared to the *Catnb*^{fl/fl} controls as measured by RT-PCR. To determine the effect of the deletion on osteoclastogenesis, triplicate BM cultures from each of 3 animals per genotype were established in the presence of RANKL and M-CSF. After 5 days TRAP positive cells with 3 or more nuclei were counted. The number of osteoclasts in cultures from the Δ Catnb;*LysM* mice was 2-fold higher than in control mice (426 \pm 18 per well versus 238 \pm 77, $p=0.015$). In line with these findings, both Δ Catnb;*LysM* female and male mice exhibited a significant decrease in femoral cortical thickness as determined by micro-CT at 28 weeks of age (0.20 \pm 0.003 versus 0.215 \pm 0.004, $p=0.03$; 0.19 \pm 0.004 versus 0.20 \pm 0.005, $p=0.01$, respectively), while vertebral trabecular bone was not affected. These results provide compelling evidence for a cell-autonomous effect of β -catenin in osteoclasts, and indicate that osteoclast β -catenin contributes to the protective effect of the canonical Wnt signaling in cortical, but not in trabecular bone.

Osteoclast-Dependent Canalicular Formation in Cortical Bone That Mediates Bone Remodeling. Nobuhito Nango^{*1}, Shogo Kubota¹, Wataru Yashiro², Atsushi Momose², Yasunari Takada³, Koichi Matsuo³. ¹Ratoc System Engineering Co., Ltd., Japan, ²Department of Advanced Materials Sciences, School of Frontier Sciences, The University of Tokyo, Japan, ³School of Medicine, Keio University, Japan

Bone remodeling occurs through osteoclastic bone resorption and osteoblastic bone formation. In addition, osteocytes presumably contribute to rapid increases and decreases in skeletal calcium levels. However, the detailed structural basis for cortical bone remodeling remains unclear. Last year, we presented the first model showing canalicular structure in cortical bone based on X-ray microscopic tomography using the Japanese synchrotron radiation facility SPring-8. We now examine a potential link between mineral metabolism and fine structures within cortical bone in relation to osteoclasts. Here, we compared cortical bones of wild-type versus Fos KO mice, which show impaired formation of the bone marrow cavity and lack osteoclasts. For comparisons, we cut 300 μ m-wide columnar cortical bone specimens bound by the endosteal and periosteal surfaces from the tibia of wild-type and mutant mice at postnatal weeks 4, 16, and 28. Using the synchrotron X-ray microscope, we scanned specimens with a spatial resolution of 0.2 μ m using a multi-scan method consisting of differential phase contrast and defocus contrast. From the former, we acquired gray-scale images revealing the degree of calcification, while defocus contrast analysis revealed fine structures inside cortical bone such as lacunae, canaliculi, and canal structures. The degree of calcification surrounding fine structures was measured under high resolution and sensitivity. In wild-type mice, a canalicular network was observed between lacunae as well as between lacunae and bone canals, and the degree of calcification was altered along canaliculi indicative of bone remodeling activity. Analysis of Fos KO mice revealed that the shell matrix of hypertrophic chondrocytes was highly calcified and trabecular bone did not form in the diaphysis. Interestingly, in Fos mutant mice, while a canal network passing through the cartilage shell was developed, canaliculi between lacunae in cortical bone formed at significantly lower levels compared to controls. From these observations, we postulate that canaliculi in cortical bone form the basis of mineral metabolism and that osteoclasts are essential for formation of canalicular structures in cortical bone.

Selective Deletion of the Receptor for CSF1, c-fms, in Mature Osteoclasts Results in a High Bone Mass Phenotype In Vivo but a Normal Response to an Anabolic PTH Regimen. Meiling Zhu^{*1}, Ben-hua Sun¹, Karl Insogna².¹Yale University, USA, ²Yale University School of Medicine, USA

The receptor for Colony Stimulating Factor 1 (CSF1), c-fms, is highly expressed on mature osteoclasts. While CSF1 is known to be required for normal osteoclastogenesis, the expression of its receptor on mature cells suggests a role for this cytokine in regulating the function of these cells. Consistent with this idea, CSF1 stimulates cytoskeletal remodeling and motility, augments the activity of the electroneutral $\text{Na}^+/\text{HCO}_3^-$ co-transporter, NBCn1 and induces c-fos gene transcription in mature osteoclasts. To better define the role of CSF1 in mature osteoclasts, we conditionally deleted c-fms in these cells (c-fms-OC^{-/-}) by crossing c-fms^{lox/lox} mice with mice expressing Cre under the control of the cathepsin K promoter. The c-fms-OC^{-/-} mice were of normal weight and had normal tooth eruption. However, BMD was significantly higher as assessed by DXA: +15% in the spine, +18% in the femur and +10% for total body ($p < 0.001$ for each site). MicroCT analysis of femurs showed that the c-fms-OC^{-/-} mice had significantly increased trabecular bone mass, BV/TV + 80% ($p = 0.02$), Conn-Density + 76% ($p = 0.003$) and Tb.N + 48% ($p = 0.002$). There was a concomitant 30% reduction in Tb.Sp ($p = 0.003$). Histomorphometric analysis of the femoral trabecular bone compartment demonstrated a trend toward increased numbers of osteoclasts, +26% in Noc/BPm and +22% in OcS/BS in the k/o animals. There was a trend toward reduced numbers of osteoblasts, -25% in Obs/BS and -24% in Nob/BPm. None of these cellular changes were significant. Typically, mature osteoclasts show a marked spreading response when exposed to CSF1 in a non-gradient fashion. However, osteoclasts freshly isolated from c-fms-OC^{-/-} mice had a near complete abrogation of this response, with a mean increase in cell area of only 143% as compared to 569% in wild-type cells ($p < 0.0001$). Interestingly, co-culturing osteoblasts and bone marrow cells isolated from c-fms-OC^{-/-} in the presence of prostaglandin E2 and 1,25-dihydroxyvitamin D₃ failed to result in osteoclast-like cell (OCL) formation while abundant numbers of OCLs were generated when the experiment was repeated using wild type cells. C-fms-OC^{-/-} mice treated with (1-34) hPTH 80 ng/kg/d for 30 days showed similar increases in BMD as did wild type animals treated in the same way. Taken together, these data indicate an important non-redundant role for c-fms in regulating mature osteoclast function in vivo.

Three Monthly, Oral 150,000 IU Cholecalciferol Supplementation Effects On Falls, Mobility and Muscle Strength in Older Postmenopausal Women. Paul Glendenning^{*1}, K Zhu², Peter Howat³, Charles Inderjeeth⁴, Joshua Lewis⁵, Richard Prince⁶. ¹Royal Perth Hospital, Australia, ²School of Medicine & Pharmacology, Australia, ³CBRCC, Curtin University, Australia, ⁴University of Western Australia, Australia, ⁵The University of Western Australia, Australia, ⁶Sir Charles Gairdner Hospital, Australia

Calcium and vitamin D supplementation has been shown to reduce falls and fractures in elderly women. Because of adherence problems we trialed the effects of supervised 3 monthly vitamin D administration.

686 women over 70 years of age were recruited at random from the ambulant population to receive either vitamin D3 150,000 IU po every 3 months (n=353) or an identical placebo (n=333) for nine months. All participants were advised to increase calcium intake by dietary means. Falls data were collected using a validated diary every 3 months, muscle strength was measured by hand held dynamometer and a subset of 40 (20 per group) patients had 25OHD measured at baseline and 3 monthly intervals after dosing.

Mean age was 76.7 ± 4.1 years. Calcium intake at baseline and 9 months was 864 ± 412 and 855 ± 357 mg/day, respectively. Hand held dynamometer strength at baseline was similar in the two groups (vitamin D 19.9 ± 4.9, placebo 19.9 ± 5.2 kg). The average serum 25(OH)D value at baseline in the 40 randomly selected subjects was 65.8 ± 22.7 nmol/L. With supplementation, the 25(OH)D levels of the vitamin D group were approximately 15 nmol/L higher than the placebo group after 3, 6 and 9 months.

Falls rates in the vitamin D group were 102/353 (31%/9mths) and in the placebo group were 89/333 (27%/9mths) OR 1.112 (95% CI 0.789, 1.567). There was no effect of vitamin D compared to placebo on muscle strength at 9 months. The study had a power of 0.8 to detect a 30% reduction in falls rate.

Oral cholecalciferol 150,000 IU every 3 months has neither beneficial nor adverse effects on falls or grip strength in elderly female subjects despite significant increases in 25OHD. Possible reasons include dosage chosen, frequency of vitamin D replacement or lack of calcium supplementation. Based on previous studies suggesting a benefit of daily calciferol therapy on falls risk reduction, daily supplementation may be desirable (despite adherence concerns) instead of less frequent, higher dose therapy as the latter does not demonstrate the same benefit on falls risk reduction.

Sclerostin Mediates the Skeletal Effects of Weight Loss and Exercise Therapy In Obese Older Adults. Reina Armamento-Villareal^{*1}, Corinn Sadler¹, Suresh Chode², Nicola Napoli³, Clifford Qualls¹, Krupa Shah⁴, David Sinacore⁵, Dennis Villareal¹. ¹University of New Mexico School of Medicine, USA, ²St. Mary's Hospital, USA, ³University Campus Biomedico, Italy, ⁴University of Rochester School of Medicine, USA, ⁵Washington University in St. Louis, USA

Purpose: The loss of mechanical stress on the skeleton from unloading is believed to result in bone loss in patients undergoing weight loss (WL) therapy. However, the primary mediator for bone loss and the osteoprotective effect of exercise (EX) is unknown. Sclerostin (SCL), a protein produced by osteocytes that inhibits bone formation, is increased with skeletal unloading, while loading inhibits SCL production. We hypothesize that the effect of WL and EX on the skeleton is modulated by changes in SCL levels. We also hypothesize that bone loss leads to deterioration in hip geometry (i.e. femoral strength) which is prevented by EX. The objective of this study is to examine the changes in SCL levels and hip geometry parameters in obese older adults undergoing WL, EX and WL+EX.

Methods: 107 obese (BMI>30), older (age ≥ 65) adults were randomized into 4 treatment groups for 1 yr: control (CTRL) (n=27), WL (n=26), EX (n=26) and WL+EX (n=28). WL was achieved by dietary/behavioral intervention designed to induce a WL of 10% of body weight. EX intervention consisted of supervised resistance/aerobic exercise sessions 3x/wk. CTRL was instructed to continue usual dietary and activity habits. Measurements of SCL and bone turnover markers were performed by ELISA at baseline, 6 and 12 mos; BMD by DXA at baseline, 6 and 12 months; and hip geometry parameters were obtained from DXA imaging at baseline and 12 mos using hip structure analysis (HSA) software.

Results: BMD data were reported elsewhere (NEJM 2011). SCL levels significantly increased ($p < 0.05$) in WL at 6 (6.0%) and 12 mos (8.7%), while the CTRL, EX and WL+EX had no change in SCL levels (Fig. 1). Changes in SCL correlated with the changes in hip BMD and in bone turnover markers (C-telopeptide and osteocalcin) (all $p < 0.05$). HSA showed negative effects of WL on hip geometry, i.e. decreased cross-sectional area of the femoral narrow neck (NN) and femoral shaft (FS), decreased section modulus in the NN and increased buckling ratio in the FS. Aside from a significant increase in FS cortical thickness in EX, there were no significant changes in any of these parameters in the other treatment groups.

Conclusion: SCL may mediate bone loss in obese older adults undergoing voluntary WL. Furthermore, hip geometry appears to be adversely affected by WL. However, the addition of EX to WL program prevented the negative effects of WL on the increase in SCL and the deterioration in measures of femoral strength.

Changes in sclerostin with weight loss

Multi-Phenotype Genome-Wide Association Meta-Analysis on both Lean Body Mass and BMD Identified Novel Pleiotropic Genes that Affected Skeletal Muscle and Bone Metabolism in European Descent Caucasian Populations. Yi-Hsiang Hsu¹, Xing Chen², Carola Zillikens³, Karol Estrada⁴, Serkalem Demissie⁵, Ching-Ti Liu⁶, Yanhua Zhou⁷, David Karasik⁸, Joanne Murabito⁹, Andre Uitterlinden¹⁰, L. Adrienne Cupples⁵, Fernando Rivadeneira⁴, Douglas Kiel⁸. ¹Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ²Harvard University, USA, ³Erasmus University Medical Center, Netherlands, ⁴Erasmus University Medical Center, The Netherlands, ⁵Dept. Biostatistics, Boston University, School of Public Health, USA, ⁶Boston University School of Public Health, USA, ⁷Boston University, USA, ⁸Hebrew SeniorLife, USA, ⁹Boston University Medical School, USA, ¹⁰Rm Ee 575, Genetic Laboratory, The Netherlands

The positive relation between muscle mass and bone mass in adults has been well established and that may be due to the physical loading of muscle on bone as well as hormone, lifestyle, dietary and genetic factors. Previously, we have demonstrated significantly genetic correlations between lean mass (whole body and appendicular) and BMD in the Framingham Study, which indicates that shared genetic determinants may regulate both muscle and bone. To identify pleiotropic genes that associated with both lean mass and BMD traits, we performed a multiple-phenotypes genome-wide association analysis (GWAS) in the Framingham Study by modeling both lean mass and BMD phenotypes simultaneously using our newly developed multivariate analytical approach, directly linear-combined test statistics (DC). BMD (at the lumbar spine and femoral neck) and lean mass (whole body and appendicular) was measured by DXA. Multivariate GWAS analysis was performed on ~2.5 millions imputed SNPs (based on HapMap CEU phase II panel) in 4,524 Framingham participants (1,984 Men and 2,542 women with mean age of 62 years old). An additive genetic effect model was applied with adjustment for age, sex, height, fat mass, ancestral genetic background and pedigree structure. SNPs with multivariate p-values less than 10^{-3} and less than univariate p-values from both lean mass and BMD traits were selected for replication. The replication was performed using the DC multivariate analysis approach by combining test statistics from univariate GWAS meta-analysis on lean mass in CHARGE consortium (n=33,824 men and women) and on BMD in GEFOS (n=32,000 men and women) consortium. SNPs with multivariate p-values $\leq 5 \times 10^{-8}$ were considered as genome-wide significance. Only SNPs with multivariate p-values significantly less than univariate p-values were considered as potential pleiotropic genetic effects. Several potential pleiotropic loci were replicated and achieved genome-wide significance with multivariate association p-values $< 5 \times 10^{-8}$, i.e. SNPs in or near *SAPL*, *GAL* (near *LRP5* gene), *TNRC6B*, *WNT2B* and *GRB10* genes. Several suggestive loci ($p < 5 \times 10^{-6}$) were also found, i.e. *RSP03/C6orf173* region, *ST7L*, *MTHFSD*, *RUNX1*, *LEPR* and *ADAMTSL3* genes. These top associated SNPs are being further evaluated in gene expression analysis of human bone and muscle tissues. In conclusion, our results reveal novel pleiotropic genes to further elucidate the link between the skeletal muscle and bone metabolism.

Effects of High Velocity Power and Functional Training on BMD and Physical Function in High Risk Older Adults: A 12-month Randomised Controlled Trial. Jenny Gianoudis¹, Christine Bailey², Peter Ebeling², Caryl Nowson³, Kerrie Sanders⁴, Keith Hill⁵, Robin Daly^{3*}. ¹Department of Medicine, The University of Melbourne, Australia, ²The University of Melbourne, Australia, ³Centre for Physical Activity & Nutrition Research, Deakin University, Australia, ⁴University of Melbourne, Australia, ⁵School of Physiotherapy, La Trobe University, Australia

Multi-component exercise programs are recommended for preventing osteoporosis and falls, but few studies have evaluated their effectiveness in high risk older adults in a 'real world' community setting. In addition, most programs have used traditional slow speed progressive resistance training (PRT) coupled with weight-bearing and/or balance activities. However, emerging data suggests that muscle power (ability to produce force rapidly) is a more crucial variable to functional decline than strength. The aim of this community-based RCT was to investigate the effects of a multi-component high speed exercise program coupled with an osteoporosis education and behavioural change program, termed *Osteo-cise: Strong Bones for Life*, on BMD and body composition as well as functional muscle power and performance in older adults. 162 men and women (meanSD; 676 years) at increased risk for falls and fractures were randomised to the *Osteo-cise* program (n=81) or a usual-care control group (n=81). Exercise consisted of high-velocity PRT and weight-bearing activities (60-180 impacts/session) and balance training 3 d/wk for 12 months. All participants were given Ca-Vit D supplements. Total body FM, LM and BMC and regional BMD were assessed by DXA at baseline and 12 months. Maximal muscle strength and functional power (stair climbing test) and performance (4-square test, functional reach, TUG, sit-to-stand) were assessed at baseline, 6 and 12 months. In total 150 participants (93%) completed the study and the groups were well matched at baseline. Exercise attendance averaged 59%. After 6 months, there were significant exercise-induced net

gains in back (13%) and leg (12%) muscle strength ($P < 0.01$), which were maintained after 12 months. There was no effect of exercise on LM or FM, but significant net gains of 1.0% (95%, 0.2, 1.8) and 1.1% (0.2, 2.0) were observed in FN and L1-L4 BMD relative to controls (both $P < 0.05$). Exercise also improved stair climbing power [net gain 4.7% (1.0, 8.4), $P < 0.05$], sit-to-stand [12.7% (6.0, 19.3), $P < 0.001$] and the 4-square balance test [0.4 sec (-0.7, -0.1), $P < 0.05$] after 6 months. These benefits were maintained after 12 months, with a further 7% improvement observed in the sit-to-stand test. In conclusion, a community-based, multifaceted program incorporating high speed PRT and functional training is effective for improving BMD, muscle strength and functional power and performance in older adults at increased risk of fracture.

Systemic Administration of Soluble Activin Receptors Produces Differential Anabolic Effects in Muscle and Bone in Mice. Douglas Digirolamo^{*}, Vandana Singhal, Thomas Clemens, Se-Jin Lee. Johns Hopkins University, USA

Myostatin and related activin ligands are powerful negative regulators of skeletal muscle growth. Recent studies demonstrate that administration of soluble ActRII (ACVR2) fusion proteins, which sequester these muscle inhibitory factors, increases both skeletal muscle and bone mass in rodents and primates. Whether the observed bone anabolism results from direct actions in osteoblasts or is secondary to the increased muscle mass is unclear. To begin to address this question, 8 week-old female C57BL/6 mice were administered 10 mg/kg of ACVR2/Fc, ACVR2B/Fc or vehicle by IP injection, once a week, for 4 weeks. Wet weights of pectoralis, triceps, quadriceps and gastrocnemius muscles were increased by ~15% over vehicle in mice receiving ACVR2/Fc and by 40% in mice treated with ACVR2B/Fc. Micro CT analysis of the distal femur revealed a striking 3-fold increase in trabecular BV/TV in the ACVR2B/Fc group, but no significant change in cortical thickness at the midshaft. By contrast, mice treated with ACVR2/Fc demonstrated a more modest increase in trabecular BV/TV (13.6% vs. 7.6% in controls), but also had significantly increased cortical thickness at the femoral midshaft (204.5µm vs. 162.1µm in controls). Interestingly, ACVR2/Fc increased calvarial bone volume to a greater extent than ACVR2B/Fc. The increase in calvarial bone (a non load-bearing bone) and rapid accrual of trabecular bone in mice administered ACVR2B/Fc suggested direct actions of activin receptor signaling in bone. Consistent with this notion, real-time PCR performed on mRNA from primary mouse osteoblasts revealed expression of activin receptors and ligands at levels comparable to those seen in skeletal muscle, with the exception of myostatin, which was not expressed by osteoblasts. Additionally, phosphorylation of Smad2, an immediate substrate of activin receptor activation, was decreased in a time- and dose-dependent manner following exposure of osteoblasts to ACVR2B/Fc. These changes in Smad phosphorylation were accompanied by a modest decrease in osteoblast proliferation as indexed by BrdU incorporation. To further explore the effects of blocking activin receptor signaling on osteoblast performance, osteoblasts were differentiated in the presence of ascorbic acid and β-glycerolphosphate, with or without increasing concentrations of ACVR2B/Fc. Alkaline phosphatase and alizarin red staining were increased in osteoblasts treated with ACVR2B/Fc versus control. Taken together, our results suggest that activin receptor signaling functions directly in osteoblasts to regulate bone mass. Further, ACVR2/Fc and ACVR2B/Fc exerted differential anabolic activity in bone and muscle, an attractive property for a potential therapy for osteopenia and/or sarcopenia.

Combined Deletion of the Transcription Factors FoxO1, 3, and 4 from Osteoblast Progenitors Expressing Osterix Causes Bone Anabolism and Postpones the Adverse Effects of Aging on Bone. Srividhya Iyer^{*}, Elena Ambrogini, Li Han, Shoshana Bartell, Aaron Warren, Randall Shelton, Robert Weinstein, Charles O'Brien, Stavros Manolagas, Maria Almeida. Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

Wnt/β-catenin signaling increases bone mass, at least in part, by promoting the progression of Osterix (Ox)-expressing cells to bone producing osteoblasts. Based on this and evidence that FoxOs compete with Tcf for β-catenin, we have deleted FoxO1,3,4 from Ox-expressing cells, by crossing mice with conditional alleles (FoxO1,3,4-flox) with mice expressing the Cre recombinase under the control of the murine osterix promoter (Ox-Cre). Both female and male FoxO1,3,4-Flox;Ox-Cre mice exhibited a 20% increase in BMD by DEXA or micro-CT analysis at 3 months of age. This was associated with an increase in cancellous bone volume, trabecular number, and connectivity in both the vertebrae and the femur. Moreover, FoxO1,3,4-Flox;Ox-Cre mice had increased femoral cortical width caused by increased periosteal apposition, indicated by a larger external, but not internal, diameter of the diaphysis of the femur. Ox-GFP positive calvaria cells sorted by flow cytometry exhibited 90% decreased mRNA and protein levels of FoxO1, 3, and 4, as well as decreased expression of the FoxO-target genes Gadd45, nocturnin, Adm, and BMP4 as determined by microarray and qRT-PCR. Consistent with the contention that

FoxOs antagonize Wnt/Tcf signaling and osteoblastogenesis, the expression of the β -catenin/Tcf target genes cyclinD1, connexin43, col6a1, and mmp16 in *Osx-GFP* positive cells, as well as the mRNA expression of osteocalcin in bone, and the bone formation rate in vertebral sections, were all increased. Further, *Osx-GFP* positive cells exhibited increased proliferation rate as determined by BrdU incorporation. Resorption markers in the serum and OPG expression were unaffected by FoxO deletion. Induction of the FoxO1,3,4 deletion at 3 months of age, by activating a Tet-off system incorporated into the *Osx-Cre* transgene led to an increase in femoral and spinal BMD 18 weeks later, similar to that observed when the deletion occurred since conception, indicating that the increased bone mass was not due to changes imparted during development or growth. Most importantly, the high bone mass phenotype of the FoxO1,3,4-Flox;*Osx-Cre* mice was maintained up to 19 months of age. These findings strongly suggest that selective inactivation of FoxOs in *Osx*-positive cells causes bone anabolism by unleashing the restraining effects of FoxOs on Wnt signaling, and may counteract the effect of aging on bone.

Hyponatremia Causes Bone Loss and Sarcopenia. Nikhil Sharma¹, Joseph G Verbalis², Michael B Manigrasso¹, Helen Tam¹, Julia (Julianna) Barsony^{*2}, Qin Xu¹. ¹Georgetown University, USA, ²Georgetown University Hospital, USA

Chronic hyponatremia (CHN) is a frequent disorder of hospitalized and ambulatory elderly people due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and other causes. The consequences of pronounced CHN (serum $[Na^+] < 130$ mmol/L) on fall and fracture risks and osteoporosis have been recognized by our studies, as well as others. We recently reported that pronounced CHN causes loss of bone mineral density (BMD) in a rat model of SIADH. Moreover, our studies on cultured cells have demonstrated that even moderate lowering of extracellular $[Na^+]$ increased osteoclastogenesis and osteoclastic resorption, and oxidative stress. Using the same rat model of SIADH, we explored the possibility that mild CHN would also cause bone loss over time. We generated hyponatremia for 3 months in female rats (8 per group) by either high dose (5 ng/h) or low dose (0.5 ng/h) desmopressin (DDAVP) infusion in conjunction with a liquid diet, whereas normonatremic controls (NN) were pair-fed with the same liquid diet without infusing DDAVP. We monitored bone mineral density (BMD) using serial *in vivo* measurements, and also measured BMD in excised femur and L4 by densitometry at the end of the study. Pronounced CHN (serum $[Na^+] = 114.58$ mmol/L) caused marked and progressive decrease of BMD both in the spine ($p < 0.01$) and femur ($p < 0.01$) compared to NN rats (serum $[Na^+] = 146.61.3$ mmol/L). Mild CHN (serum $[Na^+] = 130.92.7$ mmol/L) caused moderate decrease of BMD in the spine (*in vivo* 24.16.7% below baseline; excised L4 HN: 0.11790.0049, NN: 0.12710.007 g/cm²; $p < 0.01$) and femur (*in vivo* 7.31.8 % below baseline; CHN: 0.16000.0031, NN: 0.16860.0025 g/cm²; $p < 0.05$). In another study on aged rats, we found that pronounced CHN for 3 months induced progressive decline of thigh muscle mass with an initial 3.66 1.0 % decrease over the first two weeks of hyponatremia ($p < 0.01$), followed by a steady decline at a rate of 2.1% per month to a maximum of 17% decline by the end of the study. We also found that CHN induced cardiomyopathy, manifested as increased heart per body weight, histomorphometric evidence of reduced myocyte number, and marked perivascular and interstitial fibrosis. In summary, our studies demonstrated that even mild hyponatremia causes significant bone loss, sarcopenia and cardiomyopathy in a rat model of SIADH, and therefore likely represents a significant detrimental factor to health in the aging population by virtue of increased fall and fracture risks.

Arrest of the Reversal Phase in Postmenopausal and Glucocorticoid-Induced Osteoporosis. Pia Jensen^{*1}, Thomas Andersen², MOHAMED ABDELGAWAD³, Ellen Hauge⁴, Jens Bollerslev⁵, Jean-Marie Delaisse⁶. ¹Vejle Hospital, Denmark, ²Vejle Hospital, IRS-CSFU, University of Southern Denmark, Denmark, ³CLINICAL CELL BIOLOGY DEPARTMENT, VEJLE HOSPITAL, Denmark, ⁴Aarhus University Hospital, Denmark, ⁵National University Hospital, Norway, ⁶Vejle Hospital, CSFU-IRS, University of Southern Denmark, Denmark

Histomorphometric assessment of bone remodeling focuses generally on osteoclastic (OC) resorption and osteoblastic (OB) formation. Only little attention is given to the intermediate phase, known as the reversal phase, although it is by nature, the one coupling bone resorption to bone reconstruction. Actually, we do not even know the nature of the cells colonizing the ES after the departure of the OCs, or whether miss-function of these "reversal cells" (RvC) may contribute to bone loss in diseases such as glucocorticoid-induced (GIO) and postmenopausal osteoporosis (PMO). These two basic questions are therefore addressed in the present study.

Masson trichrome-stained plastic sections of cancellous bone from 15 GIO patients, 23 PMO patients and 10 sex- and age-matched controls were assessed for the extent of eroded (ES), osteoid (OS), osteoclast (Oc.S), and osteoblast surface (Ob.S) relative to total bone surface (BS). Reversal surfaces (Rv.S) were defined as ES without OCs. The Rv.S was subdivided into active (Ac.Rv.S) defined as Rv.S with

flanking OCs or OS and arrested (Ar.Rv.S) defined as Rv.S without neighboring OCs or OS. Immunohistochemical characterization of the RvC was conducted on paraffin sections.

RvCs stained for factors which are typically expressed by OBs, but not for markers expressed by macrophages and OCs, thereby indicating that RvCs are OB lineage cells. Arrested RvCs were flatter and about 2 times less dense than active RvCs, as assessed in PMO. While the extent of Ac.Rv.S/BS was at the same level in all groups, the extent of Ar.Rv.S/BS was increased in both GIO and PMO patients, compared to controls. Statistical significance was however only borderline in PMO. These observations show that GIO and PMO affect the bone remodeling cycle well upstream of the bone formation step. Interestingly, a close negative correlation was found between the proportion of Ar.Rv.S and the extent of OS (PMO, $r = -0.41$; GC, $r = -0.38$) and Ob.S (PMO, $r = -0.45$; GC, $r = -0.38$). These correlations and the fact that Ar.Rv.Ss are away from OCs and OS, suggest that arrest of RvCs might prevent the transition from resorption to formation thus resulting in accumulation of Ar.Rv.S and deficient bone formation.

In conclusion, the reversal phase is performed by OB lineage cells. Arrest of the reversal phase may contribute significantly to the bone loss in both PMO and GIO. Therefore, RvCs could be future targets for treating diseases characterized by deficient bone formation.

FSH is Associated with Lean Mass and Fat Mass but not with BMD in Younger Postmenopausal Women. Margaret Gourlay^{*1}, Chenxi Li¹, Catherine Hammett-Stabler¹, Jordan Renner¹, Janet Rubin². ¹University of North Carolina, USA, ²University of North Carolina, Chapel Hill, School of Medicine, USA

Higher concentrations of follicle stimulating hormone (FSH) have been associated with lower bone mineral density (BMD), but a causal relationship has not been confirmed. We found no association between FSH and low BMD in a previous multivariable analysis of younger postmenopausal women that adjusted for weight. To study relationships among FSH, lean mass, fat mass and BMD, we conducted a new cross-sectional analysis of 111 postmenopausal women aged 50 to 64 years of mixed ethnic background. Lean mass, fat mass, and areal BMD (g/cm²) at the lumbar spine, femoral neck and total hip were measured using dual-energy X-ray absorptiometry (DXA, Hologic Discovery). Trabecular and cortical BMD were measured at the 4% and 33% distal radius respectively (XCT2000 peripheral QCT scanner; Stratec/Orthometrix). Multiple linear regression models were constructed for the outcomes of lean mass and fat mass, with independent variables age, race, years since menopause, ever-use of hormone therapy, FSH, bioavailable estradiol, bioavailable testosterone, LH, PTH and SHBG. Separate linear regression models were constructed using areal BMD and pQCT measures as outcomes, with age, race, FSH, bioavailable estradiol, bioavailable testosterone, LH, TSH, SHBG, BSAP, lean mass and fat mass as independent variables. FSH (range 1.6-270 mIU/mL) was moderately and inversely correlated with lean mass ($r = -0.62$, $p < 0.001$) and fat mass ($r = -0.48$, $p < 0.001$). After adjusting for the covariates, FSH was independently associated with lean mass ($\beta = -0.079$, $p = 0.010$) and fat mass ($\beta = -0.13$, $p = 0.011$), but not with any areal BMD or pQCT outcomes. Similar associations were seen for SHBG, but not for bioavailable estradiol or testosterone. These results show consistent and independent relationships between higher concentrations of FSH and lower lean mass and lower fat mass, but no statistically significant association between FSH and BMD. Previously reported correlations between FSH and BMD might have been due to indirect effects via lean mass or fat mass.

Calcium Deficiency-induced Bone Loss is Exacerbated by Disruption of Claudin-18 Gene in Mice. Gabriel R. Linares^{*1}, Catrina Alarcon², Robert Brommage³, David Powell⁴, Weirong Xing², Jon Wergedal², Subburaman Mohan². ¹Jerry L Pettis VA Med Ctr, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³Lexicon Pharmaceuticals, USA, ⁴Lexicon Pharmaceuticals, USA

Claudin-18 (Cldn-18) is a member of tight junction family of proteins and we recently showed that targeted disruption of Cldn-18 decreases endosteal bone volume (BV) by increasing bone resorption (BR). Since calcium (Ca) deficiency decreases endosteal BV by RANKL-mediated increase in BR and Cldn-18 negatively modulates RANKL-induced osteoclast differentiation, we evaluated if Ca-deficiency induced bone loss is further exacerbated by disruption of Cldn-18 in mice. Cldn-18 knockout (KO) and control mice (16-wks) were subjected to either normal Ca (0.6%) or low Ca (0.01%) diet for 2 wks. PIXImus revealed that total body, femur and lumbar BMD were reduced by 13, 14 and 31% respectively (all $P < 0.001$) after 2 wks of Ca deficiency in control mice. As expected, total body, femur and lumbar BMD were reduced 15, 13, and 27% (all $P < 0.001$) in Cldn-18 KO mice compared to control mice at normal Ca diet. Treatment of Cldn-18 KO mice with low Ca diet resulted in further skeletal deficits (total body, femur, and lumbar BMD were reduced by 22, 22, and 43% of

control mice). Gene-diet interaction was significant for lumbar BMD. To determine if combination of low Ca diet and loss of Cldn-18 compromises bone quality, we performed μ CT analysis of vertebra. BV/TV was reduced by 42% in the low Ca Cldn-18 KO group compared to 21% in the KO control group. Trabecular (Tb) number was decreased by 30% in the low Ca Cldn-18 KO group compared to 16% in the KO control group while Tb separation was increased 40% in the low Ca Cldn-18 KO group compared to 18% in the KO control group. Changes in Tb number and separation were significantly different in the low Ca Cldn-18 KO group compared to low Ca WT and normal Ca KO group. Histomorphometric analyses of vertebra revealed that %TRAP labeled surface/bone surface was significantly greater in the low Ca KO group compared to normal Ca KO and low Ca WT group. Accordingly, elevated serum PTH levels in the normal Ca KO mice were further increased (62%, $P < 0.01$) by Ca deficiency. Measurement of bone strength parameters in the femur by 3-point bending revealed that bone breaking strength and stiffness were severely compromised by combined deficiency of Cldn-18 and Ca compared to either deficiency alone. Conclusions: 1) Loss of Cldn-18 further exacerbates Ca deficiency-induced bone loss by influencing BR. 2) Loss of Cldn-18 function together with Ca deficiency results in mechanically weaker bone and thereby increases fracture risk.

Increased Density of Capillaries and Dividing Cells at Remodeling Sites in Adult Human Bone. Helene Kristensen^{*1}, Thomas Andersen², Prof. Niels Marcussen³, Lars Rolighed⁴, Jean-Marie Delaisse⁵. ¹Vejle Hospital Kabbeltøft 257100 Vejle Denmark, Denmark, ²Vejle Hospital, IRS-CSFU, University of Southern Denmark, Denmark, ³Odense University Hospital, Denmark, ⁴Aarhus University Hospital, Denmark, ⁵Vejle Hospital, CSFU-IRS, University of Southern Denmark, Denmark

In bone development and fracture healing osteogenesis depends critically on vascularisation. It is unknown whether a similar relation exists between vascularisation and cancellous bone remodeling. Here, we investigated how capillaries and the cell division marker Ki67 distributed above eroded surface (ES), osteoid surface (OS), and quiescent surface (QS), and are related to the presence of the bone remodeling compartment (BRC) canopy. The study included 9 paraffin-embedded iliac crest biopsies from control patients. Adjacent sections were stained so that information from histomorphometry and immunohistochemistry could be combined. Capillary density was counted on the CD56/CD34 double stained section, while the density of proliferating cells was counted on the Ki67 stained section. The distance from the bone or canopy to the target of interest was measured orthogonal to the bone surface until 100 μ m into the bone marrow. Electron microscopy (EM) was performed on EPON-embedded biopsies from 3 patients with primary hyperparathyroidism. The capillary density within 0-50 μ m above ES and OS was respectively 1.85 and 1.32 times higher than above QS in the absence of the BRC canopy, while 2.78 and 1.99 times higher in the presence of the BRC canopy. The frequency of light microscope assessed contacts between capillaries and BRC canopies above ES and OS were 3.39 and 2.35 times higher than contacts between capillaries and QS. The capillary density within 51-100 μ m above ES and OS equalled the level above QS. EM showed that the capillaries line the BRC canopy at less than 1 μ m distance, and that cells performed diapedesis through the capillary wall and the BRC canopy. The density of Ki67-positive nuclei up to 50 μ m above ES was 1.45 times higher compared to QS, while the density above OS and QS was similar. The density of Ki67 positive nuclei within 51-100 μ m was similar above all surfaces, as for the capillary density. All the reported differences are statistically significant with at least $P < 0.01$. These data support that capillaries are an important component of the mechanism controlling adult human cancellous bone remodeling. The higher density of capillaries above ES compared to OS indicates that capillaries are present from the beginning of the remodeling process. Thus, capillaries appear to participate in the recruitment of osteoclast and osteoblast progenitors as also suggested by our observations of diapedesis and the distribution of dividing cells.

Peripheral Blood Monocyte-Expressed Anxa2 Gene Is Involved in Pathogenesis of Osteoporosis in Humans. Fei Yan Deng^{*1}, Shu-Feng Lei², Yan Zhang³, Yu-Ling Zhang⁴, Yan-Peng Zheng⁵, Li-Shu Zhang⁵, Yunxia (Yesha) Lundberg⁶, Yao-Zhong Liu⁷, Christopher Papasian⁸, Hong-Wen Deng¹. ¹Tulane University, USA, ²College of Life Sciences, Hunan Normal University, China, ³Department of Genetics, Boys Town National Research Hospital, USA, ⁴Center of Systematic Biomedical Research, University of Shanghai for Science & Technology, China, ⁵College of Life Sciences & Bioengineering, Beijing Jiaotong University, China, ⁶Boys Town National Research Hospital, USA, ⁷Center of Bioinformatics & Genomics, Tulane University School of Public Health & Tropical Medicine, USA, ⁸School of Medicine, University of Missouri-Kansas City, USA

Low BMD is a risk factor of osteoporosis and has strong genetic determination. Genes influencing BMD and fundamental mechanisms leading to osteoporosis have

yet to be fully determined. Peripheral blood monocytes (PBM) could access to bone resorption surfaces and differentiate into osteoclasts to resorb bone. Herein, we attempted to identify osteoporosis susceptibility gene(s) and characterize their function(s), through initial proteome profiling of PBM *in vivo*, and using a strategy of multi-disciplinary and integrative studies.

We recruited 3 independent case-control samples ($N = 28, 80, 44$, respectively), including Caucasians with extremely low vs. high hip BMD from bottom 16% vs. top 10% of distribution in population, and one population sample including 1,000 unrelated Caucasians. We utilized quantitative proteomics methodology to profile PBM proteomes in the 1st case-control sample to discover proteins, thus gene(s), functionally relevant to low BMD. Differentially expressed protein(s) identified were verified by western blotting. Then, comparative analyses at mRNA expression level in PBM in the 2nd case-control sample were conducted. For gene(s) also differentially expressed at mRNA level, we further analyzed nucleotide sequences in the 3rd case-control sample to identify sequence variations associated with low BMD; we also tested association of gene SNPs with hip BMD in the population sample. Based on integrative evidence, gene(s) of interest were selected and subjected to functional validation *in vitro*.

Among 1,539 proteins identified in PBM, *Anxa2* was up-regulated 2.0-fold in subjects with low BMD. Up-regulation of *Anxa2* gene expression in low BMD subjects were verified, and further replicated at mRNA level. Three sequence variations in *Anxa2* were found associated with low BMD ($p < 0.05$). Three SNPs in *Anxa2* were associated with BMD variation ($p < 0.05$). The above integrative evidence strongly supports that *Anxa2* is involved in the pathogenesis of osteoporosis in humans. Furthermore, monocyte migration across endothelial barrier *in vitro* was elevated up to 4.9-fold by *Anxa2* stimulation, suggesting that *Anxa2* may stimulate more PBM to migrate from blood to bone resorption surfaces to differentiate into osteoclasts *in vivo*, hence leading to increased bone resorption and decreased BMD.

In conclusion, this study identified a novel osteoporosis susceptibility gene, and suggested a novel pathophysiological mechanism, mediated by *Anxa2*, for osteoporosis in humans.

Sex-specificity in femoral neck growth during adolescence and young adulthood: evidence from 15-years of longitudinal data. Saja Kontulainen^{*1}, Stefan Jackowski¹, Joel Lanovaz², James Johnston¹, Adam Baxter-Jones¹.

¹University of Saskatchewan, Canada, ²Assistant Professor, Canada

Introduction. About 70-80% of hip fractures occur in women. Sex-specific development during growth and later deterioration in hip structure and strength may partly explain the greater hip fracture incidence in females. However, there is limited longitudinal evidence of sex-specific hip structure growth during adolescence and young adulthood. The purpose of the present study was to investigate sex differences in femoral neck development over 15-years of growth.

Methods. Data were from 121 participants (64 females) of the Saskatchewan Pediatric Bone Mineral Accrual Study (PBMA). Proximal femur and total body lean mass were measured with dual energy x-ray absorptiometry (DXA) annually from 1991-97 and 2002-2006. We used Hip Structural Analysis to estimate peri- and endosteal diameters (cm) and bone cross-sectional area (CSA, cm²) (as an indicator of compressive strength) from femoral neck DXA scans. Peak height velocity (PHV) was determined for each participant and the age from PHV was calculated to define biological age (BA=age from PHV) at each measurement time. Random effects models were used to identify the interactions and independent effects of BA, sex, height and lean mass on femoral neck growth from adolescence to adulthood.

Results. There was a sex by BA interaction in periosteal (Beta coefficient -2.2, Standard Error of Estimate, SEE 0.4) and endosteal (-3.0, SEE 0.5) diameters indicating that females had greater periosteal and endosteal diameters prior to PHV, and lower periosteal and endosteal diameters after PHV than males with same height and lean mass. Another sex by BA interaction was observed in femoral neck CSA (2.2, SEE 0.5), indicating that females had smaller CSA prior PHV and larger CSA after PHV than males when height and lean mass were controlled.

Conclusion. After the growth spurt, periosteal growth at the femoral neck is greater in males while females gain larger bone area due to diminished endosteal resorption. These longitudinal results from adolescence to young adulthood support the theory that during pubertal growth females develop bone mineral reserve at the endosteal bone surface for reproductive needs. Loss of this reserve after menopause will reduce bone area at the femoral neck, leading to thin cortices susceptible to local buckling and hip fracture if the female hip is exposed to impact forces from a fall.

Serum Osteocalcin Levels Are Associated With Testosterone Levels In Boys During Maximal Skeletal Growth. Salman Kirmani^{*1}, Elizabeth Atkinson², L. Joseph Melton¹, Byron Riggs¹, Shreevasee Amin¹, Sundeep Khosla². ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA

Recent provocative studies in rodents have demonstrated that osteocalcin (OCN) regulates testosterone (T) production and fertility in males, but not in females. This effect is mediated by the active form of OCN, undercarboxylated (UC) OCN, which binds a G-protein coupled receptor (GPCR6a). We hypothesized that this novel bone-

testis axis may be most relevant during rapid skeletal growth in adolescent males to help maximize bone size. Thus, we measured serum T levels by mass spectroscopy and total and UC OCN as well as PINP levels by immunoassay in 56 boys with a bone age of 4-20 years, in whom we also measured periosteal circumference at the radius using Xtreme CT. In all boys combined, OCN was correlated with T levels (bone age-adjusted $r = 0.30$, $P = 0.024$), with a similar trend for UC OCN. However, serum T levels did not correlate with PINP levels (bone age-adjusted $r = 0.14$, $P = 0.307$). Serum T began to increase in the boys at bone age 11 years, and serum OCN reached maximal levels at bone age 14 years, representing peak skeletal growth. Thus, we divided the boys into 3 bone age groups: 4-10 years ($n = 16$, prior to increases in T levels), 11-14 years ($n = 18$, the phase of increasing bone formation), and 15-20 years ($n = 22$, the phase of declining bone formation). Serum OCN, but not PINP, was highly correlated with T levels in the boys of bone age 11-14 years ($r = 0.57$, $P = 0.013$), with a similar trend for UC OCN. No significant associations between serum T levels and OCN, UC OCN, or PINP were found in the younger or older boys. Bone size (periosteal circumference) was highly correlated with T levels in the boys of bone age 11-14 years ($r = 0.75$, $P < 0.001$). In these boys, serum OCN levels were also correlated with periosteal circumference ($r = 0.49$, $P = 0.037$); importantly, adjusting for T levels eliminated this correlation (T adjusted $r = 0.12$, $P = 0.660$), suggesting that T mediated the association of OCN with bone size. Collectively, these human data support the recent findings in rodents of a novel bone-testis axis. Moreover, our data suggest that this axis may be most relevant during rapid skeletal growth in males, when serum T levels are rising under the influence of the hypothalamic-pituitary axis and OCN levels are rising due to skeletal growth: during this phase, OCN may further stimulate testicular T production which, in turn, leads to an increase in bone size and ensures an evolutionarily conserved sexual dimorphism of the skeleton.

Dose-Response Effect of Vigorous Aerobic Exercise on Bone Turnover, Insulin Sensitivity, and Adiposity in Obese Children: A Randomized Controlled Trial. Norman Pollock^{*1}, Paul Bernard², Barbara A. Gower³, Karl Wenger¹, Sudipta Misra¹, Jerry Allison¹, Alexis M. Stranahan¹, Catherine L. Davis¹. ¹Georgia Health Sciences University, USA, ²Medical College of Georgia, USA, ³University of Alabama-Birmingham, USA

Animal data have uncovered a unique "bone-fat-pancreas" axis that regulates energy homeostasis, coordinates energy partitioning between bone and adipose tissue, and impacts insulin sensitivity. The existence of the "bone-fat-pancreas" axis in humans is unknown. In this study, we determined the dose-response effect of vigorous aerobic exercise on bone turnover, insulin sensitivity and adiposity in obese children. We also investigated associations between the changes in bone turnover and the changes in insulin sensitivity and adiposity. Obese children ($N=222$, aged 7-11 years, 58% female, 58% black) were randomly assigned to three experimental conditions: no-exercise control condition ($n=78$), low dose (20 min/d, $n=71$), or high-dose (40 min/d, $n=73$) aerobic exercise program for 12-weeks (5 d/wk). The low- and high-dose exercise groups participated in various types of instructor-led activities that involved running, jumping, skipping, kicking, and throwing. At baseline and posttest, an oral glucose tolerance test was used for assessment of insulin sensitivity (Matsuda index), bone formation [total osteocalcin (OC) and procollagen type I amino propeptide (PINP)], and bone resorption [carboxyterminal telopeptide region of type I collagen (ICTP)]. Total fat mass (FM) and visceral adipose tissue (VAT) were measured by DXA and MRI, respectively, at baseline and posttest. A significant linear upward trend indicating dose-response to exercise was observed for OC, PINP, and insulin sensitivity (all $P < 0.04$). A dose-response benefit of exercise was also observed for FM and VAT as indicated by significant downward trends (both $P < 0.04$). There was no dose-response effect of exercise on ICTP. Multiple linear regression adjusting for age, sex and race revealed that changes in both OC and PINP were positively associated with changes in insulin sensitivity but negatively associated with changes in VAT (all $P < 0.04$). Changes in bone resorption were not associated with changes in VAT, nor were changes in bone formation or resorption associated with changes in FM. In obese children, 12-weeks of vigorous exercise increased bone formation and insulin sensitivity and decreased total and visceral adiposity in a dose-response manner. However, the relationship observed between bone formation and central, rather than total, adiposity suggests the need for further studies identifying the link between bone formation and visceral fat, which may be explained by glucose homeostasis.

Mutant Mouse Models Reveal Indispensable Role for Thyroid Hormone (TH) Acting Via Growth Hormone (GH)-dependent and -independent Mechanisms to Regulate Bone and Fat Phenotypes during the Pre-pubertal Growth Period. Weriong Xing^{*}, Heather Davidson, Sheila Pourteymoor, Anil Kapoor, Subburaman Mohan, Jerry L. Pettis Memorial VA Medical Center, USA

Mouse models with disruption of IGF-I and GH actions have shown that while GH is the major regulator of bone accretion during pubertal and post-pubertal periods, GH-independent mechanisms predominantly contribute to bone accretion during prepubertal growth. Accordingly, our recent studies with TH-deficient mutant mouse models ($Tshr^{hyt/hyt}$ and $Duox2^{-/-}$) reveal that TH is indispensable for

prepubertal bone accretion. To determine the relative contribution of GH and TH axis to prepubertal rise in bone accretion, we evaluated skeletal phenotypes in mice lacking TH ($Tshr^{hyt/hyt}$), GH ($Ghrh^{lit/lit}$) or both ($Tshr^{hyt/hyt};Ghrh^{lit/lit}$). We found TH deficiency-induced reductions in total body, femur and tibia BMD (12, 30 and 27%) were significantly greater than those (5, 13 and 10%) seen in GH-deficient mice at the end of prepubertal growth period. In contrast, % body fat was increased similarly (30%) in TH and GH-deficient mice. While mice that are deficient in both TH and GH did not exhibit significantly greater skeletal deficit than TH deficiency alone, % body fat increase (49%) was significantly greater in double mutant mice. Treatment of TH deficient $Tshr^{hyt/hyt};Ghrh^{lit/+}$ mice with administration of T3/T4 during day 5-14 rescued IGF-I, bone and fat phenotypes. Total body, femur and tibia BMD were increased by 24, 37 and 39% respectively while % body fat was decreased by 30% compared to vehicle treatment. While treatment of $Tshr^{hyt/hyt};Ghrh^{lit/lit}$ double mutant mice with both GH and T3/T4 increased total body, femur and tibia BMD by 14, 24 and 30%, respectively neither T3/T4 nor GH treatment alone rescued the skeletal phenotype in the double mutant mice. Micro-CT measurements of femur metaphysis revealed significant decreases in trabecular BV/TV (24%) and thickness (12%) in the double mutant mice that were rescued by combined GH/TH treatment but not by individual treatment. In contrast, T3/T4 or GH treatment alone significantly decreased % body fat in the double mutant mice. Conclusions: 1) TH deficiency produces greater skeletal deficit than GH deficiency during prepubertal growth period; 2) While T3/T4 treatment rescues skeletal deficit in TH deficient mice, administration of both GH and T3 are required during prepubertal growth period to rescue skeletal deficit in the double mutant mice; and 3) TH effects on fat phenotype is GH-independent, thus suggesting that mechanisms that mediate TH actions in target tissues are complex.

Catch Up in Bone Acquisition in Young Adult Men with Late Puberty. Anna Darelid^{*1}, Claes Ohlsson², Martin Nilsson³, Jenny Kindblom⁴, Dan Mellstrom², Mattias Lorentzon². ¹Gothenburg University, Sweden, ²Center for Bone Research At the Sahlgrenska Academy, Sweden, ³Centre for Bone & Arthritis Research At the Sahlgrenska Academy, Sweden, ⁴Sahlgrenska University Hospital, Sweden

Late menarche has been associated with lower bone mineral density (BMD) at the time of peak bone mass as well as lower adult BMD and elevated risk of osteoporosis in studies of women. The influence of pubertal timing on adult BMD in men is not clear. We have earlier reported, in the GOOD Study of 19-year old males in Sweden, that late puberty was associated with lower BMD in a cross-sectional study. The aim of the present study was to investigate whether late puberty was associated with remaining low BMD in early adulthood, or if a catch up effect occurs. In total, 501 men (18.90.5 yrs at baseline and 24.10.6 yrs at follow-up) were included in this five-year longitudinal study. Areal BMD (aBMD), volumetric BMD (vBMD) and cortical bone size were assessed using DXA and pQCT. Detailed growth and weight charts were used to estimate peak height velocity (PHV), an objective assessment of pubertal timing. PHV (mean 13.51.0 yrs) was found to be a positive predictor of the increase in total body, radius, and lumbar spine aBMD between 19 and 24 yrs ($p < 0.0001$). Late puberty was also associated with a lesser decrease in femoral neck aBMD ($p < 0.0001$). Subjects were divided into tertiles (early, average, late) according to PHV. At the total body, men in the late tertile gained markedly more in aBMD (0.060.04 vs 0.030.04 g/cm², $p < 0.0001$) and lost less in femoral neck aBMD (-0.020.07 vs -0.050.06, $p < 0.0001$) than men in the early tertile. A similar pattern was seen for the radius and the lumbar spine (Figure 1). At age 24, no significant differences between the tertiles in aBMD of the lumbar spine, femoral neck, or total body were observed, while a deficit of 4.2% in radius aBMD was seen for men in the late vs. the early tertile ($p < 0.0001$). However, this deficit was markedly lower than what was observed at the baseline exam (8.2%). Thus, a notable catch up in BMD occurred over the five-year study period. pQCT measurements of the radius at follow-up demonstrated no significant differences in bone size, whereas cortical and trabecular vBMD were 0.7% ($p < 0.001$) and 4.8% ($p < 0.05$) lower in the late compared to the early tertile, respectively. In conclusion, our results demonstrate that late puberty in males was associated with a substantial catch up in aBMD in young adulthood, leaving no deficits in aBMD of the lumbar spine, femoral neck or total body at age 24, whereas aBMD of the radius was still significantly lower in men with late pubertal onset.

Vitamin D Binding Protein Genotype Is Associated with Vitamin D Status and Bone Health in Finnish Children and Adolescents. Elisa Saarnio¹, Minna Pekkinen², Heli Viljakainen³, Outi Makitie⁴, Christel Lamberg-Allardt². ¹University of Helsinki, Finland, ²University of Helsinki, Finland, ³Helsinki University Central Hospital for Children & Adolescents, Fin, ⁴Hospital for Children & Adolescents, Helsinki University Hospital, Finland

Vitamin D and its metabolites in serum are transported by vitamin D binding proteins (DBP, or group-specific component, Gc) into target tissues. Studies have shown that DBP correlate positively with serum vitamin D metabolites and that DBP phenotype influences serum 25-hydroxyvitamin D (25-OHD) concentration. DBP also impacts bone cell metabolism by activating osteoclasts. Furthermore protein isoform has been associated with decreased bone mineral density (BMD) and increased fracture risk.

Our aim was to study the role DBP genotypes on vitamin D status and (BMD) in 231 healthy children and adolescents (160 girls, 71 boys) aged 7-19 years. Lumbar spine (LS), femoral head (Fem) and whole body (WB) BMD was measured with DXA (Hologic Discovery A), and for a subgroup of 174 subjects, volumetric BMD was measured from non-dominant radius with pQCT (XCT-2000; Stratec). Dietary intakes of vitamin D and calcium were calculated with a validated food frequency questionnaire. The concentrations of serum 25-OHD, PTH and Ca were determined. DNA was isolated from blood samples. Genotyping was performed with qPCR (MX3000P, Stratagene) based on single nucleotide polymorphism (rs4588=Thr420Lys) in the DBP gene (homozygote 1/1, heterozygote 1/2, homozygote 2/2). Statistical analyses were performed with PASW18.

The distribution of the SNP among the subjects was: Gc 1/1 68%, Gc 1/2 26% and Gc 2/2 6%. There was a significant difference in 25-OHD levels between the genotypes, the concentration being highest in Gc 1/1 (47.4 nmol/L), intermediate in Gc 1/2 (42.6 nmol/L) and lowest in Gc 2/2 (40.6 nmol/L) based on ANCOVA-analysis, adjusted for PTH, vitamin D and Ca intake ($p=0.018$). Gc genotype associated with BMD Z-scores in boys with mean WB BMD Z-scores of +0.23 vs -0.26 ($p=0.029$) and LS BMD Z-scores of +0.39 vs -0.20 ($p=0.017$) in genotypes 1/1 ($n=53$) 1/2 and 2/2 ($n=18$). In girls no difference in BMD values was observed between the genotype groups. In both genders, Gc genotype was independently associated with stress and strain index Z-scores (SSI) in multivariate regression models adjusted for height, Ca intake, 25-OHD, PTH, fat %, lean body mass, pubertal stage and exercise, ($p=0.001$).

These results suggest that 25-OHD differ among vitamin D binding protein genotypes and that there is variation in BMD and bone strength among them. Variation in 25-OHD among genotypes may suggest differences in vitamin D utilization. DBP may be one factor affecting bone mass accrual in adolescence.

Sc65 is a Novel Regulator of Bone Homeostasis. Brittany Hendrix¹, Katrin Gruenwald¹, Patrizio Castagnola², Dana Gaddy¹, Larry Suva¹, Roy Morello¹. ¹University of Arkansas for Medical Sciences, USA, ²National Institute for Cancer Research, Italy

We and others recently showed that mutations in the *CRTAP* (encoding cartilage-associated protein) and *LEPRE1* (encoding prolyl 3-hydroxylase 1 or P3H1) genes cause recessive osteogenesis imperfecta (OI). This represented a major step forward in understanding the molecular basis of this disease and has now led to the identification of additional genes (*PPIB*, *SERPINH1* and *FKBP10*) linked to recessive human OI.

Such findings have shifted current OI research from matrix components (i.e. type I collagens) to rough endoplasmic reticulum resident proteins, and highlighted the complex cellular task of synthesizing and folding a collagen trimeric molecule. Having previously characterized the prolyl 3-hydroxylation complex, containing *Crtap*, *P3h1* and *Cyclophilin B* (*CypB*), we now extended our studies to determine the role of *Sc65*, a poorly known member of the *Leprecan* gene family and coding for the most closely related protein to *Crtap* with >50% amino acid identity. While *Sc65* was originally described as a nuclear epitope and then more recently as a cytoplasmic 'adaptor protein', we show that it localizes to the rER similarly to the other *Leprecan* proteins and it is highly expressed during skeletal formation. We then identified a gene-trap ES cell clone containing a proviral insertion in exon 5 of the *Sc65* gene. We obtained chimeric, heterozygotic and then homozygotic mice for this insertional construct. Western blot from *Sc65* mutant and WT tissues reveal absence or markedly reduced *Sc65* protein in the former. Micro-CT analysis of the appendicular skeleton at 10 weeks of age ($n=6$ males) shows statistically significant reduction in BV/TV and other static parameters in both tibia and femur. Cortical scans of the femur also demonstrate significantly reduced cortical cross sectional area (CSA) and thickness, with increased total CSA and endosteal perimeter. Histomorphometric analysis suggests no difference in dynamic indices of bone formation or in osteoclast parameters in tibias of *Sc65* mutant mice compared to controls. Current efforts are aimed at elucidating the cellular and molecular mechanisms causing low bone mass. In conclusion, our data suggest that impaired *Sc65* function has an impact on bone homeostasis, similarly although not as dramatically to what we have observed with lack of *Crtap* function.

Aberrant Osteoblast and Osteoclast Activity in Connexin43 G60S Missense Mutant Mice Leads to Age-related Bone Anomalies. Tanya Zappitelli¹, Frieda Chen¹, Marc Grynpas², Janet E. Henderson³, Luisa Moreno², Ralph Zirngibl¹, Jane Aubin⁴. ¹University of Toronto, Canada, ²Samuel Lunenfeld Research Institute, Canada, ³McGill University, Canada, ⁴University of Toronto Faculty of Medicine, Canada

Oculodentodigital dysplasia (ODDD) is a human disease caused by a mutation in the *GJA1* gene which encodes Connexin43 (Cx43). Using a genome-wide ENU-mutagenesis screen, we isolated a mutant mouse line, *Gja1*^{Jr/+}, with a dominant negative G60S missense mutation in Cx43 (Flenniken et al. 2005). In addition to having the classical symptoms of ODDD, such as craniofacial deformities and syndactyly, *Gja1*^{Jr/+} mice are osteopenic, but differences in BMD compared to wild type (WT) littermates become less pronounced with age. To elucidate the mechanisms underlying the bone anomalies, we performed histomorphometric and cell and molecular biology experiments. Histomorphometry confirmed that *Gja1*^{Jr/+} mouse bones exhibit significantly lower BV/TV and trabecular number and thickness than WT bones at 2 and 4 months, but differences diminished to non-significance by 12 months of age, concomitant with increases in cortical bone in *Gja1*^{Jr/+} but not WT mice. No differences were seen in osteoblast or osteocyte number in bones from *Gja1*^{Jr/+} versus WT mice, but expression of several mature osteoblast markers, most notably *Bsp* and *Ocn*, were significantly higher in RNA from trabecular bone and late differentiation time points in stromal cell cultures, suggesting that *Gja1*^{Jr/+} osteoblasts make an abnormal bone matrix. Osteoprogenitor numbers in the *Gja1*^{Jr/+} mutant were largely unchanged, however a non-significant increase in older mice was noted. Osteoclast surface per bone surface was significantly increased in *Gja1*^{Jr/+} versus WT bone, along with a significant increase in expression of *Cathpsink* mRNA. *In vitro* bone marrow or spleen cell cultures supplemented with M-CSF and RANKL showed no differences in osteoclast differentiation, fusion or resorption activity in *Gja1*^{Jr/+} versus WT. However, immunoblots showed a significant increase in *Rankl* protein expression from trabecular bone of *Gja1*^{Jr/+} mice versus WT. We conclude first that the G60S allele results in hyperactivity of osteoblasts, as reflected in overexpression of *Bsp* and *Ocn* matrix proteins, as well as osteoclast differentiation and activation cytokine *Rankl*. The latter results in more and hyperactive osteoclasts in *Gja1*^{Jr/+} mice, resulting in a high turnover state and ensuing osteopenia in young *Gja1*^{Jr/+} mice. Second, increased osteoblast activity and osteoprogenitor number leads to significant new bone accrual, protecting older *Gja1*^{Jr/+} mice from the age-related bone loss that occurs in WT.

Modeling Skeletal Diseases in iPS Cells. Edward Hsiao¹, Yohei Hayashi², Trieu Nguyen², Sahar Tahari², Matthew Spindler², Christopher Schlieve², Salma Sami², Shinya Yamanaka², Bruce Conklin², Robert Nissenson³. ¹University of California, San Francisco, USA, ²Gladstone Institute of Cardiovascular Disease, USA, ³VA Medical Center & University of California, San Francisco, USA

Skeletal diseases are a growing medical concern worldwide. Human diseases affecting the skeleton are challenging to study because of the lack of human models. Skeletal tissues derived from induced pluripotent stem (iPS) cells are promising tools for studying human genetic diseases from patients with known phenotypes. However, our understanding of how pluripotent stem cells can be guided to form skeletal tissues

is rudimentary. We established a robust and simple in vitro model of osteoblast differentiation based on human iPS cell cultures. The osteogenic media contains FBS, ascorbic acid, dexamethasone, and beta glycerol phosphate. iPS cell-derived osteoblasts showed strong mineralization after day 15 as detected by von Kossa staining. We also found high expression of osterix at day 6 of differentiation and increasing levels of collagen I and osteocalcin at days 15 and 24, indicating formation of both immature and mature osteoblasts in our culture system. To test whether the iPS model could recapitulate aspects of human skeletal disease, we established human iPS cell lines from patients with Fibrodysplasia Ossificans Progressiva (FOP), a disease with dramatically increases skeletal tissue formation. Multiple iPS cell lines were successfully generated by viral transduction of four pluripotency-inducing factors (Oct4, Sox2, Klf4, and cMyc) into skin fibroblasts from two independent FOP patients carrying the classical R206H mutation in ACVR1. We confirmed that the FOP iPS cells carried the R206H mutation and expressed pluripotency markers. Embryoid bodies derived from FOP iPS cells expressed marker genes for all three germ layers, but teratomas formed by the FOP iPS cells had decreased neuronal elements by histology. Osteogenic differentiation of FOP iPS cells showed significantly more mineralization as compared to wildtype controls. Although further analysis of the gene expression profiles of these cells is underway, our current results indicate that the R206H mutation in FOP iPS cells may confer increased mineralization activity as compared to control iPS cells. These findings show that stem cell-based models could be valuable for studying genetic diseases of osteoblast formation and function. These models will also be useful for dissecting the molecular pathogenesis and identifying new therapeutic approaches for disorders affecting skeletal tissues.

Increased Levels of TAF12 with IL-6 Can Substitute for MVNP to Induce Pagetic-Osteoclasts. Jumpei Teramachi¹, Jolene Windle², Noriyoshi Kurihara¹, G. David Roodman³. ¹University of Pittsburgh & The Center for Bone Biology at UPMC, USA, ²Virginia Commonwealth University, USA, ³University of Pittsburgh, The Center for Bone Biology at UPMC, & VA Pittsburgh Healthcare System, USA

We have shown that osteoclasts (OCL) from Paget's (PD) patients express measles virus nucleocapsid protein (MVNP), that anti-sense MVNP significantly blocked the increased OCL formation and nuclei per OCL, TATA box-binding protein associated factor 12 (TAF-12) expression, 1,25-(OH)₂D₃-stimulated IL-6 production, and bone resorption characteristic of OCL formed in PD patient marrow cultures. In contrast, PD patients not expressing MVNP and normals formed normal OCL. There was no effect of anti-sense MVNP on OCL formation or any other parameters of OCL activity in cultures from PD patients not expressing MVNP or normals. These results indicate that MVNP was responsible for the unique characteristics of OCL generated from PD patients. Mice expressing MVNP in cells of the OCL lineage formed pagetic OCL and bone lesions, which were lost when they were bred with IL-6^{-/-} mice. These results demonstrate an important role for IL-6 in the development of PD OCL and bone lesions. It is our hypothesis that both increased VDR responsiveness induced by TAF12 and high levels of IL-6 are sufficient to induce pagetic OCL. Therefore, we generated transgenic mice with TAF12, IL-6 or both TAF12/IL-6 targeted to the OCL lineage using the TRAP promoter and determined if pagetic OCL formed. OCL precursors from TAF12 and TAF12/IL-6 mice were hyper-responsive to 1,25-(OH)₂D₃ and formed OCL at low concentrations (10⁻¹⁰ M) of 1,25-(OH)₂D₃ compared to WT. Further, OCL that formed from TAF12/IL-6 mice were hyper-multinucleated compared to IL-6 or WT mice. 1,25-(OH)₂D₃ increased bone resorption in marrow cultures from the three transgenic mice compared to WT with the percent of area of bone resorption dramatically increased in TAF12/IL-6 (28.02.2) compare to WT (0.80.1), TAF12 (4.91.1) and IL-6 (6.92.1) mice. OCL precursors from these mice were then incubated with 1,25-(OH)₂D₃, and activation of MAPKs and STAT3 pathways determined. Increased levels of the phosphorylated forms of Erk and p38 were found in TAF12, IL-6 and TAF12/IL-6 lysates at 2-5 minutes after incubation with 1,25-(OH)₂D₃. OCL precursors from IL-6 and TAF12/IL-6 but not TAF12 mice showed increased p-STAT3 activation (up to 3-fold) as compared to WT OCL precursors treated with 1,25-(OH)₂D₃. These results suggest increased endogenous levels of IL-6 in combination with hyper-responsivity of OCL precursors to 1,25-(OH)₂D₃ may be sufficient to induce pagetic OCL in vivo via enhanced ERK, p38 and STAT3 signaling.

Sclerostin Antibody Improves Bone Mass and Mechanical Properties in an Adult Brtl/+ Model of Osteogenesis Imperfecta. Benjamin Sinder¹, Logan White¹, Michelle Caird¹, Joan Marin², Kenneth Kozloff³. ¹University of Michigan, USA, ²National Institute of Child Health & Human Development, USA, ³University of Michigan Department of Orthopaedic Surgery, USA

Osteogenesis imperfecta (OI) is a genetic collagen disorder characterized by brittle bones. While OI fracture risk is generally greater in a pediatric population, it can remain a problem into adulthood. No anabolic therapy has yet been shown consistently effective in treating OI. Sclerostin is a negative regulator of the Wnt pathway, and a neutralizing sclerostin antibody (Scl-Ab) therapy has proven anabolic

in other fragility models. The purpose of this study was to evaluate Scl-Ab in an adult Brtl/+ mouse model of OI with G349C mutation on colla1. At 6 months, Brtl/+ has previously shown reduced trabecular MAR and BFR vs. WT, making this a good model for OI patients with diminished osteoblast activity to evaluate Scl-Ab. Male 6 month WT and Brtl/+ were treated with Scl-Ab or Vehicle twice per week, for five weeks, at 25mg/kg. All changes noted are p<0.05, n=7-9/group. Body weight was not changed by Scl-Ab therapy in either WT or Brtl/+ during the five weeks of treatment. Dynamic histomorphometry at femoral mid-diaphysis on a subset (n=5/group) showed that Scl-Ab increased periosteal BFR in both WT (159%) and Brtl/+ (205%). This was a result of increases in MAR (WT 98%; Brtl/+ 95%) and MS/BS (WT 35%; Brtl/+ 63%). MicroCT of the distal metaphyseal femur revealed Scl-Ab increased BV/TV in both WT (117%) and Brtl/+ (119%). BV/TV increases were a result of increased Tb.Th (WT 38%; Brtl/+ 29%) and Tb.N (55% WT; Brtl/+ 70%). Scl-Ab increased cortical thickness (WT 42%; Brtl/+ 22%) and cross sectional area (WT 36%; Brtl/+ 21%) at femoral mid-diaphysis with no effect on tissue mineralization (TMD). Functionally, Scl-Ab increased femoral diaphyseal Ultimate Force (WT 129%; Brtl/+ 127%) and Energy to Failure (WT 526%; Brtl/+ 509%) as measured by four-point bending. Scl-Ab did not change the estimated elastic modulus in WT or Brtl/+, in agreement with microCT TMD data. The mid span yield-displacement to failure-displacement ratio was reduced with Scl-Ab (WT 47%; Brtl/+ 36%), suggesting Scl-Ab reduced bone brittleness. In summary, Scl-Ab increased osteoblast activity, improved bone mass and whole bone mechanical properties, and reduced brittleness in an adult Brtl/+ model of OI characterized by low osteoblast activity. These initial data support that Scl-Ab may be beneficial for the treatment of OI patients by stimulating the deficient osteoblast population and reducing fracture risk.

Genetic Deletion of Osteopontin Restores Unloading Mediated Bone Loss in a NF1 Murine Model. Ping Zhang¹, Shi Chen², Yongzheng He², Xiaohua Wu², Steven D. Rhodes², Xianlin Yang², Jin Yuan², Li Jiang², Feng-Chun Yang². ¹Indiana University School of Medicine, USA, ²Indiana University School of Medicine, USA

Osteopontin (OPN), the spp1 gene product, plays an important role in bone biology. Neurofibromatosis type 1 (NF1) patients have a high incidence of osteoporosis/osteopenia. We previously reported that Nf1 haploinsufficient (^{+/-}) preosteoblasts hypersecrete OPN leading to a gain in osteoclast bone resorptive activity in vitro. The object of this study is to evaluate whether genetic deletion spp1 (OPN) prevents bone loss in hindlimb unloaded Nf1^{+/-} mice, a model of osteopenia.

Four genotypes of mice were used for this study: WT, Nf1^{+/-}, spp1^{-/-}, and Nf1^{+/-}; spp1^{-/-}. 12 age-matched mice per genotype were subjected to tail suspension for 2 weeks, and non-unloaded mice were used as controls. Changes in femoral BMD and BMC were measured by pDEXA. The impact of the osteoclast lineage on the bone loss following the unloading was also assessed by (1) scoring the osteoclast area in the femoral metaphyses following tartrate-resistant acid phosphatase (TRACP) staining and (2) scoring the frequency of osteoclast progenitors by the colony forming unit-macrophage assay (CFU-M). To assess osteoclast function in vitro, osteoclast formation and migration were examined by TRACP staining and transwell assays respectively.

Unloading induced a significantly greater loss of femoral BMD and BMC in Nf1^{+/-} mice compared to WT controls. Importantly, genetic deletion of spp1 restored BMD and BMC in Nf1^{+/-} mice to WT levels (p<0.01). In addition, the femoral metaphyses of Nf1^{+/-} unloaded mice displayed a dramatic increase in TRACP⁺ area compared to WT mice (p<0.001), and Nf1^{+/-};spp1^{-/-} mice showed significantly reduced TRACP⁺ area in the femoral metaphyses. While unloading induced a significant increase in total of CFU-M in Nf1^{+/-} mice, deletion of spp1 reduced the CFU-M in Nf1^{+/-} mice to basal levels. Furthermore, bone marrow derived osteoclastic migration and formation were dramatically reduced in Nf1^{+/-};spp1^{-/-} cultures following unloading compared to that in Nf1^{+/-} cultures as determined by the transwell assay, TRACP⁺ area, and nuclear numbers per osteoclast (p<0.05).

Taken together, this study shows that Nf1^{+/-} mice exhibit accelerated bone loss following hindlimb unloading, which is associated with increased osteoclast formation. Importantly, genetic deletion of spp1 is sufficient to prevent bone loss in unloaded Nf1^{+/-} mice. This study provides evidence that OPN may be a potential molecular target for preventing bone loss in NF1 patients.

Targeting of the DAP12-associated, Osteoclast-specific Receptor Siglec-15 by Antibody 25E9 Inhibits Differentiation and Resorption Activity. MATTHEW STUIBLE^{*}, Annie Fortin, Elisabeth Viau, Marc Sasseville, Aida Kalbakji, Anna Moraitis, Mario Filion, Gilles Tremblay. Alethia Biotherapeutics, Canada

With the objective of developing monoclonal antibodies for novel therapeutic approaches in cancer-associated bone loss, we used a sensitive discovery platform to compare the molecular signature of mature human osteoclasts with that of their

precursor cells. Expression profiling in human osteoclast samples led to the prioritization of several candidate osteoclast-specific genes. One of these encodes Siglec-15, an immunoglobulin-like sialic acid-binding receptor. Members of the Siglec family play various roles in immune signaling and have expression patterns that are characteristically restricted to specific hematopoietic lineages. We confirmed by RT-PCR that Siglec-15 mRNA is upregulated in mouse bone marrow cells, human peripheral blood mononuclear cells and RAW264.7 cells upon induction of osteoclast differentiation with RANKL. Conversely, Siglec-15 expression was not detected in other cell types with the exception of lung tissue, where very weak expression was observed. To establish its functional relevance, Siglec-15 expression was attenuated by vector-based shRNA resulting in reduced differentiation and function of osteoclasts derived from mouse and human cells. These initial results prompted us to pursue development of therapeutic antibodies against human Siglec-15. After screening a library of antibodies by various binding and functional criteria, clone 25E9 was selected as the lead candidate. 25E9 detects Siglec-15 on the cell surface, and most importantly, it impairs differentiation of osteoclast precursor cells and bone resorption similar to Siglec-15-targeted shRNA. Since little was known regarding the normal cellular function of Siglec-15, the antibodies were used to explore its role in osteoclast signaling. We found that a complex of Siglec-15 and the ITAM-bearing co-receptor DAP12 was readily detectable in lysates from osteoclasts but not their precursors. The importance of DAP12 in osteoclastogenesis is well established, but its principal partner in this context was believed to be another receptor, TREM2. Our results suggest that the Siglec-15/DAP12 complex may in fact be more specific to osteoclasts than TREM2/DAP12, and we are currently investigating the downstream signaling pathways that are modulated when Siglec-15 is bound by 25E9. In conclusion, we have identified Siglec-15 as a functionally important osteoclast receptor that could be targeted by therapeutic antibodies such as 25E9 to control bone resorption in a highly specific manner.

Knockin Mice Bearing an Inactivating Mutation in the RANK IVVY Motif Exhibit Increased Bone Mass Due to Impaired Osteoclastogenesis. Zhenqi Shi*, Joel Jules, Bob Kesterson, Xu Feng. University of Alabama at Birmingham, USA

The receptor activator of NF- κ B (RANK) ligand (RANKL) and its receptor RANK play a vital role in osteoclastogenesis. As a member of the tumor necrosis factor (TNF) receptor family, RANK has been shown to promote osteoclastogenesis by activating various signaling pathways including NF- κ B, JNK, ERK and p38 by recruiting TNF receptor-associated factors (TRAFs). Nonetheless, several lines of evidence suggested that RANK may also activate unidentified TRAF-independent signaling pathways that are essential for osteoclastogenesis. To elucidate the hypothesized novel RANK signaling pathways, we previously carried out a systematic structure/function study of the RANK cytoplasmic domain using a non-biased in vitro mutation analysis approach, leading to identification of a specific 4-AA RANK motif (IVVY⁵³⁵⁻⁵³⁸) which plays a critical role in osteoclastogenesis by mediating commitment of macrophages to the osteoclast lineage. To validate the role of this IVVY motif in osteoclastogenesis in vivo, we have developed knockin (KI) mice bearing an inactivating mutation in the IVVY motif with a replacement type targeting vector which converts the wild type RANK allele to a mutated allele encoding a 2-AA substitution in the IVVY motif (IVVY to IVAF). Homozygous KI (RANK^{AF/AF}) mice are viable, born at the expected Mendelian frequency, and have normal tooth eruption. However, X-ray and micro-computed tomography (μ CT) analysis of femurs of 8-week old wild type (WT), heterozygous (RANK^{+AF}) and RANK^{AF/AF} mice have revealed a dramatic increase in bone mass in RANK^{AF/AF} compared to age and sex matched WT counterparts. Moreover, RANK^{+AF} mice exhibit increased bone mass compared to WT mice, suggesting that the presence of a single mutant RANK in RANKL-induced RANK trimers is sufficient to impair the normal signaling from the IVVY motif. Bone marrow macrophages (BMMs) from RANK^{AF/AF} mice failed to form osteoclasts in vitro in response to M-CSF and RANKL treatment. Consistent with the in vivo data, BMMs from RANK^{+AF} demonstrated reduced capacity to form osteoclasts compared to WT BMMs. Importantly, flow cytometric analysis showed that BMMs from RANK^{AF/AF} and RANK^{+AF} have similar levels of RANK cell surface expression compared to WT cells, ruling out the possibility that the failure of RANK^{AF/AF} BMMs to form osteoclasts is caused by a decrease in RANK surface expression. Taken together, these data indicate that the RANK IVVY motif plays a crucial role in osteoclastogenesis in vivo.

Targeted FoxO3 Overexpression in Osteoclast Progenitors and Mature Osteoclasts Inhibits NF-Kb Signaling and Osteoclastogenesis and Increases Bone Mass. Shoshana M. Bartell*, Elena Ambrogini, Li Han, Aaron Warren, Randal S. Shelton, Haibo Zhao, Xiahua Qiu, Joseph Goellner, Charles A. O'Brien, Maria Jose S. Almeida, Stavros C. Manolagas. Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

An increase in the generation of reactive oxygen species (ROS) has been strongly implicated in the decreased bone formation associated with advancing age as well as the increased resorption associated with estrogen deficiency. In line with this evidence, increased ROS production in osteoblasts stimulates apoptosis and decreases bone formation. On the other hand, ROS are a critical requirement for RANKL-induced osteoclast generation, activation, and survival. Based on this and evidence that global combined deletion of FoxO1,3,4 - an important transcriptional defense mechanism against excessive ROS generation- leads to an increase in ROS and osteoclast progenitor number and that the age-associated progressive increase in ROS production is not accompanied by an increase in mature osteoclast numbers in bone, we have hypothesized that FoxO activation is responsible for the dampening of osteoclast generation in aged mice. To test this hypothesis, we generated transgenic mice overexpressing FoxO3 in cells of the monocyte/macrophage lineage by crossing FoxO3-flox stop (FS) mice with LysM-Cre mice (FoxO3-FS;LysM-Cre). These mice exhibited a significant increase in BMD, as well as an increase in cancellous bone volume at 3 months of age as determined by micro-CT, in both vertebrae and femora. FoxO3-FS;LysM-Cre mice also exhibited increased trabecular number and decreased trabecular separation. Consistent with the changes in bone mass, the serum levels of the resorption marker CTx, as well as the mRNA levels of the osteoclast markers TRAP and cathepsin K in vertebral bone, were decreased. The osteoblast marker osteocalcin was unaffected. In line with these changes, bone marrow cultures established in the presence of RANKL and M-CSF from FoxO3-FS;LysM-Cre mice exhibited a significant decrease in osteoclast progenitors and mature osteoclast formation, increased osteoclast apoptosis, but normal macrophage proliferation. In line with the decreased osteoclastogenesis, activation of NF- κ B by RANKL is attenuated in macrophages from FoxO3-FS;LysM-Cre, as determined by I κ B phosphorylation. The demonstration of a suppressive effect of the gain of FoxO function on osteoclast generation and survival suggests that FoxO activation in response to OS not only plays a major role in the adverse effects of aging on osteoblasts but may influence osteoclasts as well.

Comprehensive Epigenetic Analysis Reveals Nedd9 is a Key Downstream Molecule of TGF- β Involving in RANKL-Induced Osteoclastogenesis. Yasunori Omata*, Tetsuro Yasui¹, Takumi Matsumoto¹, Hironari Masuda¹, Jun Hirose¹, Naoto Tokuyama¹, Hisataka Yasuda², Shuichi Tsutsumi³, Aburatani Hiroyuki⁴, Kozo Nakamura¹, Sakae Tanaka¹. ¹The University of Tokyo, Japan, ²Oriental Yeast Company, Limited, Japan, ³Genome science Division, RCAST, Univ.Tokyo, Japan

Previous studies found that TGF- β promotes RANKL-induced osteoclastogenesis, however its key downstream molecules remain unclear. We employed recently-established chromatin immunoprecipitation sequencing (ChIP-seq) method and comprehensively analyzed genes regulated by TGF- β in bone marrow-derived macrophages (BMMs). Smad2/3 work as transcription factors in TGF- β signal transduction. After treating BMMs with 2 ng/ml TGF- β for 1.5 hrs, cells were collected and chromatin immunoprecipitation using anti-Smad2/3 antibody was performed. To identify Smad2/3 binding sites globally, the immunoprecipitates were subjected to massively parallel DNA sequencing and the obtained data were mapped to the genome. 2,786 Smad2/3 binding sites were detected, and 992 of them (903 genes) exist around promoter region of RefSeq genes. Microarray analysis demonstrated that the expression of these Smad2/3 target genes was significantly upregulated by TGF- β treatment. To specify the key regulatory genes of osteoclast differentiation, we analyzed histone modification profiles of BMMs. Recent studies have revealed that histone modifications such as trimethylation of histone H3 lysine 4 (H3K4me3) and lysine 27 (H3K27me3) regulate gene transcription. It is elucidated that histone modifications of key developmental genes tend to change from H3K4me3/H3K27me3 bivalent to H3K4me3 monovalent status and then active transcription is induced. Through ChIP-seq analysis using anti-H3K4me3 antibody and anti-H3K27me3 antibody, we identified 35 genes whose histone modification pattern was converted from K4/K27 bivalent to K4 monovalent by TGF- β . Seven of them were Smad2/3 target genes, and Nedd9 is one of these extracted genes. Nedd9 is known as a member of the Crk-associated substrate (CAS) family and is expressed in lymphocytes and epithelial cells, and also involved in cell migration, metastasis of cancer cell and integrin- β 1 signaling although its role in osteoclasts remains unknown. In vitro gene silencing of Nedd9 using small interfering RNA induced remarkable suppression of RANKL-induced osteoclastogenesis. Indeed, Nedd9 knockout mice exhibited increase of bone mass with decreased osteoclastogenesis. These results indicate that Nedd9 is a key downstream target of TGF- β which critically regulates osteoclast differentiation. In summary, we performed comprehensive analysis using a novel ChIP-seq method and identified Nedd9 as an important downstream molecule of TGF- β .

Bone Marrow Adiposity Affects Osteoclastogenesis by Modulating the Bone Marrow Niche. He Fu^{*1}, Dominique Pierroz², Anne Wilson³, Serge Ferrari⁴, Beatrice Desvergne⁵. ¹CIG University of Lausanne, Switzerland, ²University Hospital of Geneva, Switzerland, ³LICR@UNIL, Switzerland, ⁴Geneva University Hospital & Faculty of Medicine, Switzerland, ⁵CIG UNIL, Switzerland

The nuclear receptor PPAR γ inhibits osteogenesis by favoring adipogenesis from common mesenchymal progenitors. The PPAR γ agonist (anti-diabetic drug TZD) could cause bone loss and accumulation of marrow adiposity in mice and in postmenopausal women, suggesting a link between PPAR γ and bone turnover. Until recently PPAR γ -/- mice were not available due to embryonic lethality. However, we recently succeeded in generating mice carrying a total deletion of PPAR γ . They exhibit a severe lipodystrophy in addition to further effects on bone homeostasis.

PPAR γ +/- mice have elevated bone mineral density (BMD), consistent with previous data reported. PPAR γ -/- mice also have elevated BMD in their vertebrae. Strikingly, the tibia and femur exhibited a lower BMD than heterozygous controls (77.9 \pm 3.9a vs. 87.5 \pm 2.1). Analyses of osteoblast differentiation from mesenchymal stem cells and calcium deposition from pre-osteoblast cultures did not provide an explanation for the paradoxical phenotype between long and short bones. We thus further investigated osteoclastogenesis from hematopoietic stem cells (HSC). PPAR γ -/- HSCs produce an increased number of TRAP+ osteoclasts in culture compared to WT and heterozygous controls (171 \pm 29ab vs. 125 \pm 23 vs. 69 \pm 12). Histological analyses confirmed larger resorption areas in PPAR γ -/- long bones.

While flow cytometry analyses showed a general decrease in HSCs and progenitors, an increased proportion of osteoclast progenitors (GMP) were observed in PPAR γ -/- bone marrow. In addition extramedullary hematopoiesis was found in peripheral organs and confirmed by histological analysis. Moreover, the lack of adipose tissue created a favorable niche for osteoclastogenesis since conditioned medium made from differentiated adipocytes, 3T3L1, inhibited osteoclastogenesis from both PPAR γ -/- and WT cells. Thus, adipokine deficiency in PPAR γ -/- mice contributes to de-repress osteoclastogenesis. Using a specific blocking antibody, we further identified adiponectin as the major player among dozens of adipokines.

These data suggest that PPAR γ regulates bone turnover by both a direct effect on cell differentiation and an indirect effect on cell fate determination through adipocyte and adipokine secretion. These specific characteristics provide support for a key role of PPAR γ at the cross roads of osteogenesis, adipogenesis and hematopoiesis/osteoclastogenesis.

Lis1 Plays an Important Role in Bone Resorption by Regulating Microtubule Organization and Dynein Function in Osteoclasts. Shiqiao Ye^{*1}, Tristan Fowler¹, Nathan Pavlos², Pei Ying Ng³, Yunfeng Feng⁴, Ming Hao Zheng², Richard Kurten⁵, Stavros Manolagas¹, Haibo Zhao¹. ¹University of Arkansas for Medical Sciences, USA, ²University of Western Australia, Australia, ³The University of Western Australia, Australia, ⁴Department of Internal Medicine, Washington University School of medicine, USA, ⁵Department of Physiology & Biophysics, University of Arkansas for medical Sciences, USA

Cytoskeleton reorganization is critical for osteoclast (OC) activation and function. Microfilaments are first organized into podosomes and then form an actin-ring at the sealing zone of active OCs. Microtubules (MTs), stabilized by tubulin acetylation, are required for podosome patterning and the sealing zone formation. In mammalian cells, MT organization is regulated by MT-associated proteins (MAPs) such as MT plus-end capping proteins, CLIP-170 and EB1. The transportation of these MAPs to the cell cortex is essential for MT distribution and the process is mediated by MT-based motor, cytoplasmic dynein, and LIS1, a critical molecule regulating MT dynamics and dynein function. To determine whether the LIS1/dynein pathway plays a role in OC MT organization and bone resorption, we have generated LIS1 macrophage conditional knockout (cKO) mice by crossing LIS1-floxed mice with LysM-Cre mice. LIS1 expression was abolished in macrophages and OCs isolated from LIS1 cKO mice but not in those from wild type (WT) mice, as shown by western blots. LIS1 cKO mice were normal in size and tooth-eruption. However, at 3 months of age, the mice had increased BMD and BV/TV measured by DEXA and micro-CT, as compared to their WT littermates. Reflecting an impaired OC bone resorption in LIS1 cKO mice, macrophages isolated from these mice had intrinsic defects in OC differentiation and function as revealed by a decreased number of TRAP+ mature OCs, aberrant MT organization, decreased resorption pits formation, and reduced levels of TRAP 5b and CTx-I in culture medium. The attenuated OC formation in LIS1-null macrophages was associated with a significant decrease in macrophage proliferation, osteoclast differentiation and survival, due to a reduced activation of ERK and AKT by M-CSF and a prolonged RANKL-induced JNK activation. Consistent with its critical role in MT organization and dynein function in other cell

types, we found that LIS1 binds to and colocalizes with dynein in OCs. Loss of LIS1 led to disorganized MTs and aberrant dynein function, as demonstrated by dispersed Golgi apparatus and abnormal distribution of CLIP-170 and EB1. More importantly, depletion of LIS1 in OCs inhibited Cathepsin K secretion into the resorption lacuna and OC motility as examined by confocal and time-lapse video microscopy. In conclusions, the LIS1/dynein pathway represents a previously unappreciated and novel mechanism regulating OC MTs and differentiation/function in vivo and in vitro.

IGF-1 Maintains Bone Mass by Inducing Osteoblast Differentiation of MSCs during Bone Remodeling. Lingling Xian^{*1}, Xiangwei Wu², LIJUAN PANG², Tao Qiu², Frank Frassica³, Clifford Rosen⁴, Shouhong Xuan⁵, Argiris Efstratiadis⁵, Mei Wan², Xu Cao⁶. ¹Johns hopkins university school of Medicine, USA, ²Johns Hopkins University School of Medicine, USA, ³Department of Orthopaedic Surgery, Johns Hopkins University School of Medicine, USA, ⁴Maine Medical Center, USA, ⁵Medical Center of Genetics & Development, Columbia University, USA, ⁶Johns Hopkins University, USA

Bone mass peaks in late adolescence, plateaus for several years, and then declines to a point in which osteoporosis is established. Maintenance of peak bone mass (PBM) is thought to prevent osteoporosis and reduce risk of fracture. IGF-1 is integral to the acquisition of PBM. However, it is unclear how IGF-1, abundantly deposited in the bone matrix, maintains bone mass in adults. Here we report that IGF-1 released from bone matrix stimulates osteoblast differentiation of MSCs for bone formation during bone remodeling. The bone resorption conditioned medium (CM) induces osteoblast differentiation of MSCs, and IGF-1 antibody inhibited the differentiation. Osteoclast CM with bone slices contains high level of IGF-1, but the control CMs including osteoclasts alone do not have detectable level of IGF-1. Moreover, phosphorylated IGF-1R is primarily found at the bone resorptive sites as defined by the presence of TRAP+ osteoclasts while the IGF-1R+ cells are evenly distributed in the bone marrow, indicating that IGF-1 is released during osteoclastic bone resorption.

To demonstrate that IGF-1 induces osteoblast differentiation of the recruited MSCs at bone resorptive sites, GFP-labeled Sca-1+ MSCs isolated from either Igf-1r-/- mice or their WT littermates were injected in the femoral cavity of immunodeficient Rag2-/- mice. The injected MSCs in the femur were co-immunostained for GFP and osteocalcin. IGF-1R WT-derived GFP-labeled MSCs were found to be osteocalcin+ at bone surfaces whereas Igf-1r-/- derived MSCs were rarely positive for osteocalcin two weeks after injection, indicating IGF-1 is essential for differentiation of the recruited MSCs. The Igf-1r-/- mice exhibited low bone mass and reduced mineral apposition rates. The CFUs of Igf-1r-/- mice was equivalent to their WT littermates, but the CFU-Obs decreased, indicating the osteogenic potential of the MSCs is reduced in Igf-1r-/- mice. We then crossed the floxed IGF-1R mice with Osteix-Cre:GFP mice to generate IGF-1R knockout mice in which IGF-1R was specifically deleted in the osteoblast-expressing cells and labeled with expression of GFP. The IGF-1R-deficient osteoprogenitors were GFP+ and primarily found at the bone surface, but not osteocalcin+, indicating release of IGF-1 from bone matrix is essential for osteoblast differentiation of MSCs. Collectively, IGF-1 released from the bone matrix stimulates osteoblast differentiation of MSCs for new bone formation in each remodeling cycle to maintain bone mass.

Parathyroid Hormone-related Peptide (PTHrP) Inhibits Chondrocyte Hypertrophy by Stimulating Actions of Histone Deacetylase (HDAC) 4. Shigeki Nishimori^{*1}, Forest Lai¹, Elena Kozhemyakina², Eric Olson³, Andrew B. Lassar², Henry Kronenberg¹. ¹Massachusetts General Hospital, USA, ²Department of Biological Chemistry & Molecular Pharmacology, Harvard Medical School, USA, ³UT Southwestern Medical Center At Dallas Department of Molecular Biology, USA

Both PTHrP and HDAC4 inhibit chondrocyte hypertrophy, but it has been unknown whether they work in a common pathway. A recent report from Lassar's group used chick primary chondrocytes and a chondrocyte cell line *in vitro* to show that PTHrP, through activation of protein phosphatase 2, leads to HDAC4 inhibition of myocyte enhancer factor 2C (MEF2C), the master transcriptional regulator of chondrocyte hypertrophy (MCB, 2009). Here we report *in vivo* studies that support this hypothesis.

The HDAC4 knockout (KO) mouse has a phenotype that resembles that of the PTHrP KO mouse, with shortening of the distance from the top of the growth plate to the start of the hypertrophic region. To demonstrate that PTHrP and HDAC4 share a common pathway that slows chondrocyte hypertrophy, the phenotype of double heterozygous (het) mice was determined in the tibial growth plate. Neither the HDAC4 het mouse nor the PTHrP het mouse differs from wild type (WT) in growth cartilage. If PTHrP and HDAC4 work independently, then the double het mice should also show no phenotype. In contrast, the PTHrP and HDAC4 double het mouse has growth plates with a phenotype similar to that of the individual knockout mice,

though considerably less severe. This phenotype demonstrates that PTHrP and HDAC4 must work through a common pathway.

To determine how much PTHrP's action is dependent on the HDAC4 pathway, we examined the effect of the HDAC4 knockout on the phenotype of mice overexpressing PTHrP in the growth plate through transgenic (Tg) expression of PTHrP driven by the collagen 2 (Col2) promoter. The Col2-PTHrP-Tg mice have short limbs caused by delayed chondrocyte maturation (Weir, et al, PNAS, 1996). Their long bones are 50% shorter than those of WT at birth, and the long bones are composed of only round chondrocytes until one week after birth. Interestingly, the Col2-PTHrP Tg phenotype is reversed in the HDAC4-KO;Col2-PTHrP-Tg mice. These mice have tibiae considerably longer than those of the Col2-PTHrP Tg mice and closely resemble the HDAC4 KO mice, except that they have a longer hypertrophic layer (about 3-times longer than the HDAC4 KO or WT at birth). Even heterozygosity for HDAC4 partially reverses the Col2-PTHrP Tg phenotype; these mice have longer bones than the Col2-PTHrP Tg, as well as flat and hypertrophic chondrocytes. These results are consistent with the idea that HDAC4 is a major effector in the PTHrP signaling pathway.

Erg and PTHrP Genetically Cooperate to Maintain Articular Cartilage Long-term Function. Yoichi Ohta^{*1}, Takahiro Okabe², Shuji Asai³, Motomi Enomoto-Iwamoto³, Maurizio Pacifici⁴, Masahiro Iwamoto⁵.

¹Translational Research Program in Pediatric Orthopaedics, Division of Orthopaedic Surgery, Department of Surgery, The Children's Hospital of Philadelphia Research Institute, USA, ²Department of Orthopaedic Surgery, Osaka city University, Graduate school of Medicine, Japan, ³The Children's Hospital of Philadelphia Research Institute, USA, ⁴Children's Hospital of Philadelphia, USA, ⁵The Children's Hospital of Philadelphia, USA

During embryogenesis, chondrocytes located at the epiphyseal ends of long bone anlagen acquire a permanent articular phenotype, while those located in the shaft become organized in growth plates, undergo maturation and hypertrophy and are replaced by bone. The mechanisms regulating such critical developmental bifurcation remain unclear. Previously we showed that the ets transcription factor member Erg is preferentially expressed in developing articular cartilage and that transgenic over-expression of Erg in the embryonic skeleton suppresses chondrocyte maturation and ossification and maintains all the chondrocytes in an immature articular-like phenotype. To further analyze the roles of Erg in articular cartilage formation, we generated a floxed Erg mouse line and conditionally ablated the gene in developing joints by mating with Gdf5-Cre mice. The mutant mice did not exhibit major developmental abnormalities and appeared normal in size and general appearance postnatally. Interestingly, however, the mice exhibited signs of osteoarthritis (OA) with aging compared to age-matched controls. Developing joints are also known to express parathyroid hormone-related protein (PTHrP) that actually shares the ability with Erg to suppress chondrocyte maturation; in addition, Erg and PTHrP are often co-expressed as recent transcriptome analyses revealed. Thus, we asked whether Erg regulates PTHrP expression and whether the two factors functionally cooperate in articular chondrocytes. Adenovirus-driven over-expression of Erg in cultured chondrocytes up-regulated PTHrP expression, while siRNA inhibition of Erg strongly suppressed PTHrP expression in explant mouse limbs. In addition, Erg over-expression increased the activity of a PTHrP P2 promoter reporter, the main PTHrP promoter in cartilage and, interestingly, such increase was largely abolished when a conserved ets binding site in the promoter was mutated. Lastly, we subjected 2 month-old conditional Erg^{-/-} mice in PTHrP^{+/+} background to surgically-induced OA model and found that they exhibited OA-like defects sooner than conditional Erg^{-/-} littermates. In conclusion, the data indicate that Erg is required for long-term maintenance of permanent articular cartilage and genetically cooperates with PTHrP to exert such critical role.

The Heparin Binding Domain of IGFBP-2 is an Important Regulator of Murine Hematopoiesis and Human Stem Cell Proliferation. Anne Breggia^{*1}, Casey Doucette², Masanobu Kawai¹, David Clemmons³, Clifford Rosen¹.

¹Maine Medical Center, USA, ²Maine Medical Center Research Institute, USA, ³University of North Carolina, USA

IGFBP2 (BP2) is one of 6 IGF binding proteins that shuttles IGFs to their respective receptors. BP2 is expressed at high levels in marrow stromal cells as well as osteoblasts, and is regulated by PTH. Global deletion of BP2 results in small spleens, very low bone formation, impaired bone resorption and increased marrow adiposity. We have demonstrated BP2 null males also have a hematopoietic phenotype in which there are increased percentages of both lymphoid and myeloid subpopulations in the peripheral blood. Both the low bone phenotype and hematopoietic phenotype are rescued by non competitive bone marrow transplantation of WT donor cells. However, donor cells obtained from BP2^{-/-} male mice inefficiently engraft in the marrow of wild type (WT) recipients. We have synthesized a peptide that contains the

sequence of a unique heparin binding domain (HBD) within IGFBP-2 that increases bone density of metacarpal explants and rescues dysregulated hematopoiesis in vivo in BP2^{-/-} mice. In this study, we tested the ability of the peptide to 1) improve engraftment of BP2^{-/-} donor cells in vivo and 2) increase proliferation of human hematopoietic stem cells in vitro. Bone marrow donor cells from BP2^{-/-} male mice were transplanted into lethally irradiated LY5.1 WT recipients. Recipient mice received IP injections of HBD, scrambled control peptide (50ug of each) or PBS on the day of transplant and every other day for 2 weeks. At 8 weeks post transplant, the HBD caused a significant decrease in CD19+ B cells (p=0.005) and a significant increase in CD3+ T cells (0.05) compared to both scrambled peptide and PBS controls. In vitro, HBD significantly expanded human CD34+ hematopoietic stem cells as compared to scrambled peptide and no-treatment controls (p≤0.002). Flow cytometric analysis demonstrated the majority of HSC treated with the HBD remained undifferentiated after 7 days in culture as ≥72% of the cells were positive for the stem cell marker CD34. We have identified a putative receptor present on both osteoblasts and human HSC to which the HBD binds. Future investigations will determine if this receptor-ligand interaction is responsible for HBD-induced HSC expansion and increased bone density and identify signaling events downstream of receptor-HBD ligand binding. Taken together these data demonstrate that IGFBP2 is a potent regulator of hematopoiesis and may specifically control stem cell fate in an IGF binding independent manner within the marrow niche.

BMP4 Regulates the Hematopoietic Stem Cell Niche Size in Bone Marrow. Kunikazu Tsuji^{*}, Ichiro Sekiya, Takeshi Muneta. Tokyo Medical & Dental University, Japan

BMP4 (Bone morphogenetic protein 4) signal has critical roles in inducing hematopoietic tissues during embryogenesis. However, evaluating the importance of BMP4 in bone marrow hematopoiesis is complicated by early embryonic lethality in mice lacking BMP4, and by conservation of signaling pathways for osteogenic BMPs. To overcome these limitations and to define the roles of BMP4 in bone marrow hematopoiesis, we established BMP4 conditional knockout mice in which we inactivated BMP4 in adult bone marrow (Bmp4Mx1cre). Here we report that the loss of BMP4 in bone marrow cells significantly reduced the hematopoietic stem cell population. BMP4 gene was knocked-out by the intraperitoneal injection of poly I:C into Bmp4Mx1cre mice at 6 weeks of age. Six to 8 weeks after the injection (after inducing the genomic recombination), total bone marrow cells were isolated from femurs and tibiae, stained by hematopoietic cell surface markers, and analyzed by a flow-cytometry (BD FACS Calibur). We found that the populations of differentiated blood cells such as Erythrocytes (Ter119+), T-cells (CD3+), B-cells (CD19+), and Monocytes/Macrophages (CD11b+) were not significantly altered in the absence of BMP4. However, the hematopoietic stem cell fraction (Lin⁻, c-Kit⁺, Sca-1⁺) was significantly decreased in Bmp4Mx1cre mice. These results are specific for the loss of BMP4, because we did not observe any alteration in hematopoietic cell population in the absence of BMP7 (Bmp7Mx1cre). We also did not observe any synergistic effect in the regulation of hematopoietic stem cell population in the co-absence of BMP4 and BMP7 (Bmp4/7Mx1cre). These results suggest that the unique and important roles of BMP4 in the regulation of hematopoietic stem cell niche size in adult bone marrow.

Caspase-1 Activity is Required for Cleavage of Bone Morphogenetic Protein Receptor Type Ia and its Translocation into the Nucleus to Induce Adipogenesis. Oleksandra Moseychuk^{*}, Jeremy Bonor, Hemanth Akkiraju, Anja Nohe. University of Delaware, USA

Therapeutics that increase the number of osteoblasts and reduce the number of adipocytes in the bone marrow would be beneficial for the treatment of osteoporosis. Bone Morphogenetic Protein 2 (BMP2) is a key growth factor that drives both adipogenesis and osteogenesis. BMP2 is FDA approved for spinal fusions, complicated cases of open tibial shaft fractures, and tibial nonunions. One of the drawbacks of BMP2 is the varying responses seen with patients; this could be due to its ability to drive adipogenesis and osteogenesis. We recently identified Casein Kinase II (CK2) as a BMP receptor type Ia (BMPRIa) interacting protein at three potential sites. The release of CK2 induces mineralization in vitro, however its potential role in adipogenesis is unknown. Mutants of BMPRIa lacking the CK2 phosphorylation sites were created. The effect of overexpression of these mutants on osteoblast differentiation and adipogenesis was determined by von Kossa and Oil Red O staining. We also blocked this interaction between BMPRIa and CK2 using peptides or siRNA to downregulate CK2. Our data revealed that the different CK2 phosphorylation sites regulate either adipogenesis and/or osteogenesis. The mechanism of adipogenesis compared to osteogenesis is mediated by a Caspase-1 cleavage site between two of the CK2 binding sites. Our data indicate that CK2 release leads to Caspase-1 cleavage of the BMPRIa and translocation of a segment of BMPRIa together with peroxisome proliferator-activated receptor gamma (PPARγ) into the nucleus as measured by confocal microscopy. In conclusion our data reveal a new mechanism of BMP2 mediated adipogenesis in which a segment of BMPRIa translocates into the nucleus. Moreover, we demonstrated that Caspase-1 is a key

player in osteoblast and adipocyte differentiation and is regulated by CK2 as a key switch in stem cell differentiation.

Parathyroid Hormone 1-84 Accelerates Fracture Healing in Pubic Bones of Elderly Osteoporotic Women. Gerold Holzer^{*1}, PETER PEICHL², Lukas Holzer¹, Richard maier³. ¹Medical University of Vienna, Austria, ²EVANGELISCHES KRANKENHAUS VIENNA, Austria, ³Thermenklinikum, Austria

Background: Parathyroid hormone (PTH) was shown to increase BMD and reduce the risk of fractures in patients with osteoporosis. A few studies also tested the ability of PTH to improve fracture healing. Pelvic fractures due to osteoporosis are less frequent, but require a longer healing period with immobilisation. The effect of PTH 1-84 on the course of fracture healing and functional outcome was tested prospectively in postmenopausal women receiving PTH 1-84 for the treatment of osteoporosis and conservatively treated pelvic fractures without requiring surgery.

Methods: Six-five patients (mean age: 82.8 years) had plain x-rays and a computer tomography (CT) scan to verify fractures and were scanned for osteoporosis. Twenty-one patients received a once daily injection of 100µg PTH 1-84 starting within two days after admission to the hospital. Forty-four patients without PTH treatment served as a control group. All patients received 1000 mg Calcium and 800 IU Vitamin D. CT scans were repeated every fourth week until radiographic evidence of cortical bridging was confirmed. Functional outcome was assessed using a pain Visual Analogue Scale (VAS) and a Timed Up and Go (TUG) test.

Results: In all 21 patients treated with PTH 1-84 pelvic fractures were healed at a mean of 7.8 weeks, whereas in patients with no PTH treatment fractures had healed after 12.6 weeks ($p < 0.001$). At week 8 all fractures in the treatment group were healed and four fractures in the control group (healing rate 100% versus 9.1%; ($p < 0.001$). Both the VAS and TUG improved statistically significant ($p < 0.001$) compared to control.

Conclusions: In elderly patients with osteoporosis, PTH 1-84 accelerates fracture healing in pelvic fractures and improves functional outcome.

Increased Trabecular Tissue Mineral Density Partially Explains the Improvement in Trabecular Volumetric BMD in Premenopausal Women with Idiopathic Osteoporosis Treated with Teriparatide. Xiaowei Liu^{*1}, Adi Cohen², Emily Stein¹, David Dempster³, Hua Zhou⁴, Joan Lappe⁵, Robert Recker⁵, Polly Chen³, Donald McMahon¹, Elizabeth Shane¹. ¹Columbia University College of Physicians & Surgeons, USA, ²Columbia University Medical Center, USA, ³Columbia University, USA, ⁴Helen Hayes Hospital, USA, ⁵Creighton University Osteoporosis Research Center, USA

We have reported that premenopausal women (PreM) with idiopathic osteoporosis (IOP) have decreased volumetric BMD (vBMD), abnormal trabecular (Tb) microstructure and reduced bone stiffness. The degree of tissue mineralization, or tissue mineral density (TMD), is known to influence BMD and affect tissue-level mechanical properties. In this study, we investigated Tb TMD in PreM IOP and its response to Teriparatide (TPTD) treatment. We hypothesized that PreM IOP is associated with lower Tb TMD and that both Tb vBMD and Tb TMD would increase in response to TPTD.

High resolution peripheral quantitative CT (HRpQCT) of the distal radius (DR) and tibia (DT) was performed in 18 PreM with IOP (age 41.5 yrs) at baseline and after 12-18 months (M) of TPTD (20 mcg daily). By digital topological analysis, we classified Tb bone voxels as belonging to one of 3 envelopes: surface Tb bone, central Tb bone and intervening (middle) Tb bone occupying the envelope between surface and central Tb bone (Fig 1). TMD was calculated for surface (sTMD), central (cTMD), and middle (mTMD) envelopes. TMD increased from surface to center of trabeculae: cTMD was higher than mTMD (by 7.12.5% and 8.42.3% at DR and DT; $p < 0.001$), and mTMD was higher than sTMD (by 14.41.2% and 16.41.2% at DR and DT; $p < 0.001$). Compared to 18 PreM controls (396 yrs), PreM with IOP had 2.1% lower sTMD at DR ($p = 0.02$) and 1.4% lower sTMD at DT ($p = 0.06$).

After 12-18M of TPTD, lumbar spine (LS) BMD increased by 9.73.3% ($p < 0.05$). Tb vBMD increased by 5.28.3% at the DT and 2.32.7% at the DR (both $p < 0.05$). At the DR, sTMD increased by 0.740.99% ($p < 0.01$) while mTMD and cTMD did not change. At the DT, sTMD and mTMD increased by 0.770.75% ($p < 0.001$) and 0.631.03% ($p = 0.02$) and cTMD tended to increase by 0.541.1% ($p = 0.07$). At the DT, % change in TMD correlated with % change in vBMD: sTMD $r = 0.49$ and cTMD $r = 0.47$, $p < 0.05$; mTMD $r = 0.44$, $p = 0.08$. Moreover, % change in DT cTMD tended to correlate with % change in LS BMD ($r = 0.45$, $p = 0.07$). In addition, there was a direct, though non-significant association between cTMD and bone formation rate/bone surface on transiliac biopsy ($r = 0.40$, $p = 0.11$). In contrast, % change in DR TMD did not correlate with % change in LS BMD, vBMD or biopsy parameters.

In conclusion, PreM IOP is associated with lower Tb TMD. There were significant increases in Tb TMD measured on HRpQCT scans of the DT in PreM with IOP treated with TPTD that were associated with improved Tb vBMD.

Figure 1. Classifications of surface Tb bone (sTMD), central Tb bone (cTMD) and intervening Tb bone (mTMD) occupying the envelope between surface and central Tb bone.

Effect of Weekly Teriparatide in Patients with Osteoporosis. Toshitaka Nakamura^{*1}, Toshitsugu Sugimoto², Tetsuo Nakano³, Hideaki Kishimoto⁴, Masako Ito⁵, Masao Fukunaga⁶, Hiroshi Hagino⁷, Teruki Sone⁶, Hideki Yoshikawa⁸, Yoshiki Nishizawa⁹, Masataka Shiraki¹⁰. ¹University of Occupational & Environmental Health, Japan, ²Shimane University School of Medicine, Japan, ³Tamana Central Hospital, Japan, ⁴San-in Rosai Hospital, Japan, ⁵Nagasaki University Hospital, Japan, ⁶Kawasaki Medical School, Japan, ⁷Tottori University, Japan, ⁸Osaka University Graduate School of Medicine, Japan, ⁹Osaka City University Medical School, Japan, ¹⁰Research Institute & Practice for Involuntal Diseases, Japan

Introduction: Daily teriparatide (human parathyroid hormone 1-34) injection is effective in reducing fracture risk and increasing BMD. However, the effect of weekly subcutaneous injection of teriparatide on fracture risk has not been tested.

Methods: To examine the anti-fracture efficacy and safety of weekly subcutaneous injection of 200 units of teriparatide (56.5 µg) in Japanese patients (65-95 years old) with primary osteoporosis, a randomized, double-blind, placebo-controlled trial was conducted in 578 patients with 1-5 prevalent vertebral fractures and low BMD (L2-4 BMD $< 80\%$ of young adult mean). Patients were randomly assigned to receive weekly teriparatide injection ($n = 290$; 13 men) or placebo ($n = 288$; 10 men) for 72 weeks, with daily supplements of calcium 610 mg and vitamin D 400 IU. The primary endpoint was new vertebral fractures.

Results: As compared with placebo, teriparatide reduced the risk of new vertebral fractures, with a cumulative incidence of 3.1% in the teriparatide group, versus 14.5% in the placebo group ($p < 0.0001$), and a relative risk reduction of 79.9% (95% confidence interval, 54.7-91.1%). BMD increases at 72 weeks were significant in the teriparatide group compared to the placebo group (L2-L4: 6.7% vs. 0.3%, $P < 0.0001$; total hip: 3.1% vs. 0.1%, $P < 0.000$). Serum osteocalcin increased and urinary NTX decreased in the teriparatide group. Transient headache, malaise and nausea after injection were more frequent in the teriparatide group than in the placebo group, but were generally mild and tolerable.

Conclusion: Weekly injection of teriparatide (56.5 µg) is safe and effective in reducing vertebral fracture in patients with primary osteoporosis with prevalent vertebral fracture.

Teriparatide for Premenopausal Women with Idiopathic Osteoporosis: A Paired Transiliac Bone Biopsy Study. Adi Cohen^{*1}, Emily Stein², David Dempster³, Robert Recker⁴, Joan Lappe⁴, Hua Zhou⁵, Thomas Nickolas¹, Alexander Zwahlen⁶, Thomas Kohler⁶, Ralph Muller⁶, Polly Chen³, Kavita Pandit³, Elizabeth Shane². ¹Columbia University Medical Center, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University, USA, ⁴Creighton University Osteoporosis Research Center, USA, ⁵Helen Hayes Hospital, USA, ⁶ETH Zurich, Switzerland

Idiopathic osteoporosis (IOP) in premenopausal women is an uncommon disorder of uncertain pathogenesis in which fragility fractures and/or low bone mineral density (BMD) occur in otherwise healthy women with intact gonadal function. Transiliac bone biopsies (BX) have revealed thinner cortices, fewer, thinner, more widely separated, and heterogeneously distributed trabeculae, and reduced stiffness in women with IOP compared to controls. Although dynamic histomorphometric remodeling parameters were heterogeneous and did not differ between subjects and controls, subsets of women with IOP had low or high bone turnover assessed by bone formation rate/bone surface (BFR/BS). We hypothesized that teriparatide (TPTD), an agent that directly increases osteoblast activity, would improve BMD by DXA, trabecular (Tb) bone volume fraction (BV/TV), and bone microarchitecture in women with IOP. In an open-label pilot study of 22 premenopausal women with IOP treated with TPTD 20 mcg SC daily, lumbar spine (LS) BMD increased from baseline by 9.73.3% (SD; p<0.05) by 18 months and also increased at the total hip and femoral neck (data not shown). Herein, we report interim paired transiliac BX results (baseline and 18 months) from the first 11 subjects. BXs were analyzed by 3D micro-computed tomography (μ CT) and 2D histomorphometry (2DH). By μ CT (Table), there was a 38% increase in BV/TV, a 19% increase in Tb number, a 9% decrease in Tb separation (all p<0.01), and no change in Tb thickness; comparable effects were observed with 2DH (data not shown). By 2DH, cortical (Ct) area increased by 57%, Ct porosity by 58%, and there was a non-significant 12% increase in Ct width. Wall width (W.Wi) of completed osteons, a static parameter that reflects the amount of bone synthesized by osteoblasts, increased significantly by 14%. However, dynamic remodeling parameters did not differ from baseline. In summary, after 18 months of TPTD, there were significant increases in Tb BV/TV and Tb number, decreased Tb separation, increased cortical area and porosity. There was an increase in W.Wi, but no differences in dynamic remodeling parameters. We conclude that TPTD improves both BMD and Tb microarchitecture at the iliac crest in premenopausal women with IOP. These changes likely reflect earlier increases in bone formation rate that have returned to baseline after 18 months of TPTD.

Taylor¹⁴. ¹Regional Bone Center, Helen Hayes Hospital, USA, ²School of Medicine, Creighton University, USA, ³Groupe de recherche en maladies osseuses, Laval University, Canada, ⁴Bethesda Health Research, USA, ⁵United Osteoporosis Center, USA, ⁶Prohealth Clinical Research, Canada, ⁷New Mexico Clinical Research & Osteoporosis Center, USA, ⁸Heritage Medical Research Clinic, Canada, ⁹Henry Ford Hospital, USA, ¹⁰Colorado Center for Bone Research, USA, ¹¹Atlanta Research Center, USA, ¹²University of Wisconsin, USA, ¹³Eli Lilly & Company, USA, ¹⁴Lilly USA, LLC, USA, ¹⁵Eli Lilly Canada Inc., Canada

Purpose: Mechanisms of action (MOA) of bone active drugs are often investigated by histomorphometric analysis of bone biopsies. Standard conventions have been developed to assess a panel of tetracycline-based, dynamic parameters of bone formation to demonstrate whether a drug is anabolic or antiresorptive. Recent studies

on the MOA of osteoporosis drugs have rekindled interest in how to present and interpret dynamic histomorphometric parameters. This cross-sectional biopsy study compared the effects of an established anabolic agent, teriparatide (TPTD), with those of a prototypical antiresorptive agent, zoledronic acid (ZOL).

Methods: This randomized, double-blind, active comparator-controlled study compared histomorphometric parameters of bone remodeling in postmenopausal women with osteoporosis receiving ZOL (5 mg/y IV infusion) or TPTD (20 μ g/d SC injection). Transiliac crest bone biopsies were obtained after double tetracycline labeling from 58 subjects. The primary endpoint, cancellous mineralizing surface/bone surface (MS/BS), and a standard panel of cancellous histomorphometric indices were assessed at month 6.

Results: Dynamic indices of bone formation, including MS/BS and bone formation rate (BFR), were significantly higher in the TPTD group (Table). Mineral apposition rate (MAR) was significantly greater with TPTD than ZOL regardless of whether values for samples containing only single labels were imputed or treated as missing. However, when MAR was calculated using only double labels, fewer double labels were available for analysis in the ZOL group (53%) than in the TPTD group (100%). Also, 40% of the ZOL subjects had no detectable tetracycline labels compared to 0% in the TPTD arm. The lower BFR in the ZOL group was primarily due to the lower MS/BS rather than to the small differences in MAR, regardless of how MAR was calculated. ZOL decreased serum markers of bone formation and resorption (P1NP, OC and CTX), while TPTD increased these markers, further supporting mechanistic differences observed by histomorphometric analysis.

Conclusions: TPTD and ZOL possess fundamentally different MOAs with opposite effects on bone formation based on data that evaluated a full panel of histomorphometric indices. An important mechanistic difference between these 2 drugs was the substantially higher MS/BS in the TPTD group. These results define the dynamic histomorphometric characteristics of anabolic versus antiresorptive activity in these 2 drug classes.

Table. Dynamic Indices of Bone Formation in Postmenopausal Women

Cancellous	TPTD (n = 28)	ZOL (n = 30)	P Value
MS/BS, %	5.60 (3.00, 11.73)* (n=28)	0.16 (0.00, 0.58)* (n=30)	<0.001
MAR (1), μ m/d	0.50 (0.48, 0.62)* (n=28)	0.50 (0.48, 0.52)* (n=16)	0.03
MAR (2), μ m/d	0.56 (0.48, 0.62)* (n=28)	0.49 (0.37, 0.51)* (n=18)	0.009
BFR/BS (1), mm ³ /mm ² /y	0.0116 (0.0051, 0.0265)* (n=28)	0.0009 (0.0003, 0.0012)* (n=16)	<0.001
BFR/BS (2), mm ³ /mm ² /y	0.0116 (0.0051, 0.0265)* (n=28)	0.0008 (0.0003, 0.0011)* (n=18)	<0.001
Number of samples (%) with the following:			
Double Label			
With Single Label	28 (100%)	13 (43.33%)	NA
Without Single Label	0 (0%)	3 (10.00%)	NA
Single Label Only	0 (0%)	2 (6.67%)	NA
No Label	0 (0%)	12 (40.00%)	0.0001

*Values shown are medians (interquartile range).

BFR/BS=bone formation rate bone surface; MAR=mineral apposition rate; MS/BS=mineralizing surface/bone surface; NA=not applicable; TPTD=teriparatide 20 μ g/d subcutaneous injection; ZOL=zoledronic acid 5 mg/y intravenous infusion.

MAR and BFR calculated using: (1) double labels only; (2) double labels plus an imputed value of MAR=0.3 μ m/d in subjects with single labels only.

Statistical analyses were conducted at a 2-sided alpha level of 0.05 using Wilcoxon rank-sum test. Fisher's exact test was used to analyze the association between treatment groups and the presence or absence of label.

Increases in both Vertebral and Femoral Strength in Postmenopausal Osteoporotic Women after 18 months of Treatment with Teriparatide. Tony Keaveny^{*1}, David Kopperdahl², Valerie Ruff³, Xiaohai Wan⁴, Kelly Krohn⁵. ¹University of California, Berkeley, USA, ²O.N. Diagnostics, USA, ³LILLY USA, LLC, USA, ⁴Eli Lilly & Company, USA, ⁵Lilly USA, USA

Purpose: Finite element analysis of quantitative CT scans is one of the popular methods available in clinical studies for non-invasive assessment of vertebral and femoral bone strength. Since very few finite element data have been reported to date on changes in vertebral and femoral strength for patients treated with teriparatide [rhPTH (1-34)], the biomechanical effects of teriparatide treatment in postmenopausal women are not well understood. To address this issue, we used finite element analysis to analyze the effects of 18-month daily treatment of 20 μ g of teriparatide on both vertebral and proximal femoral strength in a new open-label study of 30 postmenopausal women with osteoporosis and related these changes in strength to changes in the underlying (volumetric) bone mineral density.

Methods: Quantitative CT of the lumbar spine and hip was obtained at baseline and 18 months (or early termination visit). All patients who had two evaluable CT scans at both time points were included in the analysis (n= 30 spine; n=26 hip). Density was measured for the trabecular, peripheral (outer 2–3 mm of bone that contained both cortical and some adjacent trabecular bone), and both (“integral”) compartments. Non-linear finite element analysis was performed for uniform compression for the spine and a sideways fall for the hip to provide measures of vertebral and femoral strength.

Results: We found statistically significant increases in both vertebral and femoral strength compared with baseline. For the spine this was accompanied by significant increases in both trabecular and peripheral densities and, for the hip, by a significant increase in the trabecular density and no change in the peripheral density (Table).

Conclusion: Both vertebral and femoral strength increased after 18 months of treatment with teriparatide compared to baseline.

FoxO1 is a Transcriptional Mediator of the Regulation of Bone Formation by Circulating Serotonin. Aruna Kode¹, Barbara Silva¹, Ioanna Mosialou¹, Charles Duncan¹, Tim M Townes², Rene Hen³, X.Edward Guo³, Stavroula Kousteni¹. ¹Columbia University Medical Center, USA, ²University of Alabama, USA, ³Columbia University, USA

Serotonin is a critical regulator of bone mass that fulfills different functions depending on its site of synthesis. Brain-derived serotonin acts as a neurotransmitter to promote osteoblast proliferation whereas duodenal-derived serotonin acts as a hormone suppressing osteoblast proliferation and bone formation. Hence, inhibiting duodenal-derived serotonin is a therapeutic target for the treatment of osteoporosis. To understand the molecular mechanisms of duodenal serotonin action on osteoblasts, we focused on the Forkhead transcription factor, FoxO1 for two reasons. First, in *C. elegans* the FoxO homolog mediates serotonin signaling in a wide spectrum of its physiological processes. Second, FoxO1 is a crucial regulator of several aspects of osteoblast biology. Using a combination of cell culture assays and mouse genetic experiments we observed that serotonin upregulates the activity of FoxO1 and the expression of FoxO1 transcriptional targets that control cell cycle. Moreover, serotonin failed to suppress osteoblast proliferation and *cyclin D1* and *D2* expression in FoxO1-deficient osteoblasts. Consistent with these results, removal of one allele of FoxO1 from *Lrp5*-deficient mice that harbor high circulating serotonin levels rescued their low bone mass phenotype by normalizing cell cycle gene expression and osteoblast proliferation. Further demonstrating that FoxO1 is a mediator of serotonin signaling, the high bone formation phenotype observed in mice lacking one allele of *Htr1b*, the predominantly expressed serotonin receptor in osteoblasts, was corrected by removing one allele of FoxO1 from osteoblasts in compound heterozygous (*Htr1b* +/-; FoxO1^{osb}/+) mice. Downstream of Htr1b, we identified CREB as the transcriptional partner that interacts with FoxO1 and regulates its activity in response to serotonin. CREB forms a functional complex with FoxO1 suppressing FoxO1 transcriptional activity. Upon treatment of cells with serotonin the FoxO1/CREB interaction is disrupted; this unleashes FoxO1 transcriptional activity resulting in suppression of *cyclin* gene expression and osteoblast proliferation. In agreement with these *in vitro* findings, removal of one allele of FoxO1 in mice haploinsufficient for FoxO1 and Creb (FoxO1^{osb}/+; Creb^{osb}/+) rescued the low bone mass phenotype of Creb knockout mice by increasing osteoblast proliferation. Collectively these findings identify FoxO1 as a crucial determinant of the anti-proliferative actions of gut-derived serotonin in osteoblasts.

Dkk1 Inhibition Promotes Bone Formation in Growing, but Not in Aged Osteopenic Rats. William G. Richards¹, Mario Grisanti², Denise Dwyer¹, Qing-Tian Niu¹, Franklin Asuncion², Marina Stolina³, Michael Ominsky², Xiaodong Li⁴. ¹Amgen Inc., USA, ²Amgen, Incorporated, USA, ³Amgen Inc, USA, ⁴Amgen, Inc., USA

Initial discoveries in individuals with osteoporosis-psuedoglioma syndrome and high bone mass that identified loss-of-function and gain-of-function mutations respectively in the Wnt co-receptor LRP5 led to the well appreciated role of the Wnt signaling pathway in bone. The contribution of various members of this complex signaling pathway to bone physiology continues to be elucidated. Towards that end we studied the role of Dickkopf-1 (Dkk1) during postnatal bone growth and in estrogen-deficient rats by utilizing an antibody to Dkk1 (Dkk1-Ab) that blocked the Wnt inhibitory activity of Dkk1.

Four-week old female Sprague Dawley rats were treated with Dkk1-Ab (30 mg/kg 2X/wk) or PTH 1-34 (100 µg/kg 5X/wk) for four weeks. Dkk1-Ab treatment resulted in a significant (P<0.001) increase in lumbar (L1-L5) BMD compared to vehicle treated young rats (0.144 vs. 0.126 g/cm²). Significant increases in trabecular BV/TV (30.21.5 vs. 21.72.3%), Tb.N (4.40.1 vs. 3.50.3); Ob.S/BS (6.21.0 vs 1.30.4%) and BFR/TV (113.411.3 vs. 70.610.4%/year) were observed at distal femur in Dkk1-Ab treated

compared to vehicle treated young rats. Cortical area (4.380.17 vs. 3.690.08mm²) and thickness (0.550.03 vs. 0.460.01mm) at the femur midshaft were both significantly increased by Dkk1-Ab treatment.

In contrast, treatment of adult ovariectomized Sprague Dawley rats (8-month old, 2-months post-OVX) with Dkk1-Ab (5 or 25 mg/kg 2X/wk) for four weeks did not appreciably impact BMD and histomorphometric parameters at either trabecular or cortical sites; the positive control PTH significantly impacted a number of these parameters. Additional studies in aged OVX rats confirmed these findings. Serum and bone tissue samples were collected from rats at various ages to determine whether changes in Dkk1 expression could account for differences in efficacy observed between young and adult rodents treated with Dkk1-Ab. Serum Dkk1 levels declined as rats age. Bone Dkk1 protein levels decreased significantly between 3 and 6 months of age, and remained low at 12 months.

The divergent effects of Dkk1-Ab on growing and adult bone were attributed to decreased Dkk1 expression in serum and bone of older rats. These data suggest that, while Dkk1 significantly regulates bone formation in younger animals, its role in older animals is limited to pathologies that lead to the induction of Dkk1 expression in bone and/or serum, such as multiple myeloma, inflammation and or traumatic injury.

Sclerostin Inhibition Prevents Low Bone Mass Associated with Type 2 Diabetes Mellitus in Rats. Christine Hamann¹, Yvonne Hoehna¹, Martina Rauner², Claudia Goettsch³, Klaus-Peter Guenther¹, Michael Ominsky⁴, Lorenz Hofbauer¹. ¹Dresden University Medical Center, Germany, ²Medical Faculty of the TU Dresden, Germany, ³Brigham & Women's Hospital/Cardiovascular Division, USA, ⁴Amgen, Incorporated, USA

The pathogenesis of low bone mass in diabetes mellitus is poorly defined and efficient therapies are limited. The Zucker Diabetic Fatty (ZDF) rats, an established rodent model of diet-induced type 2 diabetes mellitus, have low bone mass characterized by impaired osteoblastogenesis *in vitro*. We tested whether antibodies directed against sclerostin (Scl-Ab), a soluble inhibitor of Wnts and osteoblasts, could reverse diabetes-induced low bone mass in this rat model. Saline or 25 mg/kg Scl-Ab was administered S.C. twice weekly to 9-week old non-diabetic (+/+) and diabetic (fa/fa) ZDF rats for 12 weeks, and terminal BMD was assessed by pQCT. At 21-weeks of age, diabetic rats had significantly lower total BMD at the distal femur and the lumbar vertebra compared to non-diabetic rats (Table 1). At the distal femur, total, trabecular, and cortical/subcortical BMD were 22%, 63%, and 12% lower, respectively, in rats with diabetes. At the femoral shaft, cortical thickness was 15% lower in diabetic rats. At the fourth lumbar vertebra, total (-18%), trabecular (-44%), and cortical/subcortical BMD (-9%) were significantly lower in diabetic rats compared to non-diabetic rats. Scl-Ab treatment in diabetic rats resulted in increased BMD at the distal femur (total BMD +59%, trabecular BMD by 4-fold and cortical/subcortical BMD +27%), at the femoral shaft (cortical thickness +31%) and at the lumbar spine (total BMD +86%, trabecular BMD by 3-fold and cortical/subcortical BMD +39%) compared to saline controls (Table 1). The relative increase in BMD parameters with sclerostin inhibition was comparable in diabetic and non-diabetic animals. All BMD parameters of diabetic rats receiving sclerostin antibodies were significantly higher than those of non-diabetic rats treated with saline control. Treatment with sclerostin antibody was not associated with changes of renal function and serum levels of glucose, calcium, and phosphate in diabetic and non-diabetic animals after 21 weeks. In conclusion, sclerostin inhibition can fully reverse the adverse effects of type 2 diabetes mellitus on bone mass in rats.

Table 1

Parameter	Non-diabetic		Diabetic	
	Saline	Sclerostin Ab	Saline	Sclerostin Ab
L4 Vertebra Total BMD (mg/cm ³)	549 ± 10.8	852 ± 16.7*	449 ± 14.7	834 ± 22.5*
L4 Vertebra Trabecular BMD (mg/cm ³)	326 ± 24.4	800 ± 35.8*	183 ± 16.0	718 ± 42.6*
Distal Femur Total BMD (mg/cm ³)	571 ± 14.1	862 ± 7.30*	448 ± 10.9	712 ± 44.4*
Distal Femur Trabecular BMD (mg/cm ³)	244 ± 21.6	735 ± 28.4*	91.1 ± 14.2	434 ± 74.8*

Sclerostin Antibody Prevents Bone Loss and Increases Bone Formation in Female Rats with High Turnover due to Ovariectomy. Xiaodong Li^{1*}, Kelly S Warmington², Xue Chun Xia³, Aly A Williams³, Mario Grisanti², Qing-Tian Niu², Denise Dwyer², Marina Stolina⁴, Chris Paszty², Thomas Wronski³, Hua Zhu Ke². ¹Amgen, Inc., USA, ²Amgen Inc., USA, ³University of Florida, USA, ⁴Amgen Inc, USA

Purpose: Sclerostin inhibition by monoclonal antibody has been well studied in restoration studies in estrogen-deficient rodents with established osteopenia when bone turnover is relatively low (treatment). However, it has not been studied at the early stage of ovariectomy when bone turnover is relatively high (prevention). In this study, we examined the effects of sclerostin antibody (Scl-Ab) administration on bone in adult rats immediately following ovariectomy.

Methods: Six-month-old female SD rats were sham-operated or ovariectomized (OVX). Immediately after surgery, OVX rats were treated with vehicle or a ratized Scl-Ab (Scl-AbVI) at 25 mg/kg (2x/week, sc) for 6 weeks (12-13/group). Sham rats received vehicle (2x/week, sc) as controls.

Results: *In vivo* DXA measurements demonstrated progressive increases in areal BMD at the lumbar spine and femur-tibia regions in the Scl-Ab group. The percent increases from baseline in lumbar spine BMD in the Scl-Ab group were 11%, 21%, and 32% at weeks 2, 4, and 6, respectively, whereas OVX controls lost 6.5% in lumbar spine BMD at week 6. Histomorphometric analysis at the distal femoral metaphysis demonstrated that Scl-Ab increased trabecular bone volume (BV/TV) to a level that was significantly greater than Sham controls (Table 1). The increase in BV/TV was primarily due to increased trabecular thickness. There was a 3.7-fold increase in trabecular bone formation rate (BFR/BS) in the Scl-Ab group compared with OVX controls, but osteoclast surface was similar between the two groups. Histomorphometric analysis at the tibial shaft showed significant increases in cortical thickness (+13.4% vs OVX) in the Scl-Ab group. Dynamic histomorphometric analysis at the tibial shaft revealed a marked increase in endocortical BFR/BS (+84-fold vs OVX) in the Scl-Ab group. Periosteal BFR/BS was almost doubled in the Scl-Ab group compared with OVX controls. OVX controls had a 4-fold increase in Ps.BFR/BS compared with the Sham group.

Conclusions: Sclerostin antibody treatment increased trabecular and cortical bone formation, increased trabecular and cortical bone mass, and improved trabecular architecture in rats with high turnover due to ovariectomy. These results suggest that sclerostin inhibition may be a promising therapeutic approach for preventing bone loss in the early stage of disease progression in postmenopausal osteoporosis.

Site	Endpoints	Sham-Vehicle (n=13)	OVX	
			Vehicle (n=12)	Scl-Ab 25 mg/kg (n=13)

Deletion of the Pro-Apoptotic Proteins Bax and Bak from Osteoblasts and Osteocytes Increases Bone Mass, and Retards the Loss of Cancellous Bone but Dramatically Accelerates Cortical Porosity in Aged Mice. Robert Jilka^{*}, Annick DeLoose, Leslie Climer, Stuart Berryhill, Charles O'Brien, Robert Weinstein, Stavros Manolagas, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

Delay or hastening of osteoblast apoptosis has been associated with changes in bone formation and bone mass, but a cause and effect relationship has not been established. Based on evidence that both Bax and Bak, proapoptotic Bcl-2 family members, are required for activation of the mitochondrial apoptosis cascade, we sought to establish a causal link between osteoblast/osteocyte apoptosis and bone homeostasis by generating mice lacking both Bax and Bak in osteoblasts and osteocytes (Bax/BakΔOb/Ot mice). This was accomplished by crossing Bak null mice bearing a floxed Bax gene with mice expressing Cre recombinase under the control of an osteocalcin (OCN) promoter. Bax

deletion was confirmed by qPCR of DNA from the femur. Femoral but not vertebral BMD of Bax/BakΔOb/Ot mice progressively increased from 3 to 12 mo of age, whereas it reached a plateau at 6 mo of age in Bak null or OCN-Cre control mice. At 8 mo of age, Bax/BakΔOb/Ot mice exhibited cancellous bone throughout the femoral diaphysis, whereas cancellous bone was present only in the metaphyses of control mice as determined by micro-CT. Further, cancellous bone volume and connectivity density were increased, and apoptotic osteocytes were reduced, in Bax/BakΔOb/Ot mice. Moreover, the loss of femoral and vertebral cancellous bone that occurred between 12 and 22 mo of age in control mice was attenuated in Bax/BakΔOb/Ot mice. Most strikingly, Bax/BakΔOb/Ot mice exhibited an age-related increase in femoral cortical bone porosity, characterized by the presence of cortical voids containing osteoclasts. Practically identical changes in cancellous bone mass and cortical porosity were observed in a second mouse model in which Bax and Bak were deleted from osteoblast progenitors using the Osterix promoter to drive Cre expression. These findings demonstrate that the apoptosis of cells of the osteoblast lineage, perhaps at all stages of lineage progression, is a critical determinant of their genesis and function, and thereby the formation and maintenance of cancellous bone. Moreover, they indicate that lifelong prevention of apoptosis produces dysfunctional cortical osteocytes that cause an increase in intracortical resorption. This mechanism is independent of Haversian architecture, which is absent in mice, and could be informative for the increased intracortical porosity and fracture risk associated with old age in human long bones (Zebaze et al, Lancet, 375:1729, 2010).

Inhibition of BMP Signaling Using RAP-661, a Soluble Form of BMPRIA, Increases Bone Mass in Ovariectomized Mice. Aaron Mulivor^{*}, Yoshimi Kawamoto, Ravi Kumar, Jasbir Seehra, R. Scott Pearsall, Nicolas Solban, Acceleron Pharma, USA

Bone Morphogenetic Proteins (BMPs) induce endochondral bone formation and regulate osteoblastogenesis and osteoclastogenesis. Recently, it was shown that targeted inactivation of the BMP2 receptor BMPRIA (ALK3) in osteoblasts causes an increase in bone formation. To investigate new therapeutic strategies for skeletal fragility indications, a soluble BMPRIA receptor-Fc fusion protein (RAP-661) was generated to inhibit BMP signaling through the endogenous receptor.

Eight week old C57BL/6 mice underwent ovariectomy (OVX) or SHAM surgery and were aged 12 weeks post-surgery to establish an osteopenic phenotype. Mice received either twice weekly injections of RAP-661 (10 mg/kg, IP), five injections per week of parathyroid hormone (PTH: 0.08 mg/kg, SC), one injection of Zoledronate (ZOL: 0.02 mg/kg, IP) or vehicle (PBS) for six weeks. DEXA and microCT were used to evaluate the effect of RAP-661 on bone.

DEXA measurements at 6 weeks revealed increases in total BMD of 12% (RAP-661), 9% (PTH), 8% (ZOL) and 1% (PBS) compared to baseline values measured at week 0 in SHAM operated mice. In OVX mice total BMD increases of 14% (RAP-661), 14% (PTH), 7% (ZOL) and 2% (PBS) were observed after 6 weeks.

MicroCT measurements of the tibia exhibited increased cortical thickness in SHAM mice of 17% (RAP-661), 10% (PTH) and 2% (ZOL) compared to PBS treated animals. In OVX mice increases in cortical thickness of 19% (RAP-661), 16% (PTH) and 1% (ZOL) were observed after 6 weeks. Similar increases were observed in trabecular bone volume of the proximal tibia.

Serum biomarker and bone histomorphometry analysis demonstrated RAP-661 treatment was both antiresorptive and anabolic. RAP-661 treatment increased OPG 56% ($p < 0.05$), BSALP 37% ($p < 0.01$), mineralizing surface 115% ($p < 0.05$), bone formation rate 80% ($p < 0.05$) and decreased RANKL 52% ($p < 0.05$), TRAP5b levels 67% ($p < 0.01$), eroded surface 36% ($p < 0.05$), and osteoclast surface 44% ($p < 0.05$) after 2 weeks of treatment.

These preclinical results demonstrate RAP-661 increases bone mass in normal and osteopenic mice to an extent comparable to or greater than approved anabolic or antiresorptive agents. Bone biomarker analysis suggests that RAP-661 leads to new bone formation by both inhibiting osteoclast activity and increasing osteoblast activity. Therefore, inhibition of BMP signaling using a soluble form of BMPRIA represents a promising new therapeutic approach for the treatment of bone loss.

Rosiglitazone Reduced BMD in Women with Type 2 Diabetes and the Effect was Attenuated After Switching to Metformin. John P. Bilezikian¹, Richard Eastell², Antonio J. Nino³, Allison R. Northcutt³, Barbara Kravitz³, Gitanjali Paul³, Alexander R. Cobitz³, Robert Josse⁴, Lorraine Fitzpatrick^{3*}. ¹Columbia University, College of Physicians & Surgeons, USA, ²University of Sheffield, United Kingdom, ³GlaxoSmithKline Pharmaceuticals, USA, ⁴University of Toronto, Canada

Postmenopausal women (PW) treated with rosiglitazone (RSG) are at increased risk of fracture. The aim of the study was to understand the mechanism of this risk. This was a double-blind, randomized study in PW with T2DM; BMD T-score >-2.5 at femoral neck (FN), lumbar spine (LS), total hip (TH). Subjects were randomized to RSG or metformin (MET) for 52 Weeks (Wk) followed by a 24Wk open-label MET phase. In RSG, BMD at FN decreased (-1.59%) from baseline (BL) to Wk52,

decreased less from Wk52 to Wk76 (RSG to MET; -0.27%), with an overall decrease (-2.05%) from BL to Wk76. Differences in percent change from BL between groups (RSG vs. MET) were significant at Wk52 ($p=0.0039$) and Wk76 ($p=0.0036$). In RSG, BMD at LS decreased (-1.60%) from BL to Wk52, increased (0.54%) from Wk52 to Wk76. Differences from BL at the LS between groups were significant at Wk52 ($p=0.0012$) and Wk76 ($p=0.0002$). In RSG, CTX and PINP increased (18.1% and (9.0%) respectively, and BSAP decreased (-12.3%) from BL to Wk52. Differences at Wk52 from baseline (RSG vs. MET) were statistically significant, CTX ($p=0.0123$), PINP and BSAP (both $p<0.0001$). CTX (-26.3%) and PINP (-12.1%) trended towards BL levels from Wk52 to Wk76. In RSG from BL to Wk52, there were decreases in integral (INT) and trabecular (TRB) vBMD at TH and TRB vBMD at LS. INT and TRB vBMD increased at TH and LS from Wk52 to Wk76 when subjects on RSG moved to open-label MET. The overall effect from BL to Wk76 was a loss in INT and TRB vBMD at TH and in TRB vBMD in LS. In RSG cortical (CRT) vBMD decreased at TH at Wk52 from BL and there was an increase in CRT vBMD from BL to Wk76. In MET from BL to Wk52, there were increases in INT and TRB vBMD at TH, and a decrease in TRB vBMD at LS. In MET INT vBMD decreased and TRB vBMD increased at TH, and TRB vBMD decreased at the LS from Wk52 to Wk76. CRT vBMD at TH increased modestly from BL to Wk76 in MET.

Adverse events were consistent with previous studies; 5 subjects in RSG and 1 in MET experienced a fracture.

Treatment for 52Wk with RSG resulted in bone loss at the FN and LS and increased bone turnover. Changes in aBMD were attenuated and vBMD trended towards BL levels upon switching RSG to MET, and bone markers reverted towards BL levels. These data suggest that an increase in bone turnover results in BMD loss and the effect is partially attenuated when RSG is switched to MET.

Undercarboxylated Osteocalcin does not Predict Development of Diabetes In older Adults In the Health, Aging and Body Composition Study. Ann Schwartz^{*1}, Caren Gundberg², Douglas Bauer¹, Susan Ewing¹, Eric Vittinghoff¹, Elsa Strotmeyer³, Kenneth Feingold¹, Patrick Garner⁴, Tamara Harris⁵, Alka Kanaya¹, Annemarie Koster⁶, Suzanne Satterfield⁷, Steven Cummings⁸. ¹University of California, San Francisco, USA, ²Yale University School of Medicine, USA, ³University of Pittsburgh, USA, ⁴INSERM Research Unit 664 & Csbio Bioassays, France, ⁵Intramural Research Program, National Institute on Aging, USA, ⁶National Institutes of Health, USA, ⁷University of Tennessee, USA, ⁸San Francisco Coordinating Center, USA

Mouse models have identified the bone product, osteocalcin (OC), in particular the undercarboxylated form (ucOC), as a hormone affecting insulin production and sensitivity. OC^{-/-} mice are more likely to develop diabetes (DM) on a high fat diet. To assess whether this mechanism plays a role in human physiology, we used data from the Health, Aging and Body Composition longitudinal study of 3,075 older adults in a case-cohort design to determine if baseline levels of ucOC, %ucOC (ucOC/total OC) or total OC predict development of DM. Participants were asked about DM status and medication use at annual visits, and fasting glucose (FG) was measured at baseline, and 1, 3 and 5 years later. A 2-hr glucose tolerance test (OGTT) was obtained at baseline. Participants who reported use of oral steroids or warfarin at baseline were excluded. Among those without DM at baseline, a random sample was identified from those with impaired glucose metabolism (elevated FG or OGTT) (N=171) and those with normoglycemia (N=172). Incident DM cases (N=161) were identified based on self-report, initiation of DM medication, or an elevated FG (≥ 126 mg/dl) during an average follow-up of 6.0 2.5 years. OC, ucOC, N-propeptide of type I procollagen (PINP), and serum type I collagen C-telopeptides (S-CTX) were measured in baseline serum specimens. ucOC was measured with the hydroxyapatite (HAP) binding assay. The baseline sample was 52% women and 59% white with mean age 73.6 (SD 2.9) years. OC, but not ucOC or %ucOC, was lower in those with DM at baseline. However, in proportional hazards models, higher baseline levels of ucOC,

OC and PINP, but not %ucOC or sCTX, were associated with incident DM in models adjusted for age, gender, race, clinic site and baseline strata (impaired glucose metabolism or normoglycemia). After further adjustment for renal function, oral estrogen use and physical performance score, none of the baseline bone markers predicted DM. Additional adjustment for smoking status, physical activity, use of osteoporosis drugs, statins or thiazide diuretics did not substantially change the estimated associations. In contrast to mouse models that found increased DM risk in mice lacking OC, our findings do not support a role for ucOC levels in the development of type 2 diabetes in older adults.

Table. Hazard ratio (HR) and 95% confidence interval (95% CI) for incident diabetes for each 1 SD increase in baseline bone turnover marker

Marker	Minimally adjusted ^a		Multivariable adjusted ^b	
	HR	(95% CI)	HR	(95% CI)
ucOC	1.26	(1.01, 1.57)	1.17	(0.92, 1.48)
%ucOC	1.17	(0.91, 1.51)	1.19	(0.91, 1.57)
Total OC	1.32	(1.07, 1.64)	1.15	(0.89, 1.48)
PINP	1.32	(1.08, 1.62)	1.24	(0.96, 1.59)
sCTX	1.09	(0.88, 1.35)	1.01	(0.79, 1.30)

^a Adjusted for age, gender, race, clinic site, baseline strata (impaired glucose metabolism or normoglycemia).

^b Adjusted for above plus cystatin-c, oral estrogen use, physical performance score.

Deletion of *Nocturnin* Protects Against Rosiglitazone-Induced But Not Age-Related Bone Loss. Phuong Le^{*1}, Anyonya Guntur¹, Sheila Bornstein², Leeann Louis³, Masanobu Kawai², Mary Boussein³, Beata Lecka-Czernik⁴, Clifford Rosen². ¹Maine Medical Center Research Institute, USA, ²Maine Medical Center, USA, ³Beth Israel Deaconess Medical Center, USA, ⁴University of Toledo College of Medicine, USA

Nocturnin (*Noc*) is a circadian gene expressed in bone and fat which encodes a deadenylase that is a downstream target of PPAR γ and up-regulated by rosiglitazone (Rosi). *Noc* also binds to PPAR γ and enhances its transport to the nuclear membrane. Sixteen week *Noc*^{-/-} mice have high bone mass, are resistant to diet induced obesity, and have lower body temperature than ^{+/+} mice. But the importance of *Noc* in osteogenesis has not been well delineated. To test the functional importance of *Noc* relative to body composition and bone mass, we aged both *Noc*^{-/-} and *Noc*^{+/+} to 6 months. We also treated 12 wk *Noc*^{-/-} mice and their age- and gender matched ^{+/+} controls with 20 mg/kg/day Rosi for 8 wks. In the aging study, *Noc*^{-/-} total aBMD by DXA was slightly reduced compared to ^{+/+} mice ($p=0.10$). Trabecular tibial and lumbar BV/TV by μ CT were reduced by 50% in the *Noc*^{-/-} mice vs ^{+/+} ($p=0.03$ and 0.04 respectively). There were no differences in marrow fat between genotypes. Gene expression studies in femur revealed no significant differences in Wnt10b or β 3AR. However, FoxC2 expression in *Noc*^{-/-} mice was increased 1.7 fold vs ^{+/+} femurs ($p=0.04$). In the Rosi treatment study, both *Noc*^{-/-} and ^{+/+} mice gained total body weight ($p=0.002$ and 0.003 respectively vs control diet mice). The ^{+/+} mice had a 20% increase in total percent fat on Rosi ($p=0.021$) while the *Noc*^{-/-} showed no change in total percent fat on Rosi vs control feeding. Importantly, Rosi treated ^{+/+} female and ^{+/+} male mice lost total aBMD ($p=0.055$) and aBMC ($p=0.025$) compared to ^{+/+} control treated mice, while *Noc*^{-/-} male and female mice were resistant to Rosi induced bone loss. Trabecular BV/TV, Conn-Dens., and Tb.N were greater in Rosi treated ^{+/+} mice vs Rosi treated ^{+/+} ($p=0.016$, 0.010, 0.008). To explore the mechanisms responsible for the skeletal changes downstream of *Noc*, we over-expressed *Noc* in MC3T3 cells and found a marked decrease in osteocalcin ($p=0.008$) and ATF4 ($p=0.0002$) mRNA expression with a modest decrease in *FoxO1* mRNA ($p=0.06$) relative to GFP. In summary, *Nocturnin* is an important determinant of body composition through its actions on PPAR γ . Absence of *Noc* prevents rosiglitazone-induced fat mass gain and protects against skeletal bone loss. However, with age *Noc*^{-/-} lose significantly more bone than ^{+/+} mice. The effects of *Nocturnin* on bone are complex; it includes cell autonomous direct modulation of PPAR γ action and indirect actions on brown adipose tissue and the sympathetic nervous system.

N-Cadherin/Wnt Signalling Interaction Controls The Switch Between Osteoblast and Adipocyte Mesenchymal Cell Differentiation In Aging Mice. Eric Hay^{*1}, Thibault Buczkowski², Pierre Marie³. ¹INSERM 4606, France, ²INSERM U606 & University Paris Diderot, France, ³INSERM Unit 606 & University Paris Diderot, France

The aging skeleton is characterized by decreased number of bone-forming cells and increased number of adipocytes in the bone marrow. The mechanisms controlling the switch between osteoblast and adipocyte differentiation of mesenchymal stromal cells (MSC) during aging are poorly understood. Here, we investigated the role of the N-cadherin/Wnt interaction in the control of MSC bifurcation into osteoblasts or adipocytes. Overexpression of N-cadherin in C3H10T1/2 cells increased adipocyte

gene expression (PPARGgamma, C/EBPalpha, LPL) and adipogenesis, indicating that N-cadherin controls adipocyte differentiation in MSC. We next analysed bone marrow adipogenesis in aging mice overexpressing N-cadherin in osteoblasts. RT-qPCR and histomorphometric analyses showed that in adolescent (1.5 month old) mice, N-cadherin overexpression increased adipocyte gene expression, adipocyte number (+300 %, $P < 0.05$) and volume in the bone marrow (+300 %, $P < 0.05$) compared to wild-type mice. This effect was associated with decreased expression of osteoblast markers (Runx2, ALP, COL1A1, OC), decreased bone formation rate and bone mass associated with decreased Wnt5 and Wnt10b mRNA levels in the bone marrow. At 6 months of age, however, this bone phenotype was corrected and bone mass was normalized in N-cadherin transgenic mice. Remarkably, at 18 months of age, N-cadherin transgenic mice exhibited increased osteoblast markers, increased bone formation rate (+80%), and decreased adipocyte number (-75 %) and volume (-80 %) in the bone marrow compared to wild-type mice. This reversal of the bone phenotype in aging mice was associated with reduced expression of N-cadherin and increased Wnt5a and Wnt10b expression in the bone marrow. The results show that N-cadherin/Wnt signalling interaction controls the age-related switch between osteoblast and adipocyte differentiation. In young mice, N-cadherin overexpression reduces Wnt signalling, resulting in increased adipocyte differentiation and decreased osteoblast differentiation, causing decreased bone formation and bone mass. With aging, N-cadherin expression declines and Wnt signalling increases concomitantly, resulting in reduced adipogenesis and increased bone formation and bone mass. This provides novel mechanisms by which modulation of Wnt signaling by N-cadherin governs the bifurcation between osteoblasts and adipocytes which in turn regulates bone formation and bone mass in aging mice (supported by the FP7 Program Talos).

Mice Lacking AMP-activated Proteine Kinase (AMPK)-alpha1 Catalytic Subunit have Attenuated Bone Responses to Ovariectomy and Intermittent PTH Treatment. Jeshmi Jeyabalan^{*1}, Mittal Shah¹, Benoit Viollet², Marta Korbonits³, Chantal Chenu¹. ¹Royal Veterinary College, United Kingdom, ²Institut Cochin Inserm, France, ³Barts & the London Medical School, United Kingdom

AMPK is a key regulator of cellular and body energy homeostasis. We previously demonstrated that AMPK activation in osteoblasts increases bone formation in vitro while deletion of the AMPK α 1 subunit, the dominant catalytic subunit expressed in bone, leads to decreased bone mass in vivo. To determine whether bone turnover can be stimulated in the absence of AMPK α 1 subunit, we subjected wild-type (WT) and AMPK α 1^{-/-} mice to catabolic (ovariectomy: OVX) and anabolic (intermittent PTH administration: iPTH) hormonal challenges. 3 month-old female AMPK α 1^{-/-} (n=16) and WT (n=16) mice were ovariectomized. 4 weeks after OVX, mice were randomly divided into two groups, one receiving saline and the other PTH (1-34) treatment (80µg/kg/day) for 4 weeks. Tibiae were harvested from these mice, bone micro-architecture determined by micro-computed tomography and bone formation and resorption parameters measured by histomorphometric analysis. AMPK α 1^{-/-} mice displayed a decreased bone loss after OVX in the trabecular compartment compared to WT mice. This was demonstrated by higher trabecular bone volume (+38%; $p < 0.01$), trabecular number (+40%; $p < 0.001$) and decreased trabecular separation (-37%; $p < 0.001$) in AMPK α 1^{-/-} mice versus WT mice. The cortical indexes showed non-significant increases in bone area and cortical thickness in AMPK α 1^{-/-} mice versus WT mice after OVX. As expected, iPTH increased cortical and trabecular bone indexes in both WT and AMPK α 1^{-/-} mice. However, AMPK α 1^{-/-} mice showed lower trabecular bone volume (-17%; $p < 0.01$), trabecular number (-10.4%; $p < 0.05$), trabecular thickness (-10%; $p < 0.05$) and increased trabecular separation (+13%; $p < 0.05$) compared to WT mice in response to iPTH treatment. The cortical indexes, bone area (-15%; $p < 0.01$) and cortical thickness (-9.8%), were similarly lower in AMPK α 1^{-/-} mice compared to WT mice. Neither AMPK α 1^{-/-} nor WT mice bone length or body weight were altered. Surprisingly, parameters of bone formation and resorption were not significantly modified between WT and AMPK α 1^{-/-} mice, while we observed a massive decrease in the number of adipocytes in the AMPK α 1^{-/-} mice. Overall these results demonstrate that AMPK α 1^{-/-} mice are less affected by catabolic and anabolic changes in bone turnover induced by OVX and PTH respectively, suggesting that AMPK activation plays a role in the hormonal regulation of bone remodeling.

Altered Bone Fatty Acid Metabolism in Obesity and After Diet-Induced Weight Loss. Riku Kiviranta^{*1}, Jussi Raisanen², Tam Pham², Anna Karmi², Antti Viljanen², Riitta Parkkola², Jarna Hannukainen², Pirjo Nuutila². ¹Medical Biochemistry & Genetics & Turku PET Centre, University of Turku, Finland, ²Turku PET Centre, University of Turku, Finland

Obesity has complex effects on bone tissue. Overweight results in increased bone mass but is also associated with increased bone marrow adiposity, thus having putatively negative effects on bone metabolism. Free fatty acids (FFAs) serve as an energy source for several tissues. FFA tissue uptake and oxidation are increased in

obesity especially in myocardium, liver and adipose tissue while FFA uptake is reduced by weight loss in these tissues. However, there is no information on FFA utilization in bone tissue of normal or obese subjects.

To understand the crosstalk between energy metabolism and bone, we analyzed bone FFA utilization in controls and in obese subjects before and after very low calorie diet (VLCD) using positron-emission tomography (PET) imaging.

Nine control subjects (BMI=25.13.3) were imaged at baseline and seventeen obese subjects (BMI=33.94.0) before and after a six-week VLCD using [¹⁸F]-fluoro-6-thia-heptadecanoic acid ([¹⁸F]-FTHA) for the assessment of FFA uptake in tissue. FFA uptake was measured in the bone marrow area at mid-femoral diaphysis in both groups and in the trabecular bone of L3 and Th7-10 vertebral bodies in the obese subjects.

At baseline FFA uptake in the femoral diaphysis was significantly higher in obese subjects than in the nine lean ones (0.370.16 vs. 0.150.07 µmol/(min*dl), $p < 0.01$). In obese subjects the FTHA uptake was lower in femurs than in vertebrae (0.37 vs 1.41 µmol/(min*dl), $p < 0.001$), but did not differ between thoracic and lumbar vertebrae. After six weeks of VLCD, obese subjects had lost weight in average 12 kg (101 12 kgs to 89 11 kgs, $p = 0.008$). Subsequently, FFA uptake was reduced by 19% in femoral diaphysis ($p < 0.03$). The reduction in FTHA uptake was much greater in thoracic and lumbar vertebrae (-27% and -26%, respectively, $p < 0.01$), again not significantly differing between the vertebrae.

Our results indicate that FFA uptake in bone marrow is increased in obese patients and that weight loss reduces FFA utilization in bone, as we have previously observed in other tissues. Interestingly, the overall FFA uptake is significantly higher and the diet-induced reductions greater in vertebrae, where the amount of bone marrow fat is low compared to femurs. Thus FFAs are likely utilized by *bona fide* bone cells in addition to bone marrow adipocytes. In conclusion, bone FFA metabolism is altered by obesity and diet-induced weight loss further supporting the link between energy metabolism and bone.

Positive Feedback Regulation of microRNA-218 Linked to Wnt Signaling Promotes Osteoblast Differentiation. Mohammad Hassan^{*1}, Yukiko Maeda¹, Mohammad Jafferji¹, Jonathan Gordon¹, Zhaoyong Li¹, Carlo Croce², Andre Van Wijnen¹, Janet Stein¹, Gary Stein¹, Jane Lian¹. ¹University of Massachusetts Medical School, USA, ²The Ohio State University, USA

Gene expression during osteoblast differentiation is controlled at multiple transcriptional and post-transcriptional levels. MicroRNAs (miRNAs), non-coding ~22 nucleotide RNAs, regulate virtually every biological process by binding to the 3'-untranslated region (UTR) of mRNAs to attenuate protein synthesis. Using microarray and high-throughput miRNA profiling, we identified pre- and mature miRs that are up-regulated during differentiation of osteoprogenitors to mature osteoblasts. Bioinformatics revealed that several miRNAs target well established pathways for bone formation, including Wnt, BMP and MAPK pathways. Here we show that miR-218 suppresses inhibitors of Wnt signaling, Sclerostin (SOST), Dickkopf2 (DKK2) and Secreted Frizzled-Related Protein 2 (SFRP2), as well as the BMP signaling inhibitor TOB1. LUC/3'-UTR reporter assays validated that miR-218 controls each target. Endogenous expression of miR-218 increased during differentiation of calvarial osteoblasts to day 28, the mineralization stage. We tested biological activity of miR-218 by examining if its ability to suppress Wnt/BMP signaling inhibitors promotes osteoblast differentiation in MC3T3 cells. Exogenous expression of miR-218 up-regulated early markers Runx2 and Alk Phos on day 7 and late osteoblast markers at mature stages (days 21-28). Importantly, miR-218 suppressed expression of Wnt inhibitors, induced Wnt targets, and activated a canonical Wnt responsive promoter (TOP-Flash reporter assay). We also show mechanistically that miR-218 is upregulated in osteoblasts by activation of Wnt signaling, evident by elevation of LEF1, TCF1 and beta-catenin, presumably via a putative LEF1 binding site 5' to miR-218. Taken together, these results demonstrate that miR-218 is a key stimulator of osteogenic differentiation and functions in a positive Wnt/miR-218/Wnt inhibitor feedback loop that sustains Wnt signaling during osteoblast differentiation.

Wnt11 Is a Novel Inhibitor of Trabecular Bone Mass. Mariya Sweetwyne^{*}, Bernadette Hsu, Megan Hays, Kurt Hankenson. University of Pennsylvania, USA

Studies have established that Wnt signaling through beta-catenin stabilization increases bone formation. Wnts are classified as either canonical (beta-catenin dependent) or non-canonical. Previous work from our group demonstrated that over expression of Wnt11 in vitro in MC3T3E1 cells increased osteoblastogenesis through canonical signaling. Therefore, we hypothesized that loss of Wnt11 in vivo would decrease bone mass.

With the exception of female Wnt11^{-/-} mice, all genotypes and genders are fertile and produce viable offspring. However, Wnt11^{-/-} viability is low with only 20% of the offspring predicted by Mendelian inheritance surviving past postnatal day 2. Mice were harvested at 4, 8 and 12 months of age. MicroCT analysis of femurs at 4 and

8 months of age shows that total loss of Wnt11 increases trabecular, but not cortical, bone. At 8 months, Wnt11^{-/-} mice have a 2-fold increase in trabecular bone when compared to wild-type (WT). This difference is dependent on gene copy number as Wnt11^{+/-} mice have a trabecular phenotype intermediate to the null and WT mice. Regardless of genotype or gender, trabecular bone volume declines between 8 and 12 months of age.

Comparing cortical and trabecular bone volume independent of age, gender, and body weight demonstrates a positive correlation between the two sites in WT mice ($R^2 = 0.901$, $p = 0.013$) but not Wnt11^{-/-} mice ($R^2 = 0.028$, $p = 0.753$). Wnt11^{+/-} mice have an intermediate phenotype ($R^2 = 0.885$, $p = 0.057$). These results indicate that Wnt11 may play a more prominent role in trabecular bone or in coupling cortical and trabecular bone.

Western blot and immunofluorescence analysis of beta-catenin expression in primary, unstimulated mesenchymal stem cells (MSC) and dermal fibroblasts (harvested 4, 8 and 12 months of age) show that Wnt11^{-/-} cells have increased levels of active nuclear beta-catenin. In addition, Wnt11 deficient cells have reduced: actin stress fibers, rates of proliferation and cell-cell contact in proliferating colonies.

These studies are the first to demonstrate that Wnt11 regulates bone; unexpectedly, we conclude that Wnt11 is an inhibitor of trabecular bone mass. As a Wnt traditionally classified as non-canonical, Wnt11 has been shown to inhibit canonical Wnt signaling in other tissues. We hypothesize that physiological levels of Wnt11 inhibit trabecular bone formation by suppressing canonical beta-catenin signaling.

Implantation of Hedgehog-Activated Mscs Regenerates Periosteal Like Bone Formation in a Murine Bone Allograft Repair Model. Chunlan Huang¹, Ming Xue¹, Fanjie Zhang¹, Regis O'Keefe², Xinping Zhang¹. ¹University of Rochester Medical Center, USA, ²University of Rochester, USA

Periosteum plays an essential role in skeletal repair and reconstruction. To the end of understanding the molecular pathways underlying periosteum-mediated repair and reconstruction, we isolated a population of mesenchymal stem cells (MSCs) from the periosteum at the cortical bone healing site. These cells express typical MSC markers and are capable of differentiating into osteoblasts, adipocytes, and chondrocytes. Characterization of these cells demonstrates that activation of the hedgehog (Hh) pathway effectively promotes osteogenic differentiation of periosteum MSC in vitro. When implanted subcutaneously in athymic nude mice, these hedgehog-overexpressing cells induce robust bone formation in vivo. To further determine the effects of Hh-activated periosteum MSCs in repair and reconstruction, we implanted the periosteum MSCs overexpressing an N-terminal sonic hedgehog peptide around a devitalized bone allograft to repair a 4mm segmental femoral bone defect in mice. Our results demonstrated that implantation of the Hh-activated MSCs induced robust bone formation around bone allografts. MicroCT imaging analyses showed a 3-fold induction of new bone formation around bone allografts as compared to the controls ($n=6$). A contiguous periosteal collar bone was regenerated around bone allografts engrafted with Hh-activated periosteum MSCs. In comparison, the control allografts demonstrated a nearly complete absence of effective periosteal bone formation around allografts. These results strongly suggest that the engraftment of Hh activated periosteum MSCs is effective in enhancing skeletal repair and reconstruction. In an effort to further identify Hh-responsive MSCs from other available sources for repair and reconstruction, we examined the effects of Hh activation in cells isolated from murine neonatal dermis. We found that overexpression of Hh ligand or Gli1, a key activator of the Hh pathway, induced ALP staining and osteoblastic differentiation in isolated neonatal dermal cells. The induction further synergized with BMP-2. These data strongly indicate the potential utility of Hh-activated dermis MSCs as a periosteum replacement for skeletal repair and reconstruction. Taken together, our data support the role of Hedgehog pathway as a positive regulator for osteoblastic differentiation for early stage mesenchymal progenitors.

Wnt Ligands from Osteoblasts are Critical for Bone Accrual. Zhendong Zhong¹, Cassandra Diegel¹, Bart Williams². ¹Van Andel Institute, USA, ²Van Andel Research Institute, USA

A great deal of work has shown that the gain-of-function or loss-of-function mutations in the components of Wnt pathway affect the bone homeostasis. But little is known about where the Wnt ligands originate in the bone tissue.

Several recent genome-wide association studies of European and Asian descendants found that GPR177 (1p31.3) is significantly related to bone mass density (Nat. Genet. 2009 and PlosOne 2010). Wntless/GPR177 is a newly identified chaperone protein that specifically escorts Wnt ligands for secretion, which potentially plays an important role in bone metabolism by regulating Wnt/ β -catenin signaling pathway.

To investigate the necessity of Wnt ligands from osteoblasts, we generated osteoblast-specific Wntless-deficient mice (Oc-cre; Wntless-flox). Homozygous mutant mice were born at a normal Mendelian frequency with no obvious skeletal abnormality in the early stage. Whole body Dual X-Ray Absorptiometry (DXA) scan revealed that the bone mass accrual was significantly inhibited in homozygotes from 20 days of age. MicroCT analysis and histomorphometric data showed a dramatic

reduction of both trabecular bone mass and cortical bone thickness in homozygous mutants. The bone formation in vivo was severely impaired while osteoclast activity was increased significantly. No obvious phenotype change was observed for heterozygotes. In vitro study showed that Wntless-deficient osteoblasts had a dramatic defect in differentiation and mineralization with significant decreased expressions of key osteoblast differentiation regulators.

Due to spontaneous fractures causing severe retardation, premature lethality happens in most of the homozygotes shortly after the weaning age. However, these homozygotes could have a robust fracture healing shortly after fracture, which might be due to the Wnt ligands coming from chondrocytes or other cell types at the fracture site. The Wntless-deficient osteoblasts were hypersensitive to Wnt3a, and showed a strong activation of Wnt/ β -catenin signaling after Wnt3a treatment in vitro.

Taken together, these results reveal a surprising and critical role of osteoblast-secreted Wnt ligands for bone accrual, and add more complexities to how Wnt regulates the bone formation/resorption locally in the bone.

ENU Chemical Mutagenesis Reveals That the Distal Region of Mouse Chromosome 11 Contains a Key Bone Size Mechanoresponsive Gene. Chandrasekhar Kesavan¹, Apurva Srivastava², David Baylink³, Tara Azizi⁴, Subburaman Mohan¹. ¹Jerry L. Pettis Memorial VA Medical Center, USA, ²NCI (National Cancer Institute), USA, ³Loma Linda University, USA, ⁴Musculoskeletal Disease Center, JLP VA Medical Center, USA

Bone size is a particularly important contributor of its overall strength and the hereditary component contributes 50-85% to the variation in bone size. Using a sensitized N-ethyl-N-nitrosourea (ENU) mutagenesis screen, we have identified a mutant C57BL/6J mouse strain (14104) that exhibits a 40% reduction in cross sectional area. Genome-wide linkage analysis revealed that the mutant locus is located in the 109-119 Mb region of mouse chr 11 with axin2, Map2K6, Rab37, Grb2, Sox9 and Socs3 as functional positional candidates. Because mechanical strain (MS) is a known contributor to periosteal expansion during postnatal growth and because a mechanical loading (ML) QTL has been identified in the same chromosomal region in the C57BL/6J X C3H/HeJ intercross, we predicted that 14104 gene is a mediator of the MS response in the skeleton. To test this prediction, we evaluated whether skeletal anabolic response to ML is impaired in mutant mice compared to wild type (WT) mice. Because the amount of MS the skeleton receives for a given load is largely dependent on its size, we measured MS by using a strain-gauge technique on tibia metaphyses of both genotypes to ensure a similar amount of strain is applied to mutant and WT mice. We found that a 6N (641 μ e) load in mutant female mice produced MS similar to that of 10N load (623 μ e) in WT mice. Adjusted loads were applied on right tibia of both sets of mice by performing axial loading for 3 alternative days for 2 weeks while the left tibia served as an internal control. Micro-CT measurements at 10.5 μ m revealed a 40% ($p < 0.01$) increase in trabecular (Tb) BV/TV which is caused by 12% and 15% increases in the Tb number and thickness, respectively, in WT mice. In contrast, none of the Tb parameters were significantly increased in the loaded bones of mutant mice. Similarly, axial loading caused a significant increase in cortical bone area (8%, $p < 0.05$) at the tibial mid-diaphysis of WT but not mutant mice. Consistent with Micro-CT measurements, gene expression profiling revealed that levels of ephrin signaling pathway genes (EFNB1, A2 and EphB2), that are known to be modulated by ML, are increased in response to loading in WT mice (2-fold, $p < 0.05$) but not in 14104 mutant mice. Based on these data, we conclude that the distal region of mouse chr 11 harbors a mechanoresponsive gene that is upstream of the ephrin signaling pathway and plays a critical role in regulating bone size during postnatal growth in mice.

Smad4 Antagonizes Osteoblast Proliferation via Competitive Recruitment of β -catenin. Valerie Salazar¹, Nicholas Zarkadis², Lisa Huang¹, Jin Norris¹, Gabriel Mbalaviele¹, Roberto Civitelli¹. ¹Washington University in St. Louis School of Medicine, USA, ²Kansas City University of Medicine, USA

We previously demonstrated Smad4 expression inversely correlates with the ability of Wnt3a or activated β -catenin to stimulate TCF/Lef-dependent transcription, *CCND1* expression, and proliferation in C3H10T1/2 cells. We examined the molecular mechanisms of this novel interaction between Smad4 and canonical Wnt signaling. Immunoblot analysis in MC3T3 cells indicates that the abundance and phosphorylation status of critical components of the canonical Wnt pathway are not changed by Smad4 over-expression, thus making autocrine or paracrine regulation unlikely. In contrast to subconfluent MC3T3 cells where BMP2 can stimulate nuclear accumulation of β -catenin in approximately 75% of cells, confluent MC3T3 cells exhibit primarily nuclear localization of β -catenin, along with Smad4, TCF3, and TCF4. However, BMP-2 does not activate, and in fact inhibits LiCl-stimulated TCF/Lef transcriptional activity. Pull-down assays reveal that BMP-2 triggers recruitment of β -catenin to a heteromeric transcription complex that binds DNA oligonucleotides encoding classic Smad-binding sequences. Importantly, this complex also contains

Smad4, phosphorylated R-Smads (1/5/8), and TCF4; whereas TCF3 is not recruited. Mutational analysis demonstrates that disruption of Smad4 DNA-binding activity greatly diminishes its ability to antagonize basal *CCND1* promoter activity, which is regulated by TCF/Lef promoter elements. The nuclear export signal, linker domain, and Smad4-dependent transcriptional activity are not required. Such antagonism by Smad4 on cell cycle is also operative *in vivo*. Tamoxifen-induced ablation of Smad4 in *Smad4^{fllox/flox}; Osx-CreERT2* mice results in a 4-fold increase in the number of BrdU+ cells in trabecular bone, an effect significantly greater than that obtained by activating LRP5/6 with a systemic anti-Dkk1 antibody treatment. Thus, Smad4 operates at the Osterix+ stage of osteoblast differentiation to dampen proliferation, a mechanism that is at least partially mediated by BMP-2-dependent recruitment of β -catenin/TCF4 to Smad4-containing transcription complexes. Our results are consistent with a competitive recruitment model whereby Smad4 can sequester the β -catenin/TCF transcriptional machinery away from canonical Wnt target genes to BMP response elements, thereby inhibiting osteoblast proliferation.

MMP13 is A Critical Target Gene during the Development of Osteoarthritis.

Jie Shen^{*1}, Hongting Jin¹, Meina Wang¹, Bing Shu², Baoli Wang², Erik Sampson¹, Regis O'Keefe¹, Di Chen². ¹University of Rochester, USA, ²University of Rochester Medical Center, USA

Osteoarthritis (OA) is a common joint degenerative disease affecting more than 25% of people over the age of 18. The pathogenesis of OA is poorly understood and currently there is no effective disease-modifying treatment for OA. Recent human genetic studies have demonstrated that mutations in the *FrzB* and *Smad3* genes are associated with high incidence of hip and knee OA in patients. However, the downstream target gene(s) for these signaling pathways during OA development remains unknown. MMP13, also known as collagenase 3, is up-regulated in articular chondrocytes in OA patients. In this study, we investigated the role of *Mmp13* in OA development in TGF- β receptor conditional knockout [*Tgfb2(Col2ER)*] and β -catenin conditional activation [β -cat-ex3(*Col2ER*)] mice. Tamoxifen was administered to 2-week-old mice (1 mg/10g body weight, i.p., x5 days) and mice were sacrificed at 3 and 6 months of age. In 3-month-old *Tgfb2(Col2ER)* mice (n=11) and 6-month-old β -cat-ex3(*Col2ER*) mice (n=8), a severe OA-like phenotype was observed, including increased chondrocyte expression of *Col10a1* and *Mmp13* in the superficial zone of the articular cartilage, severe loss of articular cartilage tissue and osteophyte formation. To determine the role of *Mmp13* in OA development in these mice, we have crossed *Tgfb2(Col2ER)* and β -cat-ex3(*Col2ER*) mice with *Mmp13(fx/fx)* mice (n=6). Deletion of the *Mmp13* gene completely reversed most OA-like features observed in *Tgfb2(Col2ER)* and β -cat-ex3(*Col2ER*) mice. We then investigated the mechanism of *Mmp13* up-regulation and found that inhibition of TGF- β or activation of β -catenin signaling up-regulates *Mmp13* expression in a Runx2-dependent manner. Mutation of the Runx2 binding site in the proximal human *Mmp13* promoter (3.4 kb) completely blocked *Mmp13* promoter activity in the setting of TGF- β signaling inhibition (*Tgfb2* siRNA) or β -catenin activation (BIO, 1 μ M) in chondrogenic RCS cells. ChIP analysis further demonstrated binding of Runx2 to the *Mmp13* promoter. Additional studies demonstrated that deletion of the *Mmp13* gene in *Mmp13* conditional KO mice [*Mmp13(Col2ER)*], decelerated meniscal-ligamentous injury (MLI)-induced OA and treatment with an MMP13 inhibitor (CL82198, 1, 5 and 10mg/kg) also decelerated the progression of MLI-induced OA in wild-type mice. Our studies demonstrate that multiple signaling pathways involved in OA converge on MMP13 and identify MMP13 as a potential key target for therapeutic approaches.

Human Embryonic Stem Cell Derived Therapy for Articular Cartilage Shows Strong Efficacy Outcomes Without Immune Suppression. David Pier¹, Jordi Tremoleda², Derek Dauphin¹, Val mann¹, Brendon Noble^{*3}. ¹UCS, United Kingdom, ²Imperial College, United Kingdom, ³University Campus Suffolk, United Kingdom

The combined clinical burden of traumatic cartilage injuries and osteoarthritic degeneration is high due both to its prevalence and strong influence on quality of life and loss of independence. Cartilage is notable for its low or non-existent regenerative capacity. Cell-based methods of assisting regeneration will contribute to the reduction of clinical burden, however challenges remain over the sourcing and efficient production of clinical cell therapies.

To overcome these limitations, a method has been developed in which highly scaleable human embryonic stem cells (hESCs) undergo directed differentiation along the chondrogenic lineage producing a cell population capable of improving regeneration while escaping deletion by the immune system *in vivo*. Prior to implantation the expression of SOX9, was found to increase 8-fold relative to parental hESCs (P = 0.0027). Collagen type II was largely undetectable by western blot analysis and immunohistochemistry. Gene expression analysis of COL2A1 IIA splice variants increased nearly 30-fold (P = 0.0005) while COL2A1 IIB remained unchanged. No protein or gene expression of pluripotency markers was found and implanted therapy failed to produce teratomas in immune compromised rodents

indicative of commitment to the chondrogenic lineage and an absence of undifferentiated cell contaminants.

Implantation into partial thickness articular cartilage defects enhanced tissue regeneration at 1, 4 and 9-months post-implantation in wild-type rats receiving no immune suppression. Regenerate tissue exhibited characteristics of hyaline articular cartilage and achieved full integration with adjacent native tissue. Using a histological grading system incorporating measures of surface regularity, regenerate tissue and cellular morphology, architecture, tidemark formation, chondrocyte cloning, subchondral bone integrity and Safranin O staining, treatment was found to result in a significant improvement in tissue regeneration over empty defects at 1- and 4-months post-operation (P < 0.001 *** for both). Human cells were detected at the defect site throughout the 9-month study indicating they play a role the observed tissue regeneration. These results suggest that hESC-derived therapies possess clinical utility in allogenic format and without necessitating an immune suppressive regime. Their intrinsic expandable nature makes them an ideal candidate for future cell therapy development.

Accelerating Fracture Healing Correlates with Enhancing Angiogenesis and Mesenchymal Stem Cells in Matrilin-1 Knockout Mice. Xin Li¹, Qian Chen^{*2}. ¹Brown University, USA, ²Brown University School of Medicine, USA

Matrilin-1 (MATN1) is a cartilage specific, non-collagenous extracellular matrix protein produced by pre-hypertrophic chondrocytes of the growth plate, which is critical for the transition from cartilage to bone during endochondral ossification. MATN1 knock-out (KO) mice present abnormal collagen fibrils in cartilage matrix, but are otherwise normal during skeletal development. Thus, its role *in vivo* was unknown. In this study, we determined whether MATN1 plays a role in fracture healing, which begins with hematoma formation and involves the vascular network in the whole process. A closed tibia fracture was created in the right leg of mice while the left leg served as sham control with pin fixation but no fracture. Both MATN1 KO and wildtype (WT) mice were analyzed by *in vivo* imaging, real-time RT-PCR, micro-CT, and mechanical testing. MATN1 KO mice have significantly more blood vessels and blood pool formed during the early stage of fracture healing (Day 4 post-fracture). In the mid-stage (Day 14), expression levels of the mesenchymal stem cell markers including STRO-1 and N-cadherin are significantly increased in the fracture callus of MATN1 KO mice. In the late stages (Day 21), MATN1 KO mice have significant more mineralization and bone formation but less cartilaginous tissues in the fracture callus. At the end stage of fracture healing (Day 28), total callus bone volume and mechanical torsion properties are increased in the KO mice. Our data suggest that MATN1 KO mice have increased angiogenesis, mesenchymal stem cell production, and bone formation during fracture healing process. As a result, the KO mice's bone fracture heals faster than the WT mice. The mechanism for MATN1 in regulating fracture healing is not understood. Recently, we have shown strong interactions of matrilin family members with various growth factors including the angiogenic growth factor VEGF. In addition, MATN1 has been identified as an anti-angiogenic molecule in cartilage, which is devoid of blood vessels. It is thus possible for MATN1 to regulate fracture healing process by affecting angiogenesis. In summary, this study has identified the first physiological role for MATN1 *in vivo*. It shows that MATN1, as a cartilage-specific matrix molecule, negatively regulates fracture healing process by inhibiting angiogenesis, mesenchymal stem cell levels, and bone formation.

Adverse Effects of Hyperlipidemia on Bone Regeneration and Strength. Flavia Pirih^{*1}, Sotirios Tetradis², Maria-Grazia Ascenzi¹, Linda Demer³, Tara Aghaloo¹, Yin Tintut¹. ¹University of California, Los Angeles, USA, ²UCLA, USA, ³David Geffen School of Medicine At University of California Los Angeles, USA

Hyperlipidemia increases the risk for generation of lipid oxidation products, which accumulate in the subendothelial spaces of vasculature and bone. Atherogenic high-fat diets increase serum levels of oxidized lipids, which are known to attenuate osteogenesis in culture and to promote bone loss in mice. In this study, we investigated whether oxidized lipids affect bone regeneration and mechanical strength. Wild type and hyperlipidemic (*Ldlr*^{-/-}) mice were placed on a high-fat (HF) diet for 13 weeks. Bilateral cranial defects were introduced on each side of the sagittal suture, and 5 weeks post-surgery on the respective diets, the repair/regeneration of cranial bones and mechanical properties of femoral bones were assessed. MicroCT and histological analyses demonstrated that bone regeneration was significantly impaired by the HF diet in WT and *Ldlr*^{-/-} mice. In femoral bone, cortical bone volume fraction (BV/TV) was significantly reduced while cortical porosity was increased by the HF diet in *Ldlr*^{-/-} but not in WT mice. Femoral bone strength and stiffness, measured by three-point bending analysis, were significantly reduced by the HF diet in *Ldlr*^{-/-}, but not in WT mice. Serum analysis showed that the HF diet significantly increased levels of parathyroid hormone, TNF-alpha, and calcium, whereas it reduced procollagen type I

N-terminal propeptide, a serum marker of bone formation, in *Ldlr*^{-/-}, but not in WT mice. The serum level of carboxyl-terminal collagen crosslinks, a marker for bone resorption, was also 1.7-fold greater in *Ldlr*^{-/-} mice. These findings suggest that hyperlipidemia induces secondary hyperparathyroidism and impairs bone regeneration and mechanical strength.

Adipocyte-specific Expression of FoxC2 Increases Bone Mass through Upregulation of Wnt10b Expression and Increase in Energy Production in Marrow Adipocytes. Sima Rahman^{*1}, Yalin Lu¹, Piotr Czernik¹, Clifford Rosen², Ormond MacDougald³, Sven Enerback⁴, Beata Lecka-Czernik⁵.

¹University of Toledo Health Sciences Campus, USA, ²Maine Medical Center, USA, ³University of Michigan Medical School, USA, ⁴University of Gothenburg, Sweden, ⁵University of Toledo College of Medicine, USA

A relationship between the status of energy metabolism and bone mass has been actively debated. FoxC2 transcription factor regulates the expression of genes which determine the function of metabolically active brown fat, and these include an adrenergic response, adaptive thermogenesis, mitochondrial biogenesis, and angiogenesis. Ectopic expression of FoxC2 in adipose tissues under the control of FABP4 promoter renders lean animals which are insulin sensitive, and protected from high fat diet-induced obesity and insulin resistance. Most importantly, these animals acquire significantly higher bone mass. In general, bones of Tg-FoxC2 mice are larger in diameter with the same cortical thickness as compared to control mice. This results in an increase of the polar moment of inertia (pMOI) by 25%, which is an indicator of stronger bone. Both males and females have significantly more trabecular bone in proximal tibia, distal femur, and vertebra. Trabecular bone volume of Tg-FoxC2 mice is increased by approximately 2-fold due to increase in the trabecular number, thickness, and connectivity. Remarkably, increased trabecular bone mass in tibia and femur is respectively associated with 4- and 65-fold increase in fat volume within corresponding regions, indicating a positive effect of fat on bone structure. To investigate a possibility that marrow adipocytes (ADs) regulate bone remodeling by modulating marrow environment, we have expressed FoxC2 in cell line representing committed marrow ADs. Ectopic expression of FoxC2 in AD2 cells resulted in up-regulation of gene markers of brown ADs energy-producing activity, and included UCP-1, β_3 -adrenergic receptor, Prdm16, and Dio2. Conditioned media from cultures of FoxC2-ADs increased alkaline phosphatase activity in osteoblasts indicating that these cells produce pro-osteoblastic paracrine factors. Further, we have shown that FoxC2 in ADs induces the expression of Wnt10b, a member of Wnt signaling, which has an anabolic effect on bone and positive effect on energy homeostasis. Taken together, we hypothesize that FoxC2 induces BAT-like metabolic and/or paracrine activities in marrow ADs. These activities, which may include increased energy production and Wnt10b production, have beneficial effect on bone. In conclusion, the Tg-FoxC2 model provides a proof of concept that energy metabolism is integral for the maintenance of bone metabolism and allows for consideration of bone fat as therapeutic target to improve bone mass.

A Dkk3 Reporter Identifies Progenitors of the Fibrocartilage and Periosteum of the Fracture Callus. Yu Mori^{*}, Xi Jiang, Douglas Adams, David Rowe. University of Connecticut Health Center, USA

Mesenchymal progenitor cells are capable of generating a wide variety of mature cells that constitute the connective tissue system. The SMAA-GFP reporter is proving to be an effective tool for identifying these cells prior to the expression of markers of differentiation characteristic of bone, fat, muscular blood vessels or fibrocartilage. Based on a microarray study of SMAA-GFP sorted cells derived from a 4-7 day BMSC culture, we observed high expression of Dkk3, a non-canonical member of the wnt pathway. Because its expression is not associated with osteogenesis, we obtained a Dkk3-GFP reporter mouse to determine what cell type was generating the RNA signal. In primary culture, clusters of Dkk3-GFP cells developed which were independent of Col3.6GFP cells that had formed bone nodules. A 3 color reporter mouse was generated by crossing SMAA-GFPcherry x Col3.6GFPcyan x Dkk3-eGFP and subjected to tibial fracture. Three days post fracture, the proliferating SMAA-red cells were also beginning to express either Dkk3 or Col3.6. By day 5 the two populations had diverged with the Dkk3 cells being on the outer surface of the developing callus while the Col3.6 cells were forming bone at the base of the callus. By day 7 when the callus is filled with cartilage, Dkk3 is active in cells that are in transition from elongated cells on the external surface of the callus to fibrocartilaginous cells that now express low levels of Col3.6. The zone of cells that express Dkk3 appear to block the passage of the surrounding vasculature into the underlying cartilage and does not deposit fibronectin. By day 14-21 when the cartilage core is resorbed, the only remaining Dkk3 is located in the newly formed periosteum external to the active endocortical bone forming activity associated with the inward remodeling of the outer cortical shell. We interpret these findings that Dkk3 marks a non-osteogenic limb of the SMAA progenitor population that within the fracture partitions the osteogenic signals away from the surrounding skeletal muscle and the underlying differentiating fibrocartilage. It is a progenitor to cells that form

fibrocartilage in the fracture zone as well as the tenascin C positive cells that populate the fibrous zone of the periosteum, and it resides in the cambial zone of the periosteum. Knowing the biological and molecular function of these cells should lead to a fuller appreciation of the pro- and anti-osteogenic factors that regulate skeletal repair.

Prevention of Tumor Growth and Bone Destruction in Myeloma by Pim Kinase Inhibition. Masahiro Hiasa^{*1}, Ayako Nakano², Keiichi Watanabe³, Cui Qu², Takeshi Harada², Shirou Fujii², Hirokazu Miki², Shingen Nakamura², Kumiko Kagawa², Kyoko Takeuchi², Eiji Tanaka¹, Kenzo Asaoka¹, Shuji Ozaki², Toshio Matsumoto⁴, Masahiro Abe⁵.

¹University of Tokushima Graduate School, Japan, ²University of Tokushima Graduate School of Medicine, Japan, ³The University of Tokushima Graduate School of Oral Science, Japan, ⁴University of Tokushima Graduate School of Medical Sciences, Japan, ⁵University of Tokushima, Japan

Myeloma (MM) cells potentially enhance osteoclastic bone resorption and suppress osteoblastogenesis from bone marrow stromal cells (BMSCs) to cause devastating bone destruction. BMSCs and osteoclasts (OCs) create a "MM niche" to support MM cell growth and survival. We recently reported that MM-BMSC interaction potentially up-regulate in MM cells the serine/threonine kinase Pim-2 which plays as a critical survival factor in MM cells (Leukemia, 2011). We also found that the MM cells suppressed osteoblast (OB) differentiation from BMSCs along with up-regulation of Pim-2 expression in BMSCs. In the present study, we therefore explored the role of Pim-2 in osteoblastogenesis and the effects of Pim inhibition on tumor growth and bone destruction in MM. Treatment with Pim-2 siRNA or the Pim inhibitor SMI-16a facilitated mineralized nodule formation by BMP-2 in MC3T3-E1 cells. The Pim-2 siRNA also enhanced bone formation in calvaria organ cultures. However, enforced expression of Pim-2 in MC3T3-E1 cells abrogated the mineralized nodule formation, suggesting antagonism of bone formation by Pim-2. The Pim-2 knockdown further up-regulated smad1/5 and p38MAPK phosphorylation as well as osterix expression induced by BMP-2 in MC3T3-E1 cells. Importantly, the Pim-2 knockdown restored mineralized nodule formation in MC3T3-E1 cells suppressed by MM cell conditioned media. We next studied in vivo effects of Pim inhibition using SCID-rab mice in which a rabbit femur was subcutaneously implanted. INA6 MM cells were inoculated directly into the bone marrow cavity in the rabbit bones. After confirming MM cell growth, the mice were treated with the Pim inhibitor SMI-16a at 20 mg/kg every other day. Control mice exhibited extensive bone destruction along with tumor expansion in the bone marrow and outside the bone in microCT images and in bone sections. However, the treatment with SMI-16a markedly decreased MM tumor size and prevented the progression of bone destruction in the rabbit bones. Similar results were observed in MM mouse models by intratibial inoculation of murine 5TGM1 MM cells. Besides its anti-apoptotic role in MM cells in the bone marrow microenvironment, these results suggest that Pim-2 induced in BMSCs by MM cells plays as a negative regulator for bone formation, and that Pim inhibition is able to resume bone formation while reducing tumor burden in MM. Therefore, Pim inhibitors may become a candidate of novel therapeutic agents targeting the MM-BMSC interaction.

The Role of S100A4/RAGE Signaling in Prostate Cancer Bone Metastasis.

Jennifer Paige-Robinson^{*1}, Leland Chung², Omar Hameed¹, John A. Petros³, Majd Zayzafoon⁴. ¹University of Alabama-Birmingham, USA, ²Cedars Sinai Medical center, USA, ³Emory University & Atlanta VA Medical Center, USA, ⁴University of Alabama at Birmingham, USA

Prostate carcinoma (PCa) is the most commonly diagnosed cancer, and is the second leading cause of cancer mortality for men in the United States. Metastasis, specifically to the bone, is a critical step in the progression of PCa. S100A4, a member of the S100 calcium-binding protein family, has been shown to bind to and activate the Receptor for Advanced Glycation End products (RAGE) signaling pathway. Here we show that in human clinical samples RAGE is not expressed in normal and benign prostatic hyperplasia (BPH) samples, but is highly expressed in metastatic PCa tissues. In vitro data demonstrates that benign prostatic epithelial cells (RWPE-1) do not express RAGE, while the bone metastatic prostate cancer cells (C4-2B) express high levels of RAGE. To further examine the role of S100A4 on the metastatic ability of PCa cells, we treated RAGE expressing C4-2B cells with human recombinant S100A4. We discovered that C4-2B cells treated with S100A4 showed a 66% increase in invasion and a 100% increase in the gene expression of Matrix metalloproteinase 13 (MMP-13), a protein which aids in metastasis. Increases in invasion and motility in C4-2B cells are mediated by activation of Calcium calmodulin-dependent kinase II (CaMKII α), Focal Adhesion Kinase (FAK), and Ras-related C3 botulinum toxin substrate 1 (Rac1). Pre-treatment with KN93 (the pharmacologic inhibitor of CAMKII), or with soluble RAGE (the decoy receptor of RAGE), abolished the S100A4 induced Ca²⁺ dependent signaling as well as invasion and motility of C4-2B cells in vitro. C4-2B cells were also sorted using flow cytometry into two populations:

a group that expresses high levels of RAGE (RAGE-high) or low levels of RAGE (RAGE-low). Extracellular S100A4 increased the motility as well as Ca²⁺ dependent signaling in PCa RAGE-high expressing cells but not in RAGE-low expressing cells. PCa cells were then injected intratibially into athymic nude mice. We discovered that mice which were injected with RAGE-high cells developed very large tumors, as shown by x-ray, uCT imaging, and histology. This increase was not seen in mice that were injected with RAGE-low expressing cells. Taken together, our data suggests that RAGE plays a significant role in the growth and local invasion of human prostate cancer.

Leukemia Progression Depends on the Presence of Osteoblasts. Barbara Silva^{*1}, Maria Krevvata², J. Sanil Manavalan², Chiyuan Zhang³, Linda Johnson⁴, Renier Brentjens⁵, Aris Economides⁶, Ellin Berman⁵, Stavroula Koustem¹. ¹Columbia University Medical Center, USA, ²Department of Medicine, Division of Endocrinology, College of Physicians & Surgeons, Columbia University, USA, ³Columbia University, USA, ⁴Comparative Pathology & Laboratory Medicine, Cornell University & Memorial Sloan-Kettering Cancer Center, USA, ⁵Memorial Sloan-Kettering Cancer Center, USA, ⁶Regeneron Pharmaceuticals, Inc., USA

The bone marrow niche has been implicated in the pathogenesis of leukemia, as a permissive microenvironment required for the emergence and/or progression of the disease. To examine whether malignant cells influence specific cell populations within the bone niche we injected two types of leukemia cells, murine myelomonocytic or lymphoma/lymphoblastic into immunocompetent, syngenic mice. In leukemic mice osteoblastogenesis was decreased, and osteoblast - osteoclast uncoupling was noted, leading to a marked decrease in osteoblast numbers and bone formation rate and eventually trabecular bone loss. The marked changes in osteoblast number and function suggested that these cells could influence leukemia progression. To examine this hypothesis we ablated osteoblasts by crossing mice in which an inactive form of the diphtheria toxin A chain (DTA) has been introduced into the ubiquitously expressed ROSA26 locus with transgenic mice expressing Cre under the control of the osteoblast-specific collagen type I $\alpha 1$ promoter. Compound progeny carries one allele of floxed DTA locus and one with active DTA (DTAosb/+). DTAosb/+ mice show 50% reduction in osteocalcin levels, osteoblast numbers and bone formation rate. EL4 lymphoma/lymphoblastic leukemia cells transduced with a GFP/Luciferase fusion gene were injected, intravenously, into DTAosb/+ mice, and their wild type littermates (DTA fl/+). Cell trafficking and tumor progression were assessed, noninvasively, by bioluminescence imaging. Bone marrow engraftment was observed by *in vivo* images, and confirmed at autopsy. Results were averaged from the peak light-emitting exposure from each group, and mice lacking osteoblasts showed a significant increase in total counts, indicating increased tumor burden. Additionally, over a 4-week period, mice lacking osteoblasts had a significantly shorter overall survival ($P = 0.04$ log-rank test), and a 50% increase in hind-limb paralysis, suggesting increased tumor burden in bone sites in mice lacking osteoblasts. These data demonstrate that osteoblasts play a fundamental role in propagating leukemia in the bone marrow. They suggest that identifying signals emanating from osteoblasts and affecting leukemia engraftment or progression could be therapeutic targets to interfere with tumor progression.

Inhibition of Discoidin Domain Receptor-1 (DDR1) Impairs Tumor-Induced Bone Metastatic Homing and Colonization. Karmele Valencia^{*1}, Cristina Ormazabal², Carolina Zanduet², Diego Luis-Ravelo², Iker Anton², Susana Martı́nez-Canarias², Fernando Lecanda¹. ¹Foundation for Applied Medical Research, Spain, ²Center for Applied Medical Research (CIMA), Spain

Cell-matrix and cell-cell interactions within the bone microenvironment are critical for the initiation and development of osseous metastasis. However, the mechanisms mediating bone homing and colonization remain poorly understood. The aim of this study was to investigate the role of collagen binding receptor DDR1 in these processes. High levels of DDR1 were found in human lung tumor cells lines by qPCR and western blot analysis as compared to normal cells. Lentiviral transduction of a lung tumor cell line with shRNA using two different targets led to more than 80-90% inhibition. Knock-down (shDDR1) cells displayed a stunted decrease invasiveness in collagen type I and type IV substrates as compared to control and scramble cells ($p < 0.001$), whereas growth kinetics was unaltered *in vitro* and *in vivo*. To delineate the functional contribution of DDR1 in metastatic activity, tumor burden and osteolytic lesions were evaluated by bioluminescence imaging (BLI), X-Ray and μ CT image analysis, after intracardiac inoculation (i.c.) in athymic nude mice. At day 7, BLI showed a dramatic decrease in skeletal tumor burden in shDDR1 injected mice. More importantly, a marked reduction in osteolytic lesions assessed by X-Ray imaging and μ CT scans was also detected in shDDR1 inoculated mice at day 14 ($p < 0.001$). To evaluate whether these effects were the result of impaired bone homing, we performed i.c. inoculation of shDDR1 cells and we assessed tumor burden at day

5. BLI was decreased in shDDR1 injected mice as compared to control mice. Quantification of metastatic cell number in hind limbs revealed a marked decrease in shDDR1 mice ($p < 0.01$) indicating that DDR1 was critical in early events of bone homing. To explore its possible contribution in bone colonization, we intratibially injected shDDR1 cells. Significant decrease in BLI was correlated with a decrease in osseous tumor burden, evaluated by histological image analysis of shDDR1 injected mice, suggesting an impaired colonization ability of shDDR1 cells. Interestingly, antiapoptotic effects mediated by collagen type I were inhibited in shDDR1 cells, measured by PARP cleavage. Thus, these data indicate that disruption of DDR1 hampers tumor cell survival leading to impaired early tumor-bone engagement during skeletal homing. Inhibition of DDR1 critically alters osseous colonization delaying the appearance of osteolytic lesions. We suggest that DDR1 represents a novel therapeutic target involved in bone metastasis.

Disclosures: Karmele Valencia, None.

The Ubiquitin E3 Ligase WWP1 Negatively Regulates Breast Cancer Bone Metastasis by Promoting Lysosomal Degradation of CXCR4. Lei Shu^{*1}, Kristina Subik¹, Qianqian Liang¹, David Hicks¹, Brendan Boyce¹, Linda Schiffhauer¹, Di Chen¹, Ping Tang¹, Lianping Xing². ¹University of Rochester Medical Center, USA, ²University of Rochester, USA

Advanced breast cancers preferentially metastasize to bone where the bone microenvironment produces factors for cancer cell homing and growth. Expression of the ubiquitin E3 ligase WWP1 is increased in some breast cancers, but its role in bone metastasis is unknown. To examine this, we knocked down WWP1 in MDA-MB-231 breast cancer cells using shRNA and inoculated shWWP1 cells and control (Ctl) virus infected cells into the left ventricle of athymic nude mice. X-rays show that mice that given shWWP1 cells had more osteolytic lesions (4.3+0.8 vs 1.8+0.5 osteolytic lesions/mouse in Ctl cells). Histology confirmed increased tumor area in the bone marrow of the mice given shWWP1 cells (8+0.8 vs 4+0.6 mm²/leg in Ctl cells). WWP1 knockdown did not affect tumor cell growth, survival or osteoclast inducing potential *in vivo*, but significantly increased cell migration toward a CXCL12 (chemokine SDF-1) gradient (% migrated cells: 13+0.6 vs 5+0.4 in Ctl cells) *in vitro*. To examine the mechanisms whereby WWP1 affects cell migration, we treated Ctl cells with the CXCL12 and found that CXCL12 reduced the levels of its receptor CXCR4, an effect largely prevented by the lysosome inhibitor chloroquine, but only slightly by the proteasome inhibitor MG132 (% CXCR4 degradation: 75% in vehicle-, 20% in chloroquine-, 50% in MG132-treated cells). CXCL12-induced CXCR4 degradation was almost abolished in shWWP1 cells (15+1%). CXCL12 enhanced co-localization of CXCR4 with the lysosome protein, LAMP2, in Ctl cells (61% vs 39% in PBS), but not in shWWP1 cells (47% vs 41% in PBS). Stronger CXCR4 immuno-staining was detected in bone mets from mice given shWWP1 cells. To investigate the translational significance of our findings, we immuno-stained for WWP1 in a breast cancer tissue microarray containing cores of tumor samples from 118 patients and found that 80 cases were WWP1 negative or had weak staining. Among these 80 cases, 3-fold more cases were ER+/PR-, typical of breast cancers that metastasize to bone, compared to WWP1 positive tumors. In summary, WWP1 negatively regulates breast cancer cell migration to a CXCL12 gradient by promoting CXCR4 lysosomal degradation, thereby enhancing tumor cell metastasis to bone. We conclude that WWP1 is a potential prognostic indicator for breast cancer bone metastasis, and factors that increase WWP1 expression or activity in breast cancer cells may decrease their capacity to metastasize to bone.

Dual Function of the Estrogen Receptor Related Receptor Alpha (ERR α) In Breast Cancer and Bone Metastasis Formation: Implication of VEGF and Osteoprotegerin. Anais Fradet¹, Helene Sorel¹, Lamia Bouazza¹, Delphine Goehrig¹, Baptiste Depalle¹, Akeila Bellahcene², Vincent Castronovo², Helene Follet¹, Francoise Descotes³, Jane Aubin⁴, Philippe A.R. Clezardin⁵, Edith Bonnelve^{*6}. ¹Inserm, UMR1033, France, ²GIGA-Cancer, University of Liege, Belgium, ³Service de Biochimie Biologie Molculaire Sud, Centre hospitalier Lyon Sud, France, ⁴University of Toronto Faculty of Medicine, Canada, ⁵INSERM & University of Lyon, Fra, ⁶Faculte de Medecine RTH Laennec, France

Bone metastases are a frequent complication of cancer, occurring in up to 70 percent of patients with advanced breast cancer. Estrogen receptor related receptor alpha (ERR α) is a nuclear receptor that belongs to the orphan receptors family, for which no ligand have yet been determined. ERR α that shares structural similarities with the estrogen nuclear receptors ER α and ER β can impinge on estrogen pathway and is involved in breast cancer and bone development. We then decide to address ERR α function in bone metastasis development. ERR α is highly expressed *in situ* in breast cancer cells that metastasized to bone in patients. Similar observation was made in bone metastases 30 days after intravenous inoculation in mice of the MDA-231 derived cells MDA-BO2 (BO2) breast cancer cells, known to be highly metastatic to bone. Then modulation of ERR α expression in BO2 cells shows that human BO2 cells over-expressing wild-type ERR α (ERR α WT) induced osteolytic bone metastasis

in BALB/c nude mice (n=10) that were reduced (150.9 for Bone volume (BV/TV)(%) and 214.8 for skeletal tumor burden (TB/STV)(%) compared to that observed with parental BO2-CT cells (111.1(BV/TV) and 364.2(TB/STV)), whereas osteolysis was enhanced (6.40,4(BV/TV) and 713.2(TB/TV)) in animals bearing BO2 tumors expressing a dominant negative form (ERRaΔAF2(coactivator domain deleted)) of ERRa. Osteoclasts were directly affected *in vivo* and *in vitro* in primary culture of bone marrow cells performed in presence of RANKL/MCSF and BO2 clones conditioned media. Moreover the osteoprotegerin (OPG), an osteoclastogenesis inhibitor was up and down-regulated in BO2-ERRaWT and ERRaΔAF2 cells respectively. Osteopontin and MMP1 were also regulated. On the other side, we reinforce ERRa as a bad prognostic factor in primary tumor as growth of BO2-ERRaWT cells in the mammary gland was increased. Tumors were highly vascularized compared to BO2 and BO2-ERRaΔAF2 cells and the vascular endothelial growth factor (VEGF), a known target gene for ERRa was up-regulated in BO2-ERRaWT cells. Finally we show that elevated expression of ERRa mRNA in breast carcinomas (cohort of 254 patients) is also associated with high level of VEGF and OPG. In conclusion, our data provide for the first time evidence that ERRa plays a dual role during breast cancer progression, promoting local tumor growth (via angiogenesis and VEGF), but decreasing osteolytic lesions in bone (via the direct impact on osteoclasts and OPG).

Variable Bone Formation Response to Skeletal Axial Load in Mice With a Conditional Deletion of the Connexin43 (Cx43) Gene (*Gja1*). Susan Grimston^{*1}, Marcus Watkins¹, Michael Brodt², Matthew Silva¹, Roberto Civitelli¹. ¹Washington University in St. Louis School of Medicine, USA, ²Washington University in St. Louis, USA

We have previously shown an attenuated endocortical bone formation response to 3-point bending mechanical loading in mice with a conditional deletion of *Gja1* driven by the *Col1A1* promoter. Consistent with a key role of Cx43 in skeletal responses to mechanical stimuli, we have also found reduced sensitivity of cortical bone to the effects of muscle paralysis in these mice. In this study, we assess the response to tibial compression, a more physiologic loading regime, in mice where *Gja1* ablation is driven by *Dermo1/ Twist2* promoter in the entire chondro-osteoprogenitor lineage (cKO). Since these cKO mice have significantly enlarged marrow cavity and thin cortices relative to wild type (WT) mice, strain gauge studies were performed, and these indicated that a load of 12 N was required to generate a periosteal strain of 1200µε in the cKO, whereas in WT mice a load of 8N was sufficient to generate the same strain. We then tested the response to load (5 days per week, 60 cycles/day) in cKO (12N, 1200µε) relative to WT mice subjected to either the same strain (8N, 1200µε) or the same load (12N, 1900µε). Using *in vivo* µCT, we detected a significant increase in cortical bone volume in all groups post-load. Surprisingly, dynamic histomorphometry revealed a significant reduction in endocortical mineralizing surfaces in the cKO (-23.51.95%; $p < 0.05$) and downward trends in the 1200µε (-9.973.8%) and 1900µε (-5.25.7%) WT groups. However, there was a significant increase in periosteal mineralizing surface (Ps.MS/BS) in the cKO with 1200µε load (83.626.9%; $p < 0.05$), while it required 1900µε load to increase Ps.MS/BS in the WT (68.117.8%; $p < 0.05$). Periosteal MS/BS did not increase significantly in WT 1200µε (7.49.91%). Thus, contrary to 3-point bending, axial tibial compression at these loads does not stimulate endocortical bone formation, but rather periosteal bone apposition. Also at variance with the 3-point bending method, Cx43 deficiency enhances the sensitivity of periosteal bone formation response to axial loading, while it negatively affects endocortical bone formation. Therefore, the role of Cx43 in mechanotransduction is complex, and depends upon the type of mechanical stimulus and anatomical skeletal site.

Periostin Deficiency Increases Cortical Microcracks and Reduces Woven Bone Formation in Mice Subjected to Fatigue Loading. Nicolas Bonnet^{*1}, Markus burkhart², Andres Laib³, Serge Ferrari⁴. ¹Division of Bone Diseases, Geneva University Hospital & Faculty of Medicine, S, Switzerland, ²SCANCO Medical AG, Switzerland, ³Scanco Medical, Switzerland, ⁴Geneva University Hospital & Faculty of Medicine, Switzerland

Susceptibility to microcracks depends on bone microstructure, turnover and material properties, however the role of distinct bone matrix constituents on fatigue damage and repair remains poorly understood. We previously reported that deficiency of the bone matrix protein periostin is associated with decreased collagen crosslinks. Here we analyzed the role of periostin in response to fatigue, including cortical porosity, microcracks and callus formation (repair).

Twelve week-old *Postn*^{-/-} and *Postn*^{+/+} male mice were subjected to a unique fatigue stimulus of the tibia by *in vivo* axial compression. Two weeks after the fatigue, we evaluated tibia bone microarchitecture by µCT40 *ex vivo*; the number of "pores" (>14µm) and osteocytic lacunae at the 1/3rd distal by µCT50 (1µm nominal resolution); cracks by fuschin staining on undecalcified bone; and cortical strength by 3 points bending. In *Postn*^{+/+}, fatigue significantly increased Ct.TV and Ct.BV (+14.8% and +12.7% vs contralateral tibia $p < 0.05$). A woven bone response was

present in 75% of the fatigued bone by both µCT and histology. The number of pores increased 8 fold in the fatigued tibia, whereas cracks number/BPm and surface/BS increased +172% and +375%, respectively, compared to the non-fatigued side ($p < 0.05$). In contrast, in *Postn*^{-/-}, fatigue did not change Ct.TV and Ct.BV, and only 16% of the fatigued bones presented a woven bone response. In the control tibias, *Postn*^{-/-} tended to have higher number of osteocyte lacunae compared to *Postn*^{+/+} with a significant lower SMI (Shape index) (-18.7%, $p < 0.05$); and significant higher cracks surface/BS than *Postn*^{+/+} (4.181.14% vs 0.850.17%, $p < 0.05$). Fatigue increased the number of pores in the same range than *Postn*^{+/+}. Fatigue increased cracks number/BPm and surface/BS (+78% and +83% vs non fatigued bone, $p < 0.05$). Despite *Postn*^{-/-} response similarly to fatigue on cracks than *Postn*^{+/+}, cracks number/BPm was higher in the fatigued tibia of *Postn*^{-/-} compared to *Postn*^{+/+} (2.220.17 1/mm vs 0.970.10 1/mm, $p < 0.05$). In accordance with a lower repair, fatigue decreased stiffness and plastic energy in *Postn*^{-/-} (-29.4% and -38.4% in fatigue vs non-fatigue tibia, $p < 0.05$) but not in *Postn*^{+/+}. In absence of periostin, cracks reached a high proportion in fatigued bone and woven bone repair at the periosteum surface is reduced. The possible link between more osteocyte lacunae and microcracks and lower woven bone formation are still under investigation.

Osteocyte Level Strain Determination Using A Multiscale Mouse Forearm Model. Ganesh Thiagarajan¹, Yunkai Lu², Mark Dallas³, Mark Johnson^{*4}. ¹University of Missouri - Kansas City, USA, ²UMKC School of Computing & Engineering, USA, ³UMKC School of Dentistry, USA, ⁴University of Missouri, Kansas City Dental School, USA

Bone is a dynamic organ that is known to adjust its mass, material and architectural properties with respect to the load environment. We have previously developed a first generation combined ulna and radius (URM) mouse forearm finite element (FE) model that simulates *in vivo* loading and compared it with the traditional ulna only model (UM). There were significant differences in strain distributions within axial cross sections in the URM versus UM model. We observed that the URM predicts a peak strain in the bones which is twenty percent higher than the UM prediction.

The osteocyte is the mechanosensory cell in bone, and any reduction in its ability to respond to load would have significant consequences on bone mass. Whereas the magnitude of strain necessary to induce bone formation at the macro level is 1500-2000 µstrain, a major gap exists in our knowledge of what the actual magnitude of strain the individual osteocyte senses will elicit a biological response. We have developed a next generation micro FEA model at the osteocyte level of resolution (7-12 micrometers) to test the hypothesis that local (micro) strain fields around osteocytes determine osteocyte response to mechanical loading. A 3-D representation of osteocyte lacunae was obtained from histological serial sections and the lacunae locations were built into a thin (72 microns) slice of the macro model. Displacement boundary conditions obtained from a 2N level of load on the macro model were determined and applied to the micro FE model and strain fields were mapped. Peak strains around lacunae were observed as high as 20,000-30,000 microstrains and the homogenous strain fields observed in the macro FEA models were transformed into a spatially heterogeneous pattern. In addition, micro FEA modeling showed heterogeneity of strain pattern at the osteocyte lacunae from a temporal perspective.

Using the TOPGAL reporter mouse we are now determining the microstrain levels needed to activate β-catenin signaling in osteocytes using our models. By combining our micro FEA model with biological response data, we will for the first time begin to define how osteocyte level strains and the threshold for activation of a biological response are influenced by bone material properties and changes associated with aging. These findings could enable us to design skeletal anabolic strategies based on new drugs that enhance the effects of exercise and thereby reduce the risk of fracture.

Previous Exposure to Microgravity Does not Adversely Affect Second Exposure in the Tibia of Hindlimb Unloaded Adult Male Rats. Yasaman Shirazi-Fard^{*1}, DERRICK MORGAN¹, Joshua Kupke¹, JOSHUA DAVIS¹, Florence Lima², Elizabeth Greene¹, Alyssa McCue¹, Joseph Marchetti¹, Joey Thompson¹, Susan Bloomfield¹, Harry Hogan¹. ¹Texas A&M University, USA, ²University of Maryland School of Medicine, USA

Bone response to extended microgravity remains a concern for astronaut health. A particular question is how prior missions affect subsequent missions. Animal experiments were conducted to test the hypothesis that previous exposure to unloading would exacerbate the effects of a 2nd exposure. This study focused on proximal tibia metaphysis (PTM) and tibia diaphysis (TD).

Adult male Sprague-Dawley rats (6 mo.) were assigned to 2 groups: aging cage control (CC), hindlimb unloaded (HU). HU animals were further divided into subgroups: 1HU and 2HU. The 2HU group had 28d of HU at 6 mo. (2HU6), followed by 56d of recovery, and another 28d of HU (2HU9) starting at 9 mo. (day 84). The 1HU group had one bout of HU (1HU9) starting on day 84 (to match

2HU9). Animals were scanned by pQCT *in vivo* every 28d at PTM and TD. A group (n=15) was euthanized every 28d (days 0, 28, 56, 84, 112 & 168) from each of CC, 1HU, and 2HU groups. Excised tibiae were scanned by pQCT and tested to failure in 3-point bending.

PTM total (integral) BMC and vBMD decreased (7%) significantly for 2HU6 but not for 2HU9 (2nd exposure). Both were lower for 2HU9 but only by 2-3% (n.s.). Total BMC and vBMD were also significantly lower (5-7%) for 1HU9. This indicates that the 1st HU for either group has significant negative effects (5-7% reductions) despite different ages. The milder losses of 2nd HU may be attributable to the fact that 2HU animals did not recover fully from 2HU6. Means of BMC, vBMD, and Ct.Ar returned to day 0 levels after 56d of reloading, but remained lower than age-matched CC animals (and 1HU). The cross-sectional area of the cortical shell (Ct.Ar) in PTM showed a similar response. For 2HU, Ct.Ar decreased 7% for 2HU6 (sig.) but only 3% for 2HU9 (n.s.). For 1HU, Ct.Ar decreased 7% due to HU (sig.). There was only mild decrease (1-2%, n.s.) in total area, which suggests thinning of the cortical shell. TD fracture force from 3-point bending showed no effect for 2HU6, but drastic reductions (sig.) for 2HU9 (28%) and 1HU9 (29%). Stiffness was similar (11-26% losses, but n.s.). In contrast, there was no change in TD Ct.Ar for 2HU9 or 1HU9.

Contrary to our hypothesis, PTM losses from 2nd HU were less than the 1st regardless of age. For TD, losses in fracture force were dramatic for the 2nd HU vs. no change for the 1st. Unexpectedly, the same dramatic losses occurred for age-matched single HU, indicating no effect of prior exposure, with the main effect being the age at HU (9 mo.).

Increased Sensitivity to Skeletal Unloading in Connexin43-deficient Mice. Shane Lloyd*, Emmanuel Paul, Yue Zhang, Henry Donahue. The Pennsylvania State University College of Medicine, USA

Previous studies have elucidated a role of gap junctional intercellular communication in the process of bone mechanosensing. In particular, Connexin43 (Cx43) has been demonstrated as an integral component of the skeletal response to mechanical loading. However, very little work has focused on Cx43's role in mechanical unloading. Practical examples of skeletal unloading include extended periods of bed rest due to neurological injury or the microgravity environment of spaceflight. We sought to characterize the skeletal phenotype of Cx43-deficient mice in response to mechanical unloading via hindlimb suspension (HLS). We utilized 6-month-old male mice with an osteocalcin-driven deficiency of Cx43 specific to osteoblasts and osteocytes (KO) and their WT-equivalent littermates. Mice were subjected to HLS for just 7 days. At day 0 (baseline) and day 7 all mice were subjected to a microcomputed tomography scan of one hindlimb. Trabecular bone parameters were assessed at the proximal tibia and cortical bone at the femur midshaft. At baseline, KO mice demonstrated expanded cortices consistent with an osteopenic phenotype characteristic of this model: periosteal volume in KO was greater than WT (1.13 vs. 0.7 mm³; P<0.05) as was endocortical volume (0.74 vs. 0.45 mm³; P<0.05). No significant differences were seen in cortical thickness or cortical BMD at baseline, although there was a trend suggesting increased cortical porosity in KO mice vs. WT. KO mice had greater trabecular connectivity density (68 vs. 21 mm⁻³; P<0.05) and trabecular bone volume fraction (14.9 vs. 6.7%; P<0.01) than WT mice. Individual trabeculae in KO mice were also thicker than WT (0.061 vs. 0.048 mm; P<0.01). The difference between WT and KO mice on day 7 followed a similar pattern. Not surprisingly, the relatively short duration of HLS did not affect any measured bone parameters in WT mice between baseline and day 7; however, KO mice showed a significant 15% and 10% decrease in trabecular connectivity and volume fraction, respectively (P<0.05) over the period of HLS. These results confirm a phenotype of medullary expansion, but increased trabecular bone at the proximal tibia in Cx43-deficient mice. More importantly, KO mice displayed an increased sensitivity to unloading in that even short duration HLS (one week) resulted in trabecular bone loss in these skeletally mature mice. These results highlight a contrasting role for Cx43 in cortical and trabecular bone during unloading.

Mechanical Regulation of GSK3 β in MSC is Dependent on Akt Activation via Rictor/mTORC2. Natasha Case^{*1}, Jacob Thomas², Buer Sen³, Zhihui Xie², Maya Styner¹, Janet Rubin¹. ¹University of North Carolina, Chapel Hill, School of Medicine, USA, ²UNC, USA, ³University of North Carolina At Chapel Hill, USA

GSK3 β is emerging as a critical signaling node of mechanical responses in mesenchymal stem cells (MSC). Mechanical signals inactivate GSK3 β via phosphorylation, resulting in stabilization of β -catenin, and when repeated daily, block adipogenesis induced by soluble factors in the local environment. The proximal pathways required for mechanical inhibition of GSK3 β activity are unknown. We considered whether Akt, which decreases GSK3 β activity in response to insulin, was critical for mechanical effects. Mechanical strain (2%, 0.17Hz) activated Akt via phosphorylation at both Thr 308 and Ser 473 by 15 minutes. Blocking strain activation of Akt using an AKT1/2 inhibitor or by Akt siRNA knockdown resulted in a complete loss of GSK3 β Ser9~P in response to mechanical strain. PI3K is known to mediate Akt phosphorylation by membrane recruitment via PIP3, and PI3K action is

necessary for Akt~P by insulin. The PI3K inhibitor LY294002 prevented strain-induced phosphorylation at T308~P, but, in contrast to insulin treatment, phosphorylation at S473 was unimpaired; importantly, mechanical inactivation of GSK3 β was not blocked by PI3K inhibition, indicating that S473~P alone was sufficient to initiate the downstream mechanoresponse. With this information, we concentrated on S473~P: we considered that Rictor/mTORC2 is known to specifically transduce insulin-induced phosphorylation at this serine. The mTOR inhibitor KU-0063794 completely prevented S473~P by both mechanical and insulin stimulation. Blocking S473~P had differential effects on GSK3 β ~P; mechanical inactivation of GSK3 β was blocked, but insulin inhibition of GSK3 β , presumably through predominant effects on T308 was unaffected. Interestingly, the PKC inhibitor Calphostin C resulted in a loss of Akt Ser473~P by both strain and insulin, suggesting PKC involvement in mTORC2 function. In sum, mechanical input initiates a signaling cascade that requires mTORC2 phosphorylation of Akt S473, which induces Akt phosphorylation of GSK3 β , even in the absence of T308~P. Our data indicate that the mechanical regulation of GSK3 β downstream of Akt is uniquely dependent on Akt S473~P in a manner distinct from that of growth factors. We speculate that mechanical Akt/GSK3 β coupling involves molecules which are already present at the membrane. These differences provide clues as to the unique processes by which mechanical input, conscripting common signaling pathways, regulates MSC function.

A Prospective Study of Predictors of Radiographic Spine Fracture in Men: the MROS study. Dennis Black^{*1}, Katherine Wilt Peters², Kristine Ensrud³, Jane Cauley⁴, Eric Orwoll⁵, Steven Cummings⁶, John Schousboe⁷. ¹University of California, San Francisco, USA, ²California Pacific Medical Center, USA, ³Minneapolis VA Medical Center / University of Minnesota, USA, ⁴University of Pittsburgh Graduate School of Public Health, USA, ⁵Oregon Health & Science University, USA, ⁶San Francisco Coordinating Center, USA, ⁷Park Nicollet Clinic/University of Minnesota, USA

The main predictors of vertebral fracture have been well studied in women, including age, BMD and prevalent vertebral fractures. Predictors of vertebral fractures in men have been less well studied. We examined predictors of incident vertebral fracture in community dwelling older men (mean age 72.6 \pm 5.4 years) from the MROS study. For this analysis, we had baseline and follow-up lateral spine radiographs from a random sample of 841 men who also had with both DXA and QCT BMD measurements of the lumbar spine. Vertebral fracture status was evaluated by the semi-quantitative scale (SQ); incident vertebral fracture was defined by a vertebra which increased by ≥ 1 point on the SQ scale. The mean time between the baseline and follow up radiographs was 4.7 years. We examined multiple possible baseline predictors including age, weight, height, BMI, physical activity by PASE score, smoking, corticosteroid use, history of non vertebral fracture, prevalent vertebral fracture at baseline (SQ ≥ 2), and lumbar spine BMD by DXA and by QCT. Variables were included in multivariate logistic regression models if they were significant at p<0.1 in a univariate model. Age was also included in multivariate models. Odds ratios in both univariate and multivariate adjusted models are reported.

There were 44 new spine fractures among these 841 men for an incidence rate of 5.2% over the 4.7 year follow-up. In univariate analyses, a prevalent vertebral fracture was a strong predictor of incident vertebral fracture (OR=4.4, p<0.01). DXA BMD was significantly related (OR/SD = 1.9, p<0.01) as was trabecular BMD by QCT (OR/SD=1.8, p<0.01). Age was not related to risk of incident vertebral fracture nor was weight, height, BMI, physical activity, smoking, corticosteroid use, or history of non vertebral fracture. In the multivariate model including age, both prevalent fracture and DXA BMD remained predictive (OR=3.8, p<0.01, and OR/SD = 1.7, p<0.01 respectively). Remarkably similar results were observed in the multivariate QCT BMD (OR=3.5, p<0.01, and OR =1.7, p<0.01 respectively).

In conclusion, these findings suggest that older men with existing vertebral fractures and/or low BMD are at very high risk of new spine fracture within five years. Multiple other clinical risk factors, including age, had minimal value in predicting incident vertebral fracture.

Bone Loss Accelerates After Age 75: A Prospective, Longitudinal Study. Steven Cummings^{*1}, Lily Lui¹, Jane Cauley², Kristine Ensrud³, Teresa Hillier⁴, Marc Hochberg⁵. ¹San Francisco Coordinating Center, USA, ²University of Pittsburgh Graduate School of Public Health, USA, ³Minneapolis VA Medical Center / University of Minnesota, USA, ⁴Kaiser Center for Health Research, USA, ⁵University of Maryland School of Medicine, USA

Background: Loss of BMD begins in midlife, increases around menopause then continues at a slower pace. Cross-sectional studies suggest that BMD is lost at a steady rate after age 60 years. However, the course of bone loss with advanced age is not known.

Methods: We measured femoral neck BMD every 2-4 years during 20 years of follow-up of the Study of Osteoporotic Fractures, a community-based cohort of women age 65 years or older at baseline. Hip BMD was measured with Hologic QDR-1000 scanners at all exams. We analyzed rates of change in BMD in 3741 women who had at least two BMD measurements and excluded women who took treatments that may affect bone. We compared the absolute and percentage mean BMD change for each of six age groups (65-69, 70-74, 75-79, 80-84, 85-89, 90+) and tested statistical significance using pair-wise t-tests. To determine whether loss could be due to decreased weight with advancing age, we also adjusted for baseline weight.

Results: Femoral neck BMD steadily decreased at approximately 0.5% per year from age 67 through age 74 years. Bone loss began to accelerate after age 75 and doubles to 1.3% per year by age 90 years (figure). The results were similar when analyzed as absolute change in mineral or by percentage loss and were also unchanged by adjustment for weight.

Conclusion: On average, in older white women, the loss of BMD in the femoral neck remains constant through from age 65 through 74 then accelerates, to more than 1% per year after 90 years. This accelerated loss contributes to the exponential increase in risk of hip fracture after age 75. Prevention of bone loss may particularly important after age 75.

Prediction of Fracture Risk in Men: A Cohort Study. Liisa Byberg^{*1}, Rolf Gedeberg², Thomas Cars², Johan Sundstrom², Lars Berglund³, Lena Kilander², Hakan Melhus⁴, Karl Michaelsson³. ¹Uppsala Universitet, Sweden, ²Uppsala University, Sweden, ³Uppsala Clinical Research Center, Sweden, ⁴Uppsala University Hospital, Sweden

In order to target interventional efforts, accurate identification of men with a high future risk of osteoporotic fracture is of importance. Our aim was therefore to determine how much of the variation in fracture rate in men that can be explained by the WHO fracture risk assessment tool FRAX, comorbidity, medication, and behavioral factors, separately and in combination, and at different ages.

The Uppsala Longitudinal Study of Adult Men (ULSAM) is a population-based cohort study. All men born 1920-24 and resident in Uppsala in January 1970 were invited and 2322 (82%) participated. Reinvestigations among survivors were performed at ages 60 (n=1852), 71 (n=1221), and 82 (n=526) years. Follow-up was until 31 December 2009. Bone mass density (BMD) was measured using DXA at age 82. The prognostic value estimated by survival analysis R^2 representing the proportion of variation in time to any fracture and hip fracture was calculated for FRAX, comorbidity, medication, and behavioral factors, separately and in combination.

During follow-up, 897 fractures occurred in 585 individuals. The 10-year rates of any fracture were 5.7/1000 person-years at risk from age 50 and 25.9/1000 person-years at risk from age 82. Corresponding hip fractures rates were 2.9 and 11.7/1000 person-years at risk. The full model combining FRAX, comorbidity, medications, and behavioral factors had the highest R^2 values at all ages both for all fractures and for hip fracture, explaining 25-45% of all fractures and 80-92% of hip fractures, depending on age. The corresponding prognostic values of the FRAX model were 7-17% for all fractures and 41-60% for hip fractures. Within the highest quintile of predicted fracture risk with the full model, 1/3 of the men had a fracture within 10 years after the age of 71 years and 2/3 after the age of 82 years. Addition of BMD at age 82 to the full model improved discrimination further whereas number of previous falls did not.

The addition of comorbidity, medication and behavioral factors to FRAX can substantially improve the ability to identify men at high risk of fracture, especially hip fracture. Future studies need to assess whether additional measurement of BMD, vitamin status and other factors can guide the physician towards the appropriate treatment.

Variation in fracture rate explained by FRAX model and the full model, R^2 (95% confidence intervals)

	No. (%) fractures	FRAX model	Full model
Any fracture within 10 years, from age			
50 yrs	126 (5)	14.3 (6.5-24.9)	37.5 (25.8-51.3)
60 yrs	109 (6)	14.7 (5.2-28.8)	42.6 (27.6-59.6)
71 yrs	143 (12)	7.0 (2.4-15.1)	24.7 (15.1-38.5)
82 yrs	64 (12)	17.1 (6.7-33.9)	44.6 (28.5-63.3)
Hip fracture within 10 years, from age			
50 yrs	9 (0.4)	not analyzed	not analyzed
60 yrs	22 (1)	60.5 (27.8-87.6)	92.2 (71.5-99.3)
71 yrs	41 (3)	40.8 (17.6-68.2)	80.4 (64.9-92.3)
82 yrs	30 (6)	57.0 (29.8-81.9)	86.6 (67.1-97.1)

Fracture Prediction from Repeat BMD Measurements in Routine Clinical Practice for: The Manitoba BMD Cohort. William Leslie^{*1}, Suzanne Morin², Lisa Lix³. ¹University of Manitoba, Canada, ²McGill University Health Centre, Canada, ³University of Saskatchewan, Canada

BACKGROUND: In routine clinical practice, many patients receive repeat BMD measurements. Whether subsequent measurements are as useful for fracture risk assessment as the baseline measurement, and whether this is affected by recent osteoporosis therapy (OTX) or changing BMD are unclear. **METHODS:** We identified N=50,215 patients over age 50 at the time of baseline BMD testing between 1990 and 2009 in a large clinical BMD database for the Province of Manitoba, Canada. 2nd BMD tests were performed in N=14,619, 3rd BMD tests in N=4,722, and 4th BMD tests in N=1,500. Patient subgroups were identified with 2 scans (N=13,481) or 3 scans (N=4,087). Using linkage to a population-based administrative health data repository, we identified other relevant covariates, medication use, and fracture outcomes up to March 2010. Cox proportional hazards models were used to assess major osteoporotic fracture risk and hip fracture risk according to BMD (total hip [base model], lumbar spine, femoral) at baseline and follow up after adjustment for OTX and multiple covariates (sex, age, BMI, prior fracture, prolonged glucocorticoid use, rheumatoid arthritis, COPD [smoking proxy] and alcohol/substance abuse). **RESULTS:** Prevalence of recent OTX increased from 18% at baseline to 55% by scan #4. Total hip BMD was strongly predictive of major osteoporotic fractures at all time points (Figure). In the patient subgroup with 2 measurements, major fracture prediction with the 1st scan (HR per SD 1.45 [95% CI 1.34-1.56]) was similar to the 2nd scan (1.64 [1.48-1.81]). Similar results were seen in the patient subgroup with 3 scans. No significant differences were seen between when 2nd scan results were stratified by recent OTX using the medication possession ratio for the prior year (HRs 1.50 [1.28-1.76] for MPR=0, 1.46 [1.09-1.96] for MPR <0.5, 1.83 [1.30-2.58] for MPR 0.5-0.8, 2.08 [1.72-2.51] for MPR >0.8; p-interaction NS) or by BMD change (HR for 1.58 [1.37-1.82] no change, 1.50 [1.09-2.06] for significant increase, 1.66 [1.30-2.13] for significant decrease; p-interaction NS). Similar results were seen for hip fracture prediction, or when lumbar spine and femoral neck BMD were analyzed. **CONCLUSIONS:** BMD measurement is a robust predictor of fractures, and this does not diminish on repeat measurements or after prior OTX.

Subtrochanteric/femoral Shaft versus Hip Fractures: Incidence and Identification of Risk Factors. Milka Maravic^{*1}, Agnes Ostertag², Martine Cohen-Solal³. ¹Département d'Information Médicale, Hôpital Leopold Bellan, France, ²U606 INSERM, France, ³Centre Viggo Petersen, France

Introduction: Subtrochanteric and femoral shaft (ST/FS) fractures are now considered as fragility fractures in osteoporotic patients. Although rare, there is growing evidence showing the burden of this type of fracture. The evolution of the incidence of ST/FS fractures is poorly known. The aim of this study was to assess the incidence of ST/FS fractures from 2002 to 2009 in France as well as the associated risk factors.

Methods: Data were obtained from the French National Database which includes all hospital discharge codes in public and private acute care settings from 2002 to 2009. All hospital stay for primary surgical management of neck/trochanteric (hip) and subtrochanteric/femoral shaft (ST/FS) fractures in patients aged 50 years and older was selected and described in different age-groups. Incidence per million were calculated using the estimate French population adjusted for each year and by age and gender. Evolution was assessed for each site of fractures throughout this period. The factors of co-morbidity in relation to these fractures were assessed in 2009 using multivariate logistic regression.

Results: From 2002 to 2009, the incidence of hip fractures decreased significantly from 4368 to 4044 per million in women ($p<0.001$) and increased significantly from

1476 to 1609 per million in men ($p<0.0001$). In contrast, the incidence per million of ST/FS increased significantly in both gender, i.e. from 353 to 481 per million in women and from 146 to 203 per million in men. The most significant variation was particularly observed in the elderly above the age of 70 y. The percentage of ST/FS fractures among fractures of the femur was about 7.5-10.6% in women and 8.9-11.2% in men. In 2009, the incidence of ST/FS in the general population remained low at the level of 0.05% and 0.02% in women and men respectively. However, this percentage reached 0.3% and 0.2% in women and men aged 90 years and over. The adjusted risk of having a ST/FS fracture compared to hip fracture was significantly higher with obesity (OR: 2.2; 1.77-2.74) and dementia (adjusted OR 1.22; 1.16-1.29) but slightly decrease with age >84 years (OR: 0.85 (0.81-0.89), cardiac arrhythmia (OR 0.92; 0.85-0.99) and hypertension: OR (0.93; 0.88-0.98).

Conclusion: In contrast to hip fractures, the incidence of ST/FS fractures increased significantly from 2002 to 2009 in France and affects mostly the elderly. Moreover, obesity and dementia are the major risk factors associated with this fracture site.

Recent Trends in Hip Fracture Rates by Race/Ethnicity in Older US Adults. Nicole Wright^{*1}, Wilson Smith¹, Kenneth Saag¹, Jeffrey Curtis¹, Michael Morrissey¹, Meredith Kilgore², Huifeng Yun¹, Jie Zhang¹, Elizabeth Delzell¹. ¹University of Alabama at Birmingham, USA, ²University of Alabama At Birmingham School of Public Health, USA

Purpose: Hip fracture incidence among Caucasians has declined in the US since 1995. Limited data are available on recent trends in racial and ethnic minorities. The goal of this study was to investigate hip fracture incidence trends in Medicare beneficiaries.

Methods: We used the Medicare national random 5% sample to determine annual hip fracture incidence rates during 2000-2009. Eligibility in each year was restricted to days when the beneficiary was in the 5% sample, was 65+ years of age, lived in the 50 states or Washington DC, and had full fee-for-service Medicare coverage. To ensure that only incident hip fractures were identified, each day of observation was preceded by 90 days of continuous fee-for-service coverage with no hip fracture claims. Race/ethnicity was self-reported by the beneficiary. We identified incident hip fractures using claims data consisting of inpatient hospital diagnosis codes and outpatient diagnosis codes paired with fracture repair procedure codes. We computed age-standardized rates using the 2009 Medicare population ≥65 years as the standard, and tested trends in the rates over time among each racial/ethnic group using linear regression.

Results: On average, 822,000 women and 585,000 men contributed person-time to the analysis each year. Beneficiaries were predominantly White (88%), with African, Hispanic, and Asian Americans making up 8%, 2%, and 1.5% of the population, respectively. In women, a decreasing significant trend ($p<0.05$) in hip fracture incidence from 2000 to 2009 was present in all racial/ethnic groups (Figure). This trend was most consistent across years in Whites and African Americans, with the hip fracture incidence rates declining by 17% in Whites and 20% in African Americans between 2000-2009. White men also had a significant decline in hip fracture rates ($p<0.001$); however, rates for other groups of men were based on relatively small numbers and did not display consistent trends.

Conclusion: Among Medicare beneficiaries, incidence rates of hip fracture decreased between 2000-2009 in women of all racial/ethnic groups and in White men. No significant decline was observed in men of other racial/ethnic groups. The results suggest that additional hip fracture prevention efforts are needed among the growing population of ethnic/racial minorities, particularly men, in the US.

Fractures and Mortality in Relation to Different Osteoporosis Treatments. Huifeng Yun^{*1}, Elizabeth Delzell¹, Robert Matthews¹, Meredith Kilgore², Kenneth Saag¹, Cathleen Colon-Emeric³, Christopher O'Connor⁴, Kenneth Lyles³, Michael Morrissey¹, Jeffrey Curtis¹. ¹University of Alabama at Birmingham, USA, ²University of Alabama At Birmingham School of Public Health, USA, ³Duke University Medical Center, USA, ⁴Duke University, USA

BACKGROUND: Few studies have assessed the effectiveness of different drugs for postmenopausal osteoporosis (OP).

OBJECTIVES: We compared fracture incidence and mortality among Medicare beneficiaries initiating various OP medications.

METHODS: Using the Medicare national random 5% sample, we identified new users of oral bisphosphonates (BPs), intravenous (IV) ibandronate (IBN), IV zoledronic acid (ZOL), calcitonin (CAL), raloxifene (RAL) and parathyroid hormone (PTH). Eligible subjects were ≥ 65 years; continuously enrolled in fee for service and part D Medicare; and newly treated during 2006-2008. New treatment was defined as therapy initiated after 12 month baseline during which no prescription was filled for the drug. Subjects remained in their initial drug category regardless of any switching of medication during follow-up. Cox proportional hazards models evaluated associations between different OP drugs and mortality and also first hip, distal radius/ulna, clinical vertebral, or humerus fracture. Analyses used IV ZOL as the referent and adjusted for multiple confounders. Further confounder control was examined using propensity score (PS) quintile adjusted and PS matched analyses.

RESULTS: We identified 24537 new users for oral BPs, 750 for IV IBN, 1962 for IV ZOL, 7231 for CAL, 986 for PTH and 2222 for RAL. These cohorts experienced, respectively, 8.4%, 12.9%, 8.8%, 17.0%, 13.6%, 7.8% fractures and 8.8%, 7.6%, 6.1%, 21.2%, 12.9% and 6.4% deaths during follow-up. After multivariable adjustment (ZOL referent), hazard ratios for fracture were 1.41 (95% CI: 1.03-1.93) for IV IBN, 1.33 (1.06-1.66) for oral BPs; 1.47 (1.16-1.86) for CAL, 1.27 (0.97-1.67) for RAL and 1.05 (0.78-1.42) for PTH; and for mortality were 0.84 (0.60-1.22) for IBN, 0.94 (0.76-1.18) for oral BPs, 1.47 (1.17-1.85) for CAL, 0.99 (0.75-1.31) for RAL and 1.31 (0.98-1.75) for PTH.

CONCLUSIONS: Compared to IV ZOL, fracture rates among users of other BPs or CAL were 33-47% higher; mortality was 47% greater among users of CAL. While fracture benefit may be in part mediated through improved adherence to IV ZOL, the mechanism for a possible mortality benefit remains unclear.

Table: Compare the crude and adjusted hazard ratios between different osteoporosis drugs				
Treatment	Fractures		Death	
	Crude	Adjusted	Crude	Adjusted
IV Zoledronic acid	Ref	Ref	Ref	Ref
IV Ibandronate	2.30 (0.95-1.76)	1.41 (1.03-1.93)	0.86 (0.60-1.22)	0.84 (0.59-1.20)
Oral BP	0.82 (0.67-1.00)	1.33 (1.06-1.66)	1.04 (0.84-1.28)	0.94 (0.76-1.18)
Calcitonin	1.63 (1.30-2.04)	1.47 (1.16-1.86)	2.48 (1.99-3.09)	1.47 (1.17-1.85)
Raloxifene	0.73 (0.56-0.95)	1.27 (0.97-1.67)	0.75 (0.57-0.98)	0.99 (0.75-1.31)
Parathyroid Hormone	1.21 (0.90-1.62)	1.05 (0.78-1.42)	1.46 (1.10-1.93)	1.31 (0.98-1.75)

Note: We adjusted age, gender, race, geographic region, income, osteoporosis related conditions, other comorbidities and medications at baseline.

Who Is at Highest Risk for New Vertebral Fractures After 3 Years of Annual Zoledronic Acid and Who Should Remain on Treatment? Felicia Cosman^{*1}, Jane Cauley², Richard Eastell³, Steven Boonen⁴, Lisa Palermo⁵, Ian Reid⁶, Steven Cummings⁷, Dennis Black⁵. ¹Helen Hayes Hospital, USA, ²University of Pittsburgh Graduate School of Public Health, USA, ³University of Sheffield, United Kingdom, ⁴Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁵University of California, San Francisco, USA, ⁶University of Auckland, New Zealand, ⁷San Francisco Coordinating Center, USA

In the HORIZON-PFT Extension study (E1), 1223 women who had already received 3 annual zoledronic acid (ZOL) infusions in the original HORIZON-PFT trial (Core) were randomized to receive 3 more ZOL infusions (Z6, n=616) or 3 placebo infusions (Z3P3, n=617). We previously showed that there were modest, but statistically significant, reductions in hip BMD, and increments in bone turnover markers, as well as a significantly higher incidence in new morphometric vertebral fractures in Z3P3 vs Z6 during E1 (Black et al. ASBMR 2010). The goal of the current analysis was to identify the predictors of new vertebral fracture risk during E1 and to determine which subgroups of patients would be most likely to benefit from continuation of ZOL for 3 additional years. Predictor variables considered and analyzed in the Z3P3 group by logistic regression included age, persistent osteoporosis by total hip (TH) or femoral neck (FN) BMD, remote history of vertebral or nonvertebral fracture, recent incident morphometric vertebral or nonvertebral fracture (during Core), PINP level at E1 baseline, % change TH BMD during Core, BMI and weight loss. Individual logistic regression models were then

used to determine if continued treatment with ZOL during E1 affected fracture outcomes (using both Z6 and Z3P3 groups) in subgroups defined by the predictors identified in the Z3P3 group. The most important predictors of new Morphometric fracture risk in the Z3P3 group were FN or TH T-score at E1 Baseline < -2.5 [Odds Ratio (95%CI)= 3.3 (1.4,8.0), $p=0.008$; and 4.01 (1.8,8.9), $p=0.0007$, respectively], and incident morphometric vertebral fracture during Core [OR 4.74 (1.3,16.7), $p=0.0156$]. Significant treatment effects with continued ZOL in E1 were seen in these high risk subgroups (See Table). In women who appear to remain at elevated fracture risk after 3 years of ZOL (those with incident vertebral fracture during the first 3 years or persistent hip osteoporosis), absolute fracture risk reductions are greatest with continued ZOL and therefore Numbers Needed to Treat (NNT) for 3 additional years are lowest. In those women who do not appear to be at elevated risk for fracture, discontinuation of treatment should be considered.

Table. Incident Morphometric Vertebral Fracture in Z3P3 and Z6 groups by Subgroup

	Z3P3	Z6	OR (CI)	Rx Effect P	NNT/3 Yrs
FN\leq-2.5	23/250 (9.2%)	9/257 (3.5%)	0.36 (0.15, 0.77)	0.011	17.5
FN$>$-2.5	7/235 (3%)	5/210 (2.4%)	0.79 (0.23, 2.53)	0.698	167.3

Increase of Serum PINP Is Associated with Trabecular Microstructural Improvement in Patients on Teriparatide Pretreated with Alendronate. Astrid Fahrleitner-Pammer^{*1}, Harald Dobnig², Jan Stepan³, Helmut Petto⁴, Imre Pavo⁵. ¹Medical University Graz, Austria, ²Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria, ³Charles University, Czech Republic, ⁴Lilly Research Center, Austria, ⁵Eli Lilly & Company, Austria

Early increase in serum amino terminal propeptide of type I procollagen (PINP) after the initiation of teriparatide (TPTD) treatment has been demonstrated to positively correlate with increase of lumbar spine bone mineral density (BMD). Consequently, PINP response has been proposed to predict the efficacy of TPTD therapy. In the initial treatment phase with TPTD therapy, alendronate (ALN) pretreatment may blunt the PINP response. The aim of this exploratory, post-hoc analysis was to investigate the correlation between changes in PINP and bone microstructure, a component of bone quality, in patients receiving TPTD subsequent to ALN pretreatment.

Sixty-six postmenopausal women with osteoporosis (mean age of 68.0 [SD 7.0] years and mean BMD T-score of -1.7 [SD 0.9] at total hip and -2.8 [SD 0.8] at lumbar spine; 62% with prevalent fractures) have been treated with 20 µg/day subcutaneous TPTD for 24 months. Thirty-eight stopped previous ALN treatment (10 mg/day or 70 mg/week for a mean duration of 63.6 months), and switched to TPTD, while 28 were osteoporosis treatment naive (TN). Paired iliac crest biopsies were collected and analyzed by micro-CT at baseline and after 24-month TPTD administration. The serum levels of PINP, type I collagen cross-linked C-telopeptide (CTX) and bone-specific alkaline phosphatase (BSAP) were determined at baseline, 1, 3, 6, 12 and 24 months of treatment. The changes of biochemical markers from baseline to different treatment durations were correlated (Spearman rank correlation coefficient) with 24 months changes of bone microarchitectural variables.

ALN pretreatment did not delay the increase of PINP. One, 3 and 6 months changes of bone markers did not demonstrate consistently correlation with 24 months changes in microstructural variables. After 12 months, the change in PINP revealed significant positive correlations with three-dimensional indices of improved trabecular microarchitecture (Table).

The correlations were not different between TN and ALN pre-treated groups (Fisher z-test). Our results support the use of PINP as a surrogate marker of bone efficacy of teriparatide, including patients previously treated with a potent aminobisphosphonate like ALN.

3-D trabecular micro-architectural indices	Spearman Rank Correlation coefficients (95% CI)	
	All (n=45)	ALN pre-treated (n=29)
Bone tissue volume	0.49(0.23 to 0.68)**	0.55(0.22 to 0.76)**
Thickness (µm)	0.31(0.02 to 0.56)*	0.39(0.02 to 0.66)*
Number (mm ⁻³)	0.39(0.11 to 0.62)**	0.43(0.08 to 0.69)*
Separation (µm)	-0.46(-0.66 to -0.19)**	-0.48(-0.72 to -0.13)**

*p<0.05, **p<0.01

Parathyroid Hormone (1-84) and Ibandronate Administered Concurrently Vs. Sequentially: The PTH and Ibandronate Combination Study (PICS) Randomized Trial. Anne Schafer¹, Lisa Palermo², Dolores Shoback³, Deborah Sellmeyer⁴, Dennis Black². ¹University of California, San Francisco & the San Francisco VA Medical Center, USA, ²University of California, San Francisco, USA, ³VA Medical Center, USA, ⁴The Johns Hopkins Bayview Medical Center, USA

Parathyroid hormone (PTH) therapy improves bone mineral density (BMD) and decreases fracture risk in postmenopausal osteoporosis, but its use has been limited by factors including cost and the burden of daily injections. There is great interest in exploring alternative dosing strategies, with the goals of increased flexibility for patients and improved understanding of optimal dosing schedules. The objective of this study was to evaluate 2 approaches to the use of 6 months of PTH therapy. We conducted a randomized, double-blind trial of the effects of 2 combinations of PTH(1-84) (100 µg daily) and ibandronate (150 mg monthly) in 44 postmenopausal women with low bone mass. Each participant had a T-score ≤ -1.5 at the spine, total hip, or femoral neck, or a T-score ≤ -1.0 with an additional risk factor for osteoporosis. Participants received either 6 months of concurrent PTH daily injections and ibandronate monthly tablets, followed by 18 months of ibandronate (Group A); or 2 sequential courses of 3 months of PTH daily injections followed by 9 months of monthly ibandronate (Group B), for a total of 2 years of medication for each participant. Placebo injections and tablets ensured appropriate blinding. Areal and volumetric BMD (aBMD and vBMD) were assessed by dual-energy X-ray absorptiometry and quantitative computed tomography, respectively. Markers of bone turnover were measured on fasting blood samples. BMD at the spine increased similarly in the 2 groups (Table). At the total hip, vBMD increased in both groups; there was a trend towards a greater increase in Group B (sequential PTH). At the femoral neck, vBMD increased in both groups, and cortical thickness increased. Femoral neck buckling ratio, a measure of cortical instability, decreased similarly in the 2 groups (a favorable change). In Group B, the second 3-month course of PTH led to increases in markers of bone formation (e.g., a 209% increase in PINP, $p < 0.001$), on par with the increases observed during the first course. We conclude that 6 months of PTH(1-84) produces similar increases in areal and volumetric BMD, as well as decreases in cortical instability, when administered with concurrent monthly ibandronate followed by a continuation of the ibandronate, or when administered as two 3-month courses, each followed by ibandronate. Multiple short courses of PTH may provide the benefits of anabolic therapy for osteoporosis with heightened flexibility for patients.

TABLE. Mean percentage changes over 2 years

Variable	Group A (PTH+ibandronate) then ibandronate		Group B PTH → ibandronate PTH → ibandronate		p-value (between groups)
		p-value		p-value	
Spine aBMD	7.5%	<0.01	8.2%	<0.01	0.65
Total hip aBMD	3.6%	<0.01	2.9%	<0.01	0.54
Femoral neck aBMD	2.9%	<0.01	1.7%	0.08	0.39
Spine vBMD	12.5%	<0.01	14.0%	<0.01	0.77
Total hip vBMD	5.7%	<0.01	11.3%	<0.01	0.06
Total hip cortical vBMD	2.1%	0.05	4.7%	<0.01	0.08
Total hip trabecular vBMD	1.8%	0.08	2.7%	0.02	0.57
Femoral neck vBMD	4.9%	0.01	7.7%	<0.01	0.27
Femoral neck cortical thickness	12.4%	<0.01	8.7%	0.06	0.56

Use of oral Bisphosphonates and the Risk of Subtrochanteric and Diaphyseal Fractures in Older Men and Women. Suzanne Morin¹, Behloul Hassan², William Leslie³, Jacques Brown⁴, David Goltzman¹, Louise Pilote⁵. ¹McGill University Health Centre, Canada, ²McGill University Research Institute, Canada, ³University of Manitoba, Canada, ⁴Laval University, Canada, ⁵McGill University, Canada

Purpose Bisphosphonates are recommended as first-line agents to reduce fracture risk in patients with osteoporosis. However, recent studies have reported that bisphosphonates may also be associated with rare, but serious adverse effects such as atypical subtrochanteric and diaphyseal fractures of the femur. If so, bisphosphonates may be associated with increased risk of fractures at the subtrochanteric and diaphyseal sites at the population level. Methods We conducted a population-based, nested case-control study to determine if exposure to alendronate and risendronate is associated with a higher risk of subtrochanteric and diaphyseal fractures compared to femoral neck and intertrochanteric fractures. Using the Province of Quebec, Canada, administrative databases, we identified as cases all men or women 65 years and older, who experienced a subtrochanteric or diaphyseal fracture from November 8th 2005 to March 31st 2008 and matched them with up to 4 controls who sustained femoral neck or intertrochanteric fractures. Adjusted odds ratios (aOR) and 95% confidence intervals (CI) were computed using conditional logistic regression models based on the

matched sets of cases and controls to estimate the effect of any and, cumulative bisphosphonates use on the risk of subtrochanteric and diaphyseal fractures (versus femoral neck and intertrochanteric fractures). Results There were 9650 hospitalizations for proximal femur fractures (7.9% subtrochanteric, 2.5% diaphyseal, 49.8% femoral neck, 39.7% intertrochanteric) during the study period. We identified 973 individuals with a subtrochanteric or diaphyseal fracture and 3892 controls (Mean age 83.1 [SD 7.6] years, 25.5% men). Among the cases, 37.9% had claimed at least one prescription for a bisphosphonate prior the index fracture as opposed to 24.0% among the controls; most were taking a weekly dose of medication. Mean cumulative duration of use of bisphosphonates in cases was 2.8 [SD 1.9] years and 2.1 [SD 1.8] years in controls. Any use of bisphosphonate was associated with an aOR of 2.0 (95% CI 1.7- 2.4) of sustaining a subtrochanteric or diaphyseal fracture compared to femur neck and intertrochanteric fractures. Cumulative duration of use was also found to be associated with increased risk of subtrochanteric and diaphyseal fractures, both in men (for each additional year of use, aOR 1.4; 95% CI 1.1- 1.7) and in women (aOR 1.3; 95% CI 1.2- 1.4). Compared with no use, treatment for ≥ 4 years duration (at a medication possession ratio of ≥ 80%) was associated with a three-fold increase in the risk (aOR 3.3; 95% CI 2.3- 4.6) of sustaining a subtrochanteric or diaphyseal fracture. Conclusion Among older men and women, treatment with alendronate and risendronate is associated with an increased risk of subtrochanteric and diaphyseal fractures of the femur.

The Effect of Glucocorticoid Therapy on Regulators of Bone Formation in Postmenopausal Women Treated with Teriparatide or Alendronate. Fatma Gossiel¹, Nancy Lane², Richard Eastell³. ¹The University of Sheffield, United Kingdom, ²University of California, Davis Medical Center, USA, ³University of Sheffield, United Kingdom

Glucocorticoid therapy induces bone loss primarily through inhibition of osteoblast function. The osteocyte produces regulators of bone formation (RBF) that inhibit the wnt signalling pathway. Treatment of mice with prednisolone increased SOST expression in tibiae, and this effect can be reversed by treatment with parathyroid hormone but not with bisphosphonate (Yao (2008) Arthritis Rheum 58:3485-3497).

The aims of this study were to examine the effects of: 1) glucocorticoids (GC) on RBF in postmenopausal women; 2) teriparatide or alendronate therapy on RBF in these women.

We studied 53 postmenopausal women (mean age 63 years) who were randomised to receive either teriparatide (20µg/day, subcutaneous injection) (N = 28) or alendronate (10mg/day orally) (N=25). Subjects have received glucocorticoid therapy at an average dose of at least 7.5 mg/day of prednisone or its equivalent for a minimum of 3 consecutive months prior to study entry. A fasting serum sample was obtained at baseline, 6 and 18 months. Dkk1 and sclerostin were measured by ELISA (Biomedica Gruppe, Austria). We compared them to a group of 50 healthy premenopausal women (mean age 38; range 35 to 40 years).

The median levels (95% confidence intervals) of sclerostin were significantly higher in the GC group 38.6 pmol/l (35.6-47.1), compared to the premenopausal group 14.9 pmol/l (12.7-16.6) ($p < 0.0001$, Mann-Whitney test). The mean increase in GC group was 4.8 standard deviations compared to the control group. The median levels of Dkk1 were significantly lower, 133 pmol/l (112.8- 161.3) compared to 475.3 pmol/l (436.0-512.8), ($p < 0.0001$, Mann-Whitney test). The mean decrease in GC group was 3.0 standard deviations compared to the control group. There was no effect of either treatment on levels of sclerostin or Dkk-1 (repeated measures analysis of variance).

Conclusions: Glucocorticoid therapy (or the underlying disease for which therapy was given) is associated with higher levels of sclerostin (as expected from the animal model) but lower levels of Dkk-1. These changes were not reversed by treatment with licenced doses of teriparatide or alendronate.

Nuclear Factor of Activated T-Cells (NFAT)c2 Inhibits Notch Canonical Signaling. Stefano Zanotti*, Anna Smerdel-Ramoya, Ernesto Canalis. St. Francis Hospital & Medical Center, USA

Nuclear Factor of Activated T-Cells (NFAT)c1 through c4 are transcription factors expressed by osteoblasts with critical effects on osteoclastogenesis and osteoblastogenesis. Notch are transmembrane receptors that suppress osteoblastogenesis. In the Notch canonical signaling pathway, nuclear translocation of the Notch intracellular domain (NICD) and its association with the DNA-binding protein C Promoter Binding Factor 1, Suppressor of Hairless and Lag-1 (CSL) induces gene expression. To identify intracellular signals interacting with Notch, we explored the actions of Notch on NFAT expression. Notch suppressed NFATc1 transcription, induced NFATc2 expression by post-transcriptional mechanisms and did not modify NFATc3 or c4 mRNA levels in osteoblasts. We postulated that induction of NFATc2 may mediate actions of Notch and serve as control mechanism to limit Notch activity. Therefore, we studied the consequences of Notch and NFATc2 activation on the differentiation of osteoblasts harvested from *Rosa^{Notch}* mice, where NICD expression under the control of the *Rosa26* promoter is induced following the excision of a STOP

cassette flanked by *loxP* sites. To test the effects of NFATc2, *Rosa^{Notch}* osteoblasts were infected with an adenoviral vector expressing a constitutively active NFATc2 mutant. Notch and NFATc2 suppressed early osteoblast gene markers, either when expressed individually or in combination. The inhibitory effect of Notch on alkaline phosphatase activity was reversed following downregulation of NFATc2 by RNA interference, suggesting that NFATc2 mediates selected actions of Notch in osteoblasts. In parallel experiments, NFATc2 opposed the activity of a Notch reporter construct, the transactivation of Notch target genes promoter fragments, and the expression of their respective transcripts. The mechanism of the inhibitory effects of NFATc2 on Notch signaling was investigated by electrophoretic mobility shift assay. Nuclear proteins from *Rosa^{Notch}* osteoblasts bound to a radiolabeled DNA probe containing a Csl consensus sequence, which was displaced by unlabeled *Nfat* oligonucleotides. Accordingly, unlabeled Csl oligonucleotides displaced a radiolabeled *Nfat* consensus sequence bound to nuclear proteins, indicating competition of Csl and NFATc2 for DNA binding. In conclusion, Notch and NFATc2 inhibit osteoblastogenesis, and NFATc2 suppresses Notch canonical signaling establishing a local negative feedback mechanism that regulates osteoblastogenesis.

NF- κ B RelB Negatively Regulates Osteoblast Function and Bone Formation. Zhenqiang Yao^{*1}, Yanyun Li², Lianping Xing¹, Brendan Boyce². ¹University of Rochester, USA, ²University of Rochester Medical Center, USA

RelB is a member of NF- κ B family which regulates osteoclast (OC) functions. RelB null (KO) mice have normal basal OC formation but they have impaired metastasis-mediated resorption. The role of RelB in osteoblast (OB) functions is unknown. We found that KO mice develop age-related cortical bone thinning and increased diaphyseal trabecular bone mass (TBM) both starting at 4 and persisting at 12-14 wks-old. To test if the increased TBM in KO mice is due to impaired OC or enhanced OB function, we injected 4 wk-old mice with calcein and sacrificed them 6 wks later when KO mice have high TBM. We found labeling in secondary ossification centers but not in KO or WT trabeculae, indicating that labeled bone had been fully resorbed and replaced by new trabeculae in KO mice. Consistently, TNF whose concentration is elevated in KO mice generated more and larger resorption pits from KO spleen cells than WT cells. The KO mice must have enhanced OB generation or function. Indeed, 4 wk-old KO mice have increased OB surface (305 vs 216% in WT mice) although bone formation rate (BFR) was reduced in 6-8 wk-old KO mice in the diaphysis where TBM had increased. Although RelB KO bone marrow (BM) CD45-CD105+ mesenchymal stem cell (MSC) numbers were normal, KO BM cells produced more MSCs in vitro (7.2% vs 3.4% WT). Accordingly, KO BM cells formed more ALP+ colonies (1037 vs 406) and mineralized nodules (653 vs 215/mm²) with 3- and 10-fold induction of Runx2 and osteocalcin mRNA. The increased TNF in KO mice would secondarily affect OB function. Indeed TNF dose dependently inhibited ALP+ OB differentiation in both mice. Of note, KO mice had 5-fold more macrophages, a major source of TNF, mainly distributed in the diaphysis where BFR is reduced. Interestingly, the cortical thickness and TBM phenotypes were rescued in RelB/TNF double knockout mice. Finally, we filled bilateral 3x6 mm tibial cortical bone defects in SCID mice with bovine decalcified bone matrix carrying 2x10⁵ bone-derived WT or KO MSCs. The new bony callus and woven bone formed from KO MSCs was higher than from WT MSCs after 2 wks (0.370.05 vs 0.060.01 mm²) and 4 wks (0.640.03 vs 0.250.1 mm²) evaluated by histology. Micro-CT confirmed that KO MSCs formed more new bone than WT cells at 4wks: 214 vs 70.6% of the defect. We conclude that RelB negatively regulates TNF expression by macrophages to limit TNF-induced bone resorption. It also negatively regulates MSC differentiation into osteoblasts to limit trabecular bone formation. Targeted inhibition of RelB in OBs should lead to increased bone formation.

Alteration of the Wnt/ β -Catenin Pathway by Runx2 Overexpression *In Vivo*. Coline Haxaire*, Eric Hay, Valerie Geoffroy. INSERM Unit 606, France

In vivo overexpression of Runx2 (Runx2 mice) in osteoblasts leads to severe osteoporosis. We have shown that bone loss induced by high level of Runx2 is associated with an alteration of the final steps of osteoblast maturation and with an increase of bone resorption.

The aim of our study was to determine whether the Wnt/ β -Catenin pathway could affect the Runx2-dependant osteoblast differentiation.

Ex vivo, β -Catenin expression and its translocation into the nucleus are lower in Runx2 compared to wild-type (WT) primary osteoblasts. Moreover, the expression of LEF-1 was lower and DKK2, an inhibitor of Wnt/ β -Catenin pathway, was higher in Runx2 than in WT osteoblastic cells. Using WT-TopGal and Runx2-TopGal primary osteoblasts, we evaluate β -Catenin activity (by assessing β -Gal activity) in presence or absence of LiCl or Wnt3a. Both treatments significantly increased the β -Gal activity in both WT-TopGal and Runx2-TopGal osteoblasts. Surprisingly, treatments were more efficient at increasing β -Gal activity in Runx2-TopGal than in WT-TopGal primary osteoblasts suggesting deficient Wnt/ β -Catenin pathway in Runx2 mice.

To confirm these results *in vivo*, Runx2 overexpressing mice were treated with lithium chloride (LiCl) that has been recently shown to increase nuclear β -Catenin through GSK-3 inhibition. Eight-week-old WT and transgenic female mice were treated orally by LiCl (200mg/kg/day, 5 days/week) or by vehicle (Veh) during 4 weeks. Femurs were used for histomorphometric analysis.

LiCl induced a significant increase in bone volume (BV/TV; 37% and 68% respectively), and a significant decrease in trabecular separation (Tr.Sp; -20% and -45% respectively) in both WT and Runx2 mice compared to Veh-treated mice. In addition, our results showed that *in vivo* LiCl therapy completely rescue the trabecular bone phenotype in Runx2 mice as BV/TV and Tr.Sp are not significantly different between LiCl-treated Runx2 mice and Veh WT mice. Interestingly, dynamic bone formation parameters, MAR (+ 31%) and bone formation rate (BFR, +32%), were significantly increased by LiCl in Runx2 but not in WT mice.

To conclude, our data demonstrate that overexpression of Runx2 affects the Wnt/ β -Catenin pathway. Our results also suggest that this interaction may also affect bone resorption in this context. Activation of the canonical Wnt/ β -Catenin pathway using LiCl is able to rescue the bone phenotype induced by Runx2 overexpression *in vivo*.

Smad4 Coordinates BMP Signaling through p38 in Osteoblasts and is Required for Bone Anabolic Response to Canonical Wnt Signaling. Valerie Salazar*, Lisa Huang, Jin Norris, Sheri Bonar, Gabriel Mbalaviele, Roberto Civitelli. Washington University in St. Louis School of Medicine, USA

TGF β /BMP family members activate cytosolic kinase cascades and Smad transcription factors, including the common mediator, Smad4. Separately, we report that Smad4 inhibits osteoblast proliferation *in vivo*, in part via direct and competitive interference with canonical Wnt signaling. To further examine the role of Smad4 in bone formation, we generated *Smad4^{Flox/Flox}; Sp7-EGFP::Cre* mice (*Smad4^{Δ/Δ}*), where *Smad4* is ablated in Osx+ cells. Whole mount staining of *Smad4^{Δ/Δ}* neonates reveals hypomineralization of the skull, clavicle hypoplasia, and malformations of the rib cage. At day P28, *Smad4^{Δ/Δ}* mice are severely runted and μ CT indicates the cranial vault, scapulae, and sternal segment of the clavicles are still hypomineralized. Trabecular bone volume at the proximal tibia is normal relative to a smaller bone. However, *Smad4^{Δ/Δ}* mice exhibit delayed development of a medullary cavity in long bones. This correlates with diminished endocortical osteoclasts and a reduced ability of *Smad4^{Δ/Δ}* BMSCs to support osteoclastogenesis from bone marrow macrophages. *Smad4* ablation does not impede *Runx2*, *Col1 α 1*, *DMP1*, or *PheX* expression in bone, but sharply decreases expression of genes involved in collagen crosslinking including *Lox*, *Plod*, and *P4Ha*, which is consistent with abnormal Picrosirius Red staining. Importantly, *Smad4^{Δ/Δ}* mice fail to respond to the osteo-anabolic effect of anti-Dkk1 antibody, with sparse single calcein labels present on bone surfaces after 4 weeks of treatment as opposed to abundant wide double-labels in WT mice. Accordingly, *Smad4^{Δ/Δ}* BMSCs fail to mineralize in culture, and are not rescued by either BMP-2 or Wnt3a. Mechanistically, *Smad4* ablation disrupts p38 and Smad(1/5/8) phosphorylation in bone, instead enhancing Caspase-3 activity and the abundance of apoptotic TUNEL+ osteoblasts. Whereas BMP2-dependent expression of *Lox* is mediated by the p38 MAPK pathway, the resistance to anabolic Wnt signaling can be linked to loss of β -catenin transcriptional activity, a consequence of Caspase-3-mediated cleavage of the β -catenin C-terminal transcriptional activation domain. Thus, acute removal of *Smad4* directly favors canonical Wnt signaling and mitosis, while long-term deficiency of *Smad4* indirectly impairs Wnt signaling and osteoblast function. In summary, *Smad4* regulates osteoblast proliferation, survival, and function via coupling of canonical Smad with non-canonical MAPK pathways and via multifaceted regulation of canonical Wnt/ β -catenin signaling.

Blockade of EphrinB2/EphB4 Interactions Disrupts Osteoblast and Osteoclast Differentiation *In Vivo*. Farzin Takyar^{*1}, Stephen Tonna¹, Patricia Ho¹, Blessin Criméen-Irwin¹, Holly Brennan¹, Valery Krasnoperov², T. John Martin¹, Natalie Sims³. ¹St. Vincent's Institute of Medical Research, Australia, ²Vasgene Therapeutics Inc., USA, ³St. Vincent's Institute for Medical Research, Australia

Parathyroid hormone (PTH) rapidly enhances ephrinB2 expression *in vivo* and in cultured osteoblasts, and blockade of the ephrinB2/EphB4 interaction inhibits osteoblast differentiation. Furthermore, osteoclast differentiation *in vitro* is inhibited by ephrinB2 reverse signaling.

We have used a specific antagonist of EphrinB2/EphB4 signaling to determine its role in the anabolic action of PTH. Soluble extracellular domain of the receptor EphB4 (sEphB4) blocked EphB4 (but not EphB2) tyrosine phosphorylation induced by clustered ephrinB2-Fc in primary calvarial osteoblasts. 8-week-old male C57Bl/6 mice were treated with sEphB4 (10mg/kg; 3/week), either alone or with PTH (30ug/kg/day; 5/week) for 4 weeks. Femora, vertebrae and tibiae were analyzed by micro-CT and histomorphometry.

No change in bone structure was observed in sEphB4 treated mice compared to controls but osteoblast number and surface were both increased by 50% (p=0.02 and

0.01 respectively) and osteoid volume and surface were increased by 45% ($p=0.04$ and $p=0.01$). Despite this increase in osteoblast number osteoid thickness, bone formation rate and mineral apposition rate were not changed by sEphB4 treatment vs. vehicle. This indicated that sEphB4 increased formation of osteoblasts that produce less osteoid and mineralized bone. This block in osteoblast differentiation is consistent with *in vitro* effects of ephrinB2/EphB4 blockade.

PTH treatment increased trabecular number (Tb.N) and thickness (Tb.Th), and dramatically increased all osteoblast and bone formation parameters without increasing osteoclast numbers. sEphB4 significantly impaired the effect of PTH on trabecular structure; tibial Tb.N and Tb.Th were reduced by 20 and 15%, respectively ($p=0.02$ and 0.03) in sEphB4/PTH treated mice compared to PTH alone. Similar results were observed in femora and vertebrae by microCT. sEphB4 augmented the effect of PTH on osteoblast numbers (a further 30% increase, $p<0.05$), but did not increase the PTH-elevated mineral apposition rate. This suggests that increased osteoblasts formed with sEphB4 treatment have impaired ability to mineralize bone. In addition, reduced trabecular bone volume in sEphB4/PTH mice was associated with a 50% increase in osteoclast number ($p=0.05$).

These results establish that signaling between ephrinB2 and EphB4 is required for both normal mineralization and normal osteoclastogenesis in bone remodeling and that its pharmacological blockade inhibits the anabolic action of PTH.

Nck, Actin Cytoskeleton Protein, Supports Osteoblastic Bone Increment and Suppresses Osteoclastic Bone Loss. Smriti Aryal A.C.¹, Kentaro Miyai², Yoichi Ezura³, Tadayoshi Hayata⁴, Takuya Notomi⁵, Tetsuya Nakamoto², Tony pawson⁶, Masaki Noda². ¹Department of molecular pharmacology, Tokyo medical & dental university, Japan, ²Tokyo Medical & Dental University, Japan, ³Tokyo Medical & Dental University, Medical Research Institute, Japan, ⁴Medical Research Institute, Tokyo Medical & Dental University, Japan, ⁵GCOE, Tokyo Medical & Dental University, Japan, ⁶Mount Sinai hospital, Canada

Nck proteins are adaptor molecules and regulate actin organization. Mammals carry 2 Nck genes Nck1 and Nck2 (collectively termed Nck). However, the role of Nck and its mechanism of action in bone metabolism are not known. To define Nck actions in bone cells specifically in osteoblasts and osteoclasts, mice carrying floxed Nck2 allele (Nck2^{fl/fl}) in which exon I is flanked by the loxP sites and Nck1^{-/-} allele were crossed to transgenic mice expressing cre recombinase under the control of 2.3kb type I collagen promoter and also with cathepsin K promoter. Mice lacking cre expression were used as a control. Micro CT analysis of the distal femur of 10 weeks old osteoblast specific Nck-dKO (ob-Nck-dKO) showed significant reduction in trabecular bone volume (BV/TV) and trabecular number (Tb.N/BS) in comparison to the control. In contrast to the trabecular bone, the cortical bone mass was increased in the ob-Nck-dKO mice. Bodian staining of the cortical bone of ob-Nck-dKO showed reduced number of osteocytes per bone in comparison to the control. *In vitro* migration of ob-Nck-dKO derived primary osteoblasts was significantly reduced in comparison to the control. Furthermore, Nck1 over expressing stable MC3T3-E1 cells showed increased migration ability in transwell assay and motility in wound healing assay in comparison to the control. To examine the effects of Nck on bone formation in adult mice, bone marrow ablation experiments were conducted in ob-Nck-dKO (7 weeks old; $n=3$) this experiment showed reduction of BMD of newly formed bone in ob-Nck-dKO in comparison to the control. Moreover, micro CT analysis of the femur (8 weeks old; $n=3$) of osteoclast specific Nck-dKO (oc-Nck-dKO) mice showed significant reduction in BV/TV in comparison to the control. Taken together, our data shows that Nck supports osteoblastic bone increment and suppresses osteoclastic bone loss.

High Cumulative Incidences of Poor Outcomes Following Osteoporotic Fractures in Elderly Women and Men: A Competing Risk Analysis. Dana Blümc*, Nguyen Nguyen, Tuan Nguyen, John Eisman, Jacqueline Center. Garvan Institute of Medical Research, Australia

Increased risks of both subsequent fracture and mortality occur following an osteoporotic fracture in the elderly. However, the long term risks of these outcomes are less clear, partly due to their interdependency (ie risk of re-fracture depends upon survival). In this situation, Kaplan-Meier analysis can be unreliable. We thus examined cumulative incidences of re-fracture, mortality and sustaining both outcomes in men and women aged 60+ using competing risk analyses.

Subjects from the Dubbo Osteoporosis Epidemiology Study were followed from 1989-2007. Initial and subsequent fractures and mortality status were obtained. Competing risk models with 4 possible outcomes: death without re-fracture, death following re-fracture, re-fracture but alive, and event-free were considered.

There were 2245 women and 1760 men followed for 29,660 and 20,171 p-ys, respectively. 952 women and 342 men had an initial osteoporotic fracture, following which 23% of women and 21% of men re-fractured and 28% of women and 39% of

men died within the first 5 yrs. After 5yrs both mortality and re-fracture rates decreased significantly. The long term (>5-10yr) cumulative re-fracture incidence was reduced in both women and men by the competing risk of death, particularly in the older age groups with higher death rates. Following re-fracture 50% of women and 75% of men died within 5 yrs so total 5-yr mortality was 41% in women and 58% in men. By 10 years only 30% were alive and free of further fractures. The mortality following re-fracture occurred predominantly in the first 5 yrs post fracture, however, total mortality (post initial and re-fracture) was elevated above population mortality for ≥ 10 yrs following initial fracture with most of the 5-10yr excess mortality due to that following re-fracture. Re-fracture within 5 years was associated with a higher mortality than re-fracture after 5yrs [adjusted HR 2.44 (95%CI, 1.73-3.45)].

There is a high incidence of adverse outcomes following all osteoporotic fractures. Re-fracture and mortality were highest immediately post fracture, however, excess mortality was observed for up to 10yrs post fracture, primarily due to that following re-fracture. However, those who survived and were fracture-free 5-10 yrs post initial fracture had a very low risk of further adverse outcomes, suggesting a less aggressive approach may be appropriate for this population.

Cumulative incidence of adverse outcomes

Direct Medical Resources Utilization Associated with Osteoporosis-Related Fractures in Postmenopausal Women. Sonia Jean¹, Louis Bessette², Etienne Belzile³, Suzanne Morin⁴, K. Shawn Davison³, Louis-Georges Ste-Marie⁵, Bernard Candas³, Sylvie Dodin³, Jacques Brown³. ¹INSTITUT NATIONAL DE SANTE PUBLIQUE DU QUEBEC, Canada, ²Centre Hospitalier De L'Université Laval, Canada, ³Laval University, Canada, ⁴McGill University Health Centre, Canada, ⁵Hospital Saint-LucCHUM, Canada

Purpose: Although several osteoporotic fracture sites are an important and growing public health problem, research has primarily focused on hip fractures. The purpose of this study is to assess the direct medical resources utilization related to treatment of non-vertebral osteoporotic fractures within one year post-fracture.

Methods: Utilizing a previously developed and validated algorithm using physicians' claims databases, 15,327 women ≥ 50 years old with incident fractures at non vertebral osteoporotic sites were identified between January 1, 2004 and December 31, 2005 in three health regions of the province of Quebec, Canada. Fractures were grouped by sites as occurring at the hip/femur, pelvis, wrist, forearm/elbow, shoulder/humerus, tibia/fibula, or ankle/foot. Health administrative databases of the health services available to all residents in Quebec were used to establish fracture-related health resources utilization in the year following the fracture. Data were linked by a unique personal identifier, creating a longitudinal cohort of health resource utilization for all fracture cases. We assessed the proportion of fractures treated by an open reduction, closed reduction, cast or immobilization or conservative treatment (i.e. follow-up visit with an orthopaedic surgeon (OS) without casting or immobilization), the mean number of claims associated to a consultation with an OS or other clinicians, rate of hospitalization and length of stay (LOS).

Results: Table 1 and 2 provide the resources utilization related to fracture treatment, physician consultation and hospitalization. Hip/femur fractures represent the highest rate of resource utilization since the majority of these fractures require surgery (91%) and hospitalization (95%) with a mean LOS of 38.6 days. However, altogether other fracture sites require significant clinical care of surgery (27.8%), follow-up OS consultations (74.6%) and hospitalization (27.3% of total LOS). Even pelvic fractures that often not require surgical treatment, has a high rate of resource utilization due to the high rate of hospitalization (67%) with a mean LOS of 34.2 days.

Conclusions: Osteoporotic fractures account for substantial health care resource utilization. With an aging population and an increased prevalence of osteoporotic fracture, strategies for the management of osteoporotic condition need to be introduced to reduce the burden on health care resources.

Fracture site (N)	Proportion of fracture (%) ^a				Mean number of fracture related claims		
	Open Reduction	Closed Reduction	Immobilization	Principal Consultation with an OS	All claims ^b	Consultation with an OS ^c	Consultation with other clinicians ^d
Pelvis (291)	7.2	3.4	2.4	86.9	8.3	1.8	6.3
Hip/femur (4,536)	91.1	0.6	0.4	7.9	9.7	1.9	6.6
Shoulder/humerus (2,603)	16.9	9.6	24.8	48.7	5.5	2.4	2.5
Forearm/elbow (1,498)	13.0	28.8	25.9	32.2	4.4	2.2	1.4

Duration of Excess Mortality After Hip Fractures in Oslo, Norway: A Long Term Follow Up. Trine Elisabeth Finnes¹, Haakon E. Meyer², Tore Wentzell-Larsen³, Cathrine Marie Lofthus⁴. ¹Department of Internal Medicine, Innlandet Hospital Trust, Hamar, Norway, Norway, ²Department of Community Medicine, Faculty of Medicine, University of Oslo, Norway & Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway, Norway, ³Biostatistics & Epidemiology Unit, Oslo University Hospital, Norway, ⁴Department Of Clinical Endocrinology, Oslo University Hospital, Aker, Norway, Norway

Aim The aims of the study were to estimate the duration of excess mortality following hip fractures, and to investigate if the duration has changed over the past decades in Oslo, Norway.

Methods Men and women with a hip fracture identified in previous published incidence studies from three different decades (1978/79, 1988/89, and 1996/97) in Oslo, were followed with respect to all causes of mortality until 31.12.2007. Age- and sex-specific mortality rates for the general population of Oslo from 1978-2007 were provided by Statistics Norway. Expected survival curves stratified for sex and predefined age groups were estimated for each of the three cohorts. Time framed Kaplan-Meier curves for 5 years intervals were compared with the corresponding expected survival curves. Were the observed curves started to parallel the expected curves, additional curves for five- and one year survival were made to judge when mortality in hip fracture patients became the same as in the background population. One sample log rank tests were used to test for differences between the observed and expected curves. Analyses were performed using SPSS 14.0 and R 2.10.1.

Results The results for the age-group 65-84.9 years, constituting around 2/3 of all hip fractures, are presented (Table 1). The excess mortality lasted for at least 10 years in all three cohorts. In the 1978/79- and 1988/89-cohort, men had a shorter duration of excess mortality than women. In the 1996/97-cohort, the mortality among male hip fracture patients was still higher than in the background population at end of follow up (10 years). The duration of excess mortality could therefore not be estimated in this group. In women, there was a trend towards a shorter duration of excess mortality from 1978/79 to 1996/97.

Conclusion Although a trend towards shorter duration of excess mortality during the decades was observed, the excess mortality after hip fracture still lasts for up to 10 years in both men and women aged 65-85. Further studies focusing on modifiable risk factors for death after hip fractures are warranted.

Table 1

Sex	Cohort	No.	Duration of excess mortality (years)
Men	78-79	281	15
	88-89	363	11
	96/97	170	*
Women	78-79	1041	22
	88-89	1243	14
	96/97	549	10

Mortality and Fracture Rate before and after Introduction of a Fracture Liaison Service. Sandrine Bours¹, Tineke Van Geel², Piet Geusens³, Kirsten Huntjens², Geert-Jan Dinant⁴, Joop Van Den Bergh⁵. ¹Maastricht University Medical Centre, The Netherlands, ²Maastricht University, The Netherlands, ³University Hasselt, Belgium, ⁴Maastricht University, Netherlands, ⁵VieCuri MC Noord-Limburg & Maastricht UMC, USA

Purpose: To evaluate the effect of the Fracture Liaison Service (FLS) by comparing the mortality and incidence of non-vertebral fractures before and after introduction of the FLS during 2 year follow up.

Methods: In total, 1908 patients who sustained a fracture before (pre) initiation of the FLS and 666 patients after (post) initiation of the FLS were included in this study. All patients visited the emergency room of VieCuri Medical Centre, The Netherlands. Of these patients, age, fracture location(s) and date of fracture(s), whether they were deceased and date of death was known. Of the post-FLS group, patients completed a detailed questionnaire on clinical risk factors for fractures, medical history, medication, previous fractures, calcium intake and were evaluated by DXA and blood tests. Patients with osteoporosis and / or metabolic bone disease were treated. Cox proportional hazard regression models were used with pre vs. post FLS as covariate, with as dependent variables subsequent fracture or mortality. Time was calculated as initial fracture to event or end of study (24 months).

Results: Of the 1908 pre-FLS patients (mean age: 68 years, standard deviation (SD): 11.0, 70% were women) 134 (7.2%, 3.9 per 100 person-years) sustained a subsequent fracture and 237 (12.4%, 6.7 per 100 person-years) died. Of the post-FLS patients, 471 did (mean age: 66 years, SD: 10) and 195 did not (mean age: 73 years, SD: 12) show up at the FLS. In total, 498 of the post-FLS patients (75%) were women. Of the post-FLS patients, 51 (7.7%, 4.2 per 100 person-years) sustained a subsequent fracture and 52 (7.8%, 4.1 per 100 person-years) died.

After adjusting for gender, age at first fracture and fracture location, there was no significant difference between the pre- and post-FLS patients with regard to subsequent fracture risk (HR: 1.0, 95% confidence interval: 0.7-1.3). After the same adjustment, mortality was significantly lower in the post- versus pre-FLS patients (HR: 0.61, CI: 0.45-0.83).

Conclusion: After initiation of the FLS, the mortality rate decreased by nearly 40%, but fracture incidence remained unchanged. Further studies are needed to analyze which factors are predictors for the reduction in the post-FLS mortality.

Falling Rates of Fractures in the United States from 1992-1997 to 2002-2007.

Steven Cummings^{*1}, Li-Yung Lui², Jane Cauley³, Teresa Hillier⁴, Marc Hochberg⁵. ¹San Francisco Coordinating Center, USA, ²California Pacific Medical Center Research Institute, USA, ³University of Pittsburgh Graduate School of Public Health, USA, ⁴Kaiser Center for Health Research, USA, ⁵University of Maryland School of Medicine, USA

Background: According to Medicare data, the rate of hip fracture in older women declined 24.5% from 1995-2005 (Brauer, JAMA 2009;302:1573). It is not known if the rates of other fractures have also decreased. If so, could the changes be explained by improvements in BMD or other risk factors for fracture?

Methods: The Study of Osteoporotic Fractures recruited 9,704 Caucasian women from community-based listings in 4 US urban areas in 1986-8 and measured hip BMD every 2 – 4 years using the same DXA scanners. Follow-up for x-ray confirmed fractures >90% complete during >20 years follow-up; a small proportion of fractures might not be self-reported. We analyzed cohorts of women in 5-year intervals. Specifically, compared the rates of fractures and mean femoral neck BMD values in women who were age 80-84, and 85+ in 1992 to women who were 80-84 or 85+ in 2002. Fracture rates were assessed from 1992 to 1997 and 2002 to 2007. We also compared the prevalence of vertebral fractures using identical morphometric methods on lateral spine x-rays taken between 1990-92 and 2002-4. We predicted change in fracture rate from change in BMD and association between FN BMD and type of fracture. Falls were assessed every 4 months and medications every 2-4 years.

Results: Rates of self-reported hip fracture in the 80-84 and 85+ year-old women declined approximately 23.3 and 18.6% between 1992-7 and 2002-7 (table), similar to the decline in US Medicare data. We observed similar decreases in all other types of fractures. Mean FN BMD also improved by 0.28 to 0.42 standard deviations during that period, which could explain most of the decline in hip fracture but less for other types (table). Increased use of treatments that reduce fracture risk (e.g. 15% increased use of bisphosphonates in 80-84 year olds) could not explain the decreases, and rates of falling increased over that interval (e.g. 14.5% to 21.2% for 2+ falls/year in 80-84 year olds).

Conclusion: From this community-based cohort, the rates of all types of fractures decreased substantially from 1992-7 to 2002-7, at least partly due to improvements in BMD, not explained by increased use of drug therapy.

Fracture rates (per 1,000 woman-years) and percent changes

Type	1992-1997	2002-2007	% Decrease	Predicted by change in BMD	95% CI
Age 80 to 84 years old					
Hip	15.4	11.8	23.3	17.3	10.3, 23.7
Wrist	9.9	6.9	30.2	12.3	-4.0, 19.9
Humerus	6.8	4.4	33.5	9.4	-0.4, 18.2
Nonvertebral	45.8	39.7	15.6	9.6	5.9, 13.2
Vertebral*	32.5%	24.4%	25.0	12.5	7.9, 16.9
Age 85+ years old					
Hip	31.8	25.9	18.6	22.5	13.8, 30.3
Wrist	11.3	8.1	28.4	12.3	-6.2, 27.6
Humerus	8.2	6.0	27.7	18.8	-2.0, 35.4
Nonvertebral	71.0	53.4	24.8	16.9	10.7, 22.7

Secular Trends in Incidence of Osteoporosis-related Fractures Differ Depending on Fracture Type. Bjorn Rosengren^{*1}, Ingemar Peterson², Magnus Karlsson¹, Martin Englund². ¹Skane University Hospital Malmö, Lund University, Sweden, ²Musculoskeletal Sciences, Department of Orthopedics, Clinical Sciences Lund, Lund University, Lund, Sweden, Sweden

Purpose: During the recent decade the incidence of hip fracture has been reported to decrease in most parts of the world. However, if a similar decrease has occurred for other types of osteoporosis-related fractures is unknown.

Methods: Through the Skane Health Care Register, a diagnosis-based register covering all in- and outpatient health care data of residents in the County of Skane, Sweden (1.2 million inhabitants), we registered typical osteoporosis-related fractures of the hip (n=26 952), os pubis (n=4 215), proximal humerus (n=12 445), wrist (n=23 068), proximal tibia (n=3 336) and ankle (n=9 459) sustained by individuals aged 50 years or older from year 1998 until 2009 (5.1 million person-years). We calculated gender-specific age-standardized incidence for each fracture type using one-year age- and sex-specific population figures from the population register, where the average population of the examined years was used as the standard population. Trends of incidence were evaluated by linear regression, and we present data as means with their 95% confidence interval (95% CI) with two-tailed α -level set to 0.05.

Results: During the evaluated years, the age-standardized hip fracture incidence decreased significantly in both women (-12 per 100 000 and year [95% CI -15, -9]) and men (-3 per 100 000 [95% CI -5, -1]). In contrast, during the same period the annual incidence of proximal humeral fractures increased significantly in women (4 per 100 000 [95% CI 0, 7]) and non-significantly in men (1 per 100 000 [95% CI -0, 3]). Furthermore, the incidence of pubic fractures increased significantly in men (1 per 100 000 [95% CI 0, 2]) but not in women (0 per 100 000 [95% CI -2, 1]). The incidence of ankle fractures was stable in both men and women as was the annual incidence of wrist fractures and proximal tibial fractures (data not shown).

Conclusion: In this study covering the recent decade, the different types of examined osteoporosis-related fractures showed different secular trends in incidence. Hence, the decrease in hip fracture incidence evident in this and other studies can not be extrapolated to all types of osteoporosis-related fractures when estimating the future total burden of fragility fractures in society.

Deletion of the Redox Amplifier p66^{shc} Decreases ROS Production in Murine Bone and Increases Osteoblast Resistance to Oxidative Stress and Bone Mass. Shoshana M. Bartell*, Li Han, Srividhya Iyer, Aaron Warren, Robert W. Bradsher, Randal S. Shelton, Maria Jose S. Almeida, Stavros C. Manolagas. Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

P66Shc is a 66-Kd isoform of the growth factor adapter Shc with a pivotal role in oxidative stress, apoptosis, and aging, as demonstrated by evidence that deletion of p66Shc enhances resistance to oxidative stress and apoptosis, decreases mitochondrial metabolism, prolongs lifespan in mice by as much as 30%, and protects from a variety of age-associated diseases including atherosclerosis. p66Shc amplifies ROS production within mitochondria by catalyzing the reduction of O₂ to H₂O₂ through electron transfer from cytochrome c; H₂O₂ in turn causes opening of the permeability transition pore, swelling, and apoptosis. Increased ROS production and osteoblast/osteocyte apoptosis caused by aging or sex steroid deficiency in the murine skeleton is linked with an increase in the phosphorylation of p66Shc. Conversely, p66Shc phosphorylation and apoptosis decrease with antioxidant administration, estrogen, or androgen replacement. We have sought mechanistic evidence causally linking p66Shc to the adverse effects of oxidative stress and sex steroid deficiency on bone mass. For this purpose we used a p66shc knockout mouse (a model provided to us by Dr. T. Prolla, Univ. Wisconsin). We report that these mice were born at the expected Mendelian ratios and had normal body weight. The deletion of p66shc caused a decrease in ROS and an increase in the level of glutathione in the bone marrow. Moreover, calvaria-derived osteoblasts from these mice were resistant to H₂O₂-induced apoptosis as determined by caspase 3 activity. P66shc knockout mice also exhibited an increase in mesenchymal progenitor cells, as determined by the number of colony forming osteoblast progenitors (CFU-OB) present in bone marrow. Moreover, osteoblast mineralization was increased in primary cultures of bone marrow derived progenitors in the presence of ascorbic acid, as determined by alizarin red staining. In line with these findings, at six month of age, both female and male p66shc knockout mice exhibited increased bone mineral density at the spine and femur as determined by DEXA. These results strongly suggest that p66shc is an essential mediator of the deleterious effects of oxidative stress on apoptosis, osteoblastogenesis, and bone mass; hence, causally linked to the adverse effects of both aging and sex steroid deficiency on the skeleton.

Insulin Signaling in Bone Favors Male Fertility. Franck OURY*, Tatsuya YOSHIZAWA, Mathieu Ferron, Patricia Ducy, Gerard Karsenty. Columbia University, USA

Insulin is known to affect, through its signaling in a wide variety of cell types, many physiological functions. For instance, insulin signaling in osteoblasts was recently shown to affect physiological functions as diverse as bone remodeling and glucose metabolism. Since, it has also been shown previously that insulin signaling is needed for male and female fertility, we asked whether insulin favors male fertility by acting, at least in part, in osteoblasts. Consistent with this hypothesis we observed that at 3 months of age male mice lacking the insulin receptor selectively in osteoblasts (*InsR^{Ob}*^{fl/fl} mice) displayed smaller testicular and seminal vesicle size and weight, decreased sperm count and circulating testosterone levels. As a result there was a decrease in litter size and frequency when *InsR^{Ob}*^{fl/fl} male mice were crossed with WT females. Next, we asked whether this function of insulin signaling in osteoblasts occurs through its activation of osteocalcin. To test this hypothesis, we generated compound mutant male mice lacking one allele of osteocalcin and one allele of the insulin receptor selectively in osteoblasts (*Osteocalcin^{Ob}*^{fl/+}; *InsR^{Ob}*^{fl/+} male mice). These latter mutant mice demonstrated lower testicular and seminal vesicle weights, decreased sperm count and circulating testosterone levels and decreased fertility. That this reproduction phenotype is similar to the one of the *Osteocalcin*^{-/-} mice supports the notion that insulin signaling in osteoblasts favors male fertility through its documented activation of osteocalcin. To add further credence to this hypothesis we generated and analyzed mice lacking one allele of the insulin receptor in osteoblasts and one allele of Gprc6a, the receptor for osteocalcin in Leydig cells. The phenotypic analysis of these mice will be presenting at the meeting. Taken together these observations establish that insulin signaling in osteoblasts regulate male fertility. As such they highlight the growing importance of the skeleton as an integrator of multiple endocrine signals and as a global regulator of a growing number of physiological processes.

Nicotinamide Phosphoribosyltransferase (Namt) Affects the Lineage Fate Determination of Mesenchymal Stem Cells: A Possible Cause for Reduced Osteogenesis and Increased Adipogenesis In Senile Osteoporosis. Yan Li*¹, Xu He², Urban Lindgren¹. ¹Karolinska Institute, Sweden, ²a Karolinska Institute; b Jilin University, Sweden

The accelerated marrow adipogenesis in aging might reflect an unbalanced mesenchymal stem cell (MSC) differentiation scheme. However, how aging makes the preferential shift from osteogenesis to adipogenesis is largely unknown. Sirt1 has been shown to regulate lifespan in lower organisms and affect age-related diseases in mammals. We previously showed that Sirt1 activity affected the lineage fate determination between osteogenesis and adipogenesis of MSCs (Backesjo CM, Li Y, et al, 2006, J Bone Miner Res 21: 993-1002). Since Sirt1 activity is largely dependent on the availability of NAD⁺ and influenced by the intracellular concentration of nicotinamide we supposed that MSC differentiation could be affected by enzymes involved in the NAD⁺ salvaging pathway.

The present study showed that the bone marrow stromal cells derived from 15-month-old C57BL/6 mice developed fewer bone nodules (as shown by von Kossa and alizarin red staining) and more adipocytes (as shown by oil red O staining) than cells derived from 4-week-old mice (Fig. 1 A). The cells derived from aged mice had significantly lower intracellular NAD⁺ concentration (Fig. 1 B) and lower Sirt1 activity (Fig. 1 C). However, the expression of Sirt1 protein was not reduced by aging (Fig. 1 D). We also found that the potent and specific Nampt inhibitor, FK866 (Sigma) significantly increased the adipocyte formation in mesenchymal stem cell line C3H10 cells (Fig. 2 A). In addition, adipocyte formation was significantly increased in cells transfected by Nampt shRNA Lentiviral transduction particles (Sigma) (Fig. 2 B). Q-PCR analysis showed that the expression of the adipocyte specific transcription factor PPAR γ was significantly higher in Nampt deficient cells while the osteoblast key transcription factor Runx2, as well as the osteoblast marker genes, osteocalcin and OPG, were significantly downregulated (Fig. 3 A). A significant reduction of Sirt1 activity was found in Nampt deficient cells (Fig. 3 B), which had significantly lower NAD⁺ and higher intracellular concentration of NAM (Fig. 3 C).

In conclusion, the present study showed that the lineage fate determination of MSCs could be affected by the activity of Nampt, the enzyme catalyzing NAD⁺ resynthesis from nicotinamide, possible through affecting Sirt1 function. Therefore, senile osteoporosis might occur with a deregulation of cell energy metabolism in mesenchymal stem cells.

The $\hat{\text{O}}$ -catenin Activating Factor, Wnt3a, stimulates Skeletal Muscle Myogenesis. Sandra Romero-Suarez^{*1}, ChengLin Mo², Nuria Lara³, Katharina Jaehn³, Mark Johnson⁴, Lynda Bonewald³, Marco Brotto³. ¹Muscle Biology Group-MUBIG, School of Nursing, University of Missouri-Kansas City, USA, ²Muscle Biology Group-MUBIG, School of Nursing & Pharmacy, University of Missouri-Kansas City, USA, ³University of Missouri - Kansas City, USA, ⁴University of Missouri, Kansas City Dental School, USA

We hypothesized that muscle and bone communicate at a molecular level via biochemical factors that are reciprocally important for optimal function. We recently showed that conditioned media from MLO-Y4 osteocytes accelerates the differentiation of C2C12 myotubes.

Wnt signaling is critical for bone function and is also thought to be important for muscle development and maturation, but less is known about its roles in mature skeletal muscles.

The expression of Wnts, particularly Wnt3a, is dramatically increased in MLO-Y4 osteocytes exposed to fluid flow shear stress.

To test the putative role of Wnt3a in skeletal muscle myogenesis, we treated C2C12 myoblasts with 10ng Wnt3a and found that it significantly enhanced myogenesis (>13 myotubes per random field of view in Wnt3a; vs. 3-5 myotubes in Control, $n=3$, $p < 0.01$). Furthermore, myotubes formed in the presence of Wnt3a were larger (4,319 $642 \mu\text{m}^2$ untreated, $n=22$; vs. 9,833 $1013 \mu\text{m}^2$ for Wnt3a treated myotubes, $n=19$, $p < 0.001$), suggesting that hypertrophic signaling was activated under these conditions. Intriguingly, Fura-2 calcium transients induced by caffeine were characterized by multiple and oscillatory peaks in Wnt3a treated myotubes, but not in control myotubes. A custom-developed qPCR array approach revealed that Wnt3a promoted the overexpression by at least 2-fold of myogenic related factors (MyoD, myogenin) as well as specific genes related to intracellular calcium signaling and calcium homeostasis that help explain the functional changes observed in C2C12 myotubes treated with Wnt3a.

Our studies provide new evidence that Wnt3a is a potent modulator of the function of C2C12 myotubes and identify it as a candidate factor that may mediate crosstalk between bone and muscle cells.

Detailed understanding of the molecular pathways that mediate crosstalk between bone cells and muscle cells could lead to new therapeutic targets to treat musculoskeletal diseases and reduce morbidity and mortality associated with these conditions.

Genetic Variation in DHCR7/NADSYN1 (rs12785878) Predicts Skeletal Muscle Response to Resistance Training and Vitamin D Levels in Men. Sreya Talasila¹, Jordan Ruby¹, F Orkunoglu-Suer², H Gordish-Dressman², K Panchapakesan², BT Harmon², Eric Hoffman², Joe Devaney², Laura Tosi^{*2}. ¹George Washington University School of Medicine, USA, ²Children's National Medical Center, USA

Objective: The contribution of Vitamin D to the development of skeletal muscle strength has not been fully elucidated. Our goal was to determine whether genome wide association study-identified single nucleotide polymorphisms (SNPs) associated with circulating Vitamin D levels are also associated with skeletal muscle size, strength, and response to resistance training.

Methods: 753 college-aged subjects (449 female, 304 male) underwent 12 weeks of supervised resistance training of their non-dominant arm using five specific exercises. Pre- and post-training strength measurements included (one repetition max [1RM] and maximal voluntary contraction [MVC]). Upper arm skeletal muscle volume of the trained arm was measured via MRI before and after the 12-week program. The study participants were genotyped for four genetic variants (rs2282679, rs2060793, rs12785878, and rs3829251) recently demonstrated to be associated with circulating levels of Vitamin D in persons of European ancestry. Mean phenotypes were compared among genotypes using ANCOVA with age and baseline weight as covariates. For co-dominant associations showing a significant F-test, pair-wise post-hoc comparisons were performed and resulting p-values adjusted for multiple comparisons using the Sidak method.

Results: Males with two copies of the common allele (T allele) for rs12785878 demonstrated a significantly larger increase in skeletal muscle volume ($p=0.035$) with resistance training and a greater percent change in MVC ($p=0.026$). No associations with any of our measured phenotypes were demonstrated with the other three SNPs.

Conclusion: The role of genetic versus environmental influences on vitamin D status and subsequent health outcomes remains unclear. In this study, the presence of two copies of the common, T allele, at the rs12785878 SNP was associated with a greater increase in skeletal muscle size and strength following exercise training. Genetic variation in the rs12785878 SNP (DHCR7/NADSYN1) has recently been demonstrated to be correlated with vitamin D insufficiency. This SNP is located in the promoter of the DHCR7 gene that encodes the enzyme 7-dehydrocholesterol (7-DHC) reductase. This enzyme converts 7-DHC to cholesterol, thereby removing the substrate from the synthetic pathway of Vitamin D3, a precursor of 25-

hydroxyvitamin D3. The effect of this enzyme on Vitamin D levels and measures of health status requires further investigation.

High Serum Adiponectin Is Associated with Frailty and Predicts Mortality in Elderly Men. Mr OS Sweden. Dan Mellstrom¹, Helena Johansson², Carl-Johan Behre³, Hans Jutberger², John Kanis⁴, Anders Oden², Asa Tivesten³, Ulf Lerner², Magnus Karlsson⁵, Osten Ljunggren⁶, Claes Ohlsson⁷, Mattias Lorentzon⁷. ¹Sahlgrenska University Hospital, Sweden, ²Centre for Bone & Arthritis Research (CBAR), Sahlgrenska Academy University of Gothenburg Sweden, Sweden, ³Wallenberg Laboratory for Cardiovascular Research, Institute of Medicine, University of Gothenburg, Sweden, ⁴University of Sheffield, Belgium, ⁵Clinical & Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University & Department of Orthopaedics, Malmö University Hospital, Malmö, Sweden, Sweden, ⁶Department of Medical Sciences, University of Uppsala, Uppsala, Sweden, Sweden, ⁷Center for Bone Research At the Sahlgrenska Academy, Sweden

High serum concentrations of the adipokine, adiponectin, have been associated with low bone mineral density and increased risk for incident fractures in elderly men. This study examines whether serum adiponectin is related to other risk factors for frailty and mortality.

Elderly men (69-80 years) participated in the population based Mr OS Sweden, Gothenburg cohort (n=1010). All plasma and serum samples were collected at 8 am after at least 10 hours fasting and non-smoking. Serum adiponectin was analysed with an ELISA-kit (Linco Research, Missouri USA). Body composition and bone mineral density were measured with DXA (Hologic QDR 4500/A Delphi). History of falls during the last year was assessed using a questionnaire.

Serum adiponectin increased with age ($r=0.14$ $p<0.001$) and was inversely associated with BMI ($r=-0.24$ $p<0.001$) and total lean mass ($r=-0.16$ $p<0.001$). Men in the highest tertile of serum adiponectin tested against tertile 1 and 2 had an age adjusted increased risk of falls (OR=1.6; 95% CI=1.1-2.2). Poorer hand grip strength (OR=1.3; 95% CI=1.1-1.5 per SD decrease in grip strength), less total lean mass (OR=1.4; 95% CI=1.2-1.6 per SD decrease in lean mass) and longer time for rising 5 times (OR=1.2; 95% CI=1.0-1.3) was associated with increased risk of belonging to the highest tertile of adiponectin. Men in the highest tertile of adiponectin reported more often a decrease in BMI from the age of 25 years (OR=2.4; 95% CI=1.6-3.6). A linear age adjusted regression model showed that walking speed was inversely related to serum adiponectin ($p=0.015$). High serum adiponectin predicted mortality in a multivariate model (GR per SD increase=1.20; 95% CI 1.06-1.37; $p<0.01$). A large number of variables were tested as covariates including age, BMI, BMD and diabetes. A spline curve was estimated from a Poisson regression model describing the relation between serum adiponectin and risk of death (Figure).

High serum adiponectin was associated with increased risk of falls, muscle weakness, less lean mass and a decrease in BMI since the age of 25 years. High serum adiponectin predicted mortality in a multivariate model. Our data suggest that serum adiponectin is a proxy for falls, frailty and increased mortality beyond the increased risk for low bone mineral density and fractures.

Lean Mass and the Longitudinal Probability of Mobility Disability in the Framingham Study: A Multinomial Approach for Studies of Aging. Robert McLean¹, Elizabeth Newton², Alyssa Dufour², Joanne Murabito³, Marian Hannan⁴, Douglas Kiel². ¹Hebrew SeniorLife, Harvard Medical School, USA, ²Hebrew SeniorLife, USA, ³Framingham Heart Study & Boston University, USA, ⁴HSL Institute for Aging Research & Harvard Medical School, USA

Sarcopenia (age-related loss of muscle mass and strength) is common in older adults and associated with mobility disability. While longitudinal studies with repeated measures over time have examined whether baseline sarcopenia predicts mobility disability, results may represent only the healthiest elders as analyses did not account for 2 sources of missing data common to studies of aging: 1) unobserved outcomes due to missed visits, 2) high death rates. Further, prior studies have examined time to incident disability, which does not account for individuals who recover. Our objective was to determine the association of baseline lean mass with mobility disability over time in an elderly cohort using a multinomial approach to include all possible outcomes. Participants included 243 men and 440 women from the Framingham Study Original Cohort. Lean mass (appendicular lean mass divided by height²) was measured via whole body DXA (Lunar DPX-L) at visit 1 (1992-93). At each of visits 1-7 (2 yrs apart) participants experienced 1 of 4 states of a multinomial outcome (STATUS): not disabled, disabled, dead or missing. Mobility disability was defined as self-reported inability to walk 0.5 mi, walk up and down stairs, or perform heavy work around the house. Separately by sex, we used generalized logit models to predict the probability of being in 1 of the 4 STATUS states at any time over follow-up. The model gave regression coefficients for the odds of being disabled, dead or missing, relative to not disabled, as a function of baseline lean mass, age (yrs), BMI (kg/m²) and visit. A random effect for subject accounted for within-subject correlation. At visit 1 mean age was 78.2 yrs (range 72-92), and 16% of men and 29% of women were disabled. Over 12 yrs of follow-up 58% of participants died and the percent of missing outcomes at visits 2-7 ranged from 10 to 14 (Figure 1). 20% of men and 25% of women experienced disability recovery. In men, higher lean mass was associated with lower odds of being disabled or dead vs. not disabled (Table 1). In women, higher lean mass was associated with lower odds of being disabled vs. not disabled, but not with being dead. Lean mass was not associated with the status missing. Our results suggest greater lean mass is protective against mobility disability over time in elders. Previous studies that did not account for the multiple states possible during follow-up of an elderly cohort are likely biased by including only healthy survivors.

Table 1. Regression coefficients ($\beta \pm SE$) from the general logit model* for the longitudinal association of ALM/ht² with the multinomial outcome STATUS (healthy, disabled, dead, missing) among elderly men and women of the Framingham Study.

STATUS category	Men		Women	
	$\beta \pm SE$	P-value	$\beta \pm SE$	P-value
Healthy (Ref)	-	-	-	-
Disabled	-0.486 \pm 0.143	<0.001	-0.259 \pm 0.129	<0.05
Dead	-0.307 \pm 0.141	<0.03	0.035 \pm 0.140	0.80
Missing	-0.297 \pm 0.173	0.09	-0.190 \pm 0.158	0.23

*Model includes lean mass, age, BMI, visit

$$\text{STATUS} \begin{cases} \text{No disability (ref)} \\ \text{Disabled} \\ \text{Dead} \\ \text{Missing} \end{cases} = \text{lean mass} + \text{age} + \text{BMI} + \text{visit}$$

Trunk Muscle Fat Infiltration is Greater in Women than Men and Increases with Age. Dennis Anderson^{*1}, John D'Agostino¹, Alexander Bruno², Douglas Kiel³, Mary Bouxsein¹. ¹Beth Israel Deaconess Medical Center, USA, ²Stony Brook University, USA, ³Hebrew SeniorLife, USA

Age-related sarcopenia is a significant contributor to frailty and loss of function in older adults. Increased fat infiltration into muscle, as indicated by reduced x-ray attenuation of muscles in quantitative computed tomography (QCT) scans, is a marker of muscle quality and may contribute to reduced muscle function. Reduced muscle attenuation in the thigh has been associated with reduced knee extensor strength independent of muscle size and increased risk of hip fracture independent of BMD. However, sex- and age-related differences in muscle attenuation have not been examined in trunk muscles.

We randomly selected younger and older men and women (n = 25/group) from participants in the Framingham Heart Study Offspring and Third Generation Multidetector CT Study, in whom QCT scans of the trunk had been obtained. Ages of the younger and older subjects were 41.8 ± 4.1 and 78.3 ± 3.2 years, respectively. Muscle attenuation was determined for 11 muscle groups at the T8 and L3 vertebral levels. We performed a multiple regression analysis to examine age and sex differences in muscle attenuation, with and without adjustment for the self-reported physical activity index (PAI) score.

Muscle attenuation averaged 34.915.0 Hounsfield Units (HU) across all muscles, ages and sexes, and was on average 37% (15.9 HU) lower in older vs. younger adults ($p < 0.001$), and 20% (7.7 HU) lower in women than men ($p < 0.02$). Age effects were significant for all muscles, and sex effects for all muscles, except psoas major ($p = 0.05$) and external oblique ($p = 0.98$). Attenuation values as well as age and sex effects varied between muscles (Figure). Increased PAI was significantly associated with increased attenuation in pectoralis major, latissimus dorsi, and erector spinae ($p < 0.05$), but did not attenuate age and sex associations.

In summary, we found reduced muscle attenuation in women and older adults. This indicates that fat infiltration of all trunk muscles increases with age in both women and men, although intramuscular fat tends to be higher in women than men throughout adult life. In addition, while increased activity level may reduce fat infiltration of trunk muscles, it does not alter the age-related increase in intramuscular fat. Future studies should determine if increased fat infiltration of muscle contributes to reduced strength of trunk musculature in older adults, and examine effects on postural stability, spinal loading, and risk of vertebral fractures.

Mean (SD) attenuation for 5 muscles, illustrating variations with age, sex and between muscles.

FR0020

A Childhood Fracture is a Risk Factor for Both Low BMD at Growth and Low Peak Bone Mass - a Mean 28 Years Prospective Controlled Study. Magnus Karlsson¹, Christian Buttazzoni^{*2}, Lennart Landin³, Jan-Ake Nilsson³, Bjorn Rosengren¹, Magnus Tveit⁴. ¹Skane University Hospital Malmö, Lund University, Sweden, ²Department of Clinical Sciences & Orthopaedics, Lund University, Sweden, ³Department of Clinical Sciences & Orthopaedics, Lund University, Sweden, ⁴Clinical & Molecular Osteoporosis Research Unit, Sweden

Purpose: A fracture in childhood is associated with low bone mineral density (BMD). However, it is uncertain if low BMD "tracks" into adulthood with associated higher fracture risk. We therefore designed this prospective controlled study to answer if low BMD "tracks" during growth and if a fracture in childhood is a risk factor for low peak bone mass and higher fracture risk.

Methods: Distal forearm bone mineral density (BMD, g/cm²) was measured with single photon absorptiometry (SPA) in 48 boys and 26 girls with mean age 9.8 years (range 4-16), who recently had sustained a fracture, and in 41 boys and 43 girls with mean age 10.2 years (range 4-16) with no fracture. Incident fractures were then prospectively registered until peak bone mass was measured with the same SPA apparatus mean 28 years (range 26-29) later. At follow-up, BMD was also measured by dual energy absorptiometry (DXA, g/cm²) and by quantitative ultrasound (QUS, speed of sound (SOS)). BMD Z-scores at childhood and adulthood were calculated for each individual with a fracture based on our control population at childhood and adulthood, respectively. Data are presented as Z-scores with 95% confidence intervals (95% CI).

Results: There was a correlation between BMD at childhood and adulthood ($r = 0.54$, $p < 0.001$). Children with fracture had at the fracture event a mean distal forearm BMD Z-score of -0.32 (95% CI -0.54, -0.10) and at follow-up of -0.37 (95% CI -0.62, -0.12). Thus, the relative BMD deficit remained at peak bone mass since there was no changes in BMD Z score during the follow-up period (mean delta value 0.05 (95% CI -0.23, 0.33)). The BMD deficit was similar when estimated by DXA and QUS, with mean values for Z-score total hip -0.76 (95% CI -1.03, -0.49), lumbar spine -0.55 (95% CI -0.79, -0.31) and calcaneal SOS -0.44 (95% CI -0.73, -0.16). The mean BMD deficit in individuals with an index fracture was larger in boys than in girls and in those with a low than a moderate or high energy fracture. During the follow-up period, 21/73 (29%) of the children with an index fracture, and 18/84 (21%) of the children with no index fracture, sustained additional fractures.

Conclusions: BMD in childhood seems to "track" into adulthood and a childhood fracture is a risk factor for both low BMD at growth and low peak bone mass, in this study accompanied by a 38% higher fracture risk than expected.

Feeding Blueberry Diets during Early Development Is Sufficient to Prevent Senescence of Osteoblasts and Bone Loss in Adulthood. Jin-Ran Chen^{*1}, Jian Zhang², Oxana P. Lazarenko², Michael L. Blackburn², Kartik Shankar², Thomas M. Badger², Martin J. Ronis². ¹University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, ²UAMS/ACNC, USA

Appropriate nutrition during early development is essential for optimal bone mass accretion; however, linkage between early nutrition, childhood bone mass and prevention of bone loss later in life has not been extensively studied. In this report, we show that feeding a high quality diet supplemented with blueberries (BB) to pre-pubertal rats throughout development or only between postnatal day 20 (PND20) and PND34 prevented ovariectomy (OVX)-induced bone loss in adult life. This protective effect of BB is due to suppression of osteoblastic cell senescence which is associated with acute and profound loss of myosin expression after OVX. Early exposure of pre-osteoblasts to serum from BB-fed rats was found to consistently increase myosin expression. This led to maintenance osteoblastic cell development and differentiation and delay cell entrance into senescence by regulation of the Runx2 gene. High bone turnover after OVX results in insufficient collagenous matrix support for new osteoblasts and their precursors to express myosin and other cytoskeletal elements required for osteoblast activity and differentiation. Co-immuno-precipitation revealed an association between myosin and Runx2 in osteogenic cells and osteoblast precursors, and serum from OVX control rats decreased ($P<0.05$) this myosin and Runx2 complex. Knockdown of the non-muscular myosin II gene in ST2 cells resulted in reduced expression of Runx2 mRNA, and reduced the potential for cells to differentiate into osteoblasts even in the presence of BB serum. Following treatment with shRNA to myosin, ST2 cells expressed greater ($P<0.05$) senescence-associated beta-galactosidase activity, indicating increased stromal cell senescence. These results indicate: 1) a significant prevention of OVX-induced bone loss in adult rats can occur with only 14 days consumption of a BB-containing diet immediately prior to puberty; and 2) the molecular mechanisms underlying these effects involves increased myosin production which stimulates osteoblast differentiation and reduces mesenchymal stromal cell senescence. Interactions of Maternal and Postnatal Diet Alter Skeletal Acquisition in Male and Female Mice: Evidence for Developmental Programming of Bone Acquisition. Maureen Devlin^{*}, Leeann Louis, Christine Conlon, Alison Cloutier, Mary Bouxsein, Beth Israel Deaconess Medical Center, USA

Early life nutrition substantially influences postnatal health, with both low and high birthweight linked with higher offspring metabolic disease risk, but little is known about potential skeletal effects. Here we test the hypothesis that interactions of maternal and postnatal nutrition affect offspring skeletal acquisition and maintenance. Methods: We compared postnatal skeletal acquisition in pups from C57Bl/6J mothers fed a high fat (HF, 45% kCal/fat) or normal (N, 10% kCal/fat) diet from 6 wks prior to breeding through gestation and lactation. At 3 wks of age we weaned male (M) and female (F) pups ($N=2-8/\text{grp}$) onto the same diets as their mothers (HF-HF or N-N) or onto the opposite diet (HF-N). Outcomes at 12 and 20 wks of age included body mass, body length, % body fat, whole body bone mineral content (BMC, g) via PIXImus, cortical and trabecular bone architecture at the midshaft and distal femur via μCT , glucose tolerance, and serum leptin and IGF-1 levels by ELISA. Results: M and F pups from HF diet mothers were longer and heavier vs. N-N at weaning, and remained so when raised on HF diet (HF-HF) ($p<0.05$ for all). HF-HF and HF-N had impaired glucose tolerance (F) and lower leptin levels (M) vs. N-N at 12 wks of age ($p<0.05$ for all). BMC was initially 5-10% higher in HF-HF and HF-N vs. N-N, but by 20 wks of age was 20% lower in HF-HF, along with 36-50% higher body fat ($p<0.05$ for all). Offspring of HF mothers had lower distal femur Tb.BV/TV: -32-36% in F HF-HF at 12 and 20 wks of age, and -25% in M HF-N at 12 wks of age, vs. N-N ($p<0.05$ for all, Figure). Midshaft femur cortical BA/TA (%) was lower in HF-N M at 12 wks of age, but M and F HF-HF and HF-N had greater bone area and polar moment of inertia vs. N-N ($p<0.05$). In conclusion, maternal HF diet impairs skeletal acquisition and maintenance, particularly when combined with postnatal HF. HF-N exhibit lower trabecular bone volume, but higher cortical bone strength, vs. N-N. HF-HF exhibit more severe changes, including markedly lower BMC and trabecular bone volume. The fact that exposure to maternal HF worsens the skeletal effects of postnatal HF demonstrates that maternal diet induces developmental programming of the skeleton that alters response to postnatal diet.

Sport-Specific Association Between Exercise Loading and Density, Geometry, and Microstructure of Weight-Bearing Bone in Young Adult Men. Martin Nilsson^{*1}, Claes Ohlsson², Dan Mellstrom³, Mattias Lorentzon². ¹Centre for Bone & Arthritis Research At the Sahlgrenska Academy, Sweden, ²Center for Bone Research At the Sahlgrenska Academy, Sweden, ³Sahlgrenska University Hospital, Sweden

It is well known that bones adapt to the specific mechanical loading which they are habitually exposed to. Exercise by resistance training is common and increasingly popular in the younger population and can offer several health benefits. The aim of this cross-sectional study was to test the hypothesis that long-term sport-specific exercise loading determines areal and volumetric density, geometry, and microstructure of weight-bearing bone in young adult men.

A total of 186 male athletes, 24.00.6 years of age (meanSD), representing strength training and soccer, and their 177 nonathletic age matched controls, were measured with DXA, pQCT, and high resolution 3D pQCT devices. Grip strength was assessed using a Jamar hydraulic hand dynamometer.

One-way analysis of variance followed by Bonferroni post hoc test was used for evaluating differences between the groups. The mean amount of exercise exceeded three hours per week and the mean time of activity exceeded five years in all groups of athletes.

Men in the strength training group had significantly higher grip strength, 53.29.2 Nm (meanSD), and higher lean mass, 59.45.9 kg, than those in the nonathletic group (48.610.5 Nm, $p<0.01$; 56.36.1 kg, $p<0.001$, respectively). However, strength training men did not have higher bone density, or a more favourable bone microstructure or geometry than their nonathletic referents (Table 1). In contrast, men in the soccer playing group had denser bones at the femoral neck and lumbar spine, larger cortical bone size and higher trabecular number at the tibia than men in the nonathletic group (Table 1). There were no significant differences in age, height, weight, or calcium intake between the different groups.

The association between exercise loading and bone parameters was sport-specific. While, weight-bearing exercise, particularly by playing soccer, was associated with areal and volumetric density, bone geometry, as well as trabecular microstructure of weight-bearing bone, exercise by strength training was not a determinant of the corresponding bone traits in young adult men. These findings indicate that resistance exercise is not conducive to increase bone density and improve bone geometry in young men.

Table 1. Sport Specific Association Between Exercise Loading and Density, Geometry, and Microstructure of Weight-bearing Bone in Young Adult Men

	Nonathletic referents	Type of exercise		ANOVA <i>p</i>
		Strength training	Soccer	
Number of subjects	177	108	78

Determinants of Improvements in Bone Mineral Density (BMD) and Structure Following Initiation of Infliximab (IFX) Therapy for Childhood Crohn Disease (CD). Meena Thayu¹, Justine Shults², Robert Baldassano², Babette Zemel³, Mary Leonard³. ¹The Children's Hospital of Philadelphia, USA, ²University of Pennsylvania School of Medicine, USA, ³Children's Hospital of Philadelphia, USA

In addition to its role in the pathogenesis of intestinal inflammation in CD, TNF- α has direct, detrimental effects on osteoblast number and function. Objectives: To identify growth-related determinants of changes in BMD and structure following IFX (anti-TNF- α) therapy. Methods: 70 participants ages 5-21 yr with moderate to severe CD received IFX induction (5 mg/kg/dose) at weeks 0, 2, and 6 followed by maintenance therapy for 12 months. Tibia peripheral quantitative computed tomography (pQCT) scans were obtained at baseline and 12 months. Race-, sex-, age- and/or tibia length-specific Z-scores were generated for trabecular BMD, cortical BMD, cortical dimensions, and muscle area based on reference data in over 650 controls. Linear regression was used to identify determinants of changes in Z-scores, adjusted for baseline values. Results: Height, trabecular BMD, cortical BMD, and endosteal circumference Z-scores improved significantly over 12 months (Table). The average change in trabecular BMD Z-score, was greater in Tanner 1-4 vs. Tanner 5 participants (mean change: 0.53 0.74 vs. -0.14 0.42, *p*<0.005). Declines in cortical BMD Z-scores were independently associated with increases in endosteal apposition (*p*<0.001) and greater height velocity (*p*<0.01). Decreases in endosteal circumference Z-scores and increases in muscle Z-scores were associated with greater height velocity (*p*<0.0001 and *p*=0.001, respectively). Changes in cortical BMD and endosteal circumference were not associated with Tanner stage of maturation, independent of height velocity. Despite significant improvements in muscle Z-scores, periosteal circumference and section modulus Z-scores did not improve. Conclusions: These data suggest that the reversal of TNF- α effects on osteoblasts is greater in the growing vs. the mature skeleton in pediatric CD, but periosteal and section modulus deficits persist.

Z-Scores at Baseline and 12 months			
Z-Score	Baseline	12 month	p-value
Height	-0.57 ± 1.00	-0.36 ± 1.00	<0.0001
Trabecular BMD	-1.56 ± 1.13	-1.15 ± 1.07	<0.0001
Cortical BMD	0.15 ± 1.09	-0.71 ± 1.14	<0.0001
Endosteal Circumference*	0.29 ± 1.12	0.05 ± 1.01	<0.0001
Periosteal Circumference*	-0.53 ± 1.12	-0.51 ± 1.12	NS
Section Modulus*	-0.71 ± 1.28	-0.61 ± 1.24	NS

High Incidence of New Vertebral Fractures in Children with Leukemia after 12 months of Chemotherapy: Results of the Canadian Steroid-associated Osteoporosis in the Pediatric Population (STOPP) Research Program. N. Alos¹, R. Grant², J. Halton³, S. Atkinson⁴, D. Cabral⁵, R. Couch⁶, E. Cummings⁷, M. Matzinger³, P.M. Miettunen⁸, H. Nadel⁵, C. Rodd⁹, N. Shenouda³, D. Stephure⁸, R. Stein¹⁰, S. Taback¹¹, F. Rauch⁹, B. Lentle³, K. Siminoski⁶, L.M. Ward³, - and the Canadian STOPP Consortium¹². ¹Universite de Montreal, Canada, ²University of Toronto, Canada, ³University of Ottawa, Canada, ⁴McMaster University, Canada, ⁵University of British Columbia, Canada, ⁶University of Alberta, Canada, ⁷Dalhousie University, Canada, ⁸University of Calgary, Canada, ⁹McGill University, Canada, ¹⁰University of Western Ontario, Canada, ¹¹University of Manitoba, Canada, ¹²Canadian Pediatric Bone Health Working Group, Canada

Background: Vertebral fractures are an important complication of childhood acute lymphoblastic leukemia (ALL). The frequency of incident vertebral fractures (IVFs) at 12 months following initiation of chemotherapy, as well as their relationship to key clinical indices have not been systematically studied.

Methods: We evaluated spine health in children with ALL enrolled in a prospective, observational study through a national bone health research program during the first 12 months of chemotherapy. Vertebral morphometry was carried out by the Genant semi-quantitative method on lateral thoracolumbar spine radiographs around the time of diagnosis and at 12 months, with the sum of the Genant grades from T4 to L4 in each patient expressed as the Spinal Deformity Index at both timepoints. Clinical features including VF at diagnosis, lumbar spine areal BMD (LSaBMD) Z-score, back pain, and cumulative glucocorticoid/methotrexate doses were analyzed for association with IVFs.

Results: Of 155 children (median age 6.4 years, 91 boys) with natural history data to 12 months, 25 (16%) had a total of 61 IVFs (46 thoracic and 15 lumbar). Most fractures occurred in the midthoracic and thoracolumbar regions; 32/61 IVFs (52%) were moderate or severe. The clinical characteristics at diagnosis differed significantly for children with IVFs at 12 months compared to those without, as follows: 1. VFs were present at diagnosis in 52% of the children with IVFs at 12 months compared to 9 percent of children without IVFs (*p*<0.001). 2. The mean LSaBMD Z-score at diagnosis was one standard deviation lower in children with IVFs compared to those without (-2.01.5 versus -1.01.2; *p*<0.001). 3. A greater percentage of children with IVFs manifested back pain at diagnosis (52% versus 23%, *p*=0.006). There was no difference in glucocorticoid or methotrexate exposure during the 12 month period. Each unit increase in the Spinal Deformity Index at diagnosis was associated with a 35% increase in the odds for IVF at 12 months (95% CI: 9 to 68%, *p*=0.007).

Conclusions: This study shows a high incidence (16%) of IVFs at 12 months post-chemotherapy initiation in children with ALL. The Spinal Deformity Index at diagnosis was an important determinant of new VFs at 12 months

Mechanism of Hexa-D-Arginine Curative Effects on the HYP Phenotype. Baozhi Yuan¹, Stephen Bowman², Robert Blank², Iris Lindberg³, Marc Drezner². ¹University of Wisconsin, Madison, USA, ²University of Wisconsin, USA, ³University of Maryland, USA

The increased serum FGF-23 level in *hyp*-mice, a homologue of X-linked hypophosphatemia (XLH), results from impaired degradation and enhanced production of FGF-23. We have previously reported that decreased Phex-dependent 7B2 production in osteoblasts and an apparent diminished 7B2-SPC2 (subtilisin-like protein convertase 2) activity underlie the increased serum FGF-23 and biochemical phenotype in *hyp*-mice. We recently found that treatment of *hyp*-mice with Hexa-D-Arginine (D6R), a stable small peptide known to inhibit furin and stimulate SPC2, normalizes the biochemical phenotype in these mutants. In addition, we have documented that such treatment likewise normalizes the bone mineralization in *hyp*-mice and heals the rickets/osteomalacia. Despite these observations, it remains unknown if the positive effects of D6R are mediated by increasing 7B2-SPC2 activity. Therefore, in the present study, we examined the dose-dependent effects of D6R (0-200 μM) on SPC2 activity in hTert osteoblasts (MOB) and M3C3T3 osteoblasts in culture. D6R treatment of hTert osteoblasts (50 μM) for 48 hours significantly increased SPC2 activity to a maximum level (12118 vs 32917 fluorescent units/min; *p*<0.01). Treatment of MC3T3 cells for a similar period likewise increased enzyme activity to a maximum at 200 μM (12414 vs 1717 fluorescent units/min; *p*<0.05). Treatment of the MOB cell line with D6R, and the consequent increase in SPC2 enzyme activity, as anticipated, decreased FGF-23 mRNA expression (1.00.7 vs 0.20.1 fold; *p*<0.001). Further study revealed that the D6R-dependent enhancement of SPC2 enzyme activity in MOB cells occurred in association with an increase in 7B2 mRNA expression (1.00.2 vs 3.60.4 fold; *p*<0.001), but without change in SPC2 mRNA expression. In summary, our data indicate that the curative effects of D6R on the HYP phenotype likely result from enhanced osteoblast 7B2-SPC2 activity, which can normalize the decreased enzyme function present in the *hyp*-mouse osteoblast. Moreover, the associated D6R stimulation of 7B2 mRNA expression suggests that

increased enzyme activity may be secondary to enhanced 7B2 production, which overcomes the central PheX-dependent abnormality in the *hyp*-mouse osteoblast.

FR0044

Increased Cortical Bone Mass Is Associated with Increased Bone Strength by Treatment with the Cathepsin K Inhibitor, ONO-5334, but not with Alendronate in Ovariectomized Monkeys. Yasuo Ochi^{*}, Hirovuki Yamada, Yasutomo Nakanishi, Akiko Kunishige, Satoshi Nishikawa, Yasuaki Hashimoto, Hiroshi Mori, Masafumi Sugitani, Kazuhito Kawabata. Ono Pharmaceutical Co., Ltd., Japan

We have previously reported that ONO-5334 increased bone mass and bone strength in the lumbar vertebra in an ovariectomized (OVX) monkey study where animals received either vehicle, ONO-5334 (1.2, 6 or 30 mg/kg p.o., once daily), or alendronate (ALN, 0.05 mg/kg i.v., once every 2 weeks) for 16 months (N=19-20 per group)¹. Also, it has been demonstrated that ONO-5334 has an efficacy on cortical bone in the lumbar vertebra in OVX monkeys¹.

In this post-hoc analysis, we investigated the relationship between bone mass (integral vBMC measured by pQCT) and bone strength (maximum load) in the lumbar vertebra within each treated group. Linear regression lines between bone mass and bone strength with 6 and 30 mg/kg ONO-5334 groups ($r^2=0.56$ and 0.57 , respectively) shifted toward increasing bone strength compared to those with the OVX control ($r^2=0.68$) and the ALN groups ($r^2=0.37$), i.e. higher bone strength for ONO-5334 was observed compared to OVX control and ALN assessed at the same bone mass level. To further investigate this effect, we focused on the different efficacy on trabecular and cortical bone mass between ONO-5334 and ALN. Subpopulations from the 30 mg/kg ONO-5334 and the ALN groups were selected in a way that their mean values for lumbar integral vBMC were comparable (ONO-5334 subgroup; integral vBMC range 46.2-55.1 mg/mm, mean 49.5 mg/mm, N=10, ALN subgroup; integral vBMC range 46.2-52.1 mg/mm, mean 49.7 mg/mm, N=10), and compared bone strength, trabecular and cortical vBMC between both subgroups. Bone strength was significantly higher in the ONO-5334 subgroup than in the ALN subgroup ($p<0.05$) with comparable integral vBMC. The mean value of trabecular vBMC in the ALN subgroup was higher than in the ONO-5334 subgroup. Conversely, the mean value of cortical vBMC in the ONO-5334 subgroup was higher than in the ALN subgroups. This outcome was also confirmed when analyzing subpopulations with higher and lower mean values of lumbar integral vBMC covering the entire vBMC range.

These results suggest that increased cortical bone mass by treatment with ONO-5334 is associated with an increase in bone strength in the lumbar vertebra in OVX monkeys. Thus ONO-5334 may increase bone strength not only in lumbar vertebra but also in non-vertebral bone where cortical bone predominates in osteoporosis patients.

Metabolic bone disorders like rickets and osteoporosis cause significant reduction in bone material quality, leading to dramatic reductions in mechanical parameters like fracture resistance. However, the ultrastructural mechanism by which altered mineralisation & bone quality affects mechanical properties is far from well understood. Here we determine the functional link between reduced mineralization and abnormal fibrillar-level deformation & fracture using a novel real-time X-ray nanoscale imaging method on a mouse model exhibiting reduced extrafibrillar mineralization. A murine model for hypophosphatemic rickets (Elvis) was induced via *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis. The tissue and organ level phenotypic changes in Elvis mice included elevated plasma alkaline phosphatase, bowed tibia and a reduction in bone mineral density, consistent with features in X-linked Hypophosphatemic Rickets. We use high brilliance *in-situ* synchrotron small angle X-ray scattering to measure, in real-time, the changes in axial periodicity of the nanoscale mineralized fibrils (D-period) in bone during tensile loading. From these measurements, functional nanomechanical parameters like fibril elastic modulus and maximum fibril strain were determined for both Elvis and control mice femora as a function of development. The mineral content in the femora is estimated independently using backscattered electron imaging. We find a significant reduction of fibril modulus as well as an enhancement of maximum fibril strain in Elvis mice. Both modulus and maximum fibril strain increase consistently with age within both the Elvis and wild-type series. The mean mineral content is on average 21 % less for Elvis than for the wild-type mice, and is far more heterogeneous in its distribution. We show how our results are consistent with a simple nanostructural mechanism where incompletely mineralized fibrils show greater extensibility and lower stiffness, leading to known macroscopic outcomes like greater bone bending. Our results demonstrate the power of this novel *in-situ* X-ray nanomechanical imaging approach to directly link alterations in bone nanostructure to nano- and macroscale mechanical deterioration, and the technique can be applied to clinically relevant conditions like osteoporosis.

Non-Invasive Assessment of Bone Marrow Lipids Captures Fracture Risk Profile of Postmenopausal Women Irrespective of Diabetes History. Janina Patsch¹, Thomas Baum², Paron S. Yap², Xiaojuan Li², Dimitrios Karampinos², Sharmila Majumdar², Ann Schwartz², Thomas M. Link². ¹UCSF, USA, ²University of California, San Francisco, USA

Type 2 diabetes is associated with higher fracture risk and, paradoxically, with higher bone density by DXA, suggesting a deficit in bone quality that is not captured by DXA. Clinical bone marrow Magnetic Resonance (MR) Spectroscopy has been introduced as a new tool to study bone quality and has been shown to discriminate subjects of varying BMD. The purpose of this study was to non-invasively assess bone marrow fat properties of diabetic patients with and without fractures in comparison with normal postmenopausal controls and non-diabetic patients with fragility fractures. All postmenopausal subjects (controls n=17; controls with fractures n=15; diabetics without fracture n=15; diabetics with fracture n=7) underwent single-voxel proton MR spectroscopy (1H-MRS) of the lumbar spine (3T, Signa, GE; 4-channel spine coil, GE). A Point Resolved Spectral Selection (PRESS) sequence was used to acquire vertebral body spectra from L1-L3 (TR/TE=3000/37ms, 64 averages without water suppression, sweep width = 5000Hz, data point = 4096, voxel size = 15x15x20mm³ = 4.5cm³ box size). In addition DXA scans of the lumbar spine and the hip were performed. We also measured fasting blood glucose, HbA1c, c-peptide, CRP, PTH and vitamin D levels. Using DXA we found normal bone density in fractured diabetic individuals and unfractured controls, which further underlines DXA's limitations in assessing fracture risk in diabetic patients. Average BMD in non-diabetic fracture patients and non-fractured diabetics was in the osteopenic range. Total marrow fat content using 1H-MRS was similar in all four patient groups. However, the amount of unsaturated lipids was significantly reduced in controls with fractures (L2 -25.8%, p=0.047; L3 -25.1%, p=0.026) and diabetics with fractures (L2 -50.3%, p=0.007; L3 -36%, p=0.045) when compared with non-diabetic controls. We found similar unsaturation changes when comparing diabetics with and without fractures (L2 -39.2%, p=0.04; L3 -23.9%, p=0.04). Lipid unsaturation did not differ between the two unfractured groups. There were no significant correlations between 1H-MRS results, BMD and blood parameters. We conclude that bone marrow

spectroscopy seems to be a promising tool for fracture risk assessment irrespective of diabetes history. This technique could serve as a novel biomarker to identify diabetic patients at risk for fracture. However, the pathophysiology leading to decreased marrow lipid unsaturation in fracture patients remains to be elucidated.

Pubertal Influences on Bone Strength: Results from the Fels Longitudinal Study. Maja Seselj¹, Ramzi W. Nahhas¹, Richard J. Sherwood², Wm. Cameron Chumlea¹, Roger M. Siervogel¹, Stefan A. Czerwinski¹, Bradford Towne², Dana L. Duren³. ¹Lifespan Health Research Center, Department of Community Health, Wright State University, USA, ²Lifespan Health Research Center, Department of Community Health, Wright State University; Department of Pediatrics, Wright State University, USA, ³Lifespan Health Research Center, Department of Community Health, Wright State University; Department of Orthopaedic Surgery, Wright State University, USA

Elucidating the pattern of bone accrual in children is crucial for a proper understanding of bone strength and quality in later stages of life, and has significant potential for predicting adult fracture and osteoporosis risks. For example, it has been suggested that girls who enter puberty at a younger age have a higher bone mineral content (BMC) and density (BMD). A bone's ability to resist bending and torsion, however, is also a function of its cross-sectional geometric properties and is negatively impacted by reducing external bone diameter, which itself is influenced by the timing of puberty. In pubescent girls, elevated levels of estrogen impede subperiosteal bone growth and increase endosteal bone deposition, resulting in bones averaging a smaller external and internal diameter relative to boys. In addition, a secular trend for younger age at menarche is well-documented world-wide, suggesting that the age at which the rate of subperiosteal bone deposition decreases is occurring earlier as well.

In this study we examined the relationship between pubertal timing and bone strength in girls. Specifically, we investigated the effects of age at menarche on bone strength indicators (polar moment of inertia, polar section modulus) determined from cross-sectional geometry of the second metacarpal (MC2) using data derived from serial hand-wrist radiographs of 203 female participants in the Fels Longitudinal Study with repeated measures of MC2 between the ages of 7 and 38 years. These strength indicators, representing torsional and bending strength and rigidity of bone, respectively, were evaluated in multivariate regression models predicting polar moment of inertia and polar section modulus in young adulthood from their pre-pubertal values and age at menarche. Results indicate that both measures of bone strength in adulthood are positively influenced by age at menarche, i.e. a later age at menarche is associated with higher bone strength scores (R² ranged between 0.49 and 0.69, p<0.001), when controlling for pre-pubertal bone strength. Thus, although an earlier age at menarche is reportedly beneficial for BMC and BMD, it is not beneficial for bending and torsional strength and rigidity of bone. In combination, these results suggest that bone strength is multifactorial, and that prevention or intervention measures should consider those variables with the greatest influence at a specific skeletal site given its susceptibility to certain mode of fractures.

The Effect of Denosumab on the Bone Matrix Mineralization in Mice.

Barbara Misof¹, Paul Roschger^{*1}, Michael Ominsky², Phaedra Messmer¹, Paul Kostenuik³, Klaus Klaushofer¹. ¹Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, 1st Medical Department, Hanusch Hospital, Vienna, Austria, ²Amgen, Incorporated, USA, ³Amgen, Inc., USA

Introduction: Denosumab (DMAb), a potent inhibitor of bone turnover, was recently introduced for the treatment of postmenopausal osteoporotic women at increased risk of fracture. A 6-month study in mice with a humanized RANKL gene (huRANKL mice) showed that DMAb significantly increased bone mineral density (BMD) and bone volume (by microCT) of the leg and lumbar vertebrae. Compared to vehicle controls, DMAb-treated mice exhibited significantly greater femur and vertebral peak load, without changes in material parameters. We now report the first data on the effect of DMAb on bone matrix mineralization, which could enhance the understanding of treatment-related changes in BMD and bone strength.

Materials & Methods: Cancellous bone mineralization density distribution (BMDD) in the vertebra and cortical BMDD at the tibial midshaft were measured by quantitative backscattered electron imaging (qBEI) in huRANKL mice. Adult mice (6 to 8 months old) were dosed twice per week for a total of 6 months. Three groups were compared: vehicle (VEH, n=9), alendronate (ALN, 0.1mg/kg, sc; n=9), and denosumab (DMAb, 25mg/kg, iv; n=7) treated.

Results: Two-way repeated measures ANOVA revealed no interaction between treatment (VEH/ALN/DMAb) and site (trabecular/cortical) for the studied BMDD variables average and mode calcium concentration (CaMean and CaPeak, respectively) and heterogeneity of mineralization (CaWidth). Treatments did not cause a change in CaMean or CaPeak, however, CaWidth was significantly affected in both treatment groups. Both ALN and DMAb treated groups revealed lower CaWidth (-7.6%, p=0.005; -14.2%, p<0.001, respectively) compared to VEH, and CaWidth for the DMAb group was lower than the ALN group (p<0.05). Regression analyses indicated that reduced CaWidth was not associated with reduced material properties, including toughness.

Conclusion: The lack of significant changes in mean mineral content after DMAb treatment indicates that the observed increase in BMD is more likely related to an increase in bone volume than in mineral content. The reduction of the heterogeneity in mineralization is typical for a sudden reduction of bone turnover and confirms the antiresorptive action of DMAb. The data suggest that improvements in mechanical competence of whole bones in mice treated with DMAb are mainly due to an increase in bone volume, while the influence of a reduced heterogeneity in mineralization at material level remains unclear.

The Loss of ATF4 Reduces the Toughness of Bone. Jeffry Nyman^{*1}, Alexander Makowski², Sandra Wade², Matthew Murry², Xiangli Yang².

¹Vanderbilt University Medical Center, USA, ²Vanderbilt University, USA

The age-related increase in fracture risk is not solely due to a loss in bone mass, and by extension bone strength, leading to the idea that bone quality is an important attribute of fracture resistance. Despite the critical role of collagen as a determinant of bone toughness (or brittleness), there is an incomplete understanding of how genes important to its organization regulate material properties of bone. To test the hypothesis that transcriptional activity can affect bone properties related to fracture resistance, we characterized the compositional, architectural, and biomechanical properties of bones from wild-type mice and mice null for the activating transcription factor 4 (ATF4^{-/-}), a factor that influences osteoblast maturation and collagen synthesis.

Bones were harvested from ATF4^{+/+} (n=15 per age) and ATF4^{-/-} (n=9 per age) mice at 8 wk and 20 wk of age (male). μ CT analysis quantified structural differences in the femur diaphysis, architectural differences in the femur metaphysis and L6 vertebral body (VB), and tissue mineral density (TMD) of each compartment. Next, three point bending and compression testing of the femur and VB, respectively, assessed fracture resistance. The differences in each bone property among age and genotype were tested for significance using a two-way ANOVA.

Loss of ATF4 affected bone structure in that the null femurs were shorter with a thinner cortex and a ~30% lower moment of inertia, regardless of age. ATF4 deficiency also caused lower trabecular bone volume fraction and lower connectivity density in the metaphysis and VB. Not surprisingly then, the ATF4^{-/-} femur and VB were weaker in bending and compression, respectively, relative to ATF4^{+/+}. Factoring out the structural contribution, the estimated material strength of the mid-shaft was not different between ATF4^{+/+} and ATF4^{-/-} mice but increased from 8 wk to 20 wk. Interestingly, a higher TMD for the null diaphysis - a 2.2% increase from wild-type - did not impart higher material strength. Also, the ATF4^{-/-} bones were clearly more brittle with substantially lower post-yield displacement and work-to-fracture per

cross-sectional area (Fig 1). This is likely due to a defect in the ability of ATF4-deficient osteoblasts to synthesize collagen protein despite its mRNA expression being normal.

Ultimately, there could be novel targets beyond increasing bone mass for improving fracture resistance by elucidating the factors important to the organization of the organic matrix.

Fig 1: ATF4-deficient bone is brittle relative to wild-type bone.

Women with Type 2 Diabetes Have Increased Femoral Neck BMD but Not Increased Femoral Strength. Dana Carpenter^{*1}, Joyce Keyak², Janina Patsch², Paron Yap², Thomas Baum², Ann Schwartz¹, Thomas Lang², Thomas Link².

¹University of California, San Francisco, USA, ²University of California, USA

PURPOSE: Women with type 2 diabetes mellitus are at an increased risk of hip fracture. The purpose of this study was to determine whether diabetes affects the volumetric bone mineral density (BMD) and strength of the proximal femur measured with quantitative computed tomography (QCT) and finite element modeling (FEM).

METHODS: Sixty-two women aged 50-75 years were placed in four groups depending on diabetes and fracture status: 20 healthy women with no history of fracture, 18 healthy women with a history of fracture, 20 diabetic women with no history of fracture, and 7 diabetic women with a history of fracture. Subjects' hips were imaged using QCT with an in-plane pixel size of 0.94 mm and a slice thickness of 2.5 mm. Volumetric BMD of the trabecular (tBMD), cortical (cBMD), and integral (iBMD, including trabecular and cortical bone) compartments of the left femoral neck were measured using a solid calcium hydroxyapatite reference phantom. Three-dimensional FEA was used to compute the fracture load of the left proximal femur under stance and posterolateral fall loading conditions. Differences in BMD and fracture load among the four groups were detected using ANOVA and Tukey post-hoc comparisons.

RESULTS: Diabetics with no history of fracture had a higher iBMD than healthy controls with and without a history of fracture (Fig.1), and tBMD in diabetics with no history of fracture was higher than in both healthy controls with a history of fracture (p < 0.01) and diabetics with a history of fracture (p < 0.05). The cBMD of the femoral neck did not differ significantly among the four groups. Results of FEM in the fall loading configuration showed that the healthy controls had significantly higher fracture load than controls with a history of fracture and diabetics with a history of fracture, but fracture load did not differ significantly between healthy controls and diabetics with no history of fracture (Fig.1). Stance fracture load did not differ significantly among the four groups.

CONCLUSIONS: Type 2 diabetic women have increased BMD in the femoral neck, but the higher BMD does not translate to a stronger proximal femur. These results suggest that aspects of bone structure other than BMD, which are captured by QCT-based FEM, may be related to the higher risk of fracture in diabetics.

Development and Validation of a Mouse Model of Adynamic Bone Disease (ABD). Adeline Ng^{*1}, Benjamin Alman², Marc Grynpas³. ¹University of Toronto Samuel Lunenfeld Research Institute, Canada, ²SICK CHILDREN'S HOSPITAL, Canada, ³Samuel Lunenfeld Research Institute, Canada

INTRODUCTION: The etiology of Adynamic Bone Disease (ABD) is poorly understood but the hallmark of ABD is a lack of bone turnover. ABD occurs in renal osteodystrophy (ROD) and is suspected to occur in elderly patients on long-term anti-resorptive therapy. A major clinical concern of ABD is diminished bone quality and increased fracture risk. To our knowledge, experimental animal models for ABD other than RO-ABD have not been developed or studied. The objectives of this study were to develop a mouse model of ABD without the complications of renal ablation, and to characterize changes in bone quality in ABD relative to controls.

METHODS: To create the adynamic bone condition, 4-month old female Col2.3^{Atk} mice were treated with ganciclovir to specifically ablate osteoblasts, and pamidronate to inhibit osteoclastic resorption. Four groups of animals were used to characterize bone quality in ABD: Normal bone controls, No Formation controls, No Resorption controls, and an Adynamic group. After a 6-week treatment period, animals were sacrificed and bones were harvested for analyses. Bone quality assessments were conducted using established techniques including bone histology, backscattered electron imaging, DXA and microcomputed tomography.

RESULTS: Histomorphometry confirmed osteoblast-related hallmarks of ABD in our mouse model. Bone formation was near complete suppression in the No Formation and Adynamic specimens. Inhibition of bone resorption in the Adynamic group was confirmed by tartrate-resistant acid phosphatase (TRAP) stain. Normal bone mineral density and architecture was maintained in the Adynamic group, whereas the No Formation group showed a reduction in bone mineral content and trabecular thickness relative to the Adynamic group. As expected, the No Formation group had a more hypomineralized profile and the Adynamic group had a higher mean mineralization profile that is similar to low bone turnover in human. This data confirm successful replication of the adynamic bone condition in a mouse.

DISCUSSION: Similarity of our mouse model to the human condition was confirmed using the same histological technique that is used to diagnose ABD in human ROD. Our proposed approach is the first model of ABD that uses pharmacological manipulation in a transgenic mouse to mimic the bone cellular dynamics observed in the human ABD condition. Our model will help understand changes to bone quality and fracture risk as a consequence of a lack of bone turnover.

Incidence Of Skeletal Fractures After Spinal Cord Injury. Laia Gifre^{*1}, Pilar Peris², Joan Vidal³, Jesus Benito³, Enric Portell³, Margarida Valles³, Ana Monegal¹, Nuria Guanabens¹. ¹Hospital CIUñic of Barcelona, Spain, ²Hospital Clinic of Barcelona, Spain, ³Spinal Cord Unit. Guttman Institute, Spain

Spinal cord injury (SCI), due to the absence of mechanical load, is associated with a marked increase in bone remodelling and bone loss, thus increasing the risk of fractures in this process. However, few studies have analysed the incidence and complications of skeletal fractures in these patients. Therefore, we analysed the incidence of skeletal fractures in patients with traumatic SCI, as well as the factors related to the development of fractures and their clinical complications. **Methods:** Retrospective study including all patients attended in the SCI Unit (from January to December 2000) of a specialized center for a recent traumatic SCI. The medical reports were reviewed with special attention to risk factors for osteoporosis and the type of SCI injury, analyzing the incidence of fractures during a 10-year period after SCI in all patients. In addition, we evaluated the severity of SCI, through the ASIA score (American Spinal Injury Association: A-E), weight bearing rehabilitation, the level of SCI (paraplegia/tetraplegia), the type of lesion (spastic/flaccid) as well as the cause, location and evolution of the fracture. **Results:** Of the 129 patients attended at the Unit during the study period, 75 had traumatic SCI (12 died and 9 had no posterior follow-up). Finally, 54 patients were included in the study (45M/9W) with a mean age of 3318 years (13-78); 36 had paraplegia and 18 tetraplegia. 72% had complete motor injury (ASIA A score) and 85% had spasticity. 35% of patients with complete motor injury developed fractures after SCI. The femur, was the most frequent location of the fractures, followed by the tibia, vertebra, pelvis and metatarsus. Fractures were observed 53 years after SCI (range 2-10 yrs) all being observed in males. Most fractures (75%) were related to low impact injuries (including transferences), or were overlooked (no known cause for the fracture). Most patients were treated with conservative approach (75% cases). No significant differences were observed in the clinical characteristics of patients with and without fractures (including age, type and level of lesion, weight bearing, clinical risk factors for osteoporosis). **Conclusion:** After complete motor SCI 35% of patients develop fractures, especially in the femur, after 10 years of follow-up. Most of these fractures are related to minor trauma or are even overlooked. Awareness of the factors related to this complication and its therapeutic approach are mandatory in these patients.

Bone Tissue Micromechanical Properties are Altered Independently of Mineralization in Postmenopausal Osteoporotic Women Long-Term Treated with Alendronate. Yohann Bala^{*1}, Baptiste Depalle¹, Thierry Douillard², Sylvain Meille², Jerome Chevalier², Roland Chapurlat³, Georges Boivin¹. ¹INSERM, UMR 1033; Université de Lyon, France, ²INSA Lyon, MATEIS, CNRS 5510, France, ³E. Herriot Hospital, France

In the treatment of postmenopausal osteoporosis (PMOP), the bisphosphonate alendronate (ALN) decreases the risk of vertebral and non vertebral fractures over a 10 year treatment period¹. Given recent concern about long-term safety of ALN therapy, we have studied the variations of intrinsic properties on iliac bone structural unit (BSU) after a 82 yr ALN treatment (n=6, age:692 yrs, ALN_{LT}) compared to age-matched untreated PMOP women (n=5, PMOP). Quantitative microradiography² of 100 µm-thick sections from embedded bone samples allowed the measurement of the degree of mineralization of bone (DMB) in 150 cortical BSUs chosen to get the widest range of DMB (95 and 55 in ALN_{LT} and PMOP, respectively). Micromechanical properties of the same BSUs were measured on microradiographed sections. High load (>500 mN) nanoindentation tests were used to measure elastic modulus (E), contact hardness (H_c), and the elastic and plastic energies associated to an indentation loading-unloading cycle³. Mineral maturity, crystallinity index and collagen maturity were assessed in same BSUs using Fourier Transform InfraRed Microspectroscopy⁴. Mean DMB was similar between the 2 groups. Compared to PMOP, prolonged ALN treatment was associated with lower E (-12%, p<0.0001) and H_c (-6%, p<0.05) and higher collagen maturity (p<0.001). However, crystallinity index, inversely proportional to crystal size/perfection, was higher in ALN_{LT} than in PMOP (25.290.76 vs. 24.780.70, p<0.001), and was inversely correlated with E and H_c (r=-0.43 and r=-0.54, p<0.001, respectively). Collagen maturity was positively correlated to E and H_c in the two groups (r ranged from 0.40 to 0.70, p<0.0001). Stepwise forward multiple regression including partial correlations revealed that in ALN_{LT}, crystallinity index had a significant entry in the definition of both E and H_c, contrary to PMOP. Treated bone was also less able to plastically resist to deformation at constant strain. To conclude, long-term ALN treatment, while preserving the whole bone strength, may alter the mineral crystallinity and subsequently impair the mechanical behavior at BSU level. This provides rational to include multiscale analysis of material properties in the study of fragility associated with prolonged bisphosphonate therapies.

QTL that Define Trabecular Bone's Micro-mechanical Adaptations to Altered Mechanical Demand. Engin Ozcivici^{*1}, Weidong Zhang², Leah Rae Donahue³, Stefan Judex⁴. ¹Izmir Institute of Technology, Turkey, ²Jackson Laboratories, USA, ³Jackson Laboratory, USA, ⁴Stony Brook University, USA

Loss of functional weightbearing induces a catabolic response in trabecular bone while reambulation is anabolic. The magnitude of either response is modulated by an individual's genetic make-up. As changes in bone morphology are only surrogate measures for bone's risk to fail mechanically, here we identified quantitative trait loci (QTL) that define trabecular bone's micro-mechanical changes during disuse and reambulation. F2 female progeny of BALB and C3H (high and low mechanosensitivity) inbred strains (n=359) were hindlimb unloaded (disuse) for 3wks followed by 3wks of reambulation. At baseline and after the disuse and reambulation periods, the distal femoral metaphysis was scanned by in vivo microCT. Images were evaluated morphologically and micro-mechanically via finite element modeling. Losses in trabecular bone volume fraction amounted to 4317% during disuse, accompanied by a 2715% increase in peak trabecular stress and 10481% increase in skewness of the stress distribution (i.e., efficiency in load bearing with higher numbers indicating lower efficiency). Upon reambulation, trabecular bone volume showed a mean increase of 1022%, while average peak stresses decreased by 108% and the skewness of the stress distributions decreased by 2210%. Genome wide scans identified 5 major (p<0.01) QTL that accounted for 20% of the total variability in baseline peak stress while 3 major QTL accounted for 14% of the variability in the disuse induced increase in peak stress and 1 major QTL accounted for 5% of the variability in the reduction of peak stress during reambulation. The genomic locations identified here differed from previously reported QTL that may modulate morphological adaptations to altered mechanical demand, suggesting that they may harbor novel mechano-sensitive genes. Together, our data show a strong genetic role in the regulation of trabecular bone's micro-mechanical parameters during altered mechanical demand and will ultimately serve towards identifying the underlying genes.

The Role of Oxidative Stress and Antioxidant Enzymes In Bone Under Mechanical Unloading. Daichi Morikawa^{*1}, Yoshitomo Saita², Hidetoshi Nojiri², Keiji Kobayashi¹, Kenji Watanabe¹, Yoshinori Asou³, Kazuo Kaneko², Takahiko Shimizu¹. ¹Molecular Gerontology, Tokyo Metropolitan Institute of Gerontology, Japan, ²Department of Orthopaedics, Juntendo Univ., Japan, ³Tokyo Medical & Dental University, Japan

Mechanical loading is important for maintaining homeostasis both in skeletal muscle and bone. In skeletal muscles, reduced mechanical stimulation leads to increase the level of oxidative stress and change the expression level of antioxidant enzymes, resulting in imbalance of protein synthesis and degradation (i.e., muscle atrophy). However, in bone, relevance of mechanical stimulation and oxidative stress is unclear. The purpose of this study was to clarify whether skeletal unloading increases oxidative stress and changes antioxidant capacity in bone. We analyzed oxidative stress level and gene expression of antioxidant enzymes on skeletal unloading using tail suspension model in mouse.

Unloading significantly increased the level of reactive oxygen species in bone marrow cells collected from hindlimb. A serum marker of oxidative stress (derivatives of reactive oxygen metabolites: d-ROMs) was higher in unloading compared with control (p<0.05). With respect to antioxidant capacity, hindlimb unloading upregulated the expression of CuZn-SOD (*Sod1*), one of the major antioxidant enzymes in cytoplasm, while the expressions of other antioxidant enzymes did not change (Mn-SOD, catalase, glutathione peroxidase1). Therefore, we hypothesized that *Sod1* might have a role to protect from elevated oxidative stress by unloading, and we subjected skeletal unloading for 2 weeks in *Sod1*-deficient (*Sod1*^{-/-}) and wild-type mice (WT). In dual X-ray absorptiometry, *Sod1*^{-/-} showed approx 1.7-fold decrease in BMD of femur by unloading compared with WT (*Sod1*^{-/-}: -13.1%, WT: -7.7%, p<0.05). Similarly, the micro CT analysis showed that *Sod1* deficiency resulted in approx 2-fold decrease in BV/TV by unloading (*Sod1*^{-/-}: -48%, WT: -24%, p<0.01). In dynamic bone formation parameters, *Sod1* deficiency exacerbated in decrease of bone formation rate and mineralizing surface by unloading, while in bone resorption parameter, osteoclast surface, was not changed between WT and *Sod1*^{-/-}. These data indicated that *Sod1* deficiency exacerbated bone loss under reduced mechanical loading due to suppression of osteoblastic bone formation activity.

These results demonstrate that in bone reduced mechanical stimulation leads to increase oxidative stress and an antioxidant enzyme deficiency exacerbated bone loss by unloading.

A Physiome Map of Mechanical and Pharmaceutical Treatment in a Mouse Model of Postmenopausal Osteoporosis. Gisela Kuhn^{*1}, Claudia Weigt², Floor Lambers², Ralph Muller³. ¹ETH Zurich, Switzerland, ²Institute for Biomechanics, ETH Zurich, Switzerland, ³ETH Zurich, Switzerland

Comparisons of results of different studies are often difficult due to variation in design and evaluation techniques. Furthermore, in cross-sectional study designs differences between treatment groups can be alleviated by inter-individual differences at the start, which cannot be determined. Therefore, we investigated the effects of anabolic (parathyroid hormone; PTH), antiresorptive (bisphosphonate; BIS) treatment, and mechanical loading on caudal vertebrae in a mouse model for postmenopausal osteoporosis longitudinally. The ultimate goal of this project is to combine all of the results in a physiome map that allows direct comparison of all physiological effects on a standardized time axis.

Bone loss was induced in 15 week old female C57Bl/6 mice by ovariectomy (OVX). Four weeks of treatment was started either 5 or 11 weeks after OVX, and included a combination of mechanical loading (0N or 8N on the 6th tail vertebra at 3000 cycles and 10 Hz, 3x/week), and either injection of zoledronate (100 µg/kg once), PTH (80µg/kg daily), or corresponding vehicle. An additional group of sham operated animals was subjected to the mechanical loading regime. Bone microarchitectural parameters of the 6th tail vertebra were assessed by in vivo micro-CT before OVX, at treatment start and after 2 and 4 weeks of treatment.

To create the physiome map, the values at treatment start (2nd point) were normalized to the basal measurement for each mouse. The effect of the treatment was calculated regarding to treatment start and percent change was scaled according to the main scale of the first measurement. Here we show the map of trabecular bone volume fraction (Fig. 1) but corresponding maps were created for both cortical and trabecular morphometric parameters.

All OVX mice showed a significant bone loss of 24% and 30% at 5 and 11 weeks after surgery, respectively. Mechanical loading resulted in 16-28% of bone gain. While zoledronate stopped bone loss and slightly increased BV/TV, PTH treatment restored the values to the basal level. The combination of pharmaceutical treatment and mechanical loading was additive in the BIS groups while a slightly synergistic effect was found in the PTH early loading group.

The physiome map allows a fast overview on the relative efficacy of each intervention and presents a powerful tool to compare the different groups on a single time axis. By including results from future longitudinal animal studies the physiome map can be extended easily.

Does Loading Direction Influence the Cell's Response to High Frequency, Low Magnitude Vibration? Sarah Manske^{*}, Gunes Uzer, Stefan Judex. Stony Brook University, USA

Evidence from human, animal and cell culture studies suggests that cells are responsive to high-frequency mechanical input even when the magnitude of the applied force is very small. The mechanism by which cells can sense such small vibratory oscillations is unknown. It is possible that the cytoskeleton and its attachments may directly respond to the vibratory stimulus to counteract the dynamic forces to which it is subjected. If so, then exposing cells in culture dishes to different loading directions should induce different structural responses in the cells. To test this hypothesis, we applied high-frequency (60 Hz), low-magnitude (0.2 g) vibration to MC3T3-E1 cells. To evaluate short-term structural changes, cells were seeded at 3000 cells/mL on Permanox chamber slides. Cells were exposed to one of the following vibration protocols for 30min: horizontal, vertical, horizontal (15min) + vertical (15min), or no vibration (control). Cells were then stained with alexa fluor 546

phalloidin for actin filaments, and mounted with medium containing DAPI. To evaluate mineralization with alizarin red, cells were seeded at 25,000 cells/mL and cultured until they reached sub-confluency. Next, cells were vibrated 30min/d for 10d during which osteogenesis was induced by α MEM supplemented with 10% FBS, 10% β -glycerolphosphate and 1% ascorbic acid. There was no apparent trend in short-term changes in either actin filament quantity or orientation for any of the vibration protocols. After 10 d, there was a trend towards greater mineralization with horizontally vibrated groups when compared with controls. Continuum-level finite element models of our set-up showed that fluid shear stress acting on the cells is negligible during vertical but not horizontal vibration. Thus, these results suggest that either fluid shear stress may play a role in enhancing mineralization during horizontal vibration or that the signal perceived by the cell depends on the direction of loading. Further, the absence of actin stress fiber formation typically induced by larger magnitudes of fluid shear stress could indicate that either cumulative small-magnitude stimulation may induce cytoskeletal changes or that cytoskeletal changes are not required for the low-level oscillatory signal to become effective. Ultimately, a better understanding of the role that the cytoskeleton plays in sensing and responding to the signal is critical for identifying and optimizing effective and safe loading regimes.

Inhibition of Angiogenesis during Loading Induced Osteogenesis using α v β 3-targeted Nanoparticle Delivery of Fumagillin. Ryan Tomlinson^{*1}, Anne Schmieder¹, Gregory Lanza¹, Matthew Silva². ¹Washington University in St. Louis, USA, ²Washington University in St. Louis School of Medicine, USA

Angiogenesis plays an important role in regulating osteogenesis. In fact, anti-angiogenic treatment has been shown to inhibit femoral fracture healing as well as mandibular distraction osteogenesis. However, little is known about the effects of vascularity on osteogenesis following mechanical loading. In this study, we inhibited blood vessel formation following osteogenic mechanical loading using perfluorocarbon nanoparticles targeted to integrin α v β 3 that contain the anti-angiogenic agent fumagillin.

Woven bone formation was induced using an established protocol of forelimb compression in adult rats. Nanoparticles or saline was administered daily for three or five days, followed by euthanasia three or seven days after loading, respectively. The vasculature of each animal was perfused using radiopaque plastic (Microfil). Vascular outcomes were quantified in 2D using histological sections stained with H&E and in 3D using μ CT. In addition, we considered vessel maturity by quantifying histological sections stained with antibodies against CD105 and α SMA.

We observed minimal vascular effects from treatment three days after loading; there were no significant differences between treated and non-treated animals in vessel count, area, or volume, but there was a significant decrease (50%) in the number of vessels with angiogenic endothelial cells (CD105 positive) in treated animals. However, seven days after loading, we observed significant vascular differences between treated animals and non-treated controls: 30% decrease in vessel count, 40% decrease in vessel area, and 33% decrease in vessel volume (Figure 1). In addition, treatment significantly decreased mature vessel count (α SMA positive) by 33%. Finally, treatment significantly decreased new bone volume by 25% compared to non-treated controls (Figure 1).

These results indicate that anti-angiogenic treatment by α v β 3-targeted fumagillin nanoparticles impairs new vessel formation between three and seven days after mechanical loading. This decrease in vascularity is preceded by a decrease in angiogenic vessels three days after loading, and ultimately diminishes the woven bone formation response seven days after loading.

Figure 1 – Anti-angiogenic treatment results in decreases in Bone Volume and Vessel Volume on Day 7

Mechanical Induction of Focal Adhesion Assembly in MSC Amplifies Anti-adipogenic Signaling Pathways. Buer Sen^{*1}, Christophe Guilluy², Zhihui Xie², Natasha Case³, Maya Styner³, Jacob Thomas², Ipek Oguz², Clinton Rubin⁴, Keith Burrige², Janet Rubin³. ¹University of North Carolina At Chapel Hill, USA, ²UNC, USA, ³University of North Carolina, Chapel Hill, School of Medicine, USA, ⁴State University of New York at Stony Brook, USA

The differentiation of mesenchymal stem cell (MSC) integrates chemical, spatial and physical signals. Mechanical stimuli suppress adipogenesis, preserving MSC potential for alternate pathways such as osteogenesis. The converse is also true as absence of mechanical signals permits increase in adiposity and decrease in bone. The anti-adipogenic effect of mechanical signals, which requires GSK3 β inhibition with β -catenin nuclear translocation, can be enhanced if the challenges are segregated into distinct bouts, enabling both the number of cycles and the magnitude of the load to be reduced. To elucidate mechanisms responsible for the amplification of MSC mechanoreponse, we cultured bone marrow derived MSC in adipogenic medium, and applied mechanical strain at 1 or 2% in bouts of 50, 100 or 200 cycles @10 cpm. We found that mechanical suppression of adipogenesis was significantly enhanced if the mechanical bout was repeated after a 3h rest period. Mechanical induction of Akt phosphorylation and its downstream phosphorylation/inactivation of GSK3 β was also enhanced by this regimen: 100 cycles of mechanical strain induced Akt and GSK3 β phosphorylation to levels 50% higher in cells exposed to mechanical input 3 h earlier compared to cells not exposed. A third mechanical application, reflecting a 2nd recovery period of 3h, further enhanced Akt activation. To understand how mechanical force primes this MSC mechanoreponse, we asked if focal adhesion (FA) assembly was associated with Akt signal augmentation. Vinculin staining showed that FA number increased from 284.6 to 905.2/cell after 50 strain cycles. RhoA activity, which accompanies FA formation, was similarly increased by mechanical treatment. FA disassembled w/in 24h. Preventing FA assembly (blebbistatin or ROCK inhibitor) blocked mechanical Akt~P, but did not inhibit insulin induced Akt~P, indicating that cytoskeletal FA are critical to the ability of the cell to respond to physical, but not necessarily hormonal, challenges. As such, mechanically activated signaling pathways that restrict MSC adipocyte differentiation are directly regulated by force altered, adaptable cytoskeletal events. The transient nature of the cytoskeletal adaptation to mechanical input should be considered as key to optimizing mechanical input; mechanical induction of FA may enhance exercise based strategies to maximize bone quality and prevent acquisition of fat.

Mechanical Loading Activates Integrin α 5 β 1 Leading to the Opening of Connexin 43 Hemichannels in Osteocytes - a Mechanism for Extracellular Release of Small Bone Anabolic Factors. Nidhi Batra¹, Sirisha Burra², Sumin Gu², Xuechun Xia³, Lynda Bonewald⁴, Eugene Sprague², Martin Schwartz⁵, Jean Jiang^{*6}. ¹University of Texas Health Science Center at San Antonio (UTHSCSA), USA, ²University of Texas Health Science Center, USA, ³University of Florida, USA, ⁴University of Missouri - Kansas City, USA, ⁵University of Virginia, USA, ⁶University of Texas Health Science Center at San Antonio, USA

Connexin 43 (Cx43) hemichannel in osteocytes is a major portal for the release of factors important for the anabolic effects of mechanical loading on bone. Mechanical stimulation in the form of fluid flow shear stress has been shown to induce the opening of Cx43 hemichannels in MLO-Y4 osteocyte-like cells releasing prostaglandins, ATP and potentially other signaling molecules. Previously, we found that Cx43 consistently co-localizes and associates with the integrin α 5 β 1, but not with the focal adhesion proteins, vinculin or paxillin. Blocking antibody to integrin α 5 inhibits and integrin α 5 siRNA totally abolishes the opening of hemichannels. Here, by protein pull down and surface plasmon resonance (SPR) analyses, we demonstrated the direct interaction between Cx43 and integrin α 5 through their cytoplasmic C-termini. Overexpression of Cx43 C-terminal domain inhibited the hemichannel dye uptake and the interaction between endogenous Cx43 and integrin α 5, suggesting that integrin α 5 interaction with Cx43 through their cytoplasmic C-termini is critical for the opening of Cx43-hemichannel in response to mechanical stress. To examine if ligand engagement of integrin α 5 with the fibronectin substrate was required for its function upon mechanical stimulation, application of extracellular matrix substrate, fibronectin or integrin binding ligand RGD peptide, to MLO-Y4 cells had no effect on the opening of hemichannels by shear stress, indicating that integrin α 5, not fibronectin, is the target for opening hemichannels by shear stress. Furthermore, to establish a direct role for integrin α 5 β 1 in force-dependent regulation of Cx43-hemichannels, magnetic beads coated with either anti- α 5 integrin antibody or fibronectin were perturbed by a magnetic field after attachment to the cell surface which resulted in the opening of hemichannels. Moreover, incubation with an integrin β 1 activating antibody was sufficient for opening the hemichannels in the absence of any mechanical stimulation. This data suggest that activation of integrin possibly through conformational change is a likely mechanism opening the hemichannels in response to mechanical stimulation. Together, these results suggest a novel function of integrin α 5 β 1 that

acts as a mechanical tether to induce opening of hemichannels, a function independent of association with fibronectin substrate.

Runx2 S301,S319 phosphorylation Controls Mechanical Force-Induced Osteoblast Gene Expression *In Vitro* and *In Vivo*. Yan Li^{*1}, Chunxi Ge², Jason Long¹, Jose Rodriguez², Dana Begun¹, Steven Goldstein³, Renny Franceschi⁴. ¹University of Michigan, USA, ²University of Michigan School of Dentistry, USA, ³University of Michigan Orthopedic Research Labs, USA, ⁴Dept of Periodontics & Oral Medicine, University of Michigan School of Dentistry, USA

Mechanical force is a major anabolic signal in bone that enhances mass and strength. Little is known about how mechanical signals induce changes in gene expression necessary for increased bone formation. In the present study, we explore this mechanism *in vitro* and *in vivo* using fluid flow shear stress (FFSS) and ulnar loading models. The ERK/MAPK pathway is one of several signal transduction pathways induced by mechanical loading. We recently showed that activation of this pathway is required for extracellular matrix-induced osteoblast differentiation, gene expression and bone development. ERK functions in part by phosphorylating Runx2 on specific serine residues. Of these, S301 and S319 are critical for transcriptional activity (Ge et al. JBC 284:32533, 2009). To evaluate whether Runx2 phosphorylation is also important in the response to mechanical loading, we employed a recently developed antibody that specifically detects Runx2-S319-P. Exposure of MC3T3-E1 subclone 42 preosteoblast cells to cyclic FFSS (0.033 Hz, 2Pa for 60 minutes) dramatically induced osteopontin (SSP1), bone sialoprotein (Ibsp) and osteocalcin (Bglap2), but not Runx2 mRNAs. As little as 5 min. of FFSS increased P-ERK1/2 and Runx2-S319-P and this response persisted for several hours after stimulation was terminated. Immunofluorescence, co-IP and chromatin immunoprecipitation (ChIP) analysis showed that FFSS induced P-ERK translocation from cytoplasm to nucleus where it co-localized with and phosphorylated Runx2 on the chromatin of *Bglap2* and *Ibsp* target genes. Coincident with these events, increases in histone H3 and H4 acetylation and histone H3-S10 phosphorylation were also detected in promoter regions of *Ibsp* and *Bglap2*. Application of U0126, a MAP inhibitor, prior to FFSS abolished all FFSS-induced events including Runx2 phosphorylation, histone modification and gene expression. Similarly, prevention of phosphorylation by introduction of S301A,S319A mutations into Runx2 completely blocked the response to FFSS. To examine Runx2 phosphorylation *in vivo*, a murine ulnar loading model was employed. Three days of cyclical loading (2000 μ strain, 500 cycles at 2 Hz/day) on the left ulna dramatically induced gene expression of osteopontin (200 fold), *Ibsp* (500 fold), *Bglap2* (1200 fold) and *Runx2* (70 fold) compared to the unloaded right ulna. ERK and Runx2-S319-P both increased after as little as one loading cycle. These studies establish a novel mechanism to explain how mechanical loads induce changes in gene expression involving ERK/MAPK phosphorylation and activation of Runx2, histone modification and increased transcription.

Inhibition of the SDF-1/CXCR4 Signaling Axis Attenuates Load-Induced Bone Formation. Sara Temiyasathit¹, Philipp Leucht², Vasavi Ramachandran¹, Christopher Jacobs³, Jill Helms², Alesha Castillo^{*4}. ¹Veterans Affairs Palo Alto Medical Center, USA, ²Stanford University, USA, ³Columbia University, USA, ⁴Palo Alto Veterans Affairs Medical Center, USA

Introduction: Mechanical loading activates new bone formation through a complex chain of events that involves osteocyte signaling, osteoblastic differentiation, and mobilization of mesenchymal stromal cells (MSCs), but relatively little is known about signaling events controlling these processes. Stromal cell-derived factor-1 (SDF-1) is a potent attractive cue for progenitors expressing its receptor, CXCR4, which is expressed in many cell types including MSCs and osteoblasts [1]. The purpose of this study was to determine the role of SDF-1/CXCR4 signaling in load-induced bone formation.

Materials and Methods: Right ulnae in 18-wk-old C57BL/6 mice were subjected to axial loading (120 cyc, 2 Hz, 3N). SDF-1 levels in bone were detected by *in situ* hybridization [2]. MLO-Y4 osteocyte-like cells were exposed to oscillatory fluid flow (10 dyn/cm², 1 Hz), and SDF-1a concentrations in conditioned media were determined by ELISA. Eighteen-wk-old C57BL/6 mice were treated with AMD3100, a CXCR4 antagonist (5 mg/kg, IP, daily), or vehicle, and subjected to *in vivo* ulnar loading (120 cyc, 2 Hz, 2.8N). Relative periosteal bone formation rates were calculated [3, 4]. Differences in means were tested for significance using a Student's t-test. Data are presented as mean standard error.

Results: SDF-1 was expressed in osteocytes, periosteal cells and marrow cells. In *in vivo* ulnar loading resulted in enhanced expression of SDF-1 in both osteocytes, periosteal cells and bone marrow cells. MLO-Y4 cells exposed to oscillatory fluid flow exhibited greater SDF-1a release (3.71.6 pg/mg) at 2 hr post-flow compared to no flow

samples (9.84.7 pg/mg) although the difference was not significant ($p=0.23$). Blocking SDF-1/CXCR4 signaling with the CXCR4 antagonist, AMD3100, resulted in significantly attenuated relative mineralizing surface ($p<0.001$) and relative bone formation rates ($p=0.002$) (Fig. 1).

Conclusions: Taken together our data suggest that mechanical stimulation enhances expression of SDF-1 in osteocytes, periosteal cells and bone marrow cells. Blocking SDF-1/CXCR4 signaling significantly attenuates load-induced bone formation suggesting that the SDF-1 signaling plays a key role in mechanically-induced osteogenesis.

Role of CKIP-1 in Normal Fracture Healing. Yixin HE^{*1}, Baosheng GUO², Zhong Liu³, Dahu Li⁴, Fuchu HE⁴, Lingqiang Zhang⁴, Ling Qin⁵, Ge Zhang⁶. ¹The Chinese University of Hong Kong, Hong Kong, ²Prince of Wales Hospital, Hong Kong, ³The Chinese University of Hong Kong, Hong Kong, ⁴State Key Laboratory of Proteomics, Beijing Proteomics Research Center, The Academy of Military Medical Sciences, China, ⁵Chinese University of Hong Kong, Hong Kong, ⁶Prince of Wales Hospital, Hong Kong

Introduction: Bone morphogenetic protein (BMP) signaling pathway is an important one responsible for fracture healing. Smad 1/5 have been shown to be the major molecules in BMP signaling. Smurf 1 was identified as an E3 ubiquitin ligase to degrade the Smad 1/5. Recently, we have found that Casein kinase-2 interacting protein-1 (CKIP-1) interacts with Smurf1 and enhances the ligase activity of Smurf1 to promote degradation of Smad1/5. Further, active osteogenesis and subsequent high peak bone mass were found in our established CKIP-1 gene knockout mice when compared to the wild type, indicating the potential role of CKIP-1 in fracture healing. This study aimed to examine the role of CKIP-1 in fracture healing

Methods: Twelve female 3-month-old CKIP-1knockout mouse (KO) and 12 female age-matched wild type C57BL/6 mice (WT) were used in the study. Transverse fracture creation at mid-shaft of right femur will be performed in both groups. 3 mice from each group will be sacrificed at 1, 2, 4 and 6 weeks post fracture. After sacrifice, the fractured specimens will be performed by microCT examination and biomechanical testing. To differentiate newly formed mineralized callus from old cortices, the low- and high-density mineralized tissues were reconstructed using different thresholds. Morphometric parameters used for evaluation were total tissue volume (TV, μm^3), volume of high-density bone (BVh), volume of low-density bone (BVL), total bone volume (BVT, mm^3 , equivalent to BVh+BVL) and normalized percentage of the tissue volumes including BVh/TV, BVL/TV, BVT/TV.

Results: At different time points, reconstructed mineralized calluses showed different morphologic characteristics between groups in the 3D micro-CT images (Fig.1). At 1 week post-fracture, TV and BVL showed higher values in the KO group, but the differences were not statistically significant. At 2 weeks post-fracture, TV, BVT, BVL, BVL/TV and BMC were significantly higher in the KO group than in the WT group. At 4 weeks post-fracture, the KO group presented higher BVL, BVL/TV and BMC than the WT group. At 6 weeks post-fracture, KO groups still have significant larger BVL, BVL/TV and BMC than WT group. Consistently, KO mice also showed significant higher ultimate load and energy to failure compared to the WT mice at 6 weeks post-surgery (Fig.2).

Conclusion: CKIP-1 plays an important role in fracture healing in adult mice.

Hdac3 Controls Growth Plate Matrix Secretion and Akt/mTOR Pathway Activation. Elizabeth Bradley*, David Razidlo, Bridget Stensgard, Jennifer Westendorf. Mayo Clinic, USA

The histone deacetylases (Hdacs) regulate tissue development and cellular differentiation because they modify chromatin structure and influence gene expression. Endochondral ossification is a highly organized and tightly controlled developmental process that relies on Hdacs, particularly Hdac4, for proper execution. We previously demonstrated that conditional deletion of *Hdac3* in osteo-chondro-progenitor cells with osterix-Cre causes a runted phenotype characterized by decreased growth plate width and reduced bone mass. The goal of this project was to further define the role of *Hdac3* in chondrocyte differentiation using these animals. Using immunohistochemistry, we found that Hdac3 is expressed at the articular surface and within the resting and pre-hypertrophic zones of the growth plate in a two-week old mouse, but not within the proliferating and hypertrophic zones. Conditional *Hdac3* deficiency accelerated chondrocyte hypertrophy but decreased hypertrophic cell size, and disrupted the columnar chondrocyte array. This change was accompanied by decreased alcian blue staining and lower expression of *aggrecan*, *osteopontin* and *mepe*, suggesting that matrix deposition may be altered with conditional *Hdac3* deficiency. To further explore the role of *Hdac3* during chondrocyte differentiation, we developed an *in vitro* model using immature mouse articular chondrocytes (iMACs) cultured in micromass to recapitulate chondrocyte differentiation. Similar to *in vivo* results, iMACs from *Hdac3* conditional knockout mice demonstrated accelerated chondrocyte hypertrophy, but decreased matrix deposition and lower expression of matrix genes including *aggrecan*, *osteopontin* and *mepe*. Activation of the Akt/mTOR pathway increases cell size and matrix deposition. *Hdac3* conditional deficiency decreased Akt/mTOR phosphorylation and activation of the downstream translational regulator S6 kinase and 4E-BP1 in iMAC cultures. Thus, Hdac3 may regulate growth plate matrix deposition by promoting the activation of the Akt/mTOR pathway during endochondral ossification.

Disruption of Mitogen Inducible Gene 6 (MIG6) in the Mouse Genome Accelerates Surgical Induced Osteoarthritis and Down Regulates Wnt Signaling. Danese Joiner^{*1}, Michael Morris², Donald Scholten², Ben Staal³, George Vande Woude³, Clifford Jones⁴, Debra Sietsema⁴, Yu-Wen Zhang³, Jim Mason⁵. ¹Van Andel Research Institute, USA, ²Orthopaedic Cell & Tissue Mechanics Laboratory, Van Andel Research Institute, USA, ³Molecular Oncology Laboratory, Van Andel Research Institute, USA, ⁴Orthopaedic Associates of Michigan, USA, ⁵Van Andel Institute, USA

The interaction between pathological joint mechanics and osteoarthritis is recognized but not well understood. Here we examine the role of mitogen inducible gene 6 (MIG6) through its interaction with Wnt signaling in this process. Mig6 knock out (KO) mice were generated as described previously (Zhang, Y. PNAS 2005). Ligament and meniscus transections were performed on the right knee (RK) of 11 four-week-old wild type (WT) and 11 four-week-old Mig6 KO animals as described previously (Kamekura, S. OA and Cartilage 2005). The left knees (LK) of each of these animals were intact and served as a contralateral control. After 4 weeks, animals were euthanized for micro CT, histological, and RT-PCR analysis. Knees were harvested from WT (n=3) and KO (n=3) mice and scanned at a 10 micron voxel size with a Skyscan 1172 System (Skyscan, Belgium Germany). Images were reconstructed and bone and joint structure were observed. Knees were harvested from WT (n=5) and KO (n=5) mice, fixed for 48h in 10% Neutral Buffered Formalin, and then placed in Decal for 48h. Samples were embedded into a paraffin mold and sectioned at 5 um, stained with Weigerts Hematoxylin, fast green solution, Safranin O solution, dehydrated, and cleared. Mouse knees were aseptically harvested from WT (n=3) and KO (n=3) animals, homogenized in 1mL of TRIzol, chloroform-precipitated and RNA extracted with an RNeasy Mini Kit (Qiagen, Valencia, CA). Relative mRNA transcript levels were measured by RT-PCR utilizing a RT2 Profiler Wnt Signaling PCR Array (SABiosciences, Frederick, MD). Student t test statistics were applied. Joint degradation and osteophyte formation were more severe in the transected knee of Mig6 KO animals compared to the contralateral control Mig6 KO knee and Mig6 WT knees (Fig. 1A) Safranin O staining (red) suggests the formation of abnormal outgrowing nodules with abundant proteoglycans in the Mig6 KO RK (Fig. 1B). Wnt gene expression in the RK compared to the untouched LK was decreased in Mig6 KO animals compared to WT, significantly for Lrp6, Gsk3b, Kremen1, Axin1, and Dvl2 (Fig. 2). Data from this study demonstrates that OA is accelerated in Mig6 KO mice knees after ligament transection and meniscus removal. Mig6 is therefore an important regulator of mechanotransduction in the normal and pathological joint.

NELL-1 Promotes Cartilage Regeneration in an *In Vivo* Rabbit Model.

Ronald Siu^{*1}, Janette Zara², Yaping Hou¹, Jinny Kwak¹, Xinli Zhang¹, Aaron James¹, Karina Covarrubias¹, Benjamin Wu¹, Kang Ting¹, Chia Soo¹, Min Lee¹. ¹University of California, Los Angeles, USA, ²UCLA, USA

Repair of cartilage due to joint trauma remains challenging due to the poor healing capacity of cartilage, adverse effects related to current growth factor-based strategies, and the propensity of chondrocytes to dedifferentiate *in vitro*, which limits autologous chondrocyte transplantation approaches. Nell-1 (*Nel-like molecule-1*), a Runx2-regulated growth factor we first characterized in the context of premature cranial suture fusion, plays important roles in normal chondrogenesis and cartilage organization during development. Translational studies with purified Nell-1 protein support the hypothesis that Nell-1 accelerates differentiation along the osteochondral lineage.

We previously demonstrated the ability of Nell-1 protein to maintain the cartilaginous phenotype of explanted rabbit chondrocytes *in vitro*, as assessed by proteoglycan deposition and type II collagen expression. Our objective in the present study is to determine whether Nell-1 can affect endogenous chondrocytes in an *in vivo* cartilage defect model. To achieve controlled Nell-1 release and provide a biocompatible, biodegradable scaffold for tissue repair, Nell-1 was incorporated into chitosan nanoparticles and embedded into alginate hydrogels. These implants were press-fit into critical-sized, 3-mm circular osteochondral defects created in the femoral condylar cartilage of 3-month-old New Zealand White rabbits ($n=10$). Controls included unfilled defects ($n=8$) and defects filled with Nell-free alginate ($n=8$). Rabbits were sacrificed 3 months post implantation for histological analysis.

Defects filled with alginate containing Nell-1 demonstrated significantly improved cartilage regeneration. Remarkably, histology of Nell-1 treated defects closely resembled that of native cartilage, including stronger Alcian blue staining and increased deposition of type II collagen and absence of type I collagen, as demonstrated by immunohistochemistry (Figure 1). Our results suggest that Nell-1 may produce functional cartilage with properties similar to native cartilage and appropriate distributions of extracellular matrix molecules, and is an exciting candidate for novel tissue engineering-based approaches for treating osteoarthritis and other diverse pathologies of cartilage defects and degeneration.

PTHrP Blocks Thyroid Hormone Signaling Through PP2A/HDAC4/Mef2 Pathway in Growth Plate Chondrocytes. Lai Wang*, Yvonne Shao, R. Tracy Ballock. Cleveland Clinic, USA

Thyroid hormone is a critical modulator of skeletal maturation *in vivo*. Hypertrophic differentiation of growth plate chondrocytes is severely impaired in hypothyroid mice, correlated with a decrease in type X collagen expression and increased expression of PTHrP. PTHrP has been recently reported to repress chondrocyte hypertrophy through a PP2A/HDAC4/Mef2 pathway. The association of myocyte enhancer factor-2c (Mef2c) and its corepressor histone deacetylase 4 (HDAC4) controls chondrocyte hypertrophy and endochondral bone development. Our hypothesis is that PTHrP inhibits the effects of thyroid hormone on terminal differentiation of growth plate chondrocytes through the PP2A/HDAC4/Mef2c pathway.

Pellet cultures of newborn rat distal femoral growth plate chondrocytes were maintained in serum-free medium in the presence or absence of T3, PTHrP and the PP2A inhibitor okadaic acid (OA). T3 treatment significantly downregulated PTHrP mRNA expression and increased the expression of its receptor PTHR. T3 increased both Mef2c mRNA expression and Mef2 transcriptional activity, and these effects were inhibited by addition of PTHrP. PTHrP inhibited T3-dependent thyroid hormone receptor TR α 1-mediated transcriptional activation, and markedly decreased T3-increased Col10a1 mRNA expression and alkaline phosphatase (ALP) activity in a dose-dependent manner. Addition of OA reversed the inhibitory effects of PTHrP and synergistically enhanced T3 activity in growth plate chondrocytes. Overexpression of HDAC4 resulted in decreases in T3-induced Col10a1 mRNA expression and ALP activity. Immunoblot analysis showed that T3 increased phosphorylation of HDAC4 and promoted the translocation of HDAC4 from the nucleus to the cytoplasm, which prevented HDAC4 from binding to Mef2c and inhibiting its activity. PTHrP decreased T3-mediated HDAC4 phosphorylation and promoted nuclear translocation of HDAC4.

This study identifies that thyroid hormone decreases PTHrP expression and enhances Mef2c expression and activity in growth plate chondrocytes. PTHrP may suppress T3-induced hypertrophy by dephosphorylation of HDAC4, nuclear translocation of HDAC4, and consequent inhibition of Mef2c activity. In addition, PTHrP inhibits TR transcriptional activity, indicating that PTHrP is a potent negative regulator of thyroid hormone signaling in the growth plate chondrocyte terminal differentiation.

Roles of the Heterotypic CCN2/CTGF-CCN3/NOV and Homotypic CCN2-CCN2 Interactions in Matrix Synthesis in Chondrocytes. Mitsuhiro Hoshijima^{*1}, Takako Hattori², Eriko Aoyama³, Takashi Nishida¹, Takashi Yamashiro⁴, Masaharu Takigawa⁵. ¹Okayama University, Japan, ²Department of Biochemistry & Molecular Dentistry Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, ³Biodental Research Center, Okayama University Dental School, Japan, ⁴Department of Orthodontics & Dentofacial Orthopedics Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, ⁵Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci., Japan

[Objective] CCN family member 2 / Connective tissue growth factor (CCN2) is strongly expressed in cartilage and modulates chondrocyte differentiation and proliferation. The aim of this study is to identify CCN2-interactive proteins and to investigate their influence on the matrix-stimulating activity of CCN2 in chondrocytes. [Methods] We carried out a yeast two-hybrid screening of a cDNA library derived from the human chondrocytic cell line HCS-2/8, using CCN2 as a bait, and specified the interaction sites in both CCN2 and its binding partners. CCN2 and interactive proteins were expressed ectopically in the COS7 cells to study their binding and their cellular localization. In addition, direct interactions between purified recombinant proteins of CCN2 and interactive proteins were investigated by immunoprecipitation and SPR (surface plasmon resonance) analysis *in vitro*. The influence that interaction of these proteins gave on cartilage matrix gene expression was monitored by real-time PCR. [Results] The yeast two-hybrid screening for CCN2 binding proteins revealed both CCN2 and CCN3/NOV as homotypic and heterotypic ligands, respectively. Among the four domains in CCN2, the IGFBP, VWC and CT domains exhibited direct homotypic interaction with CCN2, while only VWC and CT domains of CCN2 showed direct interaction with CCN3. These interactions were confirmed by immunoprecipitation and SPR analysis *in vitro* ($KD \approx 1 \times 10^{-9}$ M), using recombinant proteins of CCN2 and CCN3. Ectopically expressed CCN2 and CCN3 in COS7 cells showed good co-localization by indirect immunofluorescence staining, and binding by immunoprecipitation *in vivo*. Addition of CCN2 to chondrocytes enhanced expression of the extracellular matrix genes such as aggrecan mRNA, whereas addition of CCN3 impaired expression of these genes. The combination of CCN2 and CCN3 abolished the impaired expression of extracellular matrices by CCN3 in a dose-dependent manner of CCN2. [Conclusion] These results suggest that CCN2 may form a homodimer as well as heterodimer with CCN3. CCN2 promotes, while CCN3 inhibits expression of aggrecan mRNA in chondrocytes. Because the restraint by CCN3 was improved dose-dependently by CCN2, our data suggests that activity of CCN2 is regulated by the interaction with CCN3.

TGF β and Substrate Stiffness Interact to Direct Chondrocyte Differentiation. Jessica Orr^{*}, Tamara Alliston. University of California, San Francisco, USA

Physical cues, like biochemical cues, can regulate cell differentiation. Specifically, the stiffness of the extracellular matrix (ECM) directs stem cell differentiation and plays a key role in cancer and other diseases. Though ECM stiffness is tightly defined throughout articular cartilage and is disrupted in osteoarthritis, the effect of ECM stiffness on chondrocyte differentiation is unclear. To test the hypothesis that chondrocyte differentiation is stiffness-sensitive, ATDC5 chondroprogenitor cells were grown for 7 days on polyacrylamide substrates with a range of stiffnesses (0.02 – 2MPa) spanning the stiffness of articular cartilage. To facilitate cell attachment, the gels are conjugated with collagen II. The substrate stiffness closest to articular cartilage (1MPa) potentially induced the expression of chondrocyte differentiation genes, Sox9, Col2a1, and aggrecan 5, 19, and 16-fold, respectively, relative to cells on plastic. Similar results are observed in mesenchymal stem cells. Like other mechanosensitive responses, the stiffness-dependent induction of chondrogenic differentiation was sensitive to inhibition of ROCK (Y27632).

Little is known about the mechanisms by which physical cues such as ECM stiffness interact with biochemical cues to direct cell differentiation. Since TGF β is a key regulator of chondrocyte differentiation, we sought to determine whether ECM stiffness and TGF β cooperate to control chondrocyte differentiation. Compared to a 5-10-fold induction of Col2a1 and aggrecan expression induced by TGF β in ATDC5

cells grown on plastic, TGF β stimulated 140 and 70-fold-induction of these genes in ATDC5 cells grown on 1MPa substrates. Cooperative induction of Col2a1 was also observed within 24 hrs of TGF β treatment. To determine if synergy utilized the Smad or non-Smad arms of the TGF β pathway, we performed loss of function studies using shRNA for Smad3 or chemical inhibitors of Erk/MAPK. Both Smad3 and p38 signaling are required for the cooperative induction of Col2a1 by TGF β and ECM stiffness. This is consistent with the increased Smad3 and p38 phosphorylation, detected by Western analysis, in ATDC5 cells grown on 1 MPa substrates relative to plastic, even in the absence of added TGF β . In summary, we found that TGF β and ECM stiffness synergize to enhance chondrocyte differentiation through Smad3 and p38 dependent pathways, revealing a novel molecular mechanism by which physical and biochemical cues interact to direct cell differentiation.

Vinculin-mediated Signaling from Extracellular Matrix Interacts with the Signaling Triggered by Humoral Factors and Regulates Chondrocyte Differentiation in a Sox9-independent Manner. Takao Koshimizu^{*1}, Masanobu Kawai¹, Kanako Tachikawa¹, Keiichi Ozono², Toshimi Michigami¹. ¹Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, ²Osaka University Graduate School of Medicine, Japan

Vinculin is a cytoskeletal protein which functions in adhesion and/or signaling between the extracellular matrix (ECM) and the cell. Although a recent work demonstrated a tissue-specific function of vinculin in cardiomyocytes, its roles in skeletogenesis have not been elucidated. We applied a gene-trap mutagenesis in a chondrogenic cell line ATDC5, and isolated a clone where *vinculin* gene was trapped. Interestingly, the trapping of *vinculin* gene resulted in impaired differentiation to mature chondrocytes, which has brought us to hypothesize that vinculin might play a role in chondrocyte differentiation. In immunostaining using an anti-vinculin antibody, chondrocytes in mouse growth plates were positively stained, and the immunoreactivity was intense in prehypertrophic and hypertrophic chondrocytes. Moreover, the expression of vinculin was gradually elevated during the differentiation of primary chondrocytes isolated from mouse rib cages. Then, we further investigated the role of vinculin in chondrocytes by miRNA-mediated knock down in primary chondrocytes using adenoviral transfer. Adhesion-induced phosphorylation of FAK was markedly increased both in *vinculin* knocked-down chondrocytes and *vinculin*-trapped clone, indicating that signaling from ECM was altered in these cells. When cultured in differentiation medium, primary chondrocytes with *vinculin* knocked-down exhibited marked decrease in the expression of *Col2a1* and *aggrecan*, and so did *vinculin*-trapped clone. To our surprise, the expression of *Sox9* was retained in both *vinculin*-knocked down chondrocytes and *vinculin*-trapped clone, suggesting that vinculin might regulate chondrocyte differentiation in a Sox9-independent manner. The expression of *Sox5* was also retained, while that of *Sox6* was decreased. Consistently, knockdown of vinculin in organ culture system of mouse embryonic metatarsal bone resulted in impaired growth of cartilage. Finally, to clarify the mechanism for the regulation of chondrocyte differentiation by vinculin, we comprehensively investigated the alteration in signaling by knockdown or trapping of *vinculin* gene during chondrocyte differentiation, and found that phosphorylation of SHP-2 and Akt was markedly increased either by knockdown or trapping of *vinculin*. Our findings imply that vinculin-mediated signaling from ECM regulates chondrocyte differentiation in a Sox9-independent manner, through the interaction with the signals evoked by growth factors such as IGF and FGF.

Wnt5a Signaling Gradient Controls Directional Cartilage Growth by Establishing Planar Cell Polarity in Chondrocytes. Bo Gao^{*1}, Hai Song¹, Kevin Bishop¹, Gene Elliot¹, Lisa Garrett¹, Milton English¹, Philipp Andre¹, James Robinson¹, Raman Sood¹, Yasuhiro Minami², Aris Economides³, YINGZI YANG⁴. ¹National Human Genome Research Institute, USA, ²Kobe University, Japan, ³Regeneron Pharmaceuticals, Inc., USA, ⁴NIH, USA

The longitudinal growth of long bone requires proximal-distal elongation of the cartilaginous anlage. However, the mechanism underlying directional elongation of the long bone cartilage is unclear. Wnts are a large family of secreted signaling molecules that govern multiple essential morphogenetic processes and adult tissue homeostasis, including bone formation and remodeling. In addition to the well-characterized canonical Wnt/beta-catenin signaling pathway, we and others have shown that the beta-catenin-independent Wnt/Planar Cell Polarity (PCP) pathway is critically required in many developmental processes by conveying and transmitting positional information. PCP, which originally refers to the polarity of epithelial cells within a plane orthogonal to their apical-basal axis, is regulated by a group of evolutionarily conserved core PCP components including a four-pass transmembrane protein, Vangl2. PCP is established in response to a global positional cue. However, the identity and mechanism of such positional cue were unknown in vertebrate

morphogenesis prior to our work. Here we found that Wnt5a signaling gradient in the limb bud controls cartilage elongation by establishing PCP in chondrocytes along the proximal-distal axis. We provided both biochemical and genetic evidence that Ror2, a Wnt5a-binding receptor tyrosine kinase, and Vangl2 transduce Wnt5a signaling in multiple developmental processes in the mouse embryos. Importantly, we found that Wnt5a induced Vangl2 phosphorylation through Ror2 in a dose-dependent manner both *in vitro* and *in vivo*, and such Vangl2 phosphorylation was essential for its function in controlling PCP. Our data revealed that dose-dependent induction of Vangl2 phosphorylation is an essential mechanism by which chondrocytes in the long bone sense positional information and establish PCP by interpreting Wnt5a doses. This study has also provided significant new insight in the molecular mechanism underlying Robinow Syndrome and Brachydactyly type B1 (BDB1) that are caused by mutations in human WNT5A or ROR2 and characterized by shortened skeletal elements. Histone Deacetylase-4 Plays a Role in Palatogenesis Through the Regulation of Neural Crest Cell Migration in Zebrafish. Yukio Nakamura^{*1}, April Delaurier², Shigeyuki Wakitani³, Hiroyuki Kato⁴, Charles Kimmel². ¹Shinshu University School of Medicine, Japan, ²Institute of Neuroscience, University of Oregon, USA, ³Department of Health & Sports Sciences, Mukogawa Women's University, Japan, ⁴Department of Orthopaedic Surgery, Shinshu University School of Medicine, Japan

Craniofacial malformations are associated with more than half of all human birth defects including cleft palate. Patients with cleft palate have impaired oral and/or auditory functions. Therefore, understanding the pathophysiology of cleft palate is important for developing effective treatments. Recently, aberrant expression of the transcriptional repressor histone deacetylase-4 (Hdac4) has been shown to underlie some cases of human cleft palate disorders. The anterior neurocranium in zebrafish is functionally equivalent to the human palate, therefore, we created the zebrafish as a model for understanding the *in vivo* role of Hdac4 in palatogenesis. Bioinformatics analyses of the zebrafish genome identified one copy of the Hdac4 gene. RNA *in situ* hybridization showed that Hdac4 was initially expressed in migrating neural crest cells (NCCs) at 15-17 hours post fertilization (hpf) and then the expression became restricted to regions in the mesenchyme surrounding the pharyngeal arch at 72hpf. Hdac4 was co-expressed with a NCC regulator platelet-derived growth factor receptor- α (pdgfra), suggesting the possible role of Hdac4 in regulation of NCC function. The functional *in vivo* assays creating Hdac4 and pdgfra double mutant zebrafish have been underway. We then knocked down Hdac4 using morpholinos (MOs). Reduced Hdac4 expression in MO-injected fish was confirmed by immunoblot and qRT-PCR analyses. MO-mediated Hdac4 knockdown resulted in failure of midline closure of the neurocranium. This defect was rescued by co-injection of Hdac4 mRNA, indicating the specificity of MO-mediated knockdown. To investigate when and how Hdac4 affects NCC migration, we used Sox10:egfp and foxp2-enhancerA:egfp zebrafish in which GFP-labeled NCCs. Sox10:egfp showed that at 14 hpf and 16 hpf, the absolute distance of cells behind the eye or dorsal to the eye was significantly reduced in the MO-injected embryos, and that the MO-injected embryos showed a substantial reduction of GFP-positive cells behind the eye. Foxp2-enhancerA:egfp revealed that trabeculae communis failed to form by 60 hpf, ethmoid plate failed to widen and a lack of cells filling the anterior-most midline of the ethmoid plate from 60 hpf onwards. These results demonstrate that Hdac4 regulates the migration of NCCs and palatal development in developing zebrafish. In contrast, overexpression of Hdac4 mRNA resulted in midline defects, including cyclopia and a "stick-like" neurocranium lacking both trabecular branching and the ethmoid plates, suggesting that the overexpressing the Hdac4 gene affects the same palatal structure as blocking the gene. Taken together, these results indicate that Hdac4 has a critical role in palatogenesis regulating NCC migration in zebrafish. Understanding the function of Hdac4 in zebrafish may lead to further understanding the mechanism of how loss of Hdac4 in humans results in midline craniofacial defects.

Long-Chain Saturated Fatty Acids Promote the Differentiation of Cells of the Marrow Stromal Line Kusa4b10 into Adipocytes. Dorit Naot^{*1}, Jessica Costa², David S Musson¹, Jian-Ming Lin¹, Jillian Cornish¹, Andrew Grey¹. ¹University of Auckland, New Zealand, ²University of Auckland, Nz

Body weight, and particularly fat mass, is positively correlated to bone mass. The relationships between fat and bone tissue are mediated directly through skeletal loading, and through hormonal and neuronal pathways. Feeding experiments, showing that fat ingestion acutely influences bone turnover, have raised the possibility that ingested nutrients have direct bone effects, and could function as an additional link between fat and bone. We have recently reported that the long-chain, saturated fatty acids palmitic acid (C18) and stearic acid (C16) inhibit osteoclastogenesis *in vitro*, and that the G-protein coupled receptors (GPR) for fatty acids are expressed in bone cells. In the current study, we investigated the effects of palmitic and stearic acids on adipogenic differentiation, using the murine marrow stromal cell line, Kusa4b10.

Kusa4b10 cells were grown to confluence and then cultured for 11 days in adipogenic medium containing dexamethasone, IBMX and insulin. BSA-conjugated palmitic and stearic acids were added at concentrations of 10-75 μ g/mL (30-225 μ M) and BSA alone served as a negative control. Adipogenesis was measured by Oil-Red-O staining and quantified by dye release and spectrophotometry. RNA extracted from the cultures on different days was used for analysis of gene expression by quantitative PCR, using TaqMan assays (ABI). We found that palmitic and stearic acids potentially induce adipogenesis in KUSA4b10 cells. Analysis of gene expression demonstrated significant induction of mRNA levels of the adipocytic genes adiponectin, AP2, adipin and PPAR γ . We found high levels of expression of the long chain fatty acid receptor GPR120 in KUSA4b10 cells, and low expression levels of GPR40/41. Treatment of the cells with the GPR40/41 GPR120 agonist GW9508 produced similar effects to the fatty acids treatment; increase in adipogenesis and in levels of mRNA of adipocyte genes.

Our results identify the marrow stromal cell as a novel target of fatty acids. Palmitic and stearic acids promote adipogenic differentiation of marrow stromal cells, possibly by signalling through GPR120 and GPR40/41.

Klf4 Regulates Osteoblast Differentiation. Ikumi Michikami^{*}, Makoto Abe. Osaka University Graduate School of Dentistry, Japan

Kruppel-Like Factor 4 (Klf4) is a Zinc finger type of transcription factor highly expressed in the skin, intestine, testis, lung and bone. It is also known as a growth inhibitor which functions through antagonizing canonical Wnt- or Notch-dependent pathways. The role played by Klf4 has been studied extensively in normal epithelial development; however its role in bone cell is completely unknown. To understand the possible role(s) played by Klf4 in bone cells, we examined the effect of over-expression and knockdown of Klf4 in mouse calvarial osteoblasts *in vitro*. Further, we examined the skeletal phenotype of the transgenic mice over-expressing Klf4 under 2.3 kb mouse *Colla1* regulatory sequence (*Colla1-Klf4 TG*).

Over-expressing Klf4 in mouse calvarial osteoblasts strongly repressed its differentiation and down-regulated most of the osteoblastic gene expressions. Unexpectedly, siRNA-mediated knockdown of Klf4 or over-expressing dominant-negative Klf4 also repressed osteoblast differentiation. Klf4 induced expressions of *Axin2* and *Left1*, which are both direct targets of canonical Wnt signaling, and Klf4 activated the canonical Wnt signaling reporter in calvarial osteoblasts. Consistent with this observation, GSK3 inhibition by LiCl strongly repressed calvarial osteoblast mineralization. *Colla1-Klf4 TG* embryos exhibited skeletal deformities including ill-formed calvarial bones and delayed formation of the primary ossification center in the long bones. These results indicate that 1) Klf4 regulates osteoblast differentiation both *in vitro* and *in vivo*, 2) precise regulation of the timing and level of Klf4 expression is crucial for normal osteoblast differentiation.

Characterization of Collagen-GFP Transgenic Mice and Evidence for Osteocyte Deposition of Perilacunar Collagen. Patricia Veno¹, Suzan Kamel¹, Yongbo Lu², Yixia Xie³, Karl Kadler⁴, Yinhui Lu⁵, Charlotte Phillips⁶, Vladimir Dusevich³, Sarah Dallas^{*3}. ¹University of Missouri, Kansas City, USA, ²Baylor College of Dentistry/Texas A&M Health Science Center, USA, ³University of Missouri - Kansas City, USA, ⁴Wellcome Trust Center for Cell Matrix Research/University of Manchester, United Kingdom, ⁵Wellcome Trust Center for Cell-Matrix Research/University of Manchester, United Kingdom, ⁶University of Missouri-Columbia, USA

Type I collagen is the major structural matrix protein in bone. It is a heterotrimer of two α 1(I) and one α 2(I) chains encoded by separate genes and mutations in either gene cause osteogenesis imperfecta. We have previously generated fluorescent collagen fusion proteins, in which GFP (green) or mCherry (red) were placed in the pro- α 2(I) N-terminus, and have reported their use in time lapse imaging studies of collagen assembly in living osteoblasts. We have also generated transgenic mice expressing α 2(I)-collagen-GFP driven by the 3.6kb *COL1A1* promoter. Here we report the further validation and characterization of these mice and using this model we show evidence for osteocyte deposition of perilacunar collagen.

Four collagen-GFP transgenic lines were obtained that showed varying levels of GFP-collagen expression in bone matrix, with line 35 giving the strongest GFP signal in bone. Intense GFP-collagen fluorescence was seen in the osteocyte perilacunar matrix in active bone forming areas. All lines also showed strong GFP-collagen expression in tendon, ligament and dentin, with moderate expression in skin. Small focal areas of GFP-collagen were present around blood vessels and in fibrous connective tissue in kidney and lung as well as in the heart valve leaflets. Low expression was seen in the intestinal submucosa. No overt abnormalities were observed in GFP-collagen mice, even though incorporation of 26kDa of GFP sequence in the α 2(I)-collagen N-terminus is analogous to mutations in patients with Ehlers Danlos type VIIb in which the N-propeptide cleavage site is lost and the propeptide is retained. These patients show skin and joint laxity. However, no significant difference in skin laxity was seen in GFP-collagen transgenic mice

compared to littermate controls and TEM analysis of skin and ligament collagen showed no Ehlers Danlos-like fibril abnormalities. No major skeletal abnormalities were observed by radiography and bone collagen fibrils appeared normal by TEM, with no significant difference in D-band periodicity. These data show the successful generation of GFP-collagen transgenic mice and suggest that the GFP insertion into pro- $\alpha 2(I)$ -collagen results in minimal disruption to collagen fibril structure in these mice. Expression of GFP-collagen in kidney, lung and skin suggests that this model will be useful for fibrosis research and the strong GFP expression in the perilacunar matrix provides new evidence for osteocyte deposition of perilacunar collagen.

Sympathetic Control of Bone Mass Regulated By Osteopontin. Masashi Nagao^{*1}, Yoshitomo Saita², RYO HANYU³, Tadayoshi Hayata⁴, Tetsuya Nakamoto⁵, Yayoi Izu⁵, Takuya Notomi⁶, Shu Takeda⁷, Gerard Karsenty⁸, Susan Rittling⁹, Yoichi Ezura¹⁰, Jean-Pierre Vilardaga¹¹, Masaki Noda⁵. ¹Juntendo University Nerima Hospital, Japan, ²Department of Orthopaedics, Juntendo University School of Medicine, Japan, ³MEDICAL RESEARCH INSTITUTE, Japan, ⁴Medical Research Institute, Tokyo Medical & Dental University, Japan, ⁵Tokyo Medical & Dental University, Japan, ⁶GCOE, Tokyo Medical & Dental University, Japan, ⁷Keio University, Dept. of Nephrology, Endocrinology & Metabolism, Japan, ⁸Columbia University, USA, ⁹The Forsyth Institute, USA, ¹⁰Tokyo Medical & Dental University, Medical Research Institute, Japan, ¹¹University of Pittsburgh, School of Medicine, USA

Stimulation of the sympathetic nervous system suppresses bone mass by mechanisms that remain incompletely elucidated. One of the major causes of bone loss is disuse-induced event. Using mice genetics and cell-based approaches, we showed that this bone deterioration requires osteopontin (OPN), a cytokine and one of the major components of non-collagenous extracellular matrix proteins of bone. The stimulation of the sympathetic tone by isoproterenol (ISO) increased the level of OPN expression in the plasma and bone. While in wild type (WT), ISO treatment reduced the levels of bone volume, OPN-deficient mice were resistant to such ISO-induced bone loss. ISO treatment suppressed bone formation parameters in WT. However, OPN deficiency mitigated ISO-induced reductions these bone formation parameters. ISO-treatment also increased the levels of bone resorption parameters in wild type, while these parameters were unaffected by ISO in OPN deficient mice. At the cell level, OPN deficiency enhanced ISO-induced CRE-luciferase activity as well as forskolin and IBMX induced events. OPN-deficiency also enhanced phosphorylation of CRE-binding protein, CREB. We therefore examined the role of OPN at the signaling levels in osteoblasts. The time course of cAMP generation by ISO was much longer in cells depleted of OPN. Conversely OPN overexpression reduced cAMP generation in response to ISO. These data indicated that OPN modulates cAMP by acting at the level of the receptor and/or the stimulatory G protein (Gs). In fact, pull-down experiment revealed the existence of OPN-Gs complex. Our results indicate that OPN plays a critical role in sympathetic tone regulation of bone mass and this OPN regulation is taking place through modulation of the $\beta 2AR/GS$ signaling system.

Temporal Analysis of mechanical force-induced bone formation Using Quantitative Proteomics based on 8 plex- iTRAQ. Wei-Bing Zhang^{*1}, Wei-Jie Zhong², Lin Wang². ¹Nanjing Medical University, Chn, ²Nanjing Medical University, China

Skeletal tissue has the capability to adapt its mass and structure in response to mechanical stress. However, the molecular mechanism of bone and cartilage to respond to mechanical stress are not fully understood. To obtain better insights into proteome analysis of bone and cartilage response to mechanical stress in vivo, we have conducted studies of midpalatal suture expansion. The midpalatal suture, located between the maxillary bones in the palate, contains secondary cartilage that is highly responsive to various mechanical forces. A total of 96 male C57BL/6 mice, 6-week-old and 19–20g in weight, were used. Half of animals were subjected to palatal suture expansion by opening loops (Fig1) for the periods of 1, 3, 7, 14 days. Specimens were harvested at a series of post load time points, and the cellular response to loading was evaluated by histomorphometric. Micro-CT was used for morphometric analysis. Fluorescence labeling by incorporation of alizarin/ calcein in newly formed bone minerals qualitatively demonstrated new bone formation (fig3). Quantitative proteomic profiling using a multiplexed approach (Fig2) capable of analyzing eight different samples simultaneously was carried out to monitor the temporal dynamics of protein abundance during the period of expansion. A catalog of ~726 proteins along with their relative quantitative expression patterns was generated. Differential expression analysis in the experimental groups and control group showed significant changes for 78 proteins. The differential expression of the large majority of these proteins has not previously been reported or studied in the context of mechanical signal transduction in mechanical force-induced bone formation. 54 proteins were upregulated in differentiating and proliferation, but 24 proteins were downregulated

related to apoptosis or catabolic. Our data suggest that 18 proteins were assigned a role in cell communication. 10 proteins were assigned a role in anabolic process. Comparisons of anabolic versus catabolic features of the proteomes show that 13 proteins were related to catabolic. 15 proteins were related to regulation of signal transduction. 7 proteins were related to regulation of angiogenesis. 26 proteins were related to apoptosis. (Fig4, Fig5) We validated some of the novel markers of the process of bone formation induced by force using immunoblotting and immunocytochemical labeling. To our knowledge, this is the first large-scale temporal proteomic profiling of bone formation induced by mechanical force highlighting proteins with limited or undefined roles.

Osteoblastic Cells Rely on MT1-MMP as a Regulator of Skeletal Homeostasis. Emily Purcell*, Joanne Shi, Susan Yamada, Pamela Robey, Kenn Holmbeck, National Institute of Dental & Craniofacial Research, USA

Purpose: Bone and cartilage formation require the ability of skeletal progenitors to remodel their resident matrix to enable proper cell function. This is achieved in part by pericellular proteolysis mediated by membrane-type matrix metalloproteinases (MT-MMPs). Accordingly, congenital or adult-onset MT-MMP deficiency results in severe disruption of skeletal development and homeostasis. Because MT-MMPs are expressed in a wide variety of skeletal-associated cells, the cell-specific contribution to the observed defects is difficult to assign. In an effort to characterize osteoblastic vs. chondrocytic dependence on MT-MMP activity, we initiated cell/tissue-specific deletion of MT-MMP in the skeleton.

Methods: We utilized a mouse strain modified with a floxed conditional knockout allele of MT1-MMP. By crossing this mouse line with an Osterix (Osx) Cre-expressing mouse, we have obtained specific ablation of MT1-MMP in Osx-expressing cells.

Results: We demonstrated that selective ablation of MT1-MMP in the Osx-expressing subset of cells leads to dwarfism, osteopenia, malocclusion of teeth, and apparent loss of bone. Computer-assisted tomography of long bones revealed a dramatic reduction of trabecular bone, thin cortices, and apparent bone loss at ligament insertion sites.

Conclusion: Based on these results, we hypothesize that cells of the osteoblastic lineage rely on MT1-MMP for proper regulation of bone development and homeostasis through pericellular proteolytic activity.

Control of Iron Status Alters Phosphate Metabolism in a Mouse Model of Autosomal Dominant Hypophosphatemic Rickets (ADHR). Emily Farrow^{*1}, Lelia Summers¹, Munro Peacock², Kenneth White¹. ¹Indiana University School of Medicine, USA, ²Indiana University Medical Center, USA

Autosomal dominant hypophosphatemic rickets (ADHR) is unique among the heritable disorders of renal phosphate wasting involving FGF23, as patients carrying the R176Q/W and R179Q/W mutations in the ¹⁷⁶RXXR₁₇₉ proteolytic cleavage motif can have early onset disease from birth, or have late onset following puberty or pregnancy, biological states prone to iron deficiency. We have shown that when placed on low-iron diet, wild type (WT) and novel R176Q-Fgf23 knock-in mice (ADHR mice) significantly increase bone Fgf23 mRNA. In the face of elevated Fgf23 production, WT mice maintained normal intact serum Fgf23 by cleaving excess Fgf23 into fragments as detected by increased C-terminal ELISA (3-6 fold; P<0.0001), whereas the low-iron ADHR mice had elevated intact and C-terminal Fgf23 with hypophosphatemia (P<0.0001) and osteomalacia after 8 weeks. To test whether control of systemic iron could rescue the ADHR phenotype, ADHR mice received low-iron diet for 6 weeks followed by iron repletion for 2 weeks. This treatment normalized serum Fgf23 (C-terminal Fgf23: 2580325 pg/mL for 8 week low-iron vs. 29520 pg/mL replete; P<0.001) and serum phosphate (7.50.2 low-iron diet vs. 100.3 replete). Anemia in pregnancy can be transferred to neonates, thus we also tested iron deficiency as a mechanism for early onset ADHR by providing female breeder mice low-iron diet on day 14 of pregnancy and during nursing. WT and ADHR pups receiving low-iron had markedly increased Fgf23 mRNA compared to control diet mice (>45 fold; P<0.01). WT mice regulated serum intact Fgf23 through proteolytic cleavage (WT intact: 17329 pg/mL; C-terminal: 14,136206 pg/mL). In contrast, the ADHR pups had >10-fold elevated intact Fgf23 (P<0.001), but C-terminal Fgf23 was not different from WT (ADHR intact: 1,911355 pg/mL; C-terminal: 14,4541338 pg/mL), as well as significant hypophosphatemia (8.0 mg/dL ADHR vs. 11.3 mg/dL WT; P<0.0001). Therefore, in ADHR mice, the increased serum Fgf23 and hypophosphatemia can be reversed by iron repletion, potentially providing novel therapeutic targets for controlling Fgf23. Further, early onset ADHR in some patients may be due to maternal-neonate transfer. The finding that Fgf23 is strongly up-regulated during iron deficiency provides insight into why ADHR patients, although hypophosphatemic are unable to suppress FGF23 production, and demonstrates that the ADHR phenotype can be dramatically influenced by gene-environment interactions.

Fgf23 Regulates Calcium and Sodium Reabsorption in Renal Distal Tubules through SGK1 Signaling. Olena Andrukhova^{*1}, Carmen Streicher², Ute Zeitze³, Beate Lanske³, Reinhold Erben². ¹Inst. of Physiology, Pathophysiology & Biophysics, Austria, ²University of Veterinary Medicine, Austria, ³Harvard School of Dental Medicine, USA

Fibroblast growth factor-23 (Fgf23) is an endocrine signal originating from osteocytes which downregulates renal tubular phosphate reabsorption and vitamin D hormone synthesis. Here, we examined the effects of long-term Fgf23 deficiency on mineral and bone homeostasis in 9-month-old wild-type (WT) mice, *vitamin D receptor (VDR)* mutant mice, and *Fgf23/VDR* compound mutant mice on both a standard rodent chow and a rescue diet (RD) enriched with calcium, phosphorus, and lactose. The RD largely corrected mineral and bone homeostasis in *VDR* mutant mice. However, compound mutants on RD showed hypocalcemia, hyperphosphatemia, and very high serum parathyroid hormone. Secondary hyperparathyroidism (sHPT) in compound mutants on RD was associated with renal calcium wasting and cortical bone thinning. Analysis of the expression of proteins involved in renal calcium transport revealed reduced membrane abundance of the fully glycosylated epithelial calcium channel TRPV5 and decreased levels of intracellular calbindin D28k in compound mutants. Similar changes in distal tubular protein expression were seen in 4-week-old *Fgf23^{-/-}*, *Klotho^{-/-}*, and *Fgf23/VDR* and *Klotho/VDR* compound mutants. Immunoprecipitation experiments revealed a physical interaction of TRPV5 and with-no-lysine kinase-4 (WNK4). Analysis of the upstream intracellular signaling mechanisms showed decreased phosphorylation of one of the main regulators of WNK4, serum- and glucocorticoid-inducible kinase-1 (SGK1), in kidneys of compound mutants. SGK1 is known to be activated by extracellular signal-regulated kinase-1/2 (ERK1/2), and to be involved in aldosterone signaling. In agreement with an Fgf23 deficiency-induced downregulation of signaling through the Fgf receptors, phosphorylated ERK1/2 was reduced in kidneys of compound mutants. Despite higher aldosterone in serum and urine, compound mutants showed increased urinary loss of sodium relative to WT and *VDR* mutants. Our data have uncovered that Fgf23 signaling regulates phosphorylation of SGK1 through ERK1/2 in renal distal tubules in a vitamin D independent fashion. Decreased SGK1 phosphorylation in *Fgf23* and *Klotho*-ablated mice leads to a downregulation in WNK4-mediated transport of glycosylated TRPV5 to the plasma membrane, and reduced sodium reabsorption despite elevated circulating aldosterone. In conclusion, our results suggest that Fgf23 has a previously unknown function in distal renal tubular calcium and sodium reabsorption.

FR0121

MEPE-derived Phosphorylated ASARM Is Involved in FGF23/soluble Klotho-dependent Hypomineralization. Yukiko Konishi^{*1}, Yuji Yoshiko², Tomoko Minamizaki¹, Hirotaaka Yoshioka¹, Masahiro Maeda³, Atsushi Shimizu⁴, Jane Aubin⁵, Norihiko Maeda¹. ¹Hiroshima University Graduate School of Biomedical Sciences, Japan, ²Hiroshima University, Japan, ³Immuno-Biological Laboratories Co., Ltd, Japan, ⁴Raffinco International Co. Ltd., Japan, ⁵University of Toronto Faculty of Medicine, Canada

Members of the small integrin-binding ligand N-linked glycoprotein (SIBLING) family, includes matrix extracellular phosphoglycoprotein (MEPE), play roles in bone mineralization. A proteolytic fragment containing an acidic serine- and aspartate-rich motif (ASARM) of SIBLINGs binds to hydroxyapatite and inhibits bone mineralization *in vitro*. ASARM peptide is also a candidate substrate for phosphate regulating endopeptidase homolog X-linked (PheX), suggesting that accumulation of ASARM in bone may cause mineralization defects in X-linked hypophosphatemic rickets. Recently, we showed that fibroblast growth factor 23 (FGF23) and the truncated form of the extracellular domain of Klotho (soluble Klotho, sKL) cooperatively inhibit bone mineralization independently of serum phosphate levels. Amongst downstream events of FGF23/sKL binding, the expression of *PheX* was downregulated in mouse bone as well as in rat/mouse osteoblast/osteocyte (Obc cell) cultures. To clarify the interplay between ASARM peptide and FGF23/sKL, we developed an antibody against human MEPE-associated phosphorylated ASARM (pASARM). This antibody recognized pASARM (Ser518/520/522) and MEPE, but not partially phosphorylated (Ser520/522, Ser518, Ser520 or Ser522) and non-phosphorylated (npASARM) ASARM or other SIBLINGs. In the rat Obc cell culture model, anti-pASARM antibody inhibited not only pASARM- but also FGF23/sKL-dependent hypomineralization. By immunohistochemistry, pASARM was localized in osteoblasts/osteocytes, and staining intensity was significantly higher in Klotho mutant (*kll/kll*) versus wild type mice. Upregulation of *PheX* in *kll/kll* bone *ex vivo* was abrogated by treatment with sKL in parallel with ERK phosphorylation and increased *Egr-1* mRNA expression, markers for FGF23-specific signaling. pASARM immunoreactivity was high in Obc cell cultures treated with FGF23/sKL, and was decreased by U0126, an inhibitor of ERK phosphorylation. The inhibitory effect of pASARM on matrix mineralization was lost when the N-terminus amino acid residues including the PheX-cleavage site or phosphorylation of Ser518/520/522 was used. Treatment with an excess amount of npASARM that included the PheX-cleavage site shifted the effective concentrations of pASARM from higher to lower. Taken together, these results suggest that FGF23/sKL negatively regulate bone mineralization via their inhibitory effect on *PheX* expression, followed by accumulation of pASARM in bone.

Mice Expressing a Phosphorylation-Deficient PTH Receptor Have Blunted Calcemic and Phosphaturic Responses to Acute PTH Challenge. Akira Maeda^{*1}, Makoto Okazaki¹, Matthew Mahon¹, Hiroko Segawa¹, Abdul Abou-Samra², Harald Jueppner¹, John Potts¹, Thomas Gardella¹. ¹Massachusetts General Hospital, USA, ²Wayne State University, School of Medicine, USA

Phosphorylation of the PTHR1 C-terminal tail is thought to play a key role in receptor signal regulation and internalization. A phosphorylation-deficient mutant PTHR1 (PD) exhibits defective internalization in cells, and PD-knock-in mice exhibit prolonged blood cAMP increases after PTH(1-34) injection (Bounoutous, 2006, Endocrinology). We now compared the acute, PTH-induced blood ionized calcium (Ca⁺⁺) and plasma phosphate (Pi) responses of PD and WT mice.

Injection of PTH(1-34) into WT mice caused Ca⁺⁺ levels to increase from 1-4 h post injection, whereas injection into PD mice caused no change in Ca⁺⁺ levels. Injection of a longer-acting PTH analog, M-PTH(1-28), into WT mice increased Ca⁺⁺ levels for at least 6 hours, whereas injection into PD mice resulted in no change in Ca⁺⁺ for up to 2 h, and only a partial increase (50% vs. WT) at 4-6 h. In WT mice, PTH(1-34) suppressed Pi levels from 1 to 2 h post injection, and M-PTH(1-28) suppressed Pi levels for at least 4 h. In contrast, in PD mice, neither PTH(1-34) nor M-PTH(1-28) suppressed Pi levels. Injection of PTH(1-34) or M-PTH(1-28) in WT mice caused transient increases in blood cAMP levels (peak at 15 min), whereas injection in PD mice caused more robust and prolonged increases in blood cAMP, as compared to WT. Surprisingly, urine cAMP did not increase in ligand-injected PD mice, whereas it rose significantly in WT mice. A very long-acting hybrid analog, M-PTH(1-14)/PTHrP(15-36) (Shimizu ASBMR 2009), induced robust and prolonged (up to 20 h) hypercalcemic and hypophosphatemic responses in WT mice; surprisingly, however, it induced frank hypocalcemia and hyperphosphatemia in PD mice. Fluorescent confocal microscopy analysis of kidneys obtained from WT mice injected with TMR-M-PTH(1-28) revealed fluorescence localized to distinct, internalized punctae below the apical membrane of proximal tubule cells, whereas in PD mice fluorescence was localized to the apical cell surface.

The findings show that PTHR1 phosphorylation plays a critical role in mediating the acute Ca and Pi responses to PTH. They further suggest that in renal tubular cells, PTHR1 internalization, as mediated by C-terminal phosphorylation, contributes

importantly to the localization of cAMP signaling and down-stream effects on Ca and Pi transporters.

PTHrP Regulated BMP Signaling Plays A Role In The Specification Of The Mammary Mesenchyme. Minoti Hiremath^{*1}, Pamela Dann², John Wysolmerski³. ¹Boise State University, USA, ²Yale University, USA, ³Yale University School of Medicine, USA

PTHrP regulates mammary cell fate by specifying the mammary mesenchyme during embryonic mammary development. Loss of PTHrP (PTHrP^{-/-}) or its receptor (PTH1R^{-/-}) permits mammary bud cells to revert to an epidermal fate and disrupts mammary bud outgrowth. In contrast, overexpression of PTHrP in the epidermis (K14-PTHrP) induces inappropriate differentiation of the ventral epidermis into nipple-like skin. In previous studies, PTHrP-mediated upregulation of BMP1a was implicated in mammary bud outgrowth. Therefore, we hypothesized that PTHrP might regulate levels of BMP signaling in the mammary mesenchyme. We first examined BMP-signaling in the embryonic mammary mesenchyme expression using a transgenic Bre-lacZ reporter mouse. The reporter transgene consists of Smad binding elements of the Id1 gene promoter placed upstream of a lacZ reporter gene. X-gal staining of whole embryos detected Bre-lacZ expression in the mammary mesenchyme as early as day 12 and up to day 18 of embryogenesis. Reporter expression was first noted in mammary bud 2, followed by bud 3, 4, 1 and 5. Interestingly, the order of reporter expression in the mammary buds did not follow the order of mammary placode development suggesting that BMP signaling in the placodes is regulated independently of mammary epithelial specification. Expression of the reporter was restricted to the mammary mesenchyme, as demonstrated by co-localization with mammary mesenchyme markers such as androgen receptor, estrogen receptor and Lef1. Reporter expression was not detected in the mammary epithelium and did not co-localize with mammary epithelial markers such as gata3, p63 and keratin 14. These data demonstrate that BMP signaling occurs specifically in the mammary mesenchyme. To determine whether PTHrP regulates BMP signaling, we examined expression of the BMP reporter in PTHrP^{-/-} and K14-PTHrP mice. Our studies show that loss of PTHrP abolishes reporter expression and overexpression of PTHrP results in ectopic activation of BMP reporter along the flank of the embryo, demonstrating that PTHrP regulates BMP signaling. To determine the contribution of BMP signaling in mammary mesenchyme specification, we genetically deleted BMP1a using the Dermo1 promoter to drive cre recombinase expression in the mammary mesenchyme of BMP1a^{lox/lox} mice. A preliminary histological analysis of mammary buds from these mice indicated that there are fewer layers of cells in the condensed mammary mesenchyme and that expression of Tenascin-c in the mesenchyme is reduced. These preliminary analyses suggest that BMP signaling via BMP1a is required for functional differentiation of the mammary mesenchyme and for mammary bud outgrowth. Taken together, our studies suggest that PTHrP regulated BMP signaling in the mammary mesenchyme is critical for mesenchyme specification.

Silencing of PTH Receptor 1 in T Cells Blunts the Bone Anabolic Activity of Intermittent PTH Treatment. Brahmchetna Bedi¹, Jau-Yi Li^{*1}, Jonathan Adams¹, Ming-Kang Chang², Tatsuya Kobayashi³, M. Neale Weitzmann⁴, Michaela Kneissel², Henry Kronenberg³, Roberto Pacifici¹. ¹Emory University School of Medicine, USA, ²Novartis Institutes for Biomedical Research, Switzerland, ³Massachusetts General Hospital, USA, ⁴Emory University School of Medicine, Atlanta VA Medical Center, USA

T cells are required for intermittent PTH (iPTH) treatment to exert its full anabolic effect as iPTH stimulates their production of Wnt10b. This osteogenic Wnt ligand is critical for iPTH-induced activation of Wnt signaling in osteoblasts (OBs) and the resulting increase in bone formation and bone mass. However it is unknown whether direct activation of the PTH receptor PTH receptor 1 (PPR) in T cells is required for iPTH to induce Wnt10b production and bone growth. To investigate this matter we generated a strain with a silent PPR in T cells (PPRT cells -/- mice) by crossing PPR floxed (PPR fl/fl) mice with LCK-Cre mice, a strain that expresses Cre recombinase in all T cells. We found that in vivo iPTH treatment (80 µg/kg/day sub-Q) for 4 weeks increased production of Wnt10b by CD8+ T cells from control (PPRfl/fl and PPRfl/+/- Lck-Cre) but not PPRT cells -/- mice. Moreover, the effect of iPTH on stromal cell differentiation, OB proliferation, differentiation and apoptosis and expression of Wnt dependent genes in OBs was 2-3 fold lower in PPRT cells -/- mice than control mice. Prospective in vivo BMD measurements revealed that iPTH caused a smaller increase in BMD in PPRT cells -/- than in control mice (26 % in PPRfl/fl mice vs. 41 % in PPRT cells -/- mice; p<0.05). Histomorphometric analysis of femoral trabecular bone volume (BV/TV) revealed a less pronounced response to PTH in PPRT cells -/- mice than in control mice (33% in PPRT cells -/- mice vs. 234 % in PPRfl/fl mice; p<0.001). µCT measurements of BV/TV confirmed that iPTH induced a smaller increase in trabecular BV/TV in PPRT cells -/- than in control mice (69 % in PPRfl/fl mice vs. 160 % in PPRT cells -/- mice; p<0.01). Trabecular number, connectivity density, and volumetric density were more substantially improved in control mice than in PPRT

cells -/- mice. Measurements of histomorphometric (N.OB/BS and Ob.S/BS) and biochemical (serum osteocalcin) indices of bone formation demonstrated that iPTH induced bone formation was attenuated in PPRT cells -/- mice as compared to control mice. Conversely, histomorphometric and biochemical indices of bone resorption were equally increased by iPTH in all strains. Taken together, these findings demonstrate that PPR signaling in T cells plays an essential role in the anabolic activity of iPTH by promoting T cell production of Wnt10b, a factor required for iPTH to stimulate osteoblastogenesis, bone formation and bone accretion.

The Adjuvant Effects of Intermittent PTH Therapy on Massive Allograft Healing are Associated with Decreased Vasculogenesis via Differential Angiopoietin Expression and Increased Allograft Remodeling. Robinder Dhillon^{*1}, Chao Xie², Laura Calvi³, Regis O'Keefe¹, Edward Schwarz¹. ¹University of Rochester, USA, ²Center for Musculoskeletal Research, University of Rochester, USA, ³University of Rochester School of Medicine, USA

Purpose: Previous studies of PTH (teriparatide) therapy for femoral allografting in mice showed remarkable decreases in fibrosis and vascularity, with increased remodeling. Here we investigated the expression of angiogenic (VEGFs), and vasculogenic (angiopoietins) factors. We also tested if the PTH effects were initiated by osteoblasts proximal to the allograft by utilizing Col1-caPTHr transgenic mice as hosts and live isograft donors.

Methods: WT mice received a 4mm mid-diaphyseal femoral osteotomy that was replaced with an allograft, and were randomized to PTH(1-34) 40ug/kg/day) or placebo. PTH effects on gene expression (*vegfs*, *ang-1*, *ang-2*, *vegfrs*, and *tie-2*) were assessed at 7, 10, 14, 21, 28 days by QRT-PCR. PTH effects on vascularity and allograft remodeling were assessed by vascular microCT and histology. In a second study, Col1-caPTHr mice and their WT littermates received allografts or live isografts from Col1-caPTHr mice, and microCT and histology were done on days 21 and 28.

Results: Vascular microCT revealed that PTH significantly decreased allograft vascularity vs. placebo (vascular volume=0.580.10vs.1.060.19 mm³; mean vessel diameter=0.080.01vs.0.100.01 mm; p<0.05). Histomorphometry confirmed PTH-inhibition of vasculogenesis with a concomitant decrease of fibrosis. qRT-PCR results were unremarkable, except for a 8-fold increase in Ang-1, and a 70-fold decrease of Ang-2 expression on day 7. Vascular micro-CT analyses of allografts in Col1-caPTHr mice revealed a decreased vascularity vs. their WT littermates on day 21 (vascular volume 0.360.09 vs.1.010.31 mm³; vessel number 1.010.11 vs.1.260.06 mm; p<0.05). Similar significant differences were also seen at 28 days. Histomorphometry confirmed the dramatic differences in vascularity between WT and Col1-caPTHr mice. It also revealed significant PTH-induced allograft resorption, with a concomitant significant increase in osteoclasts number/graft area (9.095.49vs.5.533.08; p<0.05) and resorption surface vs. allografts in WT mice. Interestingly, allografts in Col1-caPTHr mice were completely resorbed by day 42.

Conclusions: In addition to its known anabolic effects, here we demonstrate that PTH therapy augments allograft healing by decreasing vasculogenesis via differential Ang-1 vs. Ang-2 expression. It also silences the host immune/fibrotic response that inhibits osseous integration, which allows for necrotic graft remodeling into live cortical bone with marrow.

Increased Angiopoietin 1 and suppressed Angiopoietin 2 expression observed on day 7 with PTH treatment

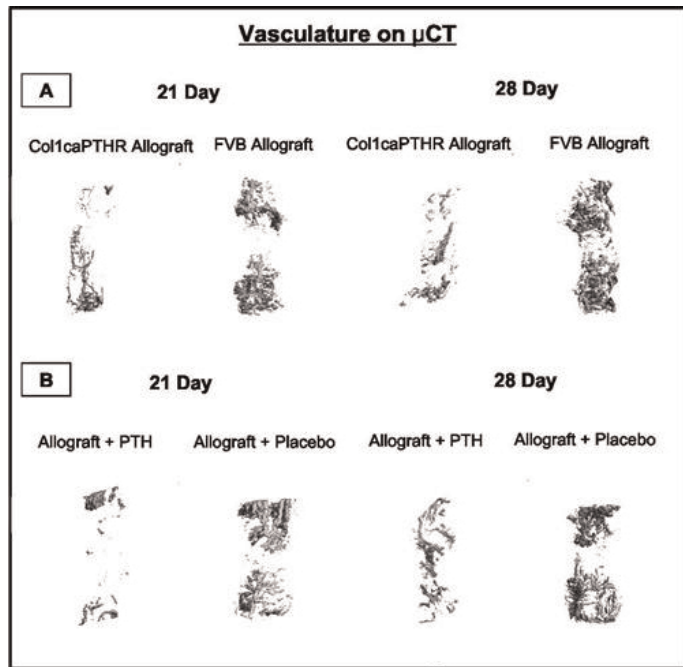

Figure 1: Decreased vasculogenesis in allografts from Col1-caPTHR mice and WT mice treated with PTH. Col1-caPTHR mice and WT littermates (A), or WT mice treated with PTH or placebo (B), received femoral allografts and were euthanized via vascular perfusion with Microfil on the indicated day (n=5). The grafted femurs were harvested for demineralized micro-CT, and representative 3D reconstructed images of the perfused vasculature are shown.

MicroCT Images

Table 1. Histomorphometry of allografts into a Col1CAPTHR and WT host mice at 21 days of healing

Parameters	Col1CaPTHR Allograft	WT Allograft
Total region of interest area (mm ²)	5.362±0.75	6.80±0.89
Host bone area (mm ²)	2.41±0.68	2.11±1.07
Graft bone area (mm ²)	0.53±0.20*	0.78±0.08
Osteoclast number/graft area (/mm ²)	9.09±5.49*	5.53±3.08
Osteoclast surface/graft surface (%)	36.37±21.97*	22.13±12.31

Values are Mean ± SD (n=5) for each group. *p<0.05 vs. WT Allograft.
ROI is 2mm of graft + 1mm of host at both proximal and distal graft host junctions.

The Transcriptional Co-Activator CITED1 is Required for Normal Bone Volume and for the Full Anabolic Response to PTH *In Vivo*. Hila Bahar¹, Jun Guo², Hiroaki Saito³, Rajaram Manoharan⁴, Dehong Yang², Toshi Shioda², Mary Boussein⁴, Roland Baron⁵, F. Richard Bringham². ¹MGH & HMS, USA, ²Massachusetts General Hospital, USA, ³Harvard School of Dental Medicine, USA, ⁴Beth Israel Deaconess Medical Center, USA, ⁵Harvard School of Medicine & of Dental Medicine, USA

CITED1, a transcriptional co-activator, interacts directly with CBP/p300 and is capable of enhancing TGF-beta and estrogen-dependent transcription and inhibiting beta-catenin-dependent transcription. CITED1 mRNA expression is rapidly and transiently upregulated by PTH in cultured osteoblasts (Obs) in a manner dependent on cAMP signaling. Also, the cAMP-mediated Obs-differentiating effect of intermittent PTH in vitro is selectively suppressed by CITED1. To define the role of CITED1 in bone and in the anabolic actions of PTH in vivo, bones of 8-week old CITED1 global knockout (KO) and wild type (WT) C57BL/6 mice were analyzed using microCT, DXA, and histomorphometry (n=6) before and after daily (5d/week) sc injections of vehicle (VEH) or 80 ug/kg hPTH(1-34) (PTH) for 4 weeks. Baseline DXA analysis at 8 weeks revealed mild osteopenia in KO mice, mainly in the trabecular (Tb) bone. MicroCT analysis showed a significantly lower (7%) Tb bone volume (BV) in KO vertebra and no difference in the distal femur and cortical bone compared to WT. Histomorphometric analysis of femurs showed a significant decrease in BV (30%), BFR (30%), Ob number (54%) and osteoclast (Oc) number (40%) but no change in MAR or O.Th, suggesting that deletion of CITED1 reduced BV by limiting the number of active Obs and decreasing bone formation in the context of a low bone-turnover state. Four weeks of PTH treatment significantly augmented Tb BV at the distal femur (100%-KO, 150%-WT) and cortical thickness (6%-KO, 17%-WT), as measured by microCT, but the overall effect was attenuated in KO. No differences were seen by microCT between WT and KO treated with VEH, and BMD of the total body and femur were similar in VEH-treated KO vs WT as well. PTH significantly increased BMD in both KO (8%-total body, 20%-distal femur) and WT (9%, 40% respectively) but the increase was significantly impaired in KO. Histomorphometry showed similar responses to PTH in KO and WT for all parameters apart from a significantly lower increase in BV in KO (210%) vs WT (315%) and higher Oc number in KO (143%) vs WT (34%), suggesting selective

enhancement of the osteoclastic component of the increased bone turnover in response to intermittent PTH. Serum Ca, Pi and creatinine were normal in all treated mice. These results suggest a possible role of CITED1 in regulating the number of active Ob, the extent of bone formation, and the balance of osteoclastic vs osteoblastic responses induced by intermittent PTH treatment.

Chronic Stress Increases Breast Cancer Metastasis to Bone via α 2AR on Osteoblasts. Florent Elefteriou¹, J. Campbell^{*2}, Julie Sterling³, Xiangli Yang¹. ¹Vanderbilt University, USA, ²Vanderbilt Center for Bone Biology, USA, ³Vanderbilt University Medical Center, USA

Increased sympathetic nervous (SNS) outflow, a hallmark of mental stress, controls multiple processes in the bone, such as hematopoietic stem cell trafficking, osteoblast proliferation, osteoclastogenesis, and inflammation via β 2-adrenergic receptors (β 2AR) and cytokines also involved in cancer metastasis, such as SDF-1, RANKL, and IL-6. These observations suggest the involvement of SNS activation in cancer osteotropism, tumor burden, and the formation of osteolytic lesions, which may underlie the increased mortality and recurrence observed clinically with prolonged psychosocial stress. To address this hypothesis, we used an established model of osteolytic metastasis in which MDA-MB-231 human breast cancer cells are injected via left cardiac ventricle into athymic nude. The effects of chronic stress, simulated with restraint stress, were compared to Isoproterenol (ISO), a β AR agonist acting independently of the hypothalamic-pituitary-adrenal axis (HPA). Osteolytic lesions, tumor burden and BV/TV were assessed with Faxitron, 3D-microtomography, and histology. Both chronic stress and ISO treatment before MDA-MB-231 inoculation increased the number of bone lytic lesions ($p < 0.05$), while treatment after bone metastasis increased the size of the lytic lesions ($p < 0.05$). Furthermore, the effects of restraint stress were rescued by treatment with a commonly prescribed β -blocker, propranolol, suggesting that chronic stress alters the bone microenvironment (BMM) through the β 2AR to make it favorable for cancer cell bone colonization and growth. *In vitro*, direct stimulation of the β 2AR in MDA-MB-231 cells produced no effect on migration, cell growth or PTHrP, Rank and CXCR4 expression. In contrast, stimulation of the β 2AR in bone marrow stromal cells, calvarial and MC3T3 osteoblasts increased Rankl but not Sdf1 expression ($p > 0.005$). The conditioned media of ISO-treated osteoblasts increased MDA-MB-231 migration ($p < 0.005$), which could be blocked by OPG but not by the CXCR4 antagonist AMD3100. These results suggest that the increase in osteolysis and metastasis observed following SNS activation *in vivo* are due predominantly to a bone stromal effect. These findings support the hypothesis that depression, via sympathetic activation, makes the BMM permissive to cancer metastasis, growth, or recurrence, and imply that β -blockers may reduce both bone tumor burden and relapse in breast cancer patients.

Genome-Wide Reciprocal Modulation of Runx2 and Estrogen Signaling in Breast Cancer Cells: Identification of a Clinically Prognostic Cell Cycle-Related Gene Cluster. Nyam-Orsor Chimgé^{*1}, Sanjeev Baniwal¹, Jingqin Luo², Simon Coetzee¹, Ben Berman¹, Debu Tripathy¹, Ellis Matthew², Baruch Frenkel¹. ¹University of Southern California, USA, ²Washington University in St. Louis, USA

The mitogenic effect of estrogens in breast epithelial cells is one of the best examples of hormonal carcinogenesis. Both estradiol (E2) and Runx2 play paradoxical roles in cancer where they can function as either dominant oncogenes or tumor suppressors. The mechanisms underlying these contrasting manifestations in cancer are not fully understood. In this study we developed a novel experimental approach that allowed us to study the complex interaction between Runx2 and E2 signaling genome-wide. MCF7/Runx2dox breast cancer (BCa) cells engineered to express Runx2 in response to doxycycline (dox) were treated with dox, E2, or both. Soft agar growth assays confirmed the reciprocal effects of E2 and Runx2 on cell proliferation. Microarray analysis of cells under the four conditions revealed that E2 globally attenuated Runx2 activity and visa versa. A substantial portion of Runx2 regulated genes was independently regulated by E2. These "common" genes were comprised of four clusters; those downregulated by both Runx2 and E2 (Cluster I), those upregulated by both (Cluster III), and those with opposite responses to Runx2 and E2 (Clusters II and IV). Cluster IV upregulated by E2 and inhibited by Runx2, was significantly enriched in cell cycle regulated genes. Given the oncogenic and tumor suppressor properties of E2 and Runx2, we speculated that genes in Cluster IV may represent a critical hybrid growth regulatory circuit mediating the oncogenic property of E2 and the tumor suppressor function of Runx2 in BCa. We therefore investigated how the status of Runx2 and E2 interactions could inform BCa treatment strategies. Estrogen deprivation by letrozole treatment in BCa patients increased overall Runx2 activity. Four weeks of letrozole treatment led to a dramatic decrease of Cluster IV metagene, indicating that absence of E2 abolished not only its stimulating effect on expression of Cluster IV genes but also inhibitory effect of E2 on Runx2 activity that strongly suppressed these genes. Remarkably, higher expression change of the Cluster IV metagene in response to letrozole was significantly associated with higher Ki67 staining at surgery, and was much stronger than that for any of 1,000

randomly selected sets of E2 stimulated genes. In summary, genes co-regulated by E2 and Runx2 may provide a powerful prognostic tool and may guide the development of novel therapeutic approaches that take into consideration the interaction between E2 and Runx2 signaling in BCa.

Identification of Runx2 Responsive Genes Counter-regulated by Estrogen: SNAI2 as a Mediator of Runx2-induced Invasiveness. Nyam-Orsor Chimgé^{*}, Sanjeev Baniwal, Yunfan Shi, Baruch Frenkel. University of Southern California, USA

Runx2 and estrogens play crucial roles in both bone metabolism and carcinogenesis. To decipher genes mediating the pro-metastatic properties of Runx2 we engineered the MCF7/Runx2^{dox} subline, which expresses Runx2 in response to doxycycline (dox). Runx2 expression in MCF7/Runx2^{dox} cells increased cell invasiveness and induced epithelial-mesenchymal transformation (EMT) evidenced by morphological changes as well as decrease of CDH1 and increase of VIM expressions. E2 attenuated the pro-invasive properties of Runx2. Genome-wide study of dox- and E2-responsive genes in MCF7 cells revealed a group of 530 genes independently regulated by both stimuli, and hierarchical clustering of these genes revealed four distinct clusters (I-IV). We speculated that Cluster II, upregulated by Runx2 and downregulated by E2, plays a role in the pro-cancerous properties of Runx2 and the favorable effect of E2 on BCa. Indeed, shRNA-mediated knockdown of SNAI2, the most responsive gene in Cluster II, abrogated Runx2-driven EMT and invasiveness. Bioinformatic analysis of a cohort of 557 BCa patients revealed that Cluster II metagene and SNAI2 were strongly associated with poor metastasis-free survival. Further analysis of the same dataset showed positive association between Runx2 activity and SNAI2, and negative correlation between estrogen receptor and SNAI2 expression. Kaplan-Meier curves of ER-positive patients showed increased metastasis-free survival by Cluster II and SNAI2 as compared to ER-negative patients; this beneficial effect of ER α was more prominent in the first 40 months. Survival probability of breast tumors that metastasized to different sites revealed that SNAI2 dramatically reduced metastasis-free survival of patients with bone, but to a lesser extent those with lung and brain metastases. These data support the view that SNAI2 is associated with more aggressive type of cancer and suggest that it may be responsible for priming breast tumors for metastasis to bone. Hierarchical clustering of 58 metastatic tissues revealed that SNAI2 was among the list of 11 genes upregulated only in bone metastasis. In summary we identified a cluster of genes, which likely contribute to the pro-metastatic property of Runx2 and its counteraction by E2 signaling. We show that SNAI2 plays a crucial role in mediating the pro-invasive and anti-tumorigenic properties of Runx2 and E2, respectively, in BCa, and provide evidence supporting a specific role for SNAI2 in bone metastasis.

Interleukin 6 Modulates Tumor Behavior in Bone via a RANKL Dependent Pathway. Yu Zheng^{*1}, Katja Boerner², Anastasia Mikusheva³, Dennis Basel⁴, Robert L Sutherland⁵, Frank Buttgeriet³, Colin Dunstan⁶, Dr. Hong Zhou⁷, Markus Seibel⁷. ¹Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, ²Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ³Department of Rheumatology & Clinical Immunology, Charite University Medicine (CCM), Germany, ⁴ANZAC Research Institute, the University of Sydney, Australia, ⁵Cancer Research Program, Garvan Institute of Medical Research, Australia, ⁶University of Sydney, Australia, ⁷Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia

High levels of circulating interleukin-6 (IL-6) in patients with metastatic breast cancer are associated with poor outcomes. In this study, we investigated the effect of tumor-derived IL-6 *in vitro*, and *in vivo* on MDA-MB-231 breast cancer cells using a xenograft model of skeletal metastasis.

In vitro studies with MDA-MB-231 cells demonstrated that RANKL up-regulates IL-6 expression by the cancer cells, while treatment with IL-6 significantly up-regulates their RANK expression. These results indicate that tumor-derived IL-6 may drive a positive forward-loop sensitizing the tumor cells to RANKL.

To further define the role of tumor-derived IL-6 on tumor growth in bone, we knocked down (by 80%) IL-6 expression in MDA-MB-231 cells via lentiviral-transduced stable shRNA expression (MDA-KD). Non-target (NT) cells served as controls. Silencing IL-6 expression significantly reduced tumor cell invasiveness but not proliferation *in vitro*. NT and MDA-KD cells were implanted intra-tibially into 4-week-old BALB/c nu/nu female mice kept on a low (0.1%) calcium diet to induce high bone turnover. Compared to NT cells, MDA-KD cells developed significantly smaller osteolytic lesions on day 10, 17 and 21 ($p < 0.05$, by X-ray analysis), and tumor area at endpoint (day 21; by histomorphometry) (3.20 0.76 vs. 5.57 0.98 mm², $p < 0.05$). When NT or MDA-KD cells were implanted into the mammary fat pad of nude mice, tumor growth was similar, indicating that the effects of tumor-derived IL-6 are mediated through the bone microenvironment.

In further experiments, IL-6 receptor (IL-6R) signalling was disrupted by treating mice implanted intra-tibially with MDA-MB-231 cells with the anti-human IL-6R antibody, Tocilizumab (Tmab). Compared to controls, Tmab at 50 mg/kg s.c every 3 days reduced the number and size of osteolytic lesions (1.530.24 vs. 1.980.23mm², $p<0.05$), and tumor area (2.170.27 vs. 5.620.67 mm², $p<0.01$). Mitotic activity decreased by 60% while apoptosis increased by 70%.

In conclusion, our results identify a new 'vicious cycle' in bone in which RANKL induces cancer cell IL-6 and subsequent RANK expression leading to enhanced tumor growth. Targeting IL-6 activity is a potential treatment strategy in breast cancer bone metastasis.

PMEPA1, a Negative Regulator of Transforming Growth Factor- β (TGF β) Signaling Pathway, Inhibits Bone Metastases from Prostate Cancer in Mice. Pierrick Fournier^{*1}, Gregory Clines², John Chirgwin¹, Theresa Guise¹. ¹Indiana University, USA, ²University of Alabama at Birmingham, USA

Most patients with advanced prostate cancer (>70%) develop metastases to bone, a rich source of TGF β that promotes bone metastases from breast cancer and melanoma. In this study, we investigated the role of TGF β signaling in prostate cancer bone metastases in mice.

A small molecule inhibitor of TGF β type 1 receptor, SD208, decreased osteolytic lesions (-56% vs vehicle, $P<0.05$) caused by PC-3 prostate cancer cells inoculated in the left cardiac ventricle of mice and increased their survival (57 vs 69 days median survival, $P<0.05$). To identify TGF β -regulated genes in prostate cancer, we analyzed PC3 cells TGF β (5ng/mL, 48h) by Affymetrix gene array and qRT-PCR. Upregulated genes included PTHrP, IL-11, CTGF and ADAM19, which increase bone resorption and MMP13 and TSP1, two TGF β activators. The most increased gene was PMEPA1 (23x, $P<0.03$). Alternate splicing gives rise to membrane-bound and cytosolic isoforms of PMEPA1 both increased by TGF β in prostate (PC3, DU145), breast (MDA-MB-231) and lung (A549) cancer cells.

Overexpression of membrane-bound PMEPA1 decreased TGF β signaling in dual-luciferase experiments. Mutation of the 2 PPxY domains that allow PMEPA1 to interact with Smurf ubiquitin ligases (regulators of Smad degradation) or the Smad Interaction Motif (SIM) that allows interaction with Smad2/3 prevented TGF β inhibition. In coimmunoprecipitation experiments, the interaction Smad2-Smurf2 was increased by PMEPA1, suggesting a role of scaffold protein. Interestingly, cytosolic PMEPA1 despite the presence of a SIM did not interact with Smad2/3 nor inhibit TGF β signaling. Knockdown of PMEPA1 (all isoforms) using siRNA increased Smad2 phosphorylation and the *IL-11*, *MMP13* and *ADAM19* mRNA induced by TGF β in PC3 cells.

The role of PMEPA1 in bone metastases was tested by stably transfecting PC3 cells to express shRNA control or anti-PMEPA1 (>90% decrease of mRNA or protein vs shRNA control) and two clones of each were inoculated in the left cardiac ventricle of mice to cause bone metastases. PMEPA1 knockdown in PC3 significantly increased osteolysis area on x-ray, compared to mice that received shCtrl cells consistent with an increased TGF β signaling.

Our results show that TGF β promotes the expression of pro-osteolytic genes in PC3 cells and of PMEPA1 that controls a negative feedback loop of TGF β signaling. Loss of PMEPA1 increases bone metastases in mice, consistent with reported decreases of PMEPA1 in prostate cancer with increasing tumor grade.

The Development of Bone Metastatic Lesions Is Modified By Circulating Fibronectin. Anja von Au, Matthaeus Vassel, Inaam Nakchbandi*. Max-Planck Institute for Biochemistry & University of Heidelberg, Germany

Fibronectin is required for new blood vessel formation. The tip cell of the newly forming blood vessel establishes a path that other endothelial cells will take and that is lined by fibronectin. The presence of fibronectin is one of the cues required by the endothelial cells to establish a blood vessel. The source of this local fibronectin and the role of circulating fibronectin during new blood vessel formation in tumors remain elusive however.

To examine this issue we used transgenic mice in which only circulating fibronectin was deleted. Using mice carrying the albumin promoter attached to cre that are at the same time homozygote for the floxed fibronectin gene we deleted fibronectin in the hepatocytes, the main source of circulating fibronectin and confirmed deletion of circulating fibronectin by almost 90% in conditional knockout mice (CT: 18526 vs. cKO: 195 mg/l, $n=8$ and 7; $p<0.001$). We then injected tumor cells (MDA-MB-231/luc+) in the tibia and followed their growth using bioluminescence. Deletion of fibronectin in the circulation resulted in a significant delay in tumor growth (Day 40: CT: 204 vs. cKO: 52 $\times 10^7$ RLU, $n=16$ and 10; $p<0.01$). This was associated with a significant decrease in osteolysis as determined by x-ray examination of the bones (Lytic surface: CT: 10.40.3 vs. cKO: 7.20.8 mm², $n=10$ and 5; $p<0.001$).

In order to determine whether this decrease in growth was due to decreased new blood vessel formation, tissue sections were stained for CD31 (PECAM-1) which stains blood vessels. There was a significant decrease in the number of blood vessels in

the tumors originating from mice lacking circulating fibronectin when compared to control mice (CT: 14811 vs. cKO: 795 blood vessels/mm², $n=8$ and 3; $p<0.01$). This was associated with a decrease in proliferation of tumor cells as detected by staining with anti-BrdU antibodies (CT: 65343 vs. cKO: 45213 cells/mm², $n=4$ and 3; $p<0.05$), without an increase in apoptosis examined by staining active caspase 3 (CT: 281 vs. cKO: 277 cells/mm², $n=7$ and 3; $p=ns$).

In summary, deletion of circulating fibronectin results in a significant decrease in tumor growth due to decreased blood vessel formation and decreased tumor cell proliferation. Thus, circulating fibronectin supports new blood vessel formation in tumors.

The Impact of Macrophage Depletion on Bone Homeostasis and Prostate Tumor Growth. Fabiana Soki^{*1}, Sun Wook Cho¹, Amy Koh², Serk In Park², Laurie McCauley³. ¹University of Michigan School of dentistry, USA, ²University of Michigan, USA, ³University of Michigan, School of Dentistry, USA

Bone contains a population of resident macrophages termed osteomacs, which play a role in bone remodeling, repair and hematopoietic stem cell niche maintenance. Macrophages are recruited to tumors where they contribute to growth, progression and metastasis in different types of cancer. The link between macrophages residing in different compartments and their functions under various environmental stimuli remain elusive. The role of macrophages in bone and tumor growth was investigated using the macrophage fas-induced apoptosis (MAFIA) mouse model. Administration of a synthetic dimerizer (AP20187) activates a suicide gene downstream of the c-fms promoter, leading to Fas-mediated apoptosis of myeloid cells. AP20187 (AP, 10mg/kg) or vehicle was administered to 16 week female MAFIA mice for 3 consecutive days for initial macrophage ablation and every third day (1mg/kg) for up to 4wks. Macrophage depletion treatment resulted in splenomegaly and a 20% reduction of total bodyweight. Bone marrow flow cytometric analysis (FACS) revealed a 22% reduction of macrophages (c-fms+CD11b+F4/80+) in AP-treated mice vs. vehicle. Serum TRAP was significantly decreased (50%) after 3d of AP injection and tended to remain suppressed for 4 weeks. Bone histomorphometric analysis revealed an osteopenic phenotype with loss of bone marrow adipocytes in macrophage depleted mice. To analyze the role of macrophages in prostate cancer tumor growth, 16wk male MAFIA mice were injected with AP or vehicle for 3d (10mg/kg) and every third day (5mg/kg) for 2wks. RM-1 (mouse prostate cancer) cells were seeded subcutaneously in MAFIA mice either by injection with Matrigel or co-implanted in single vertebral bodies dissected from 7 day old C57BL/6 mice (vossicles). Macrophage (CD11b+F4/80+) numbers in Matrigel RM-1 tumors were significantly decreased in AP treated mice. FACS confirmed an 80% macrophage suppression with an increase in CD11b+ Gr1+ myeloid derived suppressor cells (MDSCs) in the bone marrow of macrophage ablated mice. RM-1 cell tumors in matrigel or vossicles showed a trend of being smaller in macrophage depleted mice. In conclusion, macrophage depletion for 4wks altered the bone phenotype and bone marrow populations. Macrophage recruitment to tumors was reduced in macrophage ablated mice and tumors were marginally smaller. These findings demonstrate the importance of macrophages in normal bone remodeling and suggest a role for macrophages in the tumor microenvironment.

Host-derived Prostaglandin E Regulates Bone Metastases of Malignant Melanoma through Angiogenesis. Morichika Takita, Satoshi Yokoyama, Masaki Inada*, Chisato Miyaura. Tokyo University of Agriculture & Technology, Japan

Metastasized tumor is frequently accompanied by neo-vascularization in various organs. In tumor metastasis, the growth is closely related to its surrounding angiogenesis. We reported that sequential pathway of osteoblastic prostaglandin E (PGE) biosynthesis in bone, which is mediated by an inducible PGE synthase, membrane-bound PGE synthase-1 (mPGES-1). In bone tumor of malignant melanoma (B16), host-osteoblasts induced PGE production and RANKL expression in autocrine and/or paracrine manner via PGE receptor subtype EP4. The treatment of EP4 antagonist clearly suppressed bone destruction by inhibiting osteoclastogenesis. In the present study, we investigated the roles of PGE on neo-vascularization which associated with tumor metastasis, using mPGES-1-null mice (mPGES-/-). When B16 cells were injected intravenously into wild-type mice (WT), numerous metastasized loci were found in various tissues including bone, lung, liver, and kidney. In mPGES-/-, however, the number of metastasized loci was markedly suppressed at all. In the laser imaging for *in vivo* detection of neo-vascularization, a red fluorescent labeled polyethyleneglycol particle was used to detect angiogenesis, since the particle was able to incorporate specifically into growing endothelial cells. In WT, the fluorescent signals of neo-vascularization were strongly detected in B16 metastasized foci, but not in mPGES-/- . In the experiments of subcutaneous injection of B16 cells to WT and mPGES-/-, the neo-vascularization was only found in WT. To further elucidate the roles of host-stromal cell derived PGE2 in neo-vascularization for tumor, skin stromal cells from WT and mPGES-/- were co-cultured with fixed-B16

cells. In the co-cultures, stromal cells from WT, but not from mPGES^{-/-}, markedly produced PGE after cell-to-cell interaction with B16 cells. WT derived stromal cells produced vascular endothelial cell growth factor (VEGF)-A and basic fibroblast growth factor (bFGF), and the production of both factors was increased by the treatment with PGE. On the other hand, VEGF-A and bFGF production was dramatically decreased in mPGES^{-/-} derived stromal cells. These results suggest that PGE produced by host-stromal cells including osteoblasts elicits the induction of angiogenic factors such as VEGF-A and bFGF. PGE may control the circumstance of tumor associated with angiogenesis, and modulate the growth of metastasized tumor cells.

IAP antagonist BV6 Increases Bone Metastasis via NIK-Mediated Osteoclast Activation. Chang Yang^{*1}, Jennifer Davis², Kathleen McCoy¹, Roberta Faccio¹, Deborah Novack³. ¹Washington University in St Louis School of Medicine, USA, ²Washington University in St. Louis, USA, ³Washington University in St. Louis School of Medicine, USA

IAPs (inhibitor of apoptosis proteins) have been associated with cancer and resistance to chemotherapies, and IAP antagonists are currently in development as anti-cancer agents. Additionally, IAP antagonists activate alternative NF- κ B by stabilizing NIK. We have previously shown that constitutive NIK activation increases osteoclast activity and causes osteoporosis. Thus, we proposed that IAP antagonists might also cause bone loss. In mice treated weekly with IAP antagonist BV6 for 4 weeks, beginning at 6 weeks of age, bone mass (BV/TV) was decreased by 35%. Indices of both osteoclast and osteoblast activity were significantly increased (serum CTX 49%, Oc.S/BS 43%, serum osteocalcin 47%, BFR 59%; all $p < 0.05$), indicating an osteoporosis associated with high bone turnover. To understand the mechanism of BV6 activity in bone, we treated NIK-deficient mice with BV6 and found them to be completely resistant to bone loss. In vitro, BV6 increased NIK and RelB activation alone and in combination with RANKL, and enhanced RANKL-mediated osteoclastogenesis in control, but not NIK^{-/-} cultures. Since high bone turnover can provide a favorable microenvironment for tumor growth, we examined whether BV6 can alter tumor growth in bone separate from its anti-tumor effects. We utilized the 4T1 mouse breast cancer line, which is resistant to BV6-induced apoptosis, and injected 4T1-Fluc directly into the tibia or left cardiac ventricle between the 3rd and 4th BV6 doses. Consistent with its pro-resorptive effects, BV6 increased tumor growth in bone by 5.5-fold (intratibial) and 3.2-fold (intracardiac) on day 10 after tumor inoculation (both $p < 0.01$). There was no significant difference in visceral tumors between BV6 and vehicle treated mice in the cardiac injection model, indicating that the tumor-enhancing effects of BV6 are specific to bone. To examine if bisphosphonates can block the tumor enhancing effect of BV6, we gave zoledronic acid (ZA) and BV6 in both intra-tibial and intra-cardiac injection tumor models. ZA decreased tumor mass in bone to the levels found in mice receiving only vehicle in both models. In summary, although BV6 may possess anti-tumor activity, its direct effects on osteoclasts cause osteoporosis and enhance growth of drug-resistant tumors in bone by activating NIK. Increased bone metastasis can be blocked by osteoclast-targeting therapies such as bisphosphonates, preserving BV6 as a potential therapeutic agent for tumors that may spread to bone.

Oncologic Doses of Zoledronic Acid Induce ONJ-Like Lesions in Rice Rats (*Oryzomys palustris*) with Periodontitis. J. Aguirre^{*1}, Mohammed Akhter², Jennfer Pingel³, Xuechun Xia³, Aly Williams³, Marda Jorgensen⁴, Kent Edmonds⁵, Mercy Rivera⁶, Lakshmya Kesavalu⁶, Thomas Wronski¹. ¹University of Florida, USA, ²Creighton University Osteoporosis Research Center, USA, ³Department of Physiological Sciences, University of Florida, USA, ⁴Cell & Tissue Analysis Core, McKnight Brain Institute, University of Florida, USA, ⁵Department of Biology, Indiana University Southeast, USA, ⁶Department of Periodontology & Oral Biology, College of Dentistry, University of Florida, USA

Though osteonecrosis of the jaw (ONJ) is temporally associated with the use of nitrogen-containing bisphosphonates (BPs), no cause/effect relationship has been established. We hypothesize that ONJ is a two-stage process: a) risk factors initiate pathologic processes in the oral cavity that lead to a supranormal rate of hard tissue necrosis, and b) powerful anti-resorptives (e.g. N-BPs) reduce the rate of removal of necrotic bone sufficiently to allow its net accumulation in the jaw. To begin testing this hypothesis, we used the rice rat that appears to be an animal model of periodontitis. At age 28 days, rats (n=15/group; 10 males and 5 females) were placed on a pelleted high sucrose and casein diet to exacerbate the development of periodontitis. Animals were injected SC biweekly with alendronate (ALN, 0 or 15 μ g/kg), or IV once monthly with 0, 8 or 80 μ g/kg of zoledronic acid (ZOL) and sacrificed after 6, 12, and 18 wks. Mandibles and maxillae were analyzed to determine the effects on: a) progression of periodontitis, b) integrity of alveolar bone, and c) status of bone resorption and formation by using morphometric, histologic, histomorphometric, and microCT analyses. We found that rats treated with 80 μ g/kg of ZOL (oncogenic

dose) had higher incidence and severity of periodontal lesions after 18 wks of treatment than other groups, particularly in females. Histologic lesions included gingival epithelial hyperplasia, inflammatory cell infiltration, and areas of exposed alveolar bone with empty osteocyte lacunae and/or osteolysis. In males, ALN and ZOL had no effect on horizontal and vertical bone loss. In females, 80 μ g/kg of ZOL ameliorated vertical bone loss at 6 and 12 but not at 18 wks. Also, 80 μ g/kg of ZOL increased bone volume and BMD at the interdental alveolar bone at 6 and 12 but not at 18 wks. Remarkably, 80 μ g/kg of ZOL increased the area of interdental alveolar bone devoid of basic fuchsin stain (necrotic bone) only at 18 wks. All doses of ALN and ZOL decreased mineralizing surface and bone formation rate at 6, 12 and 18 wks, but reduced eroded surface and osteoclast number only at 6 and/or 12 wks. These data indicate that 80 μ g/kg of ZOL decreased bone remodeling before the appearance of increased amount of hyperdense interdental alveolar bone in the jaw. This is followed by exacerbation of the inflammatory response at the periodontium, exposed necrotic alveolar bone and/or osteolysis. These features resemble those observed in patients with ONJ.

FR0157

A Novel Mouse Model of Tibial Pseudarthrosis Featuring Localized Double Inactivation of the *Nf1* Gene. Aaron Schindeler^{*1}, Jad El-Hoss², Kate Sullivan¹, Tegan Cheng¹, Kathy Mikulec¹, Lauren Peacock¹, Paul Baldock³, Ian Alexander⁴, David Little¹. ¹The Children's Hospital at Westmead, Australia, ²University of Sydney, Australia, ³Garvan Institute of Medical Research, Australia, ⁴Children's Medical Research Institute, Australia

Congenital tibial dysplasia (CTD) is a severe orthopaedic condition, recalcitrant to standard surgical intervention. A majority of clinical cases are observed in children with Neurofibromatosis type 1 (NF1) and it has been previously reported that osseous lesions in CTD exhibit local double-inactivation of NF1 (Stevenson et al. Am J Hum Genet. 79:143-8, 2006). We have developed a mouse model that recapitulates the localized double inactivation of NF1 in cultured osteoprogenitors and in open and closed tibial fractures. *Nf1*^{flx/flx}, *Nf1*^{flx/-}, and wild type control mice had either closed fractures or open osteotomies (with periosteal stripping) performed. *Nf1*^{flx} alleles were deleted via delivery of a Cre expressing adenovirus (AdCre) injected into the fracture site at day zero. Recombination was also confirmed in ZAP reporter mice. In closed fractures, bridging was 100% in control fractures and <40% in *Nf1*^{flx} fractures ($P < 0.05$). In open fractures, bridging was 75% in control fractures and <30% in *Nf1*^{flx} fractures ($P < 0.05$). In both open and closed fracture repair models the *Nf1*^{flx} state was associated with a significant increase of up to 15-fold more fibrotic tissue invading the callus by week 3. TRAP+ cells were observed histologically in the *Nf1*^{flx} fibrotic tissue. Closed *Nf1*^{flx} fractures also showed a significant increase in proliferating BRDU labelled cells in the callus. No statistically significant differences were seen with between *Nf1*^{flx/flx} and *Nf1*^{flx/-} mice suggesting that a heterozygous background is not critical for impaired healing in this model. *In vitro* experiments demonstrated that cultured *Nf1*^{flx} calvarial pre-osteoblasts were impaired in their capacity to differentiate into osteoblasts. However, when *Nf1* was deleted later in mature osteoblasts, their capacity for mineralization was unaffected. Similar findings were found in cultured *Nf1*^{flx} primary myoblasts from a novel transgenic mouse model. In summary, we report that knocking-out *Nf1* locally in a fracture callus is sufficient to induce poor rates of bridging and can lead fibrous non-unions. This fibrous tissue contains several characteristics of a NF1 pseudarthrosis, including osteoclast-like cells surrounded by proliferative fibrous tissue. This model provides valuable insight into the pathobiology of the disease, and will be helpful for trialling new therapeutic compounds.

Patients with Turner Syndrome and Isolated *SHOX* Deficiency Have Similar Bone Geometry At the Radius. ONDREJ SOUCEK^{*1}, Jan Lebl², Jirina Zapletalova³, Dana Novotna⁴, Ivana Plasilova⁵, Stanislava Kolouskova², Dana Zemkova², Miloslav Rocek⁶, Katerina Hirschfeldova⁷, Zdenek Sumnik². ¹2nd Faculty of Medicine, Charles University, Prague, Czech Republic, ²Department of Pediatrics, Charles University, 2nd Faculty of Medicine, University Hospital Motol, Czech Republic, ³Department of Pediatrics, Palacky University, Faculty of Medicine, University Hospital Olomouc, Czech Republic, ⁴Department of Pediatrics, Masaryk University, Faculty of Medicine, University Hospital Brno, Czech Republic, ⁵Department of Pediatrics, Charles University, Faculty of Medicine, University Hospital Hradec Kralove, Czech Republic, ⁶Department of Radiology, Charles University, 2nd Faculty of Medicine, University Hospital Motol, Czech Republic, ⁷Institute of Biology & Department of Medical Genetics, Charles University, 1st Faculty of Medicine, General University Hospital, Czech Republic

Purpose

Girls with Turner syndrome (TS) have altered bone density and geometry at the radius, which may pose an increased fracture risk in adulthood. The etiology of their low bone strength remains unknown, despite assumptions have been made on the influence of hypogonadism and the haploinsufficiency of the X chromosome. Since short stature homeobox (*SHOX*) gene plays a major role in long bone growth and patients with *SHOX* deficiency share some skeletal features with TS, *SHOX* gene has been suggested as a causal one. We aimed to assess bone geometry and volumetric bone density in patients with isolated *SHOX* deficiency and to compare their results to girls with TS.

Methods

Fourteen patients with *SHOX* deficiency (median age 11.8 yrs, range 6.0-36.8, 10 children and 4 adults) were examined by peripheral quantitative CT (pQCT) at the non-dominant forearm. Results were expressed as Z-scores using published reference data and then compared to the results of 67 girls with TS (median age 13.7 yrs, range 6.0-19.4). The differences from reference data were tested by one-sample T test and differences between TS and *SHOX* deficiency were tested by two-sample T test.

Results

Trabecular volumetric bone mineral density (vBMD) was decreased in TS (mean Z-score -0.71.3, $p < 0.001$) but normal in isolated *SHOX* deficiency (Z-score 0.31.3, n.s., group difference $p < 0.01$). Cortical vBMD was low in both groups (Z-score -1.61.5, $p < 0.001$ and -1.92.3, $p < 0.01$, respectively) without significant group difference. Both groups had increased total bone cross-sectional area (CSA) at the diaphysis (Z-score 0.71.7, $p < 0.01$ and 2.31.5, $p < 0.001$, respectively), but normal cortical bone CSA (Z-score 0.01.0, n.s. and -0.72.3, n.s., respectively). Consequently, cortical thickness was decreased in both groups (Z-score -0.80.6, $p < 0.001$ and -1.41.4, $p < 0.01$, respectively).

Conclusions

Patients with Turner syndrome and isolated *SHOX* deficiency have similar bone geometry at the radius. Our results support the hypothesis that skeletal abnormalities in patients with TS are caused by *SHOX* deficiency. Low trabecular vBMD in TS is probably a consequence of hypogonadism due to ovarian failure.

FR0160

Unique Contributions of Endothelial vs. Smooth Muscle *Msx* Gene Expression In Arteriosclerotic LDLR-Deficient Mice. Jian Su Shao¹, Su-Li Cheng², Abraham Behrmann¹, Kathryn Distelhorst¹, Linda Halstead¹, Robert Maxson³, Dwight Towler^{*1}. ¹Washington University in St. Louis, USA, ²Washington University in St. Louis School of Medicine, USA, ³University of Southern California, USA

When male LDLR-deficient mice are fed high fat diabetogenic diets (HFD), osteochondrogenic transcription factors such as Runx2 and members of the *Msx* and *Sox* gene families are upregulated in the aorta with progressive calcium deposition. In vivo and in vitro, *Msx2* expression enhances osteogenic mesenchymal cell mineralization via activation of paracrine Wnt7 signals and the inhibition of Dkk1, an LRP Wnt receptor antagonist. In the absence of diabetes, *Msx* genes are dynamically expressed in postnatal endothelial cells (ECs), smooth muscle cells (SMCs), and myofibroblasts. To better understand the roles of vascular *Msx* genes in arteriosclerosis, we've implemented Tagln-Cre and Cdh5-Cre mice to conditionally delete floxed alleles in SMCs and ECs, respectively. As compared to *Msx2(f/f);LDLR +/-* controls, Tagln-Cre;*Msx2(f/f);LDLR +/-* mice exhibit only 6% of basal aortic *Msx2* mRNA expression, with no impact upon *Msx1*. Aortic Col1A1 and Col10A1 are concomitantly reduced, along with *Sox2*, a *Sox* factor required for osteoprogenitor renewal. Additional reduction in SMC *Msx* "tone" in Tagln-Cre;*Msx2(f/f);Msx1(f/+);LDLR +/-* mice, decreased aortic *Msx1* (by 70%), and *Sox9* (by 40%), but did not further reduce Col1A1, Col10A1, or *Sox2*. Significant upregulation of Dkk1 was noted but Wnt7b was unaltered. Remarkably, while Cdh5-Cre;*Msx2(f/f);LDLR +/-* animals exhibited only minor changes in aortic *Msx2* and Dkk1, aortic Wnt7b, Wnt4, Wnt3a, & Wnt10a mRNA levels were dramatically reduced by >85%. In cultured bovine aortic endothelial cells (BaEC), augmenting *Msx2* and Wnt7b expression supports EC molecular phenotype and epithelial morphology, and suppresses the endothelial-mesenchymal transition (EnMT). Consistent with this, Cdh5-Cre;*Msx2(f/f);LDLR +/-* mice exhibit significantly reduced aortic expression of claudin 5, a marker & mediator of endothelial integrity, and increased Col1A1 mRNA. Furthermore, as compared to *Msx2(f/f);LDLR +/-* controls, Cdh5-Cre;*Msx2(f/f);LDLR +/-* mice exhibited increased arterial calcification when challenged with HFD for 12 weeks (3.8+/-0.1 vs 6.2+/-1.0 ug/mg, $p = 0.04$). Thus, *Msx* genes contribute unique activities in aortic ECs vs. SMCs. *Msx2* regulates aortic Col1A1, Col10A1, and Dkk1 expression primarily in SMCs, but supports vascular Wnt7b expression primarily in ECs. Differential endothelial vs. mesenchymal *Msx*-Wnt signals may couple EC phenotypic modulation with osteo/fibrogenic arteriosclerotic responses in part via regulation of EnMT.

Measles Virus Nucleocapsid Protein induces Autophagy in Osteoclasts: Implications for the Pathogenesis of Paget's Disease of Bone. Feng-Ming Wang^{*}, Deborah L. Galson. University of Pittsburgh, Medicine/Hematology-Oncology, The Center for Bone Biology of UPMC, & VA Pittsburgh Healthcare System, USA

Paget's disease of bone (PDB) is characterized by abnormal osteoclast (OCL) that express a pagetic phenotype, that includes increased OCL number and hypermultinuclearity, as well as increased IL-6 production. Measles virus nucleocapsid protein (MVNP) contributes to the pathogenesis of PDB as demonstrated by published studies from both patients and transgenic animals. However, it remains unclear how MVNP induces the abnormal features of pagetic OCL. Recently published data revealed that measles virus infection induces autophagy in HeLa cells. Another recent report revealed that autophagy plays a pivotal regulatory role in hypoxia-induced OCL formation. Therefore, we examined the impact of MVNP expression on autophagy in the OCL generated in vitro from the bone marrow monocytes of wild-type and TRAP-MVNP transgenic mice by treatment with M-CSF and RANKL. Immunoblot measurements of microtubule-associated protein light chain 3 (LC3) conversion to the LC3-II form and degradation of p62 indicated that autophagy was induced during osteoclast differentiation. On day 3, the OCL generated from TRAP-MVNP mice had a higher ratio of LC3-II/I and lower levels of p62 than the OCL generated from wild-type mice, paralleling the increased TRAP-positive multinucleated cells observed with MVNP+ cells. We examined the LC3-II/I ratio in NIH3T3 cells stably transduced with MVNP (NIH3T3-MVNP) and compared empty vector-transduced NIH3T3 cells (NIH3T3-EV). NIH3T3-MVNP cells exhibited a higher ratio of LC3-II/I than NIH3T3-EV cells. Further, transmission electron microscopy demonstrated that NIH3T3-MVNP cells were rich in autophagosomes. Given that cytosolic FoxO1 is essential for the induction of autophagy, we investigated the sub-cellular localization of FoxO1 in these cells. We observed that cytosolic FoxO1 was increased in the NIH3T3-MVNP cells. We also found that MVNP is cytosolic in NIH3T3-MVNP cells, suggesting that MVNP may directly interact with FoxO1. Interestingly, the accumulation of FoxO1 in the nucleus was inhibited by the presence of MVNP when the cells were treated with LY294002 and resveratrol, both of which trigger nuclear translocation of FoxOs. These results suggest that MVNP induces abnormal pagetic OCL through sequestering cytosolic FoxO1 and thereby promoting autophagy in PDB.

FR0164

Microarray Profile of p62^{P392L} and Measles Virus Nucleocapsid Protein (MVNP) Regulated Gene Expression During Osteoclast Differentiation. Kumaran Sundaram^{*1}, Srinivasan Shanmugarajan¹, Sudhaker Rao², Sakamuri Reddy¹. ¹Charles P. Darby Children's Research Institute, USA, ²Henry Ford Hospital, USA

Paget's disease of bone (PDB) is a chronic localized bone disorder affecting 2-3% of the population over 60 years of age. PDB is inherited as an autosomal dominant trait with genetic heterogeneity. SQSTM1/p62 UBA domain mutation (p62^{P392L}) is widely identified in PDB and has been shown to increase osteoclastogenesis. Further, environmental factors such as paramyxovirus are implicated in PDB and MVNP has been shown to induce Pagetic phenotype in osteoclasts. However, the molecular mechanisms underlying p62^{P392L} and MVNP stimulation of osteoclast differentiation in PDB are unclear. We therefore determined p62^{P392L} and MVNP regulated gene expression profiling during osteoclast differentiation. Total RNA isolated from normal human bone marrow mononuclear cells transduced with p62^{WT}, p62^{P392L}, MVNP retroviral expression vectors and stimulated with M-CSF and RANKL for 48 h were subjected to Agilent microarray (~26,000 genes) analysis. We identified 9.7% and 8.4% of genes were upregulated (> 4-fold) in p62^{P392L} and MVNP transduced cells respectively. p62^{P392L} mutant increased Integrin β 3 (185 fold), integrin β 5 (26 fold), IL-1 α (11 fold), IL-6R (8 fold), CXCL-2 (7.5 fold), CXCL-3 (5 fold) compared to p62^{WT} transduced cells. Similarly, MVNP increased integrin β 3 (63 fold), NFAT activating protein (6.5 fold), OSCAR (5.5 fold), TRAF5 (8.5 fold) mRNA expression compared to empty vector (EV) transduced cells. MVNP also elevated gene expression of cytokines/growth factors such as IL-17 (18 fold), IL-1F7 (10 fold), IL-17R (4.5 fold) and IL-11 (7 fold). Interestingly, MVNP transduced cells demonstrated a high level expression of signal regulatory protein beta 1 (SIRPB1) (353 fold). SIRPB1 has been shown to interact with DAP 12, an ITAM containing adaptor protein which plays an important role in osteoclast differentiation. Real-time PCR analysis of total RNA isolated from normal human peripheral blood monocytes transduced with MVNP confirmed upregulation of SIRPB1 mRNA expression in the absence of RANKL stimulation. In contrast, RANKL stimulation did not alter SIRPB1 expression in these cells. Furthermore, bone marrow mononuclear cells derived from patients with PDB showed high levels of SIRPB1 mRNA expression compared to normal subjects. Thus, p62^{P392L} mutant and MVNP regulated gene expression profiling during osteoclast differentiation provides new insights into the molecular mechanisms and therapeutic targets to control elevated osteoclast activity in PDB.

TANK Binding Kinase 1 (TBK1) Mediates MVNP Effects in Pagetic Osteoclasts. Quanhong Sun^{*1}, Benedicte Sammut¹, Fengming Wang¹, Jolene J. Windle², Noriyoshi Kurihara¹, G. David Roodman¹, Deborah L. Galson¹. ¹University of Pittsburgh, Medicine/Hematology-Oncology, The Center for Bone Biology of UPMC, & VA Pittsburgh Healthcare System, USA, ²Virginia Commonwealth University, Department of Human & Molecular Genetics, USA

Paget's disease is characterized by abnormal osteoclasts (OCL) that express a phenotype which includes increased: sensitivity of OCL progenitors to 1,25(OH)₂D₃, RANKL and TNF- α , number of OCL, nuclei/OCL, and expression of the VDR coactivator TAF12 and the cytokine IL-6. Measles virus nucleocapsid protein (MVNP) contributes to the pathogenesis of pagetic osteoclasts as demonstrated by published studies from both patients and transgenic mice. However, the direct interactions of MVNP that generate pagetic OCL are unknown. TANK binding kinase 1 (TBK1) and I κ B kinase-epsilon (IKK ϵ) are IKK-related family members which have been reported to physically interact with MVNP and can activate both the IRF3 and the NF- κ B pathways. We have found in our studies that TBK1 protein, but not IKK ϵ protein, is increased in OCL precursors from TRAP-MVNP mice as compared to OCL precursors from wildtype mice. Interestingly, both TBK1 and IKK ϵ were increased early in OCL differentiation (at day 1), and then decreased at day 3, in cells from both TRAP-MVNP and wildtype mice, suggesting a possible role in normal osteoclastogenesis. However, only TBK1 was further enhanced in the presence of MVNP. Both TBK1 and IKK ϵ expression vectors co-transfected with a -1200 IL-6 promoter luciferase reporter into HEK293 cells stimulated IL-6 promoter activity. Strikingly, over-expression of both TBK1 and IKK ϵ as well as MVNP cDNA transfection induced the endogenous IL-6 gene in both NIH3T3 and pre-osteoclastogenic RAW264.7 cells. We investigated the role of TBK1 in MVNP induction of IL-6 using NIH3T3 cells stably transfected with MVNP or empty virus (EV) as a model system. The NIH3T3-MVNP cells produce much larger amounts of both IL-6 mRNA and secreted protein than NIH3T3-EV cells. We found that similar to the effects of MVNP on TBK1 levels in OCL, TBK1 protein levels were increased in NIH3T3-MVNP as compared to NIH3T3-EV cells. After overnight serum starvation (2% serum), TNF- α increased TBK1 phosphorylation in a similar biphasic pattern in both NIH3T3-EV and NIH3T3-MVNP cells, but there was significantly more phospho-TBK1:total TBK1 as well as total TBK1 in the NIH3T3-MVNP cells at each time point. Knockdown of TBK1 with a shRNA lentivirus impaired IL-6 secretion induced by MVNP as well as decreased TAF12. These results demonstrate that TBK1 plays a critical role in mediating the effects of MVNP on the expression of both TAF12 and IL-6, key contributors to the pagetic OCL phenotype.

The Expression of Measles Virus Nucleocapsid Protein (MVNP) Gene in Osteoclasts (OCLs) Induces Expression of Coupling Factors that Stimulate Bone Formation. Yoko Uehata^{*1}, Jumpei Teramachi¹, Jolene Windle², Noriyoshi Kurihara¹, G. David Roodman³. ¹University of Pittsburgh & The Center for Bone Biology at UPMC, USA, ²Virginia Commonwealth University, USA, ³University of Pittsburgh, The Center for Bone Biology at UPMC, & VA Pittsburgh Healthcare System, USA

We reported that 70% of Paget's disease (PD) patients express MVNP and that transgenic mice with targeted expression of MVNP to cells in the OCL lineage formed pagetic-like bone lesion that display both increased bone resorption and rapid new bone formation (J Bone Miner Res 2006). In contrast, mice with targeted expression of the p62^{P392L} mutation linked to OCL (TRAP-p62^{P392L}) have increased bone resorption but do not have increased bone formation in vivo (J Clin Invest 2007). Further, loss of IL-6 in TRAP-MVNP mice prevents the development of pagetic OCLs and reduces bone formation parameters in these animals. These results suggested that IL-6 plays an important role in linking bone formation to bone resorption in PD (Cell Metab 2011). Ephrin-B2 and EphB4 were recently identified as key coupling factors for OCL and osteoblasts. Ephrin-B2 is produced by OCL and dramatically enhances osteoblast function and bone formation in vitro and in vivo through specific interactions with EphB4 on osteoblasts. To determine if Ephrin-B2 and EphB4 play a role in the effects of MVNP on bone formation, we collected bone marrow from 20-month-old wild type (WT), TRAP-MVNP, TRAP-MVNP/IL-6^{-/-} and TRAP-p62^{P392L} mice and examined the role of Ephrin-B2/EphB4. Bone marrow cells were cultured 3 days on non-tissue culture dishes with 50 ng/ml of BMP-2. The adherent cell population, containing the committed OCL-precursors (OCL-P) and pre-osteoblasts, was co-cultured with 1,25(OH)₂D₃, and the levels and ratio of Ephrin-B2/EphB4 were determined. Ephrin-B2/EphB4 was increased in MVNP expressing bone marrow cultures compared to WT and p62^{P392L} cultures. CD11b(+) cells (early OCL-P) from TRAP-MVNP mice expressed decreased levels of Ephrin-B2 when treated with 1,25(OH)₂D₃ compared to WT. More differentiated MVNP expressing OCL-P expressed enhanced Ephrin-B2 compared to OCL from WT and p62^{P392L} mice. Osteoblasts derived from bone marrow cultures of MVNP mice had increased expression of EphB4 and Runx2 when treated with 1,25(OH)₂D₃ compared to WT and p62^{P392L}. Further, MVNP/IL-6^{-/-} mice had decreased expression of Ephrin-B2, EphB4 and Runx2, consistent with the lack of increased bone formation in these mice. These results show that MVNP increases both OCL activity and bone formation

by promoting OCL and osteoblast interactions, suggesting that the mechanism responsible for the increased expression of Ephrin-B2/EphB4 induced by MVNP is dependent on IL-6.

High Turnover Renal Osteodystrophy is Associated with β -Catenin Repression in Osteocytes. Yves Sabbagh^{*}, Wen Tang, Christina Bracken, Stephen O'Brien, Lucy Phillips, Sue Ryan, Shiguang Liu, Susan Schiavi. Genzyme Corporation, USA

Chronic kidney disease-mineral bone disorder (CKD-MBD) is defined by abnormalities in mineral and hormone metabolism, bone histomorphometric changes and/or the presence of vascular or soft tissue calcification. Emerging evidence suggests that features of CKD-MBD may occur early in disease progression and are associated with changes in osteocyte function. To identify early pathological changes in bone, we utilized the *Jck* mouse, a genetic model of polycystic kidney disease that exhibits progressive biochemical features of CKD-MBD, similar to what is observed in the human population. At 6 weeks of age these mice have normal renal function and no evidence of bone disease but exhibit progressive decline in renal function starting at 8 weeks and death by 18 weeks of age. We investigated temporal bone changes in *Jck* relative to wild-type (WT) mice from 6 through 18 weeks of age. The presence of high bone turnover was observed as early as 9 weeks of age based on increased BFR in *Jck* (0.570.04mm³/mm²/yr) relative to WT mice (0.360.02mm³/mm²/yr). To capture the early molecular and cellular events mediating the progression of CKD-MBD in *Jck* we examined specific molecular pathways associated with osteocyte function and bone remodeling at the protein and gene expression level. Immunohistochemistry staining for the osteocyte specific Wnt-antagonist, sclerostin (SOST) demonstrated that it was significantly elevated in *Jck* mice at 9 weeks of age. This alteration paralleled increased Phospho-Ser33/37- β -catenin protein expression in *Jck* osteocytes supporting inhibition of the Wnt/ β -catenin pathway. Although osteoprotegerin (OPG) gene expression was not altered in *Jck* bone, RANKL ligand was significantly elevated leading to a shift in the OPG/RANKL ratio favoring osteoclast activity. These results are consistent with published reports demonstrating that Wnt/ β -catenin pathway inhibition leads to enhanced osteoclast activity. As serum PTH was rising with disease progression, SOST expression was down-regulated both at the protein and mRNA level. Interestingly, sFRP4 mRNA, another Wnt antagonist, was also significantly elevated early in disease in the *Jck* but unlike SOST its elevated expression was sustained during the same time frame. These data provide evidence for early changes in osteocytes which may negatively influence bone remodeling. Overall repression of Wnt/ β -catenin pathway appears to be sustained during disease progression in CKD-MBD.

Adenovirus-Mediated Gene Transfer of Adiponectin Reduces Osteoclasts Differentiation and Bone Erosion of Collagen-Induced Arthritis in Mice. Kosuke Ebina^{*}, Kazuya Oshima, Makoto Hirao, Jun Hashimoto, Kenrin Shi, Hideki Yoshikawa. Osaka University, Graduate School of Medicine, Department of Orthopedics, Japan

Adiponectin (APN) is a hormone released by adipose tissue with anti-diabetic and anti-atherogenic properties. In addition, APN inhibits osteoclasts differentiation and pro-inflammatory cytokines production from macrophages by inhibiting NF- κ B activity *in vitro*. However, APN also exhibits pro-inflammatory effects by promoting pro-inflammatory cytokines production from synovial fibroblasts. We have previously reported that serum APN levels are elevated and associated with disease severity in patients with rheumatoid arthritis (RA), but its effect remains unclear. The purpose of this study is to examine the effects of systemic delivery of APN in murine arthritis model. Collagen-induced arthritis (CIA) is an established murine arthritis model with many similarities to RA. CIA was induced in DBA1/J mice by injection of chicken type II collagen in complete Freund's adjuvant twice with a 21-day interval. 2 \times 10⁸ plaque-forming units of adenoviral vectors encoding human APN (Ad-APN) or beta-galactosidase (Ad-b-gal) as control were injected intravenously either before or after arthritis onset. Clinical severity of arthritis was assessed by all limb swelling, yielding a maximum score of 16 per mouse. Tissue samples were obtained on 35 days after CIA induction. Serum APN levels were elevated in Ad-APN infected mice about 5-fold on 2 days, and about 30-fold on 16 days after adenovirus injection compared to control group. Systemic APN delivery at both time points significantly decreased clinical disease activity scores of CIA (before onset treatment: Ad-APN infected mice 1.76 0.63, Ad-b-gal infected mice 8.68 1.06; P < 0.001 / after onset treatment: Ad-APN infected mice 5.17 1.25, Ad-b-gal infected mice 9.17 1.15; P < 0.05). APN treatment significantly decreased histological scores of inflammation, cartilage damage, and pannus formation and mRNA levels of pro-inflammatory cytokines in the joints. Interestingly, APN treatment significantly decreased the number of TRAP-positive cells in the joints (TRAP-positive cells per field: Ad-APN infected mice 8.15 3.31, Ad-b-gal infected mice 27.6 2.85; P < 0.001). In addition, APN treatment resulted in amelioration of bone erosion in the ankle joints of CIA mice evaluated by μ CT (BV/TV(%): Ad-APN infected mice 31.9 5.01, Ad-b-gal infected

mice 21.4 \pm 5.68; $P < 0.05$). These results provide novel evidence that systemic APN delivery inhibits bone erosion and inflammation of murine arthritis model joints.

Bone Histomorphometry Findings in Pediatric Solid Organ Transplant Patients. Inari Tamminen¹, Helena Valta², Hanna Isaksson³, Sari Salminen⁴, Mervi K. Mayranpää⁵, Hannu Jalanko⁵, Heikki Kroger⁶, Outi Makitie⁷. ¹Bone & Cartilage research Unit (BCRU), University of Eastern Finland, Finland, ²Hospital for Children & Adolescents, University of Helsinki, Helsinki Finland, Finland, ³University of Eastern Finland, Finland, ⁴Children's Hospital, Helsinki University Central Hospital, Finland, ⁵Children's Hospital, Helsinki University Central Hospital & University of Helsinki, Finland, ⁶Kuopio University Hospital, Finland, ⁷Hospital for Children & Adolescents, Helsinki University Hospital, Finland

Solid organ transplantation may lead to secondary osteoporosis in children. Metabolic abnormalities related to the underlying disease, disturbances in pubertal development and medication affect bone metabolism leading to low bone mass and increased fracture risk. This study characterized bone histomorphometric findings in pediatric kidney, liver and heart transplant recipients who were assessed for suspected secondary osteoporosis.

Iliac crest biopsies were obtained from 19 children (aged 7.6-18.8 years, 11 males) who had undergone kidney ($n=6$), liver ($n=9$) or heart ($n=4$) transplantation 6.8 \pm 5.7 years (range 0.6-16.3 years) earlier. Secondary osteoporosis was suspected based on low bone mineral density (BMD) measured by DXA and/or fracture history. All children had received glucocorticoids (GCs) for several years. Results of histomorphometric analyses were compared with reference values and correlated with clinical characteristics.

Of the 19 patients, 21% had sustained peripheral fractures and vertebral compressions were found in 58%. Nine children (47%) had a lumbar spine BMD Z-score below -2.0. Histomorphometric analyses showed decreased trabecular thickness in 12 patients (63%), increased trabecular number in 14 patients (74%) and decreased trabecular separation in 8 patients (42%). Trabecular bone volume was low (<-1.0 SD) in 5 children (26%). Low turnover was observed in 37% and high turnover in 32% of the children. No significant differences in bone histomorphometry were found between children with mild vs. moderate kidney dysfunction ($p>0.05$). Children with compression fractures ($n=11$) had higher present and cumulative GC dose (mg) than children without compression fractures ($n=8$) ($p<0.05$), and their biopsies showed lower osteoblast surface (Ob.S/BS) Z-score and mineralizing surface (MS/BS) Z-score ($p<0.05$) than children without compression fractures. Turnover rate tended to be lower for children with than without vertebral fractures.

Abnormal bone biopsy findings were common in children after solid organ transplantation. The observed changes in bone quality (*i.e.* abnormal turnover rate and thin trabeculae) rather than the actual loss of trabecular bone, might explain the increased fracture risk in pediatric solid organ transplant recipients.

PHOSPHO1: a Novel Therapeutic Target for Medial Vascular Calcification. Tina Kiffer-Moreira¹, Manisha C. Yadav¹, Dongxing Zhu², Yalda Bravo³, Russell Dahl³, Sonoko Narisawa¹, Boguslaw Stec¹, Vicky E. MacRae², Colin Farquharson⁴, Jose Luis Millan¹. ¹Sanford Children's Health Research Center, Sanford-Burnham Medical Research Institute, USA, ²The Roslin Institute, The University of Edinburgh, United Kingdom, ³Conrad Prebys Center for Chemical Genomics, Sanford-Burnham Medical Research Institute, USA, ⁴The Roslin Institute, The University of Edinburgh, USA

Calcification of the medial layer of arteries, also known as Monckeberg's sclerosis, is increasingly recognized as an important clinical problem in chronic kidney disease, diabetes, and aging. Children with idiopathic infantile arterial calcification (IIAC), due to deficiency of the enzyme that produces inorganic pyrophosphate (NPP1), die of heart failure. We have documented that medial vascular calcification is accompanied by an increase in the expression of tissue-nonspecific alkaline phosphatase (TNAP) both in the *Enpp1*^{-/-} mouse model of IIAC (Narisawa et al., 2007) as well as in uremic rats (a model of end-stage renal disease) (Lomashvili et al., 2008). We have recently documented that expression of PHOSPHO1, an enzyme crucial for initiation of skeletal mineralization (Yadav et al., 2011) and the prevention of greenstick fractures (Huesa et al., 2011), affects TNAP expression. Further, we observed that *Phospho1*^{-/-} vascular smooth muscle cells (VSMCs) have markedly reduced ability to calcify in vitro compared to WT cells. PHOSPHO1 shows high phosphohydrolase activity towards phosphoethanolamine (P-Etn) and phosphocholine (P-Cho). Using high throughput screening, we have identified potent and specific inhibitors of PHOSPHO1, without the cross-inhibition of TNAP and NPP1 activity observed with lansoprazole, ebelsens and SCH-202676 (Roberts et al., 2007). Here, we present a detailed kinetic analysis of the inhibition of PHOSPHO1 with nine new small molecule compounds using PHOSPHO1's natural substrates P-Etn and P-Cho. We observed that MLS-0390837, MLS-0390838 and MLS-0263839 showed stronger inhibition than all the other compounds tested, with IC50 values of 0.22, 0.14 and 0.09 μ M, respectively. Our kinetic, computer modeling and docking predictions of MLS-0263839 and MLS-0390837 indicate a competitive type of inhibition. The MLS-0263839 and MLS-0390838 compounds were then used to demonstrate that inhibition of PHOSPHO1 leads to a reduction in the degree of calcification in *Enpp1*^{-/-} VSMCs. Thus, PHOSPHO1 appears to be a novel target for the prevention of medial vascular calcification. Narisawa et al., J. Bone Miner. Res. 22: 1700-1710 (2007). Roberts et al., J. Bone Miner. A 4-bp Deletion Mutation in DLX3 Enhances Anti-adipogenic Activity of DLX3. Hye-Lim Lee¹, Kyung Hwa Baek², Kyung Mi Woo³, Hyun-Mo Ryoo¹, Gwan-Shik Kim¹, Jeong-Hwa Baek³. ¹Seoul National University School of Dentistry, South Korea, ²Seoul National University School of Dentistry, South Korea, ³Seoul National University, School of Dentistry, South Korea

DLX3 is a homeodomain protein that is involved in osteoblast differentiation. Deletion of 4 bps in DLX3 is causally related to tricho-dento-osseous syndrome, a genetic disorder manifested by taurodontism, hair abnormalities and increased bone density. The molecular mechanisms explaining the increased bone density phenotype have not been clearly elucidated. Osteoblasts and adipocytes are derived from common bone marrow mesenchymal progenitors, and there is a reciprocal regulation in the differentiation of osteoblasts and adipocytes. In this study, we examined whether DLX3 negatively regulates adipocyte differentiation and whether there are any differences in anti-adipogenic effects between wild type DLX3 (wtDLX3) and 4-bp deletion mutant DLX3 (mtDLX3). Over-expression of wtDLX3 and mtDLX3 in human bone marrow mesenchymal stem cells or 3T3-L1 murine preadipocytes suppressed adipogenic differentiation. However, anti-adipogenic effect of mtDLX3 is much stronger than that of wtDLX3. Adipogenic induction of 3T3-L1 cells suppressed Dlx3 expression whereas knock-down of Dlx3 enhanced adipogenic differentiation of 3T3-L1 cells. The expression of PPAR γ , a master transcription factor for adipogenesis, was suppressed by wtDLX3 and mtDLX3 whereas over-expression of PPAR γ rescued adipogenic differentiation of 3T3-L1 cells that over-express wtDLX3 or mtDLX3. Although there was no putative DLX-binding element within 2 kb of the PPAR γ promoter sequence, C/EBP α -induced PPAR γ promoter activity was suppressed by both wtDLX3 and mtDLX3 and CREB-induced PPAR γ promoter activity was suppressed by mtDLX3. Co-immunoprecipitation assays demonstrated that mtDLX3 binds to CREB and C/EBP α whereas wtDLX3 binds only to C/EBP α . Furthermore, the chromatin immunoprecipitation and in vitro DNA binding assays demonstrated that mtDLX3 prevents both C/EBP α and CREB from binding the PPAR γ promoter whereas wtDLX3 inhibits the DNA binding of C/EBP α only. Binding of DLX3 to C/EBP α required only homeobox domain whereas that of CREB to mtDLX3 required both homeobox domain and frame-shifted C-terminal domain. These results indicate that DLX3 is a negative regulator for adipocyte differentiation and that a frameshift by 4-bp deletion provides enhanced anti-adipogenic activity to mtDLX3. Enhanced anti-adipogenic activity of mtDLX3 may

be involved in increased bone density phenotype of tricho-dento-osseous syndrome, at least in part.

Differential Effect of ApoE Isoforms on Trabecular Bone Mass and Bone Turnover in Mice. Marco Dieckmann¹, F. Timo Beil², R. Percy Marshall², Alexander Bartelt², Wolfgang Ruether², Michael Amling², Joachim Herz³, Andreas Niemeier^{*2}. ¹UT Southwestern Medical Center, USA, ²University Medical Center Hamburg-Eppendorf, Germany, ³Center for Alzheimer's & Neurodegenerative Disease, USA

Purpose We have previously shown that apoE ^{-/-} mice display a high bone mass phenotype due to an increased bone formation rate, but the underlying mechanism remains incompletely understood. Mice have only one form of apoE and do not express isoforms, while in humans three common isoforms of apoE (E2, E3, E4) exist. The isoforms differentially affect lipoprotein metabolism and apoE4 is a well-established risk factor for Alzheimer's disease, whereas the expression of apoE2 is associated with the development of hyperlipidemia. A substantial body of literature has been published on the question whether the human apoE isoforms have a differential impact on BMD and fractures, but the issue remains highly controversial. Part of the reason for this controversy is the asymmetric allele frequency of the apoE gene (approx. $\epsilon_2 = 0.08$, $\epsilon_3 = 0.77$, $\epsilon_4 = 0.15$ in Caucasians) which renders human studies difficult to perform. We therefore addressed the question whether human apoE isoforms have an impact on bone in vivo using apoE "knock-in" (apoE ki) mice that have been genetically modified to express the human apoE2, E3 and E4 isoforms instead of the murine apoE.

Methods Biochemical serum and urinary bone turnover markers (osteocalcin, Alkaline phosphatase, OPG, RANKL and DPD crosslinks) were measured with standard procedures. 12-week old female animals (n=8 per group) were sacrificed and the skeletal status was assessed by conventional X-ray, μ CT, histomorphometry and biomechanical testing.

Results ApoE2 ki animals, as compared to apoE3 ki and apoE4 ki displayed a significantly increased concentration of serum RANKL with decreased OPG / RANKL ratio and increased resorption markers (urinary DPD). Correspondingly, there was a significantly reduced lumbar trabecular bone mass (BV/TV) and distal femur trabecular bone mass (μ CT analyses) due to a significantly reduced bone formation rate (BFR) in apoE2 mice. In contrast, apoE4 animals, as compared to apoE2 and E3, displayed a significantly lower concentration of serum osteocalcin and urinary DPD, indicating low bone turnover but no change in lumbar or femur trabecular bone mass as compared to apoE3 ki. Accordingly, testing of the biomechanical stability revealed significantly lower maximum force resistance in lumbar vertebrae of apoE2 animals as compared to E3 and E4.

Conclusions In conclusion, this study provides the first unequivocal genetic evidence that the human apoE isoforms E2, E3 and E4 differentially affect bone turnover and bone mass in vivo in mice. It remains to be determined by which mechanisms the isoform-specific differences can be explained, but the current data strongly underline the general importance of apoE as a gene that regulates bone metabolism. Based on the current results, the rare apoE2 isoform merits further study as a potential genetic risk factor for low bone mass in human clinical investigations.

Etanercept for the Treatment of Inflammation in Cherubism Mice. Teruhito Yoshitaka^{*1}, Tomoyuki Mukai², Ernst Reichenberger³, Yasuyoshi Ueki⁴. ¹University Missouri-Kansas City School of Dentistry, USA, ²University of Missouri - Kansas City, USA, ³University of Connecticut Health Center, USA, ⁴University of Missouri-Kansas City School of Dentistry, USA

Cherubism is a genetic disorder caused by a mutation of SH3BP2, which involves bone destruction especially of the jaw. We had previously created a mouse model for cherubism and demonstrated that homozygous mutant mice show TNF α -dependent systemic inflammation leading to bone erosion and joint destruction. The critical role of TNF α in this inflammatory bone destruction was confirmed by creating TNF α -deficient homozygous cherubism mutants, in which systemic inflammation and bone destruction was dramatically reduced. These results suggest a key role of TNF α in disease progression in cherubism. In the current study, homozygous cherubism mice were injected with the anti-TNF α drug, Etanercept, which is currently used for the treatment for inflammatory disorders such as rheumatoid arthritis. Etanercept was subcutaneously injected twice a week into homozygous mutant and wild-type control mice starting from 6-11 days of age for 6.5 weeks. Homozygous mice were separated into 3 groups: low (0.5mg/kg) and high (25mg/kg) dose Etanercept and a PBS vehicle control group for comparison with wild-type mice. Histological analysis by H&E staining was performed on liver, lung, and stomach tissues to evaluate the anti-inflammatory effect of treatment. Quantitative real-time PCR analysis for TNF α in the liver was performed. For the evaluation of inflammatory joint destruction, microCT was used. Homozygous mice treated with the high dose Etanercept showed greatly decreased systemic inflammation and joint destruction while no significant effect was observed with the low dose and vehicle treated groups. In liver, the high dose treatment group showed a significant decrease in inflammatory area (0.10.1%),

while the low dose (9.97.2%) was comparable to the vehicle control group (10.65.0%). The expression level of TNF α mRNA in liver tissue of homozygotes was significantly decreased in the high dose (7.31.1-fold increase to wild-type) compared with low dose (25.816.2) and vehicle treatment (28.512.4) groups. Bone and joint destruction in the high dose group was rescued to the level of the wild-type control group. Decreased inflammation was also observed in the other tissues from the high dose group. In summary, administration of high dose Etanercept significantly reduced the progression of inflammation and bone destruction in homozygous cherubism mice. These results provide evidence that human cherubism patients might benefit from treatment with anti-TNF α therapeutics.

Mechanisms of Bone Loss in Cystic Fibrosis Bone Disease. Katrina Clines, Joon Chung, Gregory Clines^{*}. University of Alabama at Birmingham, USA

Purpose: Low bone mass and increased fracture risk occurs with cystic fibrosis (CF), a genetic disease caused by mutations in the cystic fibrosis transmembrane regulator (CFTR). Impaired osteoblast bone formation coupled with enhanced osteoclastic bone resorption is characteristic of CF bone disease in humans and in animal models. Intestinal malabsorption, vitamin D deficiency and inflammatory cytokines contribute to CF bone disease, but epidemiological investigations and animal models support a direct causal link between CFTR inactivation in bone and CF bone disease.

Methods: CFTR expression in bone was determined by mRNA analysis and immunostaining. *Ex vivo* calvarial and primary osteoblasts cultures derived from *Cfr* knock out and WT mice were examined for changes in bone formation, differentiation and gene expression.

Results: *Cfr* message was detected in murine primary osteoblasts but not RAW264.7-derived multinucleated cells. Protein expression by immunostaining paralleled mRNA expression with CFTR expressed in primary osteoblasts but not marrow-derived osteoclasts. Osteoblast CFTR was not localized to the cell membrane characteristic of epithelial cells but in the cytoplasmic compartment. In the calvarial organ culture assay, CFTR inactivation reduced bone formation and osteoblast numbers. However CFTRinh-172, a small-molecule inhibitor that blocks CFTR-specific Cl⁻ membrane conductance, did not alter osteoblast activity in this assay, a result that is consistent with CFTR absence from the cell membrane. Mechanisms for uncoupled bone turnover with CFTR inactivation were next investigated. *Cfr* null calvarial osteoblasts expressed significantly less *Osterix*, *Collagen 1a1* and *Osteocalcin* than WT osteoblasts indicating delayed osteoblast differentiation. The lack of osteoclast CFTR expression suggested dysfunction in osteoblast-derived RANKL/OPG as a cause for enhanced bone resorption of CF. *Cfr* null and WT calvarial osteoblasts expressed equivalent amounts of *Rankl* mRNA, but *Opg* mRNA was reduced by 65% in *Cfr* null osteoblasts. Overall, the *Rankl:Opg* ratio was 2.7X higher in *Cfr* null vs. WT osteoblasts translating into higher osteoclast activity and bone resorption.

Conclusion: We present a novel role for CFTR in bone and provide evidence that uncoupled bone turnover of CF bone disease is a direct consequence of osteoblast CFTR inactivation by delaying osteoblast differentiation and enhancing osteoclastogenesis via reduced osteoblast *Opg* expression.

Osteoanabolic Treatment of Adult Osteogenesis Imperfecta with Teriparatide: Preliminary Results of an 36-month prospective observational study. Parvis Farahmand^{*1}, Johann Ringe¹, Thomas Nickelsen². ¹West German Osteoporosis Center, Leverkusen Clinic, University of Cologne, Germany, ²Eli Lilly Deutschland GmbH, Germany

Introduction: Osteogenesis imperfecta (OI) is a genetic disorder of collagen synthesis. So far only antiresorptive therapies with bisphosphonates have shown beneficial effects on the clinical outcome of OI in children. The use of osteoanabolic drugs has not been described in this disorder except from interim results of this study.

Methods: The aim of the ongoing prospective, observational, single-center 36-month open-label "Teriparatide in Osteogenesis Imperfecta" trial (TOI-trial) is to study the efficacy of an anabolic treatment of teriparatide (rPTH-1-34) in adults with clinically symptomatic OI. Inclusion criteria are age >30 years, one or more prevalent vertebral and non-vertebral fracture during the last year, BMD at lumbar spine T-score <-3.0 and at total hip <-2.0. All patients received 1200mg calcium and 800 IU vitamin D per day (months 1-36). During the first 18 months all patients received subcutaneous injections of 20 μ g teriparatide. During the following 18 months all patients receive bisphosphonates.

Results: 12 patients (7 men, 5 women) were included: mean age 45.4 years, mean height 153cm, mean weight 67kg, average lumbar spine BMD -3.9 and total hip -3.0 T-score, and a mean number of 1.8 new vertebral and 0.7 non-vertebral fractures per patient during the last year before intervention. BMD measured at 6 months intervals showed highly significant increases at both sites and amounted to an average gain of 11.4% at the lumbar spine and 7.1% at the total hip after 18 months. During the 18 months we observed only one new vertebral and only two non-vertebral fractures.

This is remarkable in relation to the respective average fracture rates during the last year before intervention. There was no height loss during the first 18 months. There was a significant decrease in back pain and moderate non-persisting adverse events occurred in 6 out of 12 patients.

Conclusion: In the present cohort of adult patients with OI, treatment with teriparatide 20 µg/day over an 18-month period was associated with increases in spine and hip BMD, a numerical decrease in new fractures, and a statistically significant decline in back pain.

Teriparatide was well tolerated; adverse effects were mild and not associated with an early discontinuation of therapy. Based on these encouraging preliminary results we have included further patients. These results should encourage further, controlled trials of an anabolic therapy in osteogenesis imperfecta at a larger scale.

Disclosures: Parvis Farahmand, None.

FR0193

Over Expression of Tissue-nonspecific Alkaline Phosphatase in Osteoblasts Increases Bone Mineralization by Dephosphorylating Osteopontin. Sonoko Narisawa^{*1}, Manisha Yadav², Jose Luis Millan³. ¹Sanford Burnham Medical Research Institute, USA, ²Burnham Institute for Medical Research, USA, ³Sanford-Burnham Medical Research Institute, USA

Tissue nonspecific alkaline phosphatase (TNAP) is a marker of osteoblastic differentiation. We previously reported that inorganic pyrophosphate (PPi) is elevated in TNAP knockout mouse (*Akp2*^{-/-}), a well-characterized model of infantile hypophosphatasia (HPP) and that an important *in vivo* function of TNAP is to hydrolyze extracellular PPi to restrict the concentration of this mineralization inhibitor (Hessle et al., 2002). We also observed increased levels of osteopontin (OPN) in the plasma and bone tissue of *Akp2*^{-/-} mice and we surmised that they contribute to the HPP phenotype (Harmey et al., 2006). Phosphorylated OPN inhibits mineralization; however, the phosphorylation status of the increased OPN levels found in *Akp2*^{-/-} mice has not been studied. We have generated a transgenic mouse line expressing human TNAP under control of 2.3 kb *colla1* promoter (*colla1* TNAP Tg). The transgene is expressed in osteoblasts, periosteum, and cortical bones, and plasma levels of TNAP are 10 - 20 times higher than those in wild-type (WT) mice. The *colla1* TNAP Tg animals are healthy and exhibit increased bone mineralization, as µCT analysis reveals significantly increased bone volume fraction in the vertebrae bone. Crossbreeding *colla1* TNAP transgenic mice to *Akp2*^{-/-} mice rescues the lethal hypophosphatasia phenotype characteristic of this mouse model. Osteoblasts isolated from *colla1* TNAP Tg mice mineralize better than WT cells, and osteoblasts from [*colla1* TNAP Tg; *Akp2*^{-/-}] mice are able to mineralize to the level of *Akp2*^{+/+} osteoblasts, while *Akp2*^{-/-} osteoblasts show no mineralization. The increased levels of OPN in bone tissue of *Akp2*^{-/-} mice are comprised of only phosphorylated forms of OPN while WT and [*colla1* TNAP Tg; *Akp2*^{-/-}] mice had both phosphorylated and dephosphorylated forms of OPN, indicating that accumulated phosphorylated OPN contributes to the inhibition of mineralization in *Akp2*^{-/-} mice and that overexpression of human TNAP reduces the inhibitory effect of OPN via dephosphorylation. Our data suggest that OPN is an *in vivo* protein substrate of TNAP and that interaction between TNAP and OPN modulates mineralization of bone.

SH3BP2 Cherubism Mutation Enhances Lipopolysaccharide-induced Osteoclastogenesis. Tomoyuki Mukai^{*1}, Teruhito Yoshitaka², Yasuyoshi Ueki³. ¹University of Missouri - Kansas City, USA, ²University Missouri-Kansas City School of Dentistry, USA, ³University of Missouri-Kansas City School of Dentistry, USA

Cherubism is an autosomal dominant craniofacial disorder in children characterized by the extensive growth of fibrous lesions containing TRAP-positive multinucleated cells, resulting in facial swelling and extreme malformation of the jaw bones. We had previously reported that gain-of-function mutations in a signaling adaptor protein, SH3BP2 are responsible for cherubism and have shown that the heterozygous mouse model for cherubism (*KI/+*) exhibit trabecular bone loss and that homozygous mutant mice (*KI/KI*) develop TNF-α-dependent systemic macrophage inflammation leading to bone and joint destruction. However, it remains unclear why destructive bone resorption occurs mainly in the jaws of human cherubism patients. Given the fact that the human mouth is abundant with pathogenic microorganisms, we hypothesized the exacerbated jaw bone resorption and swelling is due to increased osteoclastogenesis in response to bacterial pathogens such as lipopolysaccharide (LPS). To test this hypothesis, we examined the effect of LPS on osteoclastogenesis in *KI/+* mice, which have trabecular bone loss but do not develop TNF-α-mediated inflammatory bone erosions. LPS (2.5mg/kg) was subcutaneously injected over the calvarial midline between eyes and ears of wild-type and *KI/+* mice and animals sacrificed after 5 days. Micro-CT analysis showed a more severely eroded bone surface in LPS-treated *KI/+* mice compared to LPS-treated wild-type mice. Bone histomorphometric analysis showed increased eroded surface per bone surface area (29.712.4%) and increased osteoclast number per bone perimeter (4.81.5) in calvarial

bone from LPS-treated *KI/+* mice compared to LPS-treated wild-type mice (11.34.2%, 2.30.6, respectively). Next we cultured bone marrow derived macrophages from *KI/+* and wild-type mice with M-CSF (25ng/ml) for 2 days followed by the LPS (100ng/ml) for 6 days. When *KI/+* bone marrow cells were cultured with M-CSF and LPS alone, TRAP-positive multinucleated cells formed (16.2021.9/well), while wild-type cells failed to form any TRAP-positive, multinucleated cells (0/well). These results suggest RANKL is not necessary and that LPS can replace RANKL in forming osteoclasts in *KI/+* cells and that SH3BP2 plays a role in LPS-induced osteoclastogenesis.

Teriparatide Increases Bone Mineral Density in a Man with Osteoporosis Pseudoglioma. John Bilezikian¹, Marise Lazaretti Castro², Elizabete Ribeiro Barros³, Henrique Arantes^{*4}, Ilda Kunii³. ¹Columbia University College of Physicians & Surgeons, USA, ²Federal University of Sao Paulo, Brazil, ³Sao Paulo Federal University, Brazil, ⁴Brazil

Osteoporosis-pseudoglioma (OPPG), a rare genetic disease characterized by severe juvenile-onset osteoporosis and ocular abnormalities, is caused by an inactivating mutation of the Lipoprotein receptor-related protein 5 (LRP5) gene. The purpose of this study was to evaluate, for the first time in an adult with OPPG, the efficacy of teriparatide. The 12-year old patient was blind, had multiple fractures, and a lumbar spine Z-score by DXA of -3.99 (0.512 g/cm²). A younger brother also had OPPG with congenital blindness and fracture. The parents were consanguineous and healthy. Molecular analysis showed a novel homozygotic missense mutation in the LRP5 gene. At age 20, 1 year after stopping pamidronate, a 2-year course of teriparatide (20 mcg/day) was initiated. He had received intravenous pamidronate for 6 years, the last 3 years of which were associated with minimal effects on BMD. Measurements in serum were made of C-terminal telopeptide of type I collagen (CTX), N-terminal propeptide of type I collagen (PINP), total and ionized calcium, phosphate, uric acid, complete blood count, renal and liver function tests. Urinary calcium/creatinine ratio was determined. BMD was measured by DXA yearly. BMD increased by 9.7% in lumbar spine and 10.2% in the hip. CTX rose early, peaking in month 3, followed by an increase in PINP, peaking in month 9. Both indices returned to baseline by month 24. There were no fractures nor any other adverse events during treatment. The gain in lumbar spine bone mass after 2 years was similar to the major densitometric gains experienced in the pivotal clinical trial that led to the approval of the drug. The time course of change in bone turnover markers – an increase in CTX before the increase in PINP – is opposite from what has traditionally been seen when teriparatide is used in subjects with osteoporosis. In other osteoblast deficiency states, such as the *Lrp5*^{-/-} knockout mouse and hypoparathyroidism, the same “reverse” pattern of bone marker changes is seen. The results indicate that in OPPG, teriparatide markedly increases BMD in the lumbar spine and hip, and that this anabolic effect does not require the LRP5 protein. Assuming that teriparatide interacts with the Wnt signaling pathway, the data suggest that teriparatide's effect occurs distal to this control point.

Bone Mineral Density is Reduced in Subjects with Familial Defective Apolipoprotein B-100. Laura Yerges-Armstrong^{*1}, Haiqing Shen¹, Elizabeth Streeten², Alan Shuldiner¹, Braxton Mitchell¹. ¹University of Maryland, USA, ²University of Maryland School of Medicine, USA, ³University of Maryland, Baltimore, USA

Although numerous epidemiologic studies have documented associations of osteoporosis and bone loss with cardiovascular disease, the mechanisms underlying this association remain to be clarified. One hypothesis is that hyperlipidemia may be a common predisposing factor to both atherosclerotic heart disease and accelerated bone turnover, although past results have been equivocal. To evaluate this hypothesis more fully, we have compared bone mineral density (BMD) between subjects with and without the R3500Q mutation that is responsible for familial defective apolipoprotein B-100 (APOB). While this mutation is relatively uncommon in most populations (<0.5% minor allele frequency), it is present at a higher frequency (~6%) in the Old Order Amish population due to a founder effect. In the Amish, each copy of this mutation is associated with a ~59 mg/dl increase in LDL cholesterol (LDL-C) levels. The relatively high frequency of the R3500Q mutation in the Old Order Amish population affords us the opportunity to evaluate skeletal traits for their association with this variant. We conducted analysis on 1068 Amish individuals from a population survey with DXA-measured BMD and who were genotyped for the R3500Q mutation in APOB. On average the population was 53.2 years old (range 20-95) and 52% were female. After adjusting for age, sex, BMI and family structure, carriers for the APOBQ risk allele had significantly lower BMD than non-carriers at the femoral neck (p=0.04), total hip (p=0.04) and lumbar spine (p=0.013). Sex stratified analyses revealed that this mutation was not associated with BMD at any skeletal site in men (p>0.2) but was associated with lower BMD at the femoral neck (p=0.005), total hip (p=0.0007) and lumbar spine (p=0.006). In women, the risk allele was associated with a 0.26-0.31 standard deviation lower BMD value at the three skeletal sites. It is possible that skeletal growth and homeostatic effects of estrogen may be muted in the hyperlipidemic environment, but additional studies to clarify the mechanism for this gender specific association are needed. These results utilize the unique genetic architecture of the Old Order Amish

population to expand on previous studies suggesting a common genetic link between cardiovascular and skeletal traits.

Large-scale Meta-analysis of Genome-Wide Association Studies for Bone Mineral Density at Radius: the GEFOS Consortium. Hou-Feng Zheng^{*1}, Laura Yerges-Armstrong², Joel Eriksson³, Emma Duncan⁴, Braxton Mitchell⁵, Claes Ohlsson⁶, Elizabeth Streeten⁷, Mattias Lorentzon⁶, Brent Richards⁸. ¹Department of Human genetics & Epidemiology & Biostatistics, McGill University, Canada, ²University of Maryland, USA, ³Center for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ⁴Royal Brisbane & Women's Hospital, Australia, ⁵University of Maryland, Baltimore, USA, ⁶Center for Bone Research At the Sahlgrenska Academy, Sweden, ⁷University of Maryland School of Medicine, USA, ⁸McGill University, Canada

Backgrounds: Recent Genome-Wide Association Studies (GWASs) have identified multiple common variants associated with bone mineral density (BMD) at lumbar spine and femoral neck sites. However, while all BMD sites across the body are partially correlated, they separately provide additional information on risks of fracture, particularly, site-specific fractures. **Aim:** To identify common genetic variants associated with BMD at the forearm, we performed a GWAS meta-analysis within the Genetic Factors of Osteoporosis (GEFOS) consortium. **Methods:** This meta-analysis comprised 4 cohorts (n=4,777). Association with radius BMD was tested for ~2.5 million imputed SNPs (HapMap CEU release 22, build 36) using linear regression models adjusted for sex, age, height, weight, family-relatedness and population stratification when applicable. Genetic effect estimates across studies were combined using an inverse-variance fixed-effects meta-analysis. **Results:** 60 SNPs in 7q31 showed genome-wide significance ($P < 5 \times 10^{-8}$), the most significant SNP was rs2536189 ($P = 3.99 \times 10^{-14}$, effect -0.16 standard deviations per risk allele). This locus maps to wingless-type MMTV integration site family member 16 (WNT16). WNT16 is a member of the Wnt signaling pathway that is known to play an important role in the regulation of bone mass and bone turnover. To investigate the effect of BMD loci on the fracture, we tested the 60 genome-wide significant SNPs in an independent cohort containing 273 forearm fracture cases and 1613 controls, and found that rs2254595 in WNT16, which was strongly associated with BMD ($P = 8.04 \times 10^{-13}$, $BETA = -0.14$), was also moderately associated with forearm fracture ($P = 9.92 \times 10^{-3}$, $OR = 1.28$). In addition, 37 SNPs showed suggestive association signals ($P < 5 \times 10^{-6}$), including 6 variants in known locus 5q14.3 (MEF2C, $P = 2.34 \times 10^{-6}$) and novel signals in or near 6q23 (RPS12, $P = 1.29 \times 10^{-6}$), 10p15 (DIP2C, $P = 1.26 \times 10^{-6}$), and 11p13 (PDHX and CD44, $P = 1.39 \times 10^{-6}$). **Conclusion:** In this first large-scale GWAS meta-analysis for forearm BMD, we identified WNT16 as an important genetic determinant of forearm BMD and fracture and highlighted other novel loci. These variants will soon undergo further replication in upcoming GWAS and by de-novo genotyping for BMD and fracture. These findings increase our understanding of the genetic basis of osteoporosis.

Inflammation Induces Expression of BMP3, an Inhibitor of Bone Formation, in Inflammatory Arthritis. Melissa Matzelle^{*1}, Anita Shaw¹, Jun Li¹, Sougata Karmakar¹, Catherine Manning¹, Nicole Walsh², Vicki Rosen³, Ellen Gravalles¹. ¹University of Massachusetts Medical School, USA, ²St Vincent's Institute of Medical Research, Australia, ³Harvard School of Dental Medicine, USA

In rheumatoid arthritis (RA), synovial inflammation leads not only to osteoclast-mediated articular bone erosion, but also to an inhibition of osteoblast-mediated bone formation. We have previously shown that formation of mineralized bone is reduced at bone surfaces adjacent to inflammation (erosion sites) in the murine K/BxN serum transfer (STA) model of inflammatory arthritis. Furthermore, cells within the arthritic synovium produce factors, including antagonists of the Wnt/ β -catenin signaling pathway, that impact osteoblast function. In addition to the Wnt signaling pathway, osteogenic BMP signaling is also critical to osteoblast differentiation. Mice deficient in BMP3, one known inhibitor of BMP signaling, accrue trabecular bone with age, supporting a role for BMP3 in the inhibition of osteoblast-mediated bone formation. To determine the potential role of BMP3 during inflammation-induced bone loss, STA was generated in 12 week-old C57Bl/6J mice and expression of BMP3 in the hind paws was assessed by immunohistochemistry, in situ hybridization, and quantitative RT-PCR (qPCR). BMP3 protein was expressed late in the course of arthritis, most notably by osteoblasts lining inflammation-bone interfaces and, to a lesser degree, by lining cells within the synovium. BMP3 mRNA expression followed a similar pattern histologically and as assessed by qPCR, with a maximal induction at day 15 in tissue isolated from the midfoot bones and a minimal induction in isolated synovial tissues. Given these cellular sources of BMP3 mRNA and protein, synovial fibroblasts and bone marrow-derived osteoblasts were isolated from C57Bl/6J mice and treated with the pro-inflammatory cytokines TNF, IL-1 β , or IL-17; expression of BMP3 mRNA was determined by quantitative RT-PCR (qPCR). TNF (10 ng/ml), but not IL-1 β or IL-17, induced expression of BMP3 mRNA approximately 20-fold in cultured synovial fibroblasts over the course of 72 hours. In contrast, IL-17 (10 and 50 ng/ml), but not TNF or IL-1 β , induced BMP3 expression 6-fold in mature differentiated osteoblasts (day 28). Together, these data implicate BMP3, which is induced within the inflamed synovium and in osteoblasts at sites of articular bone erosion, as a candidate factor that may contribute to focal bone loss in RA through impairment of osteoblast function.

Transplanted Mesenchymal Stem Cell-derived BMP2 Rescues Fracture Healing in BMP2-deficient Mouse Limbs. Timothy Myers^{*1}, Froilan Granero-Molto², Lara Longobardi², Yun Yan¹, Tieshi Li¹, Ying Li¹, Anna Spagnoli². ¹University of North Carolina, USA, ²University of North Carolina at Chapel Hill, USA

There is a compelling need to develop novel therapies to improve fracture healing and to treat fracture non-unions. Bone marrow mesenchymal stromal stem cells (MSC) are an attractive therapeutic approach due to their ability to differentiate into distinctive end stage mesenchymal cell types and secrete bioactive molecules that regulate the regenerative microenvironment. Previous results from our lab demonstrate that MSC transplant into a tibial fracture model improves healing through organization of the callus and bridge between gaps. Interestingly, only a small fraction of the transplanted MSC incorporate into new bone, suggesting the more substantial effect of MSC is due to the release of paracrine-acting factors. Bone morphogenetic protein-2 (BMP2) is a critical factor in fracture repair as evidenced by its early expression in fracture healing and the complete lack of initiation of repair in mice lacking BMP2 in mesenchyme limb progenitor cells. Our data reveals that MSC express BMP2 at the site of injury and uniquely along the endosteum. To determine the essential role of MSC-derived BMP2 in fracture healing, MSC were transplanted into mice haploinsufficient for BMP2 in early limb mesenchyme using Prx1Cre-mediated recombination (BMP2^{+/+}) with a stabilized tibia fracture. Fractured bones from BMP2^{+/+} and either BMP2^{+/+}/flox or BMP2^{flox/flox} control mice were dissected 14- and 21-days post-fracture and subjected to μ -CT, biomechanical and histological analyses. At both 14- and 21-days, BMP2^{+/+} mice had smaller calluses, less soft tissue and less new bone than control mice. Statistical significance was set at $p < 0.05$; $n \geq 5$ for each group. When MSC obtained from the bone marrow of control littermates were transplanted, formation of new bone was returned to wild type levels at day 14. Histological analyses revealed a decrease in the pre-osteoblast marker osterix at 7-days and the osteoblast marker osteocalcin at 14-days post-fracture in BMP2^{+/+} mice that was increased in MSC-BMP2^{+/+} mice. Biomechanical analyses supported the findings of rescued new bone levels. By 21-days, both MSC-BMP2^{+/+} and MSC-control mice exhibited the presence of increased highly mineralized bone that bridged the fracture gap from within the BM cavity and was mostly absent in untransplanted mice. These results demonstrate that MSC-derived BMP2 is sufficient to restore bone formation in BMP2-deficient mice through the paracrine regulation of intrinsic fracture healing cells.

Analysis of Wnt System Components in Cranial Defect Healing in CXC Receptor Knock-out (mCXCR^{-/-}) Mice by Microarray. David Bischoff^{*1}, Weibiao Huang¹, Erwin Kruger², Nalini Makhijani³, Dean Yamaguchi⁴.
¹VA Greater Los Angeles Healthcare System & David Geffen School of Medicine at UCLA, USA, ²UCLA, USA, ³VA GLAHS, USA, ⁴VA Greater Los Angeles Healthcare System, USA

The role of CXC chemokines bearing the glu-leu-arg (ELR⁺) motif in bone repair was studied using a mouse cranial defect (CD) model in mCXCR^{-/-} mice. During bone repair, ELR⁺ CXC chemokines, released by inflammatory cells, serve as angiogenic factors signaling through mouse CXC receptor (mCXCR) which is homologous to the human CXC receptor 2). Previously we showed that osteogenic differentiation of human mesenchymal stem cells increases expression of the ELR⁺ CXC chemokine, CXCL8, and that mice lacking mCXCR were osteopenic and had a defect in bone repair. In this study we explored the possibility of ELR⁺ chemokine signaling through the wnt system. We created 1.8 mm CDs in 6 week old male mCXCR^{-/-} and wild-type mice and allowed the CDs to heal for 7 days. RNA was isolated from the CD early callus and microarray analysis was used to determine >2-fold differences in wnt system gene expression with the Mouse Wnt Signaling Pathway RT² Profiler PCR Array from SABiosciences. Expression of several genes involved in degradation of β -catenin under non-wnt conditions was downregulated in mCXCR^{-/-} mice (APC, GSK3B, BtrC). Genes involved in canonical wnt signal activation (Dvl1, LRP5), β -catenin regulated transcription (TCF7, LEF1), lipidation of wnt proteins for secretion/activation (Porcn), and several genes involved in negative regulation of wnt signaling including NKD1 (inhibits Dvl1), DKK1 (inhibits LRP5), WIF1 (Frizzled [Fz] dummy receptor), Fz1B (soluble Fz1 receptor expressed in cartilage), and Sox17 (inhibits TCF transcription) were also downregulated. Expression of several wnt ligands and Fz1 receptors was also decreased in mCXCR^{-/-} mice including wnt4, wnt5a (non-canonical wnt signaling, inhibition of cell proliferation, chondrocyte differentiation), wnt5b, wnt6, wnt7a (CNS vascularity), Fz3 (wnt4 receptor), and Fz5 (yolk sac/placental angiogenesis, co-localization with wnt5a). There were only 5 genes up-regulated >2-fold and four have roles in cell proliferation including Fosl1, RhoU (induced by non-canonical wnt1), wnt2, and wnt11 (non-canonical signaling). The expression of cell proliferation co-repressors Tle1 and Tle2 was also decreased suggesting more cell proliferation in mCXCR^{-/-} mice, although due to lack of wnt signaling, less differentiation. Conclusion: mCXCR^{-/-} mice have decreased expression of genes involved in wnt activation/expression, inhibition of cell proliferation, and Fz1 receptors and wnt proteins involved in angiogenesis.

Differential Impact of Dkk1 Neutralizing Antibodies on Wnt Signaling and Bone Mineral Density. Wei Fan^{*1}, Grisanti Mario¹, Jilin Sun¹, Hsieng S. Lu¹, Xiaodong Li², William G. Richards¹. ¹Amgen Inc., USA, ²Amgen, Inc., USA

Dickkopf-1 (Dkk1) inhibits canonical Wnt signaling through different mechanisms: by promoting the internalization of the wnt co-receptors LRP5 and LRP6 through interactions with kremen proteins, and by directly blocking the ability of wnt proteins to bind these receptors. To study the role of this wnt signaling inhibitor in bone formation we developed antibodies that blocked the activity of Dkk1.

The neutralizing antibodies identified recognized distinct epitopes on Dkk1. Antibodies from bin A (Dkk1-AbA) recognized a C-terminal epitope on Dkk1, whereas antibodies from bin B (Dkk1-AbB) recognized a more N-terminal epitope. Dkk1-AbA was capable of blocking wnt signaling, as assayed in a wnt dependent TCF-lef luciferase assay, to a greater extent than Dkk1-AbB. Additionally, in co-immunoprecipitation experiments Dkk1-AbA was capable of blocking the interaction of Dkk1 with both LRP6 and Kremen2. Dkk1-AbB did not prevent the interaction of Dkk1 with either LRP6 or Kremen2.

To determine whether the cell-based and biochemical differences between the epitope bins translated into different responses on bone mineral density, six-week old male mice were injected with either Dkk1-AbA or Dkk1-AbB (3, 10 and 30 mg/kg; 2 times per week). After two-weeks of dosing the lumbar vertebrae (L1-L5) and whole leg were analyzed by DXA. Mice injected with the 30 mg/kg dose of Dkk1-AbA had a significant (P<0.05) increase in BMD compared to vehicle-injected control mice at both the lumbar vertebrae (0.057 vs. 0.050 g/cm²) and whole leg (0.056 vs. 0.051 g/cm²). BMD was not significant altered in mice injected with Dkk1-AbB. BMD in mice injected with Dkk1-AbA trended to be greater at all doses when compared to Dkk1-AbB, and was significantly greater (P<0.05) at the lumbar spine with the 30 mg/kg dose (0.057 vs. 0.051 g/cm²).

These data confirm the ability of Dkk1 inhibition to increase bone mass in growing mice. Furthermore the data indicate that antibodies recognizing different epitopes are capable of inhibiting Dkk1 activity by different mechanisms that translate into differential responses in both cell-based assays and in vivo. We suggest that Dkk1-AbA prevents Dkk1 from both blocking wnt binding to and promoting internalization of LRP5/6, and that Dkk1-AbB bound Dkk1 may not impair LRP5/6 internalization and likely prevents Dkk1 from blocking a subset of Wnts from binding LRP5/6.

Increased WNT Signaling in Sclerostin/Sostdc1 Double Knockouts Causes Preaxial Polydactyly. Richard Harland¹, Deepa Muruges², Gabriela Loots³, Cristal Yee⁴, Nicole Collette^{*2}. ¹University of California, Berkeley, USA, ²Lawrence Livermore National Laboratory, USA, ³LLNLUC Merced, USA, ⁴University of California, Merced, USA

Sclerostin (Sost) is negative regulator of bone formation; loss-of-function mutations associated with this gene cause sclerosteosis and van Buchem disease, two rare skeletal dysplasias characterized by increased bone density throughout the skeleton. Sostdc1 (aka Sostl, USAG-1, Wise, ectodin) is a paralog of Sost. Loss of Sostdc1 has been shown to cause supernumerary tooth development. Both proteins are secreted cysteine knot proteins that function as antagonists of both BMP and WNT signaling. We have recently shown that overexpression of human SOST causes dosage-dependent loss of distal posterior skeletal elements. This loss results from altered FGF, WNT, and SHH signaling during the patterning of the limb bud. Sostdc1 was shown by others to antagonize LRP receptor signaling and to similarly affect FGF and SHH signaling in the developing tooth bud, suggesting that Sostdc1 may antagonize similar pathways as Sost, in vivo. Sost knockout mice display a low penetrance (~5% of KOs) of limb defects consistent with the soft-tissue syndactyly, nail dysplasia, and radial deviation that occurs in some sclerosteosis patients; while Sostdc1 knockouts show no limb defects. Here we show that Sost; Sostdc1 double mutant mice exhibit preaxial polydactyly, a common limb-associated birth defect characterized by extra digit(s) in the anterior autopod, and is often caused by ectopic sonic hedgehog (Shh) expression in the anterior limb bud. Sost and Sostdc1 are expressed in complementary yet non-overlapping domains in the developing limb, where their combined domains cover most of the ectoderm and mesenchyme of the developing limb bud prior to cartilage condensation. Through a combination of skeletal stains and in situ hybridization we show here that Wnt signaling functions upstream of Shh to restrict Shh expression in the posterior limb. Through the release of Lrp5/6 receptor inhibition from Sost and Sostdc1 Wnt antagonists expressed in the ectoderm and mesenchyme, hyperactive Wnt signaling ectopically activates Shh in the anterior limb bud to transform autopod patterning and morphology.

Intermittent Injections Of Osteocalcin Improve Glucose Metabolism and Prevent Type 2 Diabetes In Mice. Mathieu Ferron^{*1}, Marc McKee², Patricia Ducy¹, Gerard Karsenty¹. ¹Columbia University, USA, ²McGill University, Canada

We have shown previously that the uncarboxylated form of the osteoblast-specific secreted molecule osteocalcin functions as a hormone favoring glucose handling and increasing energy expenditure. As a result, the absence of osteocalcin leads to glucose intolerance in mice, and genetically modified mice with an increase in uncarboxylated osteocalcin are protected from type 2 diabetes and obesity.

To assess the therapeutic relevance of these observations we tested whether osteocalcin injected once daily could affect glucose metabolism in wildtype (WT) mice. We show here that injection of osteocalcin (3 or 30 ng/g/day) once a day significantly improved glucose tolerance, as assessed by glucose tolerance tests (GTT), in WT mice fed a normal chow. Moreover, insulin sensitivity was also improved after 4 weeks of this regimen as measured by insulin tolerance tests (ITT). Blood glucose after feeding was significantly reduced following osteocalcin daily injections. Remarkably, daily injections of osteocalcin increased β -cell proliferation, β -cell mass and insulin secretion. Thus, daily injection of osteocalcin has a beneficial effect on glucose metabolism in mice fed a normal chow.

We next asked whether daily injections of osteocalcin could have these beneficial effects on glucose tolerance and insulin sensitivity in a model of diet-induced type 2 diabetes. To that end WT mice were fed a high fat diet (HFD) for 8 weeks and then injected once a day with osteocalcin (30 ng/g/day) for 8 weeks. Osteocalcin daily injections increased the number of mitochondria in skeletal muscle and stimulated energy expenditure, thereby preventing body weight gain. Moreover, fasting blood glucose and serum insulin levels were markedly reduced when compared to placebo-treated mice, and insulin sensitivity, as measured by the Homeostasis Model Assessment (HOMA), was partially restored. As a result, glucose tolerance was significantly improved in animals maintained on HFD and injected once a day with osteocalcin. Finally, the hepatic steatosis induced by HFD was completely absent in mice fed a HFD and receiving osteocalcin daily. Overall these results provide evidence that, at least in mice, osteocalcin injected once a day does improve glucose handling and prevents the development of type 2 diabetes.

Modulation of SDF-1/CXCR4 Axis Enhances rhBMP-2-induced Ectopic Bone Formation. Joel Wise, D. Rick Sumner, Amarjit Viridi*. Rush University Medical Center, USA

Enhancement of in vivo mobilization and homing of endogenous mesenchymal stem cells (MSCs) to an injury site is an innovative strategy for improvement of bone tissue engineering and repair. The present study was designed to determine if the delivery of agents known to affect mobilization (AMD3100) and homing (stromal cell-derived factor-1; SDF-1) of MSCs enhance de novo bone formation induced by rhBMP-2 in absorbable collagen sponges (ACS) in vivo at the ectopic implant site in an established rat model. Sprague-Dawley rats (male; ~350g; 12 weeks old) received intraperitoneal injection of either saline or AMD3100 treatment 1 hour prior to harvesting of bone marrow for in vitro CFU-F assay or the in vivo subcutaneous implantation of absorbable collagen sponges loaded with saline (n=6), rhBMP-2 (10µg; n=6), SDF-1 (200ng; n=6), or the combination of SDF-1 and rhBMP-2 (n=6), for ectopic bone formation assay.

AMD3100 treatment (n=5) resulted in a significant decrease in CFU-F number in bone marrow cultures, compared to saline (n=3), which confirmed that a single systemic AMD3100 treatment rapidly mobilized MSCs from the bone marrow. At 28 and 56 days, bone formation in the explanted ACS was assessed by microcomputed tomography (µCT) and histology. At 28 days, AMD3100 and/or SDF-1 had no statistically significant effect on bone volume (BV) or bone mineral content (BMC), but histology revealed more active bone formation with treatment of AMD3100, loading of SDF-1, or the combination of both AMD3100 and SDF-1, compared to saline-treated rhBMP-2 loaded ACS. At 56 days, the addition of AMD3100 treatment, loading of SDF-1, or the combination of both, resulted in a statistically significant stimulatory effect on BV and BMC, compared to the saline-treated rhBMP-2 loaded ACS. Histology of the 56-day ACS were consistent with the µCT analysis, exhibiting more mature and mineralized bone formation with AMD3100 treatment, SDF-1 loading, or the combination of both, compared to saline-treated rhBMP-2 loaded ACS. The present study is the first to provide evidence of the efficacy of AMD3100 and SDF-1 treatment to stimulate trafficking of MSCs to an ectopic implant site, in order to ultimately enhance rhBMP-2-induced long-term bone formation.

New Function of Nell-1 Protein in Regulating Bone Maintenance. Aaron James*, Xinli Zhang¹, Janette Zara², Michael Chiang¹, Wei Yuan¹, Raghav Goyal¹, Cymbeline Culiati³, Kang Ting¹, Chia Soo¹. ¹University of California, Los Angeles, USA, ²UCLA, USA, ³Oak Ridge Laboratories, USA

Introduction: Osteoporosis is a multifactorial disease process involving genetic and environmental etiologies. Nell-1 is a potent, pro-osteogenic molecule first identified to have osteogenic properties by its isolation from prematurely fusing cranial sutures. A recent study of genome wide polymorphisms implicated the cytokine Nell-1 in the etiology of osteoporosis.

Methods: This study expands on this association between Nell-1 and bone maintenance, by examining the effects of loss of function in Nell-1. Deficiency in Nell-1 was achieved via ENU-mutagenesis in mice. Analysis of the axial and appendicular skeleton was performed in neonatal, young (1 month) and aged (18 months) mice by high-resolution micro computed tomography (CT), live combined CT / fluoride ion incorporation assays, serum studies (serum TRAP5b, PINP), and standard histologic analysis.

Results: Although Nell-1 haploinsufficient mice appeared normal at birth and 1 month of age by all examined markers (N=10 per group), Nell-1 loss resulted in significant and severe osteopenia in aged mice, including significant reductions in BV, BMD and BV/TV (N=30 per group). This was due to a defect in bone formation (reduction in fluoride ion uptake and serum PINP concentration) as well as inappropriate osteoclast activity (increased TRAP5b concentration when normalized to bone volume). Histological analysis confirmed these biochemical and radiologic findings.

Discussion: Results demonstrate a new and critical role of Nell-1 in bone maintenance and osteoblast:osteoclast crosstalk. Not only is Nell-1 of importance in developmental bone biology, but these studies highlight a critical role of Nell-1 in bone maintenance across an animal's lifetime. This new finding has significant ramifications for the genesis of osteoporosis and potential new osteoporotic therapies.

Disclosures: Aaron James, None.

Transgenic Adult Murine Mesenchymal Stem Cells Conditionally Over-expressing SDF-1β Enhance New Bone Formation in Both *In Vitro* and *In Vivo* Model Systems. Samuel Herberg*, Sadanand Fulzele, Nianlan Yang, Galina Kondrikova, Khaled Hussein, Mohammed E. Elsalanty, Maribeth Johnson, Xingming Shi, Mark Hamrick, William D. Hill, Georgia Health Sciences University, USA

Purpose: BMSC differentiation is regulated through SDF-1. Interaction with its receptor CXCR4 directs the migration of stem cells in injury repair. In vitro preconditioning with SDF-1 prior to transplantation enhances cell engraftment and new tissue formation; however, it does not allow for direct modulation of SDF-1 in vivo. Tetracycline-dependent regulatory systems provide for tight control of transgene expression in vitro and in vivo. SDF-1α is the most abundant splice variant, however, SDF-1β is twice as potent. Recently, we described the development of a Tet-Off-SDF-1β transgenic stem cell line conditionally overexpressing SDF-1β. The current study evaluated the regenerative potential of this novel cell line using in vitro and in vivo analyses. **Methods:** In vitro osteogenic differentiation of Tet-Off-SDF-1β BMSCs was assessed using ELISA (osteocalcin; OCN), Alizarin red S (ARS) staining, and qRT-PCR analysis (e.g., OCN, Runx2, Col1) after culturing cells in differentiation medium BMP-2 for 21 d. Doxycycline (Dox) was added to suppress SDF-1β transgene expression in controls. For in vivo studies, lethally irradiated 6-month-old C57BL/6 male mice were given tibial transplants (left: 9.24x10⁵ cells/70 µl; right: saline for vehicle control). Control mice had access to Dox in drinking water +5% glucose. After 4 wks, animals were euthanized and tibias collected for BMD analysis and 3-D histomorphometry with µCT (e.g., BV/TV, Tb.N). **Results:** ELISA of Tet-Off-SDF-1β BMSCs (-Dox) revealed increased OCN production relative to controls. SDF-1β transgene expression accelerated and significantly enhanced osteogenic differentiation (BMP-2) compared to controls, detected by ARS staining (p<0.001). qRT-PCR confirmed that SDF-1β transgene expression enhanced BMP-2-induced upregulation of osteogenic markers (e.g., OCN: 17.2-fold/-Dox; 6.5-fold/+Dox; p<0.05). Tibial µCT analyses showed significant augmentation of new bone formation in experimental and control transplants relative to vehicle controls (p<0.0001). SDF-1β transgene expression resulted in even greater bone formation compared to controls (e.g., BV/TV: 46.0/-Dox; 28.5/+Dox; p<0.05). **Conclusion:** In vitro and in vivo analyses indicate a critical role of SDF-1β in BMP-2-induced osteogenic differentiation and high regenerative potential of our novel Tet-Off-SDF-1β transgenic stem cell line. Future studies will examine the use of these cells in acute and chronic bone injury models.

Ephrin B2-EphB4 Bidirectional Signaling Mediates the Actions of IGF-I Signaling in Regulating Chondrocyte and Osteoclast Differentiation. Yongmei Wang*, Hashem Elalieh, Wenhan Chang, Daniel Bikle. Endocrine Unit, University of California, San Francisco/VA Medical Center, USA

It has been proposed that chondrocytes, osteoblasts (OB) and osteoclasts (OCL) interact to control skeletal development, but the mechanisms underlying these interactions remain unclear. We and others have shown that insulin-like growth factor-I (IGF-I) stimulates proliferation and differentiation of these cells and is required for the interactions between OBs and OCLs via RANK/RANKL signaling. Recent studies found that ephrin B2-EphB4 bidirectional signaling mediates OB and OCL differentiation and communication. To address whether such signaling is involved in IGF-I action, we used knockout mouse models and in vitro culture systems to investigate the role of IGF-I signaling in regulating the interaction between chondrocytes and OCLs with particular attention to the role of ephrin B2/EphB4. In wild-type (WT) bones, immunohistochemistry demonstrated that ephrin B2 is expressed in OBs and OCLs, while EphB4 is expressed only in OBs. In the growth plate (GP) cartilage, both ephrin B2 and EphB4 are expressed in late-stage proliferating and prehypertrophic chondrocytes. The mRNA levels of ephrin B2, EphB4 and RANKL were decreased 40%, 43% and 88%, respectively, in mice lacking the IGF-I receptor (IGF-IR) specifically in chondrocytes (cart.IGF-IR KO, floxed IGF-IR X type II collagen driven Cre recombinase) compared with their WT littermates. In mice with an IGF-IR null mutation in OCLs (OCLIGF-IRKO), (floxed IGF-IR X TRAP5b driven Cre recombinase), immunohistochemistry identified a reduction in ephrin B2 not only in OCLs, but also, to our surprise, in the late-stage proliferating and prehypertrophic chondrocytes in the GP. In vitro, blocking the interaction of EphB4 and ephrin B2 by TNYL-RAW in ATDC5 cell cultures (a chondrocyte cell line) significantly decreased mRNA levels of type II collagen (40%) and type X collagen (45%), and reduced the mineralization in the cultures. Compared with the vehicle treated co-cultures of ATDC5 cells and OCL, blocking the interaction of EphB4 and ephrin B2 by TNYL-RAW in these co-cultures decreased the formation of TRAP positive cells by 55%, with a 43% reduction in the mRNA levels of NFATc1. OPG was much less effective in preventing ATDC5 induction of OCL formation. Our data indicate that IGF-I/IGF-IR modulates OCL and chondrocyte differentiation in part through the ephrin B2/EphB4-mediated cell-cell interactions.

Requirement of Shp2 in Chondrogenesis and Cartilage Homeostasis. Yingnan Yu^{*1}, Jianguo Wang², Kai Zhao², Douglas Moore², Zhengke Wang³, Qian Wu⁴, Di Chen⁵, Quesenberry Peter⁶, Wentian Yang⁷. ¹Brown University Alpert Medical School & Rhode Island Hospital, USA, ²Departments of Orthopedics, RI Hospital & Brown University Alpert Medical School, USA, ³Roger Williams Hospital, USA, ⁴Department of Pathology & Laboratory Medicine, University of Connecticut Health Center, USA, ⁵Center for Musculoskeletal Research, Department of Orthopaedics & Rehabilitation, University of Rochester, Rochester, NY, USA, ⁶Departments of Medicine, RI Hospital & Brown University Alpert Medical School, USA, ⁷Brown University Alpert Medical School, USA

The src homology 2 domain-containing protein tyrosine phosphatase (PTPase) Shp2 (Ptpn11) is required for most, if not all, receptor tyrosine kinases (RTK), cytokines and extracellular matrix protein signaling to regulate the proliferation and differentiation of various types of cells, but its role in chondrogenesis and cartilage homeostasis remains elusive due to the early embryonic lethality caused by global Shp2 deficiency. Understanding how cellular signal transduction governing chondrogenesis and cartilage homeostasis is regulated by PTPase Shp2 will provide insights for developing novel therapeutics to treat cartilage-related skeletal diseases. We hypothesize that Shp2 is essential for chondrocyte development and cartilage homeostasis by regulating RTK and cytokine signaling in chondrocytes. To test this hypothesis, we previously generated a Ptpn11 floxed allele; mice carrying Ptpn11 floxed allele were crossed to collagen 2 α 1-Cre(Col2 α 1-Cre) and tamoxifen inducible Col2 α 1-Cre (Col2 α 1-CreERTm) mice respectively to generate cartilage-specific Shp2 deficient animals. Surprisingly, mice lacking Shp2 in Col2 α 1-expressing cells were embryonic lethal (around E11.5). Inducible ablation of Shp2 in these cells leads to dwarfism and multiple joint deformations by impairing both the column organization of growth plate cartilage and the cellular structure of articular cartilage. Expression of chondrogenic genes Sox9, runx2, Col2 α 1 and Col10 α 1 were all compromised in the epiphyseal cartilage of Shp2 mutant mice. By focusing on IGF1 signaling in chondroprogenitor ATDC5 cells, we found that Shp2 is required, at least, for IGF1-evoked chondrogenesis by negatively regulating the tyrosyl phosphorylation of IGF1-Rbeta, IRS1 and subsequent Erk and Akt activation. Altered signaling in these pathways in Shp2 mutant chondrocytes may contribute to the defective chondrogenesis and cartilage homeostasis. Our study found that Shp2 is a key regulator for chondrogenesis and cartilage homeostasis. Manipulating Shp2 and Shp2-regulated signaling pathways in cartilage has the potential for developing novel means to prevent and treat cartilage developmental and degenerative diseases.

Decreased Bone Formation and Bone Resorption Following Fracture in Osteoblast-Osteocyte Specific Connexin 43 Deficient Mice. Alayna Loiselle^{*1}, Emmanuel Paul², Gregory Lewis², Henry Donahue³. ¹Penn State Hershey, USA, ²Penn State College of Medicine, USA, ³The Pennsylvania State University College of Medicine, USA

Connexin 43 (Cx43), the most abundant gap junction protein in bone, is required for osteoblast differentiation. Mice with osteoblast/osteocyte specific loss of Cx43 display decreased gap junctional intercellular communication (GJIC), bone density and cortical thickness. To determine the role of Cx43 in fracture healing, a closed fracture was produced in femurs by three-point bending in Osteocalcin-Cre+; Cx43^{flx/flx} (Cx43cKO) and Cre- Cx43^{flx/flx} (WT) mice. We tested the hypothesis that loss of Cx43 results in decreased bone formation and impaired healing following fracture.

Abundant Cx43 expression was observed in the fracture callus in WT but not Cx43cKO mice, between 10 and 35 days. Alterations in bone formation were observed in Cx43cKO fractures with decreased areas of mineralized tissue, relative to WT, in the fracture callus. This observation was consistent with decreased Collagen I expression, and a significant decrease in total bone volume at day 28 (WT:2.7 0.7; KO:1.3 0.5, n=5, p=0.04). A dramatic reduction in the size of the callus, relative to WT fractures, occurred by 21 days in Cx43cKO fractures. Additionally, there was a significant decrease in TRAP+ osteoclast number in Cx43cKO fractures compared to WT at 14 and 28 days post-fracture (Day 14- WT:62.5 2.6, KO:31.6 1.9 p=0.021; Day 28- WT:33.9 2.8, KO:13.4 3.6, p=0.024, n=4). Furthermore, using a novel μ CT parameter to measure low-density bone volume (BVlow) as an indicator of remodeling, a significant decrease in BVlow was detected at 28 days in Cx43cKO fractures compared to WT (WT: 0.8 0.15; KO:0.38 0.02, p=0.038, n=5). RANKL was decreased, while Osteoprotegerin was increased in Cx43cKO compared to WT fractures by *in situ* hybridization. Taken together, these data suggest that Cx43cKO fractures, relative to WT fractures, heal with less mineralized callus formation, and subsequently decreased osteoclastic remodeling. Despite changes in both bone formation and osteoclastic remodeling, there was no significant difference in the ultimate torque at failure in WT and KO fractures at 21(WT: 18.3 3.2, KO:19.5 5.7) and 35 days post-fracture (WT:18.8 4.1, KO:21.2 4.1).

These studies identify a novel role for the gap junction protein Cx43 during fracture healing, suggesting that loss of Cx43 can result in both decreased bone

formation, and bone resorption. Therefore, enhancing Cx43 expression or GJIC may provide a novel means to enhance bone formation during fracture healing.

Disruption of the Runx2 Response to SMAD signaling Affects Bone Turnover in Adult Mice. Yang Lou^{*1}, Sadiq Hussain², Dana Frederick², Andre Van Wijnen², Garv Stein², Jane Lian², Janet Stein². ¹University of Massachusetts, USA, ²University of Massachusetts Medical School, USA

Bone morphogenetic protein (BMP) and transforming growth factor- β (TGF β) are required for bone formation and bone turnover *in vivo*. Previous studies have shown that three critical residues (HTY426-428) of the transcription factor RUNX2 are required for its interaction with Smad proteins. Mutation of HTY426-428 to AAA426-428 can abolish the activity of RUNX2 to execute and complete BMP2/TGF β signaling for osteoblastogenesis in culture. Here, we describe a mouse model with this triple amino acid mutation inserted into the endogenous Runx2 locus to test the consequences of disruption of a Runx2-Smad transcriptional complex *in vivo*. Although development of craniofacial intramembranous bone appeared normal immediately after birth, the RUNX2^{HTY426-428AAA} mice began to exhibit increased trabecular bone by 3 months of age. Compared to wild-type, the adult homozygous mice have similar bone length but have an extended length of trabecular area in tibia and femur (P<0.01) together with a decreased bone marrow cavity area, observed by histology and microCT imaging. Dynamic bone formation measurement of femurs in 5-month-old mice show no significant difference between wild type and mutants. Histological analysis reveals that the homozygous mice have fewer osteoclasts in the trabecular bone area and significantly decreased mRNA levels of TRAP (n=5 mice per group, P<0.01), as well as lower levels (about ~25% decrease) of RANKL in the metaphyses of the tibia. Because RANKL is regulated by Runx2-related BMP2 signaling, our results suggest that bone resorption is partly compromised by the Runx2HTY mutation, which caused increased trabecular bone in our RUNX2^{HTY426-428AAA} knock-in mice. Taken together, our findings suggest that a RUNX2-SMAD functional complex may be dispensable for normal skeletal development, but is required for the balance between bone formation and bone resorption *in vivo*.

Osterix Deficiency Disrupts Ameloblast and Odontoblast Maturation but Not Tooth Morphogenesis. Ji-Myung Bae^{*1}, Harunur Rashid¹, Haiyan Chen², David Summerford¹, Mitra Adhami¹, Dobrawa Napierala³, Krishna Sinha⁴, Soraya Gutierrez⁵, Benoit DeCrombrughe⁴, Amjad Javed². ¹School of Dentistry, University of Alabama at Birmingham, USA, ²University of Alabama at Birmingham, USA, ³University of Alabama at Birmingham School of Dentistry, USA, ⁴UT MD Anderson Cancer Center, USA, ⁵Universidad De Concepcion, Chile

Runx2 and Osterix (Osx) are master genes essential for osteoblast differentiation and bone formation. In humans, mutations in Runx2 and Osx are associated with CCD and osteogenesis imperfecta, respectively. Tooth development in Runx2 null mice is arrested at late bud stage. Unlike Runx2, nothing is known about Osx role in tooth morphogenesis or differentiation of ameloblasts and odontoblasts. During skeletogenesis, Osx functions downstream of Runx2, but it is not clear if both act independently or are part of the same pathway that controls tooth morphogenesis. To investigate tooth development we established Osx null mouse and performed analysis at embryonic day 18 (E18), a stage by which basic morphogenesis is established. In sharp contrast to Runx2, tooth development in Osx null mice progressed till late bell stage. The incisor and multi-cusped 1st and 2nd molar were noted in wild type (WT) and homozygous mutants. During normal development, tooth epithelium differentiates into ameloblasts that synthesize enamel, and tooth mesenchyme gives rise to odontoblasts which produce dentin. Maturation of both cell types progressed simultaneously in WT embryos with elongated and well separated ameloblasts and odontoblasts. However, Osx null showed only cuboidal and aggregated cells in epithelial and mesenchyme portions of teeth. To better understand if the Osx null reflects a developmental arrest or a delayed differentiation, we compared tooth organs of new born littermates. WT mice clearly exhibited nuclear polarity with columnar shape of ameloblast and odontoblast. Osx null mutants on the other hand showed only cuboidal and disorganized cells as noted at E18. Together, these data demonstrate that during tooth development, Osx is required for maturation of both ameloblast and odontoblast. Since the Osx null died shortly after birth, we analyzed post-natal tooth development in surviving heterozygotes (Het). Although we observed normal and age appropriate dentition in both mice, ameloblasts and odontoblasts of WT were well differentiated from a morphological standpoint than those of Het mice. Moreover, the deposited enamel and dentin layers were 20-24% smaller in Het mice. Thus Osx haploinsufficiency affect the terminal phases of ameloblast and odontoblast differentiation. In conclusion, we report for the first time that Osx is obligatory for epithelial and mesenchymal cell signaling but not tooth development.

Protection of Bone Loss by Targeting of Semaphorin 4D Expressed by Osteoclasts. Takako Koga*, Masahiro Shinohara, Hiroshi Takayanagi. Tokyo Medical & Dental University, Japan

Bone is continuously renewed by a process called bone remodeling, in which the resorption phase is followed by the formation phase. Each of these phases and also the transition between them requires a fine regulation by humoral factors or molecules mediating the communication among bone cells, which are either secreted by bone cells, expressed on the membrane of bone cells or released from the bone matrix.

Osteoporosis results from an ongoing imbalance between the processes of bone formation and resorption. While most of the currently available drugs inhibit the osteoclastic bone resorption, there are a few drugs which promote the osteoblastic bone formation. It is thus becoming increasingly important to identify the factors which regulate bone formation.

We found that osteoclasts express semaphorin 4D (Sema4D), known as an axon guidance molecule, which potentially inhibits bone formation. As expected, the mice lacking Sema4D exhibited the high bone mass phenotype due to an increase in bone formation activity by osteoblasts. We found that the binding of Sema4D to its receptor Plexin-B1 on osteoblasts led to the activation of the small GTPase RhoA, which inhibited osteoblast differentiation. Similar to Sema4D knockout mice, both Plexin-B1 knockout mice and the mice expressing dominant negative-RhoA specifically in osteoblasts had a high bone mass. Notably, anti-Sema4D antibody treatment significantly prevented bone loss in a model of postmenopausal osteoporosis.

Thus, this study identifies osteoclast-derived Sema4D as a crucial mediator of osteoclast-osteoblast communication in bone remodeling. Sema4D may function as an inhibitor of bone formation in the bone resorption phase, in which osteoblast differentiation and function are suppressed until osteoclastic bone resorption is accomplished. Now Sema4D has emerged as a new therapeutic target for the discovery and development of bone-increasing drugs.

R-spondin 2 is a New Key Player in Human Osteoarthritis Osteoblasts to Orchestrate Their Abnormal Canonical Wnt Signaling. Elie Abed*, Thomas Chan¹, Aline Delalandre¹, Johanne Martel-Pelletier¹, Jean-Pierre Pelletier¹, Daniel Lajeunesse². ¹CHUM, Hopital Notre-Dame, Canada, ²CRCHUM, Hopital Notre-Dame, Canada

The canonical Wnt/ β -catenin (cWnt) signaling pathway plays a key role in osteogenesis by promoting the differentiation and mineralization of osteoblasts (Ob). R-spondin-1 (Rspo1) and 2, members of a family of secreted proteins, act as Wnt agonists and are present in bone tissues. Both clinical and in vitro studies suggest that subchondral bone sclerosis and altered bone remodeling, due to abnormal functions of Ob, are involved in the progression and/or onset of osteoarthritis (OA). Here, we questioned if an alteration of cWnt in OA Ob could be responsible for their abnormal osteogenesis and the potential role of Rspo1 and 2 in this process. We prepared primary human subchondral Ob using the sclerotic medial portion of the tibial plateaus of OA patients undergoing total knee arthroplasty, or from normal individuals at autopsy. The expression and production of Rspo1 and 2 were evaluated by qRT-PCR and by Western blot (WB) analysis. The regulation of Rspo1 and 2 was evaluated in response to transforming growth factor- β 1 (TGF- β 1) and the differentiation of Ob. The inhibition of Rspo2 was performed using siRNA and the effect of Rspo2 was evaluated using human recombinant Rspo2. cWnt signaling was evaluated by measuring target gene activity using the TOPflash TCF/lef luciferase reporter assay, and intracellular β -catenin levels by WB. Mineralization was evaluated by Alizarin red staining. TGF- β 1 expression and production were evaluated by qRT-PCR and ELISA. The expression and production of Rspo1 were similar in all Ob whereas they were reduced for Rspo2 in OA Ob compared to normal. TGF- β 1 expression and production were elevated in OA Ob, and TGF- β 1 reduced Rspo2 expression in all Ob. Wnt3a-dependent cWnt signaling and mineralization were reduced in OA Ob compared to normal. Recombinant human Rspo2 alone failed to trigger cWnt signaling in OA Ob, however, it stimulated about two-fold the Wnt3a-dependent cWnt signaling in these cells and increased their β -catenin levels. Rspo2 treatments also corrected the abnormal mineralization of OA Ob. Conversely, inhibition of Rspo2 by siRNA reduced cWnt signaling and the mineralization of normal Ob. These data demonstrate for the first time that Rspo2 is a new key player in abnormal OA Ob function. Reduced Rspo2 levels in OA Ob are responsible, at least in part, for their reduced cWnt signaling and abnormal mineralization. As Rspo2 is a secreted soluble protein, this could lead to potential new avenues of treatment of OA.

FR0235

Vitamin D Signaling in Osteoblasts/Osteocytes Is Required to Shift Calcium from Bone to Serum. Liesbet Lieben*, Karen Moermans¹, Lynda Bonewald², Jian Feng³, Geert Carmeliet¹. ¹Katholieke Universiteit Leuven, Belgium, ²University of Missouri - Kansas City, USA, ³Texas A&M Health Science Center, USA

The direct role of active vitamin D, 1,25(OH)₂D, on the skeleton is unclear. The beneficial effects of vitamin D receptor (VDR) signaling are mainly attributed to the stimulation of intestinal calcium transport and we recently observed that increased 1,25(OH)₂D levels reduce bone mass and mineralization to transfer calcium to serum in response to a negative calcium balance. We therefore hypothesized that VDR action in bone is redundant when sufficient calcium is absorbed, but is crucial to preserve normocalcemia when calcium supply is compromised. To validate this hypothesis, we genetically inactivated the VDR in the late stages of the osteoblastic lineage, by crossing *Vdr*^{fllox} mice with *Dmp1-Cre* mice (*Vdr*^{fllox}).

On a standard calcium diet, *Vdr*^{fllox} mice displayed no abnormalities in calcium and bone homeostasis. Serum calcium levels and bone mass (μ CT) were comparable to *Vdr*^{fllox} mice. Osteoblast differentiation and function was not changed as assessed by serum osteocalcin, gene expression of osteoblastic differentiation markers, histomorphometric analysis of osteoblast number and osteoid abundance, and dynamic bone formation parameters. Also bone resorption was unaltered, shown by normal serum CTx levels, *Rankl/Opg* mRNA ratio, and presence of TRAP⁺ cells. No manifest defects were observed in the osteocytes as histological and gene expression analysis revealed regular cell numbers and differentiation markers.

An inappropriate increase of 1,25(OH)₂D is known to cause hypercalcemia and bone defects. In *Vdr*^{fllox} mice, 1,25(OH)₂D treatment (0.5 μ g/kg BW/d for 1 wk) indeed resulted in hypercalcemia and mobilization of calcium from bone through an increase in bone resorption (serum CTx) and inhibition of bone mineralization (excess osteoid). In *Vdr*^{fllox} mice, the increase in serum calcium was less pronounced and bone mass was better preserved with normal CTx and osteoid levels. *In vitro* experiments confirmed that 1,25(OH)₂D inhibits the mineralization of osteoblastic (MC3T3-E1) cells and showed that this effect was accompanied by increased levels of the mineralization inhibitor PPI (pyrophosphate). Lowering PPI levels rescued the 1,25(OH)₂D-mediated inhibition of mineralization.

In conclusion, these findings demonstrate that VDR signaling in late osteoblasts/osteocytes is not essential for bone homeostasis in normal conditions, but that VDR is required to transfer calcium from bone to serum by increasing bone resorption and inhibiting mineralization via increased PPI levels.

Disclosures: Liesbet Lieben, None.

Environment Contaminant Tributyltin-Induced Osteoporosis: Distinct Involvement of PPAR γ and RXR in Suppression of Osteogenesis. Amelia Baker*, Brett D Meeks¹, Faye V. Andrews², Danielle Salazar¹, Louis Gerstenfeld¹, Jennifer Schlezinger³. ¹Boston University School of Medicine, USA, ²Boston University School of Public Health, USA, ³Boston University School of Public Health, USA

Bone marrow performs multiple functions, from maintaining bone homeostasis to sustaining hematopoiesis. The balance of differentiation of multipotent mesenchymal stromal cells (MSC) between osteogenesis and adipogenesis is a central element of bone homeostasis. Peroxisome proliferator activated receptor γ (PPAR γ) sits at the crossroad, promoting adipogenesis and suppressing osteogenesis. Exposure to environmental PPAR γ agonists (phthalates, organotins) is ubiquitous. Tributyltin (TBT) is unique in that it is a highly potent ligand for both PPAR γ and retinoid X receptors (RXR). While PPAR γ forms a permissive heterodimer with RXR, it has recently been shown that the efficacy of heterodimer activation by RXR ligands is cell-type dependent. Here, we determined the mechanisms by which TBT alters MSC differentiation and, subsequently, impacts bone structure. We also explored the role of RXR and the permissivity of PPAR γ during the differentiation of primary MSCs. TBT's ability to bind PPAR γ and RXRs suggests that it would have similar yet distinct effects than either a PPAR γ (rosiglitazone; Rosi) or RXR (bexarotene; Bex) agonist. TBT, Rosi, and Bex increased adipocyte-specific proteins (PPAR γ 2, FABP4) with similar potency (EC50 ~10 nM) but differing efficacy (Rosi>TBT>Bex) in a PPAR γ -dependent manner in an MSC line (BMS2). Knockdown of PPAR γ reduced adipogenic response (Nile Red staining) to TBT to a lesser extent than to rosiglitazone. Gene expression studies support the idea that the TBT-induced transcriptional program is distinct from that induced by Rosi. While both induce FABP4, induction of TGM2 and ABCA1 only by TBT suggests recruitment of multiple nuclear receptor pathways (RXR homodimers and LXR/RXR, respectively). In primary bone marrow cultures, TBT induced adipogenesis and suppressed osteogenesis (alkaline phosphatase activity, nodule number, mineralization); Bex suppressed osteogenesis without stimulating adipogenesis; Rosi dramatically increased adipogenesis and also suppressed osteogenesis. *In vivo* exposure to TBT and Rosi altered serum markers of bone turnover (TRAP5b, PINP), decreased cortical thickness and increased marrow adiposity by histology. These data suggest TBT alters bone homeostasis and that RXR and PPAR γ may contribute independently to TBT-induced adipogenesis and reduction in osteogenesis. These studies show that exposure to TBT shifts MSC differentiation *in vitro* from osteoblasts to adipocytes and *in vivo* leads to bone loss.

defects in hair, teeth and bone development. Although clinical observations suggest that *Dlx3* plays a crucial role in craniofacial bone development, the function of *Dlx3* in these tissues has not been elucidated.

As *Dlx3* is expressed in several structures derived from the neural crest cell population, including craniofacial bones, we address the role of *Dlx3* in craniofacial bone development by deleting *Dlx3* in the neural crest using *Wnt1-cre* and *Dlx3*-floxed mice.

Our data show that mice lacking *Dlx3* (cKO) in the neural crest exhibit developmental defects in craniofacial bone structure. High-resolution X-ray and micro-CT analysis at 8 weeks reveal that cKO mice present higher alveolar bone porosity, a more rounded shape for the calvarial bones, suggesting an early developmental defect, and a significant reduction in parietal and frontal bone thickness ($p < 0.01$) compared to controls. These defects are associated with a significant decrease ($p < 0.0001$) in bone mineral density in alveolar, frontal and parietal bones of cKO mice. In addition to bone defects, cKO mice also exhibit teeth malformations such as dentin hypoplasia.

At the molecular level, microarray and qPCR analysis at P0 show that the neural crest deletion of *Dlx3* alters the mRNA expression of several markers of bone and tooth involved in mineralized tissue formation in cKO mice (e.g. Osteocalcin).

In this study, we establish that neural crest specific deletion of *Dlx3* results in alterations in bone structure, in bone mineral density, and in the expression of proteins associated with a mature mineralized tissue. Our findings demonstrate that the expression of *Dlx3* in neural crest-derived cells is essential for normal development of teeth, and mandible/ calvarial bones that are formed by intramembranous ossification.

Identification of a Transcriptional Network Associated with Osteoblast Activity Using Systems Genetics. Charles Farber¹, Ana Lira¹, Brian Bennett², Luz Orozco², Hyun Kang², Calvin Pan², Eleazar Eskin², Aldons Lusis². ¹University of Virginia, USA, ²University of California, Los Angeles, USA

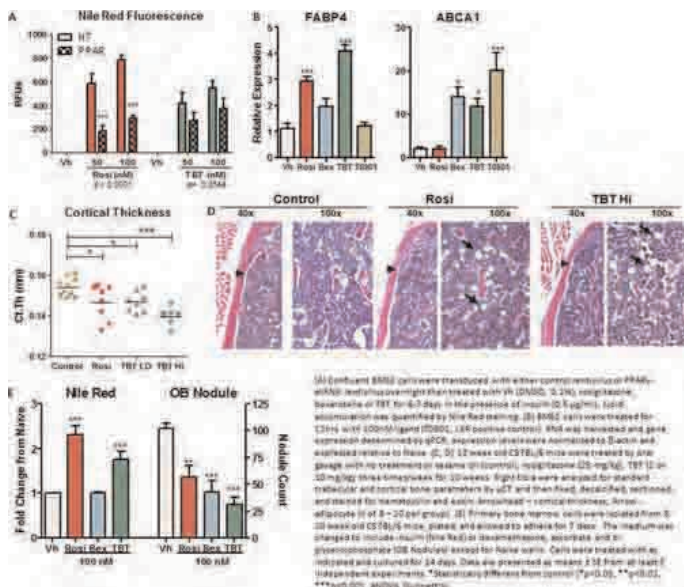

One of the main goals of systems genetics is to unravel the molecular mechanisms of disease by determining how genetic variation perturbs cellular networks. Here, we used systems genetics to identify and characterize an *in vivo* gene co-expression network for cells of the osteoblast lineage. A gene co-expression network was generated using bone microarray data from 96 different inbred mouse strains that are part of the Hybrid Mouse Diversity Panel. The resulting network consisted of 10 co-expression gene modules. Of the 10, one module (the purple module or PM) of 259 genes was significantly enriched for genes that were i) preferentially expressed in osteoblasts and ii) known to participate in osteoblast biology. These data suggested that PM genes and their interactions were important for osteoblast activity. To investigate the importance of the PM in an independent model, siRNAs were used to knockdown the expression of its most highly connected gene, *Maged1*, in primary calvarial osteoblasts. The reduction in *Maged1* preferentially altered the expression of PM genes (but not genes from other modules), and increased osteoblast proliferation and differentiation. We next identified specific genetic variants in the mouse genome that regulated the expression of PM genes. This analysis uncovered a single nucleotide polymorphism (SNP) on Chromosome 8 that was significantly associated with PM gene expression. This SNP was located ~20 Kbp downstream of *Sfrp1*, an antagonist of Wnt signaling and a known negative regulator of osteoblast proliferation and differentiation. This SNP was also found to regulate *Sfrp1* expression. Causality modeling predicted that 162 of the 259 PM genes were downstream targets of *Sfrp1*. Many of these genes have not been previously implicated in osteoblast function. This work identifies a novel network of genes involved in regulating osteoblast activity in mice.

Overexpression of Transcription Factor Pitx1 Inhibits Osteoblast Differentiation and Bone Mineralization. Alain Moreau¹, Nancy Karam², Anita Franco³. ¹Sainte-Justine Hospital, Canada, ²Sainte-Justine University Hospital Research Center, Canada, ³Sainte-Justine-University Hospital Research Center, Canada

During mouse development, PITX1, a homeobox transcription factor, is highly expressed in articular joints and in the perichondrium of hind limb long bones suggesting its importance in skeletal development. Indeed, Pitx1-null mice displayed poorly developed joints with reduced length of adjacent skeletal elements exhibiting a marked expansion of the hypertrophic chondrocyte zone in the growth plate. Interestingly, ageing Pitx1^{+/+} heterozygous mice, which are normal at birth, progressively developed OA-like lesions in cartilage associated with a drastic increase in cortical and trabecular bone formation. Conversely, expression analysis of osteoblasts derived from monozygotic twins discordant for osteoporosis reported a 10-fold up-regulation of Pitx1 expression in osteoblasts from osteoporotic twins when compared to healthy ones. Collectively, these data prompted us to investigate the role of this transcription factor in osteoblast differentiation and bone mineralization. Transgenic mice (mCol1a1-Pitx1) over-expressing Pitx1 specifically in bone tissue

Epigenetic Regulation of Mesenchymal Cell Commitment to the Osteoblast Lineage by *Dlx3*. Jonathan Gordon¹, Mohammad Hassan¹, Hai Wu¹, Maria Morasso², Andre Van Wijnen¹, Janet Stein¹, Gary Stein¹, Jane Lian¹. ¹University of Massachusetts Medical School, USA, ²Developmental Skin Biology Section, NIAMS/NIH, USA

Homeobox genes encode DNA-binding proteins well known for their ability to establish body axes during embryonic development and regulate lineage commitment in a wide variety of cells. Homeodomain proteins are primary targets for a wide variety of signaling molecules and are primary mediators involved in the initiation of chromatin remodeling during lineage commitment. One specific homeodomain-containing protein, *Dlx3*, is vital for craniofacial development and has been reported to activate several gene promoters in osteoprogenitors and early stage osteoblasts. In order to establish the role of *Dlx3* in mesenchymal cell commitment, a genome-wide screen of *Dlx3* targets in bone marrow stromal cells undergoing osteogenic differentiation was performed using chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-seq). Analysis of *Dlx3* binding sites within the mouse genome revealed that *Dlx3* associates primarily with the conventional homeobox group A motif (TAAAT), which is mainly distributed within intergenic and promoter regions of genes encoding known osteogenic regulators. Thus we find *Dlx3* bound to osteoblast growth and differentiation markers (*Twist2*, *Spp1*, *Gli3*, *Smad2*, *Ibsp*, *Bglap2*), as well as several homeodomain-containing proteins involved in developmental regulation and tissue morphogenesis (*Pknox2*, *Pax8*, *Six2*, *Irx6*). *Dlx3* is bound to the proximal promoters (<2000 bp from transcriptional start site) of 356 genes. Analysis of H3K4 trimethylation (related to chromatin activation) demonstrated that *Dlx3* was associated with 232 active genes. Analysis of H3K9 trimethylation (linked to chromatin repression) revealed *Dlx3* association with 63 repressed genes. *Dlx3*-mediated gene expression was validated using cells isolated from mice with conditionally ablated *Dlx3* or BMSCs treated with *Dlx3*-shRNA. Gene ontology analysis of genes regulated by *Dlx3* in BMSC-derived osteoblastic cells suggests that *Dlx3* plays a central role in several regulatory loops involved in tissue morphogenesis, cell fate commitment and skeletal development. The present studies support an important role for homeodomain proteins in promoting adult bone development and provide mechanistic insight for increased bone density in *Dlx3*-conditional null mice. In addition, these results may provide insight into the bone mass phenotypes in patients with aberrant *Dlx3* protein (TDO).

Expression of *Dlx3* in Neural Crest-derived Cells Is Essential for Normal Formation of Craniofacial Bones. Olivier Duverger¹, Juliane Isaac¹, Anne K. Bartels¹, Angela Zah¹, Jane Lian², Ariane Berdal³, Joonsung Hwang¹, Maria I. Morasso¹. ¹Developmental Skin Biology Section, NIAMS/NIH, USA, ²University of Massachusetts Medical School, USA, ³INSERM, UMR872, Universites Paris 5 & 6, Team 5, France

Human mutations in the homeodomain transcription factor *DLX3* gene are etiologic to Tricho-dento-osseous (TDO), an ectodermal dysplasia characterized by

under the type-I collagen promoter (2.1kb fragment) were generated and phenotypically characterized. MicroCT analysis showed a 30% decrease in the cortical thickness of transgenic mice affecting both males (M) and females (F) at 2, 5 and 7.5 months ($p < 0.0025$), a decrease in the trabecular thickness by 15 to 30% and a 16% to 50% reduction in the trabecular separation and connectivity, with a shift of the trabecular micro-architecture from rod-like to plate-like forms when compared to the wild-type ones. Biomechanical assessment of transgenic bones (femurs) using the tribending test points revealed a reduction of 25% and 58% in bone strength for females and males respectively when compared to age- and sex-matched wild-type mice ($F p < 0.037$ and $M p < 0.042$). At the biochemical level, plasma OPG levels were increased by 50% ($p < 0.0046$) and RANKL levels decreased by 50% in transgenic mice when compared to wild-type ones suggesting a compensatory mechanism to alleviate the effects of PITX1 by reducing osteoclastogenesis. Differentiation assays *in vitro* showed that overexpression of PITX1 hardly abrogates the maturation of mColla1-Pitx1 osteoblasts when compared with wild-type ones. Collectively, these data define an unrecognized and crucial role for PITX1 in the regulation of osteoblast differentiation and bone mineralization.

Activation of Distinct Nucleotide Receptor Subtypes Determines the Duration of Calcium-NFATc1 Signaling in Osteoblasts over a Remarkably Wide Dynamic Range of ATP Concentrations: A Novel Mechanism for Dose-to-Duration Coupling. Matthew Grol¹*, Shu Xing², Alexey Pereverzev¹, Stephen M. Sims¹, Svetlana Komarova², S. Jeffrey Dixon¹. ¹The University of Western Ontario, Canada, ²McGill University, Canada

Nucleotides, released by mechanical stimuli, signal through two families of P2 receptors. P2Y are G protein-coupled receptors that often couple to release of calcium from intracellular stores; whereas P2X are ATP-gated channels that permit influx of calcium. Osteoblasts express a number of P2 receptors, including P2Y1,2,4,6 and P2X2,4-7; however, the significance of expression of multiple receptors with varying affinities for ATP is unexplored. Our purpose was to characterize signaling in osteoblasts by P2 receptors through calcium and its downstream target NFATc1. To monitor cytosolic free calcium, osteoblasts were loaded with fluo-4. A low concentration of ATP (10 μ M, activates some P2Y and all P2X receptors except P2X7, [low ATP]) induced transient elevation of cytosolic free calcium; whereas a high concentration of ATP (1 mM, activates some P2Y and all P2X receptors including P2X7, [high ATP]) elicited more sustained elevation. Further analyses revealed that graded increases in the calcium signal could be achieved over a remarkable million-fold range of ATP concentrations (1 nM to 1 mM). In this regard, mathematical modeling demonstrated that a wide dynamic range in ATP sensitivity can arise through coexpression of P2 receptors with varying affinities for ATP. To assess activation of NFATc1, we monitored subcellular localization of EGFP-tagged NFATc1. [Low ATP] caused transient nuclear localization of NFATc1; whereas [high ATP] elicited more sustained localization. Osteoblasts from P2X7 knockout mice stimulated with [high ATP] or the P2X7 agonist BzATP showed only transient calcium-NFATc1 signaling, in contrast to sustained signaling observed in wild type cells, establishing that prolonged calcium-NFATc1 signaling is mediated by the low affinity P2X7 receptor. [High ATP] and BzATP, but not [low ATP], elicited robust expression of the NFAT target gene *Ptgs2* (encoding COX2), consistent with a critical role for duration of calcium-NFAT signaling in regulating target gene expression. Taken together, this study provides the first evidence that P2 receptors couple to the calcium-NFATc1 pathway in osteoblasts and, for the first time in any system, that expression of multiple P2 subtypes increases the range over which differences in ATP concentration can be sensed by the cell. This phenomenon provides a novel mechanism by which osteoblasts may transduce differences in ATP concentration and intensity of mechanical stimuli over a remarkably wide dynamic range.

PTH differentially regulates PRG expression in Osteoblasts. Hyewon Choi¹*, Clara Magyar¹, Guillermo Arellano², Olga Bezouglia¹, Jeanne Nervina³, Sotirios Tetradis⁴. ¹University of California, Los Angeles, USA, ²University of Nevada, Las Vegas, USA, ³University of Michigan, USA, ⁴UCLA, USA

Intermittent PTH (iPTH) is anabolic, while continuous PTH (cPTH) is catabolic in bone homeostasis. Primary response genes (PRGs) are the first genes to be induced in PTH responsive cells. We explored the role of PTH exposure and signaling activation in PRG expression in primary osteoblasts and MC3T3-E1 cells. To mimic iPTH, cells were treated with 10 nM PTH, washed, and PTH-free media was added for the remaining treatment. For cPTH, cells were treated the same except that media containing 10 nM PTH was added after the washes. Interestingly, 30 min iPTH maximally induced *Nurr1*, *Nur77* and *cox2*, while cPTH was required for maximal *RANKL* and *IL-6* induction. This suggests two classes of PTH-induced PRGs: those requiring continuous PTH presence for maximal induction and those that do not. Intriguingly, *Nurr1* is associated with anabolic PTH effects, while *RANKL* mediates catabolic PTH effects. We then examined time-dependent pathway manipulation on PTH-induced *Nurr1* and *RANKL* expression. PKA inhibition before PTH attenuated

both *Nurr1* and *RANKL* expression. However, PKA inhibition 1 or 2 h after PTH increased *Nurr1*, but inhibited *RANKL* expression. Thus, initiating PKA activity appears sufficient for *Nurr1* induction, but continuous PKA activity is required for *RANKL* induction. Additionally, *Nurr1* expression was unaffected by pre- or post-PTH erk inhibition, while *RANKL* expression was attenuated in both cases. Importantly, PTH increased histone H4 acetylation at the transcription start site (TSS) of both *Nurr1* and *RANKL*. PKA, but not erk, inhibition decreased this effect. PTH alters actin organization. Inhibiting actin polymerization blocked PTH-induced *RANKL*, but not *Nurr1* expression. Furthermore, PTH-induced erk activity was required for Rho activation. Blocking the downstream Rho GTPase effector ROCK inhibited *RANKL*, but not *Nurr1*, induction. Interestingly, H4 acetylation on *Nurr1* and *RANKL* TSS was unaffected. This suggests that PTH-induced cytoskeletal rearrangement is involved in *RANKL* regulation through PTH-activated Rho GTPase. Together, our data reveal two classes of PTH-induced PRGs. Those for which PTH-initiated PKA signaling triggers maximal induction that proceeds independent of PTH or PKA vs those for which continuous PTH presence, continuous PKA and erk activation, and actin cytoskeleton rearrangement are required for maximal induction. These distinctions may contribute to the *in vivo* anabolic vs catabolic effects of iPTH vs cPTH.

The p38 α MAPK Regulates Osteoblast Function and Postnatal Bone Acquisition. Cyril Thouverey¹, Joseph Caverzasio²*, ¹Division of Bone Diseases, Switzerland, ²Division Bone Diseases, Switzerland

Various osteogenic ligands that stimulate osteoblast differentiation and function act, in part, through the p38 mitogen-activated protein kinase (MAPK) pathway. A recent *in vivo* investigation has highlighted the physiological role of the TAK1 in osteoblastogenesis and bone formation (M.B. Greenblatt et al., J. Clin. Invest. 2010). Although TAK1 can activate different signaling cascades, the authors have suggested that the MKK3/6-p38 pathway may be an important regulator of osteoblast function. To elucidate the specific role of p38 α in regulating osteoblast function, we generated mice lacking p38 α in mature osteoblasts. Mice expressing Cre recombinase under the control of the *osteocalcin* promoter (*Ocn-Cre*) were crossed with mice harboring floxed p38 α -encoding gene (*p38 α ^{fl}*). The bone phenotype of control (*p38 α ^{fl}*) and mutant (*Ocn-Cre;p38 α ^{fl}*) female mice was assessed by dual energy X-ray absorptiometry, micro-computed tomography, histomorphometry and *ex vivo* gene expression analyses at 3 months of age (n=6 per group). Mutant mice exhibited lower bone mineral density compared to control mice (-8.2 %, $p=0.003$). *Ocn-Cre;p38 α ^{fl}* mice displayed an important reduction in trabecular bone volume at the distal femoral metaphysis (-37.1 %, $p=0.002$) associated with low trabecular thickness (-20.7 %, $p<0.001$). A similar pattern of low trabecular bone mass was observed at the fifth lumbar vertebral body. In addition, *Ocn-Cre;p38 α ^{fl}* mice also showed a decreased cortical thickness at the femoral midshaft (-20.2 %, $p<0.001$) that was associated with reduced endosteal mineral apposition rate (-22.7 %, $p=0.007$) and bone formation rate (-40.8 %, $p<0.001$). Consistent with this low bone mass phenotype, *Oss*, *Colla1*, *Alp* and *Ocn* expressions were respectively reduced by 34, 32, 10 and 40 % in long bones of mutant mice, indicating a defective function of osteoblasts lacking p38 α . These findings indicate that p38 α is an essential regulator of osteoblast function and bone formation *in vivo*.

WNT5A Is a Novel Regulator of Cytokine and Chemokine Expression In Bone Marrow Stromal Cells. Martina Rauner¹*, Nicola Stein², Maria Winzer², Claudia Goettsch³, Lorenz Hofbauer⁴. ¹Medical Faculty of the TU Dresden, Germany, ²Technical University Dresden, Department of Medicine III, Germany, ³Brigham & Women's Hospital/Cardiometabolic Division, USA, ⁴Dresden University Medical Center, Germany

Rheumatoid arthritis (RA) is a chronic inflammatory disease that negatively affects bone mass by enhancing cytokine-driven osteoclastogenesis and suppressing osteoblast functions. Recently, Dickkopf-1, an inhibitor of WNT signaling, has been found to be induced by TNF- α and suppress bone formation in RA. Here, we aimed to identify other members of the WNT signaling pathway that are regulated by inflammatory stimuli and affect bone remodelling. Of several WNT ligands investigated, only WNT5A was consistently induced by 3-fold at the mRNA and protein level in human bone marrow stromal cells (BMSCs) after stimulation with 1 μ g/ml lipopolysaccharide (LPS). In addition, an increased expression of WNT5A was found in the synovial tissue of 10 weeks-old TNF-transgenic mice compared to wild-type controls as assessed by immunohistochemistry. The LPS-induced WNT5A expression in BMSCs was completely blocked when cells were pre-treated with an antibody against toll-like receptor 4 (10 μ g/ml) or with specific inhibitors of the NF- κ B (BAY-7082, 1 μ M) and MAPK (U0126, 10 μ M) pathways. Of note, the WNT5A receptor ROR2 was up-regulated 6-fold by LPS and the induction was also NF- κ B and MAPK-dependent. BMSCs respond to LPS stimulation by highly up-regulating the expression of several cytokines and chemokines including IL-1b, IL-6, TNF- α , CCL2, CCL5, and CXCL12. Knock-down of WNT5A using siRNA potently suppressed the basal and LPS-induced expression of IL-1b, IL-6, CCL2, and CCL5,

but not that of TNF- α or CXCL12. In line with these data, BMSCs treated with 500 ng/ml human recombinant WNT5A for 48 h induced the expression of IL-1b, IL-6, CCL2, and CCL5. To unravel the underlying signaling pathways, cells were pre-treated for 1 h with pathway blockers (NF- κ B: BAY-7082, 1 μ M; MAPK: UO126, 10 μ M; PI-3K: LY-294002, 50 μ M, NFAT: VIVIT, 1 μ M). While WNT5A-induced IL-1b expression was solely regulated by the MAPK pathway, the induction of IL-6 expression was dependent on the NF- κ B and MAPK pathways. The chemokines CCL2 and CCL5 were regulated by multiple pathways including NF- κ B, MAPK, and Ca2+/NFAT. Of note, WNT5A also induced its own expression, which was dependent on the Ca2+/NFAT pathway. Taken together, WNT5A is induced under inflammatory conditions in BMSCs and controls the expression of cytokines and chemokines. The relevance of this regulatory circuit for osteoimmunology needs to be further explored *in vivo*.

Connexin43 (Cx43) in Osteogenic Cells Regulates Osteoclastogenesis via Paracrine Osteoprotegerin (OPG) Production, without Direct Osteoblast-Osteoclast Gap Junctional Communication. Marcus Watkins*, Roberto Civitelli. Washington University in St. Louis School of Medicine, USA

We have previously reported that conditional ablation of the Cx43 gene (Gja1) in differentiated osteoblasts or osteoprogenitors results in increased cross-sectional bone area, expansion of the marrow cavity and thinning of cortical bone; the result of increased endocortical osteoclast number and bone resorption. Furthermore, bone marrow stromal cells (BMSC) isolated from conditionally Gja1 ablated mice using the Dermo-1 promoter (cKO) induce 4-fold higher number of osteoclasts when cultured with either wild type (WT) or cKO macrophages. Since Cx43 is expressed in both the osteoblast and osteoclast lineages, we studied the potential role of loss of gap junction communication in this phenotype. Undifferentiated WT BMSC express low levels of Cx43, but its abundance rapidly increases with progressing differentiation, whereas extremely low Cx43 abundance is seen in cKO BMSC. Conversely, both WT and cKO bone marrow macrophages and differentiated osteoclasts express Cx43, confirming specificity of Gja1 ablation. We tested gap junctional intercellular communication (GJIC) by monitoring the diffusion of calcein from pre-loaded cells grown in monolayer to lipophilic carbocyanine-labeled acceptor cells "parachuted" on top of the monolayer. As anticipated, differentiated BMSC osteoblasts exhibit a high degree of GJIC when parachuted onto other osteoblasts; whereas macrophages do not show GJIC when parachuted on other macrophages. Some dye diffusion occurs among multinucleated osteoclasts, although to a lesser extent than among BMSC. Importantly, undifferentiated BMSCs do not exhibit GJIC when in contact with other BMSCs, macrophages, osteoclasts or even osteoblasts, consistent with low Cx43 abundance. Furthermore, differentiated osteoblasts did not exchange dye with macrophages or differentiated osteoclasts. BMSC isolated from cKO mice rapidly up-regulate Rankl when cultured in osteoclastogenic media (containing vitamin D3 and dexamethasone), as do WT cells. However, cKO BMSC fail to upregulate Opg mRNA and protein, consistent with the reported decreased Opg, but unchanged Rankl mRNA expression in cKO bone extracts. In summary, despite Cx43 expression by both lineages, there is no evidence of direct GJIC between osteogenic and osteoclastic cells. Thus, the increased osteoclastogenesis in cKO mice cannot be related to loss of heterotypic gap junctional communication, but rather to altered Opg expression by osteoblastic cells.

CXCR4 Signaling in Osteoblasts is Essential for Bone Homeostasis. Vivian Chu¹, Mohammad Shahnazari², Thomas Wronski³, Bernard Halloran^{*1}. ¹VA Medical Center (111N), USA, ²UCSF VA Medical Center, USA, ³University of Florida, USA

CXCR4 is the G-protein coupled receptor for CXCL12 (stromal derived factor-1). CXCL12/CXCR4 signaling plays an important role in hematopoiesis. CXCL12 is necessary to maintain the hematopoietic stem cell niche and is known to play a critical role in the formation and survival of osteoclasts (OC). The role of CXCL12/CXCR4 signaling in osteoblasts (OB), however, has yet to be adequately described. Using Cre-Lox technology to selectively ablate CXCR4 signaling in maturing OB we studied the role of signaling in OB function. We interbred CXCR4^{fllox/fllox} mice with collagen type 1a1 (Col2.3)-Cre mice to yield conditional knockouts (KO) in which CXCR4 was deleted from OB expressing Col2.3. We have characterized the bones of mice at 6 weeks of age by using microCT analysis, histomorphometry, cell culture, and gene expression analysis. CXCR4 KO mice were compared to wild-type, CXCR4^{fllox/fllox}, and Col2.3-Cre only littermates as controls. MicroCT analysis revealed significant differences at the distal femur. CXCR4 KO mice exhibited a 40% decrease in cancellous bone volume fraction (p=0.01), which was associated with decreased connectivity density, trabecular number and thickness, and increased trabecular spacing. Cancellous bone took on a more rod-like structure. Bone marrow stromal cell cultures (BMSC) showed 400% more colony forming units compared to controls. BMSC from KO mice also demonstrated 660% more alkaline phosphatase-positive colonies by Day 9 of culture. Induction of osteoclastogenesis in the non-adherent fraction of BMSC cultures yielded fewer osteoclasts (TRAP+, multinucleated cells) when compared to controls. Gene expression analysis of OB cultures on Day 14 indicated that CXCR4

ablated mice had decreased expression of CXCR4 and increased expression of CXCL12, Runx2, osterix, ALP, and Col2.3. Our data suggests that CXCL12/CXCR4 signaling in the maturing OB plays an important role in bone homeostasis. Signaling in OB appears to regulate cancellous bone volume, the mesenchymal stem cell and osteoprogenitor pool sizes, recruitment to the OB lineage and OB maturation. It also appears crucial for communication between OB and hematopoietic cells to regulate the osteoclast precursor pool size.

Engineering Vascularized Bone: Osteogenic and Pro-Angiogenic Potential of Murine Periosteal Cells. Nick Van Gestel^{*1}, Scott Roberts², Sophie Torrekens¹, Jan Schrooten¹, Frank Luyten³, Geert Carmeliet¹. ¹Katholieke Universiteit Leuven, Belgium, ²KULEUVEN, Belgium, ³University Hospitals KU Leuven, Belgium

One of the key challenges in cell-based bone tissue engineering is the timely formation of blood vessels that promote the survival of the cells in the implant. The presence of cells with pro-angiogenic properties could thus be crucial for the successful outcome of a tissue engineered construct. Since fracture healing is enhanced when the periosteum is present, periosteum-derived cells (PDC) may prove to contribute not only to osteogenesis but also to angiogenesis. In this study, we therefore characterized the ability of murine PDC (mPDC) to support angiogenesis, in addition to their osteogenic potential.

We first established a protocol to specifically isolate periosteal cells from long bones of adult mice and characterized the obtained cell population. Mesenchymal stem cells (MSC) were abundantly present as more than 50% of the mPDC expressed the MSC markers CD105, CD90, CD73 and SCA-1, whereas hematopoietic and endothelial markers were not detected. The mPDC furthermore possessed trilineage differentiation potential *in vitro* (osteogenic, chondrogenic, adipogenic), confirming the presence of MSC in the mPDC population and their osteogenic capacity.

When seeded on a calcium phosphate-collagen carrier and implanted ectopically in mice for 8 weeks, mPDC formed mature bone, illustrated by the presence of osteocytes and osteocalcin-positive osteoblasts. When compared to carriers implanted without cells, mPDC-seeded scaffolds attracted numerous blood vessels which were closely associated with the sites of bone formation. Moreover, some of the blood vessels had developed into larger, sinusoid-like structures and the formation of a bone marrow compartment was observed.

To further elucidate the pro-angiogenic properties of mPDC, we used an *in vitro* culture system. Culturing mPDC under low oxygen tension increased HIF-1 α and VEGF protein levels and hypoxia-conditioned medium from mPDC enhanced the proliferation of human umbilical vein endothelial cells (HUVEC). In addition, co-culture of mPDC with HUVEC resulted in stabilization of the pseudo-vascular structures formed by the HUVEC, in which the mPDC were localized in a pericyte-like fashion. Consistent herewith, mPDC express pericyte markers such as α -SMA and PDGFR- β .

In conclusion, we demonstrate that periosteal cells can contribute to fracture repair, not only through their strong osteogenic potential, but also their pro-angiogenic features and thus may provide an ideal cell source for bone regeneration.

PPR-Dependent Signaling in the Osteoblast Lineage Regulates Bone Marrow B Cell Development. Cristina Panaroni^{*1}, Rhiannon Chubb¹, Joy Wu². ¹Endocrine Unit, Massachusetts General Hospital, USA, ²Massachusetts General Hospital, USA

It is now widely accepted that osteoblasts are a crucial component of the hematopoietic stem cell (HSC) niche. Signaling through the parathyroid hormone (PTH)/PTH-related peptide (PTHrP) receptor (PPR) in osteoblastic cells can increase HSC numbers, as demonstrated using mice expressing a constitutively active form of PPR targeted to osteoblasts. Recent findings demonstrate that, beyond support of HSCs, osteoblasts are also necessary to sustain B lymphopoiesis in bone marrow. The PPR is a G protein-coupled receptor (GPCR) that signals through multiple G proteins. One major downstream mediator of PPR signaling is Gs α , which stimulates cyclic-AMP-dependent signaling. We have previously demonstrated that deletion of Gs α early in the osteoblast lineage in Osterix-Cre:Gs α (fl/fl) mice results in reduced bone mass with fewer osteoblasts and impaired differentiation of bone marrow B cell precursors blocked at the pre-pro B to pro-B transition *in vivo*. The relevant GPCR upstream of Gs α is of great interest. Since PTH is known to regulate HSCs *in vivo* and enhances support of B lymphocytes differentiation by osteoblastic cells *in vitro*, signaling downstream of the PPR may be relevant to the regulation of B lymphopoiesis in addition to HSCs. We therefore hypothesized that ablation of PPR in osteoblasts would negatively affect bone marrow B lymphopoiesis. Osterix-Cre:PPR(fl/fl) conditional knockout (KO) mice were generated using the Cre recombinase under the control of the Osterix promoter to ablate PPR in osteoblast precursors. The resulting mutant mice develop postnatal growth retardation and a dramatic decrease in trabecular bone at 3 weeks of age. Compared to WT littermates,

3 week-old PPR KO mice were significantly smaller but bone marrow cellularity was not affected. Analysis of the bone marrow of PPR KO mice revealed, as previously shown in Gsz KO mice, a reduction in the B220+IgM-CD93+ B cell precursor population. More specifically, we found a statistically significant increase in pre-pro-B cells accompanied by a decrease in pro-B cells and pre-B cells. Our results demonstrate that PPR signaling upstream of Gsz in cells of the osteoblast lineage plays a direct role in bone marrow B cell differentiation.

The Host Immune Response to Allogeneic and Syngeneic Mesenchymal Stem Cells Modulates Osteogenesis. Scott Yang*, Vedavathi Madhu, Abhijit Dighe, Gary Balian, Quanjun Cui. University of Virginia, USA

Purpose: Evidence from major histocompatibility complex (MHC) mismatched allogeneic mesenchymal stem cell (MSC) implantation animal studies have shown controversial evidence for both bone formation and rejection. A systematic analysis of the whether MSCs are capable of evading MHC barriers in different immune models and ultimately produce a relevant bone forming response is imperative.

Methods: The MSC line (D1), isolated from bone marrow of Balb/c mice was injected subcutaneously in six each of syngeneic Balb/c, allogeneic immunocompetent C57BL/6, allogeneic immunocompromised NCR Nude/Nude and C57BL/6 Pfp/Rag2 KO mice. NCR Nude mice are athymic, and lack T-cell function. C57BL/6 Pfp/Rag2 KO mice lack mature T & B-cells and also lack perforin mediated cytolytic activities of NK & CD8+T-cells. D1 cells were labeled with PKH26 to track survival. Implants were analyzed at four time points post cell injection: 36 hrs, 1-, 3-, and 6 weeks by analysis with x-ray and micro-CT, histology for PKH26 labeled cell survival, flow cytometry of immune cell populations, and RT-PCR of osteogenic markers.

Results: Ectopic bone formed only in syngeneic or allogeneic immunocompromised mouse groups (Fig. 1). The survival of D1 cells was also evident through six weeks in these mouse groups. Although no ectopic bone formed in allogeneic immunocompetent hosts, the implanted cells partially survived for up to three weeks before rejection (Fig. 2). A significantly greater proportion of F4/80+ macrophages (at 36 hours) and CD4+ T-cells (at 1 week) was present in C57BL/6 implants as compared to Balb/c implants. Also, the proportion of CD4+CD25+ T reg cells in Balb/c mice increased compared to C57BL/6 mice. In addition, the immune response in all allogeneic hosts inhibited expression of the Wnt/ β -catenin pathway genes as well as the alkaline phosphatase and osteocalcin genes. However, expression of the runx2 and BSP genes was not inhibited in implants retrieved from allogeneic immunocompromised C57BL/6 Pfp/Rag2 KO mice.

Conclusions: The late rejection of D1 cells after the 3rd week in C57BL/6 mice suggests that a T-cell mediated adaptive host response is responsible. The host immune response modulated not only the survival of D1 cells but also osteogenic differentiation of D1 cells. Although allogeneic stem cell mediated bone repair is attractive, further investigation is required to design interventional strategies to reduce host immune response to stem cells.

Transplantation of Human Umbilical Cord Blood-Derived Mesenchymal Stem Cells or Their Conditioned Medium Prevent Bone Loss in Ovariectomized Nude Mice. Jee Hyun An*, Jung Ah Song¹, Kyoung Ho Ki¹, Sol Ip Jung¹, Jae-Yeon Yang¹, Hyung Jin Choi¹, Sun Wook Cho², Sang Wan Kim³, Seong Yeon Kim¹, Soo Jin Choi⁴, Wonil Oh⁴, Chan Soo Shin¹.

¹Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ²University of Michigan School of Dentistry, USA, ³Seoul National University Boramae Hospital, South Korea, ⁴Biomedical Research Institute, MEDIPOST, Co., Ltd., South Korea

Umbilical cord blood-derived mesenchymal stem cells (UCB-MSCs) have advantages over other source of MSCs, including the ease of harvesting and storage, the low immunogenic potential, and the high capacity of differentiation into osteoblasts. We studied the effects of systemic injection of human UCB-MSCs and their conditioned medium (CM) on ovariectomy (OVX)-induced bone loss in nude mice. Ten-week-old female nude mice were divided into 5 groups: Sham-operated mice treated with Vehicle (Sham-Vehicle); OVX mice treated with UCB-MSCs (OVX-MSC); CM of UCB-MSCs (OVX-CM); Zoledronate (OVX-Zol) or Vehicle (OVX-Vehicle). Whole body bone mineral density (BMD) measurement by PIXIMUS showed that OVX-MSC group exhibited significant attenuation of OVX-induced bone loss compared with OVX-Vehicle group (0.0479 ± 0.0008 vs. 0.0459 ± 0.0004 g/cm² at 4 weeks, $p < 0.01$; 0.0483 ± 0.0008 vs. 0.0465 ± 0.0004 g/cm² at 8 weeks, $p < 0.01$). Furthermore, microCT analysis of proximal tibia at 8 weeks after treatment demonstrated significant increase in trabecular bone volume (BV/TV, 49 %), trabecular number (TbN, 48 %) and trabecular thickness (TbTh, 15 %) in OVX-MSC group compared to OVX-Vehicle group (all $p < 0.01$). Notably, the effects on bone density and microstructures in OVX-CM group were comparable to that in OVX-MSC group (6.2 % higher BMD, 51 % higher BV/TV, 49 % higher TbN, 14 % higher TbTh, all $p < 0.01$). In addition, OVX-MSC and OVX-CM group showed higher bone formation rate (38 % and 41 %, respectively, all $p < 0.01$) and mineral apposition rate (29 % and 32 %, respectively, all $p < 0.01$) than OVX-Vehicle group in dynamic histomorphometric analysis of lumbar spine. Serum PINP levels were also significantly higher in OVX-MSC (1.42 ± 0.13 ng/ml) and OVX-CM (1.58 ± 0.31 ng/ml) group compared with OVX-Vehicle group (1.23 ± 0.11 ng/ml, $p < 0.01$). However, cell trafficking analysis with FACS for detecting CFDA-labeled MSCs in bone marrow of OVX mice was not able to demonstrate engraftment of MSCs in bone after 24hr of treatment. In vitro, when C3H10T1/2 cells were treated with CM of UCB-MSCs, alkaline phosphatase (ALP) activities and expression of Col type 1, Runx2, osterix measured by quantitative real-time PCR were significantly increased. Furthermore, treatment of CM of UCB-MSCs inhibited osteoclastic differentiation in bone marrow macrophage culture, and enhanced the osteocyte-like morphological changes of MLO-Y4 cells and their survival in apoptosis assay. Taken together, these results suggest transplantation of UCB-MSC is a promising option for treatment of osteoporosis and the effect seems to be mediated by paracrine factors rather than direct engraftment of the MSCs.

FR0274

The Association Between The Microtubule Plus End Protein EB1 And Cortactin Controls Podosomes And Bone Resorption. Martin Blosse Duplan^{*1}, Sebastien Stephens¹, Frank PL Lai², Margit Oelkers³, Daisuke Kitamura⁴, Klemens Rottner³, William Horne¹, Roland Baron⁵. ¹Harvard School of Dental Medicine, USA, ²Institute of Medical Biology, Immunology, Singapore, ³Institute of Genetics, University of Bonn, Germany, ⁴Research Institute for Biological Sciences, Tokyo University of Science, Japan, ⁵Harvard School of Medicine & of Dental Medicine, USA

We and others have established the importance of microtubules (MTs) for the formation and stability of the peripheral podosome belt (PB), a unique feature of osteoclasts (OCs) that is critical for bone resorption. Although roles for Pyk2 and c-Cbl have been suggested, the mechanism by which MTs interact with and control podosomes has yet to be identified.

We performed a genome-wide screen of genes expressed in OCs and identified several "plus end tracking proteins" (+TIPs), proteins that are present at the growing ends of MTs, including EB1, a master regulator of +TIP interaction complexes. Expression of EB1 increased significantly as OCs matured. Live cell imaging revealed that EB1-positive MT ends targeted podosomes and EB1 was enriched in the PB. Agents that disturb or stabilize the association of EB1 with MTs respectively decreased or increased podosome density at the OC periphery, and depleting EB1 or expressing a dominant-negative mutant of EB1 in OCs strongly antagonized PB formation. Looking for targets of EB1 in podosomes, we found that cortactin (CTTN), an actin regulatory protein enriched in podosomes, associated with EB1 and that this interaction was dependent on MT stability. OCs from CTTN knockout mice showed reduced PB formation and bone resorption, whereas deletion of its close homolog hematopoietic lineage cell-specific protein 1 (HS1) did not alter OC activity. The SH3 domain of CTTN was required both for the interaction with EB1 and for rescuing PB formation and bone resorption in the CTTN KO OCs, supporting our hypothesis that EB1 and CTTN interact in a pathway that connects MTs and podosomes. Also, in the absence of CTTN, MT targeting of podosomes was reduced. Mechanistically, disrupting MTs or depleting EB1 increased CTTN phosphorylation by Src whereas stabilizing MTs decreased it. In addition, CTTN phosphorylation was decreased by another post-translational modification of CTTN, acetylation, and both phosphorylation and acetylation had to be reversible for normal PB formation. Finally, to investigate *in vivo* the role of CTTN, we examined the bone phenotype of mice lacking HS1 or CTTN in mature OCs (HS1^{-/-} and Cathepsin K^{Cre/+}: CTTN^{fl/fl} mice) by μ CT and histomorphometry. Bone resorption was impaired in 6 week old CTTN-KO mice, resulting in increased bone mass, whereas HS1 deletion did not affect bone mass.

These data identify a novel pathway that links MTs to podosomes and is critical for OC podosome organization and bone resorption.

Unique RANKL Determinants Associated with RANK Versus OPG Engagement. Julia Warren^{*}, Christopher Nelson, Yik Yu, Steven Teitelbaum, Daved Fremont. Washington University in St. Louis School of Medicine, USA

The interaction between Receptor Activator of NF- κ B Ligand (RANKL) and its receptor RANK is key to the differentiation and function of the osteoclast, the sole bone resorbing cell. Osteoprotegerin (OPG), a soluble homodimer, acts as a decoy receptor for RANKL. RANK and OPG contain a similar four cysteine-rich repeat domain (CRD) region but OPG binds RANKL with markedly different kinetics. An imbalance in the RANK/RANKL/OPG axis with decreased OPG and/or increased RANKL is associated with diseases that favor bone loss, including osteoporosis. The co-crystal structures of RANK/RANKL and OPG/RANKL show that both receptors use primarily CRD-2 and CRD-3 to form the interface with RANKL; however, the details of these interfaces are distinct. To explore the structural basis of RANK versus OPG binding to RANKL, we designed more than thirty point and short insertional RANKL mutations. We focused on three critical RANKL loops (the AA' loop, the CD loop, and the GH loop) along with several residues that form salt bridges or hydrogen bonds to RANK and/or OPG. These mutant RANKL proteins were expressed in *E. Coli*, purified, and screened for osteoclast formation and function using TRAP staining, TRAP solution assay, qRT-PCR, and western blotting for proximal signaling events. We also determined the apparent K_D of RANKL binding to OPG or RANK using Bio-layer Interferometry (BLI) spectroscopy. Our initial screens have identified six candidate RANKL mutants, all of which contain CD loop insertions that retain variable levels of OPG binding (including normal) but no detectable binding to RANK. In keeping with absent RANK association, the same mutants are incapable of promoting osteoclastogenesis. These findings are also in accordance with the crystal structures which demonstrate a dramatic rearrangement of the RANKL CD loop when bound to RANK versus OPG and may explain the observed differences in kinetics despite the similar footprints of the interfaces. Importantly, our findings suggest an anti-bone resorption therapeutic strategy involving the targeting of specific components of RANKL.

Apoptotic Osteocytes Promote In Vitro Osteoclastogenesis Directly through RANKL and Indirectly Through M-CSF and VEGF. Saja Al-Dujaili^{*1}, Esther Lau¹, Axel Guenther¹, Lidan You². ¹University of Toronto, Canada, ²Mechanical & Industrial Engineering, University of Toronto, Canada

Fatigue-induced bone microdamage has been implicated with increased osteocyte apoptosis that is co-localized with bone resorption spaces [1]. We hypothesize that apoptotic osteocytes may target bone resorption by regulating osteoclast precursor recruitment and osteoclast formation. We previously used *in vitro* serum-starvation to model reduced nutrient transport in microdamaged bone, thus inducing apoptosis in MLO-Y4 osteocyte-like cells [2]. We obtained conditioned media from: 1) serum-starved apoptotic osteocytes (aOCY), 2) osteocytes treated with aOCY conditioned media (i.e. healthy osteocytes in the presence of apoptosis cues; atOCY), and 3) osteocytes treated with non-apoptosis conditioned media (i.e. healthy osteocytes in the absence of apoptosis cues; natOCY). We found that aOCY and atOCY promoted osteoclast precursor migration and osteoclast formation, while natOCY had no effect.

Here, we aimed to determine the mechanism for aOCY and atOCY induced osteoclastogenesis. We measured RANKL, M-CSF and VEGF (known osteoclastogenic factors expressed by osteocytes) concentration in conditioned media. RANKL was upregulated in aOCY up to 426% relative to atOCY and natOCY conditioned media ($p < 0.001$). M-CSF was elevated up to 70% and VEGF up to 286% relative to aOCY and natOCY conditioned media ($p < 0.001$).

To determine if these factors are indeed responsible for increased osteoclastogenesis, we used antibodies to neutralize the effect of RANKL in aOCY, and VEGF and M-CSF in atOCY conditioned media. Conditioned media were then applied to RAW264.7 cells to induce migration through Boyden chambers, or osteoclast formation. RANKL blocking abolished the effect of aOCY on osteoclast precursor migration (up to 42% decrease; $p < 0.002$) and osteoclast formation (up to 66% decrease; $p < 0.03$).

Blocking either VEGF or M-CSF in atOCY conditioned media had similar effects with up to 63% reduction in osteoclast precursor migration ($p < 0.001$) and 50% reduction in osteoclast formation ($p < 0.003$), thus abolishing the effect of atOCY. Neutralizing both VEGF and M-CSF had the same response as blocking individual proteins, suggesting that VEGF and M-CSF act synergistically on osteoclast precursors. Findings from this study support our hypothesis that in the presence of microdamage apoptotic osteocytes directly and indirectly (through neighboring healthy osteocytes) regulate osteoclastogenesis.

Diacylglycerol Maintains Bone Homeostasis by Regulating Osteoclast Differentiation and Function. Corinne Decker^{*1}, Viviana Cremasco², Roberta Faccio³. ¹Washington University in St. Louis, USA, ²Washington University School of Medicine, USA, ³Washington University in St Louis School of Medicine, USA

Previous work from our lab identified PLC γ 2 as a central mediator of both osteoclast (OC) development and bone resorption. PLC γ 2 is activated downstream of RANK and α v β 3 integrin to generate IP3 and diacylglycerol (DAG). The relative contribution of these second messengers is not completely understood; in particular, the role of DAG in OC formation and function is unclear, in part due to the impossibility of direct genetic manipulation of DAG. To gain more insight into the role of DAG in the OC, we turned to the diacylglycerol kinase (DGK)- ζ $-/-$ mice, which accumulate DAG due to lack of DGK ζ -mediated DAG turnover. In contrast to osteopetrotic PLC γ 2 $-/-$ mice (decreased DAG), we find that DGK ζ $-/-$ mice (increased DAG) are osteopenic by 4 weeks of age (BV/TV: WT=14.4; KO=8.4 $p=0.003$). DGK ζ $-/-$ mice have fewer trabeculae and significant erosion of cortical bone owing to an increase in OC number. DGK ζ $-/-$ bone marrow macrophages (BMM) cultured with MCSF and RANKL form more OC than WT with enhanced mRNA expression of common OC markers. DGK ζ $-/-$ OC plated on bone in equal number as WT cells also display increased resorptive activity (pit area: WT=29.4; KO=66.2 $p=0.03$), indicating a critical role of DAG in both OC formation and function. To further characterize downstream signaling, we investigated DAG-dependent pathways in DGK ζ $-/-$ cells. We found that phosphorylation of protein kinase C (PKC)- δ , a DAG-dependent kinase, is enhanced in DGK ζ $-/-$ BMM compared to WT. PKC δ is also activated in OC plated on bone. Deletion of the DAG-dependent effector PKC δ leads to 397% increase in BV/TV compared to WT at 6 weeks of age, supporting the conclusion that DAG accumulation is responsible for the osteopenic phenotype of DGK ζ $-/-$ mice. PKC δ $-/-$ mice continue to maintain high bone mass with age and are protected from bone loss after ovariectomy (% loss: WT=29.53; KO=8.95 $p=0.002$). This phenotype is not due to a defect in OC formation, as PKC δ $-/-$ mice have similar numbers of OC as WT *in vivo* and *in vitro*. Instead, we found that PKC δ $-/-$ OC fail to resorb bone (pit area: WT=28.75; KO=6.82 $p=0.008$). Despite forming normal actin rings and ruffled borders, PKC δ $-/-$ OC cultured on bone fail to localize Cathepsin K vesicles within the resorptive lacunae. Altogether, our findings indicate that DAG initiates distinct pathways in the OC: a PKC δ -independent mechanism of OC formation and a PKC δ -dependent mechanism of bone resorption.

Dual Osteoclast Precursor and Suppressor Function of a Ly6C^{hi} Population Increased in Murine Inflammatory Arthritis. Julia Charles^{*1}, Lih-Yun Hsu², Erene C. Niemi², Arthur Weiss², Mary Nakamura². ¹University of California, San Francisco & VA Medical Center, USA, ²University of California, San Francisco, USA

We have identified a CD11b^{lo} Ly6C^{hi} bone marrow population with osteoclast precursor activity that is increased in murine autoimmune arthritis. CD11b^{lo} Ly6C^{hi} cells isolated from bone marrow by fluorescence activated cell sorting contain the majority of osteoclast precursor (OCP) activity present in bone marrow, and colonies expanded from single cells retain the ability to differentiate into osteoclasts. OCP are further defined by the markers CX3CR1⁺ CCR2⁺ CD135^{lo} CD115⁺ CD11c⁻ and are distinct from previously characterized myeloid precursors, suggesting that osteoclasts derive from a distinct precursor analogous to the common dendritic cell precursor. OCP have features of both M1 and M2 monocytes and are significantly increased in inflammatory arthritis. However, further increasing OCP number in inflammatory arthritis by adoptive transfer does not increase erosive disease, but instead decreases arthritis severity. Using the adoptive transfer model of SKG arthritis, we find that co-adoptive transfer of OCP with SKG CD4⁺ T-cells into RAG^{-/-} recipients ameliorated inflammatory arthritis compared to transfer of CD4⁺ T-cells alone, suggesting OCP might have suppressive function. Isolated OCP robustly suppress *in vitro* antibody-stimulated T-cell proliferation, and share characteristics with previously described monocytic myeloid derived suppressor cells (M-MDSC), including monocytic morphology, CD49d and CD124/IL4R α expression. Using antibody blockade, genetically deficient animals, and enzyme inhibitors, we show that suppression by OCP is dependent on IFN γ and NOS2, similar to the mechanism described for M-MDSC. Our findings suggest that a myeloid precursor population with both T-cell suppressive activity and the potential to become osteoclasts is expanded in inflammatory arthritis.

Dynamic *in vivo* Imaging of Bone-Resorptive Functions of Mature Osteoclasts in Live Bones By Using Intravital Two-Photon Microscopy. Junichi Kikuta^{*1}, Yoh Wada², Masaru Ishii¹. ¹Immunology Frontier Research Center, Osaka University, Japan, ²Institute of Scientific & Industrial Research, Osaka University, Japan

Osteoclasts are bone-resorbing giant polykaryons that differentiate from mononuclear macrophage/monocyte-lineage hematopoietic precursors. Upon the stimulation of essential factors such as M-CSF and RANKL, monocytoïd cells isolated from bone marrow can successfully be differentiated into multinucleated cells *in vitro*, called 'osteoclast-like cells', which often contain more than one hundred nuclei. However it remains unclear whether such extraordinarily large polykaryons are formed *in vivo* and how the activity of osteoclasts is controlled *in vivo* once they form. To answer these questions, we utilized an advanced imaging system for visualizing live bone tissues with intravital two-photon microscopy that we have recently established.

Fully differentiated osteoclasts form an extracellular compartment ('resorption lacunae') between the plasma membrane ('ruffled border') and the bone surface. A large number of vacuolar type H⁺-ATPases (V-ATPase) are specifically expressed along the ruffled border membrane to keep highly acidic conditions in resorption pit. V-ATPase consists of multiple subunits and each subunit has several isoforms. Among them the $\alpha 3$ isoform of 'a subunit' is specifically expressed in osteoclasts. To label mature osteoclasts fluorescently, we generated mice in which $\alpha 3$ subunit-GFP fusion proteins are expressed under the original promoter of the $\alpha 3$ subunit ($\alpha 3$ -GFP knock-in mice).

By using intravital two-photon microscopy of calvaria bone tissues of $\alpha 3$ -GFP knock-in mice, we have succeeded in visualization of live mature osteoclasts on the bone surface. Because GFP is expressed as a fusion protein with $\alpha 3$ subunit, GFP fluorescence not only serves as a marker for mature osteoclasts, but it provides information on the subcellular distribution of V-ATPase in osteoclasts. We identified two different populations of live mature osteoclasts on the bone surface, such as 'static - bone resorptive' and 'moving - non resorptive' ones. Furthermore treatment with recombinant RANKL or bisphosphonate (risedronate) changed the composition of these two populations as well as total number of mature osteoclasts. These approaches would be quite beneficial for studying the osteoclast dynamics *in vivo* and thus useful also for evaluating novel anti-bone resorptive drugs currently developed in the world.

Identification and Characterization of OCAN, a Novel Osteoclastogenic Co-activator for NFATc1. Min-Young Youn^{*}, Sally Fujiyama-Nakamura, Yuuki Imai, Shigeaki Kato. The University of Tokyo, Japan

Osteoclastogenesis is the highly regulated process governed by diverse transcriptional factors. Among them, NFATc1 is a prime transcriptional factor throughout osteoclastogenesis. During differentiation stages, NFATc1 can interact with

epigenetic factors to regulate a particular set of target genes at each stage, indicating that distinct epigenetic complexes contribute to the spatiotemporal regulation of each gene expression by NFATc1 during osteoclastogenesis. However, epigenetic complexes assisting transcriptional activity of NFATc1 during osteoclastogenesis remain to be identified. To address this issue, we tried to biochemically purify epigenetic regulators associating with NFATc1. Nuclear extracts prepared from RANKL-induced Raw264 cells were applied into NFATc1-antibody column, and then candidate proteins were identified by MALDI-TOF/MS analysis. Among several identified factors, we focused on an uncharacterized protein 'osteoclastogenic co-activator for NFATc1 (designated as OCAN)', which has shown relatively high expression in osteoclasts. Simultaneously, Brg1 and Baf proteins involved in SWI/SNF-type chromatin remodeler complex were purified with OCAN. These physical interactions were also confirmed by co-immunoprecipitation experiment, suggesting that OCAN is a novel component of SWI/SNF-type chromatin remodeler complex in osteoclasts to support NFATc1 function. To uncover the function of OCAN, transcriptional activity of NFATc1 with OCAN over-expression was examined by luciferase assay. Interestingly, its transcriptional activity was enhanced by OCAN over-expression. Consistently, OCAN knockdown resulted in decreased expression of osteoclast-specific genes, such as Ctsk and TRAP, with inhibiting osteoclast formation. These results indicate that OCAN plays a role as a co-activator of NFATc1 during osteoclastogenesis. To define the molecular mechanism of OCAN, the recruitment of NFATc1 on promoters of its target genes was detected with ChIP assay. NFATc1 could not be recruited on its target genes without OCAN protein. Similarly, recruitment of Brg1 was reduced in OCAN-knockdown cells. Taken together, OCAN can be considered as a novel component of a SWI/SNF-type chromatin remodeler complex to reorganize the chromatin status for DNA-binding ability of NFATc1. Generation of the osteoclast-specific OCAN knockout mice must help to clarify the physiological function of OCAN in bone metabolism *in vivo*.

Microtubule Contribution to Osteoclastogenesis – Stathmin Deficiency Induces Low Bone Mass In Mice by Increasing Osteoclastogenesis. Hongbin Liu^{*1}, Rongrong Zhang¹, Babatunde Oyajobi², Hong-Wen Deng¹, Ming Zhao¹. ¹Tulane University, USA, ²University of Texas Health Science Center at San Antonio, USA

The small cytosolic phosphoprotein, stathmin is a ubiquitous endogenous microtubule regulating protein that inhibits microtubule assembly and disrupts microtubule network within cells. In this study, we investigated the skeletal phenotype of mice engineered to be deficient in stathmin, particularly focusing on osteoclastogenesis. The global stathmin knockout mice, in which exons 2 and 3 of stathmin gene were removed, were maintained as heterozygotes on a C57BL/6 background and the bone phenotype of homozygous mutant mice and their wild-type littermates were examined at two months of age. μ CT and histological analyses revealed a substantial reduction in bone mass in stathmin-deficient mice compared with control age-matched littermates, as evidenced by decreased bone mineral density, trabecular bone volume, trabecular thickness, trabecular number and increased trabecular separation in long bones. Histomorphometry showed that deletion of the stathmin gene promoted osteoclast formation, as evidenced by increased number of TRAP positive multi-nucleated cells and increased bone resorptive surface in metaphysis. Real time PCR showed that the mRNA levels of osteoclast marker genes, including Rank, Rankl, Atp6, Ctsk, were all significantly increased in bone tissues from stathmin knockout mice, compared to their wild-type littermate controls. This was accompanied by a decrease in Opg level, which in turn resulted in an increase in Rankl/Opg ratio. The increase in expression of osteoclast markers RANKL and CTSK in stathmin-deficient bone tissues was further confirmed immunohistochemically. These results suggest that stathmin deficiency in bone induces osteoclastogenesis. To further confirm a role for stathmin in regulating osteoclast formation, stathmin was overexpressed in osteoclast progenitor RAW264.7 cells and normal primary bone marrow-derived cells and this resulted in significantly reduced formation of TRAP positive osteoclasts in culture. The reduction in osteoclast formation in RAW264.7 cells overexpressing stathmin was associated with marked disruption in the microtubule filament structure detected by immunofluorescence. Together, the findings from these loss- and gain-of-function studies demonstrate that the microtubule targeting protein stathmin is an endogenous inhibitor of osteoclastogenesis, and suggest that microtubules play an essential role in osteoclastogenesis and maintenance of postnatal bone mass.

Molecular Basis of the Requirement of RANK Signaling for Interleukin-1 (IL-1)-Mediated Osteoclastogenesis. Joel Jules^{*}, Jason Ashley, Ping Zhang, Shi Wei, Zhenqi Shi, Jianzhong Liu, Suzanne Michalek, Xu Feng. University of Alabama at Birmingham, USA

Interleukin-1 (IL-1), a proinflammatory cytokine, plays a crucial role in immune and inflammatory responses. However, IL-1 production is markedly elevated in various pathological conditions and deregulation of IL-1 expression has been implicated in the pathogenesis of postmenopausal osteoporosis and inflammatory

bone loss associated with rheumatoid arthritis (RA) and periodontitis. IL-1 induces bone loss by stimulating the formation, survival, and function of osteoclasts. While IL-1 can directly target mature osteoclasts to prolong survival and activate function, this cytokine can only promote osteoclastogenesis in the presence of permissive levels of RANKL. However, the precise molecular mechanism underlying the requirement of RANKL for IL-1-mediated osteoclastogenesis has not been fully elucidated. In this study, we show that while IL-1 is unable to activate the expression of the genes encoding matrix metalloproteinase 9 (MMP9), cathepsin K (Ctsk), tartrate-resistant acid phosphatase (TRAP) and carbonic anhydrase II (Car2) in bone marrow macrophages (BMMs), RANKL renders these osteoclast genes responsive to IL-1. RANK, the receptor for RANKL, has an IVVY535-538 motif which commits BMMs to the osteoclast lineage in RANKL- and tumor necrosis factor- α (TNF)-mediated osteoclastogenesis. Here, we further demonstrate that the IVVY motif also controls the RANKL-induced osteoclast lineage commitment in IL-1-mediated osteoclastogenesis by changing osteoclast genes to an IL-1-inducible state. Mechanistically, while IL-1 alone fails to induce the BMM expression of NFATc1, a master transcriptional regulator of osteoclastogenesis, this cytokine can up-regulate NFATc1 expression in BMMs in the presence of permissive levels of RANKL or with RANKL pretreatment. Moreover, the IVVY motif is specifically involved in rendering the NFATc1 gene responsive to IL-1. Finally, we show that MyD88, a known critical component of the IL-1R signaling pathway, plays a crucial role in IL-1-mediated osteoclastogenesis from RANKL-primed BMMs by up-regulating the expression of NFATc1 and the four osteoclast genes (MMP9, Ctsk, TRAP and Car2). These findings provide important new insights into the molecular basis of the dependence of IL-1-mediated osteoclastogenesis on RANKL. Significantly, the IVVY motif, due to its critical role in IL-1- and TNF-mediated osteoclastogenesis, has the potential to serve as a therapeutic target for bone disorders such as osteoporosis, RA and periodontitis.

NIBP: A Novel Regulator of Osteoclast Differentiation and Function. Kevin Crawford¹, Joyce Belcher², Roshanak Razmpour¹, Yonggang Zhang³, Wen-Hui Hu³, Steven Popoff¹, Fayez Safadi¹. ¹Temple University School of Medicine, USA, ²Temple University, School of Medicine, USA, ³Temple University School of Medicine Department of Neuroscience, USA

NF- κ B (Nuclear Factor of activated B cells) is a family of transcription factors involved in a number of different clinical pathologies. In bone, NF- κ B is involved in osteoclast differentiation upon stimulation with the RANKL. NIBP (NIK and IKK β Binding Protein) also known as TRAPPC9 (Trafficking Protein Particle Complex 9), is a novel upstream regulator of the NF- κ B pathway. NIBP enhances NF- κ B activity by binding to NIK (NF- κ B Inducing Kinase) and IKK β (a I κ B kinase subunit) in multiple cell types. Mutations in the NIBP gene in human have been associated with mental retardation and postnatal microcephaly. To date, NIBP expression has been identified in several cell types; however, its expression and function in bone is unknown. In this study, we identify the expression of NIBP in osteoclasts, and examine its regulatory role in osteoclast differentiation and function. Immunohistochemical staining of NIBP in mouse embryo (e 14.5) and mouse femur (12 week) identify protein expression in osteoclasts, osteoblasts, and chondrocytes. Cultured bone marrow osteoclasts from 8 week-old C57Black6 mice were differentiated in the presence of RANKL and M-CSF. Immunofluorescent staining shows NIBP is localized in the cytoplasm of osteoclasts, particularly in perinuclear regions suggesting its role as a trafficking protein.

Next, we examined the temporal expression pattern of NIBP during osteoclast differentiation. NIBP expression was highest during mature stages of osteoclast differentiation. Similar pattern of expression was also observed in the RAW264.7 cell line. To determine the functionality of NIBP in vitro, loss of function experiments using shRNA specific for NIBP in the RAW264.7 cells showed that knocking down NIBP inhibits osteoclast differentiation and function determined by TRAP positive multinucleated osteoclasts. In addition, we have utilized a Tamoxifen inducible Cre-Lox NIBP knockdown approach. Bone marrow osteoclast derived from the cre (control) and cre-lox mice and treated with Tamoxifen ex vivo, only the cre-lox (NIBP knockdown) osteoclast exhibited impaired differentiation and function. These results suggest NIBP plays a critical role in osteoclast differentiation and function. Taken together, further studies are warranted to elucidate the functional role of NIBP in osteoclast differentiation and function in vivo.

Osteoclasts in Bone Modeling, As Revealed By In Vivo Imaging, Are Essential for Organogenesis in Fish. Masahiro Chatani¹, Yoshiro Takano², Akira Kudo¹. ¹Tokyo institute of technology, Japan, ²Tokyo Medical & Dental University, Japan

The organs, nerves, blood vessels, bones, etc. grow with an increase in body size from birth to adult. Bone modeling is the central system controlling the formation of bone including bone growth and shape in early development, in which bone is continuously resorbed by osteoclasts and formed by osteoblasts. However, this system has not been well documented, because it is difficult to trace osteoclasts and osteoblasts in vivo during development. Here we showed the important role of

osteoclasts in organogenesis by establishing osteoclast-specific transgenic medaka lines and by using a zebrafish osteoclast-deficient line. Using in vivo imaging of osteoclasts in the transgenic medaka carrying an enhanced GFP (EGFP) or DsRed reporter gene driven by the medaka TRAP (Tartrate-Resistant Acid Phosphatase) or Cathepsin K promoter, respectively, we examined the maturation and migration of osteoclasts. Our results showed that osteoclasts in the vertebral body were specifically localized at the inside of the neural and hemal arches, but not at the vertebral centrum, as flat-shaped multinucleated cells that had initially differentiated from TRAP- or cathepsin K-positive mononuclear cells residing around bone. These mononuclear cells became multinucleated and then later died by apoptosis on the bone surface. The zebrafish panther mutant lacks a functional c-fms (receptor for macrophage colony-stimulating factor) gene crucial for osteoclast proliferation and differentiation and thus has a low number of osteoclasts. Analysis of this mutant revealed deformities in both its neural and hemal vertebral arches, which resulted in abnormal development of the neural tube and blood vessels located inside these arches. Our results provide the first demonstration that bone resorption during bone modeling is essential for proper development of neural and vascular systems associated with fish vertebrae.

Runx-related transcription factor 1 (Runx1) Regulates Macrophage/Osteoclast Lineage Commitment and Osteoclast Differentiation. Wei Chen, Yi-Ping Li^{*}. University of Alabama at Birmingham, USA

Despite the recent insights gained from the effects of targeted deletion of the c-fos, PU.1, NF- κ B, and NFATc1 transcription factor genes, further study is needed to define the mechanism underlying why M-CSF alone induces precursors to differentiate into macrophage while both M-CSF and RANKL induce precursors to differentiate into osteoclasts.

The cathepsin K critical cis regulatory element (CCRE) that responds to M-CSF/RANKL stimulation was analyzed using the CAT assay. We used livers derived from E12.5 Runx1^{+/+}, Runx1^{-/-}, and PU.1^{-/-} embryos as a source of myeloid cells with M-CSF and RANKL stimulation for osteoclast differentiation analysis. Runx1 expression was knocked down by lentivirus-mediated shRNA in mouse bone marrow cells (MBM) induced by M-CSF/RANKL. In addition, we forced expression of Runx1 in WT MBM cells and RAW264.7 cells induced with varying doses of RANKL. Western blot, Northern blot, RT-PCR, and immunohistochemical staining were used to characterize the expression of Runx1, PU.1, and Nfatc1. We used nonspecific esterase staining and immunostaining of CD11b and F4/80 antibodies to determine monocyte/macrophage formation. Osteoclast formation, acid production, and resorption pits were evaluated by TRAP, acridine orange, and a scanning electronic microscope respectively.

Our results revealed that Runx1 is a trans-regulatory factor of the cathepsin K CCRE. Runx1 expression is only induced by the simultaneous application of M-CSF and RANKL. Knockout of Runx1 impaired commitment and differentiation of both the osteoclast and monocyte/macrophage lineages. However, Runx1 RNAi knock-down *in vitro* impaired osteoclast differentiation, activation, and function, but had no effect on monocyte/macrophage differentiation. Forced expression of Runx1 increased osteoclast differentiation. Neither Runx1 nor PU.1 was detected in Runx1^{-/-} cultured myeloid cells, but Runx1 expression was normal in PU.1^{-/-} cultured myeloid cells.

In conclusion, the presence of RANKL and M-CSF together cause higher levels of Runx1, which promotes osteoclast commitment and differentiation. Thus, Runx1 may be a key regulator for osteoclast differentiation, functioning downstream of RANKL. Runx1 potentially controls osteoclast cell lineage commitment and regulate osteoclast gene expression and differentiation through up-regulating PU.1 and NFATc1. These results may provide additional targets for therapeutic intervention in diseases of excessive bone resorption

Disclosures: Yi-Ping Li, None.

IL-17 Mediates Estrogen-deficient Osteoporosis. Carl DeSelm¹, Yoshifumi Takahata², Jean Chappel², Taimur Khan², Xiaoxia Li³, Wei Zou⁴, Steven Teitelbaum⁴. ¹Washington University School of Medicine, USA, ²Washington University in St. Louis, USA, ³Cleveland Clinic, USA, ⁴Washington University in St. Louis School of Medicine, USA

Estrogen-deficient osteoporosis may be an inflammatory disorder and we therefore asked if IL-17 participates in its pathogenesis. Deletion of the principal IL-17 receptor, (IL-17RA) protects mice from ovariectomy (OVX)-induced bone loss. Further supporting a central role of IL-17 in its pathogenesis, OVX-induced osteoporosis is prevented by a blocking antibody targeting the cytokine. The source of IL-17 is likely IL-17-expressing NK1.1 cells as they increase 10 fold within the marrow following OVX. IL-17 promotes osteoclastogenesis by stimulating RANK ligand (RANKL) expression by osteoblastic cells, mediated by the IL-17RA SEFIR/TILL domain which recruits the adaptor protein and E3 ubiquitin ligase, Act1. Similar to IL-17RA^{-/-} mice, those lacking Act1 are protected from OVX-induced bone loss. Also mirroring IL-17RA-deficiency, absence of Act1 in osteoblasts, but not osteoclasts, impairs osteoclastogenesis via dampened RANKL expression. While transduction of WT Act1 into Act1^{-/-} osteoblasts substantially rescues their

osteoclastogenic capacity, the same construct, lacking its SEFIR domain or ubiquitinating U-box, fails to do so. These data suggest NK cell-produced IL-17 and its effector molecules are candidate therapeutic targets in post-menopausal osteoporosis.

The ADP receptor P2Y₁₂ Regulates Osteoclast Function and Pathologic Bone Loss. Xinming Su^{*1}, Desiree Floyd², alun hughes³, Kaiming Wu², Ozge Uluckan², Sarah Townsley², Angela Hirbe², Jochen Schneider⁴, Emanuella Heller², Michelle Hurchla², Hongju Deng³, Mark Eagleton², Deborah Novack⁵, Pamela Conley², Michael Rogers³, Katherine Weilbaecher⁵. ¹Washington University in Saint Louis, USA, ²Washington University in St. Louis, USA, ³University of Aberdeen, United Kingdom, ⁴Washu, USA, ⁵Washington University in St. Louis School of Medicine, USA

The ADP receptor P2Y₁₂ plays a critical role in platelet aggregation and microglial migration, and P2Y₁₂ inhibitors are clinically used to prevent cardiac and cerebral thrombotic events. ADP has been shown to increase osteoclast (OC) activity, but the expression and function of P2Y₁₂ in OC biology has not been evaluated. Mice lacking P2ry12 had increased bone mass and decreased serum levels of osteoclast activity marker, CTX, and were partially protected from age associated bone loss compared to littermate controls. We found that P2Y₁₂ was expressed in developing OCs. Loss of P2ry12 resulted in delayed OC formation, Exogenous ADP enhanced WT OC formation but had little effect on P2ry12^{-/-} OCs. In the presence of ADP, P2ry12^{-/-} OCs had impaired adhesion and bone resorption pit formation compared to P2ry12^{+/+} OCs. Ligation of the P2Y₁₂ receptor results in the activation of the alpha IIb beta 3 platelet integrin through Rap1 phosphorylation. Likewise, P2ry12^{-/-} OCs had decreased Rap1 phosphorylation in response to ADP stimulation compared to WT OCs. Expression levels of Rap1 family genes and P2ry1 were not significantly different between P2ry12^{-/-} and WT OCs. Evaluation of OC mediated pathologic bone loss demonstrated that P2ry12^{-/-} mice were partially protected from osteolysis associated with serum transfer arthritis and tumor growth in bone. Wild-type mice administered the clinical therapeutic P2Y₁₂ inhibitor, clopidogrel, had modest increases in trabecular bone volume compared to vehicle-treated mice. These results demonstrate a role for exogenous ADP and the ADP receptor P2Y₁₂ in OC-mediated bone resorption and suggest that ADP and P2Y₁₂-targeted therapies may affect bone mass and prevent pathologic bone loss.

Disclosures: Xinming Su, None.

P²¹Ras Mediated Activation of PI3K Results in Enhanced Survival of Osteoclasts in the Absence of Cbl-PI3K Interaction Independent of Cbl-b. Nagasuresh Adapala^{*1}, Alexander Tsygankov², Mary Barbe³, Archana Sanjay³. ¹University of connecticut health center, USA, ²Temple University, USA, ³Temple University School of Medicine, USA

Cbl and Cbl-b are E3 ubiquitin ligases and adaptor proteins required for normal osteoclast (OC) survival and function. Cbl interacts with PI3K upon phosphorylation of tyrosine-737 in YEAM motif, which is absent in Cbl-b. Loss of Cbl-PI3K interaction due to Y737F mutation in mice led to enhanced OC survival, but defective resorption, whereas loss of Cbl-b resulted in hyperresorptive OCs suggesting that Cbl and Cbl-b perform very distinct roles in OCs. To investigate if Cbl-b affects survival mediated by Cbl-PI3K interaction and whether defective function due to YF mutation can negate hyperresorption by Cbl-bKO OCs, we generated Y737F mice lacking Cbl-b (CYB mice). Following RANK stimulation, Cbl-PI3K interaction leads to PI3K activation which promotes OC survival. Paradoxically, loss of this interaction resulted in enhanced PI3K activity in both YF and CYB as reflected by increased AKT phosphorylation, along with enhanced RANK signaling leading to increased ERK phosphorylation, suggesting hyperactivation of Ras-Raf-1 pathway. PI3K is a major substrate of Ras and co-IP with p85 subunit of PI3K showed more Ras-PI3K binding in YF and CYB OCs, compared to WT and Cbl-bKO OCs. In addition, Ras GTPase activity in response to RANKL was also increased in both YF and CYB OCs. Ras inhibition by FPT III resulted in decreased ERK activation in both CYB and WT OCs but PI3K activity was inhibited only in CYB OCs suggesting that when unsequestered by Cbl, PI3K becomes available for activation by Ras independent of Cbl-b. Increased PI3K activity in CYB OCs resulted in increased survival and Ras inhibition abrogated enhanced survival of CYB OCs (%TUNEL+: 24.2 7.3; FPTIII: 76.2 5), but not in WT OCs (%TUNEL+: 42.6 5.4; FPTIII: 41.1 8.3). While Cbl-b did not influence OC survival, it negatively regulated bone resorption. In contrast to WT and YF OCs both CYB and Cbl-b KO OCs were hyperresorptive and their resorption ability was comparable (pit area/OC: WT 0.660.02; CYB 1.430.28; Cbl-bKO 1.630.01). The increased OC function resulted in decreased bone volume in CYB mice (BV/TV% 6.40.1) compared to WT (% 8.20.1) suggesting that defective OC function due to CblYF mutation does not rescue increased bone resorption caused by the loss of Cbl-b in CYB mice. Therefore, Cbl modulates PI3K availability preventing excessive activation by Ras thus controlling OC survival whereas Cbl-b negatively regulates bone resorption, which is not affected by loss of Cbl-PI3K interaction.

Selective Deletion of Rac1 and Rac2 in Mature Osteoclasts Results in Osteopetrosis, Failed Tooth Eruption and Defects in both Osteoclast and Osteoblast Function. Meiling Zhu^{*1}, Ben-hua Sun¹, Katarzyna Kolodziejczak¹, Karl Insogna². ¹Yale University, USA, ²Yale University School of Medicine, USA

Rac plays a central role in mediating cytoskeletal reorganization and bone resorption in osteoclasts. There are three Rac isoforms 1, 2 and 3. Rac1 and Rac2 are the two isoforms expressed by osteoclasts but their roles in regulating mature osteoclast function have not been well-defined. It has been reported that Rac2^{-/-} mice grow normally and have normal tooth eruption but have increased bone mass despite greater numbers of osteoclasts (OCs) in bone. Rac2^{-/-} OCs have an abnormal actin cytoskeleton and reduced resorptive activity in vitro. We have generated mice with selective deletion of Rac1 in mature OCs (Rac1-OC^{-/-}) by crossing Rac1^{fllox/fllox} mice with mice expressing Cre under the control of the cathepsin K promoter. These mice have normal BMD by DXA and normal tooth eruption when studied up to 2 months of age. Rac1-OC^{-/-} mice were crossed with Rac2^{-/-} animals to generate mice with selective deletion of both isoforms in mature OCs (DKO). DKO mice were small and either toothless or had markedly delayed tooth eruption. Compared to CTRL animals, DKO mice had significantly higher BMD by DXA at all measured sites: +33% at the spine (P<0.05), +21% at the femur, and +24% (P<0.001) for total body (p<0.001). DKO mice had a 15% lower mean body weight and when normalized to weight, the differences in BMD were magnified: +59% at the spine, +45% at the femur and +49% for total body BMD (p<0.0001 for each site). Bone histology revealed a marked increase in metaphyseal trabecular bone in the DKO mice extending well into the diaphysis of the femur. In contrast, the cortices were thin and porous in these animals. Consistent with this latter finding, μ CT analysis showed a marked reduction in cortical bone volume (-89%; p= 0.002). Histomorphometric analysis showed a significant reduction in OcS/BS (-35%) and Noc/BPm (-34%) in DKO animals but also in Obs/BS (-45%), Nob/Opm (-23%) and OS/BS (-32%); p \leq 0.05 for each. Serum CTX was 52% lower than CTRL mice (p<0.01). DKO OCs had markedly impaired actin ring formation with only 18% of DKO OCs able to form actin rings, while 87% of wild type cells had normal actin ring formation. In an initial experiment, osteoblasts isolated from DKO animals were able to mineralize normally in vitro suggesting that reduction on bone formation in vivo was secondary to an osteoclast-induced defect in bone modeling/remodeling. These data highlight the complementary and critical roles of Rac1 and Rac2 in skeletal metabolism.

The Rho-GEF Kalirin Regulates Dynamin's GTPase Activity and Osteoclast Function. Pierre Eleniste^{*}, Su Huang, Heather Largura, Angela Bruzzaniti. Indiana University School of Dentistry, USA

Dysregulated osteoclast activity can lead to bone loss and osteoporosis. Kalirin, a Rho GDP-GTP exchange factor (GEF), plays a key role in cytoskeletal organization and dendritic synapse formation in hippocampal neurons. Three major kalirin isoforms have been reported (Kal7, Kal9 and Kal12) which potentially have unique cellular functions. We recently found that global deletion of kalirin in mice leads to a decrease in bone mass, in part due to increased osteoclast (OC) differentiation and bone resorbing activity. However the mechanism of action of Kalirin in OCs and the signaling pathways that regulate OC function are unknown. Dynamin is a GTP-hydrolyzing protein that functions in actin cytoskeletal remodeling and endocytosis. Previously, we reported that dynamin stimulates OC bone-resorbing activity in a GTPase-dependent manner. Dynamin exists as a monomer, dimer or tetramer in solution, and liposomes induce the tetrameric form of dynamin, which further increases its GTPase activity and is essential for its role in endocytosis. However, the function of the monomeric or dimeric forms of dynamin are unknown. In this study, we sought to further examine the role of dynamin and Kalirin in OCs and to determine if Kalirin regulates the GTPase activity of dynamin. We coexpressed wild-type dynamin or the assembly-defective mutant (dyn-I684K) in the presence or absence of different Kalirin isoforms in HEK293cells stably expressing the vitronectin receptor (293VnR). Dynamin was immunoprecipitated and its activity determined using a calorimetric GTPase assay in vitro. Our data revealed that the GTPase activity of wild-type dynamin was differentially regulated by the Kalirin isoforms. Moreover, a GEF-inactive Kal7 mutant stimulated dynamin's activity to a much greater extent than active Kal7, suggesting that kalirin GEF activity may also important for regulating dynamin function. We next examined the role of Kalirin in the assembly-stimulated increase in dynamin GTPase activity. As expected, the GTPase activity of assembly-defective dyn-I684K was significantly lower than WT dynamin. However, the activity of dynamin-I684K was increased close to wild-type levels by GEF-inactive Kal7. In contrast, Kal12 failed to stimulate dyn-I684K GTPase activity. Thus, our data indicate that Kalirin influences dynamin's basal GTPase activity and potentially its oligomerization which may control dynamin's effects on actin remodeling, endocytosis and OC bone resorbing activity.

Constitutive Protein Kinase A Activities in Osteocytes Leads to Increased Bone Formation without Increased Bone Resorption. Richard Kao^{*1}, Wei-Dar Lu², Dylan O'Carroll², Peter Mailhot², Robert Nissenson³. ¹UCSF/VAMC, USA, ²VA Medical Center, USA, ³VA Medical Center & University of California, San Francisco, USA

Osteocytes have been implicated in regulating the rate of bone formation. However, the signal transduction pathways that regulate the physiological function of osteocytes are poorly defined. Limited evidence suggests an important role for the cAMP/PKA pathway in osteocyte function. We explored the hypothesis that PKA activation in osteocytes plays a key role in controlling skeletal homeostasis. To test this hypothesis, we mated mice harboring a Cre-conditional, mutated PKA catalytic subunit allele that encodes a constitutively-active form of PKA (CA-PKA) with mice expressing Cre under the control of the osteocyte-specific promoter, DMP1. This allowed us to direct the expression of CA-PKA to osteocytes in double transgenic progeny. Expression of CA-PKA in osteocytes produced significant increases in periosteal (+8.5%, $p < 0.01$) and endosteal (+20.8%, $p < 0.01$) perimeters of the region proximal to the tibio-fibular junction (TFJ) in 3-month old female mice, as assessed by static histomorphometry. In the distal femur, trabecular bone volume over total volume (+146.8%, $p < 0.01$), trabecular thickness (+28.7%, $p < 0.05$), and trabecular number (+78.7%, $p < 0.01$) all significantly increased compared to sex-matched littermate controls. Dynamic histomorphometry demonstrated increased endocortical bone formation rate per bone surface (BFR/BS; +132.3%, $p < 0.001$) as well as increased periosteal mineral apposition rate (+68.2%, $p < 0.05$) in the cortical bone proximal to the TFJ. Trabecular BFR/BS (+30.6%, $p < 0.05$) in the distal femur also significantly increased. Elevated serum alkaline phosphatase (ALP) levels (+30.5%, $p < 0.05$) corroborated the dynamic histomorphometric results. Analysis of whole bone transcript levels of osteoblast and osteocyte marker genes detected significantly up-regulated expression of *runx2* and *collagen 1a1*. On the other hand, serum levels of pyridinoline were unchanged, and the ratio of the transcript levels of *RANKL:OPG* was not significantly altered. Indeed, the percent osteoclast surface/bone surface (-25.9%, $p < 0.01$) was reduced. In summary, constitutive PKA signaling in osteocytes increased cortical and trabecular bone formation. This was associated with up-regulation of serum ALP and genes associated with osteoblast differentiation. No evidence for changes in bone resorption was detected. We conclude that constitutive PKA signaling in osteocytes can increase bone formation without an accompanied increase in bone resorption.

Estrogen Receptor α (ER α) Expression in Osteocytes is Necessary to Maintain Normal Bone Mineral Density (BMD) and Reduce Bone Loss due to Unloading. Yuuki Imai¹, Lynda Bonewald², Shino Kondoh^{*1}, Shigeaki Kato¹. ¹The University of Tokyo, Japan, ²University of Missouri - Kansas City, USA

Estrogen is thought to be a viability factor for cells of the osteoblast lineage and is also thought to increase bone mechanosensitivity so that bone responds more favorably to loading. Osteocytes make up more than 90-95% of cells in adult bone where they are thought to function as mechanosensors. To determine the role of estrogen in osteocytes, ER α was deleted in late osteoblasts/osteocytes by crossing ER α floxed mice with Cre recombinase expressing mice driven by the *Dmp1* promoter (cKO). BMD of 12-week-old female cKO mice was significantly decreased at the proximal tibia compared to control mice (-5.6%, $p < 0.05$ DXA, -10.1%, $p < 0.01$ μ CT). To further explore the cellular basis for the bone loss seen in the cKO, dynamic bone histomorphometry was performed showing that the number of osteoblasts (-46.5%, $p < 0.005$), osteoblast surface (-41.6%, $p < 0.001$) and bone formation rate (-11.3%, $p < 0.05$) in cKO were significantly decreased, as was the number of osteocytes/area (-16.0%, $p < 0.05$). Bone resorption parameters such as osteoclast numbers or surfaces were not altered which was consistent with the observation that TUNEL staining for osteoblast/osteocyte apoptosis was not significantly different between control and cKO. This was unexpected as estrogen is thought to be a viability factor for osteocytes and that apoptotic osteocytes send signals to initiate osteoclastic bone resorption. These data suggest other functions for estrogen during osteoblast to osteocyte differentiation and of an osteoprotective function by maintaining positive signals from osteocytes to osteoblasts.

Estrogen/ER α signaling is known to be involved in mechanosensing and increasing bone formation under loading conditions. Also, it is reported that tail suspension induced bone loss is significantly enhanced by ovariectomy. To determine if ER α in osteocytes plays a role in bone loss due to unloading, tail suspension experiments were performed starting at 8 weeks of age for 4 weeks. Tail suspension induced bone loss in the femoral diaphysis of cKO female mice greater than that of control mice (% reduction: -5.06.7% control, -12.74.8% cKO, $p < 0.05$) suggesting that estrogen reduces bone loss due to immobilization.

In summary, these findings indicate that ER α in osteocytes is not involved in prevention of osteocyte apoptosis and recruitment of osteoclasts, but is a pivotal factor to protect bone mass under normal loading and unloading conditions by regulating osteoblast activity.

NFATc1 Expression in Osteocytes Regulates Bone Formation by Regulating Sclerostin Expression. Todd Spears^{*1}, Jennifer Paige-Robinson², Majd Zayzafoon¹. ¹University of Alabama at Birmingham, USA, ²University of Alabama-Birmingham, USA

We have previously reported that calcineurin/Nuclear Factor of Activated T Cells (Cn/NFAT) in osteoblasts negatively regulates osteoblast differentiation and bone formation. The role of Cn/NFAT in osteocytes is not known. To determine whether Cn/NFAT exerts direct actions in osteocytes, we generated mice lacking Cnbl (Cn regulatory subunit) in osteocytes (Δ CnblOCY) using Cre-mediated recombination methods. Transgenic mice expressing Cre recombinase, driven by the dentin matrix protein 1 (DMP1) promoter, were crossed with homozygous mice that express loxP-flanked Cnbl. Bone mineral density and bone mineral content increased 4% and 10%, respectively in Δ CnblOCY mice. Microcomputed tomography analysis of femora at 12 weeks revealed an increase in bone mass in Δ CnblOCY mice when compared with controls. In order to characterize NFATc1 during osteocyte differentiation, western blot analysis was performed and showed that during osteocyte differentiation the activation of NFAT is significantly increased 21% by 3 days and 15% by 7 days in MLO-Y4 osteocytes. This indicates that NFAT effects on bone are indirectly mediated by regulating secreted factors from osteocytes. To examine the direct role of NFATc1 during osteocyte differentiation, we used shRNA technology to knockdown NFATc1 in MLO-Y4 cells. We saw no effect on osteocytic markers, indicating NFATc1 does not directly affect osteocytes. However, we discovered a 6-fold reduction in sclerostin gene expression. Sclerostin is known to negatively regulate canonical Wnt signaling, which is important for osteoblast differentiation. Therefore, we treated MC3T3-E1 osteoblasts with conditioned media collected from NFATc1-deficient osteocytes, which resulted in an increase in differentiation and mineralization and was associated with an increase in TCF/LEF transactivation when compared with control. In order to demonstrate whether NFATc1 regulates sclerostin gene expression, we performed chromatin immunoprecipitation (ChIP) assay and noted that NFATc1 associates with SOST gene regulatory regions in MLO-Y4 cells. In shNFATc1 MLO-Y4 cells, this association was reduced preventing the transcription of the SOST gene. Our findings suggest that NFATc1 in osteocytes regulates bone formation by the regulation of sclerostin.

Pharmacological Activation of Canonical Wnt Signaling Improves Bone Homeostasis and Regeneration by Directly Promoting MSC Osteoblast Differentiation. Tripti Gaur^{*1}, John Wixted¹, Sadiq Hussain¹, Jennifer Colby¹, Mary Clare McCorry¹, Stacey Russell¹, Ellen Gravallese¹, Andre Van Wijnen¹, Ivo Kalajic², David Rowe², Janet Stein¹, Gary Stein¹, Jane Lian¹. ¹University of Massachusetts Medical School, USA, ²University of Connecticut Health Center, USA

Genetic mouse models have firmly established that physiological activation of Wnt signaling has an anabolic effect on bone. Here we addressed the in vivo effects on bone homeostasis and fracture healing by inducing canonical Wnt signaling using the small molecule GSK3 β inhibitor TDZD8. We observed that TDZD8 does not affect bone marrow stromal cell (BMSC) proliferation. However, TDZD8 effectively enhances osteogenic differentiation of BMSCs, as reflected by a ~2-fold upregulation of the osteoblast-specific markers *Col1a1*, *Osx* and *OC*, 14 days after Wnt induction. Next, we generated mid-diaphyseal transverse fractures in femurs of WT mice, and treated them with either vehicle or TDZD8 (1mg/kg/day) beginning 24 hrs post-surgery for 2 weeks. MicroCT on day 14 indicated reduced total volume (TV) of the fracture callus, but increased bone volume (BV; expressed as %BV/TV) in TDZD8-treated mice compared to controls. Molecular mechanisms supporting bone repair in TDZD8-treated mice were identified. On day 7 post-fracture, decreased histone H4 transcript levels reflected a reduced number of proliferating cells, consistent with decreased callus size; on day 14, *Col2a1* and *Sox9* levels were significantly downregulated, indicating reduced chondrogenesis. Osteocalcin expression was upregulated in treated mice, reflecting increased bone and decreased cartilage. Furthermore, after 3-weeks of TDZD8 administration, μ CT identified increased bone mass in trabecular bone of the contralateral non-fractured limb. Based on these findings, we postulate that TDZD8 directs mesenchymal cells into the osteoblast lineage. Therefore, we performed lineage tracing in femoral fractures in double fluorescent reporter mice (expressing SMAA-Cherry, marking mesenchymal cells, and Col3.6-Cyan, marking early osteoblasts). The results show that TDZD8 does not increase Col3.6-Cyan positive osteoblasts, but increases SMAA-Cherry positive stem cells in areas of new bone formation. The latter indicates that an increased number of mesenchymal stem cells has directly entered the osteoblast lineage. Our findings indicate that pharmacological stimulation of canonical Wnt signaling by the GSK3 β inhibitor TDZD8 promotes fracture repair and increased bone mass through recruitment of MSCs directly into the osteoblast lineage.

Association of the $\alpha_2\delta_1$ Subunit with $\text{Ca}_v3.2$ Enhances Membrane Expression and Regulates Mechanically-Induced ATP Release and ERK1/2 Signaling in Osteocytes. William Thompson^{*1}, Amber Majid², Kirk Czymmek², Albert Ruff³, Jesus Garc  a⁴, Randall Duncan¹, Mary Farach-Carson⁵.

¹University of Delaware, USA, ²University of Delaware, Department of Biological Sciences, USA, ³US Army Medical Research Institute of Chemical Defense, Cell & Molecular Biology Branch, Research Division, USA, ⁴University of Illinois at Chicago, Department of Physiology & Biophysics, USA, ⁵Rice University, USA

Voltage sensitive calcium channels (VSCCs) mediate signaling events in bone cells in response to mechanical loading. Osteoblasts predominantly express L-type VSCCs composed of the α_1 pore-forming subunit and several auxiliary subunits. Osteocytes, in contrast, express T-type VSCCs, but relatively few L-type α_1 subunits. Auxiliary VSCC subunits have several functions including modulating gating kinetics, trafficking of the channel and phosphorylation events. The influence of the $\alpha_2\delta$ auxiliary subunit on T-type VSCCs and the physiological consequences of that association are incompletely understood and have yet to be investigated in bone. In this study, we postulated that the auxiliary $\alpha_2\delta$ subunit of the VSCC complex modulates mechanically-regulated ATP release in osteocytes via its association with the T-type, $\text{Ca}_v3.2$ (α_{1H}) subunit. We demonstrated by RT-PCR, Western blotting, and immunostaining that both MLO-Y4 osteocyte-like cells and osteocytes in cortical bone express the T-type, $\text{Ca}_v3.2$ (α_{1H}) subunit more abundantly than the L-type, $\text{Ca}_v1.2$ (α_{1C}). We also demonstrated that the $\alpha_2\delta_1$ subunit, previously described as an L-type auxiliary subunit, complexes with the T-type $\text{Ca}_v3.2$ (α_{1H}) subunit in MLO-Y4 cells. Interestingly, siRNA mediated knockdown of $\alpha_2\delta_1$ completely abrogated ATP release in response to membrane stretch in MLO-Y4 cells. Additionally, knockdown of the $\alpha_2\delta_1$ subunit reduced ERK1/2 activation. Together these data demonstrate a functional VSCC complex that plays a critical role in osteocyte signaling. Immunocytochemistry following $\alpha_2\delta_1$ knockdown showed decreased membrane localization of $\text{Ca}_v3.2$ (α_{1H}) at the plasma membrane, suggesting that the diminished ATP release and ERK1/2 activation in response to membrane stretch resulted from a lack of $\text{Ca}_v3.2$ (α_{1H}) at the cell membrane. Together, these studies identify a new functional complex that plays a role in bone responses to mechanical signals.

Evidence that Osteocytes Elaborate Endocrine Regulation of Internal Organs Size: Data From the Osteocytes IGF-I Conditional Knockout Mice. Xiaodong Zhou^{*1}, Kin-Hing William Lau², Lynda Bonewald³, David Baylink¹, Matilda Sheng¹. ¹Loma Linda University, USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³University of Missouri - Kansas City, USA

As in various cell types, cellular organs also need to communicate and coordinate with each other. Recent studies have shown that the bone is no exception. This is substantiated by our studies in mice with conditional IGF-I KO in osteocytes (generated from crossing DMP1-Cre with IGF-I Loxp mice). The IGF-I expression in the bone of these KO mice was decreased by 52% ($p < 0.01$) but IGF-I expression in osteoblasts isolated from these KO mice was not different from that in wild-type osteoblasts, indicating that the osteocyte is a major cell source of IGF-I in the bone. The KO mice had a 9-20% decrease in body weight ($p < 0.01$) in as early as 2 weeks of age and sustained throughout the entire growth period. This was not due to retarded endochondral ossification as their long bones were normal in length. The periosteal circumference was smaller by 8% ($P = .01$) in KO mice, suggesting that osteocytic IGF-I is essential for periosteal expansion but not endochondral bone growth. The marrow space ($P = .03$) and cortical bone area ($P = .05$) were each reduced by $>12\%$ in KO mice. We next evaluated the effect of the IGF-I KO in osteocytes on the development of key organs such as the kidney, liver and spleen. All of these organs in KO mice were smaller by 14-20% ($P < 0.05$ for each) compared to those of control mice. There was no difference in serum IGF-I level between KO mice and WT controls (373.624 vs. 379.8 vs. 21.6 ng/ml, $P > .05$), indicating that the reduced organ sizes in KO mice were not due to lower circulating IGF-I levels. The effect of osteocytic IGF-I on other key organs is exciting. First, it implies that osteocytes in the bone have a regulatory endocrine action on other organs in the body. This is analogous to the secretion by osteocytes of FGF23 to regulate phosphate metabolism and by osteoblasts of osteocalcin to regulate energy metabolism. Accordingly, our study provides a mechanism for the coordinated growth of the skeleton with other key organs. Second, this study differs from other IGF-I KO studies. Total or liver IGF-I KO mice showed a generalized retardation of growth. Conditional KO of IGF-I in osteoblasts or chondrocytes led to a coordinated decrease in longitudinal bone growth and bone size. In conclusion, our study solidifies the concepts that osteocytes are an endocrine organ and specifically that an important part of the action of the osteocyte to accomplish this coordinated growth is mediated in part by osteocytic IGF-I.

Allowing Patient Self-Referral of DXA Significantly Improves Osteoporosis Screening. Amy Warriner^{*1}, Ryan Outman², Jeffrey Curtis², Adrienne Feldstein³, David Redden², Mary Rix³, Brandi Robinson³, Douglas Roblin³, Ana Rosales³, Monika Safford², Kenneth Saag². ¹UAB, USA, ²University of Alabama at Birmingham, USA, ³Kaiser Permanente Center for Health Research, USA

Purpose: Current U.S. guidelines recommend bone density screening with central dual energy x-ray absorptiometry (DXA) in all women 65 years or older. However, less than one-third of eligible U.S. women undergo this testing. We evaluated whether a simple, low-cost intervention for patients to more easily schedule DXAs might improve osteoporosis screening rates compared to the current requirement of physician referral.

Methods: We conducted a group randomized controlled trial involving 14 primary care clinics within the Kaiser Permanente Northwest Region (KPNW). Women 65 years or older with no identifiable DXA scan in the past 5 years and no identifiable anti-osteoporosis treatment in the past 12 months were eligible for the study. Clinics were randomized into 1 of 3 groups: A self-referral intervention (SELF) (eligible patients invited by mail to get a DXA and provided opportunity to self-schedule a DXA); self referral + DVD (SELF+DVD) (consisting of SELF, plus an educational brochure and DVD promoting patient-provider communication about osteoporosis screening, enhanced through patient story-telling); and, Usual care (UC) (No DVD or self referral). Providers in all groups were directed to web-based CME training on osteoporosis screening and treatment.

Results: Of 8879 eligible women, 3218 women were randomized to SELF, 3752 to SELF+DVD, and 1909 to UC. A total of 29.6% of women in SELF and 28.4% in SELF+DVD completed a DXA scan, compared to 9.3% of women in UC; the risk difference for DXA receipt in SELF and DVD+SELF vs. UC was 19.6, (95% CI 17.9 – 21.3).

Conclusions: DXA scan scheduling and receipt was improved significantly by allowing patients to self-schedule their own scans. The addition of an educational DVD using patient story-telling to promote patient-provider communication did not significantly improve DXA screening over DXA self-scheduling alone. Allowing eligible women to self-schedule screening DXA scans (similar to mammography self-scheduling) may be an effective low cost strategy to increase rates of osteoporosis screening.

Receipt of DXA by Week

Degenerative Changes at the Lumbar Spine - Implications for Bone Mineral Density Measurement in Elderly Women. Kristina Akesson^{*1}, Max Tenne², Jack Besjakov³, Paul Gerdhem⁴, Fiona McGuigan⁵. ¹Skane University Hospital, Malmo, Sweden, ²Clinical & Molecular Osteoporosis Research Unit, Department of Clinical Science Malmo, Lund University, Sweden, ³Dept of Radiology Malmo, Skane University Hospital, Malmo, Sweden, ⁴Karolinska Institutet, Sweden, ⁵University of Lund, Malmo, Skane University Hospital, Malmo, Sweden

Purpose: In the elderly, degenerative manifestations in the lumbar spine may result in falsely elevated BMD values, consequently missing a large proportion of those with osteoporosis. Our aim is to determine the impact of degenerative changes on lumbar spine dual energy x-ray absorptiometry (DXA) measurements over time and the implications for the clinical diagnosis of osteoporosis.

Methods: The study participants were 1044 Swedish women from the population based Osteoporosis Prospective Risk Assessment study (OPRA) cohort. All the women were 75 years old at invitation and followed up after 5 years ($n = 698$) and at 10 years ($n = 380$). BMD was assessed using the Lunar DPX-L DXA. Degenerative changes (disc space narrowing, osteophytes, asymmetric subchondral sclerosis or facet joint sclerosis) were evaluated visually on the DXA image for each vertebra L1-L4

(intra observer precision kappa values 0.66-0.7). Evaluation of spinal X-rays was also made for comparison.

Results: At baseline, degenerative changes were more frequent in the distal part of the lumbar spine: 5% (L1), 15% (L2), 26% (L3), 36% (L3) and increased over time. At 10-year follow-up incidence was: 20% (L1), 39% (L2), 59% (L3), 72% (L3), manifesting as a significant increase in overall BMD. Re-analysis following exclusion of all cases with degenerative changes resulted in BMD remaining stable between 75-85 rather than the expected bone loss. Using the criteria (L2-L4 BMD <2.5SD), at baseline, 33% of women had osteoporosis. Excluding individuals with degenerative changes, this proportion increased to 42%. Using L1-L2, which are less prone to degenerative changes, as the diagnostic site, 46% of women were classified as osteoporotic. Use of bisphosphonates, calcium, D-vitamin or HRT did not significantly alter the results.

Conclusions: Our results confirm that degenerative changes are common in elderly women, accelerate disproportionately over time, are more frequent in vertebrae further distally, with a gradient from L1-L4 and have significant impact on DXA measurements. Interestingly, even in the absence of degenerative changes, BMD is maintained rather than lost over time in elderly women. We conclude that the DXA image offers sufficient precision to detect degenerative changes and used in conjunction with BMD measurements improves interpretation of osteoporosis status. Clinically, diagnosis of osteoporosis and evaluation of therapy would be improved by routinely assessing vertebrae L1-L2.

Distal Forearm BMD combined with FRAX Probabilities for Fracture Prediction. Sreekanth Vasireddy¹, Helena Johansson², Anders Oden³, Diane Charlesworth¹, John Kanis⁴, Eugene McCloskey^{*1}. ¹University of Sheffield, United Kingdom, ²Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, ³University of Gothenburg, Sweden, ⁴University of Sheffield, Belgium

The objective of this study was to evaluate the impact of combining distal forearm bone mineral density (BMD) with FRAX 10-years probabilities, calculated by clinical risk factors (CRFs) alone, on predicting future fractures in an elderly female population. Comparison was made with combining with femoral neck (FN) BMD.

5212 women, aged 75 years and older, randomly selected from the local population were studied regardless of the presence or absence of osteoporosis. The incidence of hip or any osteoporotic fractures was captured during a median of 4 years follow-up. The baseline 10-year probability of major osteoporotic or hip fracture in each woman was computed by the FRAX[®] tool using clinical risk factors including BMI, prior fracture, corticosteroid use, parental hip fracture, smoking, alcohol and secondary osteoporosis, but not femoral neck BMD. The combination of this probability with distal forearm BMD, FN BMD or both was examined by Poisson regression analysis and expressed as the gradient of risk (GR) per standard deviation decrease in BMD.

In analyses adjusted for age and time since baseline, distal forearm BMD was comparable to that of FN BMD for prediction of any fracture (GR 1.5, 95%CI 1.4-1.6 and 1.6, 1.5-1.8 respectively, both p<0.001) but the prediction of hip fracture was somewhat lower than FN BMD (1.7, 1.4-2.0 vs. 2.3, 2.2-2.5 respectively, both p<0.001). Further adjustment for FRAX probabilities of major osteoporotic fractures had little impact on the GRs of forearm and FN BMD for predicting any fracture (1.4, 1.3-1.6 vs. 1.5, 1.4-1.7 respectively, both p<0.001). Similarly, the GRs for hip fracture were little altered following adjustment for FRAX hip fracture probabilities (1.6, 1.3-1.9 vs. 2.2, 1.9-2.7 respectively, p<0.001). When forearm BMD and FN BMD were included in the same model, and adjusted for the appropriate FRAX probabilities, forearm BMD remained a weak but significant predictor of any fracture (Table) but was no longer associated with future hip fracture.

Distal forearm BMD is a significant predictor of osteoporotic fractures including hip fractures. Its predictive ability, alone or in combination with FRAX probabilities, is somewhat less than FN BMD and measurement of forearm BMD is of little additional value when Fn BMD is known. In the absence of access to FN BMD, it should be possible to develop algorithms which combine forearm BMD in a FRAX-like model.

Outcome	Any fracture		Hip fracture	
	p-value	GR (95% CI)	p-value	GR (95% CI)
Forearm BMD	0.0012	1.2 (1.1, 1.3)	>0.30	1.0 (0.8, 1.3)
FN BMD	<0.001	1.4 (1.3, 1.6)	<0.001	2.2 (1.8, 2.7)

GRs for combined FN and forearm BMD models

Forearm BMD Measurement Variability Using DXA. Diane Krueger^{*1}, Nellie Vallarta-Ast², Jessie Libber³, Mary Checovich¹, Neil Binkley³. ¹University of Wisconsin, Madison, USA, ²UW Osteoporosis Research, USA, ³University of Wisconsin, USA

Background: Radius BMD is a valuable cortical bone measurement in clinical trials, patients with hyperparathyroidism and older adults with spinal degenerative changes. However, we have observed substantial variability in serial forearm measurements. Here we report precision assessment, identify a confounder to radius BMD measurement and propose a technical approach to avoid this inaccuracy.

Methods: Three technologists performed forearm BMD precision assessment following ISCD recommendations using a Lunar iDXA. Briefly, each technologist scanned 30 men and 30 women (n = 180) twice with repositioning between scans. Mixed effects linear regression models were used to estimate precision error and least significant change (LSC), based on technologist and sex. Upon demonstration of a larger than expected LSC, and substantial between technologist differences, detailed examination of all images, including bone, soft tissue, neutral and air point-typing was conducted. An "ideal" LSC was calculated using 30 scan pairs with optimal point-typing. Potential causes of point-typing variability were explored.

Results: Substantial differences (p < 0.001) in BMD variability, e.g., an almost two-fold difference in LSC (0.038 to 0.073 g/cm²), was observed between technologists and with our "ideal" LSC (0.031 g/cm²). Much of this appears to result from differences in automated "soft tissue" identification in these scans. Investigation of potential confounders, e.g., sex, BMI, and positioner placement did not reveal an apparent explanation for these inconsistencies. Compared to the manufacturer's ideal depiction, suboptimal soft tissue point-typing was present in 25/190 individuals (14%). In these 25 individuals, 22 (88%) had a paired scan appropriately point typed; BMD variability between these scan pairs greater than our ideal LSC was found in 17/25. In the entire group of 180, 34 individuals had BMD differences greater than our ideal LSC, of these, 17 had suboptimal soft tissue identification.

Conclusions: In this older adult cohort, substantial variability in one-third radius BMD measurement was not rare. This appears to result from automated soft tissue detection inaccuracies. It seems probable that clinicians will not appreciate these occurrences, thus leading to incorrect interpretation. Technologists must evaluate soft tissue assessment as part of routine forearm DXA analysis and, if suboptimal, an immediate scan reacquisition to produce a valid scan is required.

Rate of BMD Change Does Not Enhance Fracture Prediction: The Manitoba BMD Cohort. William Leslie^{*1}, Suzanne Morin², Lisa Lix³. ¹University of Manitoba, Canada, ²McGill University Health Centre, Canada, ³University of Saskatchewan, Canada

BACKGROUND: BMD measurements are widely used in clinical practice to assess fracture risk and for monitoring. Decrease in BMD likely contributes to the age-related increase in fractures, but there are conflicting data on whether rate of BMD loss is independently predictive. METHODS: We identified all women over age 50 at the time of second (repeat) BMD testing between April 1996 and March 2007 in a large clinical BMD database for the Province of Manitoba, Canada. The median interval between tests was 3.7 years (IQR 2.9-5.1). Using linkage to a population-based administrative health data repository, we identified other relevant covariates, medication use, and fracture outcomes up to March 2010 (median observation 3.2 years, IQR 1.6-5.5). Among 12,457 women, 3,926 were designated as untreated (less than 90 days use of HRT or non-HRT osteoporosis therapies before and between BMD tests). Cox proportional hazards models were used to assess major osteoporotic fracture risk according to BMD change after adjustment for final BMD, baseline BMD, treatment and FRAX covariates. RESULTS: 562 women sustained a major osteoporotic fracture (147 among the untreated women). Annualized percent change in total hip BMD was similar for fracture versus non-fracture women in the overall group (+0.12.1% vs +0.12.3%, P=.928) and in the untreated subgroup (-0.31.8% vs -0.61.5%, P=.077). After adjustment for final total hip BMD, other covariates and medication use, rate of total hip BMD change did not predict major osteoporotic fractures in the overall cohort (HR 1.07 per SD decrease, 95% CI 0.99-1.16) or in the untreated subgroup (HR 0.96 per SD decrease, 95% CI 0.81-1.14). When baseline (rather than final) total hip BMD was used then hip BMD change was statistically significant in the overall cohort (HR 1.22 per SD decrease, 95% CI 1.13-1.32). Secondary analysis showed similar negative results for a categorical decrease in total hip BMD exceeding the 95% LSC for the overall cohort (HR 1.12, 95% CI 0.86-1.46) and the untreated subgroup (HR 0.95, 95% CI 0.58-1.53). There was no evidence of a significant age (decade) interaction. Parallel analyses based upon change in lumbar spine and femoral neck BMD gave similar results (see Table). CONCLUSIONS: Rate of BMD change does not enhance future fracture prediction in older women when adjusted for final BMD and other covariates. This would argue against inclusion of BMD change in future modifications to the FRAX algorithm.

	Adjusted for final BMD *		Adjusted for baseline BMD *	
	HR (95% CI)	p-value	HR (95% CI)	p-value
ΔTotal hip BMD per y	1.07 (0.99-1.16)	0.093	1.22 (1.13-1.32)	<.001
ΔL14 BMD per y	1.05 (0.96-1.15)	0.268	1.12 (1.02-1.23)	0.013
ΔFemoral neck BMD per y	1.02 (0.95-1.09)	0.667	1.14 (1.07-1.23)	<.001

The Discriminatory Capacity of Clinical Risk Factors and BMD Measurements at Different Skeletal Sites for Detecting Patients with Vertebral Fractures. Christian Muschitz^{*1}, Friederike Kuehne², Roland Kocijan³, Angela Trubrich², Christina Bittighofer², Reinhart Waneck⁴, Heinrich Resch⁵. ¹St. Vincent's Hospital, Austria, ²The VINFORCE Study Group - St. Vincent Hospital - Medical Department II, Austria, ³St. Vincent Hospital Vienna, Austria, ⁴St. Vincent Hospital - Department of Radiology, Austria, ⁵Medical University Vienna, Austria

Purpose: Since the clinical outcome of osteoporosis is bone fracture, attention is focused on the identification of patients at high risk for fractures rather than the identification of people with osteoporosis defined by BMD. We investigated measurements of BMD of the calcaneus by DXL as a possible alternative device for the assessment of BMD together with the implementation of clinical risk factors (CRF) compared to DXA at standard skeletal sites.

Methods: Baseline characteristics of 494 outpatient treatment naive postmenopausal women (67.915.0 ys) and 97 men (61.512.7 ys) were evaluated for a preplanned 5 year follow up period. All subjects had prior spine X-rays and evaluation of CRF according to FRAX guidelines. Each subject had DXA of spine/hip and DXL of the calcaneus on the same day. We calculated receiver operating curves (ROC) expressed as area under the curve (AUC) to describe the sensitivity and specificity of DXA of spine/hip and for DXL at calcaneus to discriminate between patients at risk for vertebral fracture. Furthermore we generated a univariate multiple logistic regression model for CRF alone and for CRF including BMD by DXA or DXL.

Results: Out of 591 subjects, 160 patients had prevalent vertebral fractures (72.612.1 vs 61.4 9.3ys; P<0.001). In the ROC analysis the AUC of BMD alone was 0.669 for DXA femoral neck, 0.665 for DXL calcaneus, 0.661 for DXA total hip and 0.598 for DXA lumbar spine (P=0.034). The AUC for CRF without BMD was 0.805. In this model significant CRF (P<0.05) were previous fragility fractures (OR 24.5; 95%CI 13.4, 44.6), age (OR 1.04; 95%CI 1.02; 1.06) and BMI (OR 1.05; 95%CI 1.00; 1.90). After combination of DXA femoral neck and CRF the AUC improved to 0.869. Significant ORs (P<0.05) were previous fractures (20.9; 95%CI 10.5; 41.6), alcohol use (3.9; 95%CI 1.05; 14.46) and BMD femoral neck (0.68; 95%CI 0.48; 0.94). The AUC for DXL calcaneus and CRF was 0.861 including significant factors (P<0.05) such as age (OR 1.03; 95%CI 1.00; 1.05), previous fracture (OR 23.9; 95%CI 12.5; 45.7) alcohol use (OR 2.94; 95%CI 0.86; 10.02) and BMD calcaneus (OR 0.77; 95%CI 0.57; 1.04; P=0.09).

Conclusions: Our data clearly demonstrate that the predictive value of specific CRFs and BMD measured by DXA or DXL is similar and improves the discriminatory capacity for detecting patients with vertebral fractures compared to BMD measurements or assessment of CRF alone

Reproducibility of a Vertebral Deformity Tool (VDT) using an Statistical Shape Modeling Workflow Tool. Colin Miller^{*1}, Alan Brett², Eric Bogner³, Monique Tan⁴, Rebecca Cope⁵, Melanie Jenkins⁶, Jane Haslam⁷, Joes Staal⁸, Curtis Hayes⁹. ¹BioClinica, Inc. (formerly Bio-Imaging Technologies, Inc.), USA, ²Optasia Medical Ltd., United Kingdom, ³Hospital for Special Surgery, USA, ⁴Novartis Pharmaceutical, USA, ⁵BioClinica Inc, USA, ⁶Novartis Pharmaceuticals, USA, ⁷Optasia Medical Ltd, United Kingdom, ⁸Optasia Medical, United Kingdom, ⁹Virginia Commonwealth University School of Medicine, USA

Introduction: There is need for enhanced radiographic measurement techniques for the detection and diagnosis of vertebral deformities (VDs). This study assesses the inter and intra reader reproducibility of a novel clinical workflow tool that uses model-based shape recognition technology for the semi-automated annotation of T4 to L4 vertebrae using digitized plain-film radiography.

Methods: Lateral spine radiographs digitized at 150µm of 52 subjects with suspected VDs, obtained from the Canadian Multicenter Osteoporosis Study (CaMos) were independently assessed by two radiologists (EB & CH) using a semi-automated protocol based on a previously described 95 point vertebral annotation¹. This annotation captures the full lateral vertebral shape including endplate rims, endplate depression and osteophytes. This VD Tool (VDT) was applied using a read system developed by BioClinica and embedded software from Optasia Medical. For

each vertebra, the mean position of each of the 95 points was computed. Then, for each point, the squared distance between the mean position and each read was computed and summed to assess the variance of each point in the contour. Also we collated all variance measures and computed their mean value and 95% confidence interval (CI) using a bootstrap method at each vertebral level. After taking the square root of the mean value and the confidence interval we obtained the average reproducibility (RMSSD) for each vertebral level in millimeters displacement. Reproducibility in terms of percentage of average vertebral height was also calculated using a similar method.

Results: There were nine intra-reader labeling differences and 17 intra-reader labeling disagreements due to different choices being made of eg T12 annotation in either the thoracic or lumbar image of each subject pair. The mean reproducibility in mm (percent of vertebral height) for CH ranged between 0.53 (1.87%) - 0.94 (2.77%), and for EB between 0.87 (3.46%) to 1.53 (5.27%). The inter-reader variability ranged from 0.87 to 1.34 mm or 3.17% to 4.57%. See Table 1.

Conclusion: We report good reproducibility of 95 point placement using this tool. This software tool shows potential for full vertebral shape characterization which may be used as a diagnostic tool for vertebral deformity. This method minimizes the user time and variability seen in manual vertebral six-point morphometry placement.¹ Brett et al, *Spine* 34(22): 2437-2443, 2009.

Quantitative Ultrasound Measurements Predict Fracture Risk in Non-osteoporotic Women. Tuan Nguyen¹, John Eisman¹, Jacqueline Center¹, Mei Chan^{*2}, Nguyen Nguyen¹. ¹Garvan Institute of Medical Research, Australia, ²Osteoporosis & Bone Biology, Australia

Fracture is a multi-factorial disorder, and bone mineral density (BMD) alone account for around 50% of fracture cases. Indeed, more than 50% of women who sustained a fracture have BMD above osteoporotic threshold (T-score > -2.5). Calcaneal quantitative ultrasound measurements (QUS) are significant predictors of fracture. This study was designed to test the hypothesis that in non-osteoporotic women, lower measured values of QUS are associated with increased fracture risk.

The study is part of the on-going Dubbo Osteoporosis Epidemiology Study, which is a prospective population-based study of risk factors for fracture and outcomes. The study included 340 women aged 62-89 with BMD T-score > -2.5 who had QUS measurements. QUS was measured in broadband ultrasound attenuation (BUA) at calcaneus using CUBA sonometer (McCue Ultrasonics, Winchester, UK). BMD was measured at the femoral neck (FNBMD) by dual energy X-ray absorptiometry (DXA) using GE Lunar DPX-L densitometer (Lunar Corporation, Madison, Wisconsin, USA). The individuals had been followed-up for a median of 13 years (from 1994 to 2009). The incidence of fragility fracture during the follow-up period was ascertained by X-ray report.

Of the 340 women without osteoporosis, 27% (n = 92) had experienced at least one fragility fracture during the follow up. Women with fracture had significantly lower baseline FNBMD and BUA than those without fracture (P< 0.001). In unadjusted analysis, increased fracture risk was associated with decrease in QUS (RR 1.68 per standard deviation [SD]; 95% CI: 1.25-2.29), and reduced BMD (1.51 per SD; 1.07-2.18). After adjusting for age, weight, and lifestyle factors, increased risk of fracture was significantly associated with decreased BUA (RR 1.37; 1.05-1.77), but not with FNBMD (RR 1.23; 0.97-1.55). The association between BUA and fracture was also observed for hip fracture (RR 2.93; 1.26-6.82), but not for vertebral fracture (RR 1.28; 0.83-1.97).

These results suggest that calcaneal QUS is an independent predictor of any and hip fracture in women without osteoporosis. The results further underscore the potential utility of QUS in the enhancement of fracture prediction at the individual level.

Peri-Aortic Fat Is Negatively Associated with Volumetric Bone Mineral Density, Cross-Sectional Area and Compressive Strength of Lumbar Vertebrae: the Framingham Osteoporosis Study. Yi-Hsiang Hsu¹, Caroline S. Fox², Mary Bouxsein³, Udo Hoffmann⁴, LA Cupples⁵, Douglas Kiel⁶. ¹Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ²National Heart, Lung, & Blood's Framingham Heart Study, USA, ³Beth Israel Deaconess Medical Center, USA, ⁴Massachusetts General Hospital, Department of Cardiac MR PET CT & Harvard University, USA, ⁵Biostatistics Dept., School of Public Health, Boston University, USA, ⁶Hebrew SeniorLife, USA

Both obesity and osteoporosis are increasingly recognized as major health problems worldwide. The long prevailing view that BMI defined obesity is associated with beneficial effects on the skeleton has recently been challenged by contrasting studies demonstrating that visceral fat is associated with lower bone density. Peri-aortic adipose tissue volume (PAAT) is the adipose tissue surrounding the aorta, which is anatomically adjacent to the spine. Cellular studies have suggested that PAAT may have a paracrine effect on the adjacent aortic vessel walls leading to a higher risk of arterial disease. We hypothesized that PAAT is associated with bone measures and it may be due to its local paracrine effect on the adjacent lumbar vertebrae. Methods: To determine the association between PAAT and bone measures at the lumbar vertebrae, PAAT (cm³) and volumetric integral BMD (In.vBMD, cm³); volumetric trabecular BMD (Tb.vBMD, cm³); and cross-sectional area (CSA, cm²) of L3 were measured by QCT on 1,631 men and 1,507 women (mean age: 53.12.3 years old) from the Framingham Osteoporosis Study. The Compress Strength (CS, Newtons) of vertebrae body was calculated as ((In.vBMD x 3230) - 34.7) x CSA x 0.68. Subcutaneous abdominal tissue volume (SAT) and visceral abdominal tissue volume (VAT) were also estimated from the same QCT scans. Pearson partial correlation coefficients between PAAT and the QCT bone measures were estimated. Sex-specific mixed effects models were used to calculate least-squares means and to assess regression coefficients for the bone measures across PAAT quartiles. Results: PAAT was positively correlated with VAT, BMI and SAT with partial correlation coefficients (adjusted for age, sex and height) equal to 0.75, 0.52 and 0.41, respectively. Significantly negative correlations (-0.21 ~ -0.08) between PAAT and the bone measures were found in both men and women after adjusting for age, height, BMI and menopause status (women only). The magnitude of the correlations was stronger than that between BMI and the bone measures, and was in the opposite direction (Table). Adjusted for age, height and BMI, the multivariable-adjusted mean In.vBMD, Tb.vBMD, CSA and CS all significantly decreased from the lowest (Q1) to the highest (Q4) PAAT quartile (Figure: representative CS result) in both men and women. In conclusion, our study suggests that increased fat deposits adjacent to vertebrae may have a detrimental effect on bone density and strength of vertebrae.

Determination of Absolute Risk of Fracture Threshold for Intervention: A Decision Curve Analysis. Nguyen Nguyen¹, Dana Blünc¹, Steven Frost², Jacqueline Center¹, John Eisman¹, Tuan Nguyen¹. ¹Garvan Institute of Medical Research, Australia, ²University of Western Sydney, Australia

The assessment of fracture risk can now be individualized by existing absolute risk models based on an individual's risk profile. However, one of the most important questions in using these absolute risk models is: what is the appropriate threshold of

risk that is warranted an intervention. In this study, we used the decision curve analysis (DCA) method to determine the intervention threshold.

The present study was part of the ongoing Dubbo Osteoporosis Epidemiology Study which involved 1358 women and 858 men, whose bone health has continuously been monitored since 1989. All individuals aged 60 or older as at 1989. Baseline measurements included femoral neck BMD, prior fracture, a history of falls and body weight. During the follow-up period, 426 women and 149 men had sustained a low-trauma fracture. We considered 3 Cox's proportional hazards models for predicting fracture risk: model I included only prior fracture; model II included age and BMD; and model III included age, BMD, prior fracture and falls. From each model, we estimated 10-y predicted probability of any fracture and hip fracture for each individual. We then calculated the "net benefit" for each intervention threshold (T). The net benefit (NB) is a function of total sample size (n), true positives (TP) and false negatives (FN) as follows: $NB = TP/n - (FN/n) * (T/(1-T))$.

Decision curve analysis suggested that for any fracture, optimal net benefit was reached when the 10-year fracture risk is 10% regardless of models used; however, at this risk level, almost all individuals are subject to intervention. For risk threshold between 10% and 20%, optimal net benefit was achieved with model III. For risk threshold between 20% and 50%, the net benefit would be declined in women, but not in men (Figures A-B). For hip fracture, models II and III yielded similar optimal net benefit at threshold between 6% and 10%. Clinical decision based on prior fracture alone yielded suboptimal net benefit for hip fracture (Figures C-D). For all models and for a given threshold, the net benefit was greater in women than in men.

These results suggest that a 10-year risk of any fracture between 10-20% or hip fracture risk between 6-10% provides optimal net benefit.

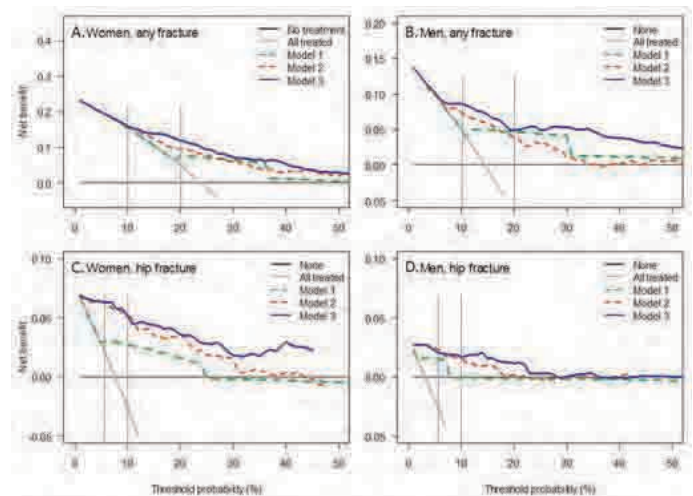

Figure. Decision curve for prognostic models predicting absolute risk for any fracture in women (A) and men (B), and for hip fracture in women (C) and men (D).

The gray line is the net benefit of treatment all population; the "zero" horizontal line is the net benefit of no treatment.

Model 1 included only prior fracture; model 2 included age and femoral neck BMD; and model 3 included age, BMD, prior fracture and falls.

Figure. Decision curve for prognostic models predicting absolute risk

Epidemiologic Findings Shed Light Upon A Case Definition For Atypical Subtrochanteric and Femoral Shaft Femoral Fractures (STFSF). Adrianne Feldstein¹, Dennis Black², Nancy Perrin³, A. Gabriela Rosales³, Darin Friess⁴, David Boardman⁵, Richard Dell⁶, Arthur Santora⁷, Julie Chandler⁷, Anne De Papp⁸, Mary Rix³, Eric Orwoll⁴. ¹Kaiser Permanente Center for Health Research, USA, ²University of California, San Francisco, USA, ³Kaiser Permanente Northwest, Center for Health Research, USA, ⁴Oregon Health & Science University, USA, ⁵Kaiser Permanente NW, USA, ⁶Kaiser, USA, ⁷Merck Research Laboratories, USA, ⁸Merck & Co., Inc., USA

The case definition for atypical Subtrochanteric and Femoral Shaft Femoral Fractures (STFSF) is critical for evaluating their risk factors. The incidence and characteristics of subtrochanteric and femoral shaft fractures (STFSF) with and without atypia were determined from electronic medical record and radiograph review at Kaiser Permanente Northwest from January 1996 – June 2009. Of 197 STFSF observed over 13.5 years, 75 met ASBMR major criteria [AFM= shaft location, minimal trauma, transverse or short oblique, non-comminuted] (5.9/100,000 py (95% CI 4.6,7.4)). Of those, 22 also met ASBMR criteria for minor features (lateral beaking, increased cortical thickness, signs of stress fracture) (1.7/ 100,000 person-years (95% CI= 1.1-2.6)). Whereas the incidence of AFM appeared flat, the proportion of atypical fractures with major and minor features [AFMm] increased over time. AFM subjects were older, and had fewer dispensings of bisphosphonates and glucocorticoids compared to subjects with AFMm.

Conclusions: Patients with atypical subtrochanteric fractures with major features only appear to be different from patients with atypical subtrochanteric fractures with major and minor features and it may be that the former group constitutes a long-standing type of osteoporotic fracture and that only the latter group is atypical and increasing in frequency. There may be multiple associated risk factors for atypical fractures. Future epidemiologic studies of atypical STFSF should evaluate AFM and AFMm separately.

Incidence of and Predictors of False Negative Self-Reports of Hip Fractures in Cohort Studies: the Study of Osteoporotic Fractures (SOF). *Beth Vinnig¹, Brent Taylor¹, Kristine Ensrud², Misti Paudel¹, Sara Durham¹, John Schousboe³*. ¹University of Minnesota, USA, ²Minneapolis VA Medical Center / University of Minnesota, USA, ³Park Nicollet Clinic/University of Minnesota, USA

Background: Cohort studies generally rely on patient self-report to identify incident fractures. While follow-up examination of clinical radiographs can identify false positive self-reports, few studies have examined the proportion of fracture self-reports that are false negatives. Medicare claims data has been shown to identify incident hip fractures with 98% accuracy. Our study aims were; a) using SOF data merged with Medicare claims, determine the proportion of incident hip fractures identified in claims that were NOT reported to SOF; and b) identify predictors of false negative self reports.

Methods: Successful matches of SOF participants from 3 of the 4 SOF study sites with their Medicare claims were confirmed for 92.1% (6,285 women) of the cohort still alive and enrolled in the SOF study as of 1/1/1992. Incident first hip fractures were identified for this subset in available claims between 1/1/1992 and 12/31/2007 by a primary or secondary discharge ICD-9 diagnosis of hip fracture (820.0x). Fracture self reports were solicited on post-cards mailed to participants every 4 months, with a 99% response rate. True positive self-reports were those confirmed by review of reports of x-rays taken within 31 days of the first hip fracture admission date in claims. False negative self reports were follow-up post-cards with no self-reported pelvis, proximal femur, or distal femur fractures in SOF within 31 days of the fracture date in claims. The multivariable adjusted associations of predictor variables with false negative hip fracture self reports were estimated with logistic regression.

Results: Of 770 women identified with an incident hip fracture in Medicare claims, 161 (20.9%) did not report their hip fracture to SOF. Living with others (compared to living alone), lower mini-mental status exam score (MMSE), and being unable to stand without use of arms were associated with false negative hip fracture self-reports (table).

Conclusions: A significant minority of hip fractures are likely to be missed in cohort studies that rely on self-report to be the first signal of a fracture event. This misclassification of hip fracture events may bias estimated associations of predictors with hip fractures toward the null, and reduces power to establish the statistical significance of these associations. Strategies to detect fracture events with higher accuracy in cohort studies are needed.

Predictor	Odds of False Negative vs. True Positive Hip Fracture Self Report (95% C.I.)
Age Category:	
<80 years	1.00 (Reference)
80-84 years	0.82 (0.40 – 1.69)
≥ 85 years	0.98 (0.75 – 1.28)
Unable to stand without use of arms	2.89 (1.04 – 8.03)
MMSE score (1 SD decrease)	1.25 (1.04 – 1.50)
Living With Others (vs. living alone)	1.59 (1.08 – 2.34)

Muscle Density, a Surrogate of Intermuscular Adiposity Derived from pQCT, Is an Independent Correlate of Fractures in Women. *Andy Kin On Wong^{*1}, Aakash Bhargava¹, Karen Beattie¹, Christopher Gordon¹, Laura Pickard¹, Colin Webber², Alexandra Papaioannou², Jonathan Adachi³*. ¹McMaster University, Canada, ²Hamilton Health Sciences, Canada, ³St. Joseph's Hospital, Canada

Muscle loading contributes to stronger bones and lower fracture risk, but may be affected by adiposity. Objective: To determine the influence of pQCT-derived muscle measures on fragility fractures in women.

Methods: A single slice (2.30.5 mm) scan at the 66% site of the calf muscle was acquired in women ≥ 50 years of age from the Hamilton cohort of the Canadian Multicentre Osteoporosis Study (CaMos) using peripheral quantitative computed tomography (pQCT). Grip strength and timed 'up-and-go' (TUG) physical function tests were assessed at study visit. Participants also completed a questionnaire on duration of antiresorptive therapy, vitamin D and calcium supplements. Prevalence of fragility fractures over the past 15 years was determined from the CaMos database archive. Muscle was segmented from bone and subcutaneous fat using density thresholds. Muscle area and density were computed using manufacturer software. Binary logistic regression analyses determined the relationship between prevalence of fractures and muscle measures, adjusting for age, body mass index (BMI), duration of medication use, physical function, and total hip (TH) areal bone density (aBMD). Odds ratios were reported with 95% confidence intervals (CI). Receiver-operator characteristics (ROC) curve analyses for fractures was examined for the same variables, reporting areas under the curve (AUC). AUCs for muscle measures were compared with AUC for TH aBMD, and with a null AUC of 0.50 using a Wilcoxon signed ranks test.

Results: Of 38 women (mean age: 74.6 \pm 8.4 years; BMI: 26.5 \pm 4.2 kg/m²), 16 (42.1%) had sustained a fragility fracture. Higher muscle density, but not area, was significantly associated with reduced odds for fracture independent of anthropometrics and medication use (Table 1). Including muscle area or TH aBMD led to lower odds for fractures but not to significance. Higher physical function contributed to 36% reduction in fracture odds. Muscle density exhibited an AUC of 0.835 (95% CI: 0.705, 0.966) for discriminating those with fractures, significantly larger than 0.50 and AUC for TH aBMD of 0.638 (95% CI: 0.500, 0.756). 87.5% sensitivity and 68.2% specificity was observed.

Conclusions: pQCT-derived muscle density, reflective of intermuscular fat, is an independent risk factor for fractures able to discriminate women with fractures with over 80% accuracy. Women with greater physical function plus denser or leaner calf muscles have further reduction in odds for fracturing.

Table 1. Odds for fractures in women explained by pQCT muscle measures. Muscle volumetric density was examined as a correlate of fractures in conjunction with muscle area and total hip areal bone mineral density (TH aBMD) with adjustment for anthropometrics (age, BMI), medication use (duration of antiresorptive therapy, vitamin D and calcium), and physical function measures (maximum grip strength (GSMax), timed 'up-and-go' (TUG) time). Bold p-values indicate significance at the 95% confidence level.

Model	Covariates	OR	Lower CI	Upper CI	P-value

Aim: Genome-Wide Association Studies (GWAS) have identified 22 BMD loci associated at genome-wide significant (GWS) level, none of which were GWS-associated with fracture (FX) risk. The aim of this study was to identify additional BMD loci and test for association with FX risk, using novel data from the largest meta-analyses conducted to date from the Genetic Factors of Osteoporosis (GEFOS) consortium. **Methods:** The discovery meta-analysis consisted of 17 GWAS (n=34,191) studying ~2.5 million SNPs in relation to lumbar spine (LS-) and femoral neck (FN-) BMD. The top-associated BMD SNPs (P<5x10⁻⁶) were assessed in 50,933 independent subjects for association with BMD, and for risk of (any type of) FX in 31,016 cases and 102,444 controls from 50 studies of the GENOMOS consortium including subjects of European (predominantly) and Asian ancestry. We applied pathway analysis (GRAIL) and modeled allelic risk scores for low BMD (n=36,917) and fracture risk (n= 45,359). **Results:** The meta-analysis of BMD GWAS identified 82 loci with P<5x10⁻⁶; after replication 54 reached GWS (44 FN-BMD, 40 LS-BMD, 30 both). GRAIL analysis identified relationships between 25/82 loci within RANK/RANKL/OPG, Wnt or MSC-differentiation signaling pathways. Of the GWS BMD loci, 15 were associated with FX risk (Bonferroni P<5x10⁻⁴; six were GWS). FX Odds ratios (OR) ranged from 1.04 to 1.09. The strongest FX risk locus (OR: 1.09, 95%CI

1.06-1.11; $P=2 \times 10^{-14}$) contains a gene coding for a protein of unknown function on 18p11 (C18orf19). Notably, no variants in the RANK/RANKL/OPG loci were associated with FX. Mean FN-BMD difference between subjects with high number of BMD-decreasing alleles ($>64\%$; $n=217$) and the population mean (50-52% of alleles; $n=6,434$) was 0.52 SDs. Subjects with a high number of FX risk alleles ($>70\%$; $n=178$ cases/252 controls) had 1.2 increased risk compared to subjects carrying 50-55% of FX risk alleles (4635 cases/8961 controls). Conclusion: We identified 33 novel and confirmed 22 loci underlying BMD variation, 15 of which are associated with FX risk highlighting potential clinical implications. Individuals carrying the highest number of BMD decreasing alleles have a difference in BMD analogous to the effect of being 16 years older. The joint effect of the FX risk alleles (e.g. OR:1.2 increased risk from subjects with highest number of FX alleles) is similar to those of some environmental risk factors for fracture (e.g. OR:1.3 for corticosteroids).

Objective Assessment of Physical Activity and Risk of Non-spine Fractures: Osteoporotic Fractures in Men Study: (MrOS). Jane Cauley^{*1}, Stephanie Harrison², Dawn Mackey³, Kristine Ensrud⁴, Eric Orwoll⁵, Peggy Cawthon⁶. ¹University of Pittsburgh Graduate School of Public Health, USA, ²San Francisco Coordinating Center, USA, ³CPMC Research Institute, USA, ⁴Minneapolis VA Medical Center / University of Minnesota, USA, ⁵Oregon Health & Science University, USA, ⁶California Pacific Medical Center Research Institute, USA

Few studies have examined the association between physical activity (PA) and non-spine fractures in older men and existing studies are inconclusive. Most previous studies relied on self-reported PA questionnaires which primarily focus on leisure time sports participation. Lower intensity PA is more difficult to quantify by self-report. As part of the third MrOS visit (2007-09), we measured energy expenditure and minutes of PA objectively in 3137 men, average age 79 years using the multi-sensor SenseWear Pro Armband (Innervue software version 5.1, Body Media, Pittsburgh, PA). Men wore the armband for an average of 5 days (range 1-10). Total daily energy expenditure (TEE) and minutes spent in sedentary (metabolic equivalent (MET) <3 e.g., computer usage, laundry), moderate (MET 3- <6 e.g., golf, dancing) and vigorous (MET >6 e.g., running) activities were quantified and divided into quintiles (Q). Non-spine fractures were identified through postcards/phone calls every 4 months. All fractures were confirmed by radiographic report. 150 men (4.8%) experienced an incident non-spine fracture over an average follow-up of 2.7 0.6 years. Cox proportional hazards models were used to assess the relative hazard (RH) (95% confidence interval (CI)) of non-spine fracture across quintiles of PA; quintile 5 (Q5) formed the referent group. Of the total minutes per day, average number of minutes of sedentary activity was 1286; moderate, 74.6 minutes and vigorous, 7.4 minutes. Median TEE (kcal/d) was lower in men who fractured (2127) vs no fracture (2287), $p=0.008$. Median minutes of moderate or greater (MET >3) PA per day was also lower in men who had a non-spine fracture (51.7) vs no fracture (67.6), $p=0.003$. In multiply adjusted models, men with the lowest (Q1) total TEE had a higher risk of non-spine fracture (HR=1.57; 95% CI, 1.07-2.31) compared to men with higher activity (Q2-Q5). However, separate examination of the average minutes of sedentary, moderate and vigorous activity revealed different results by activity intensity (Table). Sedentary activity was unrelated to the risk of non-spine fracture. Men with the lowest minutes of moderate and vigorous activity had a higher risk of fracture that was independent of age, BMD and other covariates (p trend, <0.05). Our results suggest that PA must be at least of moderate intensity to lower risk against non-spine fractures; 30-50 m/day of moderate activity or greater is needed.

Table: Multivariable adjusted* relative hazard (95% CI) of non-spine fracture across quintiles of minutes (m/day) of physical activity of various intensities

Interaction of Genome Wide Variants with Dietary Vitamin D Intake on Serum Vitamin D Concentration: The Framingham Osteoporosis Study. Yue Fang^{*1}, Ching-Ti Liu², Yi-Hsiang Hsu³, Adrienne Cupples⁴, David Karasik⁵, Douglas Kiel⁵. ¹Hebrew SeniorLife Center at Harvard Medical School, USA, ²Boston University School of Public Health, USA, ³Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ⁴Department of Biostatistics, Boston University School of Public Health, USA, ⁵Hebrew SeniorLife, USA

Vitamin D is an important contributor to many diseases and health conditions, including osteoporosis. As is true for other complex genetic traits, vitamin D status is regulated by multiple genetic and environmental factors, as well as their interaction. Most Genome Wide Association Studies (GWAS) have focused on the independent main genetic effects on phenotypes, including a recent meta-analysis from the "SUNLIGHT Consortium". These studies ignore the observation that the serum response to vitamin D intake varies considerably between individuals, suggesting that genetic factors may interact with dietary of vitamin D on serum concentrations. We therefore investigated the interaction between whole genome single nucleotide polymorphisms (SNPs) and dietary vitamin D intake on serum vitamin D level in the Framingham Osteoporosis Study (2,315 men and 2,668 women, mean age = 65 yrs). Dietary vitamin D intake was estimated by food frequency questionnaire that included the use of vitamin D supplements. 25(OH)D concentration was measured by radioimmunoassay. Genotyping used the Affymetrix 500+50K Genechips, and >2.4 mil genome-wide SNPs imputed with the HapMap CEU phase II panel. The interaction between each genome-wide SNP and continuous vitamin D intake on ln25 (OH)D was assessed with the linear regression that included an interaction term between SNP and vitamin D intake, adjusted for age, sex, BMI, season of vitamin D measurement, total energy intake and principal components of ancestry. We observed 17 SNPs with an interaction p -value $<10^{-6}$. Eight common SNPs (allele frequencies 9-19%), six in the cadherin 11 (CDH11) and two in the tetratricopeptide repeat domain 27 (TTC27) gene, had interaction p -values of $2.6-4.4 \times 10^{-7}$, which indicated that genotypes of SNPs in CDH11 and TTC27 genes may modify the association between dietary vitamin D intake and serum vitamin D concentration. Though CDH11 gene was reported to modulate postnatal bone growth and osteoblast differentiation in vivo and in vitro, TTC27 gene was sensitive to damage by hypoxic condition in brain, we are unclear how they influence the association of vitamin D intake and serum level. Thus, our findings need to be replicated in other independent studies. In conclusion, we observed potential interaction between CDH11 and TTC27 genes with dietary vitamin D intake on serum vitamin D concentration in our cohort, it suggests that there may be genes that modify the serum response to vitamin D intake.

Meta-analysis of Genome-wide Association Studies in Premenopausal White Women Identifies Variants in WNT16, ESR1, and Novel BMD Loci. Daniel Koller^{*1}, David Karasik², Hou-Feng Zheng³, Laura Yerges-Armstrong⁴, Ching-Ti Liu⁵, Dongbing Lai¹, Karol Estrada⁶, Fernando Rivadeneira⁶, Andre Uitterlinden⁷, Sylvie Giroux⁸, Francois Rousseau⁹, Stefan Czerwinski¹⁰, Bradford Towne¹⁰, Michael Econs¹, Braxton Mitchell¹¹, Brent Richards³, Douglas Kiel², Tatiana Foroud¹. ¹Indiana University School of Medicine, USA, ²Hebrew SeniorLife, USA, ³McGill University, Canada, ⁴University of Maryland, USA, ⁵Boston University School of Public Health, USA, ⁶Erasmus University Medical Center, The Netherlands, ⁷Rm Ee 575, Genetic Laboratory, The Netherlands, ⁸Centre de recherche CHUQ-SFA, Canada, ⁹University Laval, Canada, ¹⁰Wright State University Boonshoft School of Medicine, USA, ¹¹University of Maryland, Baltimore, USA

Several genome-wide association studies (GWAS) have identified gene variants associated with bone mineral density (BMD) variation, typically in combined samples of elderly women and men. Meta-analysis of these results (Rivadeneira et al, Nat Gen 2009) identified 20 genome-wide significant SNPs of modest effect in both novel genes as well as in genes previously shown to influence BMD variation. BMD in older adults is influenced by genes underlying bone accrual as well as bone loss processes. To identify genes influencing peak bone mass, we performed a GWAS meta-analysis restricted to premenopausal white women ($n=4,061$ women, ages 20 to 45) from 4 cohorts (Framingham Osteoporosis Study, Amish Family Osteoporosis Study, Indiana Sisters Study, and Twins UK). BMD was measured at the lumbar spine and femoral neck by DXA. GWAS genotypes in each cohort were imputed to HapMap II r22 and samples with call rates below 95% as well as SNPs with deviation from Hardy-Weinberg equilibrium ($p<0.0001$) were removed. Age- and weight-adjusted BMD values were tested for association with each SNP. Inverse variance fixed-effects meta-analysis using METAL was performed, applying double-genomic control correction.

22 SNPs (Table) provided suggestive evidence of association ($p<10^{-5}$) with either spine or femoral neck BMD after pruning by minor allele frequency ($<3\%$), LD ($r^2>0.2$) with a SNP already identified, and singleton associations in high LD ($r^2>0.5$)

with other non-associated SNPs. Several of these associations were previously reported in men and women across a broad age range (e.g. *WNT16*, *ESR1*, *C6orf97* and *SOX6*). In addition, we identified several SNPs in genes not previously associated with BMD that provided suggestive evidence of association in our sample of premenopausal women (bold in Table). We are currently performing replication genotyping in approximately 3,700 independent samples of premenopausal women. Our results confirm that some of the genes contributing to peak BMD in premenopausal women also influence BMD variation across sexes and ages. However, our approach also seems to identify novel BMD associations that may be more specific to premenopausal women.

Women With Inadequately Controlled Type 2 Diabetes Are At Increased Risk Of Osteoporotic Fractures Despite Higher Bone Mineral Density: The Rotterdam Study. Ling Oei^{*1}, Martha Castano-Betancourt¹, Huibert Pols¹, Abbas Dehghan², Andre Uitterlinden³, Fernando Rivadeneira¹, M Zillikens⁴. ¹Erasmus University Medical Center, The Netherlands, ²Erasmus MC, Netherlands, ³Rm Ee 575, Genetic Laboratory, The Netherlands, ⁴Erasmus MC Rotterdam, The Netherlands

Aim: Patients with type 2 diabetes mellitus display an increased fracture risk found after controlling for higher BMD. The increased fracture risk is mainly attributable to the increased risk of falling. Our aim was to investigate if the relationship between diabetes, BMD and osteoporotic (OP) fractures is influenced by diabetes control across genders.

Methods: This is a large prospective population-based study including 4135 participants with baseline (1991-1993) information on diabetes status, BMD, and incident OP fracture events with follow-up (mean 8.2 years SD=2.95). HbA1c was computed at baseline from fructosamine levels:

HbA1c = 0.017 * Fructosamine [μmol/L] + 1.61. Inadequate glucose control in diabetes was defined as a serum HbA1c level ≥ 7.5%. Comparison groups included non-diabetics (ND;n=3715), adequately controlled diabetics (ACDM;n=203) and inadequately controlled diabetics (ICDM;n=217) stratified by gender. Femoral neck (FN) and lumbar spine (LS) BMD was measured by DXA. Mean differences in BMD levels were tested in linear regression models adjusted for age and BMI. OPfx were defined as those not caused by focal lesions, hand, skull or facial fracture and derived from physician records. Cox proportional hazard regression models were used to estimate the risk of fracture adjusted for age and weight.

Results: In both genders diabetics had higher BMD. ICDM women had significantly higher BMD (g/cm²) at both the LS (1.10;P=0.0001) and FN (0.86; P=0.005) as compared to ACDM women (LS:1.03;FN:0.83) and non-diabetics (LS:1.03;FN:0.82). No differences in BMD were seen between ACDM and ICDM men. No increased risk for incident non-vertebral fracture was observed in either type of diabetics in either gender after correction for age and BMI. After additional correction for FN-BMD ICDM women had 1.6 times (95%CI 1.07-2.25; P=0.02) increased risk of fracture as compared to non-diabetics. ACDM women had no increased risk of fracture (HR: 0.88 95%CI 0.57-1.36; P=0.57). In men no significant risk of fracture was observed in either group of diabetics.

Conclusion: Elderly subjects with Type 2 diabetes have higher BMD levels than non-diabetics. In women higher levels are mostly driven by inadequately controlled

diabetics. After correcting for femoral neck BMD, inadequately controlled diabetic women have increased risk of incident non-vertebral fracture. These findings suggest inadequate control of diabetes is a risk for fracture in elderly women.

BMD and Breast Cancer Risk: A Positive Association in Women ≥50 Years and a Negative in Women <50 Years? The HUNT Study, Norway. Siri Forsmo^{*1}, Kathinka Slørdahl², Arnulf Langhammer³. ¹Norwegian University of Science & Technology, Norway, ²Faculty of Medicine, Norwegian University of Science & Technology, Norway, ³Dept. of Public Health & General Practice, Norwegian University of Science & Technology, Norway

Purpose: To explore the association between forearm bone mineral density (BMD) and incident breast cancer in a cohort of 13,072 Norwegian women aged 19-89 years, followed up to 14 years.

Methods: Distal and ultradistal forearm BMD was measured in the second Nord-Trøndelag Health Study (1995-97), a multipurpose health survey. Reproductive health and life-style data were collected by self-administered questionnaires. A total of 210 incident breast cancer cases were identified by record linkage with the Norwegian Cancer Registry. Limits of identification were set for breast cancer registered between two months after BMD assessment until the end of follow-up at Dec. 31, 2008. Follow-up time was calculated as the difference in time between BMD assessment until the event of incident breast cancer, death (N=2,598), emigration (N=25) or the end of follow-up, whichever occurred first. Due to missing or incomplete BMD, weight or height measurements, a total of 12,881 women were eligible for analyses. The association between BMD and incident breast cancer was analysed in Cox' proportional regression models with BMD in tertiles of Z-score, i.e. standard deviations from age-specific mean BMD. The analyses were performed in two age strata, under 50 years and 50 and above.

Results: Mean time of follow-up was 11.4 years (3 weeks-14.1 years) or 146,614 person-years. A total of 42 cases (0.8/1000 person-years) was observed among women <50 years and 168 (1.8/1000 person-years) among women aged 50 or above. The risk of incident breast cancer was positively associated with BMD in women 50+ with a hazard ratio (HR) of 0.65 (95% CI, 0.45-0.94) for women in the lowest tertile of Z-scores relative to women in the highest (HR=1) and with a statistically significant linear trend across the Z-score tertiles (p=0.02). The association between BMD and breast cancer risk in the younger women seemed to be negative, especially for BMD measured at the ultradistal radius where the HR of breast cancer was 1.9 (95% CI, 0.9-4.1) for women in the lowest tertile compared to those in the highest and with a linear trend across the tertiles (p=0.1). Adjusting for weight explained some of the association found in women 50+, but not among the younger.

Conclusion: High BMD in women aged 50+ is associated with increased risk of breast cancer whereas the inverse association is observed in younger women, indicating age-related differences in breast cancer etiology.

Fat Mass and Fracture Risk in Elderly Men and Women: A Prospective Study. Shuman Yang^{*1}, Nguyen Nguyen², Jacqueline Center², John Eisman², Tuan Nguyen². ¹Garvan Institute, Australia, ²Garvan Institute of Medical Research, Australia

Background and aim: The relationship between body fat mass and fracture risk is controversial, due primarily to lack of prospective data. The present study sought to examine the association between whole body and abdominal fat mass and fracture risk in postmenopausal women and elderly men.

Materials and methods: The present study was part of the ongoing Dubbo Osteoporosis Epidemiology Study (DOES) recruited a cohort of 1129 participants (361 men and 768 women), whose total body bone mineral density (BMD) scans were available. BMD at the femoral neck and lumbar spine, total body fat mass and abdominal fat mass were measured by dual energy X-ray absorptiometry (GE-LUNAR Corp, Madison, WI). Baseline characteristics of participants including age, height, physical activity, history of falls, smoking and prior fracture were ascertained at the initial visit. The incidence of low-trauma and non-pathological fractures was ascertained from X-ray reports. The Cox's proportional hazards regression was used to evaluate the association between fat mass and fracture risk, with adjustment for baseline covariates.

Results: During the median 5 years of follow-up, 19 (5%) men and 107 (14%) women had sustained a fragility fracture. Women with fracture had lower BMD, lower body fat mass and body weight than those without a fracture. In women, increased risk of fracture was associated with lower abdominal fat mass (hazard ratio/standard deviation [HR/SD]: 1.33; 95% CI: 1.07-1.65), after adjusting for age (HR/SD: 1.32; 1.08-1.63), femoral neck BMD (HR/SD: 1.26; 1.03-1.56), and prior fracture (HR/SD: 1.41; 1.15-1.73). Compared with women in the highest tertile of abdominal fat, those in the lowest tertile had a 2.1-fold (95%CI: 1.25-3.55) increase in fracture risk. Further analyses revealed that lower body fat mass was also associated with increased fracture risk, but the association was not independent of BMD. The

magnitude of association between fat mass and fracture risk (HR/SD: 1.32; 1.08-1.63) was greater than that of body weight and fracture risk (HR/SD: 1.15; 0.94-1.41). Approximately 27% of population fracture liability was attributable to abdominal fat mass.

Conclusion: Lower total body fat mass, particular lower abdominal fat, was significantly associated with increased fracture risk in women, not in men. These results suggest that the incorporation of fat mass into existing fracture prognostic models may enhance their predictive accuracy.

Fracture Incidence in Obese Postmenopausal Women: The Global Longitudinal Study of Osteoporosis in Women. Juliet Compston^{*1}, Nelson Watts², Roland Chapurlat³, Cyrus Cooper⁴, Steven Boonen⁵, Susan Greenspan⁶, Johannes Pfeilschifter⁷, Stuart Silverman⁸, Adolfo Diez-Perez⁹, Robert Lindsay¹⁰, Kenneth Saag¹¹, Coen Netelenbos¹², Stephen Gelhbach¹³, Frederick Hooven¹⁴, Julie Flahive¹³, Jonathan Adachi¹⁵, Maurizio Rossini¹⁶, Andrea Lacroix¹⁷, Christian Roux¹⁸, Philip Sambrook¹⁹, Ethel Siris²⁰. ¹University of Cambridge School of Clinical Medicine, United Kingdom, ²University of Cincinnati Bone Health & Osteoporosis Center, USA, ³E. Herriot Hospital, France, ⁴University of Southampton, United Kingdom, ⁵Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁶University of Pittsburgh, USA, ⁷Alfried Krupp Krankenhaus Steele, Germany, ⁸Cedars-Sinai/UCLA, USA, ⁹Autonomous University of Barcelona, Spain, ¹⁰Helen Hayes Hospital, USA, ¹¹University of Alabama at Birmingham, USA, ¹²VU Medical Center, The Netherlands, ¹³UMass Medical School, USA, ¹⁴University of Massachusetts Medical School, USA, ¹⁵St. Joseph's Hospital, Canada, ¹⁶University of Verona, Italy, ¹⁷Fred Hutchinson Cancer Research Center, USA, ¹⁸Hospital Cochin, France, ¹⁹Royal North Shore Hospital, Australia, ²⁰Columbia University College of Physicians & Surgeons, USA

Purpose: Low body mass is an important risk factor for fracture, while obesity is widely believed to be protective. However, two recent studies in postmenopausal women have challenged this view [1,2]. The aim of this study was to examine the incidence of clinical fractures in obese postmenopausal women in the Global Longitudinal study of Osteoporosis in Women (GLOW) study - a multinational, prospective, population-based observational study in 60,393 women - over a 2-year follow-up period.

Methods: Data were collected using self-administered questionnaires covering domains that included patient characteristics, fracture history, risk factors for fracture, and anti-osteoporosis therapy.

Results: Fracture history and body mass index (BMI) were available at baseline and at 2 years in 44,534 women. Of these, 23.4% were obese (BMI ≥ 30 kg/m²), 74.9% non-obese (BMI 18.5-29.9 kg/m²), and 1.7% underweight (BMI < 18.5 kg/m²). In obese women, the prevalence of fractures at baseline was 222 per 1,000 and incidence at 2 years was 61.7 per 1,000, similar to rates in non-obese women (227 and 66.0 per 1,000, respectively). Fractures in obese women accounted for 22% of all incident fractures. Higher BMI was associated with ankle ($p < 0.001$) and lower leg fractures ($p = 0.02$) and was inversely related to wrist ($p = 0.01$) and pelvis fractures ($p = 0.02$). Non-obese and obese women with incident fracture had similar rates of previous fracture (42% and 39%, respectively). Obese women with incident fracture were more likely to have experienced early menopause and to report two or more falls in the past year ($p < 0.001$). Self-reported asthma, osteoarthritis, and type 1 diabetes were all significantly associated with higher BMI ($p < 0.001$). At 2 years, only 27% of obese women with incident fracture were receiving bone-protective medication, compared with 41% of non-obese and 57% of underweight women.

Conclusions: Our results demonstrate that nearly one in four postmenopausal women with an incident clinical fracture is obese and that obesity is a risk factor for fractures of the lower leg and ankle. Our findings have major public health implications in view of the rapidly rising incidence of obesity. Further studies are required to establish the pathogenesis of fractures in the obese population and to develop effective strategies for their prevention.

New Loop Diuretic Prescriptions Increase the Acute Risk of Hip Fracture.

Sarah Berry^{*1}, Yanyan Zhu², Hyon Choi², Douglas Kiel³, Yuqing Zhang².

¹Hebrew SeniorLife/Beth Israel Deaconess Medical Center, USA, ²Boston University School of Medicine, USA, ³Hebrew SeniorLife, USA

Purpose: Conflicting data exist on the association between diuretics and risk of hip fracture. We hypothesized that older adults would have a short term increased risk of hip fracture following a new prescription for a diuretic due to acute urinary symptoms that could result in a fall due to hurrying. We determined the effect of a new loop and other diuretic prescription on the acute risk of hip fracture using a case-crossover study design in The Health Improvement Network (THIN).

Methods: THIN is a primary care database from more than 400 practices and 7 million persons in the UK. Participants of the current study (1986-2010) included 28,707 members, aged ≥ 50 years, who experienced a hip fracture > 365 days from enrollment. Fractures were identified using diagnostic codes. A new diuretic prescription was defined as an oral diuretic prescription without a history of use within the past 180 days. We defined the case period as 1-7 days before the fracture and the control period as 31-37 days before the fracture in the same individual. Odds ratios of hip fracture were estimated by comparing the frequency of new loop and other diuretic prescriptions during the case and control periods using conditional logistic regression models. To address confounding by indication we repeated our analysis using a comparator class of medications that are not expected to be associated with falls or fractures: ACE-inhibitors.

Results: Mean age was 89 yrs (SD 10 yrs), and 77% were female. During the case periods, 64 subjects with hip fracture received a new prescription for a loop diuretic compared with 35 in the control periods. The odds ratio of experiencing a hip fracture within 7 days of a new loop diuretic prescription was 1.8 (95%CI 1.2, 2.8). There was no association between a new prescription of other diuretics (OR:1.1, 95% CI 0.7, 1.7) or ACE-inhibitors (OR:0.8, 95% CI 0.4, 1.5) and the acute risk of hip fracture.

Conclusions: Risk of hip fracture was elevated by 80% during the week following a new loop diuretic prescription, but not following other diuretic or ACE-inhibitor prescriptions. The acute risk may relate in part to urinary symptoms, which are more prominent with loop diuretic initiation. Although new loop diuretic prescriptions were associated with a small absolute number of excess hip fractures, increased awareness and toileting interventions might be effective in reducing hip fractures and other injurious falls in vulnerable older adults during this time.

QCT vBMD and Vascular and Valvular Calcification: The Framingham Study.

Elizabeth Samelson^{*1}, Christopher O'Donnell², Kerry Broe³, Udo Hoffmann⁴, Sekar Kathiresan², Serkalem Demissie⁵, L. Adrienne Cupples², Mary Boussein⁶, Douglas Kiel⁷.

¹Hebrew SeniorLife, Harvard Medical School, USA, ²National Heart, Lung & Blood Institute's Framingham Heart Study, USA, ³Hebrew Senior Life, USA, ⁴Massachusetts General Hospital, USA, ⁵Department of Biostatistics, Boston University School of Public Health, USA, ⁶Beth Israel Deaconess Medical Center, USA, ⁷Hebrew SeniorLife, USA

Previous studies provide evidence for a shared pathogenesis between osteoporosis and atherosclerosis, highly prevalent conditions with significant morbidity and mortality in older adults. Because DXA assessment of lumbar spine BMD can be confounded by the presence of abdominal aortic calcification and by bone size, 3-D technology is needed for precise measurement. Prior work focused on the association of coronary artery and aortic calcification to BMD in highly selected individuals.

Valve calcification and resulting stenosis are also clinically significant. Similar to vascular calcification, valve calcification is an active process sharing features of bone formation. We conducted a cross-sectional study to determine the association between volumetric bone density (vBMD) and severity of atherosclerotic and valvular calcification in the community-based Framingham Study.

Participants included 700 women and 630 men in the Framingham Offspring Study (mean age 60 years, range 36-83 years) who underwent imaging using an 8-slice MDCT scanner in 2002-05. Coronary artery, abdominal aortic, aortic valve, and mitral valve calcium were each scored using previously published, modified Agatston methods. ANCOVA was used to calculate mean log-transformed calcium scores across sex-specific quartiles (1=low) of integral vBMD at the lumbar spine (L3), adjusted for age, BMI, height, smoking, physical activity, and for women, menopause status and estrogen use.

Prevalence of any calcium (score > 0) was 57% for coronary artery, 77% for abdominal aorta, 20% for mitral valve, and 32% for aortic valve calcium. We found an inverse association between severity of vascular calcification (coronary artery and abdominal aorta) and vBMD in women (TABLE), although no association was observed in men. No association between aortic and mitral valve calcium and vBMD was seen in women or men.

We used MDCT technology to measure both vascular and valvular calcification as well as spine bone density in a community-based population of women and men. The sex-specific findings of an inverse association between vascular calcification and vBMD are consistent with previous studies suggesting differences between women and men in the underlying pathophysiology of bone mineralization, vascular calcification, or both. A lack of association between vBMD and valve calcification may be due to a low prevalence compared to vascular calcification or due to pathophysiological or other differences.

Temporal Trends in 25-Hydroxyvitamin D levels and parathyroid hormone in a population-based study. Claudia Berger^{*1}, Linda Greene-Finestone², Lisa Langsetmo³, Lawrence Joseph¹, Nancy Kreiger⁴, Brent Richards¹, Christopher Kovacs⁵, Kurtis Sarafin⁶, K. Shawn Davison⁷, Jonathan Adachi⁸, Jacques Brown⁷, David Hanley⁹, David Goltzman¹⁰. ¹McGill University, Canada, ²Public Health Agency of Canada, Canada, ³Canadian Multicenter Osteoporosis Study, Canada, ⁴University of Toronto, Canada, ⁵Memorial University of Newfoundland, Canada, ⁶Health Canada, Canada, ⁷Laval University, Canada, ⁸St. Joseph's Hospital, Canada, ⁹University of Calgary, Canada, ¹⁰McGill University Health Centre, Canada

We examined vitamin D and calcium intake, sun-exposure, and body mass index (BMI) in relation to changes in serum 25-hydroxyvitamin D [25(OH)D] and parathyroid hormone (PTH) over a ten-year period among participants in the Canadian Multicenter Osteoporosis Study.

We studied 1896 women and 829 men aged 25+ years who had 3896 blood samples drawn in 1995-1997, 2000-2002 and/or 2005-2007. PTH and 25(OH)D were analyzed in the same laboratory using a Diasorin Liaison instrument. Hierarchical models using up to 10 years of longitudinal data were used to determine changes over time in vitamin D supplement intake and in serum 25(OH)D and PTH; the non-linear association between PTH and 25(OH)D (polynomials); and predictors of 25(OH)D and PTH. All models were adjusted for season.

Vitamin D supplement intake increased annually by 31.7 (27.2; 35.9) IU/day in women and 19.3 (13.5; 25.2) IU/day in men. 25(OH)D increased annually by 0.9 (0.7; 1.1) nmol/L in women and by 0.4 (0.1; 0.6) nmol/L in men. When adjusted for vitamin D supplement intake, 25(OH)D still increased annually by 0.5 (0.2; 0.7) nmol/L in women and by 0.3 (-0.1; 0.6) nmol/L in men. PTH decreased annually by 0.8 (95% CI: 0.6; 1.2) pg/ml in women and by 0.5 (0.0; 0.9) pg/ml in men. After adjustment for serum 25(OH)D levels, there was still an annual decline of 0.6 (0.3; 0.8) pg/ml and 0.3 (-0.1; 0.8) pg/ml in PTH in women and men. Further adjusting for total calcium intake did not change the decrease in PTH over time. Figure 1 shows the relation obtained from PTH and 25(OH)D. Serum 25(OH)D samples collected in summer were higher in both women [6.9 (4.9; 8.8) nmol/L] and men [8.4 (5.4; 11.5) nmol/L]. Higher 25(OH)D levels were also associated with younger age, lower BMI, participation in regular physical activity, sun exposure and higher total calcium intake. Lower PTH levels

were associated with younger age and higher 25(OH)D levels in both women and men. In women, it was further associated with lower BMI and participation in a regular physical activity. PTH levels were not associated with total calcium intake.

These results indicate a trend toward increasing 25(OH)D levels and decreasing PTH levels over 10 years. Secular increases in supplemental vitamin D have impacted both serum 25(OH)D and PTH, but do not explain all variation in these measures.

Figure 1: PTH by 25(OH)D in women and men

The Association Between Fracture and Obesity Is Site-Dependent: A Population-Based Study. Daniel Prieto-alhambra^{*1}, Francesc Fina Aviles², Eduard Hermosilla³, Daniel Martinez-Laguna⁴, Cristina Carbonell⁵, Robert Guerri⁶, Xavier Nogues⁶, Adolfo Diez-Perez⁶. ¹Institut Municipal D'Investigacio Medica, Spain, ²SIDIAP Database, IDIAP Jordi Gol i Gurina; Barcelona Primary Care Dept, Institut Catala de la Salut, Spain, ³SIDIAP Database, IDIAP Jordi Gol i Gurina, Spain, ⁴Barcelona Primary Health Care Department, Institut Catala de la Salut, Spain, ⁵Healthy Primary Care Via Roma Barcelona.Facultat de Medicina Universitat de Barcelona, Spain, ⁶Department of Internal Medicine, URFOA IMIM-Hospital del Mar, Parc de Salut Mar, Autonomous University of Barcelona, RETICEF (Red Tematica de Investigacion Cooperativa en Envejecimiento y Fragilidad), Instituto Carlos III, Barcelona, Spain, Spain

OBJECTIVE: The available evidence on the association between obesity and fracture is controversial. We aimed to study the existing relationship between body mass index (BMI) and fracture occurrence at different sites among women aged ≥ 50 .

METHODS: The Spanish public health system covers >98% of the population. The SIDIAP database (www.idiapigol.org/sidiap.php) contains the validated clinical information collected in the computerized medical records of >2,500 GPs in Catalonia (North-East Spain), with information on a representative sample which accounts for 80% of the population (>5 million people). In 2009, 1,039,878 women ≥ 50 were eligible in SIDIAP, and 832,775 (80.1%) of them had a BMI measurement available. These were categorized (according to WHO criteria) as underweight/normal (302,414 women), overweight (266,798 subjects) and obese (263,563 people). Fractures were ascertained using ICD-10 codes. We derived age-specific fracture incidence rates for diverse fracture sites (hip, clinical spine, wrist/forearm, tibia, pelvis and proximal humerus) for the 2 extreme BMI groups. Secondly, we estimated age-adjusted rate ratios (and p-values) to compare obese and normal/underweight women using Poisson Regression.

RESULTS: Age-specific fracture rates for extreme BMI groups (normal/underweight versus obese) are shown in Figure 1. Hip (RR 0.49 [95CI 0.44 to 0.55] $p<0.001$), clinical spine (RR 0.87 [95CI 0.77 to 0.98] $p=0.021$), wrist/forearm (RR 0.83 [95CI 0.75 to 0.91] $p<0.001$) and pelvis fracture rates (RR 0.43 [95CI 0.19 to 0.97] $p=0.028$) were higher in the normal/underweight than in the obese. Conversely, obese women were at significantly higher risk of proximal humerus fracture than the normal/underweight: RR 1.23 [95CI 1.07 to 1.41] $p=0.002$. Tibial fracture rates were not different between groups ($p=0.488$).

DISCUSSION: The association between obesity and fracture is site-dependent: while obesity protects from hip, clinical spine, wrist/forearm and pelvis fractures, it is also related to an almost 25% increase in risk for proximal humerus fractures. This should be considered for fracture prevention among obese patients.

FR0392

Chronic Central Administration of Ghrelin Increases Bone Mass Through Mechanisms Independent of Appetite Regulation. Hyung Jin Choi¹, Kyoung Ho Ki¹, Jae-Yeon Yang¹, Bo Young Jang¹, Jung Ah Song¹, Wook-Young Baek², Jung Hee Kim³, Jee Hyun An¹, Sang Wan Kim⁴, Seong Yeon Kim¹, Jung-Eun Kim⁵, Chan Soo Shin¹. ¹Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ²Department of Molecular Medicine, Cell & Matrix Research Institute, Kyungpook National University School of Medicine, South Korea, ³Seoul National University College of Medicine, South Korea, ⁴Seoul National University Boramae Hospital, South Korea, ⁵Kyungpook National University School of Medicine, South Korea

Leptin has been shown to play a critical role in the central regulation of bone mass. Ghrelin is a gut-derived hormone that counteracts leptin in hypothalamus regarding appetite control. In the present study, we have investigated the effect of chronic intracerebroventricular (ICV) administration of ghrelin on bone mass changes. The effects of ghrelin on food intake, body weight, and bone metabolism were determined following ICV administration of ghrelin (1.5ug/day) for 21 days in Sprague-Dawley rats. Rats were divided into control, ad lib-fed, and pair-fed groups. Bone mineral density, bone microstructure, bone formation rate and daily body weight were determined by DXA, MicroCT, and calcein double labeling. ICV infusion of ghrelin for 21 days significantly increased body weight in ad lib-fed rats (331.4 g, $p < 0.05$) but not in pair-fed rats (311.9 g) compared with control rats (312.9 g). Ghrelin ad lib-fed rats had significantly higher spine BMD compared with control rats (0.161 vs. 0.148 g/cm²; $P < 0.05$). Ghrelin pair-fed rats tended to have a higher bone mass in femur (BV/TV) (26.6 vs. 22.4 %; $p = 0.07$) and had significantly higher trabecular thickness in femur (72.1 vs. 67.8 μ m; $p < 0.05$) compared with control rats. There was no significant change in trabecular number or trabecular spacing between ghrelin pair-fed and control group. In dynamic assessment of bone formation using calcein double labeling study, ghrelin pair-fed rats (5.2 \pm 1.0 μ m/d, $p < 0.05$) and ghrelin ad lib-fed rats (5.6 \pm 1.3 μ m/d) had significantly higher mineral apposition rate (MAR) compared with control (3.8 \pm 0.9 μ m/d). However, we were unable to demonstrate significant changes in serum PINP at 9 weeks of age. In conclusion, chronic central administration of ghrelin increased bone mass through mechanisms independent of body weight changes, suggesting that ghrelin antagonizes leptin in bone mass regulation as it does in appetite control.

FR0394

Circulating Sclerostin Levels and Bone Turnover in Type 1 and 2 Diabetes. Ranuccio Nuti¹, Roberto Valenti², Daniela Merlotti¹, Elena Ceccarelli³, Martina Ruvio³, Maria Giulia Pietrini³, Cosimo Capodacqua³, Maria Beatrice Franci³, Anna Calabro³, Konstantinos Stolkis³, Francesco Dotta³, Luigi Gennari¹. ¹University of Siena, Italy, ²S. Maria Alle Scotte Hospital, Italy, ³Dept. Internal Medicine Endocrine Metabolic Sciences & Biochemistry University of Siena, Italy

Evidence from experimental and clinical studies indicates that both type 1 (DM1) and 2 (DM2) diabetes can impact bone strength and increase fracture risk. However the pathogenetic mechanisms remain in great part unknown and are only in part reflected by variation in BMD. Previous experimental and histomorphometry observations often evidenced a condition of low bone turnover and decreased osteoblast activity in both DM1 and DM2. Sclerostin (SOST) is a secreted Wnt antagonist produced by osteocytes that regulate osteoblast activity and thus bone metabolism. Its levels increase with age and are regulated by both estrogens and PTH in both women and men. The aim of the present study was to evaluate SOST levels in patients with DM1 (n= 43) or DM2 (n=40) with normal renal function, compared with age and sex-matched control subjects (CT, n= 50), and to analyze its relationship with PTH, 25 OH-vitamin D and bone turnover markers (bone alkaline phosphatase, BALP; total osteocalcin, OC; and serum crosslaps, CTX). As expected BMD at the femoral neck was lower in DM1 and slightly higher in DM2 with respect to age-matched controls, while a reduction in bone turnover markers was observed in both DM1 and DM2. In the overall cohort of subjects, circulating SOST levels were higher in males than in females and significantly increased with age and BMI in both genders. The positive correlation between SOST and age was maintained in both DM1 and DM2 patients. In all study groups bone turnover markers were not significantly correlated with serum SOST, except that BALP that was negatively associated with SOST in control men ($r = -0.46$, $p = 0.02$). Moreover, SOST levels were higher in DM2 than in controls or DM1 patients, and this difference persisted when adjustments were made for age and BMI. Consistent with previous clinical and experimental observations, SOST levels were negatively correlated with serum PTH in nondiabetic patients ($r = -0.59$, $p < 0.001$), independently of age and gender. Conversely, an unexpected positive correlation between PTH and SOST was observed in both DM1 ($r = 0.26$, $p = 0.09$) and DM2 ($r = 0.32$, $p = 0.07$) groups. Taken together our findings suggest that the transcriptional suppression of SOST production by PTH (previously demonstrated in animal and human studies) is impaired in both DM1 and DM2.

Blockade of Endogenous Gi Signaling in Osteoblasts Stimulates Bone Formation and Prevents Age-Related Bone Loss. Liping Wang¹, Susan M. Millard², Dylan O'Carroll¹, Lalita Wattanachanya³, Richard Kao⁴, Wei-Dar Lu¹, Aaron J. Fields⁵, Jeffrey C. Lotz⁵, Robert Nissenson³. ¹VA Medical Center, San Francisco, USA, ²University of Queensland, Australia, ³VA Medical Center & University of California, San Francisco, USA, ⁴UCSF/VAMC, USA, ⁵Department of Orthopaedic Surgery, UCSF, USA

Loss of bone with aging is an important risk factor for fractures in the elderly. Signaling by G protein-coupled receptors (GPCRs) plays a crucial role in regulating osteoblast function. We previously demonstrated that endogenous Gi signaling in osteoblasts restricts bone formation in adult mice and hypothesized that blockade of Gi signaling in osteoblasts may prevent bone loss during aging. We used female transgenic mice in which expression of the pertussis toxin (PTX) gene, under the control of 2.3 kb Collagen I α promoter (Col1(2.3)), was regulated via a tetracycline responsive promoter. Expression of PTX was delayed until 8 weeks of age and the distal femurs were then studied by μ CT in vivo at 2.5, 6, 9, and 12 months of age. It was found that from 2.5 to 12 months of age, the cancellous BV/TV had progressively decreased by 64% ($p < 0.001$) in the littermate control mice while BV/TV had increased by 181.4% ($p < 0.001$) in the Col1(2.3).PTX mice. With histomorphometry, we found that at 12 months of age, the PTX transgenic mice had higher cancellous BV/TV (25.17.6 vs. 1.90.4%, $p < 0.001$), trabecular number (8.982.6 vs. 0.520.1mm⁻¹, $p < 0.001$), and bone formation rate (BFR) (1.590.4 vs. 0.470.3 μ m/day, $p < 0.001$) in the distal femur than the age-matched controls. Moreover, the Col1(2.3).PTX mice had increased cortical thickness (409108 vs. 27434 μ m, $p < 0.01$) and decreased bone marrow area (0.840.1 vs. 1.270.2mm², $p < 0.01$) at mid-femur, with a higher BFR seen only at the endocortical surface (0.590.28 vs. 0.040.04 μ m/day, $p < 0.001$). A 3 point bending test of femoral diaphyses revealed that bone strength was 29% higher in the transgenic than in the control mice (47.06.4 vs. 36.23.1N, $p < 0.05$). To test the effects of the blockade of Gi signaling on fracture healing, we fractured the tibiae of 3 month old female mice and found that, 4 weeks after fracture, the PTX transgenic mice had higher fractional BV/TV (43.03.6 vs. 30.52.8%, $p < 0.01$) and higher BFR (1.930.2 vs. 1.090.4 μ m/day, $p < 0.01$) within the callus as compared to the fractured control mice. Collectively, our results indicate that blockade of Gi signaling with PTX in osteoblasts stimulates bone formation, increases bone strength, and accelerates fracture healing in the adult female Col1(2.3). PTX mice. Therapies designed to inhibit GPCR-mediated Gi activation in osteoblasts could be useful in the treatment of age-related osteoporosis and in promoting fracture repair.

Bone Microarchitecture Assessment in Postmenopausal Women with Atypical Fractures of the Femur and Long Term Bisphosphonate Therapy. Maria Belen Zanchetta¹, Ana Galich¹, mirena buttazzoni², maria diehl², Candela Fernandez³, fernando silveira², Fabio Massari¹, Cesar Bogado¹, Jose Ruben Zanchetta¹. ¹Instituto de Investigaciones Metabolicas (IDIM), Argentina, ²md, Argentina, ³Hospital De Clinicas - Universidad De Buenos Aires, Argentina

In recent years concern has been raised on a possible association between atypical fractures at the subtrochanteric region of the femur and long-term bisphosphonate use. The pathophysiology of these events remains unknown.

Our aim was to describe bone microarchitecture in patients with atypical fractures during long term bisphosphonate treatment using High Resolution peripheral computerized Tomography (HR-pQCT) scans of the distal radius and tibia. Additionally, to compare these results with two control groups with similar age and BMI selected from our database: one of postmenopausal women chronically treated with bisphosphonates and one of postmenopausal women who have never received treatment. We identified 10 postmenopausal women who suffered an atypical fracture of the femur during long term bisphosphonate treatment (mean treatment time 16.2 \pm 5.1 years). All major features defined by the ASBMR Task Force (location in the subtrochanteric region and femoral shaft, transverse or short oblique orientation, minimal or no associated trauma, a medial spike when the fracture is complete, and absence of comminution) were present to designate a femoral fracture as atypical. Minor features and clinical characteristics are described in table1. We compared bone volumetric density and architectural parameters measured by HR-pQCT of the radius and tibia in these patients with 30 postmenopausal women who have also received long term treatment with bisphosphonate (mean 8.63.5 years) and who have not suffered an atypical fracture and with 54 postmenopausal women who have never received treatment. All women had no conditions known to affect bone or mineral metabolism. Areal BMD at the lumbar spine and femoral neck was measured using DXA. Volumetric BMD and microarchitecture were measured at the distal radius and tibia using a HR-pQCT scanner (XtremeCT; Scanco Medical AG). Comparisons between groups was assessed by the two-sample T test. A p value <0.05 was considered statistically significant.

There were no statistically significant differences in age, years since menopause, BMI and BMD T-scores between the three groups. There were no statistically significant differences in almost any of the parameters measured by HR-pQCT between the groups. However, in atypically fractured patients cortical thickness was 9% lower in radius and 4% lower in tibia compared to the chronically treated women and 6% lower in radius and 5 % lower in tibia compared to the non treated group. These differences must be confirmed in larger studies.

Bone Steatosis And Osteocyte Apoptosis In Alcohol-induced Bone Loss. Delphine Maurel¹, Stephane Pallu², Christelle Jaffre³, Nathalie Boisseau⁴, Nick Fazzalari⁵, Rustem Uzbekov⁶, Gael Rochefort⁷, Claude-Laurent Benhamou⁸. ¹Inserm Unit 658Hôpital Porte MadeleineOrleansFrance, France, ²INSERM U 658 / University of Orleans, France, ³INSERM Unit U658, France, ⁴Laboratory of Physical Activity Biology, Blaise Pascal University, France, ⁵Institute of Medical & Veterinary Science, Australia, ⁶Microscopy Department, Medical Faculty, Tours University, France, ⁷INSERM U658, France, ⁸INSERM Unit U658, CHR Orleans, France

Alcoholism is one of the world's major health problems and it has long been known that excessive alcohol consumption has catastrophic effects on many organs. In bone tissue, alcohol has been shown to decrease osteoblast number and proliferation and to increase osteoclast activity in vitro, thus modifying bone metabolism and causing bone loss. Alcohol consumption has been shown to induce osteocyte apoptosis and fat excess but the relationship between osteocyte apoptosis and fat excess in bone is not well understood. We thus designed an in vivo study to assess the relationship between increase of adiposity in the marrow and osteocyte apoptosis in the case of alcohol-induced bone loss.

12 male Wistar rats, 8 weeks old at baseline, were treated with 35% v/v ethanol in the drinking water during 17 weeks (A) and compared to 12 control animals (C). At the end of the study, we measured whole body weight, lean, fat mass and bone mineral density (BMD) by DXA. Osteocyte apoptosis was assessed through cleaved caspase-3 and toluidine blue staining while osteocyte morphology and organelles were analyzed with transmission electron microscopy on ultra-thin tibia sections. Fat content in bone marrow and cortical bone micro-vessels were evaluated on semi-thin sections stained with toluidine blue.

BMD confirmed that chronic alcohol consumption induces bone loss. After alcohol treatment, the number of apoptotic osteocytes was increased, as shown by the increased cleaved caspase-3 staining (186.2 \pm 42.7 vs 23.9 \pm 7.2 in A and C, p < 0.001) and the higher empty osteocyte lacunae in A versus C. We observed lipid droplet accumulation within the osteocytes (95.5 \pm 7.2 vs 11.2 \pm 13.1%, p < 0.001), the bone marrow (29.3 \pm 13.0 vs 4.1 \pm 4.9%, p < 0.001) and the cortical bone micro-vessels in A vs C (21.3 \pm 15.5 vs 0.2 \pm 0.5%, p < 0.003). At last, we found an inverse correlation between BMD and osteocyte apoptosis (r = -0.72, p = 0.002) and strong significant correlations between osteocyte apoptotic number and lipid droplet accumulation in osteocyte (r = 0.95, p < 0.001), bone marrow (r = 0.65, p < 0.02) and bone micro-vessels (r = 0.83, p < 0.005).

These data show that the alcohol-induced bone loss is associated with osteocyte apoptosis and lipid accumulation in the bone tissue. This bone "steatosis" is correlated to lipid accumulation in bone marrow and blood micro-vessels.

Anti-Retroviral Therapy Drives Bone Loss in AIDS Patients as a Consequence of Immune Reconstitution. Ighovwerha Ofotokun¹, Tatvana Vikulina¹, Ashwini Vunnavu¹, Susanne Roser-Page¹, Masayoshi Yamaguchi¹, Francois Villinger¹, Kenneth Rogers¹, Majid Zayzafoon², Anandi Sheth¹, Jeffrey Lennox¹, M. Neale Weitzmann¹. ¹Emory University School of Medicine, USA, ²University of Alabama at Birmingham, USA

Skeletal renewal is strongly influenced by the immune system, a consequence of a deep integration and centralization of common cell types and cytokine mediators

comprising the “immuno-skeletal interface”. This includes T cells and B cells, a significant source of osteoclastogenic cytokines including RANKL and TNF and/or the RANKL decoy receptor OPG. Consequently, bone loss is common in conditions associated with immune activation but also in immunodeficiency, including infection by the human immunodeficiency virus (HIV) that leads to acquired immunodeficiency syndrome (AIDS). In fact, osteoporosis and bone fracture are recognized as serious complications of HIV/AIDS and 75% of AIDS patients are already osteopenic at first diagnosis. However, contrary to expectation, anti-retroviral therapy (ART) exacerbates rather than ameliorates bone loss. Recent studies show a reduction in BMD within the first 2 years of ART before tapering off suggesting that the majority of bone loss occurs early on during ART. As the majority of previous studies have focused on relatively late time points we examined C-terminal telopeptide of collagen (CTX), an index of in vivo bone resorption, at early time points following ART initiation. We found a spike in bone resorption within just 2 weeks, peaking around 12 weeks, and remaining significantly elevated for at least 24 weeks. Consistent with the surge in bone resorption serum concentrations of RANKL and TNF, but not OPG, climbed to significant levels by 24 weeks. Interestingly, T cell recovery with ART is established to reach a significant magnitude at 12 weeks, the same time point at which the surge in resorption peaked. As lymphocytes are known to mediate bone loss in inflammatory contexts by secreting RANKL and/or TNF this suggested a possible link between immune reconstitution and bone resorption. We hypothesized that bone resorption may be driven by a mechanism involving immune recovery and reconstitution, synonymous with T cell and/or B cell activation, as a consequence of ART-induced disease reversal. To investigate this hypothesis we mimicked ART-induced immune reconstitution in vivo by means of T cell adoptive transfer into T cell null TCR β knockout mice. T cell reconstitution likewise initiated a surge in bone resorption (CTX), concurrent with pronounced loss of bone mineral density (BMD) and bone volume within the same 12 week window. As in humans on ART, RANKL and TNF, but not OPG, were significantly elevated in T cell reconstituted mice. Taken together our data suggest that the majority of bone loss associated with ART may occur in the early period of therapy as a consequence of immune reconstitution. Importantly, our data suggest the possibility that short-term preemptive antiresorptive treatment may be effective in blocking ART-induced bone loss thus preserving BMD during the early phase of ART when bone resorption peaks.

Circulating Levels of Sclerostin Are Increased In Patients With Type 2 Diabetes Mellitus. Antonia Garc  a-Mart  n¹, Pedro Rozas-Moreno², Sonia Morales-Santana³, Beatriz Garc  a-Fontana³, Jose Antonio Garc  a-Salcedo⁴, Rebeca Reyes⁵, Manuel Munoz-Torres⁶. ¹Bone Metabolic Unit. Endocrinology Division., Spain, ²Endocrinology Division. Hospital General de Ciudad Real. Ciudad Real, Spain., Spain, ³Proteomic Research Service. Hospital Universitario San Cecilio., Spain, ⁴Bone Metabolic Unit (RETICEF). Endocrinology Division. Hospital Universitario San Cecilio., Spain, ⁵Bone Metabolic Unit., Spain, ⁶University Hospital, Spain

Sclerostin, produced by osteocytes, is a potent inhibitor of Wnt signaling and bone formation. Diabetes mellitus is a risk factor for osteoporotic fractures. However, there is currently no information on the circulating levels of sclerostin in type 2 diabetes mellitus (T2DM). We tested the hypothesis that sclerostin concentrations are elevated in patients with T2DM, which promotes the deterioration of osteoblastogenesis and increased bone fragility. Sclerostin was measured in serum from 76 patients with T2DM and 54 healthy controls using enzyme-linked-immunosorbent assays (ELISA). Sclerostin levels were significantly higher in T2DM than controls (53.9 29.9 vs 41.3 15.9 pmol/L, $p=0.007$). Sclerostin levels were significantly higher in men than women, both in T2DM (63.2 27.1 vs 43.1 17.1 pmol/L, $p=0.001$) and controls (46.8 18.3 vs 36.9 12.5 pmol/L, $p=0.03$). In T2DM males and controls, sclerostin levels were positively associated with age ($r=0.338$, $p=0.031$ and $r=0.251$, $p=0.04$, respectively) but no in T2DM women. In analysis age-adjusted, serum sclerostin concentration was positively correlated with glycated haemoglobin (A1c) in T2DM ($\beta=0.262$, $p=0.023$). In T2DM males, lumbar spine, femoral neck and total hip bone mineral density (BMD) by dual-energy X-ray absorptiometry (DXA) were positively correlated with serum sclerostin levels ($r=0.325$, $p=0.05$, $r=0.382$, $p=0.018$ and $r=0.470$, $p=0.003$, respectively) but in analysis age-adjusted no significant association. In T2DM patients, sclerostin levels were significantly lower in osteoporotic than non-osteoporotic (42.9 19.2 vs 56.9 25.9 pmol/L, $p=0.041$). There were no differences according to presence or absence of morphometric vertebral fractures. In conclusion, (1) patients with T2DM have higher serum sclerostin than healthy controls, (2) circulating sclerostin levels are related to A1c and (3) circulating sclerostin levels are lower in T2DM with osteoporosis. Further studies are needed to evaluate the role of sclerostin as a marker of bone metabolism in this population.

RANKL Production by B Lymphocytes Contributes to the Bone Loss Induced by Inflammation and Ovariectomy. Melda Onal^{*}, Jinhu Xiong, Priscilla Cazer, Stavros Manolagas, Charles O'Brien. Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

Increased production of RANKL by B cells is thought to contribute to the bone loss associated with inflammation or sex steroid deficiency. However, heretofore, there have been no studies that functionally link RANKL expression in B cells with bone loss in these conditions. Therefore, we deleted the RANKL gene specifically from B cells by crossing CD19-Cre mice, which express Cre recombinase in B cells beginning early in their differentiation, with mice harboring a RANKL conditional allele and examined the impact of this deletion on the loss of bone associated with inflammation or estrogen deficiency. Quantitative PCR confirmed deletion of the RANKL gene in B cells, but not in T cells or in cortical bone, demonstrating the specificity of the deletion. Bone mass, as measured by DEXA, was not altered in mice lacking RANKL in B cells compared to control littermates up to 7 months of age, suggesting that RANKL produced by B cells does not play a role in basal bone remodeling. However, consistent with the role of RANKL in B cell lymphopoiesis, deletion of RANKL led to a small decrease in the percentage of CD19-positive B cells in the bone marrow and spleen, while the percentage of T cells was not affected. To examine the role of B cell RANKL during inflammatory bone loss, 4-month-old conditional KO mice and control littermates were injected with LPS (10 mg/kg bw) every 4 days for 16 days. LPS caused a decrease in bone mineral density (BMD) at all sites examined in control mice. However, deletion of RANKL from B cells partially protected mice from inflammatory bone loss in the femur and total body as measured by DEXA. Moreover, microCT analysis of the L4 vertebra revealed that conditional KO mice were protected from cancellous bone loss. We next assessed the role of B cell RANKL in ovariectomy (OVX)-induced bone loss using 6-month-old conditional KO and control mice. Deletion of RANKL from B cells blunted the OVX-induced increase in B cells that occurred in control mice. Moreover, conditional KO mice were partially protected from OVX-induced bone loss in the spine but not in the femur as measured by DEXA. MicroCT analysis of L4 vertebra demonstrated that cancellous bone loss was blunted in the spines of the conditional KO mice. Taken together, these results demonstrate that RANKL produced by B lymphocytes contributes to inflammation- and OVX-induced bone loss.

Rapid Loss of Bone Mass and Strength after Non-bone Focal X-ray Irradiation in Growing Mice. Peter Corry, Dan Jia^{*}. University of Arkansas for Medical Sciences, USA

Introduction: Partial abdominal irradiation (AI) is a common anti-tumor modality for malignancies residing in the pelvis-abdomen cavities. We have reported that AI elicits significant suppression of the un-irradiated bone marrow (BM) in mice. Since BM hosts the precursors of the osteoblastic and osteoclastic lineages and supports the survival and function of these cells, we reasoned that a depletion of the bone marrow cell pool by AI would have a profound impact on the skeleton. **Methods:** Male C57BL/6 mice, 10-12 weeks of age, were given either a single dose (0, 5, 10, 15, or 20 Gy) or fractionated (3 Gy per fraction, twice per day for 15 consecutive fractions) x-ray AI, resembling the total dose and dose schedule used in a pelvic-abdominal radiotherapy. Longitudinal assessment of bone mineral density (BMD) was done by DEXA. Blood and BM cells were collected for bone turnover marker and ex vivo bone cell differentiation assays. **Results:** Serum TRAP5b increased while osteocalcin decreased in irradiated mice measured 7 days after a single dose AI ($p < 0.05$ vs sham controls). Ex vivo BM osteoblast differentiation was greatly suppressed ($p < 0.01$) while osteoclast formation was slightly increased ($p > 0.05$) evaluated 7 days after a single dose AI. DEXA analysis revealed a dose- and time-dependent loss of whole body BMD detected 7-14 days after a single dose AI ($p < 0.001$ vs sham controls) and 14-28 days after fractionated AI. Under both irradiation schemes tibia and femurs showed the greatest susceptibility to AI-induced BMD loss (up to -7.5%/-3.5% in tibia, $p < 0.001$ vs sham controls), whereas the spine was the least affected ($p > 0.05$ vs sham controls). Furthermore, AI induced a 10-15% decrease in femoral peak load tested by 3-point bending 7-14 days after a single dose AI ($p < 0.01$ vs sham controls). **Summary and conclusions:** These results demonstrate that AI at dose schedules mimicking the clinical use could induce adverse effects on the non-exposed skeleton in growing mice. These effects are mediated by altered number and activity of the cells of both osteoblast and osteoclast lineages, and manifested by the deterioration of BMD and strength of the affected bones. These skeletal responses to AI are previously unknown side effects of radiotherapy. This phenomenon merits further investigations in basic research and additional cautions in treatment planning.

Sclerostin and Risk of Hip Fracture in Older Women. Aarthi Arasu¹, Peggy Cawthon², Thy Do³, Puneet Arora⁴, Li-Yung Lui², Jane Cauley⁵, Kristine Ensrud⁶, Steven Cummings⁷. ¹University of California, San Francisco, USA, ²California Pacific Medical Center Research Institute, USA, ³Amgen, Inc., USA, ⁴Amgen, USA, ⁵University of Pittsburgh Graduate School of Public Health, USA, ⁶Minneapolis VA Medical Center / University of Minnesota, USA, ⁷San Francisco Coordinating Center, USA

Context: Sclerostin, a protein secreted by osteocytes, antagonizes osteoblast differentiation and mineralization, and increases mature osteoblast apoptosis by inhibiting the Wnt pathway. Individuals with absent or reduced circulating levels of sclerostin due to genetic mutations have very high bone mass. Therefore, it is hypothesized that women with increased circulating sclerostin levels have a greater risk for hip fractures.

Design, Setting and Participants: This is a case-cohort study of community-dwelling women from the Study of Osteoporotic Fractures (SOF) database, a prospective cohort of 9516 women aged 65 years and greater. Hip fractures, including both intertrochanteric and femoral neck, were adjudicated centrally. Serum was collected at visit 2 in 1988-89 and stored at -190 C. In 2010, serum sclerostin levels were measured by an electrochemiluminescence sandwich assay in 228 women with incident hip fractures and 227 women in a randomly selected sample; average follow up time was 9.8 years.

Results: Sclerostin levels (mean 293.5 SD 122.4 pg/mL) were significantly associated with hip fracture risk, which was further strengthened after adjustment for total hip bone mineral density (BMD). Compared to women in the lowest quartile of sclerostin, the risk of hip fracture was significantly elevated among those in the third quartile (HR 2.1, 95% CI 1.1-3.8) and fourth quartile (HR 3.4, 95% CI 1.7-7.0), after adjusting for age, body mass index, total hip BMD, estrogen use, and history of fracture since age 50. The test for linear trend in hazard ratios across the quartiles was statistically significant ($P < 0.001$) suggesting a linear relationship between the quartile of sclerostin concentration and risk of hip fracture. The results were similar for both femoral neck and intertrochanteric hip fractures.

Conclusion: We conclude that higher sclerostin levels are associated with a greater risk of hip fractures in older women.

Risk of Hip Fracture Across Sclerostin Quartiles

Comparative Effects of Teriparatide and Risedronate in Glucocorticoid-Induced Osteoporosis in Men: 18-Month Results of the EuroGIOPS Trial. Claus-C Gluer¹, Fernando Marin², Christian Graeff¹, Jaime Pena³, Andreas Reisinger⁴, Helmut Petto⁵, Philippe Zysset⁴. ¹Biomedical Imaging, Department of Diagnostic Radiology, UKSH, Germany, ²Lilly Research Center, United Kingdom, ³Biomedical Imaging, Department of Diagnostic Radiology, UKSH, Germany, ⁴Institute for Lightweight Design & Structural Biomechanics, Vienna University of Technology, Austria, ⁵Lilly Research Center, Austria

Bone loss and fractures secondary to glucocorticoid (GC) use is the most prevalent form of secondary osteoporosis. Data on the effects of osteoporosis drugs in men with GC-induced osteoporosis are scarce. We ran an 18-month randomized, open-label, controlled trial in men who had taken GCs for >3 months (prednisone equivalent >5

mg/d), and had an areal BMD T-score <-1.5 SD. Subjects received either 20 µg/d teriparatide (TPTD, n=45) or 35 mg/wk risedronate (RIS, n=47), and 1 g calcium and 1200 IU vitamin D daily. The primary objective was to compare the increase in lumbar spine (L1-L3) volumetric BMD between groups, as measured by quantitative computed tomography (QCT). Secondary outcomes were changes in 3D microstructure variables measured by high-resolution QCT (HRQCT) at T12, biomechanical effects evaluated by finite element (FE) analysis, areal BMD determined by dual-energy X-ray absorptiometry (DXA), biochemical markers and safety. Radiological evaluations were performed at 0, 6, and 18 months. The calibrated HRQCT images of T12 were converted into digital FE models and subjected to axial compression, anterior bending and axial torsion. Stiffness and strength were computed for each model and loading mode. A predefined mixed model repeated measures (MMRM) was used to analyze the changes from baseline and the between-group differences. Subjects had a mean [SD] age of 56. [14.2] years. Median GC daily dose and use duration was 8.8 mg and 6.4 years, respectively. A total of 36 (39.1%) randomized subjects had a prevalent fracture, and 30 subjects (32.6%) were prior bisphosphonate users. Both treatments significantly increased L1-L3 vBMD, with greater increases in the TPTD group in the fully-adjusted analysis at 18 months (median: 17.1% vs 5.3%; $p=0.004$ from MMRM model). Microstructure-derived HRQCT trabecular and cortical variables significantly increased from baseline in both groups, but they did not reach between-group significant differences. There was a trend for higher BV/TV in the TPTD group (median: 23.1% vs 7.3%; $p=0.074$). Vertebral stiffness and strength increased significantly in both groups, with statistically higher increases in the TPTD group for all tests. Adverse events were not different between groups. Fewer patients had a new clinical fracture with TPTD (0/45, 0%) than with RIS (5/47, 10.6%) ($p=0.056$). In this 18 month trial in men with GC-induced osteoporosis TPTD showed higher increases in spine vBMD and biomechanical properties than RIS

Effects of Teriparatide on Cortical Histomorphometric Variables in Patients Receiving Long-term Alendronate Therapy. Jan Stepan¹, Harald Dobnig², Astrid Fahrleitner-Pammer³, Yanfei Ma⁴, Qing Zeng⁴, Xiaohai Wan⁴, Fernando Marin⁵, Imre Pavo⁶. ¹Charles University, Czech Republic, ²Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria, ³Medical University Graz, Austria, ⁴Eli Lilly & Company, USA, ⁵Eli Lilly & Company, Spain, ⁶Eli Lilly & Company, Austria

Teriparatide (TPTD) treatment increases bone turnover and bone formation in patients previously treated with potent antiresorptives, such as alendronate (ALN, Stepan et al. 2010)⁴. However, no histological information exists on the effects of TPTD on cortical bone in the ALN pre-treated patients. In addition, there is limited information of osteoporosis medications on their effects on the periosteal surface of the bone. The aim of this post-hoc analysis was to investigate the changes in cortical microstructure and dynamic histomorphometric indices in patients with osteoporosis with or without prior therapy with ALN, who were treated with TPTD 20 µg/day subcutaneous for 24 months.

Sixty-six postmenopausal women with osteoporosis, mean age (SD) of 68.0 (7.0) years and mean BMD T-score of -1.7 (0.9) at total hip and -2.8 (0.8) at lumbar spine; 62% with prevalent fractures) were included in the study. Thirty-eight stopped previous ALN treatment (10 mg/day or 70 mg/week for a mean duration of 63.6 months), and switched to TPTD, while 28 were osteoporosis pre-treatment naive (TN). 45 paired iliac crest biopsies were collected and analyzed by micro-computer tomography for three dimensional structural and dynamic cortical histomorphometry indices at baseline and after 24-month (BFR/BS=bone formation rate/bone surface). Wilcoxon rank sum test and two-sample t-test were used to compare differences between groups. Nonparametric signed-rank test was used to compare the effect after TPTD treatment with baseline within each group or for the overall population. In the ALN pretreated group, mineralizing surface/bone surface (MS/BS, %) values were lower than in the TN, at both the periosteal (baseline: 0.611.29 vs 1.390.96; $p=0.04$; post-TPTD: 1.341.05 vs 3.942.7; $p=0.002$), and endocortical levels (baseline: 3.165.05 vs 6.195.07; $p=0.06$; post TPTD: 4.954.03 vs 119.57; $p=0.027$). In the pooled analysis, indices of periosteal and endocortical dynamic variables, cortical thickness and porosity increased significantly compared to baseline (Table).

Our results indicate the bone forming effects of TPTD in the cortical bone in patients previously treated with the ALN or treatment naive. The observed increase in cortical porosity in both groups may be the consequence of increased intracortical remodeling. ⁵Stepan et al. Osteoporos Int (2010), 21:2027-2036

% Change in indices Mean	Pre-treatment naïve (n=16)	ALN pre-treated (n=29)	Pooled (n=45)

In Premenopausal Women with Idiopathic Osteoporosis, Baseline Bone Turnover Predicts Response to Teriparatide. Adi Cohen¹, Emily Stein², David Dempster³, Hua Zhou⁴, Robert Recker⁵, Joan Lappe⁵, Chiyuan Zhang³, Donald McMahon², Polly Chen³, Kavita Pandit³, Clifford Rosen⁶, Elizabeth Shane². ¹Columbia University Medical Center, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University, USA, ⁴Helen Hayes Hospital, USA, ⁵Creighton University Osteoporosis Research Center, USA, ⁶Maine Medical Center, USA

Idiopathic osteoporosis (IOP) in premenopausal women is an uncommon disorder of uncertain pathogenesis in which fragility fractures and/or low bone mineral density (BMD) occur in otherwise healthy women with intact gonadal function. We have reported that women with IOP have thinner cortices, fewer, thinner, more widely separated, and heterogeneously distributed trabeculae, reduced stiffness, and lower osteoid width and mean wall width than controls. Dynamic histomorphometric remodeling parameters were heterogeneous and did not differ between subjects and controls. However, the IOP group included women with low and high bone turnover as assessed by bone formation rate/bone surface (BFR/BS). We hypothesized that teriparatide (TPTD), an agent that directly increases osteoblast activity, would improve BMD in IOP. Herein, we report interim results of an open-label pilot study of 22 premenopausal women with IOP (17 with fractures, age 39.6 yrs) treated with TPTD 20 mcg SC daily. At 12 months (12M) and 18M, lumbar spine (LS) BMD increased from baseline by 7.5 3.8% (SD) and 9.7 3.3% respectively (both p<0.05). Total hip and femoral neck (FN) BMD rose by 2.4 2.3 and 2.3 3.3%, respectively, at 12M (p<0.05) but did not increase further at 18M. There was no change at the radius (0.6 1.9%; p=0.3). Baseline serum bone turnover markers (BTMs) correlated with 12M percent change in BMD at the LS (osteocalcin: r=0.512, p=0.02) and FN (CTX: r=0.445, p=0.049; PINP: r=0.453, p=0.04). Five women did not have a significant increase in LSBMD at 12M; Non-responders resembled Responders in terms of age, BMI, baseline BMD, calciotropic and gonadal hormones, and bone volume fraction. However, baseline serum CTx, cancellous and endocortical BFR/BS were significantly lower and serum IGF1 was significantly higher in Non-responders (Table). In conclusion, TPTD resulted in significant increases in BMD in most premenopausal women with IOP. Those who did not respond were characterized by very low bone turnover and high IGF1 at baseline, suggesting that osteoblast dysfunction and IGF-1 resistance may limit responsiveness to TPTD in IOP.

	Responders (n=17)	Non-responders (n=5)	p
Mean 12M % Change in LS BMD	9.3 ± 4.1	1.0 ± 1.3	<0.0001
BASELINE:			
Cancellous BV/TV by µCT (%)	21.3 ± 7.1	20.9 ± 5.4	0.9
IGF-1 (age adjusted, ng/mL)	153 ± 38	209 ± 38	0.01

Teriparatide and Antiresorptive Combination Treatment subsequent to 9 months of Teriparatide Monotherapy. Christian Muschitz^{*1}, Roland Kocjan², Astrid Fahrleitner-Pammer³, Friederike Kuhne⁴, Christina Bittighofer⁴, Angela Trubrich⁴, Reinhart Waneck⁵, Heinrich Resch⁶. ¹St. Vincent's Hospital, Austria, ²St. Vincent Hospital Vienna, Austria, ³Medical University Graz - division of Endocrinology & Metabolism, Department of Internal Medicine, Austria, ⁴The VINFORCE Study Group - St. Vincent Hospital - Medical Department II, Austria, ⁵St. Vincent Hospital - Department of Radiology, Austria, ⁶Medical University Vienna, Austria

Purpose: Increased bone formation without meaningful increase of resorption and a consequent marked anabolic response on teriparatide (TPTD) is evident shortly after treatment initiation. This anabolic window is supposed to be reflected also in the marked initial BMD increase on TPTD. Due to coupling mechanisms, the sustained increase of bone formation and ongoing anabolic effects are associated with significantly increased bone resorption as well. Antiresorptives are able to influence the balance of formation and resorption. We investigated effects of addition of antiresorptives to the second half of TPTD cycle when resorption is already also markedly elevated. Methods: We prospectively randomized 117 pmp women (mean age 71.7 8.5 years, T-score L1-L4 -2.45 1.38; 91.5% prevalent fractures) after 9 months of TPTD treatment into three different open-label groups for another 9 months: either alendronate (ALN, 70 mg/week, 41 patients), raloxifene (RAL, 60 mg/day, 34 patients) or no medication (TPTD mono, 42 patients) was added to the continued TPTD treatment. All subjects received daily supplementation of 1000mg calcium and 800 IU vitamin D. Serum level of intact amino terminal propeptide of type I procollagen (PINP) and type I collagen cross-linked C-telopeptide (CTX) as well as BMD measured by DXA at lumbar spine, total hip and femoral neck BMD was evaluated from the time of TPTD treatment initiation, at baseline of randomization, and after 3, 6 and 9 months during the combination treatment. Results: After 18 months TPTD treatment, the increase in lumbar spine BMD was significantly higher in the ALN (+0.08 g/cm², p=0.046) and RAL (+0.09 g/cm², p=0.026) group when compared with the TPTD mono group (+0.05 g/cm²). In the total hip region, addition of RAL (+0.03 g/cm²) did not alter the BMD effects of TPTD monotherapy (+0.03 g/cm²), but addition of ALN resulted in significantly more increase in total hip BMD (+0.05 g/cm²) than RAL (p=0.026) or TPTD alone (p=0.048). Elevation of PINP and CTX was significantly lower in the ALN and RAL group at the end of the 18 months treatment compared to TPTD treatment alone. Conclusions: Our data suggest that addition of ALN to the second 9 months of TPTD treatment cycle results in augmented BMD increase. This BMD increase may reflect either favorable balance of bone formation and resorption towards more formation or increased secondary mineralization of newly formed bone matrix.

Teriparatide has Different Effects on Trabecular and Cortical Bone as Measured by ¹⁸F-Fluoride Positron Emission Tomography. Michelle Frost^{*1}, Musib Siddique¹, Glen M. Blake¹, Amelia EB. Moore¹, Paul J. Schleyer¹, Paul K. Marsden¹, Richard Eastell², Ignac Fogelman³. ¹King's College London, United Kingdom, ²University of Sheffield, United Kingdom, ³Guy's Hospital, United Kingdom

We used ¹⁸F-fluoride positron emission tomography (¹⁸F PET) to compare the changes in bone metabolism at trabecular and cortical sites in response to teriparatide. The subjects were 18 postmenopausal women with osteoporosis (mean age 65.3 years). Subjects had a 1-hour dynamic PET/CT scan of the spine (L1-L4) followed by a 10-minute static scan of the pelvis and femur at baseline and after 6 months treatment with teriparatide 20 µg/day. Blood samples were taken to find the arterial input function. We evaluated the ¹⁸F plasma clearance to trabecular bone (units mL min⁻¹ mL⁻¹) by placing an elliptical region of interest (ROI) in each vertebral body on the dynamic scan and analysing the bone time-activity curve using the Hawkins 3-compartment model. Spine plasma clearance was also estimated by the Patlak plot method using the 10-60 minute dynamic scan data, and also by a new two-point Patlak method that used a single bone uptake measurement at the end of the dynamic scan together with the population mean volume of distribution of ¹⁸F tracer in the bone ROI. CT scans were used to define ROIs in a 6 cm section of cortical bone in the femoral shaft, an area equivalent to the DXA total hip ROI, and the pelvis. After the CT defined ROIs were mapped onto the static PET scan, ¹⁸F plasma clearances at these sites were evaluated using the two-point Patlak method. Data for right and left were averaged. After 6 months treatment with teriparatide ¹⁸F plasma clearance in trabecular bone in the spine increased by 23.8% (P = 0.0003) when calculated using the Hawkins model, by 24.1% (P < 0.0001) when using the 10-60 minute Patlak plot, and by 26.4% (P < 0.0001) when using the two-point Patlak method. When data from the static scans were analysed ¹⁸F plasma clearance at the femoral shaft increased by 71% (P = 0.0001), at the total hip ROI by 47% (P = 0.0008), and at the pelvis by 34% (P = 0.0006). When compared with the changes in trabecular bone in the spine, the changes in the cortical bone at the femoral shaft were statistically significantly different (P = 0.006), while differences between the spine and total hip ROI approached but did not

quite attain significance ($P = 0.068$). Changes in bone turnover markers and BMD were consistent with previous trials of teriparatide. We conclude that the changes in bone metabolism during teriparatide treatment as measured by ^{18}F PET differ at different skeletal sites, with larger increases in cortical bone than in trabecular bone.

A Single Dose of Zoledronic Acid Prevents Periprosthetic Bone Loss in Female Patients with Cementless Total Hip Arthroplasty. Hannu Aro^{*1}, Niko Moritz¹, Petteri Lankinen¹, Satu Timlin², Erkki Svedstrom².
¹University of Turku, Finland, ²Turku University Hospital, Finland

Periprosthetic bone loss is common during the first year after total hip arthroplasty (THA). The factors that lead to periprosthetic bone loss are not clearly understood but are thought to be associated with an increase in osteoclastic activity. The primary objective of this trial was to demonstrate that zoledronic acid, given as a single intravenous infusion after THA, reduces periprosthetic bone loss measured by DXA.

This randomized double-blind placebo-controlled trial included postmenopausal female patients with hip osteoarthritis. Excluding criteria included evidence of secondary osteoporosis, an ongoing bisphosphonate or corticosteroid therapy. Of the 49 eligible patients, 14 (29%) had normal preoperative systemic BMD, 24 (49%) osteopenia and 11 (22%) osteoporosis. All patients received a cementless total hip prosthesis with marked stem for RSA (radiostereometric analysis). Postoperatively, the patients received a single dose (5mg) of zoledronic acid or placebo intravenously. In cases of postoperative hypocalcaemia, the infusion was postponed until normocalcaemic state was achieved. All patients received calcium and D-vitamin supplementation. The response to zoledronic acid therapy was monitored by measurements of serum markers (CTX, TRAP, and PINP). Periprosthetic BMD was measured by DXA at 0, 3, 6, and 12 months. In order to measure 3D migration of the femoral stem, RSA imaging was performed at 0, 3, 6, and 12 months. Functional recovery was evaluated by means of gait analysis, balance master, and patient reported outcome measures.

At the baseline, the patients of zoledronic acid (n=25) and placebo (n=24) groups showed minor imbalances in the mean age (65 vs. 71 years), 25(OH)D-vitamin levels (65 vs. 52) and HSS scores (55 vs. 43). Periprosthetic total hip BMD did not change with time in patients with zoledronic acid treatment, while placebo-treated patients showed loss of periprosthetic bone. The intergroup difference was 6.3 % at 3 months ($p=0.0071$), 6.0% at 6 months ($p=0.0105$) and 6.8% at 12 months, $p=0.0039$, RMANCOVA). RSA imaging showed no significant difference in stem migration between the two patient groups. Based on WOMAC and HSS scores, the two groups showed no significant differences in the functional outcome at 12 months.

This trial demonstrates that zoledronic acid is efficient in prevention of early periprosthetic bone loss in female THA patients. Based on RSA, the treatment had no adverse effects on implant osseointegration.

Bisphosphonates and acute kidney injury. Safety signal identification in the Food and Drug Administration Adverse events reporting system (FDA AERS): A Report from the Research on Adverse Drug events And Reports (RADAR) Project. Beatrice Edwards^{*1}, Sarah Usmani², Dennis Raisch³, June McKoy⁴, Steve Belknap⁵, Athena Samaras⁵, Dustin Liebling⁴, Jaimie Holbrook⁵, Craig Langman⁶, Ali Abu Alfa⁷, Dennis P. West⁵.
¹Northwestern University Medical School, USA, ²Northwestern University Hospital, USA, ³University of New Mexico College of Pharmacy, USA, ⁴Northwestern University, Division of Geriatrics, USA, ⁵Northwestern University, Department of Dermatology, USA, ⁶Children's Memorial Hospital, USA, ⁷Yale School of Medicine, Division of Nephrology, USA

Objective: The FDA placed on alert on Zoledronic acid for acute kidney injury (AKI) in 2009. We evaluated the existence of an association between bisphosphonate (BP) exposure and AKI in The FDA AERS. Methods: Searches of adverse event reports in FDA Adverse Event Reporting System (AERS) dataset, the peer-reviewed medical literature, and safety publications from FDA, websites and safety databases maintained by the FDA, European Medicines Agency (EMA), Canada Health, and Australia's Adverse Drug Reactions Advisory Committee (ADRAC) and Advisory Committee on the Safety of Medicines (ACSOM) were completed. The FDA AERS database was searched (period: January 1998-June 2009), using 76 terms relating to renal problems combined with all drug names for BPs. We identified signals of disproportional association by calculating the proportional reporting ratio (PRR) for zoledronic acid, alendronate, risendronate, and ibandronate. Results: The FDA reported 24 cases of AKI associated with use of zoledronic acid (Reclast) in 2009. Within the FDA AERS dataset from January 1987- December 2008, there were 633 cases associated with BP use in the setting of non-malignant disease, with 328, 147, 80,

43, and 22 cases associated with zoledronic acid ZOL (zometa), alendronate, zoledronic acid (reclast), risendronate and ibandronate. Co-morbidities: diabetes mellitus, heart failure, and hypertension. The PRR was 0.94 (95% C.I. 0.89-0.98), reflecting a non-significant safety signal. An additional 480 cases of AKI in cancer patients were reported. Malignancies: multiple myeloma (n=220, 46%), breast cancer (n=98, 20%), prostate cancer (n=24, 5%) and undefined (n=139, 29%). Agents: ZOL (n=411, 87.5%), pamidronate PAM (n=8, 17%), and alendronate (n=36, 2%). The PRR for ZOL was 1.22 (95% C.I. 1.13, 1.22) and for PAM 1.55 (95% C.I. 1.25, 1.65). BPs are highly effective agents in osteoporotic fractures, skeletal metastasis, and hypercalcemia. Conclusions: Although safety notifications by the FDA have focused on zoledronic acid, AKI with other BPs have also been reported. Our analysis of the FDA AERS did not identify an association with AKI in the setting of osteoporosis or cancer. Nonetheless, clinicians should be aware that creatinine clearance or glomerular filtration rate (GFR) are sensitive measures of renal function and BP use is best reserved for patients with GFR > 30 cc/min/m². AKI is not clearly identified within the FDA AERS as a manifestation of BP therapy.

Long-Term Impact of Adherence to Oral Bisphosphonates on Osteoporotic Fracture Incidence. John S. Sampalis^{*1}, Jonathan Adachi², Emmanouil Rampakakis³, Julie Vaillancourt³, Angela Karellis³, Christian Kindundu⁴.
¹McGill University & Jewish General Hospital, Canada, ²St. Joseph's Hospital, Canada, ³JSS Medical Research, Canada, ⁴Novartis, Canada

Background

Adherence to osteoporosis treatments is a critical parameter resulting in suboptimal effectiveness in real-life practice. The long-term effect of adherence on fracture risk has not been assessed.

Methods

Retrospective study using provincial health insurance claims databases to assess the association between adherence to oral bisphosphonates (OBP) and incidence of osteoporotic fractures in all Ontario patients with osteoporosis between April 1996 and December 2009. Multivariate logistic regression models were used to assess the association between OBP adherence and fracture risk. Treatment duration was classified into two-year intervals. Compliance was estimated with the medication possession ratio (MPR) and persistence was defined as the length of continuous therapy without a gap in refills >30 days.

Results

A total of 636,114 patients comprised the study cohort with a mean age of 72 years and 84% being female. Overall, the mean compliance for the total cohort was 0.72 (0.30) with 53.5% of the patients having a compliance of >80% during the 14-year follow-up period. Among the patients with 0-2 years of follow-up only 49.9% were compliant. After this period, compliance declined steadily with time from 58.9% in patients with 2-4 years of follow-up to 49.9% in patients treated for 12-14 years. With regards to persistence, 24.6% of the total cohort was persistent during the 14-year period. Persistence decreased steadily from 41.0% in patients with 0-2 years of treatment to 3.3% in patients with 12-14 years of treatment. Significant associations between high compliance and persistence and reduced fracture risk over the entire 14-year period of the study were observed. The overall odds ratio for categorical compliance (MPR > 80% or MPR ≤ 80%), continuous compliance and persistence were 0.909 (95% C.I. 0.893-0.925), 0.918 (95% C.I. 0.893 and 0.944) and 0.804 (95% C.I. 0.787-0.821), respectively.

Conclusions

In a real-life setting, adherence to OBP in osteoporosis management is suboptimal. A significant positive association exists between poor adherence and increased risk of osteoporotic fractures which becomes augmented with longer treatment duration.

FR0433

Adherence with Intravenous Zoledronic Acid and Ibandronate for Osteoporosis among U.S. Medicare Beneficiaries. Jeffrey Curtis^{*}, Huifeng Yun, Robert Matthews, Kenneth Saag, Elizabeth Delzell, University of Alabama at Birmingham, USA

Background: Poor long-term adherence with oral bisphosphonates is widely recognized. The extent to which less frequently dosed intravenous (IV) bisphosphonates might yield better adherence is unknown.

Objectives: To evaluate adherence beyond 1 yr among new users of zoledronic acid (ZA) and IV ibandronate (IB) among Medicare enrollees.

Methods: We used 5% random sample Medicare data from 1/05-12/09 to evaluate new users of IV ZA and IB. Eligibility: Medicare part A+B+D, 18 months followup. A 1-yr baseline characterized covariates. ZA adherence defined as 2 ZA infusions or switching to IB; IB adherence defined as 5 IB infusions or switching to ZA. Hypothesized factors associated with ZA adherence > 1 yr were evaluated with logistic regression.

Results: Among 22,220 eligible patients, 15,100 were new users of ZA and 7,120 were new users of IV IB. The median (IQR) age was 78 (8) and 78 (9) yrs. A majority

received prescription(s) for oral glucocorticoids (62 and 73%, respectively). For both drugs, 43% of 1st infusions were in a facility setting; for infusions performed in physician offices, 26 (ZA) and 31% (IB) were rheumatologist/endocrinologists, 15 (ZA) and 6% (IB) oncologists, and 10 (ZA) and 13% (IB) internal medicine. The proportion of ZA users persistent >1 yr was 66% and was greater than with IV IB (35%, $p < 0.0001$). Factors associated with ZA adherence (referent to non-persistent with ZA) were male gender (odds ratio [OR]=0.35, 95% CI 0.11-1.11), age 85+ (referent to age 65-69) (OR=0.41, 0.21- 0.80), glucocorticoid use (OR=0.74, 0.53-1.03), prior non-adherence of osteoporosis drugs

(OR=0.66, 0.42-1.04) and prior fractures (OR=0.89, 0.51-1.56). Compared to infusions from oncologists, adherence was greater for those receiving infusions from internal medicine (OR=1.84, 0.92-3.70) and rheum/endocrinologists (OR=1.45, 0.86-2.45).

Conclusions: Adherence > 1 yr with IV ZA and IV IB was comparable or somewhat greater than adherence reports with oral bisphosphonates. However, > 1/3 of IV bisphosphonate users did not continue > 1 yr. Less frequently dosed medications may improve adherence but ongoing efforts are needed to maximize adherence with osteoporosis therapies.

Population-Based Trends in BMD Testing and Osteoporosis Treatment for New Initiations of Long-Term Systemic Glucocorticoids (1998-2008). Sumit Majumdar¹, Lisa M. Lix², Colleen Metge³, Suzanne Morin⁴, Marina Yogendran³, William Leslie³. ¹University of Alberta, Canada, ²University of Saskatchewan, Canada, ³University of Manitoba, Canada, ⁴McGill University Health Centre, Canada

OBJECTIVES: To determine rates and correlates of bone mineral density (BMD) testing or osteoporosis treatment in new long-term glucocorticoid initiations and describe changes in glucocorticoid-induced osteoporosis (GIOP) care from 1998-2008.

METHODS: A population-based study of all adults 20-years and older in Manitoba, Canada, was conducted using comprehensive healthcare databases. We identified subjects each fiscal year with long-term systemic glucocorticoid use (defined as >90-days per year) and then restricted analyses to new initiations by excluding those with >90-days of use in the previous year. High quality GIOP care was defined by the composite of new BMD tests or new osteoporosis treatments dispensed within 6-months of starting glucocorticoids. We describe temporal trends and analyses of GIOP care stratified by age, sex, and dose based on daily prednisone-equivalents (low <5mg; medium 5-10mg; high>10mg).

RESULTS: We studied 17,736 new long-term glucocorticoid initiations (32% low-, 36% medium-, 32% high-dose). Among all new initiations, the overall 6-month rates of new BMD testing were 6%, osteoporosis treatment starts were 22%, and the composite of BMD testing or treatment was 25%. From 1998-2008 (FIGURE), there were statistically significant ($p < 0.001$ for each trend) but modest increases in BMD testing (from 2% to 6%), osteoporosis treatments dispensed (from 10% to 24%), and the composite of testing or treatment (from 11% to 27%). High quality GIOP care varied significantly ($p < 0.001$ for each comparison) according to age (12% for those <50-years vs 29% for those 50-years and older), sex (13% for men vs 34% for women), and glucocorticoid dose (23% low- vs 26% medium- vs 27% high-dose).

CONCLUSIONS: The quality of GIOP care has improved slowly over time but remains suboptimal with only one-quarter of those starting long-term systemic glucocorticoids receiving BMD testing or osteoporosis treatment within 6-months of initiation. Interventions to improve GIOP care, especially targeting younger patients and men, need to be developed.

Predicting Adherence among Women Participating in the Global Longitudinal Registry of Osteoporosis in Women. Jeffrey Curtis¹, Allison Wyman², Gordon FitzGerald², Adolfo Diez-Perez³, Stephen Gehlbach⁴, Christian Roux⁵, Kenneth Saag¹, Ethel Siris⁶, Stuart Silverman⁷. ¹University of Alabama at Birmingham, USA, ²University of Massachusetts Medical Center, USA, ³Autonomous University of Barcelona, Spain, ⁴University of Massachusetts, USA, ⁵Hospital Cochin, France, ⁶Columbia University College of Physicians & Surgeons, USA, ⁷Cedars-Sinai/UCLA, USA

Background

Numerous factors have been associated with adherence to osteoporosis medications, but only limited work has been focused on developing tools to predict future adherence.

Objective

To develop a predicted adherence score that validly identifies future 1-year persistence among women initiating osteoporosis medications.

Methods

Participants who were not current users of any osteoporosis medication at baseline were identified within the Global Longitudinal Registry of Osteoporosis in Women (GLOW). Women self-reporting new use of any oral or injected (but not intravenous) osteoporosis medication on the year 1 GLOW survey were eligible for analysis (n=1450). The outcome was 1-year persistence measured at the year 2 GLOW survey. Women who switched therapies and remained on any osteoporosis treatment at the date of the year 2 survey were considered persistent. All GLOW survey questions were assessed; factors associated with persistence with bivariate $p < 0.20$ were included in a backwards elimination multivariable logistic regression model; significant variables (adjusted $p < 0.10$) were retained in the final model. Model estimates from the logistic regression were converted to an integer-based clinical prediction rule. Calibration of the final prediction model was assessed using the Hosmer-Lemeshow goodness of fit (GoF) test and by evaluating observed persistence across deciles of predicted persistence categories.

Results

Among eligible GLOW women initiating a new osteoporosis medication, 1077 (74%) were persistent 1 year later. Of the women who persisted on therapy, most continued their initial medication and approximately 11% switched therapies.

Numerous factors measured at baseline were significantly associated with future persistence; 12 were included in the final adherence risk score. Of the 12, 7 were demographic characteristics or comorbidities; 5 were from GLOW surveys. The strongest factors associated with persistence were paternal history of hip fracture, prior hip or vertebral fracture, BMI < 20 and being a non-smoker. Calibration of the adherence risk score was good: Hosmer-Lemeshow GoF $p = 0.24$; there was high agreement between predicted persistence categories and observed persistence (Figure).

Conclusion

One-year persistence could be predicted with high validity among new users of osteoporosis medications participating in GLOW. Women predicted to be less persistent by adherence score might be targeted for further intervention to promote adherence.

Observed vs. Predicted Persistence across Deciles of Predicted Risk

Discontinuation of Denosumab and Associated Fracture Incidence: Analysis From the FREEDOM Trial. Jacques P. Brown^{*1}, Jens-Erik Beck Jensen², Nigel Gilchrist³, Chris Recknor⁴, Christian Roux⁵, Ove T'rring⁶, Matt Austin⁷, Andrea Wang⁷, Andreas Grauer⁷, Rachel B. Wagman⁷. ¹CHUQ-CHUL Research Centre, Canada, ²Hvidovre Hospital, Denmark, ³Canterbury Geriatric Medical Research Trust, New Zealand, ⁴United Osteoporosis Centers, USA, ⁵Paris Descartes University, France, ⁶Karolinska Institutet Sodersjukhuset, Sweden, ⁷Amgen Inc., USA

Denosumab (DMAb), a reversible RANKL inhibitor, decreases osteoclast formation, function, and survival. In the pivotal phase 3 fracture trial, FREEDOM, DMAB 60 mg administered every 6 months decreased the risk for new vertebral, nonvertebral, and hip fractures at 3 years compared with placebo (Cummings *NEJM* 2009). Osteoporosis is a chronic disease, and continued treatment is required to provide anti-fracture efficacy. While cessation of DMAB treatment has been associated with transient increases in bone remodeling and declines in bone mineral density (BMD) (Miller *Bone* 2008; Bone *JCEM* 2011), the effect on fracture risk is not as well characterized. To understand fracture incidence in an osteoporotic population after treatment cessation, we evaluated subjects in FREEDOM who discontinued treatment after receiving 2 to 5 doses of investigational product (IP), either DMAB or placebo, and continued study participation for ≥ 6 months since the last dose + 1-month study visit window (≥ 7 months). The off-treatment observation period began 7 months after the last dose of IP and lasted for approximately 6 to 24 months (for subjects who received 5 and 2 doses, respectively). This subgroup of 797 subjects (470 placebo, 327 DMAB) showed similar baseline characteristics for age, prevalent fracture, and lumbar spine and total hip BMD T-scores. During the treatment period, more subjects treated with placebo as compared with DMAB sustained a fracture and had significant decreases in BMD (Table). In addition, 42% of placebo-treated subjects vs 28% of DMAB-treated subjects initiated an alternative therapy after the last dose. After treatment discontinuation, similar percentages of subjects in both groups sustained a new fracture (9% placebo, 7% DMAB), resulting in a fracture rate per 100 subject-years of 13.5 for placebo and 9.7 for DMAB (HR 0.82; 95% CI: 0.49, 1.38), adjusted for age and total hip BMD T-score at baseline. There was no apparent difference in fracture occurrence pattern between the treatment groups during the off-treatment period (Figure). We conclude from this analysis that there was not an excess in fracture risk after treatment cessation with DMAB when compared with placebo during the off-treatment period for up to 24 months.

Table: Subject Characteristics at Treatment Discontinuation

	Placebo (N = 470)	Denosumab (N = 327)
Number of doses received		
2	114 (24)	86 (26)
3	138 (29)	99 (30)
4	90 (19)	68 (21)
5	128 (27)	74 (23)
Fracture during treatment*	90 (19)	36 (11)
Significant BMD reduction† during treatment*	80 (17)	4 (1)
Treatment discontinuation due to requiring alternative therapy or disease progression	116 (25)	29 (9)
Started alternative therapy after last dose	197 (42)	90 (28)

Values are number (%) of subjects. N = number of subjects who discontinued treatment after receiving 2 to 5 doses of investigational product, either denosumab or placebo, and continued study participation for ≥ 7 months after the last dose. *Treatment period = first dose through last dose + 7 months.

†Significant BMD reduction is defined as $\geq 7\%$ BMD reduction at total hip within any 12-month period, $\geq 10\%$ BMD reduction at total hip from baseline at any time point, or total hip BMD T-score < -4 at any time point.

FR0448

Effect of a New Sustained-release Formulation of the Novel Cathepsin K Inhibitor, ONO-5334, on Serum and Urine Biochemical Markers of Bone Turnover in Healthy Post-menopausal Women. Shinichi Nagase¹, Yoshitaka Hashimoto², Maria Small¹, Mitchy Ohyama², JUNICHIRO MANAKO², Tomohiro Kuwayama¹, Stephen Deacon^{*3}. ¹Ono Pharma UK Ltd, United Kingdom, ²Ono Pharmaceutical Co., Ltd., Japan, ³Ono Pharma, United Kingdom

The novel cathepsin K inhibitor, ONO-5334, has been shown to effectively suppress bone resorption markers and increase BMD at a comparable level with alendronate [ALN] (with 300mg qd ONO-5334) in patients with osteoporosis [1]. In that study a twice daily formulation (50mg bd) showed equivalent or even better results compared to the once daily 100mg dose. This may suggest that a prolonged PK profile would allow greater suppression of bone resorption dose for dose. A sustained release tablet (SRT) was developed and compared to the immediate release tablet (IRT) dose that showed comparable results to ALN [1].

The single dose phase was a randomised, partial single-blind, crossover study where 50, 100 and 300mg SRT and 300mg IRT was administered as a single dose to 9 subjects. The multiple dose phase was a randomised, double-blind, placebo-controlled, parallel-group study where 100, 300mg SRT or placebo (PBO) was administered in repeated doses (on Day 1 then on Days 4-10) to two treatment groups of 12 subjects (9 active and 3 PBO). All subjects were post-menopausal women (aged 45-75y) and their status was confirmed by FSH >30 IU/L and Estradiol <92 pmol/L. PK, serum and urine bone resorption markers (CTX-I) (second morning void and 24h cumulative) were assessed.

After a single administration of 300mg SRT, median Tmax was delayed by 1.5h, mean Cmax was 3.3-fold lower, mean C24h was 5.4 times higher compared with 300mg IRT. Mean AUCinf was 0.83 fold compared to 300mg IRT and T1/2 was not significantly different. Repeated dosing of SRT was not considered to majorly affect PK. After a single dose of ONO-5334, serum CTX-I was suppressed by approx. 50% or more within 1h of administration reaching maximum suppression 6h post-dose (regardless of dose or formulation). Greater suppression was maintained for longer by 300mg SRT vs 300mg IRT. Second morning void and cumulative 24h urine CTX-I showed clear dose response effects for SRT with maximum suppression occurring at 24h for all treatments except for 300mg SRT in 24h cumulative urine where maximum suppression occurred in the 24-48h collection. With repeated dosing there appeared to be greater suppression in the 24h cumulative urine CTX-I.

Compared with the IRT, the SRT shows reduced Cmax, greater C24 but comparable overall AUCinf dose for dose. The SRT shows clear dose response suppression on bone resorption markers and greater efficacy dose for dose versus the IRT.

Effect of the Cathepsin K Inhibitor, ONO-5334, on Biochemical Markers of Bone Turnover in the Treatment of Postmenopausal Osteopenia or Osteoporosis: 2-Year Results from the OCEAN Study. Richard Eastell^{1*}, Shinichi Nagase², Maria Small², Steven Boonen³, Tim Spector⁴, Tomohiro Kuwayama², Stephen Deacon⁵. ¹University of Sheffield, United Kingdom, ²Ono Pharma UK Ltd, United Kingdom, ³Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁴King's College London, United Kingdom, ⁵Ono Pharma, United Kingdom

The one year OCEAN results for ONO-5334, a Cathepsin K Inhibitor, have been previously reported. The aims of this extension study analysis were to observe whether ONO-5334 continued to increase BMD and decrease bone resorption markers (with little or no effect on bone formation). The effect of ONO-5334 (50mg bd, 100 or 300mg qd), on biochemical markers of bone turnover (BTM) was investigated in a randomised, placebo (PBO)-controlled, double-blind, 1y parallel-group study with a 1y extension, enrolling 285 postmenopausal women. Alendronate (ALN, 70mg qw) was used as an active reference. Patients were equally randomised to 5 treatment arms. Calcium and vitamin D were given to all patients. Subjects were 55-75 years old and had osteoporosis (with no fragility fractures) or osteopenia (with a fragility vertebral fracture). 197 women from the 1y base study continued into the 1y extension and 186 women completed 2y. Subjects and Investigators remained blinded to treatment allocation during the extension phase. We measured bone ALP, PINP, Osteocalcin and TRACP5b in serum(s) and CTX and NTX in urine(u) throughout the study. Lumbar spine (LS) and hip BMD were also assessed. 300mg ONO-5334 appeared to suppress bone resorption markers as potently as ALN (Table). Whilst ALN maintained suppression of bone formation markers after 2y at similar levels to 1y, ONO-5334 did not show suppression at 2y and even significant increases with lower doses. 50mg bd and 100mg qd showed significant increases in TRACP5b and no effect with 300mg qd. ALN maintained significant suppression of TRACP5b. All doses of ONO-5334 resulted in significant and dose-dependent increases in spine and hip BMD vs PBO. Mean \pm SE shown. At month 24, 300mg ONO-5334 increased lumbar spine (LS) BMD by 6.7% (\pm 0.6) ($p < 0.001$ vs. PBO 0.4% \pm 0.6), total hip BMD by 3.4% (\pm 0.4) ($p < 0.001$ vs. PBO 0.4% \pm 0.4) and femoral neck BMD by 3.7% (\pm 0.5) ($p < 0.001$ vs. PBO -0.5% \pm 0.5). ALN BMD results for LS, total hip and femoral hip were 6.3% \pm 0.6, 4.2% \pm 0.4 and 2.9% \pm 0.5, respectively ($p < 0.001$ vs. PBO). ALN continued to suppress all BTM at 2y whereas ONO-5334 showed no suppression of bone formation markers at 2y even at the highest dose and this differed from the 1y result. Thus, ONO-5334 continued to decrease bone resorption markers with little or no effect on bone formation. With comparable increases in BMD to ALN, this highlights a difference in the mechanism of action from bisphosphonates.

Table: Percentage change from baseline (95% CI) as a difference from PBO in BTMs

Treatment with the Cathepsin K Inhibitor Odanacatib in Postmenopausal Women with Low BMD: 5 Year Results of a Phase 2 Trial. Neil Binkley^{1*}, Henry Bone², Nigel Gilchrist³, Bente Langdahl⁴, Heinrich Resch⁵, Jose Rodriguez-Portales⁶, Albert Leung⁷, Antonio Lombardi⁸, Celine Le Bailly De Tillegem⁹, Carolyn DaSilva⁸, Elizabeth Rosenberg⁸, Andrew Denker⁸. ¹University of Wisconsin, USA, ²Michigan Bone & Mineral Clinic, USA, ³Department of Orthopaedic Medicine & Surgery, Christchurch Hospital, New Zealand, ⁴Aarhus Sygehus, Aarhus University Hospital, Denmark, ⁵Medical University Vienna, Austria, ⁶Pontificia Universidad Catolica de Chile, Chile, ⁷Merck Research Laboratories, USA, ⁸Merck & Co., Inc., USA, ⁹Merck & Co., Inc., Belgium

The selective cathepsin K inhibitor odanacatib (ODN) progressively increased BMD at the spine and hip over the course of a 2-year trial and its 2-year extension. The trial extension is continuing, and we are reporting the results of an additional year. Postmenopausal women of mean age 63 years, with BMD T-scores initially between -2.0 and -3.5 at the lumbar spine or hip, received weekly placebo or ODN 3, 10, 25, or 50 mg for 2 years in addition to calcium, if needed, and vitamin D3. In year 3, women in each treatment group were re-randomized to ODN 50 mg or placebo. For years 4-5, women receiving placebo or ODN 3 mg in years 1-2 and placebo in year 3 were switched to ODN 50 mg; all others continued with their year 3 treatments. BMD at the lumbar spine (primary endpoint), femoral neck, trochanter, and 1/3 radius; bone turnover markers; and safety were assessed. Women entering the year 4-5 extension receiving placebo (n=41) or ODN 50 mg (n=100) had similar baseline characteristics. After 5 years, for women who received ODN 50 mg continuously from year 1 (n=13), mean % changes (SE) in BMD from baseline were: lumbar spine 11.9 (2.1) (Figure), femoral neck 9.8 (1.9), trochanter 10.9 (1.4), total hip 8.5 (1.0), and 1/3 radius -1.0 (1.3). In women who were switched from ODN 50 mg to placebo after 2 years (n=14), BMD mean % changes (SE) from baseline were: lumbar spine -0.4 (1.3) (Figure), femoral neck -1.6 (1.0), trochanter -1.0 (0.8), total hip -1.8 (0.8), and 1/3 radius -4.7 (1.7). After 5 years, for women continuously receiving ODN 50 mg (n=9-10), geometric mean % changes from baseline (SE) were -67.4 (10.1) for urine NTX/creatinine, but only -15.3 (5.9) for serum BSAP, whereas for women switched from ODN 50 mg to placebo after 2 years (n=10) these changes were 6.0 (7.6) and -11.9 (3.9), respectively. The administration of ODN over 5 years compared to placebo was generally well-tolerated. In summary, women who received ODN 50 mg for 5 years had a gain in spine and hip BMD over 5 years and showed a sustained reduction in urine NTX/creatinine and a smaller reduction in serum BSAP. As previously reported, discontinuation of odanacatib results in reversal of BMD gains.

Percent Change from Baseline in Lumbar Spine BMD (g/cm²) (Mean \pm SE)

JTT-305 (MK-5442), an Orally Active Calcium-Sensing Receptor Antagonist, Stimulates Transient Parathyroid Hormone Release and Bone Formation. Shuichi Kimura*, Takashi Nakagawa, Yoshihisa Okamoto, Yuji Ishida, Yushi Matsuo, Yuko Shinagawa, MIKIO HAYASHI, Central Pharmaceutical Research Institute, JAPAN TOBACCO INC., Japan

Intermittent administration of parathyroid hormone (PTH) has a potent anabolic effect on bone in humans and animals. Calcium-sensing receptor (CaSR) antagonists stimulate endogenous PTH secretion through CaSRs on the surface of the parathyroid cells and thereby may be anabolic agents for osteoporosis. JTT-305 has been discovered as a potent, orally active CaSR antagonist. This study describes the pharmacological characteristics of JTT-305 (MK-5442). JTT-305 inhibited the increases in intracellular Ca^{2+} induced by extracellular calcium stimulation in COS-7 cells transiently transfected with human CaSR ($\text{IC}_{50} = 86 \text{ nM}$). JTT-305 stimulated PTH secretion from bovine parathyroid cells ($\text{EC}_{50} = 16 \text{ nM}$). Single doses of JTT-305 (0.3-3 mg/kg) were administered orally as a suspension in 0.5% aqueous methyl cellulose to male Sprague-Dawley (SD) rats. The pharmacokinetic and pharmacodynamic profiles were monitored over eight hours. Plasma levels of JTT-305 rapidly increased ($T_{\text{max}} = 30 \text{ min}$) and were cleared in a dose-dependent manner. Serum PTH levels rapidly increased in a dose-dependent manner ($T_{\text{max}} = 15\text{-}30 \text{ min}$, up to 7-8 fold above baseline) and returned to baseline in one to four hours. To evaluate the effect of JTT-305 on OVX-induced bone loss female SD rats, immediately after OVX, were administered JTT-305 (0.3, 1 or 3 mg/kg) orally once daily for 12 weeks. Both doses of JTT-305 prevented OVX-induced decreases in cancellous bone and total BMD at the proximal tibia. Compared to vehicle, JTT-305 increased bone volume, trabecular thickness, trabecular number, and trabecular bone pattern factor in microstructural analyses, and increased mineralizing surface and bone formation rate in histomorphometric analyses. In summary, JTT-305 is a potent, orally active CaSR antagonist that stimulates transient PTH release and prevents bone loss in OVX rats through stimulation of bone formation. These results suggest that JTT-305 is orally active and has the potential to be an anabolic agent for the treatment of osteoporosis.

Sclerostin Antibody Enhances Distraction Osteogenesis in Rats. David Little*¹, Oliver Birke¹, Michelle McDonald¹, Kathy Mikulec¹, Lauren Peacock¹, Alyson Morse¹, Min Liu², Hua Zhu Ke³. ¹The Children's Hospital At Westmead, Australia, ²Amgen, USA, ³Amgen, Inc., USA

Sclerostin is a negative regulator of osteoblast differentiation and bone formation, via antagonism of the Wnt/ β -catenin pathway and/or BMP activity. A sclerostin antibody (Scl-AbIII) has recently been shown to increase bone formation in ovariectomized rats and enhance fracture healing in rats. Distraction osteogenesis is widely used in limb lengthening and reconstruction surgery. Complications of this technique include disuse osteopenia and poor regenerate bone healing, both of which would benefit from pro-anabolic therapy.

A femoral osteotomy was stabilized externally in male Sprague Dawley rats. After a week of latency, the gap was distracted twice daily for 14 days to a total of 7mm. Saline or Scl-Ab (Scl-AbIII) was administered twice weekly throughout the distraction period and up to 4, 6 or 8 weeks post commencement of distraction. Three groups were examined, Saline, Continuous Scl-Ab (C Scl-Ab) and Delayed Scl-Ab with commencement after distraction was complete (D Scl-Ab).

DXA scans at 2 weeks revealed a 67% increase in regenerate BMC in the C Scl-Ab group over Saline ($p < 0.01$). By 6 weeks, regenerate BMC was increased 86% in C Scl-Ab ($p < 0.05$). Further, C Scl-Ab treatment increased BMC proximal to the regenerate compared to Saline at 2, 4, 6 and 8 weeks ($p < 0.05$). MicroCT scans of the regenerate revealed increases in bone volume of 89% with C Scl-Ab and 85% with D Scl-Ab compared to Saline at 6 weeks ($p < 0.05$). By 8 weeks these increases were 53% with C Scl-Ab ($p < 0.01$) and 30% with D Scl-Ab ($p < 0.05$). Further, BV/TV was increased 77% with C Scl-Ab and 82% with D Scl-Ab at 6 weeks compared to Saline ($p < 0.05$) and 40% with C Scl-Ab at 8 weeks ($p < 0.05$). Histology at 6 weeks confirmed MicroCT with 130% increases in BV/TV in the regenerate in C Scl-Ab and D Scl-Ab groups compared to Saline ($p < 0.05$). Analysis of mineral apposition rate showed increases of 56% in C Scl-Ab and 52% in D Scl-Ab over Saline ($p < 0.05$).

Scl-Ab treatment increased bone formation in this model of distraction osteogenesis resulting in a larger regenerate, with increased BMC and bone volume. We expect further studies to reveal increases in mechanical strength. C Scl-Ab and D Scl-Ab showed similar results by MicroCT, suggesting that timing of Scl-Ab is not pivotal. Scl-Ab is hence a candidate for clinical development to accelerate regenerate formation in distraction osteogenesis, which could shorten fixation time and decrease complications or re-fracture.

FR0466

The Tamoxifen Metabolite, Endoxifen, has Anabolic Actions on the Skeleton. John Hawse*¹, Malayannan Subramaniam², Muzaffer Cicek², Kevin Pite³, Kenneth Peters¹, Sarah Grygo¹, Xianglin Wu¹, Glenda Evans², James Ingle¹, Matthew Goetz¹, Thomas Spelsberg². ¹Mayo Clinic College of Medicine, USA, ²Mayo Clinic, USA, ³University of Minnesota, USA

Tamoxifen, an anti-estrogen, has been used for over 30 years as the primary therapy for the treatment of women with endocrine sensitive breast cancer. Recently, our laboratory has demonstrated that endoxifen is the active tamoxifen metabolite responsible for eliciting the anti-cancer effects of this drug. Based on these studies, clinical trials are now underway to treat breast cancer patients with endoxifen. For these reasons, it is imperative to understand the potential side effects of endoxifen on other endocrine sensitive organ systems such as the skeleton. As a first step, we examined the effects of endoxifen on both osteoblasts and osteoclasts in vitro. Endoxifen significantly induced the expression of critical bone marker genes such as Runx2, osterix, osteocalcin, osteoprotegerin and alkaline phosphatase in mouse bone marrow stromal cells and human osteoblasts. Induction of these genes occurred in a dose dependent manner and was associated with increased expression of estrogen receptor-beta ($\text{ER}\beta$), but not $\text{ER}\alpha$, suggesting that $\text{ER}\beta$ may primarily mediate endoxifen's effects on osteoblasts. Endoxifen was also shown to suppress the differentiation of osteoclast precursors derived from mouse bone marrow. We next administered endoxifen (50mg/kg) or vehicle control on a daily basis to 2 month old ovariectomized C57BL/6 mice ($n=10$) for 30 days. DXA analysis revealed significant increases in total body bone mineral density (BMD) (6%) and content (BMC) (9%), which was accompanied by a 23% decrease in fat tissue mass, in the endoxifen treated group. Dramatic increases in BMD (35%) and BMC (20%), as well as trabecular density (52%), cortical content (62%), cortical area (60%) and cortical thickness (78%), were also observed in the tibial metaphysis of endoxifen treated animals as assayed by pQCT. micro-CT analysis of the femoral metaphysis also revealed increases in bone volume/total volume (200%), trabecular number (38%) and trabecular thickness (18%), as well as decreased trabecular spacing (29%), following endoxifen treatment (see figure for representative image). These data are the first to demonstrate that endoxifen has anabolic effects on the skeleton and suggest that the use of endoxifen for the treatment of breast cancer may be more favorable than other new generation therapies which are known to have significant deleterious skeletal effects. Finally, endoxifen may also prove to be an effective therapy for the treatment and/or prevention of osteoporosis.

Representative micro-CT image of the femoral metaphysis following 30 days of vehicle control or endoxifen treatment of 2 month old ovariectomized C57BL/6 mice.

Differential Effects of Odanacatib and Alendronate on Bone Turnover in the Femoral Neck of Adult Ovariectomized Rhesus Monkeys. Tara Cusick*¹, Brenda Pennypacker², Maureen Pickarski¹, Le Thi Duong². ¹Merck & Co., Inc., USA, ²Merck Research Laboratories, USA

Odanacatib (ODN) is a selective, potent and reversible cathepsin K inhibitor in development for the treatment of osteoporosis. Here, we report the effects of ODN and alendronate (ALN) on bone mass and turnover in the femoral neck (FN) of OVX-rhesus monkeys after 20-months treatment. Monkeys (age 12-22 yrs; N=16/group) were dosed in prevention mode with either vehicle (Veh), ODN (2mg/kg/d, po), or ALN (30µg/kg/wk, sc). The ODN dose provided steady state exposure of 11µM·24h as compared to the equivalent clinical 50mg dose at a daily exposure of ~7µM·24h. A separate group of age- and BMD-matched intact monkeys (Int, N=12) was included as control. From *ex vivo* DXA, ODN and ALN displayed comparable trends of FN BMD increases by 5% (NS) compared to Veh. From shear strength test,

regression analysis of all groups showed that peak load of the FN was positively correlated to BMD ($R=0.705$; $p<0.0001$) and BMC ($R=0.740$; $p<0.0001$). Dynamic histomorphometry on both trabecular and periosteal surfaces was determined from 120 μ m-thick cross-sections from double fluorochrome labels, calcein (CAL, 8mg/kg, 15d, sc) at 12 mo. and tetracycline (TCY, 40mg/kg, 14d, IV) just prior to study end. Long-term (LT) bone formation (BF) was calculated based on the CAL-TCY labeling interval of ~228 days. In trabecular FN at both 12 and 20 mo. treatment, ODN tended to reduce and ALN significantly decreased short term (ST) mineralizing surface (MS/BS) vs. Veh. Whereas mineral apposition rate (MAR) remained unchanged, both agents significantly decreased BFR/BS at 12 mo. ($p<0.01$) and 20 mo. ($p<0.05$) vs. Veh. On the periosteal (Ps) cortical surface, all ST BF parameters were not affected by ODN or ALN treatment. However, ODN but not ALN significantly increased LT Ps. MS/BS and Ps.BFR/BS without affecting MAR compared to Veh. The increased LT BF by ODN resulted in a significant increase in cortical thickness by 23% ($p<0.05$) and cortical area per tissue area by 18% ($p<0.05$) and a decrease in marrow area per tissue area by 11% ($p<0.05$) vs. Veh. In summary, comparable to ALN, ODN treatment protected bone mass and maintained normal biomechanical property at the femoral neck of OVX monkeys. This study supports earlier findings that ODN effectively reduces trabecular bone remodeling, yet ODN differs from the bisphosphonates by simultaneously building cortical bone of the femoral neck, in part via stimulating periosteal bone formation.

Inhibition of GSK3 Modulates Early Biomarkers of Bone Turnover in Rats. Peter S Gilmour^{*1}, Witte Koopmann², Hitesh Sangane¹, Hiroki Wada¹, Ashwani Bahl¹, Stefan Kavanagh¹, Peter A Hall¹, Katherine Escott¹.
¹Astrazeneca R&D, United Kingdom, ²AstraZeneca, Sweden

Bone turnover is affected by a number of different mechanisms, including modulators of the wnt signaling pathway such as glycogen synthase kinase 3 (GSK3) inhibitors, anti-resorptive agents such as bisphosphonates, and bone anabolic agents such as parathyroid hormone (PTH1-34). Clinically, a variety of serum biomarkers have been used to measure early changes in bone resorption (e.g., tartrate-resistant acid phosphatase 5b, TRAcP-5b) and bone anabolism (e.g., procollagen type I N-terminal propeptide, PINP).

We investigated the utility of these serum biomarkers as early indicators of changes in bone turnover in rats in vivo. Eleven week old Sprague-Dawley rats were treated with vehicle, GSK3 inhibitors (AR28 and AZ241, po, UID), PTH1-34 (30 μ g/kg, s.c. every second day) or the bisphosphonate alendronate (30 μ g/kg, s.c. every second day). After 3 to 28 days treatment, rats were sacrificed and blood was taken for serum biomarker measurements using commercial assay kits for TRAcP-5b and PINP. Femurs were removed for histopathological assessment following formalin fixation, sectioning and H&E staining. A time course experiment was carried out with AR28 (30 μ mol/kg, po, UID), in which serum PINP was increased by 38% and 40% after 3 and 7 days dosing, respectively, and returned to baseline levels 14 days post-dosing. Serum TRAcP-5b was decreased by 48% at day 3, 65% at day 7 and 68% at day 28 with AR28. In a second experiment, after 7 days of treatment with AR28 (15 μ mol/kg, po, UID) or AZ241 (96 μ mol/kg, po, UID), TRAcP-5b was reduced by 60% and 79% and PINP increased by 37% and 100%, respectively. PTH1-34 produced an increase in PINP (30%) but did not affect TRAcP-5b at day 7. Alendronate inhibited TRAcP-5b (71%) but did not affect PINP at day 7. In contrast to PTH1-34 and alendronate, inhibitors of GSK3 altered both PINP and TRAcP-5b, suggesting both a reduction in bone resorption and an increase in bone formation. Evidence of increased bone formation was observed by histopathological assessment of femurs following treatment with AR28 and AZ241. The findings included trabecular and cortical bone hyperplasia, increased focal osteoid, and osteoblast hypertrophy from day 7 onwards. Thus, treatment with either AR28 or AZ241 led to a net increase in bone formation in rat femurs in vivo. In conclusion, changes in serum biomarkers of bone turnover, PINP and TRAcP-5b, are early indicators of bone turnover modulation in rats treated with GSK3 inhibitors.

Altered Balance between Chondrocyte Apoptosis and Proliferation is Associated with Growth Plate Fusion in Mice with a Specific Inactivation of AF-1 in Estrogen Receptor (ER)- α while Total Inactivation of ER α Results in Prolonged and Enhanced Longitudinal Bone Growth. Anna Borjesson^{*1}, Sara Windahl¹, Marie Lagerquist², Cecilia Engdahl³, Elham Karimian⁴, Emma E Eriksson⁴, Maria Cristina Antal⁵, Andree Krust⁵, Pierre Chambon⁵, Lars Savendahl⁴, Claes Ohlsson⁶.
¹Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, ²Sahlgrenska University Hospital, Sweden, ³Centre for Bone & Arthritis Research, GU, Sahlgrenska Academy, Medicine, Sweden, ⁴Division of Pediatric Endocrinology, Department of Womens & Childrens Health, Karolinska Institutet, Sweden, ⁵Institut de Genetique et de Biologie Moleculaire et Cellulaire (CNRS, INSERM, UoS, College de France), Illkirch, France, ⁶Center for Bone Research At the Sahlgrenska Academy, Sweden

The key role for estrogen and estrogen receptor (ER)- α in the regulation of the growth plate and longitudinal bone growth is demonstrated by the findings that a nonfunctional ER α , or estrogen deficiency caused by a mutation in the aromatase gene, lead to continued growth after sexual maturation owing to non-fused growth plates. In rodents, the growth plates do not fuse directly after sexual maturation, but old mice have reduced growth plate heights and long-term high-dose estradiol treatment results in growth plate fusion.

ER α stimulates target gene transcription via two activation functions (AFs), AF-1 and AF-2. To evaluate the role of AF-1 for longitudinal skeletal growth and growth plate morphology, female mice with specific inactivation of AF-1 in ER α (ER α AF-1⁰) and mice with total inactivation of ER α (ER α ^{-/-}) were evaluated from a pre-pubertal age until they were old (16-19 months old).

Interestingly, the length- and growth plate phenotypes in the ER α ^{-/-} mice correspond with those found in patients with nonfunctional ER α or aromatase deficiency. Accordingly, old ER α ^{-/-} mice showed increased length of the appendicular skeleton (femur: +6.0%, tibia: +8.3%, $p<0.01$) and increased height of the proximal tibial growth plate (+18%, $p<0.05$) compared with WT mice, an effect that was not seen in young adult ER α ^{-/-} mice.

In contrast, the length of the appendicular skeleton was decreased in old ER α AF-1⁰ mice compared with WT mice (femur: -4.0%, tibia: -4.9%, $p<0.01$). Further, the proximal tibial growth plates were fused in all old ER α AF-1⁰ mice, while it was open in all WT mice. The proliferative zone of the growth plate was decreased already in the young adult ER α AF-1⁰ mice (proximal tibia: -17%, $p<0.01$). The fusion of the growth plate was associated with an altered balance between chondrocyte apoptosis and proliferation in the growth plate ($p<0.05$).

In conclusion, old mice with complete inactivation of ER α display a prolonged and enhanced longitudinal bone growth associated with increased growth plate height, resembling the appendicular bone phenotype of a patient lacking ER α . In contrast, specific inactivation of ER α AF-1 results in a hyperactive ER α , altering the balance between chondrocyte apoptosis and proliferation in the growth plate, leading to growth plate fusion.

Androgen Directly Exerts Anabolic Action through Osteoblastic Androgen Receptor. Yuuki Imai^{*1}, Min-Young Youn¹, Min Ni², Kazuki Inoue¹, Shino Kondoh¹, Takahiro Matsumoto³, Myles Brown², Shigeaki Kato¹.
¹The University of Tokyo, Japan, ²University of Tokyo, Japan, ³Department of Medical Oncology, Dana-Farber Cancer Institute, USA, ³Tokushima University, Japan

Sex steroid hormones play important roles to maintain bone tissues through various mechanisms. However, it remains unclear whether androgen directly targets on bone tissue. To clarify physiological impact of AR in bone, we generated and analyzed osteoblast specific KO (*ObARKO*) and male, but not female, *ObARKO* mice exhibited decreased bone mineral density (BMD) in diaphysis of long bones and calvaria. Furthermore, bone histomorphometric analyses revealed that no apparent change was found in static parameters although dynamic parameters, such as MAR and BFR were reduced in both cortical and trabecular bone of *ObARKO*. These results suggested that AR in osteoblasts mediates androgen anabolic actions.

Therefore, to characterize the impact of AR in osteoblasts, gene expression microarray was performed using mRNA extracted from primary cultured calvarial osteoblasts from control and *ObARKO* mice. As a result, more than 500 genes were significantly changed in expression level. Moreover, gene ontology analysis of these genes reveals that categories of extracellular protein, growth factor activity and protein binding were highly ranked. Furthermore, to determine the direct target genes of AR in osteoblasts, a Chromatin Immunoprecipitation sequencing (ChIP-seq) was performed for an osteoblastic cell line, MC3T3E1, treated with DHT. ChIP-Seq analysis revealed 4018 AR binding sites in the mouse genome of MC3T3E1 cells with p value cut off of e^{-5} . Among these binding sites, 2329 Refseq genes have AR binding sites located between 10kb upstream of transcriptional start site to 10kb downstream from transcriptional terminate site. Twenty-four candidate genes of direct AR target in osteoblasts were raised from these two kinds of genome-wide data sets. Among the

candidate genes, Bmper was validated by qPCR. Bmper is the modulator of BMPs by binding with BMPs in extracellular spaces as reported. However, little is known about relationship between Bmper and androgen signaling. To answer this question, the effects of ORX were assessed for WT and Bmper heterozygous deficient male mice (*Bmper^{+/-}*), because of neonatal lethality of homozygous Bmper KO mice. As the results of BMD analysis, ORX failed to decrease BMD of *Bmper^{+/-}* although BMD of WT was significantly reduced by ORX.

These results indicate that AR can directly regulate the transcription of Bmper and androgen directly exerts anabolic action via osteoblastic AR by modulating BMP action.

A Human BAC Transgene Containing the Vitamin D Receptor Gene Locus Humanizes the VDR-null Mouse and Rescues the Aberrant Biological Phenotype of VDR Deficiency. Seong-Min Lee^{*1}, Kathleen Bishop¹, Charles O'Brien², J. Pike¹. ¹University of Wisconsin-Madison, USA, ²University of Arkansas for Medical Science, USA

The biological actions of 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) are mediated by the vitamin D receptor (VDR), a transcription factor expressed in a cell-type specific manner in the intestinal tract, kidney tubules, the parathyroid gland, skin and in bone cells, and regulated by hormones that include PTH, retinoic acid and 1,25(OH)2D3. Recent studies using genomic ChIP-chip and ChIP-seq together with recombinant BAC clone analyses have both defined the functional boundaries of the mouse and human VDR genes and identified a series of intronic and promoter-distal enhancers that contribute to the genes' basal as well as hormone-regulated expression in cultured cells. More recently, we have shown that when employed as transgenes in mice, these mouse and human VDR BAC clones are fully capable of recapitulating tissue-specific expression of the endogenous mouse VDR and directing bone cell-specific up-regulation of VDR in response to exogenous 1,25(OH)2D3 and cAMP. In the present studies, we crossed these transgenic mice with the VDR-null mouse and examined their ability to rescue the VDR-deficient phenotype. All aberrant parameters of systemic calcium and phosphate homeostasis in the VDR null mouse were normalized with each transgene, including a striking reduction in the high systemic levels of PTH inherent to VDR deficiency. Parathyroid hyperplasia apparent in the VDR-null mouse was also rescued. The two transgenes also normalized the expanded hypertrophic chondrocyte layer in the growth plate, corrected the tibia size-defect, and restored skeletal bone mineral density observed due to VDR deficiency. In the kidney, high levels of *Cyp27b1* and low levels of *Cyp24a1* expression in the VDR-null mouse were also restored. VDR action via transgenic expression also restored VDR-null defects in the skin, reducing the presence of dermal cysts and restoring postnatal hair cycling. Finally, VDR transgene expression also restored 1,25(OH)2D3's ability to induce expression of key genes in the intestine, kidney and bone. These studies demonstrate that BAC transgenes containing mouse and human VDR gene loci can direct tissue-specific expression of the VDR *in vivo* and fully rescue the VDR-null phenotype. Relative to the human transgene, this rescue results in the creation of a humanized VDR-null mouse. These studies will enable future identification of determinants of tissue-specific VDR expression and evaluation of VDR function *in vivo*.

DNA Methylation Levels of CYP2R1 and CYP24A1 Predict Vitamin D Dose-response Variation. Xiaojing Xu^{*1}, YU ZHOU², Fengxiao Bu², An Ye¹, Boting Zhou¹, Robert Recker¹, Joan Lappe¹, Lanjuan Zhao³. ¹Creighton University Osteoporosis Research Center, USA, ²CREIGHTON UNIVERSITY, USA, ³Creighton University Medical Center, USA

The wide variation of serum 25(OH)D in response to a given dose of vitamin D supplementation is a daunting challenge for vitamin D deficiency treatment. The goal of this study is to test whether DNA methylation levels of cytochrome P450 (CYP) enzymes (*CYP2R1*, *CYP27A1*, *CYP24A1*, and *CYP27B1*) are biomarkers predicting vitamin D dose-response variation.

Our preliminary data indicated that DNA methylation level of *CYP2R1* was associated with vitamin D dose-response variation in 18 responders and 18 non-responders, who were selected at two extreme tails of 12-month increase of serum 25(OH)D levels, from 446 white postmenopausal women who completed 12 months of a vitamin D3 (1100 IU/day) intervention. In this study, we further tested the importance of *CYP27A1*, *CYP24A1*, and *CYP27B1* in the 18 paired extreme samples. For each subject, genomic DNA at baseline and after the 12-month intervention was extracted from frozen serum. Methylation specific PCR (MSP) results in the promoter region of *CYP2R1*, *CYP27A1*, *CYP24A1*, and *CYP27B1* indicated that, compared to non-responders, responders have a significantly lower baseline DNA methylation level in the promoter region of *CYP2R1* (8% in responders, 30% in non-responders, $P=0.004$), and *CYP24A1* (13% in responders, 32% in non-responders, $P<0.0001$).

In order to validate our pilot results and identify specific CpG sites, pyrosequencing was conducted in 14 CpG sites of *CYP2R1* and 16 CpG sites of *CYP24A1* in

another independent 145 paired serum DNA samples. After the 12-month vitamin D3 intervention, all 14 CpG sites of *CYP2R1* became significantly lower methylated (average methylation level: 11% at 12-month vs 15% at baseline, $P<0.0001$). For *CYP2R1*, baseline DNA methylation levels at 8 CpG sites (-4C, +28C, +30C, +33C, +40C, +43C, +69C, +80C) were negatively associated with 12-month increase of serum 25(OH)D ($P<0.05$). For *CYP24A1*, baseline DNA methylation level at -342C and -293C were also negatively associated with vitamin D dose-response variation ($r=-0.151$, $P=0.011$; $r=-0.131$, $P=0.025$). These negative associations were consistent with our pilot MSP results. That is, high baseline DNA methylation levels of *CYP2R1* and *CYP24A1* gene were significantly associated with reduced conversion of vitamin D3 into 25(OH)D.

For the first time, our results indicated that DNA methylation levels of *CYP2R1* and *CYP24A1* at baseline may be potential biomarkers in predicting vitamin D dose-response variation.

Enhanced Vitamin D Synthesis in Osteoblasts Protects Against Age-Related Bone Loss. Paul Anderson^{*1}, Andrew Turner², Rebecca Sawyer¹, Peter O'Loughlin³, Gerald Atkins⁴, Howard Morris². ¹Musculoskeletal Biology Research, University of South Australia, Australia, ²SA Pathology, Australia, ³Chemical Pathology, SA Pathology, Australia, ⁴University of Adelaide, Australia

Age-related bone loss is associated with a change in bone remodeling characterized by an imbalance between bone formation and bone resorption. Our previous studies in rodents demonstrate that age-related bone loss occurs independently of sex hormone deficiency. While, the physiology of such age-related changes in bone volume remains unclear, ours and other studies suggest that vitamin D activity in the bone is critical for optimizing bone turnover and the prevention of osteoporosis. Furthermore while 1,25D treatment regulates osteoblast gene transcription, proliferation, differentiation and mineralization *in vitro*, the synthesis of 1,25D within osteoblasts also plays a critical role in the inhibition of cell proliferation, stimulating differentiation, and increasing matrix mineralisation by osteoblasts. To demonstrate the *in vivo* role for vitamin D synthesis within osteoblasts, we have created a transgenic mouse model in which transcription of the human *Cyp27b1* sequence is driven by the osteocalcin promoter (OSCyp27b1) only in mature osteoblasts. In primary osteoblasts cultures from OsCyp27b1 mice, increased 1,25D synthesis and enhanced mineralisation. Both male and female OsCyp27b1 mice demonstrate increased bone mineral volume due to increased trabecular number. Interestingly, while male OSCyp27b1 mice demonstrate increased bone from at least 7 weeks of age (12% increase in femoral trabecular BV/TV, $n=11$, $P<0.05$), female OSCyp27b1 mice demonstrate a marked increase in trabecular bone volume only at 20 weeks of age (19% increase femoral metaphyseal, $P<0.05$; 7% increase femoral epiphysis, $P<0.05$; 11% increase lumbar vertebrae $P<0.05$, $n=14$). These data suggest that in female mice increased CYP27B1 activity in osteoblasts protects against bone loss that occurs with aging. Consistent with this observation, TRAP-positive osteoclast numbers on trabecular surfaces are reduced by 26% in 20 week old OSCyp27b1 female mice when compared to WT ($n=3$ /grp). Thus our data strongly suggest that Cyp27b1 activity in mature osteoblasts and osteocytes modulates bone formation as well as resorption with an overall increase in bone mineral. Furthermore, the identification of CYP27B1 activity in osteoblasts as protective mechanism of age-related bone loss and provides a potential mechanism whereby a therapeutic intervention may be developed to improve bone formation and bone mass in the aging population.

Age-related Changes in the Activin A-myostatin-follistatin System within the Bone Marrow Microenvironment. Matthew Bowser¹, Norman Chutkan², John Martell¹, Raymond Corpe¹, Carlos Isales³, Mary Anne Park¹, Demetric Hillman¹, Mark Hamrick^{*1}. ¹Georgia Health Sciences University, USA, ²Georgia Health Sciences University, USA, ³Medical College of Georgia, USA

In vitro and in vivo studies have demonstrated that both activin A and its antagonist follistatin play important roles in bone formation. Activin A treatment can inhibit mineralization in cultured osteoblasts, whereas follistatin increases mineralization. Furthermore, inhibiting activin A in vivo using a decoy soluble activin A receptor (ActRIIA) increases bone formation in mice. Follistatin also antagonizes myostatin (GDF-8), and mice lacking myostatin show increased bone density. Thus, interactions among these factors are likely to be involved in the regulation of bone mass throughout growth, development and aging. Yet, changes in the relative levels of these factors within the bone marrow microenvironment with increasing age are not well understood. We investigated age-related changes in the activin A-myostatin-follistatin system using femoral bone marrow aspirates from young (12 months) and aged (24 months) mice, as well as bone marrow samples from young (<50 years) and older (>70 years) knee arthroplasty patients. Samples were processed using centrifugation to obtain bone marrow supernatant fluid from both mice and humans, since the soluble factors within the marrow supernatant in part define the extracellular milieu to which bone cells are regularly exposed. Supernatant samples were analyzed using ELISA. Results indicate that follistatin levels are not significantly altered with age in bone marrow supernatants from either mice or humans. Myostatin levels were significantly (+75%) increased in mouse bone marrow with age, but did not increase with age in human bone marrow. Activin A levels increased with age (+17%) in mouse bone marrow, and increased by more than 120% in human bone marrow. The marked increase in activin A levels with age in the patient samples was associated with a similar increase in the activin A: follistatin ratio. These findings suggest that activin A bioavailability is altered with age in the bone marrow microenvironment, and may therefore play a role in age-associated changes in bone metabolism. Funding for this research was provided by the Congressionally Directed Medical Research Programs (USAMRAA).

Body Composition in Patients with Type 2 Diabetes Treated with Metformin and Incretin-Based Drugs. Olga Sukhareva, Irina Schmushkovich^{*}, Marina Shestakova, Tatyana Chernova. National Endocrinology Research Center, Russia

Background and goals: The main type 2 diabetes related issues, insulin resistance and impaired beta cell function, are often treated with metformin and incretin-based drugs, respectively. This combination therapy may have some additional benefits, too. One of the main problems in the therapy of such patients is excessive weight and obesity. The goal of this study was an assessment of patients' body composition and its dynamics for patients on such combination therapy.

Patients and methods: As a part of a bigger study we examined a subgroup of 16 patients, aged 45 to 74, with mean duration of T2D 5 years, with HbA1c level more than 7% and less than 10%. We performed the body composition analysis using DEXA Lunar Prodigy GE before and after 6 months of therapy. We analyzed body mass, fat, lean mass, and the percentage of tissue and regional fat in dynamics.

Results: the obtained results are following - mean body mass (kg) before therapy was 86,2310,41, after therapy - 83,4211,58 (P=0,023), fat mass (g) before therapy 32942,94950,16, after therapy - 30651,65721,39 (p=0,042), tissue fat (%) 39,776,49 before therapy and 38,176,41 after therapy (p=0,068). We also determines regional fat (%) before 38,496,29 and 36,916,25 after therapy (p=0,064) and lean mass (g), which

was 50465,59989,82 before and practically did not change after the therapy 49961,59931,08 (p=0,23).

Conclusion: During such therapy we obtained results showing a statistically significant decrease of body mass and body fat, while lean mass remained practically unchanged. These observations should be taken into account when choosing the diabetes therapy.

Changes in tissue and regional fat and A/G ratio observed in this study did not reach statistical significance. It should be noted that previously it had been shown that the change in these parameters lags behind the total fat decrease. Therefore, some trends may not be visible in the data obtained so far due to a short duration of this preliminary study.

Disclosures: Irina Schmushkovich, None.

Diminished Mechanical Stimuli Following Transient Muscle Paralysis Are Not Associated with Acute Trabecular Bone Loss. Jitendra Prasad, Phillipe Huber, Steven Bain, Ted Gross^{*}. University of Washington, USA

Bone loss associated with muscle dysfunction (e.g., SCI, stroke) has been primarily attributed to diminished mechanical stimuli within the afflicted portion of the skeleton. Accordingly, we hypothesized that trabecular bone loss following transient muscle paralysis would be correlated to the loss of gait-induced mechanical stimuli. To test this hypothesis, C57 female mice (16 wk) were exposed to transient muscle paralysis of the quadriceps (Quad, n=6) or calf (Calf, n=6) via a single injection of botulinum toxin A (2 U/100g). Peak normal strains in the tibia during locomotion, calf muscle volume and trabecular bone morphology (BV/TV) of the proximal tibia were then quantified. To determine normal strains, hindlimb ground reaction forces were measured during spontaneous locomotion over a custom walkway with in-line force plate. Kinematic data were simultaneously collected and beam theory used to calculate peak normal strains at the tibia mid-diaphysis. All outcome measures were assessed at d 0 (prior to muscle paralysis) and d 12 (the time of maximal trabecular bone loss in this model). T-tests were used to detect significant differences (p<0.05) and Pearson correlations were used to assess the dependency of BV/TV on diminished normal strain and diminished muscle volume. Qualitatively, quadriceps paralysis induced a more severe gait defect than calf paralysis. Quantitative data supported this observation as peak normal strains in the Quad group were reduced -91.10.9% vs d 0 (p<0.001), while strains in the Calf group were diminished by -42.62.7% (p<0.001 vs. d 0 and p<0.001 vs Quad). In the Quad group, calf volume was significantly decreased (-13.62.6%, p<0.001). Atrophy in the Calf group was 2-fold greater than the Quad group (-26.62.2%, p<0.001 vs d 0, p<0.01 vs Quad). Independent of changes in normal strain and muscle volume, BV/TV was significantly and equivalently diminished in both Quad (-72.36.7%, p<0.001) and Calf groups (-65.33.5%, p<0.001). Consequently, neither diminished peak normal strains (r²=0.14) nor muscle atrophy (r²=0.04) accounted for acute trabecular bone degradation induced by muscle paralysis. We therefore conclude that these factors are unlikely to serve as the primary mediators of the observed bone degradation. Instead, these data emphasize consideration of alternative mechanisms underlying how muscle function modulates trabecular bone homeostasis.

Effect of a Single Oral Dose of 600,000 IU of Cholecalciferol on Muscle Strength in Young Women with Vitamin D Deficiency: a Prospective Intervention Study. Cristiana Cipriani^{*1}, Elisabetta Romagnoli¹, Stefania Russo², Addolorata Scarpello², Claudia Castro², Roberta Pilotto², Federica De Lucia³, Jessica Pepe², Laura Lenge², Salvatore Minisola¹. ¹University of Rome, Italy, ²Department of Internal Medicine & Medical Specialties, University of Rome "Sapienza", Italy, ³Universita Di Roma "Sapienza, Italy

Purpose: The positive effects of vitamin D supplementation on muscle strength and tendency to fall is widely reported, particularly in the elderly. Few data are available in young people with low vitamin D status.

Methods: Eighteen young women (mean age 32.14.7 yrs, range 25-39; BMI 23.84.01 kg/m²) with vitamin D deficiency received a single oral dose of 600,000 IU of cholecalciferol. Isometric grip strength of the upper dominant limb was evaluated using a hand held dynamometer (Kayser Italia s.r.l., Livorno, Italy). Maximal voluntary contraction force (MVC, Newton, N) and speed of contraction (S, Newton/second, N/s) were measured in the sitting position in each subject at baseline and at day (d) 3, 15, 30, 60 and 90. Serum 25(OH)D, ionized calcium (Ca⁺⁺), phosphorus (P), PTH and 1,25(OH)₂D were measured at each time point.

Results: Mean MVC and S values did not change throughout the entire observation period. On the contrary, 25(OH)D levels significantly changed (p<0.001), with a rapid increase at d 3 (75.116.6 ng/mL; p<0.001) and up to d 90 (31.713.3; p<0.01), compared to baseline levels. A concomitant significant decrease in PTH concentration (p<0.01) was found, as soon as d 3 (-18.215.3 pg/mL; p<0.001) and up to d 90 (-19.812.9; p<0.001). A rapid increase in 1,25(OH)₂D serum levels, at d 3 (96.637.4 pg/mL, p<0.001) and up to d 60 (59.828.8; p<0.05) was observed. Mean Ca⁺⁺ levels did not change, whereas mean levels of P showed a significant increase at d 3 (3.80.6 mg/dL; p<0.05). Furthermore, no significant correlation was found between

both MVC and S with 25(OH)D, Ca⁺⁺, PTH and 1,25(OH)₂D levels at each time point. Interestingly, a positive significant correlation was found between both indices of muscle function and P levels at 60 d (MVC, r=0.546 and S, r=0.557 respectively; p<0.02 for both).

Conclusions: A single huge dose of 600,000 IU of cholecalciferol is not effective in enhancing skeletal muscle strength in young women with vitamin D deficiency. This finding could be partly due to the small sample study, and/or the relatively short period of follow-up. Another possibility is that the effect is not picked up exploring this group of muscles. However, our results are in line with recent data demonstrating that the effect of vitamin D on skeletal muscle is probably indirect since vitamin D receptor are absent in this tissue. An increase of serum phosphate could be a possible link between vitamin D administration and improvement of muscle function.

Lumbar Vertebral Bone Density is Positively Associated with Psoas Muscle Mass among Elderly Men. Lynn Marshall¹, Kathleen Holton¹, Joseph Zmuda², Jung Yoo¹, Nels Carlson¹, Yahtyng Sheu², Eric Orwoll¹. ¹Oregon Health & Science University, USA, ²University of Pittsburgh Graduate School of Public Health, USA

Muscle deterioration with aging is characterized by reduced mass, lipid accumulation within muscle fibers, and accretion of adipose tissue beneath the muscle fascia. These features of aging muscle could affect bone strength by altering loads to the skeleton, especially at muscle attachment sites. We evaluated the relation of vertebral volumetric bone mineral density (vBMD) and vertebral size to psoas and paraspinal muscle features. Data were from community dwelling men aged ≥ 65 years participating in the Osteoporotic Fractures in Men (MOS) study. At baseline, quantitative computed tomography (QCT) scans were obtained at the L1/L2 and L4/L5 levels. Vertebral integral and trabecular vBMD (g/cm³) and cross-sectional area (CSA) (cm²) were derived for L1 and L2 vertebrae. In a random sample of 667 men with L4/L5 scans, we derived psoas and paraspinal muscle measures. Muscle groups were manually segmented with contours drawn along the muscle fascia on both sides of the L4 vertebra. All voxels in each contour were summed to compute total volumes (cm³) for the psoas and paraspinal muscle groups separately. Muscle density, a marker of lipid accumulation, was computed as the average attenuation in Hounsfield units (HU) within the total volume of each muscle group. Intermuscular adipose tissue (IMAT) (cm³) volume in each muscle group was the sum of voxels in the HU range (-190 to -30) for AT. The analytic cohort included 510 men who all had the vertebral and muscle QCT measures. Generalized linear regression was used to estimate least square (LS) means and 95% confidence intervals (CI) of each vertebral measure within quartiles of the muscle parameter after adjusting for age, enrollment site, body mass index, and height. Terms for muscle volume and density were fit together; then terms for IMAT replaced those for density. Both integral and trabecular vBMD increased with psoas muscle volume (Table). However, the vBMD measures were unrelated to psoas muscle density or IMAT. Vertebral CSA was not associated with psoas muscle volume or IMAT, but was associated with psoas muscle density. LS means for CSA of L2 were 12.6 (95% CI: 12.1-13.0) in quartile 1 and 13.2 (95% CI: 12.8-13.6) in quartile 4 (p-trend=0.01). None of the vertebral measures was associated with paraspinal muscle volume, density, or IMAT. Among elderly men, vertebral measures that confer bone strength were positively associated with the size and density of psoas muscles, but with not paraspinal muscles.

Adjusted mean vertebral volumetric bone mineral density according to psoas muscle volume among 510 men aged ≥65 years.

Psoas muscle volume (cm ³)		Integral vBMD	Trabecular vBMD
Quartile	Range	LS Mean (95% CI)*	LS Mean (95% CI)*
1	4.6-9.0	0.210 (0.201-0.218)	0.099 (0.091-0.106)
2	9.1-10.7	0.221 (0.214-0.227)	0.106 (0.100-0.112)
3	10.8-12.6	0.226 (0.220-0.232)	0.113 (0.107-0.119)
4	12.7-19.6	0.230 (0.220-0.238)	0.114 (0.108-0.121)

Bone Responses to Body Fat Mass Loss Induced by an Exercise and Nutritional Program in Obese Rats. Maude Gerbaix¹, Lore Metz¹, Fabrice Mac-Way², Christelle Guillet³, Stephane Walrand³, Aurelie Masgraud³, Laurence Vico⁴, Daniel Courteix¹. ¹Universite Clermont Ferrand Laboratoire De Biologie Des APS, France, ²Hotel-Dieu de Quebec, Canada, ³INRA Universite d'Auvergne, France, ⁴University of St-Etienne, France

The association of a well-balanced diet with exercise is a key strategy to treat obesity. However, weight loss is linked to accelerated bone loss. On the other hand, exercise is known to induce beneficial effects on bone. The purpose of this study was to investigate the bone responses to body fat loss induced by an exercise and nutritional program in obese rats. Sixty Wistar male rats, aged 11 months, were previously fed with a high fat/high sucrose diet (HF/HS) for 4 months to induce obesity. Then, four regimens: Lipid and Sucrose Restrictive diet (LSR diet) plus exercise (treadmill: 50 min/day, 5 days/weeks); HF/HS diet plus exercise; LSR diet plus inactivity; HF/HS diet plus inactivity were initiated for 2 months. The body composition including specific central fat mass analysis was assessed by DXA. Visceral fat mass was evaluated by weighing perirenal and peri-epididymal adipose tissues. Lipid and hormonal profiles were assayed. Bone densitometry was assessed on tibia by Piximus. Bone histomorphometry was performed on the proximal metaphysis of tibia and L2 vertebrae (L2). Trabecular micro architectural parameters were measured on tibia and L2 by 3D microtomography. Osteocalcin and CTX were assayed to calculate the bone Uncoupling Index (UI). Global mass, global fat mass, central fat mass and ex-vivo fat mass were significantly lower (p<0.01) in exercised groups compared with sedentary groups. Except global mass, these parameters were significantly lower (p<0.05) in LSR diet groups than HF/HS diet groups. Trained rats showed significant lower triglyceride (p<0.05) and higher free fatty acids (p<0.01) levels than sedentary rats. LSR diet groups had significant higher triglyceride level than HF/HS groups. Both exercise and LSR diet had reduced significantly the leptin and adiponectin levels (p<0.05). BV Density and degree of anisotropy of tibia were lower in LSR diet groups (p<0.05) compared with HF/HS diet groups. Moreover, groups which were given LSR diet had significant lower BV/TV (p<0.001), MS/BS (p<0.001) and BFR/BS (p<0.05) in L2 compared with HF/HS groups. Exercise had increased significantly BMD of tibia and UI (p<0.05) but reduced significantly MAR of L2 vertebrae (p<0.05). In the present study a diet inducing fat mass loss had altered the bone tissue of obese rats. The moderate intensity exercise performed had increased BMD and UI but did not protect bone tissue from trabecular alterations.

HIV-Cox2-based, but not HIV-BMP4-based, In Vivo Gene Transfer Strategy Promotes Osteointegration in a Rat Model of Biceps Tenodesis. Shin-Tai Chen¹, Michael Coen², Jon Wergedal¹, Charles Rundle¹, Kin-Hing William Lau¹. ¹Jerry L. Pettis Memorial VA Medical Center, USA, ²Loma Linda University, USA

Lesions of the long head of the biceps tendon are a significant source of shoulder pain. Biceps tenodesis is a frequently used surgical option, which involves cutting the injured tendon at the site of its attachment into the labrum and reattaching it to the humerus. The success of the surgery depends on an effective bony incorporation of the graft (osteointegration) that would increase the return of its tensile strength. This study sought to determine if our HIV-Cox2-based gene transfer strategy would promote osteointegration, using our rat model of biceps tenodesis. We were interested in Cox2 because the Cox2 gene therapy is highly effective in promoting bony bridging of the fracture gap, which involves similar histologic transitions seen in osteointegration. BMP4 was included in this study for comparison. Briefly, a 1.14-mm diameter tunnel was drilled in the mid-groove of the humerus of adult Fischer 344 rats. The HIV-Cox2, BMP4, or β-gal control vector was applied directly into the bone tunnel and onto the end of the tendon graft, which was then pulled into the bone tunnel. A 1.1-mm diameter poly-L-lactide pin was press-fitted into the tunnel as interference fixation. Animals were sacrificed at 3 or 8 weeks for histology analysis of osteointegration. Both strategies enhanced chondrogenesis at the tendon/bone interface. The HIV-BMP4 treatment increased trabecular bone formation (BF) by 32% compared to the control (1,000.08 vs. 0,670.10 mm², p<0.05). In contrast, the effect of the HIV-Cox2 strategy on de novo BF was much smaller than that of the HIV-BMP4 strategy. The tendon/bone interface of the Cox2-treated tenodesis showed the well-characterized tendon-to-fibrocartilage-to-bone histologic transitions that are indicative of osteointegration. No such transitions were seen in the BMP4-treated graft. Thus, Cox2, but not BMP4, promoted osteointegration. To determine if the enhanced osteointegration would be translated into an improved mechanical property, the pull-out strength of the Cox2 and BMP4-treated tendon grafts was determined with our recently established mechanical testing that is suitable for the rat biceps tendon. Fig. 1 shows that the HIV-Cox2 strategy yielded a much better return of the pull-out strength of the tendon graft than the HIV-BMP4 strategy after 8

weeks. In conclusion, the HIV-Cox2-based, but not HIV-BMP4-based, gene transfer strategy enhanced osteointegration that improved return of the pull-out strength of the tendon graft.

Is Vitamin D Level for Muscle Strength Improvement Higher Than That for Mobility Improvement for Japanese Pre-Frail Elderly Attending a Nursing Care Prevention Class? : Examination of Alfacalcidol Supplementation and Renal Function. JUNKO OKUNO¹, Shigeo Tamura², Takako Fukasaku³, Noriko Yabushita³, Mi-Ji Kim⁴, Tomohiro Okura³, Kivoji Tanaka³, Hisako Yanagi³. ¹UNIVERSITY OF TSUKUBA, Japan, ²Urawa University, Department of General Welfare, Japan, ³University of Tsukuba, Graduate School of Comprehensive Human Sciences, Japan, ⁴Tokyo Metropolitan Geriatric Hospital & Institute of Gerontology, Japan

A key characteristic of the pre-frail elderly is decreased mobility, which is reported to be associated with vitamin D levels and renal function. The aim of this study was to examine the association between physical fitness improvement which might have hierarchical levels and vitamin D levels by examining vitamin D supplementation and renal function in the pre-frail elderly. A longitudinal study was conducted in two towns (latitude 36 degree north) from June 2006 to December 2009 in Japan. Subjects consisted of 177 community-dwelling pre-frail elderly, aged 65 years and over (meanSD:76.45.5 yr) who attended a nursing care preventive exercise program for 3 months. A face-to-face interview was conducted based on a questionnaire. Serum levels of intact parathyroid hormone (iPTH), 25-hydroxyvitamin D (25(OH)D), 1,25-dihydroxyvitamin D (1,25(OH)₂D), creatinine, and calcium were measured. Estimated GFR (eGFR) (mL/min/1.73m²) was calculated using a new Japanese formula of 2008. Alfacalcidol 1μg/day was administered to elderly for three months and we assumed the elderly who took VD more than 80% a VD group. The following physical fitness tests were performed at baseline and at the end of a 3-month follow-up period: walking ability (timed up and go: TUG, a 5-meter walk), balance (functional reach: FR, one-legged stance with open eyes, tandem stance, tandem walk), and muscle strength (alternate step, 5-chair sit-to-stands). We conducted multiple linear regression analysis for the factors of physical fitness improvement. The prevalence of eGFR < 60.0 mL/min/1.73m² was about 24.3%, that of 25(OH)D < 50 nmol/L was 28.8%, and that of 25(OH)D < 75 nmol/L was 86.4%. Physical fitness tests except one-legged stance improved significantly in all subjects. Pre eGFR and pre 25(OH)D were significantly associated with improvement of timed up and go (TUG), vitamin D supplementation with FR, pre25(OH)D (<50nmol/L, >=50nmol/L) with tandem stance, post 1,25(OH)₂D with tandem walk, and pre 25(OH)D (<75nmol/L, >=75nmol/L) with alternate step and 5 chair sit-to-stands. Our data suggest that assessment of renal function and maintaining appropriate vitamin D levels seem to be significant for independent living in the pre-frail elderly and higher 25(OH)D level might be needed for improvement of muscle strength than mobility; if possible, a 25 (OH)D level greater than 75 nmol/L is preferable.

The Effect of Sciatic Neurotomy and Nerve Repair on Cancellous Bone in Rat Femurs and Tibias. Glenda Evans¹, Huan Wang², Stephen Hodgson¹, M. Brett Runge², Anthony J. Windebank², Robert J. Spinner², Michael Yaszemski². ¹Mayo Clinic, USA, ²Mayo Clinic College of Medicine, USA

It is well established that bone loss occurs in the limbs of humans and animals following regional traumatic nerve resection and after surgically controlled unilateral sciatic neurotomy (USN) in animals. The mechanism of bone loss is presumably due to denervation muscle atrophy with resulting mechanical limb unloading.

Objective: Does reestablishment of neuronal function ameliorate and/or prevent bone loss due to denervation?

Methods: Unilateral left sciatic neurotomy was performed on three-month-old virgin female Lewis rats to create a 1-cm defect, which was immediately repaired by suturing the resected nerve ends to an intervening 1-cm polymer tube. The animals were allowed a recovery time of 16 weeks before sacrifice. Tibias and femurs were harvested and fixed in 70% ethanol and scanned at medium resolution (12um). Analysis was performed on 100 slices using micro computerized tomography (Scanco 35 μ CT). Continuity and quality of reattached nerves were evaluated by nerve conduction studies prior to sacrifice and muscle weights at sacrifice.

Results: The microCT revealed that bone loss occurred in all animals in the USN affected limb, greater in the tibia than femur (tibia -16%, femur -7%), when compared to tibias and femurs from the contralateral limb. The amount of bone loss inversely related to the magnitude of nerve conduction following reinnervation. Trabecular number decreased 11% in the tibia and 2% in the femur. Trabecular thickness decreased 14% in the tibia and 10% in the femur.

Conclusions: The system described above may represent a useful animal model for the study of effects of denervation and reinnervation on bone loss and for investigating potential preventive and therapeutic interventions of bone loss.

Disclosures: Glenda Evans, None.

Effects of Laparoscopic Adjustable Gastric Banding and Weight Loss on Bone Turnover Markers in Morbidly Obese Adolescents. Marisa Censani¹, Ilene Fennoy¹, Shulamit Lerner¹, Rushika Conroy¹, Sharon Oberfield¹, Jeffrey Zitsman¹, Donald McMahon², Shonni Silverberg³. ¹Columbia University Medical Center, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University, USA

The adolescent obesity rate has more than tripled in the United States over the past 30 years. Bariatric surgery is widely used in the morbidly obese adult population as an effective treatment for weight loss and is currently being evaluated in the adolescent population. While there are many reports in the adult literature on skeletal and mineral metabolism consequences of obesity and bariatric surgery, there are limited data on changes in bone turnover markers after rapid weight loss from bariatric surgery in adolescents.

Methods: The Center for Adolescent Bariatric Surgery is a multidisciplinary program of nutrition, medical care, and laparoscopic adjustable gastric banding (LAGB) for adolescents between the ages of 14-18 years who have BMI >40 kg/m² or >35 kg/m² and at least one co-morbidity. A pilot study in 12 adolescents (7 females, 5 males; mean age 16.5 ± 1.06 yrs; mean BMI 44.2 ± 7.26 kg/m²) assessed bone turnover markers (formation marker: osteocalcin and resorption marker: C-telopeptide [CTX]) at baseline and 12 months post-operatively. Comparison of within subject changes was performed using paired t-test and ANOVA with repeated measures and correlations between parameters of weight loss and bone turnover.

Results: By 12 months postoperatively (Table), mean BMI declined by 6.071.14 kg/m² (p=0.0003), with an absolute weight loss of 14.93 ± 2.69 kg (p=0.0002) and mean percent excess body weight loss of 28.39.0% (P=0.01). Bone turnover markers rose markedly after bariatric surgery, with osteocalcin rising 3.5-fold and C-telopeptide doubling by 12 months (p<0.001 for both). Change in osteocalcin tended to be inversely associated with percent excess body weight loss (adjusted r = -0.52; p<0.09).

Conclusions: In a pilot study of 12 morbidly obese adolescents, weight loss from LAGB was associated with marked increases in bone turnover. Significant increases were noted in markers of both formation and resorption 1 year after surgery. Despite our small numbers, the data suggest that the extent of increase in bone turnover may be associated with degree of weight loss. Whether the increased bone turnover will be associated with a decline in bone density in obese adolescent population undergoing bariatric surgery remains to be seen.

Variable	Baseline	12 m post LAGB
Age (years)	16.5 ± 1.06 (15.08-17.83)	
Weight (kg)	118.6 ± 28.59 (83.9-161.3)	105.8 ± 30.13 (66.7-153.2)
BMI (kg/m ²)	44.24 ± 7.26 (35.8-57.8)	39.08 ± 8.37 (28-52.7)
Excess Body wt (kg)	51.78 ± 22.85 (24-89.3)	39.04 ± 24.26 (8.2-79.5)
Serum osteocalcin (ng/ml)	8.92 ± 1.21 (0.51-16.55)	18.45 ± 1.21 (4.56-27.32)
Serum CTX (ng/ml)	0.18 ± 0.07 (0.06-0.37)	0.64 ± 0.07 (0.17-1.35)

Data are presented as Mean ± SEM (Range)

Incident Vertebral Fractures among Children with Rheumatic Disorders 12 months Post-Glucocorticoid Initiation: a National Observational Study. L. M. Ward¹, C. Rodd², B. Lang³, N. Alos⁴, S. Atkinson⁵, D. Cabral⁶, R. Couch⁷, E. Cummings³, A. Huber³, P.M. Miettinen⁸, H. Nadel⁶, D. Stephure⁸, R. Stein⁹, S. Taback¹⁰, M. Matzinger¹, N. Shenouda¹, B. Lentle⁶, F. Rauch², K. Siminoski⁷, - and the Canadian STOPP Consortium¹¹. ¹University of Ottawa, Canada, ²McGill University, Canada, ³Dalhousie University, Canada, ⁴Universite de Montreal, Canada, ⁵McMaster University, Canada, ⁶University of British Columbia, Canada, ⁷University of Alberta, Canada, ⁸University of Calgary, Canada, ⁹University of Western Ontario, Canada, ¹⁰University of Manitoba, Canada, ¹¹Canadian Pediatric Bone Health Working Group, Canada

Background: Vertebral fractures are a potential complication of childhood rheumatic disorders or their treatment. The purpose of this study was to determine the frequency of incident (i.e. new) vertebral fractures (IVFs) 12 months after glucocorticoid (GC) initiation in children with rheumatic diseases and to describe the profile of children with IVFs compared to those without.

Methods: Children with rheumatic diseases initiating GCs were enrolled in a national, prospective observational study. Annual spine radiographs were evaluated using the Genant semi-quantitative method and spine areal bone mineral density (aBMD) was measured every 6 months. Clinical features, including GC exposure, back pain, disease and physical activity, calcium and vitamin D intake, and changes in spine aBMD Z-scores were also assessed.

Results: Of 118 children followed to 12 months post-GC initiation, 7 (6%) manifested IVFs. The diagnoses for these 7 children were: juvenile dermatomyositis (N=2), systemic lupus erythematosus (N=3), systemic vasculitis (N=1) and mixed connective tissue disease (N=1). The child with mixed connective tissue disease was excluded from the natural history analyses from 4 months onward because of the need for bisphosphonate therapy to treat multiple, painful IVFs at this time. Six children with natural history data to 12 months had a total of 7 IVFs (4 mild and 3 moderate; 5 thoracic and 2 lumbar). These children with IVFs received on average 50% more steroid over the 12 month period compared to those without as assessed by both cumulative GC dose (94523447 mg/m2 versus 62035181; p=0.030) and average GC dose (249 mg/m2/day versus 1613; p=0.044). At 6 months, the children with IVFs also had greater increases in body mass index (BMI) Z-scores (1.408 versus 0.508; p=0.010) and decrements in spine aBMD Z-scores (-0.805 versus -0.405; p=0.048). Four of 6 children (67%) with IVFs and natural history analyses to 12 months had spine aBMD Z-scores less than -2.0 at 12 months compared to 16% of children without (p=0.011).

Conclusions: IVFs were not frequent after one year of GC treatment in this cohort; however, children with IVFs at 12 months received more GC and manifested greater increases in BMI Z-scores and declines in spine aBMD Z-scores in the first 6 months of GC therapy.

An Appropriate Animal Model for Studying Maternal Bone Changes during Pregnancy: A Model Resembling Winter Pregnancy in Youth. Negar Tabatabaei¹, Celia Rodd¹, Richard Kremer², Hope Weiler¹. ¹McGill University, Canada, ²McGill University, Royal Victoria Hospital, Canada

Establishing an appropriate animal model which would resemble human pregnancy in bone metabolism is crucial to examine bone physiology during this period. The objective of our study was to investigate the effect of pregnancy on maternal bone mass and metabolism using a guinea pig model. Female pigmented guinea pigs (n=44), 16 weeks of age, were randomized to isocaloric diets containing different dosages of vitamin D (0 IU/g (n=9), 0.25 IU/g (n=9), 0.5 IU/g (n=9), 1 IU/g (n=9) and 2 IU/g (n=8)) and then mated and maintained in a UV-free environment. Blood samples were drawn just before mating, d 21, d 42 of pregnancy and 24-36h after delivery. Plasma concentrations of 25(OH)D, deoxypyridinoline and total alkaline phosphatase were measured at all four time points. Whole body, spine (L1-L4), tibia and femur DXA scans were measured before mating and 24-36h after delivery. Statistical analyses were performed using a mixed model repeated measures ANOVA with a fixed effect of time and litter size and a random effect of sow and block. There was a strong dose-response effect of different dosages of dietary vitamin D on plasma 25(OH)D concentration (P<0.0001), but despite this effect, no differences were observed among the five different diets on plasma bone biomarkers and DXA measurements. Plasma concentrations of 25(OH)D decreased during pregnancy whereas deoxypyridinoline and alkaline phosphatase remained unchanged (Table 1). In post-partum blood 25OHD and alkaline phosphatase significantly decreased while deoxypyridinoline significantly increased compared to pre-delivery concentrations (Table 1). Compared to preconception indices postpartum whole body

BMD did not differ. Tibial and femoral BMD increased while the trend was different in L1-L4; showing a decrease in BMD (Table 2). Since plasma 25(OH)D concentrations were high at preconception and considering that guinea pigs at this age are still growing, this model may be suitable for studying the effect of pregnancy on adolescent bones in which conception is induced at the beginning of winter when 25(OH)D concentration are likely to be high. Changes in BMD at the femur, tibiae and spine early post-partum vs preconception suggest an increase in cortical bone and a decrease in trabeculae bone. Changes in post-partum bone markers suggest an uncoupling of bone resorption and formation. The decrease in maternal 25(OH)D likely reflects maternal-fetal transfer and physiological demands of reproduction.

Table 1. Maternal plasma 25(OH)D, deoxypyridinoline and total alkaline phosphatase at baseline, d21, d42 and post-partum of pregnancy

Outcome	Time-point				SEM	Effect of Time
	Pre-conception	d 21	d 42	Post-partum		
25(OH)D (nmol/L)	260.4 ^a	174.4 ^b	151.4 ^c	113.5 ^d	9.5	p<0.0001
Deoxypyridinoline (nmol/L)	10.2 ^a	11.4 ^a	14.9 ^a	26.2 ^b	6.5	p<0.02
Alkaline phosphatase (U/L)	104.3 ^a	99.3 ^a	105.2 ^a	44.4 ^b	6.6	p<0.0001

Data are estimated means ± SEM. Means reflect all diets combined. Means within a row with superscripts without a common letter differ, P<0.05.

Table 2. Maternal whole body, tibia, femur and spine (L1-L4) BMD at pre-conception and postpartum

Outcome (g cm ²)	Time-point		SEM	Effect of Time
	Pre-conception	Post-partum		
Whole Body BMD	0.228	0.229	0.002	p<0.10
Tibia BMD	0.286	0.291	0.004	p<0.01
Femur BMD	0.465	0.500	0.010	p<0.0001
Spine (L1-L4) BMD	0.282	0.271	0.004	p<0.0001

Effect of Letrozole, an Aromatase Inhibitor, on Skeletal and Sexual Maturation in Rats. Rana Samadfam¹, Louise Pouliot², Keith Robinson², Paul Vancuntsem³, Marilynn Schneider⁴, Susan Y. Smith¹. ¹Charles River Laboratories, Canada, ²Charles River, Canada, ³Novartis, Germany, ⁴Novartis Pharmaceuticals Corporation, USA

Aromatase is the enzyme catalyzing the last step of estrogen production in the ovary and in peripheral tissues (males-converting testosterone to estrogen). Sex hormones are involved in the regulation of bone growth during puberty and maintaining bone mass in adulthood. The role of estrogen in the female reproductive system development has been well documented. Estrogen receptors are expressed in the male reproductive system during development, indicating roles for estrogen in regulating male tissue development and reproductive events. The objective of this study was to determine the effect of letrozole on bone growth and density when administered orally to juvenile rats (beginning on day 7 post partum) for up to 12 weeks followed by a 6 week recovery period. The effect on the reproductive system was also evaluated. Pups (20/sex/group) were assigned to four groups each receiving daily oral gavage of either vehicle control or letrozole at 0.003, 0.03 and 0.3 mg/kg/day. 10 per group were sacrificed at the end of the treatment period (day 92 pp) and the remaining animals were sacrificed following a 6 week recovery period (day 134 post partum). Decreases in bone length measured by radiography, area measured by DXA and total slice area measured by pQCT were observed for letrozole treated males relative to controls, while all these parameters were generally increased for females. The effects on bone length and area for both males and females, in most part correlated with the body weight gains (lower for males and higher for females). A significantly higher serum ALP level for females treated at 0.3 mg/kg/day compared to controls was consistent with increased bone formation. A statistically significant decrease in proximal tibia metaphyseal BMD was observed for females at the end of the treatment period. Withdrawal of treatment for up to 6 weeks showed evidence of recovery for both males and females treated at the low dose however recovery was less evident at the high dose. Evaluation of the reproductive system indicated delayed sexual maturation for both males and females consistent with the action of the compound to reduce sex hormones. In conclusion, the findings indicate that letrozole has the same effect in both males and females resulting in a delay in bone maturation and prevention of pubertal progression. These results provide unique insight into the effects of sex steroid hormones on bone growth and development in male and female rats.

SA0024**High Bone Mass Radiographically Mimicking Osteopetrosis but with Rapid Skeletal Turnover and Maxillofacial Giant Cell Reparative Granuloma.**

Michael P. Whyte^{*1}, Katherine L. Madson², Steven Mumm¹, William H. McAlister³, Deborah V. Novack⁴, Deborah Wenkert², Joanne Blair⁵, Nicholas J. Shaw⁶. ¹Shriners Hospital for Children & Washington University School of Medicine, St. Louis, USA, ²Shriners Hospital for Children in St. Louis, USA, ³Department of Pediatric Radiology at the Mallinckrodt Institute of Radiology, St Louis Childrens Hospital at the Washington University School of Medicine, St. Louis, USA, ⁴Washington University in St. Louis School of Medicine, USA, ⁵Alder Hey Children's Hospital, United Kingdom, ⁶Birmingham Children's Hospital, United Kingdom

Disorders of high bone mass are important for revealing genes and signaling pathways that condition skeletal homeostasis. They can be divided into two main types, those due to osteoclast dysfunction (eg, osteopetrosis), and those due to excessive osteoblast activity (eg, sclerosteosis).

An 8-yr-old boy presented at age 2 years with a visual field defect for which an MRI scan identified a large mass in the perisellar region. Histology of the resected lesion showed features of a giant cell reparative granuloma. Radiographs showed evidence of dense bones with thick cortices and narrowing of the medullary spaces resembling osteopetrosis. However, bone turnover markers were markedly elevated with serum alkaline phosphatase > 5,000 iu/l (normal < 850 iu/l). Because of rapid regrowth of the tumor which appeared to contain osteoclasts he received pamidronate given intravenously and intermittently for three years which reduced, but did not normalize, the serum alkaline phosphatase level with no subsequent regrowth of the tumor.

Bone mineral density assessed by DXA showed a z-score in the lumbar spine of + 9.1 and in the hip of + 5.8. Radiographic skeletal survey before and after pamidronate treatment confirmed sclerotic bones with thickened cortices and narrow medullary cavities with interference of tubulation in many long bones similar to that seen in osteopetrosis. Two years after the last pamidronate dose, an iliac crest bone biopsy showed the majority of the bone to be trabecular with a large amount of osteoid containing an abundance of osteoblasts. Osteoclasts were readily seen with evidence of bone resorption. There was no retention of calcified cartilage as seen in osteopetrosis. Tetracycline labeling confirmed rapid bone remodeling. Mutation analysis excluded defects in the LRP5, RANKL, RANK, OPG, SQSTM1, TGFβ1, and sFRP1 genes which are known to cause various high bone mass disorders.

Our patient has a unique high bone mass disorder which radiographically resembled a form of osteopetrosis but on biochemistry and bone histology was instead consistent with rapid bone formation.

Figure A: Radiograph of the left knee two years after the previous dose of pamidronate. An Erlenmeyer flask deformity is apparent in the distal femoral metaphysis. The bones are radiographically dense and widened.

Figure B: Tetracycline double-labels (arrows) are apparent at this time in the iliac crest.

SA0027**Limited Skeletal Deficits by Peripheral Quantitative Computed Tomography in Adolescents with Anorexia Nervosa.**

Amy DiVasta^{*1}, Natalie Stokes¹, Catherine Gordon². ¹Children's Hospital Boston, USA, ²Children's Hospital Boston & Harvard Medical School, USA

Purpose: Young women with anorexia nervosa (AN) commonly exhibit bone loss of the axial skeleton. We previously reported deficits in bone geometry and strength measured at the hip in adolescents with AN. However, the effects of AN on the peripheral skeleton are unknown. In the current study, we aimed to determine the effects of malnutrition on bone strength and geometry measured by pQCT in young women with AN.

Methods: Ten adolescents with AN and fifty healthy adolescents, aged 13-22 yr, were recruited from an adolescent medicine clinic. Volumetric bone mineral density (vBMD), cross-sectional area (CSA), cortical thickness (CTh), and strength-strain index (SSI) were measured by pQCT at the radius (4%, 50%, 66% site) and tibia (4%, 38%, 66% site). Anthropometrics were measured in all participants, and health history obtained by interview.

Results: Adolescents with AN were malnourished (BMI 17.5 1.6 kg/m²) compared to healthy young women (BMI 22.4 3.1 kg/m²; p<0.0001). All healthy subjects were regularly menstruating; girls with AN had been amenorrheic for a mean of 11.2 15.8 months (range 3-54 months). At the radius, significant differences in cortical thickness were demonstrated (50% site: AN 2.8 0.2 mm vs. Control 3.1 0.3 mm, p=0.03 and 66% site: AN 2.1 0.4 mm vs. Control 2.4 0.4 mm, p=0.04). At the tibia 4% site, both total CSA (846.4 99.3 mm vs. 955.8 140.3 mm, p=0.02) and trabecular CSA (659.9 96.9 mm vs. 765.6 127.5 mm, p=0.02) were significantly lower in girls with AN than controls. No difference in SSI or vBMD was noted between groups. The duration of amenorrhea was negatively correlated with total CSA at the radius, and with trabecular vBMD at the tibia (r= -0.63 to -0.78, p<0.05).

Conclusions: In young women with AN, cortical thickness and CSA measured at the radius and tibia by pQCT differed from that of healthy, age-matched control subjects. The duration of amenorrhea seen in the adolescents with AN was negatively associated with peripheral measures of skeletal health, particularly those at trabecular-rich skeletal sites. These results indicate that the impact of malnutrition and amenorrhea on the peripheral skeleton of young women with AN may differ from that of the axial skeleton.

SA0028**Reduced Volumetric Trabecular Bone Mineral Density of the Lumbar Spine in Adolescents with Anorexia Nervosa.**

Lily Wheeler^{*1}, M. Zulf Mughal², Jane Whittaker³, Judith Adams⁴, Sarah Ehtisham³. ¹University of Manchester, United Kingdom, ²The University of Manchester & Royal Manchester Children's Hospital, Endocrinology, United Kingdom, ³Royal Manchester Children's Hospital, United Kingdom, ⁴Manchester Royal Infirmary, United Kingdom

Introduction

It is well known that anorexia nervosa (AN) in adolescents is associated with reduced bone mineral density (BMD). Factors that contribute to low BMD in AN include low body mass index, secondary hypogonadism, resistance to growth hormone, low Insulin-Like Growth Factor-1 levels, high serum cortisol levels and alterations in various appetite-regulating hormones. Studies using high resolution quantitative computed tomography (QCT) have shown that adolescent girls with AN have lower distal radial trabecular bone volume, trabecular thickness and greater trabecular separation, compared with controls.

Objectives

A retrospective evaluation of patients with AN referred for endocrine and metabolic bone health assessment between February and September 2010 was made. Lumbar spine (LS) BMD was measured by dual-energy X-ray absorptiometry (DXA) and quantitative computed tomography (QCT). Distal radial total and trabecular BMD was measured by peripheral QCT (pQCT).

Methods

BMD of L1-L4 was measured by DXA. These data were expressed as bone mineral apparent density (BMAD; g/cm³) and values transformed to Z scores using local normative data (ADC;2007;92(1);53-9). Volumetric trabecular BMD (TBMD; mg/cm³) at L1-L3 was measured by QCT and values transformed to Z scores using Mindways softwareTM (Austin, Texas). Distal radial (4%) total and TBMD was measured by pQCT and values transformed to Z scores using local normative data (Osteoporos Int. 2009;20(8):1337-46).

Results

Twelve females and one male aged 13.6-16.9 years with a diagnosis of AN were evaluated. The mean duration of AN was 3.5 (0.7 to 8) years. Eleven of the females

had amenorrhoea; 2 primary, 9 secondary (mean duration 1.2 years). Mean BMI SDS was -1.74 (-4.2 to 0.19). A table of Z scores is shown below.

Conclusions

Results of this preliminary study suggest that adolescents with AN have reduced trabecular LS BMD. Further studies are needed to elucidate the reasons for reduction of trabecular BMD in the central, but not at the appendicular skeletal sites in this group of patients.

g/cm ³	Median Z score	Range Z scores	P value
DXA LS BMAD	-0.45	-2.36 to 0.79	<0.05
QCT LS TBMD	-1.91	-3.42 to -0.42	<0.001
Distal radius total BMD	0.06	-1.83 to 1.08	0.656
Distal radius trabecular BMD	-0.05	-1.91 to 0.81	0.416

A table of Z scores of LS BMAD, LS TBMD, distal radial total BMD and distal radial trabecular BMD.

Denosumab Treatment of Fibrous Dysplasia of Bone. Alison M. Boyce^{*1}, Jack Yao², Marilyn H. Kelly³, Chris Chamberlain², William Chong⁴, Rachel Gafni², Alfredo Molinolo⁵, Natasha Cherman⁶, Nisan Bhattacharyya⁷, Michelle Ellsworth⁸, Josephine Kasa-Vubu⁸, Michael Collins². ¹NICHD, NIDCR, NIH, USA, ²National Institutes of Health, USA, ³SCSU, CSDB, NIDCR, NIH, USA, ⁴National Institute of Health, USA, ⁵OCBP, NIDCR, National Institutes of Health, USA, ⁶CSDB, NIDCR, NIH, USA, ⁷NIDCR, NIH, USA, ⁸University of Michigan Health Center, USA

Fibrous dysplasia (FD) is a benign fibroosseous skeletal disease caused by somatic activating mutations of the cAMP-regulating protein, Gsz. These mutations lead to replacement of normal bone by proliferative malfunctioning osteogenic precursors, leading to abnormal bone formation, deformity, fracture, and pain. Medical treatment has been ineffective in altering the disease course. Receptor activator of nuclear factor kappa-B ligand (RANKL) is a cell surface protein involved in many cellular processes, including osteoclastogenesis, and is reported to be overexpressed in FD-like bone cells. Denosumab is a humanized monoclonal antibody to RANKL approved for treatment of osteoporosis and prevention of skeletal-related events from bone metastases.

A 9-year-old boy with FD presented with rapid and dramatic expansion of FD in the right femur, not responsive to bisphosphonate therapy and necessitating amputation of the right lower extremity. Months later, the left thigh began a similar rapid and painful expansion, requiring daily narcotics, and a second amputation was planned. Immunohistochemical staining on a bone biopsy specimen taken prior to initiation of treatment revealed marked RANKL expression. A 12-month trial of denosumab was instituted to attempt to slow disease progression and prevent amputation. Denosumab was given by subcutaneous injection monthly at 1 mg/kg, with escalation to 1.25 mg/kg after 3 doses. Bone turnover markers were monitored monthly, and tumor volume was measured by CT 1 year prior to treatment, start of treatment, and after 3 months of therapy.

During the first 3 months of denosumab, pain resolved allowing discontinuation of all analgesics, and bone turnover markers declined significantly: alk phos 1683 U/L to 234 (86-315), P1NP 1300 mcg/L to 119 (22-105), B-CTX 1924 pg/mL to 251. Tumor volume 1 year prior to treatment was 170 cm³, and at treatment start had increased 56.5% to 266 cm³. While there were 13.5 months between studies, per report expansion began 6 weeks prior to treatment start. Assuming linear expansion over 13.5 months, the rate of growth was 4.2%/mo. Less conservative but likely more accurate estimates over 1.5 months show expansion of 37.5%/mo. After 3 months of denosumab, the volume was 277 cm³, representing a decreasing rate of expansion at 1.4%/mo.

Preliminary data after a 3-month treatment course suggests denosumab may be effective in slowing expansion of fibrous dysplasia.

A Phantom for Calibrating Accuracy of DXA-Derived Femoral Neck Geometry. Thomas Beck¹, Ben Khoo², Roger Price³, Thomas Beck^{*1}, Richard Prince³, Roger Price³. ¹Quantum Medical Metrics, LLC, USA, ²Western Australian Health Department, Australia, ³Sir Charles Gairdner Hospital, Australia

There has been an increase in the use of structural geometry, measured by DXA and QCT methods to facilitate understanding of bone fragility. However, good methods for assessing and calibrating geometric accuracy are lacking. This study reports the development of a 3D anthropometric proximal femur phantom for calibration of femoral neck structural geometry. The phantom consists of a femoral shaft, head and seven interchangeable neck modules varying in size and shape to span the range of geometries commonly observed in adult femurs, with cortical thicknesses from 0.7 mm in a circular annulus (Module 1) to 3 mm and 8 mm in an asymmetric elliptical cross-section (Module 7).

Phantom was scanned (each module 10 times) in a water bath using Hologic Discovery DXA in hip-array mode and analysed using hip structural analysis (HSA) software at QMM.

All measured parameters were very highly correlated ($r=1.00$) with phantom dimensions but with some systematic errors as high as 98%. However, high correlations validate the use of the phantom as a calibration method. Linear prediction equations were generated for each variable (exponential for buckling ratio [BR]), then used to predict correct values using scan data. After calibration, maximum errors in the thinnest module (1) ranged from -22% in average cortical thickness (aCt) to +6% in aBMD. All variables in other modules showed a maximum error of 5% with most values <3%. Table summarises correlations and percentage differences between phantom geometry and HSA measurements for aBMD, cross-sectional area (CSA), cross-sectional moment of inertia (CSMI), outer diameter (OD) section modulus (Z), estimated aCt and Buckling Ratio (BR), after calibration with the pre-calibration value in parentheses.

Aging-Related Changes in Plasticity and Toughness of Human Cortical Bone at Multiple Length-Scales. Elizabeth Zimmermann^{*1}, Eric Schaible², Hrishikesh Bale², Holly Barth¹, Simon Tang³, Bjoern Busse¹, Tamara Alliston³, Joel Ager², Robert O. Ritchie¹. ¹University of California, Berkeley, USA, ²Lawrence Berkeley National Laboratory, USA, ³University of California, San Francisco, USA

The complex structure of human cortical bone evolves at multiple length-scales from its basic constituents of collagen molecules and hydroxyapatite crystals at the nanoscale to the osteonal (Haversian) structures at near-millimeter dimensions. Such a characteristic multi-scale structure provides the basis for its mechanical properties. With respect to resistance to fracture, toughness in bone is derived intrinsically, *i.e.*, from plastic deformation, at structural scales typically below a micrometer by such mechanisms as fibrillar sliding, whereas bone's extrinsic (crack-growth) toughness results from mechanisms such as crack deflection and bridging that are generated at much larger structural levels in the tens to hundreds of micrometers. Biological factors can degrade fracture resistance, such that the risk of bone fracture is markedly increased with aging. Although an important reason for the decreased fracture resistance is the loss of bone mass (or bone-mineral density) with age (*bone quantity*), we find here that significant aging-related changes in the bone-matrix structure can occur at multiple length-scales, which are detrimental to fracture resistance (*bone quality*). Specifically, non-enzymatic advanced glycation end-product measurements and (synchrotron) small-/wide-angle x-ray scattering (SAXS/WAXS) were used to characterize changes in the bone structure at sub-micrometer dimensions, while computed synchrotron x-ray tomography and *in situ* fracture toughness measurements in the environmental scanning electron microscope (ESEM) were used to characterize corresponding changes at micron-scale dimensions. Our results show how aging-related structural changes at differing size-scales can degrade both the intrinsic toughness by increased cross-linking at nanoscale dimensions, which acts to suppress plasticity, as well as the extrinsic toughness of bone by an increased osteonal density at the scale of tens to hundreds of micrometers, which acts to limit the potency of crack bridging mechanisms. The link between these processes is that the increased stiffness of the collagen fibrils from cross-linking requires energy to be absorbed by "plastic" deformation at higher structural levels; this is primarily achieved by the process of microcracking, which in turn has a profound effect on the mechanisms of extrinsic toughening in bone.

Areal Bone Mineral Density and DXA Derived Geometrical Parameters at the Tibial Diaphysis Predict 3D Indexes of Bone Strength Assessed by HR-pQCT. Albrecht Popp^{*1}, Markus Windolf², Kurt Lippuner¹, Stefano Brianza², Andrea Tami², R.G. Richards², Damiano Schiama². ¹Osteoporosis Policlinic, University of Bern, Switzerland, ²AO Research Institute Davos, Switzerland

Background: The predictive value of areal bone mineral density (aBMD) at the distal tibia for fracture risk has been demonstrated in a population-based cohort of elderly women (Popp AW et al. Osteoporosis Int 2009). The tibial diaphysis applies as a model for bone strength assessment due to its geometrical structure and the high percentage of cortical bone. The aim of this study was to demonstrate that DXA at the tibial diaphysis is able to predict parameters of bone strength assessed by HR-pQCT.

Methods: Cadaveric tibias from female donors were scanned with DXA (Hologic QDR 4500 ATM, Hologic, Bedford, MA, USA) and high-resolution peripheral quantitative computed tomography (HR-pQCT, XtremeCTTM Scanco Medical, Brüttisellen, Switzerland). Parameters of interest were the total bone mineral density (vBMD) and the cortical thickness (CTH) obtained by HR-pQCT, the DXA derived CTH calculated with a Canny threshold-based DICOM analysis tool implemented in MATLABTM (MathWorks, Natick, MA, USA), and the product of BMD with the polar moment of inertia (pMOI), which was considered as index of bone strength.

Results: Sixty tibias from 35 female donors were included in this study corresponding to 25 pairs and 10 single tibias. The mean (SD) age of the donors was 78.5 ± 9.3 yr with mean height of 160.1 ± 7.8 cm and mean weight of 57.2 ± 11.4 kg. Ex vivo T-scores for distal tibial diaphysis and epiphysis were -2.0 SD and -2.3 SD, respectively. High correlation was found between parameters of bone strength, derived by DXA and HR-pQCT, respectively (table).

Conclusions: As a potential index of bone strength the product of aBMD with pMOI could be applied to a DXA cohort in order to assess its ability to predict fracture risk.

Association of QCT-Based Bone Strength Indices with Hip Fracture Risk among Older Men. Jan Borggreffe^{*1}, Timm de Buhr², Smriti Shrestha³, Carrie Nielson³, Eric Orwoll³, Lynn Marshall³, Dennis Black⁴, Claus-C Glueer⁵. ¹Klinik für Diagnostische Radiologie, Universitätsklinik Kiel, Germany, ²Klinik für Diagnostische Radiologie, Universitätsklinikum Schleswig Holstein, Campus Kiel, Germany, ³Oregon Health & Science University, USA, ⁴University of California, San Francisco, USA, ⁵Christian Albrechts Universität zu Kiel, Germany

Improved prediction of hip fracture risk and better understanding of relevant failure modes remain two key goals for osteoporosis research. We investigated the associations of biomechanically motivated strength indices of the proximal femur derived from quantitative computed tomography (QCT) with hip fracture risk among elderly men.

Using a case-cohort sampling design nested within the MrOS cohort, we evaluated QCT scans of 230 men (age 74.3 ± 6 years, 65 with confirmed hip fractures) with Mindways' QCTPRO BIT software. New failure mode specific bone strength indices for the femoral neck (FN) and for the trochanteric (TR) regions were defined, both for the respective entire cross sections and their quadrants. For FN and TR regions bending strength was estimated by minimum section modulus (Zmin) and quadrant bending index (QBI); buckling strength by buckling ratio (BR) and the local thinning index (LTI) of the quadrant of lowest strength. Integral and trabecular BMD were also derived for the two anatomic regions. Areal BMD (aBMD) of the total proximal femur from DXA is presented for comparison. Hip fractures occurring after enrolment through August 2010 (mean follow-up time: 7.4 yrs) were adjudicated centrally. Hazard ratios (HR) and 95% confidence intervals (CI) per standard deviation of the population variance were calculated from Cox proportional hazards models. Prentice weights were used to account for the case-cohort sampling design. All models were adjusted for age, BMI and center. Receiver operating characteristics areas under the curve (AUC) were calculated to characterize multivariate models.

Men with hip fractures were older than non-fx cases (77.1 ± 6.0 years vs. 73.3 ± 5.7 years, p<0.0001). HRs were significant for all indices tested except for TR LTI, with DXA aBMD being the strongest single predictor (see Table). In multivariate models, among QCT variables FN BR (HR=1.8; 1.2-2.8), TR BMD trab (HR=2.3; 1.4-4.0), and TR QBI (HR=2.4; 1.4-4.0) contributed independently (joint AUC=0.80), even in a model additionally including aBMD: FN BR (HR=1.6; 1.0-2.5), TR BMD trab (HR=2.0; 1.1-3.5), TR QBI (HR=2.1; 1.1-3.9), aBMD (HR=2.1; 1.1-4.0) (joint AUC=0.82).

QCT derived biomechanical indices of hip fracture risk add predictive value independent of DXA aBMD. These strength indices permit insight into the biomechanics of fracture risk: buckling of the FN and bending of the TR are relevant failure modes in older men not entirely captured by DXA.

Hip bone density or geometric measure	Adj. HR Mean (95% CI)	AUC
DXA aBMD total [g/cm ²]	4.3 (2.3, 8.2)	0.81
FN BMD integral [mg/cm ²]	3.4 (1.9, 5.9)	0.79
FN Zmin [cm ²]	2.0 (1.4, 3.0)	0.75
FN BR	2.4 (1.7, 3.6)	0.78
FN LTI [mg/cm]	2.0 (1.4, 2.9)	0.75
FN QBI [mg/cm]	1.7 (1.1, 2.6)	0.74
TR BMD trabecular [mg/cm ²]	2.8 (1.8, 4.6)	0.77
TR Zmin [cm ²]	2.0 (1.4, 3.1)	0.75
TR BR	1.5 (1.1, 2.1)	0.74

Baseline Characteristics of Veterans Screened for VIVA-VA Study. Violet Lagari^{*1}, Orlando Gomez-Marin², Silvina Levis². ¹University of Miami, USA, ²University of Miami School of Medicine, USA

Purpose: Sedentary lifestyle is an important risk factor associated with the decline in physical performance that occurs with advancing age. Hypovitaminosis D (LoD) has been associated with age-related physical decline and an increased risk for falls. Studies have shown that older active individuals on small doses of vitamin D have improved results on isolated tests of physical performance, and nursing home residents with LoD show a significant reduction in the number of falls. The objective of this study is to test whether supplementation with 4000 IU of vitamin D3 (cholecalciferol) for 9 months will improve, or slow the decline of, the ability to perform physical tests which have been shown to be associated with the preservation of independence in the elderly.

Methods: We describe the study design and the baseline characteristics of the first 46 men screened in the VIVA-VA Study (Vitamin D In Vulnerable Adults in the VA), a 3-year, single-site, double-blind, placebo-controlled, randomized clinical trial that enrolls sedentary male veterans ages 65 to 90. The main inclusion criteria are 25-OH vitamin D (25OHD) levels ≥10 and ≤ 30 ng/ml and daily caloric expenditure ≤2600 (as assessed by CHAMPS questionnaire). The primary outcome of the study is the Short Performance Physical Battery (SPPB). Secondary outcomes include handgrip test and body composition by DXA. Subjects were recruited from the Miami Veterans Medical Center (MVAMC) clinics.

Results: The baseline characteristics (mean ± SD) of the 46 sedentary male veterans screened thus far are: age 75.5 ± 7.2 years; 25OHD 26 ± 9 ng/ml (range 10-51); systolic blood pressure (BP), 132.7 ± 17.8 and diastolic BP 75.6 ± 10.1 mm Hg; pulse rate 68.8 ± 11.7 beats per minute; waist circumference 107.1 ± 15.3 cm; and hip circumference 106.3 ± 13.9 cm. SPPB scores and its individual components are: total 6.5 ± 2.2 (range 2-10); balance test 3.1 ± 1.1; short walk test 1.9 ± 1.0; and 5 time chair sit to stand 1.4 ± 1.1. Mean hand grip was 35.8 ± 15.8 kg.

Conclusion: Thus far, the baseline characteristics observed of the first 46 men screened in the VIVA-VA Study are consistent with what is expected in a cohort of elderly frail men: low physical performance scores, including individual and total components of the SPPB and hand grip test, and low 25OHD levels despite living in South Florida. Recruitment is still underway and will continue through the upcoming months.

Bone Tissue Material Properties as Assessed by Reference Probe Indentation Are Associated with Proximal Femur Strength Independent of BMD. Sean Serell, Mary Bouxsein, Benjamin Roberts*. Beth Israel Deaconess Medical Center, USA

Whole bone strength is determined by bone mass, morphology, and bone tissue material properties. However, to date there are few techniques for direct assessment of bone material properties, and consequently little is known about the contribution of tissue-level mechanical properties to skeletal fragility. Reference probe microindentation is a new method for direct assessment of these properties. Our goal was to determine age- and sex- related differences in tissue-level mechanical properties, and whether these properties contribute to whole bone strength in human cadaveric femurs. **Methods:** We obtained 25 human proximal femora (16 women, 9 men, mean age=72.5 ± 9.3 yo). Following imaging with DXA (total femur aBMD, mg/cm²), femurs were mechanically tested in a sideways fall configuration. Cortical bone

material properties at the diaphysis were then assessed in the longitudinal direction with a microindentation system equipped with a tip sharpened to a 90 conical, 2.5µm radius (BioDent 1000, Active Life Technologies, Santa Barbara, CA). Five indentation tests per specimen were performed; outcomes included stiffness (N/µm), total indentation distance (TID, µm), indentation distance increase (IDI, µm), and creep indentation distance (CID, µm). Results: Women had 11% and 10% higher (ie worse) total ID and Creep ID, respectively, compared to men ($p<0.05$, table). Among microindentation properties, only CID significantly increased with age ($r=0.36$). Total femoral aBMD was negatively correlated with IDI ($r=-0.39$), CID ($r=-0.65$), and TID ($r=-0.74$). Femoral max force was moderately correlated with IDI ($r=-0.38$), CID ($r=-0.51$), and TID ($r=-0.64$). In a stepwise multiple regression vs. Max Force, only Creep ID significantly added to Max Force, increasing the correlation from $r^2=0.84$ to 0.87. Conclusion: After adjusting for BMD, some parameters from microindentation remain significantly correlated with femoral strength, showing that variation in material properties contributes in part to whole bone strength. These data illustrate provide strong rationale for further testing of in vivo microindentation to describe age- and sex-related differences in material properties, but also to determine their contribution to whole bone strength and fracture risk.

	Women	Men	Correl. w/ aBMD	Correl. w/ Max Force
IDI (µm)	29.59 (5.44)	26.18 (7.88)	-0.39	-0.38
Total ID (µm)	168.4 (16.7)*	151.5 (18.5)	-0.74	-0.64
Creep ID (µm)	4.72 (0.43)*	4.30 (0.54)	-0.48	-0.51
Stiffness (N/µm)	1.16 (0.12)	1.14 (0.13)	NS	NS

Changes in Tibial Density and Geometry in Infantry Trainees Following Initial Military Training. Rachel Izard¹, Julie Greeves², Charles Negus³, Craig Sale⁴, William Fraser⁵. ¹HQ ARTD, MOD, United Kingdom, ²HQ Army Recruiting & Training Division, United Kingdom, ³L-3 Applied Technologies, USA, ⁴Nottingham Trent University, United Kingdom, ⁵Norwich Medical School, University of East Anglia, UK, United Kingdom

Smaller cross-sectional area but higher density of the tibia, measured using peripheral computed tomography (pQCT), have been shown to increase the risk of tibial injuries in military trainees (Evans et al., 2010). The incidence of tibial injuries is typically higher during the initial phase of military training as bone responds to the rapid onset of increased loads. However, the functional adaptation of bone to initial military training has not been investigated. The purpose of this study was to monitor changes in tibial bone mass and geometry after 10 weeks of initial military training in male infantry recruits. Ninety recruits (mean±SD, age 21 + 3 y, height 1.78 + 0.06 m and body mass 73.95 + 9.76 kg) undertaking initial infantry training at the Infantry Training Centre (Catterick, UK) volunteered to take part. pQCT scans (XCT2000L, Stratec Pforzheim, Germany) were taken before (baseline) and after 10 weeks of training. Scans were performed at the 4% (trabecular bone), 38% and 66% (cortical bone) of the length measured from the distal end plate of the tibia. BAMPack software (L-3 Jaycor, San Diego, CA) was used to calculate whole and regional (60o sectors) bone parameters using previously described methods (Evans et al., 2008). Parameters included trabecular density (TbDn, mg/cm³), cortical density (CtDn, mg/cm³), cortical area (CtAr, mm²) and cortical thickness (CtTh, mm). Biomechanical strength indices were also recorded and included the bone strength index (BSI) and moment of inertia in the anterior – posterior (mmiAP) and medial – lateral (mmiML) planes. Wilcoxon-signed rank tests (SPSS v17.0) were used to analyse data. Statistical significance was set a-priori at $P<0.05$. Significant increases were observed in bone mineralisation (TbDn and CtDn) at all sites and bone geometry (CtAr and CtTh) and bone strength (mmi and BSI) at the 38 and 66% sites (Table 1). Changes were predominantly observed in the anterior, medial-anterior and anterior-posterior sectors. Increased mineralisation at the distal tibia and increased cortical area of the tibial shaft suggest that rapid and marked adaptations of bone take place within 10 weeks of military training. Further analysis will establish whether individuals who exhibit the greatest changes in, or have higher initial bone strength are better protected from tibial injury. This work was sponsored by the UK Ministry of Defence (Army).

Site	Parameter	Baseline	Week 10	P
4%	TbDn (mg cm ⁻³)	301.6 ± 27.8	304.4 ± 26.4	.000
	TbAr (mm ²)	1155.3 ± 175.2	1162.1 ± 170.2	.668
	CtDn (mg cm ⁻³)	1154.3 ± 24.3	1156.5 ± 21.8	.003
38%	CtAr (mm ²)	317.0 ± 35.1	319.0 ± 34.7	.000
	CtTh (mm)	5.16 ± 0.67	5.19 ± 0.66	.000
	mmiAP (mg cm ³)	301.4 ± 62.0	305.1 ± 63.1	.000
	mmiML (mg cm ³)	532.3 ± 106.9	537.9 ± 104.9	.000

Effects of Multiple Exposures to Microgravity on the Femur of Adult Male Hindlimb Unloaded Rats. DERRICK MORGAN, JOSHUA DAVIS, Yasaman Shirazi-Fard, Josh Kupke, Joseph Marchetti, Alyssa McCue, Susan Bloomfield, Harry Hogan*. Texas A&M University, USA

Bone response to extended microgravity remains a concern for astronaut health. A particular question is how prior missions affect subsequent missions. Animal experiments were conducted to test the hypothesis that previous exposure to mechanical unloading would exacerbate the effects of a 2nd exposure. This study focused on the distal femur metaphysis (DFM) and femoral neck (FN).

Adult male Sprague-Dawley rats (6 mo.) were assigned to 2 groups: aging cage control (CC), hindlimb unloaded (HU). HU animals were further divided into subcategories: 1HU and 2HU. The 2HU group had 28d of HU at 6 mo. (2HU6), followed by 56d of recovery, and another 28d of HU (2HU9) starting at 9 mo. (day 84). The 1HU group had one bout of HU (1HU9) starting on day 84 (to match 2HU9). A group (n=15) was euthanized every 28d (days 0, 28, 56, 84, 112 & 168) from each of CC, 1HU, and 2HU groups. Excised femora were scanned by pQCT at the DFM and FN, and the FN was mechanically tested to failure.

Total (integral) BMC and vBMD for the DFM decreased significantly for 2HU6 (9% & 13%, resp.). Decreases for 2HU9 (second exposure) were less (2% & 7%, resp.), and only the latter was significant (7% for vBMD). Decreases for the age-matched single HU (1HU9) were quite similar to those for 2HU9 (3% & 6%, resp.), but once again, the decrease was significant for only vBMD (6%). Thus, for the DFM, negative effects were most prominent at the younger age (2HU6). HU effects at the older age (2HU9 & 1HU9) were milder and significant for only vBMD. The cross-sectional area of the cortical shell (Ct.Ar) at the DFM showed a similar response. Ct.Ar decreased 7.5% for 2HU6 (sig.) but only 2% for 2HU9 (n.s.) and 1.5% for 1HU9 (n.s.). Total BMC and vBMD for the FN were similar to results for the DFM. Both decreased significantly for 2HU6 (6.4% & 7.2%, resp.), with milder reductions (n.s.) for both 2HU9 and 1HU9 (from -3% to -5.5%). For mechanical strength of the FN, reductions due to HU were substantial (18-26%), significant, and similar regardless of age or prior HU exposure. The greatest reductions were at 9 mo. (26% for 2HU9, 22% for 1HU9), even though corresponding reductions in BMC and vBMD were mild (3-5.5%) and not significant.

These results are contrary to the initial hypothesis. Reductions in BMC and vBMD at the DFM and FN were affected by age but not prior HU. For strength of the FN, negative effects of HU were dramatic and similar in extent regardless of age or prior HU.

Evolution of Bone Strength with Age: A Large Micro-Finite Element Analysis in Women from the OFELY Cohort. Nicolas Vilayphiou¹, Stephanie Boutroy¹, Elisabeth Sornay-Rendu¹, Bert van Rietbergen², Roland Chapurlat¹. ¹INSERM UMR1033, Université de Lyon & Hospices Civils de Lyon, France, ²Department of Biomedical Engineering, Eindhoven University of Technology, Netherlands

Areal bone mineral density (aBMD) decreases with age in women, but our knowledge of the effect on bone biomechanical properties is limited. So, we have studied the decline of bone strength with age, with micro-finite element analysis (µFEA) using high resolution peripheral QCT (HR-pQCT) images.

Our cross-sectional analysis has involved 831 women who had a valid HR-pQCT radius scan in the OFELY cohort. There were 228 pre- (preM) and 603 postmenopausal (postM) women, aged 407 and 679 years old respectively; 117 postM women have sustained fragility fractures before the visit.

Distal radius HR-pQCT scans were used to measure volumetric BMD (vBMD) and microarchitecture parameters, after segmentation of cortical (Ct) bone with

advanced algorithm (Burghardt, Buie et al. Bone 2010). Estimated failure load was assessed by μ FEA as the main outcome of radius bone strength, and permitted to derive the load to strength ratio Φ as an estimate of fracture risk. Total hip aBMD was recorded by DXA at the same visit. In preM women, most parameters did not vary with age. In postM women, Ct porosity and trabecular (Tb) heterogeneity significantly increased throughout the menopause, respectively from 0.7 to 3.4% and from 215 to 571 μ m. Total, Ct and Tb vBMD decreased with age, as well as Ct thickness and Tb number ($r=-0.41$ to -0.65 , $p<0.001$). The deterioration of microarchitecture with age resulted in a decrease of the μ FE-failure load with an overall loss of a third of bone strength throughout the postmenopausal period compared to preM women. A quadratic relationship between failure load and age was found (see Figure: $R^2=0.32$, $p<0.001$).

A total increase of Φ by 50% was observed, so that after the age of 70 more than half (60%) of the elderly women had a factor of risk $\Phi>1$. Considering Φ as a factor of risk for all fragility fractures, we compared the ROC curves of Φ and total hip aBMD, with respect to prevalent fractures. The area under the curves was slightly higher for Φ than for total hip aBMD (AUC [95%CI] =0.72 [0.66-0.78] and 0.69 [0.62-0.75], respectively). However, sensitivity and specificity for fracture of the mechanical criterion $\Phi>1$ were 73% and 58% respectively, whereas that of the T-score <-2.5 were 20% and 97% respectively.

To conclude, we observed a substantial decline of bone strength with age at the radius. We suggest that the calculated load to strength ratio Φ might be a relevant indicator of fracture risk, more sensitive than hip aBMD.

Finite Element Prediction of Proximal Femur Fracture Profile Based on Anisotropic Behaviour Law Coupled to Damage. Awad Bettamer^{*1}, Ridha Hambli², Samir Allaoui². ¹L'Université d'Orléans, France, ²PRISME Institute, France

Introduction: A femoral fracture caused by the osteoporosis becomes increasingly important goal for both clinicians and biomedical researchers in order to evaluate and to prevent the risk of neck femur fracture. The purpose of this study was to develop a computed 3-D anisotropic model based on continuum damage mechanics to simulate the profile of the fractured area of proximal femur. The model was developed in term of anisotropic coupled behaviour law (strain-quasi-brittle damage) to describe the progressive crack initiation and propagation within proximal femoral. **Materials and methods:** The proposed model was implemented in ABAQUS/Standard FE software as a user subroutine. To illustrate the potential of the current approach, the right adult human femur previously investigated by Keyak et al., J.Medical Engineering & Physics. 781:7,2003 (Model B: male, age 61) was simulated till complete fracture under one-legged stance load. This proposed damaged model can be used successfully to simulate many different fracture patterns such as intracapsular (subcapital, transcervical and basal). In the current work our model is further applied on a patient aged 80 years, Konishiike T. et al., Journal of bone and joint surgery. 596:4,1999 in order to simulate its fracture type as well as to investigate how its crack was propagated. **Results:** The fracture profile was predicted (Fig.1-a) and the complete force-displacement curve from the beginning until complete fracture was predicted. The damage subsequent to the ultimate predicted force of (6 kN) with the assumption of brittle bone with () or (8 kN) with a brittle bone () result in a reduction of the mechanical properties in bone strength and stiffness of bone material that caused by the apparition of microcracks corresponds to crack displacement of (4.4 mm). The predicted fracture profile resulted can be registered as a type of Garden undisplaced fracture (stages 1 and 2). The obtained results were compared with similar clinical observed results (Fig.1-b) and (Fig.1-c). Good agreements were obtained and the model succeeded to predict the fracture profiles such as Garden undisplaced fracture (stages 1 and 2) as well as the displaced fracture (stages 3 and 4).

High Resolution-pQCT Scanning of Radius and Tibia in Adult Patients with Osteogenesis Imperfecta. Roland Kocijan^{*1}, Christian Muschitz², Angela Trubrich², Christina Bittighofer², Franz Kainberger³, Heinrich Resch⁴. ¹St. Vincent Hospital Vienna, Austria, ²St. Vincent's Hospital, Austria, ³Medical University of Vienna, Austria, ⁴Medical University Vienna, Austria

Purpose Osteogenesis imperfecta (OI) is an inherited disorder characterized by increased bone fragility with recurrent fractures due to a defect in collagen metabolism. OI is also characterized by a low bone mass and a deterioration of cortical and trabecular bone microarchitecture. HR-pQCT is a non-invasive, radiological method for the analysis of bone structure and density. Recent studies have shown that the method can provide additional information about bone strength in patients with osteoporosis, however, the method has not yet been applied in patients with OI. **Methods** We performed HR-pQCT scans (XtremeCT, SCANCO Medical) in 10 patients with OI type I, III and IV by Sillence classification (OI, mean age 51.3 years) at the ultradistal radius and distal tibia. We assessed different density values and parameters of cortical and trabecular bone structure including trabecular volume (BV/TV), trabecular number (Tb.N), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), cortical thickness (Ct.Th) and inhomogeneity of the network (Tb.I/N.SD). The results were compared to a young, healthy control group at peak bone mass (CO, mean age 31.9 years). In addition, we compared the mild OI type I group to the severe, immobile OI III/IV group. **Results** We found significant changes ($p<0.05$) in different density parameters at the radius and the tibia between OI and CO. Trabecular structure parameters at the radius (Tb.N, Tb.Sp, Tb.I/N.SD) and tibia (Tb.N, Tb.Sp, Tb.I/N.SD, BV/TV) were significantly decreased in the total OI group. Ct.Th was markedly lower at the tibia and not at the radius in this group. In comparison to the controls all density and structure parameters were significantly decreased in the OI III/IV group except Tb.Th, whereas the mild form of OI I had no changes in Tb.Th and Ct.Th at both skeletal sites. Comparing the two OI subgroups Ct.Th was the most different parameter at both sites. **Conclusion** This is the first study so far applying HR-pQCT in patients with different classifications of OI. This non invasive imaging technique has the capability to display the structure alterations of bone architecture at cortical and trabecular sites.

Marrow Recovery from Sub-Lethal Irradiation Is Evident Long Before Any Sign of Trabecular Bone Restoration. Danielle Green^{*1}, Benjamin Adler¹, Ete Meilin Chan¹, Clinton Rubin². ¹Stony Brook University, USA, ²State University of New York at Stony Brook, USA

Stem cell depletion and compromised bone marrow (BM) following radiation exposure inherently expedite long term detrimental effects on numerous physiologic systems including the skeletal system, ultimately increasing the risk of fractures due to osteoporosis. To study the interrelationship of a damaged BM cell population on trabecular microarchitecture, 8w & 16w C57BL/6 male mice were sub-lethally irradiated with 6 Gy of ¹³⁷Cs γ -rays, and adult stem cells residing in the BM, as well as bone quantity and quality, were evaluated in the proximal tibia following 2d, 10d & 8w, as compared to age-matched controls. Total extracted BM cells in the 8w mice, including hematopoietic stem cells (HSC), collapsed by 6511% after 2d, remaining at those suppressed levels at 10d, but showing full recovery by 8w. While the 16w mice showed a similar (6318%) cellular depletion after 2d & 10d, full recovery of the cell population had not been realized at 8w, remaining 129% below their age-matched controls. The rate of detriment and repair of the BM cells though was dependent on both the hematopoietic phenotype and the age of the mice. At 2d, the 16w mice showed an 897% collapse in lineage restricted lin-Sca-1+c-kit+ (LSK) progenitor cells, whereas the 8w mice showed no decline until 10d (616%). In contrast, the long term HSC (SP-LSK) in the 8w & 16w mice declined by 8710% and 895%, respectively at 2d, and showed no sign of recovery by 10d. By 8w, the LSK and SP-LSK cells returned to age-matched control levels for the younger mice, but the LSK and SP-LSK cells in the 16w mice remained 3914% and 2823% lower than age-matched controls. Evident as early as 10d following irradiation, 8w mice showed a 4112% and 334% decline in bone volume fraction and trabecular number respectively, and a 5010% increase in trabecular spacing as compared to controls, with compromised structure showing no sign of restoration even at 8w post-irradiation. Devastation of trabecular bone of the 16w mice was similar to the 8w mice, suggesting irradiation damage to bone structure is independent of skeletal maturity. Conceivably, efforts to recover the BM cell population following injury may restore bone architectural quality. However with such drastic declines in the BM and HSC populations at 2d & 10d, the drop in bone quality cannot solely be attributed to an active osteoclast response, but perhaps a physicochemical response enabled by irradiation compromises the bone matrix itself.

Microarchitecture Is Impaired In Postmenopausal Caucasian Women With Fracture Independently Of Total Hip T-score - The MultiXCT Study. Stephanie Boutroy^{*1}, Sundeep Khosla², Elizabeth Sornay-Rendu³, Maria Belen Zanchetta⁴, Donald McMahon⁵, Chiyuan Zhang⁶, Roland Chapurlat⁷, Jose Ruben Zanchetta⁴, Emily Stein⁵, Cesar Bogado⁴, Sharmila Majumdar⁸, Andrew Burghardt⁸, Elizabeth Shane⁵. ¹Columbia University Medical Center, USA, ²College of Medicine, Mayo Clinic, USA, ³INSERM, France, ⁴Instituto de Investigaciones Metabolicas (IDIM), Argentina, ⁵Columbia University College of Physicians & Surgeons, USA, ⁶Columbia University, USA, ⁷E. Herriot Hospital, France, ⁸University of California, San Francisco, USA

As half of all postmenopausal fractures (FX) occur in women with T-scores <-2.5, there is interest in investigating the influence of bone microarchitecture assessed by HR-pQCT (Scanco Medical AG) on FX risk. As single-center studies have reported conflicting associations between microarchitecture and FX prevalence, we included HR-pQCT data from 4 centers worldwide into a large multicenter analysis of postmenopausal women with and without FX. Volumetric density (vBMD) and microarchitecture were assessed at the distal radius (DR) and tibia (DT) in 1250 Caucasian postmenopausal women (678 yr); 435 (35%) had at least one FX (171 vertebral, 183 forearm, 17 hip, 33 humerus...). All had lumbar spine (LS) and total hip (TH) BMD by DXA (Hologic or GE-Lunar). Age, height, weight, menopause age and total hip T-score differed across centers. Women with FX had higher BMI (26.75.3 vs 25.94.7 kg/m², p<0.01), were older (699 vs 668, p<0.001), and 1 year younger at menopause (487 vs 495, p<0.01). TH T-score was lower in the FX group (-1.21.0 vs -0.90.9, p<0.001) and LS T-score was similar (-1.41.4 vs -1.51.3). Logistic regression identified age, height and TH T-score as covariates for between-center differences. As DR and DT vBMD and/or microarchitecture also varied by center, center was added as a covariate in GLM models assessing center, FX status and FX by center interactions.

At the DR, total and trabecular (Tb) vBMD were significantly lower in FX women in 3/4 centers (by 7%-9% and 13%-14% respectively, p<0.05). Tb number and cortical thickness were also significantly lower in 2 centers (by 9% and 6%-9% respectively, p<0.05), and not in 2 other centers (lower by 4% and 2%-4% respectively). Similar results were found at the DT. When data from 4 centers were combined, however, women with FX had significantly lower total, Tb and cortical vBMD (by 1.2%-10.7%, p<0.05) and Tb microarchitectural deficits (lower Tb number and thickness by 2.9%-6.7%, p<0.05) than women without FX. Results were similar at DR and DT and remained significant after adjustment for TH T-score

In conclusion, we observed differences by center in the magnitude of FX/non FX differences at both the distal radius and tibia. However, when data were pooled across centers and the sample size increased, we observed significant and consistent deficits in

vBMD and microarchitecture independent of total hip T-score in postmenopausal Caucasian women with FX compared to women who never had a FX.

Microstructural and Mechanical Differences among Postmenopausal Caucasian, African, and Hispanic American Women. Bin Zhou^{*1}, Xiaowei Liu², Marcella Walker¹, Emily Stein², Thomas Nickolas³, Michael Yin¹, Donald McMahon², Elizabeth Shane², X Guo¹. ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University Medical Center, USA

Many studies suggest that BMD is higher and fracture risk is lower in African American (AA) than Caucasian (CA) women. However, few data are available on three-dimensional trabecular bone microstructure and mechanical competence in AA, which may underlie these differences in BMD and fracture risk. Moreover, data on Hispanic (HISP) women of Caribbean origin, who manifest significant racial admixture and comprise a large proportion of the Latina population of the eastern US, are lacking. To explore racial/ethnic differences in trabecular bone microstructure in these underrepresented populations, we applied novel individual trabeculae segmentation (ITS) and micro finite element (μ FE) analyses to high resolution peripheral QCT (HR-pQCT; Xtreme CT, Scanco Medical) scans of postmenopausal women (27 CA age 623; 18 AA age 586; and 30 HISP age 597). At the distal radius (DR), total bone area for CA and HISP women was 15% and 12% lower than AA women, respectively (p<0.05). As a result, whole bone stiffness of CA and HISP women was 17% and 24% lower respectively than African-American women (p<0.05). At the distal tibia (DT), total bone area for HISP women was 10% and 11% lower than CA and AA women, respectively (p<0.05); cortical thickness of CA and HISP women was 25% and 6% lower than AA women, respectively (p<0.001), resulting in 16% and 21% lower whole bone stiffness than AA women (p<0.01). Trabecular microstructure was similar in three racial groups at DR. However, DT rod bone volume fraction (rBV/TV) of CA women was 24% and 26% higher, and rod trabecular number (rTb.N) 10% and 11% higher than AA and HISP women, respectively (p<0.05). Furthermore, rod-rod junction density of CA women was 43% and 41% higher than AA and HISP women (p<0.005). In addition, CA trabecular area was 15% higher and BV/TV was 15% higher than HISP (p<0.05), resulting in 30% lower trabecular stiffness in HISP compared with CA. These data suggest that HISP women more closely resemble CA than AA women in terms of whole bone size and strength. In contrast, however, trabecular bone microstructure of HISP women more closely resembles that of AA than CA women, in that both HISP and AA women have less "rod-like" microstructure than CA women. These results illustrate the importance of more complete characterization of bone microstructure and strength in premenopausal and postmenopausal CA and AA women, and HISP women of Caribbean descent.

Porosity, Mineralization and Morphology Interactions At The Human Tibial Cortex. Naomi Hampson^{*1}, Remi Gendron², Guillermo Duarte², Surva R. Kalidindi¹, Karl Jepsen², Haviva Goldman³. ¹Drexel University, USA, ²Mount Sinai School of Medicine, USA, ³Drexel University College of Medicine, USA

Purpose: Previous studies of the human tibia have demonstrated a higher ash content amongst individuals with more slender bone phenotypes possibly as a compensatory mechanism to increase whole bone stiffness. We aimed to investigate the relationship between cortical porosity and ash content, relative to cross-sectional robustness in order to better understand the tissue level adaptations that may occur in the establishment of whole bone function.

Methods: 2.5mm cross-sections of 10 tibiae (age 37 +/- 8 yrs) were obtained from 38% and 66% from the distal articular surface, radially sectioned into 6 wedges, and

imaged using a Skyscan 1172 μ CT at 5 μ m resolution. Cortical tissue volume (TV) and canal volume (CV) were determined using Skyscan's CT Analyzer for each location and wedge to obtain a measure of %CV. Following μ CT imaging, each wedge was ashed. Tissue Mineral Density (TMD) for the entire cross section was obtained from pQCT of the adjacent block of tissue. Robustness was calculated as cross sectional area divided by tibial length.

Results: When adjusted for age and robustness, porosity values were significantly ($p < 0.05$) higher anteriorly (and to a lesser degree, posteriorly) relative to medial and lateral segments. At both locations, age had a significant ($p < 0.05$) effect on porosity distribution, while robustness had a significant effect only at 66%. Ash content was significantly ($p < 0.01$) lower anteriorly relative to all other wedges at both 38% and 66% locations. Porosity and ash content were non-linearly correlated, with the relationship driven primarily by the more slender individuals in the sample. Both were significantly correlated with TMD, with porosity explaining more of the variability in TMD ($r^2 = 0.51$) than ash content ($r^2 = 0.34$).

Conclusions: Significant differences were found around the cortex with respect to porosity and ash content, and both demonstrated relationships to TMD, robustness and age. Higher remodeling rates anteriorly (and to a lesser extent posteriorly) may reflect higher remodeling rates in these cortices, and relate to the A-P orientation of the axis of greatest bending rigidity. The non-linear relationship between porosity and ash content may indicate a novel biological strategy for establishing tissue quality through internal remodeling that is predictable based on the natural variation in skeletal robustness, which in turn may result in significant differences in bone aging between these bone phenotypes.

Prediction of Forearm Impact Forces during Falls on the Outstretched Hand.

Chantal Kawalilak^{*1}, Joel L. Lanovaz², James D. Johnston², Adam D.G. Baxter-Jones², Saija Kontulainen². ¹College of Kinesiology, Can, ²University of Saskatchewan, Canada

Wrist and forearm fractures commonly result from a fall onto the outstretched forearm when the impact force exceeds bone strength. A commonly used mathematical model representing the response of the upper extremity and torso during a fall is the two-mass spring-damper model. This model is often used to predict the impact force experienced during a standing height fall, which can be related to image based estimates of bone strength to create an index of fracture risk (impact force: bone strength). However, the model has only been validated with experimental data for fall heights up to 5 cm. It is unknown whether the model will accurately predict impact forces at higher fall heights. Additionally, the relationship between impact force and forearm muscle cross sectional area (MCSA), which may influence the choice of model parameters, is unknown. The primary objective of this study was to compare experimentally measured forces in falls on an outstretched hand to forces predicted by the two-mass spring-damper model at heights greater than 5 cm. The second objective was to investigate the relationship between the experimental impact forces and forearm MCSA. Peak impact forces in the vertical direction were measured using a force platform for 10 healthy young adult males and females at 8 randomized fall heights from 1 to 25 cm. Forearm MCSA was measured using periperal quantitative computed tomography (pQCT). 2x8 factorial ANOVAs determined the difference between the experimental and model force peaks. Relationships between forearm MCSA and impact forces were investigated with Pearson's bivariate correlations. Recorded force patterns typically displayed an initial impact peak followed by a second peak corresponding to body deceleration. There were no significant differences between the model and experimental data ($p > 0.05$) for the first peak force across any fall heights. However, the model over predicted the second experimental peak force ($p < 0.05$) across all fall heights. Impact forces were related to MCSA ($r = 0.3-0.6$) and stature ($r = 0.4-0.6$); these relationships were stronger at higher fall heights. In conclusion, the two-mass spring-damper model appears capable of predicting the first impact force for fall heights up to, and including, 25 cm. Further research is needed to incorporate the observed associations between MCSA and peak forces within the model parameters.

Quantifying Bound and Pore Water in Cortical Bone with MRI. Adam Horch^{*1}, Dan Gochberg¹, Jeffry Nyman², Mark Does¹. ¹Vanderbilt University, USA, ²Vanderbilt University Medical Center, USA

Human cortical bone magnetic resonance imaging (MRI) has become clinically feasible with ultrashort-echo time (uTE) methods [1]. The cortical bone MRI signal arises from a combination of collagen-bound water and pore space water, which exhibit different transverse relaxation times (T2) [2]. Using a gold-standard CPMG, which is not clinically-compatible, bound and pore water signals have been directly ($r^2 = 0.68$) and inversely ($r^2 = 0.61$) correlated with peak stress (and other mechanical properties), respectively [3]. The net cortical bone water signal was poorly correlated

($r^2 = 0.06$), indicating that diagnostic MRI must discriminate bound from pore water. However, to date, MRI techniques have not been developed for such discrimination. This work demonstrates clinically-compatible cortical bone MRI methods for bound and pore water quantitation using bone T2 features.

Human cortical bone was obtained from medial midshafts of 14 human donor femurs (Mustuloskeletal Tissue Foundation, Edison, NJ). NMR measurements were performed on cortical bone specimens at 4.7T, consisting of 1) a non-imaging adiabatic inversion-recovery (AIR)-prepared uTE sequence, which isolates bound water by selectively inverting and then nulling the pore water via appropriate choice of AFP parameters and inversion time; and 2) a non-imaging double adiabatic full passage (DAFP) uTE sequence, which strongly attenuates bound water signals while leaving pore water signals largely intact. AIR and DAFP signals were converted to apparent 1H concentration by comparing signal size to that of a known water phantom. 3pt-bend mechanical testing (40 mm span) was performed to determine peak stress.

The AIR signal contains negligible signals in the pore water T2 spectral domain and is thus dominated by bound water (Fig 1). AIR-derived estimates of bound water concentration exhibited a moderate correlation to peak stress (Fig 2), although the correlation is weakened by one apparent outlier. Conversely, the DAFP signal is dominated by pore water (Fig 1), and DAFP-derived pore water concentration exhibited a moderately-strong correlation to peak stress. Importantly, the AIR and DAFP methods demonstrated here utilize clinically-compatible MRI parameters and are thus readily translatable for in vivo imaging. Given their bound/pore water specificity, these methods provide more utility than conventional uTE MRI.

Quantitative Computed Tomography-Based Nonlinear Finite Element Method is a More Sensitive Tool for the Assessment of Therapeutic Effects of Alendronate in Elderly Osteoporotic Women. MASAKO KANEKO¹, Isao Ohnishi², Masahiko Bessho², Takuya Matsumoto³, Satoru Ohashi³, Kenji Tobita³, Kozo Nakamura¹. ¹The University of Tokyo, Japan, ²Center for Clinical Medical Science International University of Health & Welfare, Japan, ³Department of Orthopaedic Surgery, University of Tokyo, Japan

Introduction

Quantitative computed tomography -based finite element methods (QCT/FEM) are reportedly able to accurately predict bone strength. We prospectively assessed the effects of alendronate(ALE) in patients with elderly osteoporosis by analyzing vertebral and proximal femur strengths using our originally developed QCT/FEM and calculated mean percent changes of bone strength at 6 and 12 months from baseline, and the data were compared to those from other existing bone densitometries.

Patients and Method

The inclusion criteria of patients included primary osteoporotic elderly Japanese women over 75 years of age. There were also exclusion criteria. The participants were treated using oral ALE at a dose of 35 mg/week. In patients who were enrolled in the study to assess the therapeutic effects of ALE, axial QCT with simultaneous scans of a calibration phantom containing hydroxyapatite rods, scans of the 2nd lumbar (L2) and proximal femur were obtained at baseline, 6, and 12 months. The bone strengths were analyzed using the QCT/FEM. The aBMD of the AP lumbar spine (L1-4) and the hip were measured by DXA at baseline, 6 and 12 months. The vBMD (L2) was analyzed using the QCT data (QCTpro). In the QCT/FEM analysis, a uniaxial compressive load with a uniform distribution and uniform load increment was applied for L2, and stance and fall configuration were applied for the proximal femur.

Results

The participants were included 31 women (mean age, 79.5 years; range, 75-85 years). The proximal femur was analyzed in all and the lumbar spine in 25. 6 patients were excluded because a fragility fracture existed at L2. The mean percent changes from baseline in vertebral bone strength were +8.4% at 6 months, and +10.1% at 12 months, whereas they were +3.5%, and +4.7% in aBMD, and +3.3%, and +2.6% in vBMD. The mean percent changes from baseline in proximal femur strength under stance configuration were +3.5% at 6 months, and +3.3% at 12 months, and under fall configuration, were +0.36%, and -0.33%. The increases in aBMD (femoral neck) were +1.7%, and +2.0%, and those in aBMD (total hip) were +2.0%, and +1.8%, respectively.

Conclusions

In this study, vertebral bone strength by QCT/FEM was significantly more sensitive in evaluating the therapeutic effects of ALE than aBMD or vBMD. Proximal femur bone strength under stance configuration had greater sensitivity than aBMD. QCT/FEM is a highly useful and sensitive tool compared to existing densitometries.

Relationships between Failure Patterns and Trabecular Architecture in the Thoracic Spine. Amira Hussein^{*}, Elise Morgan. Boston University, USA

Despite the high prevalence of vertebral fractures, their pathogenesis remains poorly understood. Studies have suggested that the mechanisms of vertebral fracture are closely linked to the substantial intra-vertebral heterogeneity in trabecular microstructure. However, this link has not been established. The overall goal of this study was to examine relationships between failure patterns and trabecular microstructure near the thoraco-lumbar junction.

Thirty, fresh-frozen vertebrae (15 T10, 15 T11) from 16 donors (age: 70-91 years; 8 male, 8 female) were scanned via μ CT (37 μ m/voxel). Volume fraction (Vf), apparent density (ρ_{app}), trabecular separation (Tb.Sp^{*}), trabecular number (Tb.N^{*}), connectivity density (ConnD), degree of anisotropy (DA) and structural model index (SMI) were calculated for contiguous, 5mm cubes within the centrum. The vertebrae were then compressed to failure, followed by a second μ CT scan. The pairs of pre- and post-test images were analyzed using digital volume correlation in order to quantify the failure patterns, as defined by the distributions of residual strains throughout the vertebral body. For statistical comparison via analysis of covariance, the microstructural values and residual strains for the cubes were grouped by anatomic location: 1) superior, middle, or inferior transverse plane; and 2) posterior, middle, or anterior coronal plane.

Residual strains were highest in the middle transverse plane ($p=0.002$), particularly in the anterior region of this plane. Near the superior endplates, higher residual strains occurred in the center as compared to the periphery; a similar, though milder, trend was found near the inferior endplate. High residual strains were associated with low values of SMI (more plate-like trabeculae) ($p=0.02$). Residual strains were also dependent on the interaction between anatomic location and each of Tb.N^{*} and Tb.Sp^{*} ($p\leq 0.002$).

These findings reveal failure patterns characterized by anterior wedge-type deformations and concomitant endplate biconcavity in response to axial compression. Although regions of sparse, rod-like trabeculae in the vertebra have often been hypothesized to be those at greatest risk for failure, our results instead indicate that failure patterns involve regions of more plate-like trabeculae. Together, these results suggest that the mechanisms of vertebral fracture relate to both the anatomic shape of the vertebra and the intra-vertebral distribution of trabecular architecture.

Strontium Ranelate Fully Prevents Alteration of Bone Mechanical Properties in Response to Cyclical Loading. Patrick Ammann^{*}¹, Rene Rizzoli².

¹Division of Bone Diseases, Switzerland, ²University Hospital, Switzerland

Microarchitecture and intrinsic bone tissue properties contribute independently and significantly to the improvement of bone strength induced by strontium ranelate (SrRan) treatment as evaluated by μ CT-based Finite Element Analysis. How improvement of bone material quality by SrRan could influence bone mechanical properties is unknown. One hypothesis is that SrRan present in bone tissue could prevent the formation of micro cracks and/or their propagation, thus influencing the capacity of the bones to cumulate micro-damage. The aim of the present study was to investigate whether SrRan could prevent alteration of bone mechanical properties in response to fatigue as evaluated at the level of vertebrae. Vertebrae of intact female rats treated 5 days a week over 12 weeks with SrRan at a dose-level of 625 mg/kg (corresponding approximately to the human SrRan exposure) or with a vehicle (control) were in silico cyclically loaded in axial compression under a controlled load for 100 cycles. The selected peak load corresponded to 5% of the maximal load of the adjacent vertebra, thus in the domain of elastic deformation. This peak load was determined to induce alteration of post yield load without any effects on vertebral

height i.e without fracture. The vertebrae were then loaded to failure. We compared the load/displacement curve of the cyclically loaded vertebra (L4) to the adjacent one (L3), not submitted to cyclic loading. Bone mechanical properties including post-yield load and deflection, which characterize post yield behaviour, were investigated. * $p < 0.05$ as compared to control unloaded adjacent vertebra (meanSEM). Maximal load was 26719 and 23320 (N) in unloaded SrRan and Control groups, respectively. Cyclic loading induced a deterioration of post Yield load (-40%) in control rats. This effect was fully prevented in SrRan-treated rats. The post Yield deflection was unaffected in either group. These results indicate that fatigue-induced alterations of post yield behaviour were fully prevented by SrRan treatment. They may also suggest that bone micro-damages could be less prominent in rats treated with SrRan (histological analysis is in progress). In conclusion, the improvement of bone intrinsic mechanical properties by SrRan could influence the response to cyclical loading (fatigue) and thus represents an original mechanism of action.

	Unloaded control	Fatigue control	Unloaded SrRan	Fatigue SrRan
Post Yield load (N)	19.61±3.36 (n=9)	11.80±2.03 (n=9)*	18.42±4.00 (n=8)	18.78±3.71 (n=8)
Post Yield deflection (mm)	0.067±0.007 (n=9)	0.073±0.017 (n=9)	0.063±0.011 (n=8)	0.072±0.012 (n=8)

Synchrotron Radiation Micro-CT of Intra-Element Variation in Osteocyte Lacunar Volume and Density of the Human Femur. Yasmin Carter^{*1}, DAVID THOMAS², John G. Clement³, Andrew G. Peele⁴, Kevin Hannah⁴, David Cooper¹. ¹University of Saskatchewan, Canada, ²MELBOURNE DENTAL SCHOOL, Australia, ³University of Melbourne, Australia, ⁴LaTrobe University, Australia

In recent years there has been growing interest in the properties of osteocytes (including density and morphology) and how these potentially relate to adaptation, disease and aging. This interest has, in part, arisen from the availability of increasingly high resolution 3D imaging modalities such as synchrotron radiation (SR) micro-CT. As resolution increases, field of view generally decreases. Thus, while increasingly detailed spatial information is obtained, it is unclear how representative this information is of the skeleton or even the isolated bone. The purpose of this research was to describe intra-element variation in osteocyte lacunar density and volume within a healthy young (20 yr old male) human femur. Anterior, posterior, medial and lateral blocks (2 mm x 2 mm) were prepared from a diaphyseal ring of the proximal femoral shaft. These blocks (n=3, 3, 3 and 4, respectively) were SR micro-CT imaged using the 2BM beamline of the Advanced Photon Source synchrotron at 1.47µm pixel size. A cylindrical 0.786mm³ region of interest was analyzed for each block. SR micro-CT enabled tens of thousands of lacunae (mean of 31,461 per block) to be assessed in 3D. Average lacunar density (standard deviation) from the anterior, posterior, medial and lateral regions was 27,169/1935, 26,343/1262, 37,521/6416 and 33,972/2513 lacunae per mm³ of bone tissue, respectively. These values were significantly different between the medial and both the anterior and posterior regions ($p < 0.05$). The density of the combined anterior and posterior regions (26,756/1529) was also significantly lower ($p = 0.001$) than the combined density of the medial and lateral regions (35,493/4525). There were no significant differences ($p = 0.862$) between mean lacunar volumes (anterior 378µm³, posterior 400µm³, medial 409µm³ and lateral 408µm³). The results indicated that variation in osteocyte lacunar density, even within a single bone of a single individual, can be considerable (up to 30% between regions). The underlying functional significance of the observed variation in lacunar density is unclear, but it may relate to axes of mechanical loading - a hypothesis we believe warrants further study. Our findings demonstrate that the functional and pathological interpretations which are increasingly being drawn from high resolution imaging of osteocyte lacunae need to be better situated within the broader context of normal variation, including that which occurs within a single skeletal element.

Type 1 Diabetes Mellitus Effects on Bone: Preliminary Results of Peripheral Quantitative Computed Tomography (pQCT) Analysis. Robert Recker¹, Diane Cullen², Laura Armas^{*2}. ¹Creighton University Osteoporosis Research Center, USA, ²Creighton University, USA

Diabetes Mellitus has a detrimental effect on the body's microvascular system affecting the kidneys, eyes and nerves. The effect on bone is less well known. Patients with Type 1 diabetes have lower bone mass and higher fracture risk than age and sex matched controls. The effect of diabetes on bone micro-architecture is not well elucidated. We report here preliminary results of 29 diabetic subjects (19 females, 10 males, ages 20-50) with Type 1 diabetes for a median of 19 years and 30 controls (20 females, 10 males, ages 20-46). The subjects were otherwise healthy without diabetic complications and the females were premenopausal. The Stratec XCT 3000 (Norland, White Plains NY) was used to measure the non-dominant distal tibia at the 4, 38 and 66% sites and at the 4 and 30% sites on the non-dominant radius. Measurements of the total bone area, total marrow area, cortical bone area, trabecular bone area, density and predicted strength density were obtained at these 4 sites. Descriptive statistics were calculated and ANOVA was used to test differences between diabetics and controls. Pearson correlation was used to find correlations between variables. There were no significant differences between diabetics and controls in cortical measurements at either the radius or the tibia. The trabecular bone density at the radius was diminished in the diabetics ($P = 0.009$). While the sample size was small, there was also a trend in the diabetic group for low total and trabecular area with decreased predicted bone strength at the 4% radius site ($P < 0.1$). Trabecular measures of density were highly correlated between the tibia and radius ($P < 0.001$) and a trend was also detected for lower trabecular density in the tibia 4% site of diabetic patients. In this group of healthy diabetics, the main effect of the disease is on the trabecular variables. The link between diabetic complications and bone fractures is unknown. Based on this sample of diabetics who have no known diabetic complications, there may be an early direct or indirect effect of diabetes on bone health.

Material Characterization of Bone Matrix in Rats: Effect of Treatment and Treatment Withdrawal. Daniel Nicoletta^{*1}, Ryan Potter¹, Don Moravits¹, Wei Yao², Nancy Lane². ¹Southwest Research Institute, USA, ²University of California, Davis Medical Center, USA

Bone strength depends on complex and interrelated characteristics of the bone matrix, the organization of the bone tissue, the shape of the bone, and bone density. The physicochemical and micromechanical properties of bone in aged rats subjected to various treatments and treatment-withdrawals were studied.

Methods. 12-month-old female rats were either ovariectomized (OVX) or sham operated and allowed to develop osteopenia for 2 months. The treatment groups studied were: 6 months OVX + vehicle (n=4) and 6 months post-sham operated (n=3), 4 months of treatment of either alendronate (OVX+ALN, n=4), Raloxifene (OVX+RAL, n=4), or hPTH (1-34) (OVX+PTH, n=4). Also, we characterized cortical and trabecular bone from animals from the following additional groups: 4 months treatment followed by both 4 and 8 months of treatment withdrawal from the sham, OVX, OVX+ALN, OVX+RAL, OVX+PTH groups. Using Raman spectroscopy, we measured the mineralization, carbonate substitution, crystallinity, and collagen cross links of bone matrix and nanoindentation was used to measure local bone modulus and hardness at the proximal tibia.

Results. Compared to the OVX group, matrix mineralization of the OVX+RAL treatment group was higher after 4 months of treatment (12.6 vs. 14.6, $p = 0.001$); the other groups were not different from the OVX group. 8 months after treatment withdrawal, tissue mineralization for the OVX+PTH treatment group was significantly lower than the OVX group (14.0 vs. 12.6, $p = 0.018$); all other groups were not different than OVX. Mineral crystallinity was significantly greater after 4 months of treatment in the OVX+PTH and OVX+RAL groups compared to OVX alone; at 8 months after treatment withdrawal, OVX+ALN, OVX+PTH, and OVX+RAL were greater than OVX. Tissue modulus was unchanged after 4 months treatment in all treatment groups compared to OVX; tissue hardness was greater in the OVX+ALN (0.995 GPa, $p = 0.006$) and OVX+RAL (0.947 GPa, $p = 0.046$) groups compared to OVX (0.83 GPa). 8 months after treatment withdrawal, tissue hardness increased in

the OVX (1.0GPa), $p=0.012$ group compared to the sham group (0.85 GPa). These data indicate that the effect of treatment and treatment-withdrawal on the bone matrix is complex and each treatment type and/or regimen alters the matrix differently. This data emphasizes that bone strength is not a function of a small number of traits or factors, but can be affected by combinations of traits/factors acting at multiple length scales.

Risedronate Improves Bone Architecture in Goto-Kakizaki Rats, a Spontaneous Non-obese Model of type 2 Diabetes. Tetsuo Yano^{*1}, Mei Yamada¹, Tomoyuki Konda², Makoto Shiozaki¹, Daisuke Inoue³. ¹Ajinomoto Pharmaceuticals Co., LTD, Japan, ²Ajinomoto Pharmaceuticals Co., LTD., Japan, ³Teikyo University Chiba Medical Center, Japan

Background/Aim: Patients with type 2 diabetes exhibit decreased bone strength and increased fracture risk in part independently of bone mineral density (BMD). However, the molecular basis of the bone fragility and specific treatment for such diabetes-associated osteoporosis remain to be established. A previous report has demonstrated that alendronate (ALN) did increase BMD in patients with type 2 diabetes, but whether or not ALN and other bisphosphonates improve bone quality in diabetic subjects is unknown. The aim of the present study was to establish the ability of bisphosphonates to improve bone quality in type 2 diabetes by analyzing effect of risedronate (RIS) on bone architecture as compared to that of ALN in Goto-Kakizaki (GK) rats.

Methods: GK rats, a spontaneous non-obese model of type 2 diabetes, and Wistar rats as a control were used. Starting at 36 weeks of age the rats received treatment for 12 weeks with either vehicle, RIS, or ALN, subcutaneously, once a week. After 4 and 12 weeks of treatment, bone architecture in distal epiphysis of the femur and femoral diaphysis was examined by micro CT.

Results: Development of diabetes was confirmed just prior to the initiation of treatment, as blood glucose concentrations were significantly increased in GK rats compared with Wistar rats both under a fasting condition and after oral glucose challenge. In GK rats compared with Wistar rats, trabecular BMD (~25% at 12 weeks), bone volume fraction, trabecular number, trabecular separation (Tb.Sp) and connectivity density (Conn.D) were significantly decreased, and structure model index was significantly increased, indicating transition from plate-like architecture of trabeculae to a more rod-like structure. Analysis of cortical bone revealed increased periosteal perimeter, but there was no significant decrease in cortical thickness or BMD. We found that at 12 weeks RIS significantly improved Tb.Sp and Conn.D., while no significant effect of ALN was detected in any bone parameters measured. Neither RIS nor ALN had statistically significant effect on cortical bone architecture.

Conclusion: GK rats developed osteopenia predominantly in trabecular bone. And RIS significantly improved parameters of bone architecture. We therefore conclude that bisphosphonate, particularly RIS, can be effective treatment of osteoporosis associated with type 2 diabetes by improving both bone mass and quality.

Adenylyl Cyclase 6 Mediates In Vivo Mechanotransduction In Bone. Kristen Lee^{*1}, Dr. David A. Hoey¹, Dr. Tong Tang², Dr. H. Kirk Hammond², Christopher Jacobs¹. ¹Columbia University, USA, ²University of California San Diego, USA

Mechanical loading is an important stimulus that modulates bone development and adaptation. However the molecular mechanisms that regulate mechanotransduction in bone are unknown. Adenylyl cyclase 6 (AC6) is a membrane-bound enzyme isoform that is responsible for converting ATP into cAMP, a second messenger. Previously, we demonstrated that 2 minutes of oscillatory fluid flow induced a decrease in cAMP which was dependent on AC6 in MLO-Y4 osteocyte-like cells. This transient decrease in cAMP resulted in a subsequent increase in COX2, a gene involved in bone metabolism and turnover. The purpose of this study was to determine the in vivo role of AC6 in adult bone adaptation. Our hypothesis was that the loss of AC6 in vivo would inhibit mechanical load-induced bone formation. Virgin C57BL/6J transgenic mice with global deletion of AC6 and intact littermate controls were anesthetized and placed under compressive axial loading of the ulna characterized by 120 cycles per day with a 2Hz sine wave at 3N for Days 1-3. Right limbs were loaded while left limbs were not loaded and served as controls for normal cage activity. On Day 5 and 9, mice were subcutaneously injected with Calcein (10 mg/kg) and Alizarin Red (70 mg/kg), respectively. Mice were sacrificed on Day 15, and right and left ulnae were removed and embedded in PMMA. Sections were taken at the mid-shaft and images for histomorphometric analysis were captured using confocal microscopy (see Fig. 1). AC6 knockout mice (n=2) demonstrated a decreasing trend in relative MS/BS (%), MAR ($\mu\text{m}/\text{day}$), and BFR/BS ($\mu\text{m}^3/\mu\text{m}^2/\text{year}$) compared to control mice (n=3). Therefore our preliminary study indicates that AC6 is involved in mechanical loading-induced bone formation. Collectively, this data suggest that AC6 plays a role in the adaptation of adult bone to mechanical stimulus in vivo. Acknowledgements: Funding for this work was provided by NIH grants AR45989 and AR45156 and the NSF Graduate Research Fellowship.

Effects of A 16-Week Obesogenic Diet Program on Bone Densitometry, Microarchitecture and Metabolism in Male Rat. Maude GERBAIX¹, Aurelie MASGRAU², Fabrice MAC WAY³, Christelle GUILLET², Stephane WALRAND², Marie Therese LINOSSIER³, Laurence Vico⁴, Daniel Courteix⁵, Lore METZ¹. ¹Laboratoire de Biologie des APS, EA 3533, PRES Clermont Université, Université Blaise Pascal, 24 avenue des Landais, France, ²Unité de Nutrition Humaine, UMR 1019, INRA/ Université d'Auvergne, France, ³Laboratoire de Biologie du Tissu Osseux, Inserm U890/IFR143, université de Lyon, France, ⁴University of St-Etienne, France, ⁵Université Clermont Ferrand Laboratoire De Biologie Des APS, France

A high-fat/high-sucrose acute diet has been shown to induce harmful effects on bone micro architecture and bone biomechanics of rat. If such chronic diet leads to obesity it may induce an improvement of biomechanical bone parameters.

The aim of this study was to assess the impact of a high-fat/high-sucrose diet on the body composition and its resulting effects on bone in male rats.

43 Wistar rats aged 7 months were split into 3 groups: 1 subjected to 16 weeks of high-fat/high-sucrose diet (HF/HS, n=14); 1 subjected to standard diet (Control, n=15) and 1 sacrificed before diet (BD, n=14). The body composition with specific central fat mass has been assessed by DXA every 3 weeks for the period of diet. One week before sacrifice, body composition, abdominal circumference and insulin sensitivity were measured. Visceral fat mass was assessed by weighing the total perirenal and peri-epididymal adipose tissues.

The bone mineral density (BMD) was analyzed at the whole body and tibiae by DXA. Microcomputed tomography and histomorphometric analysis were performed at L2 vertebrae and tibiae to study the trabecular and cortical bone structures and the bone cell activities. Osteocalcin and CTx were assayed to calculate the bone uncoupling index (UC) as suggested by Eastell et al.[1], in order to assess the relative balance of the formation and resorption processes of bone remodeling.

The HF/HS and Control groups had increased their total and abdominal fat mass and decreased bone parameters compared to BD group. The HF/HS group had higher body mass, global, central and visceral fat masses and abdominal circumference compared with Control group ($p < 0.001$). Insulin resistance appeared in HF/HS group. Bone mass ($p < 0.001$) and BMD ($p < 0.05$) were higher at the whole body and the cortical porosity was improved ($p < 0.05$) for HF/HS group vs. Controls. When adjusted for the total fat mass, all these differences disappeared. UC was positive (favor of bone formation) in HF/HS and negative (favor of bone resorption) in Controls.

The ageing process had increased the fat mass and produced deleterious effects on bone tissue in both groups. The HF/HS diet had induced obesity and insulin resistance also. These changes were linked to an improvement of quantitative and metabolic bone parameters. The fat mass increase partly explained these observations.

Translating the Strain Stimulus Equation from Animals to Humans. William Edwards, Karen Troy*. University of Illinois at Chicago, USA

Mechanical loads make an important contribution to bone health. The strain stimulus equation, $E = k \cdot \epsilon \cdot f$, was proposed to describe the relationship between mechanical loading environment and the resulting bone adaptive response. Here, ϵ is bone strain magnitude, f is the frequency of the loading waveform, and k is a proportionality constant. This equation appears to be valid in controlled animal experiments but has never been prospectively tested in humans.

Our purpose was to evaluate the applicability of the strain stimulus equation in humans. We hypothesized that subjects with larger strain stimulus values would experience greater increases in bone mineral content (BMC) after a 14-week mechanical loading regime.

Thirteen subjects (8 young and 5 postmenopausal women) participated in this institutionally approved study. Each applied an axially-directed force of 300 N to the palm of her non-dominant hand. With assistance from sound cues and visual feedback, subjects completed 50 cycles/day, 3 days/week. BMC was measured at weeks 0 and 14. Subjects applied either "rapid" or "slow" (i.e. high or low frequency) loading waveforms to achieve a range of strain stimuli.

Computed tomography data were acquired at baseline and validated techniques were used to generate subject-specific finite element (FE) models. These models, combined with load cell recordings, were used to calculate subject-specific values of

Diet and Exercise Affect Postcranial - but Not Cranial - Robusticity in Mice.

Lynn Copes¹, Margaret R. Brown¹, Elizabeth M. Dlugosz², Stefan Judex³, Svetlana Lublinsky³, Aleksandra Oldak⁴, Heidi Schutz⁴, Steven Tommasini³, Katie Whitmore¹, Theodore Garland². ¹Arizona State University, USA, ²University of California, USA, ³Stony Brook University, USA, ⁴California Polytechnic University, USA

Modern *Homo sapiens* show a recent, but dramatic, decrease in cranial vault thickness (CVT) relative to earlier hominin ancestral species. Two competing hypotheses for this hypertrophy involve 1) a hormonal increase mediated by exercise and causing systemic increases in skeletal robusticity, and 2) a localized effect of increased masticatory stress causing only an increase in CVT. We tested these hypotheses by manipulating the exercise and diet of several groups of mice.

In the exercise study, 50 female mice from lines artificially selected over 60 generations for endurance running ability and 50 female controls were split between cages with wheel access and no wheel access. The study began at weaning and lasted 3 months, after which skeletal elements were harvested at the conclusion of the experiment, and the humerus, femur, mandible, parietal and interparietal bones were scanned via desktop μ CT at 36 μ m. No significant differences in CVT were seen among groups, and no relationship between activity or hormone levels and CVT were found. Postcranial bones were significantly more robust in the selected mice than in controls, however.

A second experiment with similar parameters used 50 inbred and 50 wild-type female mice, divided at weaning into soft, cold, and control diet groups. The soft diet group was fed food the consistency of dough, while the cold group was housed in a 10C room in order to manipulate their food consumption by increasing resting metabolic rate. The inbred mice in the cold group had significantly lower CVT than other groups (0.19 mm mean vs. >0.21 mm; $p = 0.04$), but no other differences were found. While masseter mass differed significantly among the groups (soft < control < cold), its association with CVT was insignificant. Inbred and outbred strains showed identical variation in the trait, suggesting a very strong genetic control of its development. There were significant differences in postcranial robusticity, mostly related to differences in body mass. No relationship was found between hormone levels and CVT.

Our data suggest that the cranium is less sensitive than postcrania to environmental perturbations affecting muscle mass and hormone changes. Studies of morphological, hormonal, and behavioral correlates with cranial vault thickness in non-human primates and humans are needed to further establish the relative plasticity of the trait and its associations in our species.

Disclosures: Lynn Copes, None.

strain stimulus. Strain magnitude, ϵ , was assigned the peak strain predicted within the volume of the distal radius. This value was normalized and multiplied by a weighted sum from the frequency spectrum of the load cell signal. The constant k was assigned a value of 1. Pearson's correlations were calculated to compare change in BMC to strain stimulus.

Change in BMC was correlated with strain stimulus ($r=-0.735$, $P=0.004$, Figure 1). The greater the strain stimulus, the greater the resorptive response at 14 weeks. This is consistent with our previous reports of a temporary decrease in cancellous BMC in a separate group of subjects. High strain stimulus values may be associated with localized trabecular damage and the initiation of a remodeling and repair response that involves resorption. More data is needed to determine if strain stimulus is related to chronic changes in BMC.

In summary, we have developed methods to noninvasively quantify strain stimulus, and have shown that short-term changes in bone mass are related to strain stimulus in young and older women.

Advanced Imaging to Assess Age-Induced Mineralization Changes in Teeth.

Dana Begun¹, Rachel Caspari², Rihana Bokhari³, Kristina Galdes⁴, Steven Goldstein⁵. ¹University of Michigan Orthopaedic Research Lab, USA, ²Department of Anthropology, Central Michigan University, USA, ³University of Michigan, USA, ⁴University of Montana, USA, ⁵University of Michigan Orthopaedic Research Labs, USA

Dental remains are less susceptible to taphonomic changes, and thus are useful in estimation of age-at-death in forensic and archaeological inquiries. However, age estimates past dental maturity are often subjective and require destruction of the specimen. With aging, a number of alterations occur in the mineralization patterns of the teeth. Vascular root tubules become occluded with mineral deposit. The homogenization of density creates a translucent appearance when backlit. Another product of aging is the deposition of secondary dentine which results in a reduction of the pulp cavity volume. The purpose of this study is to validate the utility of micro-computed tomography and Raman spectroscopy in age estimation of teeth. The age-related parameters of root transparency, secondary dentine, root resorption, and enamel wear are quantified with these imaging modalities and accuracy of results compared to previous methods. With the development of these methods, regressions for the rate of modification with age can be elucidated and used to estimate ages in unknown remains. Medial and lateral incisors, as well as canines, were loaned by the University of Tennessee. The sample included 31 individuals of known age, ranging from 24 to 87. Previously developed manual measures of transparency, wear, and root attrition were taken by 3 individuals. Additionally, teeth were scanned in a specimen μ CT scanner (GE Healthcare Preclinical Imaging) at $27\mu\text{m}$ resolution. A global threshold was defined for dentine and enamel. A custom probe holder was used to take surface and offset Raman measures at increments along the tooth root. Manual measures of enamel wear did not accurately estimate age. Hand-taken transparency height was positively related to age (canines: $\beta=0.1073$, $p=5.977E-05$). However, due to inter-observer error, there was a high level of variance in multiple measures. μ CT measures of enamel and root attrition were not significantly related to age. Pulp volume ratio was inversely related to chronological age (canines: $\beta=-0.0008$, $p=1.972E-07$). Histogram analysis of Hounsfield values was also able to make similar transparency height estimates as those taken by hand. These methods provide more accurate and non-destructive approaches for assessing age in forensic and archaeological remains. Here we present results that establish the reliability of μ CT and Raman as substitutes for destructive and semi-quantitative techniques.

New Method for *in vitro* Glycation of Proteins. Grazyna Sroga*, Deepak Vashishth, Robert Davignon. Rensselaer Polytechnic Institute, USA

Glucose and other reducing sugars react with proteins *in vivo* and *in vitro* by a slow non-enzymatic process termed glycation. As a result crosslinks, known as advanced glycation end products (AGEs), are formed within and between proteins [1, 2]. The formation of AGEs in long-lived tissues such as bone mainly accounts for the increase of collagen crosslinking. This process accompanies normal aging and is accelerated in diabetes. Accumulation of AGEs causes age-related degradation of the bone's mechanical properties. The time-frame for *in vitro* glycation of bone samples using glucose ranges from a few weeks to several months [3]. The goal of the current work was to develop an efficient *in vitro* glycation method that uses glucose instead of more reactive ribose as a substrate and efficiently glycates a given protein within a few days.

Using a novel combination of several methods, we first attached glucose under *in vacuo* conditions to a protein, and then, converted it into pentosidine (PEN) within 8 to 9 days. Total AGEs were measured using fluorescent-based colorimetric assay and ultrahigh pressure liquid chromatography (UPLC) [4].

We determined that the amount of produced total AGEs increased over the experimental period and reached a plateau by the 7th day. PEN followed the same trend, but reached the plateau at the later time point.

In summary, we developed a new *in vitro* glycation method that uses less reactive sugar (glucose) than ribose and is more physiologically relevant. The novelty of our method lies in the introduction of *in vacuo* incubation of protein samples, with glucose as the first reaction step. This approach significantly speeds up the glycation process (2 weeks) as compared to a standard "in solution" method that takes over 5 months [3].

Bone Tissue Mineral Content Is Greater in the Subtrochanteric Cortex Than in the Trochanteric or Iliac Crest Cortices. Eve Donnelly*, Dennis Meredith, Joseph Nguyen, Adele Boskey. Hospital for Special Surgery, USA

Pathologic changes in bone composition with osteoporosis are typically assumed to occur throughout the skeleton, and not only at sites that fracture, as evidenced by the diagnostic use of biopsies of the iliac crest, a site that rarely fractures. However, the extent to which bone tissue composition varies across anatomic sites in normal or pathologic tissue is unknown. Our objective was to compare the composition of normal cortical and cancellous bone tissue across anatomic sites in the iliac crest and proximal femur. We hypothesized that the tissue composition of the iliac crest is representative of that of the proximal femur.

In an IRB-approved study, cadaveric tissue from 3 sites (iliac crest, greater trochanter, and sub-trochanter) was collected from 10 donors (sex: 3 M, 7 F; age: 53-90 y, mean 69 SD 12 y) with no history of bone disease. Cortical and cancellous regions were analyzed separately with Fourier transform infrared imaging (FTIRI) to assess the mineral:matrix ratio, carbonate:phosphate ratio, collagen cross-link maturity, and mineral crystallinity (XST). The pixel histograms of the FTIR images of each parameter were characterized by their mean and full width at half maximum (FWHM) values.

The mean mineral:matrix ratio was greater in the subtrochanteric cortex than in the cortices of the iliac crest (+20%) or the greater trochanter (+20%) (Table 1). There were also trends that did not reach statistical significance toward reduced width of the mineral:matrix distributions in the subtrochanteric cortex vs. iliac crest (-17%) and increased width of the XST distributions in the subtrochanteric trabeculae vs. iliac crest (+30%) and greater trochanter (+30%). The mean and FWHM values of all other FTIR parameter distributions were similar across sites.

Bone tissue composition differed across anatomic sites in the iliac crest and the proximal femur. In particular, bone mineral content was 20% greater in the subtrochanteric cortex than in the trochanteric or iliac crest cortices. Thus, in non-pathologic cadaveric bone, the cortex of the iliac crest has reduced mineral content relative to subtrochanteric tissue and may have limited utility as a surrogate for subtrochanteric bone.

Table 1: FTIR parameter distribution mean and full width at half maximum (FWHM) values reported as mean (SD) for iliac crest (IC), greater trochanter (GT), and subtrochanteric (ST) sites. * p < 0.05 vs. GT, ST; ^ p < 0.2 vs. GT, ST; ^^ p < 0.2 vs. GT by RM-ANOVA.

Mineral and Matrix Changes in Brlt/+ Bones and Teeth Provide Insight into Mineralization Mechanisms. Adele Boskey*¹, Lyudmila Spevak¹, Lyudmila Lukashova¹, Kostas Verdelis¹, Joan Marini². ¹Hospital for Special Surgery, USA, ²Bone & Extracellular Matrix Branch, NIH/NICHD, USA

The Brlt/+ mouse is a knock-in model for osteogenesis imperfecta (OI) type IV in which a Gly349Cys substitution was introduced into one colla1 allele, resulting in a phenotype representative of the disease. Changes in whole bone mechanical strength and collagen d- spacing in the Brlt/+ mice have previously been reported (Kozloff et al., 2004; Wallace et al., 2010). In this study we compared the bones and teeth of 2 month old wildtype (+/+) and Brlt/+ mice using micro-computed tomography (micro-CT; teeth) and infrared microscopic imaging (bones/teeth). The teeth of the Brlt/+ animals were visually different when examined by micro-CT with significant (p<0.05) increases in Brlt/+ crown total mineral density and decreased dentin, enamel, and root volumes, and decreased mineralized tissue volume/total volume in the roots; all indicative of delayed matrix formation. Fourier transform infrared imaging (FTIRI) showed mineral/matrix ratio was also increased in the Brlt/+ molars, which had previously been reported to have an odontogenesis imperfecta phenotype (Forlino et al., 1999). These data represent the first quantitative evaluations of the teeth in the Brlt/+ mice.

FTIRI was used to map the chemical composition of the bones at ~6 micron spatial resolution. While there were no statistically significant differences in global FTIRI parameters in the bones (tibias), the collagen spectra were broadened and differed in shape from the WT. To define the origin of the broadening, factor analysis of the collagen spectra from the trabecular region was used. An increase was noted in a subband at 1640 cm⁻¹; the ratio of the intensity of the 1640 cm⁻¹ subband to that of the major collagen band at 1660 cm⁻¹ varied from 0.800.02 in Brlt/+ to 0.770.02 in +/+ (p=0.02), with a similar but marginally significant trend (p=0.10) in cortical bone. This change suggests disruption of the collagen 310 helix in the Brlt/+ bones. The measured changes in FTIRI mineral/matrix ratio in both cortical and cancellous bone paralleled the bone mineralization density distribution (BMDD) measurements of Camean reported elsewhere. The increases in mineralization in the developing bones and teeth, along with the altered collagen structure imply that the hypermineralization in classical OI is associated with an abnormal collagen matrix, and provide one possible mechanism for the way these abnormal collagen matrices can affect initial mineralization.

Raman Microscopy Detection of Cyclic Mineralization Events in Perinatal Murine Calvaria. John-David McElderry*, Guisheng Zhao, Renny Franceschi, Michael Morris. University of Michigan, USA

Cyclic events, driven by clock genes in the hypothalamus, occur in many organs in the body. Cultured tissue separated from the brain can continue to display typical cyclic fluctuations for up to several days. Bone formation is thought to be regulated by clock genes through leptin hormone release and the sympathetic nervous system. Type I collagen deposition and osteocalcin blood levels both display diurnal cycles in the body confirming rhythmic influences in bone formation and turnover. Other processes in bone formation may also be regulated by clock genes.

Osteoblastic mineralization of the bone collagenous matrix is an extensively studied protein mediated process. However, current models for mineral deposition are not able to adequately describe apatitic crystal nucleation and propagation dynamics, both of which are essential for understanding mineral altering bone diseases. In the present study, intercollagenous deposition of apatitic mineral in ex vivo cultures of perinatal C57BL/6 murine calvaria (n=8) was monitored using a Raman microscope (830 nm laser) operated in an inverted configuration to accommodate a stage incubation chamber (5% CO₂, 37C, >90% humidity). Mineral deposition kinetics was measured in a 5x25 µm region at the occipital bone/anterior fontanel interface with a time resolution of 20 min. Mineral content in the tissue increased in periodically repeating intervals with near-diurnal frequency, while matrix components remained constant. Newly deposited mineral had the Raman spectral signature of small apatitic crystallites. A parallel study monitoring alkaline phosphatase (ALP) and inorganic phosphate (Pi) in medium of calvarial cultures using pups from the same litter (n=3) showed gradual decreasing levels of Pi, followed by near-synchronous fluctuations occurring over two days. ALP levels also showed large fluctuations but were asynchronous among pups. Our data suggests a bone mineral deposition mechanism that proceeds rapidly to the apatitic crystalline form and deposits in periodic steps probably regulated by clock gene expression. Video of tissue mineralization dynamics will be available during author presentation.

Shh Secreted By Nucleus Pulposus Cells Is Required for the Maintenance of Postnatal Mouse Disc. Chitra Dahia*, Eric Mahoney, Christopher Wylie. Cincinnati Children's Hospital Medical Center, USA

Background: Degenerative disc disease is a major cause of lower back pain. However, the molecular signals that control normal growth and differentiation of the disc are not well defined. We hypothesize that nucleus pulposus (NP) cells, which originate from the embryonic notochord, provide signals that control growth and differentiation of the postnatal disc.

Methods: Postnatal day 4 mice IVDs were cultured in serum-free DMEM Ham/F12 medium at 37°C in 5% CO₂ for 2-5 days on type IV collagen-coated cell culture inserts. Cyclopamine (250 µM) was used as a Shh antagonist, and its specificity was tested by add-back experiments using 100 nM recombinant Shh (rShh). Cell proliferation was assayed using pulse-labelling with BrdU. 6 µm thick cryosections were immunostained (IHC) using antibodies specific to IVD differentiation markers, and Cy5 conjugated secondary antibodies. Imaging was carried out using confocal microscope. To test the role of Shh *in vivo*, triple transgenic mice [(tetO)7CMV-cre: R26 rtTA:Shh^{flx/flx}] were injected with 2 µg of doxycycline on postnatal day 4 to conditionally delete Shh, and the lumbar spine were collected 5 days later. Results were compared to vehicle treated controls.

Results: Both cyclopamine treatment *in vitro* and conditional Shh knockout *in vivo* caused rounding up and aggregation of the NP cells, and loss of orientation of the layers of the annulus fibrosus (AF). There was also a loss of expression of both NP and AF differentiation markers. BrdU incorporation studies showed loss of proliferation of NP cells. IHC for activated caspase-3 showed increased levels of apoptosis of NP cells rShh replacement reversed the cyclopamine phenotype *in vitro*.

Conclusions: These results show that Shh is essential for postnatal growth and differentiation of both the NP and AF.

Significance: Identification of signals controlling IVD growth and differentiation offers the opportunity for the development of biological repair as an alternative to surgery.

Time and Indentation Dependent Mechanical Response of Chondrocytes to Cyclic Loading. Cynthia Thomas¹, Nadeen Chahine², Craig Blanchette^{*3}, Gabriela Loots⁴, Todd Sulchek⁵. ¹LLNL, USA, ²Feinstein Institute for Medical Research, USA, ³Lawrence Livermore National Laboratories, USA, ⁴LLNLUC Merced, USA, ⁵Georgia Tech Research Institute, USA

Chondrocytes are responsible for the elaboration and maintenance of the extracellular matrix in articular cartilage. The biosynthetic responses of chondrocytes are known to be regulated by mechanical loading; therefore, mechanical properties of the cells play a pivotal role in the regulation of articular cartilage. In this study, the indentation and time-dependent mechanical response of individual chondrocytes was evaluated using atomic force microscopy (AFM). To measure the indentation-dependent response, chondrocytes were mechanically indented from 0.8 – 4 µm and the Young's modulus was calculated using the Hertzian model. The mechanical stiffness of chondrocytes isolated from 1 day old bovine was shown to dramatically increase between an indentation depth of 0.8 – 2 µm, and plateau at higher indentations. The time-dependent response of chondrocytes was evaluated as a function of the resting time between successive cyclic indentations (relax time). In these experiments, the compressive modulus of chondrocytes isolated from 1 day old bovine was shown to drastically decrease between a relax time of 0.5 s and 2 s. These results suggest that immediately after cyclic indentation, chondrocytes experienced a higher stiffness that decreases with increasing relaxation time. This relaxation behavior may be due to fluid pressurization inside the cell or viscoelastic elements in the membrane or organelles. To determine if these effects were dependent on the structural components of the cells, actin and/or intermediate filaments, these experiments were repeated in the presence of agents that disrupt the actin (cytochalasin B) and intermediate filaments (acrylamide) and the resulting mechanical response to cyclic loading were evaluated. In addition, to assess the effects of chondrocyte age on mechanical stiffness, the time and indentation dependent mechanical response of chondrocytes isolated from different aged bovine, immature (1-3 week old bovine calf), young (1-2 year old bovine) and aged (5-7 year old bovine), to cyclic loading was measured.

Disruption of Aldehyde Dehydrogenase 2 Gene Resulted in Altered Cortical Bone Structure and Increased Cortical BMD without Affecting Bone Length and Trabecular BMD in Femurs of Mice. Takuto Tsuchiya*, Akinori Sakai, Toshiharu Mori, Kunitaka Menuki, Yoshinori Takeuchi, Shinkichi Kanoh, Hajime Utsunomiya, Teppei Murai, Toyohi Isse, Tsunehiro Oyama, Toshihiro Kawamoto, Toshitaka Nakamura. University of Occupational & Environmental Health, Japan

Aldehyde dehydrogenase 2 (ALDH2) is the enzyme which degrades and detoxifies acetaldehyde, which is in turn is metabolized from alcohol. More than 40% of Chinese and Japanese people have the inactive ALDH2 phenotype. In our previous study, trabecular bone volume decreased in ALDH2 knock-out (Aldh2^{-/-}) mice with alcohol drinking compared with wild type (Aldh2^{+/+}) mice. On the other hand, skeletal phenotype of ALDH2 gene except for alcohol factor remains unknown. The aim of this study is to clarify the skeletal phenotypic analysis of ALDH2 knock-out (Aldh2^{-/-}) mice at 12-weeks of age without alcohol drinking. We evaluated the femoral bone length and bone mineral density (BMD) was measured in the femur using peripheral quantitative computed tomography (pQCT). There were no significant differences in the femoral bone length and trabecular BMD in distal metaphysis of femurs between male and female Aldh2^{-/-} mice (n=8 in each group) and respective Aldh2^{+/+} mice (n=8 in each group). However, mid-shaft cortical BMD and cortical thickness were significantly increased, and cross-sectional area and bone marrow area were significantly decreased in femurs of male and female Aldh2^{-/-} mice compared with those in respective Aldh2^{+/+} mice. In Conclusion, disruption of ALDH2 gene resulted in altered cortical bone structure and increased cortical BMD without affecting bone length and trabecular BMD in femurs of mice.

Frzb is Dominant Regulator of Wnt Signaling During Early Fracture Healing in Mice. Travis Burgers^{*1}, Martin Hoffmann², Debra Sietsema³, Bart Williams⁴, Clifford Jones³, Jim Mason¹. ¹Van Andel Institute, USA, ²Grand Rapids Medical Education Partners, USA, ³Orthopaedic Associates of Michigan, USA, ⁴Van Andel Research Institute, USA

Purpose: Wnt signaling plays a role in normal and pathological bone healing and bone mass regulation through control of cell differentiation along the osteoblast or chondrocyte lineages. Here we hypothesize that Wnt signaling regulates bone healing in a stage-dependent manner through differential utilization of beta-catenin signal transduction.

Methods: Twelve-week-old male C57/BL6 mice were used in this study. A closed mid-diaphyseal femoral fracture was induced after retrograde insertion of a 23G intramedullary needle under sterile conditions (Figure 1). Two mice were sacrificed at 5, 14 and 21 days post-fracture (PF). The fracture callus and corresponding segment of the contralateral femur were harvested and the bone marrow removed under RNase-free conditions. RNA was extracted (QiaShredder, Qiagen Inc., Valencia, CA). Reverse transcriptase and real time polymerase chain reaction were performed (RT2 Nano PreAMP cDNA Synthesis Kit and Mouse WNT signaling pathway RT2 Profile PCR Array, SABiosciences). The increase in gene expression of the fracture callus with respect to a contralateral limb was calculated.

Results: At a minimum of one of the three time points, 19 different genes were up-regulated more than 10-fold in the fracture callus and nine genes more than 20-fold (Figure 2). Frzb (aka Sfrp3) was the most highly up-regulated gene. Many Wnts (1, 2b, 4, 5a, 5b, 7b, 8b, 11 and 16) were up-regulated at all three time points during healing. Wnt3a, 6 and 8a are all down-regulated on Day 5 PF and up-regulated on Day 21 PF. Wnt9a and 16 are up-regulated on Days 5 and 14 PF but down-regulated on Day 21 PF.

Conclusion: Frzb, Sfrp1, Sfrp2, Dkk1 and Wnt5a are negative regulators of canonical Wnt signaling that are initially up-regulated before returning to near-normal levels. Frzb has been shown to be related to endochondral bone formation [Enomoto-Iwamoto et al. Dev Biol. 2002] and pathologies in the chondrocyte lineage [Lories et al. Arthritis Rheum. 2007]. Anecdotally, when Sfrp1, one of the negative regulators for canonical Wnt signaling, was knocked out in a mouse, fracture healing was improved [Gaur et al. J Cell Physiol. 2009]. The results of this study demonstrate that knockout of Frzb (Sfrp3) may have an even more dramatic effect.

Immunohistochemical and Histological Study on Periodontal Tissue in GK Rat. Fumihiko Suwa¹, Akimichi Takemura¹, Naoko Yoshikawa^{*2}, Masatoshi Ueda³. ¹Osaka Dental University, Department of Anatomy, Japan, ²Osaka Dental University, Department of Periodontology, Japan, ³Osaka Dental University, Japan

It has been reported that 95 % of diabetes mellitus (DM) patients in Japan exhibit the non-insulin dependent type II disease. Diabetes is a risk factor for periodontitis, which is considered the sixth most common complication of the disease. It has been pointed out that bone metabolic abnormalities induced by diabetes include osteoporosis, and there is a relation between systemic bone metabolic disorders like osteoporosis and alveolar bone resorption in periodontitis. We investigated the relation between periodontal tissue and type 2 diabetes mellitus.

We used 9 eight month old Goto-Kakizaki (GK) rats, which is a type 2 DM model rat, as the experimental animals. 9 eight month old Wistar rats (NDM) were used as controls. We examined the development of connective tissue papillae in the free gingiva of external marginal epithelium on the lingual side of mandibular first molars using normal rats under light and scanning electron microscopy and immunohistochemically examined RANKL and OPG on alveolar bone. We also histochemically examined TRAP-positive cells and ALP-positive cells.

In observation of the specimen under a scanning electron microscope, the height of papillae of the DM was lower than that of the NDM. In histological measurement and statistical observation, the height and area of connective tissue showed smaller figures in the DM compared to the NDM, and significance difference was observed in both. However, neither showed difference in the number of connective tissue papillae. The development was poor in the DM compared to the NDM. There were distinct morphological differences.

In enzyme histochemical findings for TRAP and ALP, many TRAP positive multinucleated giant cells were observed in the alveolar bone around the root apex in NDM compared with DM, and many ALP were observed near the root apex in

NDM. In immunohistochemical findings for RANKL, many RANKL were observed from the alveolar bone in the mid portion root to the alveolar crests in NDM. In immunohistochemical findings for OPG, many OPG were observed from the alveolar bone in the mid portion root to the alveolar crests in DM.

These results suggest that diabetes may not only impair the development of connective tissue papillae by causing regressive changes and play an important role as a risk factor for low-turnover bone disease, but also delay periodontal tissue healing and aggravate periodontal diseases.

Bioinspired Silicon Carbide Ceramics as Bone Substitute in an Experimental Bone Defect Rabbit Model. David Guede^{*1}, I Pereiro², E Solla², J Serra³, M Lopez-Pena⁴, F Munoz⁴, Antonio Gonzalez-Cantalapiedra⁴, Jose Caeiro⁵, PUo Gonzalez². ¹Trabeculae, S.L., Spain, ²Dept. Física Aplicada, Universidad de Vigo, Spain, ³Departamento de Física Aplicada, Universidade de Vigo, Spain, ⁴Departamento de Ciencias Clínicas Veterinarias, Universidade de Santiago de Compostela, Spain, ⁵Orthopaedic Surgeon, Spain

INTRODUCTION

The new generation of materials for medical implants must mimic the smart hierarchical structures present in nature and optimized by evolution. Bio-inspired silicon carbide (BioSiC) is a light and high-strength ceramic, produced from wood, presenting a natural structure similar to the one present in bone tissues, incorporating the unique property of interconnected porosity, which allows the internal growth of tissue and favors angiogenesis.

OBJECTIVES

The aim of this study was to test the osseointegration of BioSiC implants in femoral bone defects in an experimental rabbit model, and the possible enhancement of their bioactivity with a 50 nm surface coating of Si-substituted hydroxyapatite (Si-HA).

MATERIAL AND METHODS

BioSiC cylinders were manufactured from sapelli wood (Entandrophragma cylindricum) with the pyrolysis of selected wood at 1000C in inert atmosphere followed by the infiltration of the obtained carbon preform with molten silicon at 1550C. Of the 36 cylinders produced, 18 were coated with Si-HA (7.5 at. %) by pulsed laser deposition (PLD).

The cylinders were implanted in the femoral condyles of New Zealand rabbits. Animals were sacrificed at 1, 4 or 12 weeks after implantation resulting 3 subgroups for each type of implant. Samples were analyzed by histological examination using optical microscopy and by X-ray micro-computed tomography (micro-CT) to assess bone growth on the periphery and inside the pores of the implants. The statistical comparison was carried out by applying the Mann-Whitney U test and the relationship between both techniques was studied using Pearson correlation.

RESULTS

BioSiC implants showed a good osseointegration presenting both ongrowth and ingrowth. At 4 weeks of implantation the integration was nearly complete with no significant differences between 4 and 12 weeks in any of the analyzed parameters. The Si-HA coating did not significantly improve the value of any parameter with respect to uncoated implants. Histological parameters showed a good correlation with their analog micro-CT parameters.

CONCLUSIONS

BioSiC ceramics, fabricated from porous wood, present a good osseointegration when implanted and its interconnected porosity is colonized by bone tissue, together with lightweight and high strength for optimum biomechanical performance. Additionally, it does not require the bioactivity of a HA coating to improve the apposition of new-formed bone. Thus, BioSiC stands as a new material for biomedical applications.

Conditional Profilin1 Deficiency in Multiple Cell Lineages of Mesenchyme Origin Based on Prx1-Cre System Severely Disrupts Axial and Appendicular Skeletal Development. Daisuke Miyajima^{*1}, Tadayoshi Hayata², Takafumi Suzuki¹, Yoichi Ezura³, Tetsuya Nakamoto¹, Takuya Notomi⁴, Teruo Amagasa⁵, Ralph T Bottocher⁶, Reinhard Fässler⁶, Masaki Noda¹. ¹Tokyo Medical & Dental University, Japan, ²Medical Research Institute, Tokyo Medical & Dental University, Japan, ³Tokyo Medical & Dental University, Medical Research Institute, Japan, ⁴GCOE, Tokyo Medical & Dental University, Japan, ⁵Department of Maxillofacial Surgery, Tokyo Medical Dental University, Japan, ⁶Department of Molecular Medicine, Max Planck Institute of Biochemistry, Germany

Profilin1 (Pfn1), an actin monomer-binding protein, is thought to play key roles in cell activity through modulation of actin cytoskeleton during embryogenesis because Pfn1-null mice die as early as the two-cell stage. The analysis of cartilage-specific Pfn1-deficient mice demonstrated that Pfn1 is required for cytokinesis of chondrocytes (EMBO, 2009). However, the functions of Pfn1 in multi-cellular interplay involved in skeletal development have not been investigated. Since multi-cellular interaction is essential during skeletal development, we hypothesized that Pfn1 may play roles in this regard. To test this hypothesis, we conditionally inactivated Pfn1 by using Prx1-cre mice to examine the influences of Pfn1 deletion in multi cellular interaction during skeletal development. Mice with homozygous deletion of Pfn1 (Prx1-cre⁺; Pfn1^{fl/fl}, Prx1Pfn1) were born at the normal Mendelian ratio. They had complete cleft sternums and died shortly after birth due to inability to breathe. Newborn (P0) Prx1Pfn1 mice exhibited shorter limbs compared with control mice, though their body length was similar to the control. Histological analysis of P0 Prx1Pfn1-limbs revealed that the columnar structures of the growth plate were disorganized and that the hypertrophic zone, where average cell size was enlarged compared to those of control, was expanded to the other end, suggesting that the degradation of the cartilage matrix did not progress normally. In addition, the trabecular bone appearance of P0 Prx1Pfn1 was completely missing. Interestingly, blood cells and osteoclasts of P0 Prx1Pfn1 were localized only in mid-diaphysis. The invasion of blood vessels occurred in mid-diaphysis but the vascular ingrowth did not progress normally at this stage. In vitro experiment revealed that knockdown of Pfn1 by siRNA in MC3T3-E1 osteoblast-like cells inhibited cell migration and proliferation. Taken together, these findings indicate that Pfn1 is required for axial and appendicular skeletal development.

Effects of Different Treatment Regimes on Collagen-Induced Arthritic Response in the Female Lewis Rat. CAROLINE RUH^{*1}, Richard Gregson¹, Aurore Varela², Susan Y. Smith², Richard Watson³. ¹Charles River, Canada, ²Charles River Laboratories, Canada, ³Revaliesio Corporation, USA

The collagen-induced arthritis (CIA) rat model is widely used to assess efficacy of potential drugs to treat rheumatoid arthritis. The study objective was to compare the arthritic response in female Lewis rats following treatment with vehicle controls via different routes of administration and dosing frequencies.

Type II porcine collagen (in IFA) was injected intradermally. As arthritis developed, rats were randomly assigned to 4 groups (10 rats/group). One group was treated daily for 42 days with saline intravenously (IV), one was treated weekly with saline subcutaneously (SC), one was treated daily with water by oral gavage (PO) and one was treated daily with Dexamethasone (Dex) as a positive control to give perspective to the magnitude of changes. Dosing was initiated the day after assignment to study. The following were performed: qualitative arthritis evaluation (AE), paw thickness (PT), C Telopeptide of Collagen type II (CTxII) in serum, X Ray evaluation of ankle joints, macroscopic and microscopic evaluation and paw weights (PW).

There were no notable differences between groups in CTxII, macroscopic observations or PW. The SC group had a higher incidence of disease-related clinical signs when compared to IV and PO. Statistically significant increases were obtained in mean AE results (at Day 43) and PT measurements (by Day 10) for SC when compared to IV and PO. The area under the curve (AUC) for PT was calculated and SC showed a 6% increase in AUC compared to IV or PO. X-Ray evaluation confirmed a higher score for SC with increases of 12 and 21% compared to IV and PO, respectively. Similarly, microscopic evaluation showed higher arthritis scores for SC compared to IV and PO with increases of 13 and 30%, respectively. There were no X Ray lesions or microscopic changes in Dex animals.

In summary, minimal differences in disease severity were observed between the 3 vehicle control treatment regimes, however animals treated once weekly SC were the most severely affected. Animals treated by daily oral gavage showed lower X-Ray and microscopic scores than animals treated by more invasive routes (SC or IV). These results provide intriguing evidence linking disease severity with stress levels that may be influenced by the frequency of manipulation and the ease of the dosing procedure. Thus, when assessing efficacy of a potential drug, the treatment regime for controls should be identical to drug-treated animals to avoid any possible bias associated with stress.

Human Perivascular Stem Cells and Nell-1 in Ectopic Bone Formation. Janette Zara^{*1}, Xinli Zhang², Aaron James², Mirko Corselli², Michael Chiang², Jonguk Chung², Kang Ting², Bruno Peault², Chia Soo². ¹UCLA, USA, ²University of California, Los Angeles, USA

Purpose: Conventional stem cell sources for bone regeneration such as bone marrow stem cells (BMSCs) or adipose derived stem cells (ASCs) have significant drawbacks such as donor site morbidity, low stem cell yield, or long culture derivation time. In comparison, perivascular stem cells (PSCs), a primitive origin of mesenchymal stem cells (MSCs), isolated through fluorescence activated cell sorting (FACS), are a more highly purified cell population that may be more effective in regenerating bone. The objectives of this study are to establish a novel source of stem cells for bone repair combined with potent osteogenic factors, and to compare the osteogenic potential of PSCs to human stromal vascular fraction (SVF) from adipose tissue.

Methods: FACS sorted PSCs (CD146⁺, CD34⁻, CD45⁻, CD56⁻) were derived from human liver, pancreas and adipose tissue, and their osteogenic capacity tested in vitro. In vivo bone formation was tested using 2.5 x 10⁵ PSCs mixed with a 100 uL demineralized bone matrix putty (DBX) and implanted in a nude mouse muscle pouch model. PSC-mediated bone formation was compared to bone formation by SVF + DBX, and DBX alone as control. Each group was also analyzed in the presence of the osteoinductive growth factor Nell-1. Analysis was by RT-PCR, in vivo PSC tracking, microCT, histology, immunohistochemistry, and histomorphometry.

Results: PSCs grown on standard culture ware or DBX scaffold exhibited osteogenic differentiation with elevated gene expression of osteogenic markers and alizarin red staining in vitro. In vivo, PSC implantation resulted in significantly higher bone formation compared to SVF and control, as shown by microCT analysis of bone volume and bone mineral density, histomorphometric analysis of serial sections of aniline blue slides, as well as increased bone sialoprotein (BSP) and osteocalcin (OCN) staining. Furthermore, addition of Nell-1 to PSC resulted in greater bone formation than PSC alone. Nell-1 also exhibited proangiogenic effects on PSCs, both in vitro and in vivo accompanied by elevated VEGF mRNA or protein expression and more small blood vessels throughout the implanted tissues.

Conclusions: These results indicate that human PSCs are a superior new source of stem cells for skeletal regenerative medicine in comparison to human SVF, and that Nell-1 protein is capable of stimulating and enhancing the osteogenic capacity of highly purified human PSCs as well as having proangiogenic effects to facilitate bone formation.

In Vitro Testing of Biomaterial Scaffolds For Musculoskeletal Regenerative Medicine. Brya Matthews^{*}, Vieri Terreni, Sandy Lin, Karen Callon, David Musson, Ji-zhong Bai, Dorit Naot, Jillian Cornish. University of Auckland, New Zealand

Injuries to bone and tendons can cause major morbidity in healthy, active people, particularly if they heal slowly or fail to heal. Providing a scaffold that encourages appropriate cell attachment, growth, and ultimately tissue regeneration could improve the clinical outcomes from injuries such as rotator cuff tears and non-union fractures. We have tested several scaffold materials of both natural and synthetic origin to evaluate their biomaterial properties and their potential utility in musculoskeletal regenerative medicine.

Five different types of scaffolds were evaluated as biomaterials. The natural scaffolds tested were Endoform, a decellularized ovine forestomach matrix, Spidrex

543 spider silk fabric and hydroxyapatite (HA) particles derived from mussel shells and incorporated into collagen gels. Synthetic nanofibrous scaffolds were produced from polylactic acid (PLA) and polyethylene terephthalate (PET) using either electrospinning or a microfibrillar composite (MFC) technique. Attachment, growth and morphology of primary rat osteoblasts, MC3T3-E1 cells and primary rat tenocytes were analyzed using live-dead staining, alamar blue fluorescence and confocal microscopy. Scaffold structure and cell attachment were also evaluated using SEM. Cell differentiation was evaluated by calcein incorporation and gene expression.

Osteoblasts and tenocytes both successfully adhered to, and grew on the luminal and abluminal surfaces of Endoform, and on the silk. SEM examination of the synthetic scaffolds showed that both methods of production create three-dimensional networks. Electrospun scaffolds comprised of a fibrillar, cross-ply structure with 125 - 145 nm diameter fibrils, and MFC scaffolds consisted of an interconnected porous network with 70 - 75 nm fibril diameter. Osteoblast-like cells attached and grew on these scaffolds, with PLA scaffolds tending to show better cell growth than PET material. None of the HA particle preparations tested had a significant effect on osteoblast cell growth when incorporated into collagen gels at a concentration of 0.25%. Cells were able to form new mineralized areas in the presence of HA, and some preparations appeared to promote mineralization.

We have identified a number of scaffold materials that show potential for use in bone or tendon regeneration. More testing is required to determine if they support cell differentiation and appropriate tissue formation.

Lymph Vessel-forming Factors and Receptors in Tooth Development in Mice. Shinya Takahashi^{*1}, Yuriko Moro¹, Hiroki Watanabe¹, Kimiharu Ambe², Toshihiro Nakagawa¹. ¹Ohu University School of Dentistry, Japan, ²OHU University, school of dentistry, Japan

Vascular endothelial growth factor (VEGF) is a family of factors that control angiogenesis and lymphangiogenesis. Factors playing important roles in lymph vessel formation have recently been clarified, such as VEGF-C and -D and their receptor, VEGF receptor 3 (VEGFR-3). In this study, we immunohistochemically investigated lymph vessel formation and control with tooth development in the mouse lower molars using antibodies against VEGF-C and -D and VEGFR-3. We also used von Willebrand factor (vWF) to distinguish between the blood vessels and lymph vessels. Mouse (C57BL/6L) dental papilla and pulp sections were immunohistochemically stained with specific antibodies for VEGF-C, VEGF-D, VEGFR-3 and vWF. In the cap-stage dental papilla after 14 days of gestational age, undifferentiated mesenchymal cells involved in blood and lymph vessel formation showed positive reactions to anti-VEGF-C and -D and VEGFR-3 and vWF antibodies. In the dental papilla in the uncalcified bell stage at 17 days of gestational age, positive undifferentiated mesenchymal cells increased, and lumen-forming endothelial cells also showed positive reactions, but anti-vWF showed a negative reaction. Positive undifferentiated mesenchymal and endothelial cells were also present in the coronal pulp at 0,3, and 7 days after birth, and the number of positive cells increased with aging. At 10 days of age, anti-VEGF-C, VEGF-D and VEGFR-3 staining showed many strongly positive undifferentiated mesenchymal and endothelial cells in the coronal and radicular pulp. The endothelial cells that showed weakly positive or positive reactions to anti-VEGF-C, -D, VEGFR-3 and vWF existed, but the numbers relatively decreased before 10 days of age. These findings suggest that VEGF-C and -D and VEGFR-3 are closely involved in lymph vessel formation on tooth development in mice.

Modulation of Trabecular Bone Formation by Dioxin Exposure and Aryl Hydrocarbon Receptor Ablation. Mikko Finnila^{*1}, Maria Herlin², Antti Aula³, Hanna Miettinen⁴, Merja Korkalainen⁴, Juha Tuukkanen¹, Timo Jamsa¹, Helen Hakansson², Matti Viluksela⁵. ¹University of Oulu, Finland, ²Karolinska Institutet, Sweden, ³University of Eastern Finland, Finland, ⁴National Institute for Health & Welfare, Finland, ⁵National Public Health Institute, Finland

Dioxins are a group of environmental contaminants able to interfere with bone modeling and remodeling. Exposure to these compounds has been shown to decrease bone strength, cortical area and mineralization. Most of the toxic effects of dioxins are suggested to be mediated through the Aryl hydrocarbon Receptor (AhR), a key regulator of cell metabolism, proliferation and differentiation. This study aims to characterize trabecular bone properties after dioxin exposure in wild type (*Ahr*^{+/+}) and AhR knockout (*Ahr*^{-/-}) mice.

Both genders of *Ahr*^{+/+} and *Ahr*^{-/-} mice were exposed once weekly either to the total dose of 200 µg/kg of 2,3,7,8-Tetrachlorodibenzo-p-dioxin or corn oil vehicle (controls) for 10 weeks by oral gavage. Samples were collected one week after the last dosing.

Tibia and L3 vertebra from each mouse were microCT scanned using voxel sizes of 4.7 µm and 9.9 µm, respectively. In tibia volume of interest was drawn starting 0.19 mm after the distal end of the growth plate and extended to 1.64mm towards the metaphysis. For vertebrae corresponding values were 0.1mm and 0.81mm.

Exposure to TCDD increased trabecular bone formation (BV/TV) in vertebra by 55% and 28% (p<0.05) in *Ahr*^{+/+} females and males, respectively, while no effects were seen in either male or female *Ahr*^{-/-}. These trabeculae were significantly thicker, closer to each other and have more plate-like structure. Also a negative trabecular pattern factor indicated that there are enclosed cavities within trabecular network in TCDD exposed *Ahr*^{+/+}. Tibial trabecular bone responded similarly to dioxin exposure, however, AhR ablation caused here site specific increase in trabecular bone formation. However, this increase was not further driven by TCDD exposure. The trabeculae in tibia of *Ahr*^{-/-} were also thicker and closer to each other and had a more plate-like structure, but there were no indications of closed cavities.

Previous observations on serum biomarkers indicated suppressed bone formation and increased bone resorption after TCDD exposure, whereas AhR ablation lead to increase in both formation and resorption markers, supporting the increased trabecular bone formation in *Ahr*^{-/-} presented here. These data suggests that dioxin exposure has opposite effect on trabecular bone than on cortical bone, for which we have previously shown decreased cortical bone area, increased porosity and decreased strength.

Proteoglycan-4: A Dynamic Regulator of Skeletogenesis and PTH Skeletal Anabolism. Chad Novince^{*1}, Megan Michalski², Benjamin Sinder², Payam Entezami², Amy Koh², Matthew Eber², Thomas Rosol³, Thomas Wronski⁴, Kenneth Kozloff⁵, Laurie McCauley¹. ¹University of Michigan, School of Dentistry, USA, ²University of Michigan, USA, ³The Ohio State University, USA, ⁴University of Florida, USA, ⁵University of Michigan Department of Orthopaedic Surgery, USA

Proteoglycan-4 (*prg4*), known for its lubricating and protective actions in joints, is a strong candidate regulator of skeletal homeostasis and parathyroid hormone (PTH) anabolic actions in the skeleton. *Prg4* loss-of-function mutations result in the human condition camptodactyly-arthritis-coxa vara-pericarditis syndrome, which is characterized by precocious joint failure and osteopenia. The purpose of this study was to investigate the role of proteoglycan-4 as a regulator of skeletal development, remodeling, and PTH anabolic actions. C57BL/6 wildtype (WT) mice were subjected to a single PTH (1-34) injection, and bone marrow and liver were harvested at 1, 4, 8, 12 hours for real-time qPCR analysis. Acute PTH treatment regulated gene expression similarly in bone marrow and liver; decreasing PPR, increasing *prg4*, and increasing FGF-2. *Prg4* KO and WT mice were treated with daily intermittent PTH from 4-21d (young model) or 16-22wk (adult model). Joint range of motion and animal mobility were assessed prior to sacrifice. Static and dynamic histomorphometry were carried out in proximal tibiae and micro-CT performed in distal femurs. Bone marrow stromal cells (BMSCs) were analyzed for cell autonomous alterations, serum markers for bone turnover and mineral homeostasis were measured, and bone marrow and liver gene expression were evaluated by real-time qPCR. Young *prg4* KO mice had decreased growth plate hypertrophic zones, trabecular bone, and serum bone formation markers. Adult *prg4* KO mice had decreased trabecular and cortical bone, blunted PTH anabolic responses, but normal bone turnover. Joint range of motion and animal mobility were restricted in adult *prg4* KO mice. Adult *prg4* KO mice had reduced marrow and liver FGF-2 mRNA levels and reduced serum FGF-2 protein levels, which were normalized with PTH treatment. These data suggest proteoglycan-4 supports endochondral bone formation and the attainment of peak trabecular bone mass, while indirectly supporting cortical bone homeostasis via protecting joint function. FGF-2 is a candidate regulator of proteoglycan-4 actions in the support of basal bony trabecular numbers. Finally, blunted anabolic responses in adult *prg4* mutant mice are likely associated with the developmental reduction in bony trabeculae as well as reduced biomechanical impact. The novel finding that PTH similarly regulates gene expression in bone and liver strongly suggests that the liver plays a role in regulating PTH biologic actions.

Tgf-β and Erg in Intervertebral Disc Development. Megan Cox^{*1}, Rosa Serra². ¹UAB, USA, ²University of Alabama at Birmingham, USA

Transforming growth factor β (Tgf-β) signaling plays an integral part in skeletal development. Conditional deletion of Tgf-β type II receptor (Tgfr2) from type II Collagen expressing cells has been shown to cause defects development of the intervertebral disk (IVD) specifically development of the annulus fibrosus was disrupted. We previously used microarray analysis to search for marker genes of IVD as well as transcription factors regulated by Tgf-β during IVD development. The transcription factor Erg was identified in the microarray screen as a candidate regulator of IVD development. To study the in vivo effects of Tgf-β over expression in axial skeleton development, we used the chick model system. Tgf-β soaked Affi-gel beads were placed into the lumbar region of the axial skeleton at stage HH 25. Within 5d post-implantation, we were able to see inhibition of cartilage formation as

determined by Alcian blue staining in the area surrounding the bead. This suggested that Tgf- β acts to suppress cartilage formation. We also showed that the beads soaked in Tgf- β induce mRNA expression of Versican, a marker of IVD development, and Erg, a disc enriched transcription factor, around the bead within 24h. As one of the candidate genes, we created an adenovirus to over-express Erg in primary sclerotomy micromass cultures. Over-expression of Erg led to a change in cell morphology and inhibition of differentiation into cartilage as seen by alcian blue staining. We also demonstrated an increase in expression of several IVD markers in the Erg expressing cultures, suggesting that these cells may be becoming more like annulus cells associated with the IVD. Overall, the data support a model in which Tgf- β acts to maintain the IVD and prevent differentiation into cartilage potentially through the transcription factor Erg. These experiments help to address fundamental questions about development of the axial skeleton and provide a basis for future studies aimed at disc repair or replacement.

In Vivo Analysis of Epithelial Dental and Bone Cell Cross-talks in Transgenic Mice: Experimental Models to Delineate Jaw Bone Specificity. Ariane Berdal¹, beatriz castadena², muriel de la dure molla³, chris mueller⁴, frederic lezot⁵. ¹University Paris-Diderot, France, ²INSERM UMRS 872 University Antioquia, France, ³INSERM UMRS 872 University Paris-Diderot, France, ⁴CNRS, UPR 9021 University Strasbourg, France, ⁵INSERM UMRS 957 University Nantes, France

Jaw bone shows a unique physiopathology, illustrated by regional osteonecrosis under anti-osteolytic agents. Our hypothesis is that Msx2/amelogenin/RANK pathway would play a part in this physiological specificity. Msx2 -/- (knock-in) mice harbour regional jaw osteopetrosis relied to epithelial dental cell (EDC) anomalies (Am J Pathol 177, 2516, 2011). Jaw osteoclast activation impacts EDC fate (targeted RANK overexpression in RANK-Tg mice; J. Cell Physiol., 226: 74, 2011). Msx2 knock-in line was crossed with RANK-Tg line to explore reciprocal EDC/bone cross-talks. Continuously growing incisor and growth-limited molars were analyzed from birth to 6 months. Analysis of microdissected dental and bone tissues by RT-qPCR, Western-blotting was associated with in situ RNA/protein mapping (Msx2, amelogenin, TRAP, PCNA, TNF?) as well as 2D- and 3D-morphology (micro-CT, histology). EDC harboured opposite expression for Msx2 and amelogenin (distribution patterns and relative levels in Msx2 +/-, Msx2 +/- and Msx2 -/- mice). Co-variations in the grade of EDC anomalies and osteoclast impairment characterized Msx2 -/- mice, culminating in the third molar which never erupted. There, EDC islands accumulated over months and overexpressed amelogenin. And, regional decreased RANK ligand and increased Runx2 expression levels (Msx2-/- versus Msx2 +/-) were measured. In the molar region of Msx2-/-; RANK-Tg double mutants, after a transient increase of EDC pool during growth, EDC anomalies and osteoclast impairment were normalised in adults. In contrast, incisor territories exhibited giant osteolytic and hyperproliferative epithelial tumour-like structures relied to increased TNF? expression. (1) From EDC to bone cells, Msx2-dependant amelogenins produced by dental cells would control, as established in the literature, Runx2 and RANK ligand levels and therefore osteoblast/osteoclast balance and (2) from bone to EDC, EDC growing niches were stimulated by activated resorption. Its impact followed specific frames (time-limited, continuous and inflammatory tumour-like growth). In conclusion, in contrast to vertebral and appendicular bones, cell network leading jaw bone balance would include additional EDC partners. According to EDC status which would vary in various bone physiopathological and inflammatory conditions, EDC would deliver specific signals to bone cells.

Molecular Characterization of MMP7-BMP2 Complex and the Implications for Fracture Nonunion. Abdulhazef Selim¹, Hsiu Ying Sherry Wang², Ashraf Moharam³, Marina D'Angelo⁴. ¹Center for Chronic Disorders of Aging, PCOM, USA, ²Inspire Pharma, Egypt, ³Orthopaedic Surgery, Cairo University School of Medicine, Egypt, ⁴Philadelphia College of Osteopathic Medicine, USA

A delayed union or a nonunion of a fracture is a potentially adverse complication. Understanding the mechanisms of nonunion development may lead to improved treatment modalities. Proteases such as the matrix metalloproteinases (MMPs) play important roles in bone remodeling and repair, in which an imbalance or a nonfunctioning enzyme may lead to defects in bone healing (nonunion). MMP-7 and MMP-12 have been identified in fracture nonunion tissue and a role for them in direct binding to and degradation of bone morphogenetic protein-2 has been described. In this pilot study, we generated models of BMP2-MMP complexes and identified the interfacing residues in these complexes. MMP7-BMP2 complex has the following features; 1103.3 Å² interfacing area, Δ^1G -14.4 kcal/M (the solvation free energy gain

upon formation of the interface) indicating high affinity, Δ^1G p-value 0.34 indicating high specificity and 37 residues of MMP7 are interfacing 35 residues of BMP2. Interface analysis predicted formation of 9 hydrogen bonds between MMP7 and BMP2. No covalent bonds, disulphide bonds or salt bridges were predicted. This is the first study to characterize the nature of MMP7-BMP2 interaction at the molecular level. The data in this study will help to further understand the molecular pathology of fracture nonunion.

Salmon Calcitonin Suppressed Chondrocyte Hypertrophy and Cartilage Calcification ex vivo. Pingping Chen¹, Kim Henriksen¹, Kim Vietz Andreassen¹, Morten Karsdal¹, Anne-Christine Bay-Jensen². ¹Nordic Bioscience A/S, Denmark, ²Nordic Bioscience, Denmark

Calcitonin is known as an anti-resorptive agent for the treatment of osteoporosis. However, the application of calcitonin in treatment of joint degenerative disease has likewise been investigated, but is less understood. A key event of cartilage degenerations is hypertrophy, which leads to cartilage calcification. The effect of calcitonin on cartilage hypertrophy and calcification is yet to be understood. The aim of our work was to investigate the effect of salmon calcitonin (sCT) on hypertrophic chondrocytes, in a validated ex vivo model.

Full depth cartilage (FDC) explants (from superficial to calcified cartilage) were isolated from bovine femoral condyle and hypertrophy was induced by culture for 13 days with triiodo-L-thyronine (T3) stimulation. Non-stimulated explants were cultured as control (W/O). Doses of sCT ranged from 1nM to 100nM were added from day 4 to day 13. Type X collagen (COL X) localization on hypertrophic chondrocytes and calcitonin receptor (CTR) expression were evaluated at day 4. Type II collagen (COL II) turnover and aggrecan degradation were measured by PIINP (formation), CIIM (degradation) and AGNx-II assay, respectively. Expression of markers of hypertrophic chondrocytes (Indian hedgehog (IHH), COL X, ALP and MMP-13) were evaluated using RT-PCR at day 13.

At day 4 induction of hypertrophy led to expression of COL X and a ~10 fold higher CTR expression level than W/O (p<0.05). sCT suppressed COL II degradation dose-dependently. In contrast, 10nM sCT showed positive effect on COL II formation whereas 1nM and 100nM sCT did not. Three doses of sCT all decreased aggrecan degradation, in which 1nM sCT had significant effect (p<0.05). The expression of COL X, ALP and MMP-13 were suppressed by doses of sCT, in which 1nM

suppressed COL X expression significantly ($p < 0.01$). 1nM sCT also decreased expression of IHH, whereas 10nM and 100nM sCT did not.

In conclusion, T3 induced hypertrophic chondrocytes. The calcitonin receptor was upregulated in hypertrophic chondrocytes compared to non-hypertrophic chondrocytes. Hypertrophy led to significantly increased levels of cartilage degradation measured by collagen and aggrecan. sCT suppressed expression of markers of hypertrophic chondrocytes, and cartilage degradation. This is the first model of hypertrophic chondrocytes that is an integrated part of the pathogenesis of OA. This model may be used to better understand the molecular mechanism leading to OA, and how to block these processes.

All-Trans-Retinoic Acid Inhibits Intestinal Phosphate Uptake and Type IIb Sodium-Dependent Phosphate Co-Transporter Gene Expression in Rat.

Hironroi Yamamoto^{*1}, Masashi Masuda¹, Mina Kozai¹, Sarasa Tanaka¹, Otoki Nakahashi¹, Shoko Ikeda¹, Hiroko Segawa², Yutaka Taketani¹, Ken-Ichi Miyamoto², Eiji Takeda¹. ¹Dept. Clinical Nutrition, University of Tokushima, Japan, ²Dept. Molecular Nutrition, University of Tokushima, Japan

The hyperphosphatemia is assumed to be one of the causes of the ectopic calcification in dialysis patients. Therefore, the phosphorus (Pi) management by the inhibition of the Pi uptake from small intestine using the Pi-binders and/or the Pi restricted diets is thought to be important by the CKD-MBD treatment and prevention. The type II sodium-dependent phosphate co-transporters family (Npt2a, Npt2b and Npt2c) play a critical role for the Pi homeostasis in kidney and intestine. Recently, we have reported that VAD (vitamin A-deficient) rats increased the levels of urine Pi and renal expression of Npt2a and Npt2c genes are transcriptionally up-regulated by ATRA (all-trans retinoic acid) and its receptors. However, the effect of vitamin A status on the intestinal Pi absorption remains unclear. In this study, we observed the effect of VAD diets and ATRA administration on the Pi homeostasis and Npt2b gene expression in small intestine.

Although plasma levels of Pi, calcium, 1,25-dihydroxyvitamin D and parathyroid hormone did not differ between VAD and control rats, VAD rats significantly decreased feces Pi excretion and increased intestinal Pi uptake activity. Western blots and quantitative RT-PCR analysis revealed that Npt2b protein and its mRNA expression were up-regulated in VAD rats. In contrast, the administration of ATRA significantly suppressed the Pi uptake activity and the Npt2b gene expression in VAD rat intestine. Promoter analysis with a luciferase assay revealed that transcriptional activity of a reporter gene containing the Npt2b promoter was markedly decreased by ATRA and a RAR (retinoic acid receptor)-specific analogue in retinoid receptors (RAR and RXR) overexpressing cells. Furthermore, we identified nRARE (negative retinoic acid responsive element) in the Npt2b gene promoter. These results suggest that ATRA inhibits the intestinal Pi uptake through the negative transcriptional regulation of Npt2b gene in small intestine.

Study of the Phosphaturic Tumors that Cause Tumor-induced Osteomalacia Suggest that they Derive from Inducible Osteoprogenitor Cells. William Chong^{*1}, Rachel Gafni², Alfredo Molinolo³, Nisan Bhattacharyya⁴, Michael Collins². ¹National Institute of Health, USA, ²National Institutes of Health, USA, ³National Institutes of Health, National Institute of Dental & Craniofacial Research, USA, ⁴NIDCR, NIH, USA

Tumor-induced osteomalacia (TIO) is a rare disease characterized by renal phosphate wasting, hypophosphatemia and osteomalacia due to ectopic oversecretion of fibroblast growth factor-23 (FGF23). TIO tumors have been reported in diverse locations, and can occur in bone or soft tissue. Histologically, the majority of these tumors have been classified as hemangiopericytomas, implicating a potential role for pericytes in tumor development. Two lines of reasoning led us to hypothesize that

pericytes in these tumors may be induced by factors yet unknown to become osteoprogenitor-like cells: 1) TIO tumors commonly exhibit bone-related features (osteoclasts, chondroid matrix, and even lamellar bone), 2) the primary physiologic source of FGF23 is osteocytes. In addition, the mammalian target of rapamycin (mTOR) pathway is central to normal cell growth and proliferation, and dysregulation of this pathway has been implicated in tumorigenesis in some vascular-derived tumors. To better understand tumorigenesis in TIO, we investigated bone cell differentiation markers and components of the mTOR pathway.

Tumors from 10 patients with TIO, all of which met the criteria for phosphaturic mesenchymal tumor, but which included a spectrum of histopathologic findings were studied. Immunohistochemical staining for FGF23, bone-related markers and mTOR-pathway markers was performed.

Staining was positive for FGF23 in all of the tumors, consistent with the clinical diagnosis. Tumor cells were positive for CD146, a pericyte marker, RANKL, a marker of osteogenic cells capable of promoting osteoclastogenesis, osteopontin, a late marker in bone cell differentiation, and dentin matrix acidic phosphoprotein 1, a marker for fully differentiated osteocytes. Preliminary findings indicate that the mTOR pathway is activated in a subset of these tumors, suggesting that this may be the driving proliferative pathway for at least some of these tumors.

Based on the positive staining for FGF23 in all the tumors, and for skeletal markers indicative of various stages of differentiation, we suggest that these tumors are derived from cells (perhaps pericytes) that were induced to become osteogenic due to a change in the local environment, and that dysregulation of the mTOR pathway may play a role in TIO tumorigenesis. Increased understanding of the origins of these tumors may enhance understanding of FGF23 physiology and result in new diagnostic and therapeutic options for TIO.

Comparative Gene Expression in Parathyroid Oxyphil and Chief Cells. Cynthia Ritter^{*1}, Bruce H Haughey², Brent Miller³, Alex Brown⁴.

¹Washington University School of Medicine, USA, ²Department of Otolaryngology - Head & Neck Surgery, USA, ³Renal Division, USA, ⁴Washington University in St. Louis School of Medicine, USA

The parathyroid glands (PTGs) of young adults are composed almost entirely of chief cells, but with age and stress another cell type appears: the oxyphil cell. These cells are thought to be derived by transdifferentiation of chief cells, but how and why they form, as well as their function, is totally unknown. Oxyphil cell number increases in PTGs of patients with chronic kidney disease (CKD) and increases further after treatment of hyperparathyroidism with calcitriol and cinacalcet (Lomonte, CJASN 2008). Here, we compared the gene expression in oxyphil and chief cells of PTGs of CKD patients by immunostaining for PTH, PTHrP, CaR, VDR and 25-hydroxyvitamin D-1 α -hydroxylase (1 α OHase or CYP27B1). Oxyphil cells, which are found in defined nodules or as diffuse, undefined "islands," were identified by H&E staining. Both oxyphil nodules and islands expressed PTH at a level equal to or greater than chief cells. PTHrP was most highly expressed in oxyphil islands, compared to lesser amounts in oxyphil nodules and chief cells. CaR was expressed in oxyphil islands at a level equal to or greater than in chief cells, but was virtually absent in oxyphil nodules. The VDR was expressed in both oxyphil nodules and oxyphil islands, at a level equal to or higher than in chief cells. The greatest difference was seen with the 1 α OHase, which was very highly expressed in oxyphil islands, with only trace levels in oxyphil nodules and virtually none in chief cells. The hypothesis that CaR activation by cinacalcet or calcitriol (indirect via Ca) is supported by our observation that incubation of normal rat parathyroid glands in high Ca medium led to the formation of oxyphilic cells. Studies are underway to further characterize and quantify the gene expression profile and secretome of parathyroid oxyphil cells, and to determine the role of these cells (positive or negative) in the morbidity and mortality of CKD patients.

P₁-Transport Links the Functions of PHOSPHO1 and TNAP During the Initiation of Skeletal Mineralization. Manisha Yadav^{*1}, Carmen Huesa², Tina Moreira³, Colin Farquharson⁴, Jose Luis Millan³. ¹Burnham Institute for Medical Research, USA, ²Roslin Institute University of Edinburgh, United Kingdom, ³Sanford-Burnham Medical Research Institute, USA, ⁴Roslin Institute, University of Edinburgh, United Kingdom

Endochondral ossification is a carefully orchestrated process mediated by promoters and inhibitors of mineralization. Tissue-nonspecific alkaline phosphatase (TNAP) plays a crucial role promoting mineralization of the extracellular matrix by restricting the concentration of the calcification inhibitor inorganic pyrophosphate (PPi). TNAP knockout mice (Akp2^{-/-}) faithfully mimic all the skeletal and dental

deficits characteristic of infantile hypophosphatasia. PHOSPHO1, a phosphatase with specificity for phosphoethanolamine (P-Etn) and phosphocholine (P-Cho), has a role in scavenging Pi from MV membrane phospholipids to favor intravesicular hydroxyapatite (HA) deposition. Phospho1^{-/-} mice display growth plate abnormalities, spontaneous fractures, bowed long bones, osteomalacia and scoliosis in early life^{1,2}. Importantly ablation of both TNAP and PHOSPHO1 function leads to complete absence of skeletal mineralization¹. Our working hypothesis is that transporter-mediated influx of extra-vesicular Pi, produced by the ATPase activity of TNAP, contributes to Pi accumulation and HA formation within MVs. This will occur even in the absence of PHOSPHO1 and explains why MVs from Phospho1^{-/-} mice still form mineral. Here, we have used ex vivo metatarsal cultures to provide an initial test for this premise. Metatarsals from E16.5 wild-type (WT) and Phospho1^{-/-} mice were cultured under mineralizing conditions for six days. Three different substrates were used: 4 mM ATP and 10 mM β -glycerolphosphate (β GP) (specific substrates for TNAP), and 3 mM P-Cho, which is hydrolyzed by both TNAP and PHOSPHO1. This experiment was also performed using foscarnet (phosphonoformic acid), an inhibitor of Pi-transporters, and MLS-026839, a specific inhibitor of PHOSPHO1. Mineralization of the WT metatarsals was significantly reduced with foscarnet when using ATP and β GP as substrates but remained unchanged when using P-Cho as substrate. PHOSPHO1 inhibitor MLS-026839 reduced mineralization of the WT metatarsals and adding foscarnet with MLS-026839 reduced it further. Phospho1^{-/-} metatarsals did not show any mineralization with foscarnet when using β GP as a substrate. Experiments are currently underway to confirm these ex vivo metatarsal data using in vitro chondrocytes and osteoblasts cultures as well as their isolated MVs. The data support the premise that Pi-transporters contribute to the PHOSPHO1-generated pool of intravesicular Pi for initiation of MV-mediated mineralization.

Regulation of Bone Homeostasis by Transcription Factor Epiprotein. Takashi Nakamura^{*1}, Takahiro Okabe², Takanaga Ochiai³, Eiki Koyama⁴, Motomi Enomoto-Iwamoto⁵, Satoshi Fukumoto¹, Maurizio Pacifici⁴, Masahiro Iwamoto⁶, Yoshihiko Yamada⁷. ¹Tohoku University Graduate School of Dentistry, Japan, ²Nagano Hospital, Japan, ³Matsumoto dental university, Japan, ⁴Children's Hospital of Philadelphia, USA, ⁵The Children's Hospital of Philadelphia Research Institute, USA, ⁶The Children's Hospital of Philadelphia, USA, ⁷The Laboratory of Cell & Developmental Biology, NIDCR, USA

Formation, growth and homeostasis of skeletal elements are sustained through life by a fine balance between bone deposition and resorption and are regulated by systemic and local factors. Bone homeostasis is particularly important for normal skeletal function, biomechanical adaptation and quality of life and its crucial importance is widely appreciated, but much remains to be understood about its regulation, particularly at the molecular level. Parathyroid hormone (PTH) is a key systemic component of mechanisms regulating calcium homeostasis through its action on bone, kidneys and intestine. PTH is a polypeptide containing 84 amino acids and regulates blood calcium concentration by affecting bone resorption (osteoclastogenesis) and vitamin D action and by enhancing calcium reuptake in renal distal tubules and intestine. Recently we identified Epiprotein/Sp6 (Epf) as a zinc finger transcription factor belonging to the Sp family. *Epf* is preferentially expressed in developing ectodermal tissues such as teeth, and *Epf* ablation causes enamel defect and dentin abnormalities, formation of supernumerary teeth, and dental epithelial multilayering and hypercellularity. We also found that mutant mice are characterized by a severe decrease in bone density and volume in calvaria and other skeletal elements. Surprisingly the expression of *Epf* in bone, kidney or intestine tissues and cells was nearly undetectable. After further inquiry, we discovered that *Epf* is abundantly expressed in the parathyroid gland, but not in the thyroid gland or surrounding tissues. Interestingly, the parathyroid gland in mutant mice was enlarged and the parathyroid cells displayed abnormal cytological characteristics. Moreover PTH levels in blood serum of mutant mice were significantly increased compared with those of control littermates. These results suggest that *Epf* is a novel regulator of parathyroid development and function and bone homeostasis and abnormal development of the parathyroid and overproduction of PTH cause impaired bone formation in *Epf* deficient mice. *Epf* appears to act as a negative modulator or optimizer of PTH expression and could do so by binding the promoter region(s) of PTH gene under the control of calcium sensor receptor signaling.

The extra-long Gas variant XL α s Escapes Activation-Induced Subcellular Redistribution, Thus Leading to Sustained Production of Camp and Severe Impairment of Bone Differentiation. Zun Liu¹, Serap Turan¹, Vanessa Webbi², Jean-Pierre Vilardaga³, Murat Bastepe^{*1}. ¹Massachusetts General Hospital, Harvard Medical School, USA, ²University of Pittsburgh, USA, ³University of Pittsburgh, School of Medicine, USA

Murine models indicate that *G α s* and its extra-long variant XL α s, both of which are derived from *GNAS*, markedly differ regarding their cellular actions, but these differences are unknown. Here we investigated activation-induced trafficking of *G α s* and XL α s, using immunofluorescence microscopy and cell fractionation. In transfected cells XL α s remained localized to the plasma membrane, whereas *G α s* redistributed to the cytosol after activation by GTPase inhibiting mutations, cholera-toxin treatment, or isoproterenol. Total internal reflection fluorescence microscopy of live HEK293 cells transiently expressing type 1 PTH/PTHrP receptor (PTHR) and *G α s*-GFP or XL α s-GFP showed that *G α s*, but not XL α s, was depleted in the plasma membrane upon treatment with 10 nM PTH(1-34). Cholera toxin treatment of PC12 cells expressing *G α s* and XL α s endogenously led to an increased abundance of *G α s*, but not XL α s, in the soluble fraction. Mutational analyses revealed two conserved cysteines, and the highly charged domain as being critically involved in the plasma membrane anchoring of XL α s. An XL α s-*G α s* chimera in which a 72-bp portion of XL α s comprising these regions is added onto the N-terminus of *G α s* behaved similarly to XL α s regarding its subcellular localization upon mutational activation or cholera toxin treatment. Moreover, inhibition of palmitoylation by 2BP treatment resulted in the retardation of XL α s in the soluble fraction, suggesting that palmitoylation is required for the plasma membrane targeting of XL α s at the steady state. To determine whether the retention of activated XL α s in the plasma membrane correlates with enhanced adenylyl cyclase stimulation, we measured cAMP production in live cells by using a FRET-based assay. The cAMP response induced by M-PTH(1-14), a parathyroid hormone analog, terminated quickly in HEK293 cells stably expressing PTHR, whereas the response remained maximal for at least 6 min in cells that co-expressed PTHR and XL α s. Furthermore, a GTPase deficient XL α s mutant (R543H) found in certain tumors and patients with fibrous dysplasia of bone and McCune-Albright syndrome generated more basal cAMP accumulation in HEK293 cells and caused more severe impairment of osteoblastic differentiation of MC3T3-E1 cells than the cognate *G α s* mutant (R201H; *gsp* oncogene). Thus, activated XL α s and *G α s* traffic differently, and this may form the basis for the differences in their cellular actions.

Halofuginone Reduces Bone Metastases:TGF- β dependent and Independent Effects. Patricia Juarez Camacho^{*1}, Khalid Mohammad¹, Ryan McKenna², Holly Davis², Xianghong Peng¹, Desiree Lane¹, Maryla Niewolna¹, Larry Suva³, John Chirgwin¹, Theresa Guise¹. ¹Indiana University, USA, ²University of Virginia, USA, ³University of Arkansas for Medical Sciences, USA

Transforming growth factor- β (TGF β) and bone morphogenic protein (BMP) control cellular processes to maintain homeostasis. Dysregulation of TGF β or BMP activity leads to developmental defects and diseases including bone metastases. Halofuginone (Hfg) is a plant alkaloid derivative with antiangiogenic and antiproliferative

ferative effects. Here we demonstrate that Hfg therapy decreases bone metastasis caused by breast & prostate cancer by inhibiting TGF β and BMP signaling.

Nude mice were inoculated into the left cardiac ventricle with MDA-MB-231/PC3 cancer cells and developed osteolytic bone metastases by 4 weeks. Mice treated with 5 μ g/d Hfg had significantly less osteolysis on x-ray compared with PBS-treated mice (2.11.2 vs 6.23.4mm² p<0.01). Bone histomorphometry showed less tumor in Hfg-treated mice compared to controls (4.31.5 vs 12.22.9mm² p<0.01). Hfg treatment (5 μ g) also decreased mammary fat pad tumor. Similar data were obtained with PC3 prostate cancer.

Further, in MDA-MB-231/PC3 cells, Hfg (100nM, 24h) significantly decreased TGF β -responsive reporter & genes, CXCR4, PTHrP & CTGF, important for bone metastases. Hfg increased Smad7 expression and decreased TGFBR2 levels, but Smad7 knockdown or TGFBR2 overexpression failed to prevent Hfg-inhibition of TGF β signaling. Thus, we studied Hfg effect on BMP signaling pathway. Treatment of MDA-MB-231/PC3 cells with Hfg inhibited BMP-reporter activity & ID1 expression induced by BMP7. Immunostaining of phosphorylated Smad2/3 & Smad1/5/8 showed that Hfg significantly reduced TGF β & BMP signaling in tumor cells from mouse bone metastases compared to control-treated mice.

We tested Hfg effect on bone of mice unaffected by cancer. Hfg (5 μ g) significantly decreased whole body BMD, trabecular & cortical volume and osteoblast number (175 vs 93 p<0.001). Bone marrow cultures from mice treated with Hfg increased TRAP+ osteoclast compared to placebo (1286 vs 803 p<0.001). Hfg effects on bone remodeling are in contrast with other TGF β inhibitors that increase bone mass suggesting that some effects of Hfg are independent of TGF β signaling and may be explained by inhibition of BMP signaling.

Halofuginone completed Phase II trials in sarcoma patients and could rapidly be brought to the clinic for the treatment of bone metastases in breast cancer patients. However, effects of Hfg on normal bone remodeling will need to be assessed in such patients, and measures taken to prevent bone loss at non-tumor-bearing sites.

The Mechanotransduction Pathway Regulates Tumor Response to Rigidity and PTHrP Expression. Nazanin Ruppender¹, Alyssa Merkel¹, Scott Guelcher¹, Julie Sterling^{*2}. ¹Vanderbilt University, USA, ²Vanderbilt University Medical Center, USA

Breast cancer frequently metastasizes to bone where tumors promote bone resorption, pain, and fracture susceptibility. While the pathways regulating tumor-induced bone disease have been much studied, the reasons why tumor cells behave differently in bone versus other tissues has never been fully explained. Studies in soft tissue tumors have indicated that tumor cell behavior and gene expression change as tumors become more rigid. Since bone is several orders of magnitude more rigid than breast tissue or sites of soft tissue metastasis, we reasoned that this substantial difference in rigidity may regulate bone specific gene expression. Indeed, as we have recently published, the expression of parathyroid hormone related protein (PTHrP) and Gli2 (a Hedgehog transcription factor) were increased with increasing substrate rigidity, while other genes associated with tumor-induced bone disease were unchanged. Others have shown that tumors respond to the rigidity of their surrounding matrix through mechano-sensing pathways involving integrin signaling. Therefore, we hypothesized that tumor cell gene expression in response to rigidity is mediated through mechanotransduction signaling in an integrin-dependent manner, and utilized cells with alterations in the integrin-dependent mechanotransduction pathway. We found that inhibition of α v β 3 integrin using the integrin inhibitor LM609 blocked the rigidity-mediated increases in PTHrP and Gli2. Interestingly, this increase was mediated in a TGF- β (transforming growth factor- β)-dependent manner through the co-localization of α v β 3 with TGF- β Receptor type II (RII). Furthermore,

inhibition of down-stream mechanotransduction mediators, such as Src, reduced the rigidity-mediated increase in PTHrP. Additional studies revealed that the TGF- β dependent response was mediated through MAPK and not Smad signaling, since rigidity increased p38 phosphorylation but not Smad 2 or 3 phosphorylation. We have translated this approach to 3D matrices, where similar increases occur in PTHrP expression with increasing rigidity. The 3D matrices are well-tolerated in mice and in vivo experiments are currently underway in which tumor-seeded 3D scaffolds are implanted into the flank of athymic nude mice. In conclusion, these studies suggest that inhibition of mechanically transduced signaling pathways is a potential clinical target for the inhibition of tumor-induced bone disease.

The Relationship Between the Presence of Parathyroid Hormone-related Protein and Molecular Subtyping in Canine Mammary Tumors: A Good Model for Human Breast Cancer. Kristi Milley^{*1}, Chantal Denham², Judith Nimmo³, Samantha Richardson¹, Thomas John Martin⁴, Janine Danks¹. ¹School of Medical Sciences, RMIT University, Australia, ²St John of God Anatomical Pathology, Australia, ³ASAP Laboratory, Australia, ⁴St. Vincent's Institute of Medical Research, Australia

Parathyroid hormone-related protein (PTHrP) has been localized in 60% of primary breast tumors (Southby et al, Cancer Res. 50:7710, 1990) and in 11/13 bony metastases (Powell et al, Cancer Res. 51:3059, 1991). In clinical studies it has been shown that the presence of PTHrP in primary tumors gives a better patient prognosis and a lower rate of metastasis to any site (Henderson et al, Cancer Res. 66:2250, 2006).

In humans, better diagnostic and treatment tools have resulted in limited pathological material available for research and this has lead to a renewed search for new breast cancer models. Some groups have used transgenic animal models and others have suggested natural models, including canine mammary tumors (Rivera et al, Cancer Res. 69:8770, 2009). Dogs are considered a model of natural occurring breast cancer and they live in the same environment as humans and epidemiological, clinical, morphologic and prognostic features similar to human breast cancer.

In this study canine mammary tumors (CMT) have been collected from specialist veterinary pathologists and veterinary surgeons. The large amount of canine mammary tissue is collected as part of normal treatment and this has allowed a direct comparison of full tumor histopathological samples with tissue micro arrays (TMA). These tumours were classified histopathologically and subtyped using a panel of six antibodies using immunohistochemistry (IHC). Molecular subtyping has five subtypes: Luminal A, Luminal B, Basal-like, HER2+ and Normal-like. The antibodies are estrogen receptor (ER), progesterone receptor (PR), epidermal growth factor receptor (HER2), p63, CK5, vimentin, Ki67. This molecular subtypes have been suggested to better reflect patient prognosis (Perou et al, Nature 406:747, 2000) than the current typing by ER/PR status. Seventy-two benign and malignant CMTs had both PTHrP and parathyroid hormone receptor 1 (PTH1R) IHC carried out in both full tumor sections and TMAs. Polyclonal antisera to human PTHrP (1-14) and monoclonal antiserum to PTH1R were used and their presence in the CMTs indicated that there was a relationship between the presence of PTHrP and the molecular subtypes. Luminal subtypes have a better prognosis while Basal-like have a poor prognosis and the PTHrP presence in CMTs reflect this prognostic outlook. This could provide an explanation for the presence of PTHrP in the primary human breast cancers and its association with a better patient prognosis.

Validation Of In Vitro Assays For Identifying Compounds That Affect Breast And Prostate Cancer Cells. Katja Fagerlund^{*1}, Jukka Rissanen², Jani Seppanen¹, Mari Suominen¹, Heikki Vuorikoski¹, Jussi Hallee¹. ¹Pharmatest Services Ltd, Finland, ²Pharmatest Services, Limited, Finland

Breast and prostate cancer are among the most common types of cancer that metastasize to bone. Skeletal metastases can lead to severe pain, pathological fractures, paralysis and eventually increased morbidity. Although there is no curative medication for bone metastases, there are many treatments that can be used to treat the symptoms. Bone resorption inhibitors can be used to inhibit osteolysis, whereas chemotherapy drugs can be used to prevent cancer for spreading. However, the responses to treatments depend on the patient and the type of underlying cancer, and it is therefore of importance to know the direct response of treatment on cancer cells. We have optimized in vitro cancer cell culture models for testing the effects of new chemotherapy agents. MDA-MB-231 and MCF-7 breast cancer cells and PC-3 and LNCaP prostate cancer cells metastasizing to bone were used in the study. Seven known clinically used chemotherapy drugs with different modes of actions, including an alkylating agent N,N'-triethylenethiophosphoramide (ThioTEPA), a pyrimidine analog fluorouracil, an antimetabolic agent Cytosine arabinoside (Ara-C), a topoisomerase I inhibitor topotecan, an anthracycline antibiotic doxorubicin, a mitotic inhibitor paclitaxel and a nucleoside analog gemcitabine, were tested as reference compounds with the range of 1 nM to 1 μ M concentrations. The cells were cultured for 5 days and the effects of the chemotherapy drugs were identified by measuring proliferation of the cells at days 1, 3 and 5 using a commercial WST-1

based proliferation kit. ThioTEPA and fluorouracil showed no effect or only mild effects at 1 μ M concentration on the tested cell lines. Ara-C was a potent inhibitor at 1 μ M concentration, whereas topotecan and doxorubicin were potent inhibitors already at 100 nM concentration. The most potent inhibitors of cancer cell proliferation were paclitaxel and gemcitabine, which were potent inhibitors already at 10 nM concentration. There were no major differences of treatment responses between the cell lines, with the exception that gemcitabine was more potent to breast cancer cells than to prostate cancer cells. These results suggest that paclitaxel, gemcitabine, doxorubicin, topotecan and Ara-C inhibit cell proliferation of breast and prostate cancer cells in this cancer cell culture system. We conclude that this culture system can be used as a screening tool for finding new chemotherapy agents on bone metastatic cancer cells.

Aggravation of Myeloma Growth and Its Drug Resistance By an Acidic Milieu Created in Myeloma-Osteoclast Interaction. Keiichi Watanabe^{*1}, Qu Cui², Masahiro Hiasa³, Makoto Kawatani⁴, Shiro Fujii², Takeshi Harada², Shingen Nakamura², Hirokazu Miki², Ayako Nakano⁵, Kumiko Kagawa², Kyoko Takeuchi², Hiroyuki Osada⁴, Eiji Tanaka⁶, Toshio Matsumoto⁷, Masahiro Abe⁸. ¹The University of Tokushima Graduate School of Oral Science, Japan, ²Department of Medicine & Bioregulatory Sciences, The University of Tokushima Graduate School, Japan, ³University of Tokushima Graduate School, Japan, ⁴Chemical Biology Core Facility, RIKEN Advanced Science Institute, Japan, ⁵University of Tokushima Graduate School of Medicine, Japan, ⁶Department of Orthodontics & Dentofacial Orthopedics, The University of Tokushima Graduate School of Oral Sciences, Japan, ⁷University of Tokushima Graduate School of Medical Sciences, Japan, ⁸University of Tokushima, Japan

Myeloma (MM) cells and osteoclasts (OCs) mutually interact in MM to confer aggressiveness and drug resistance in MM cells along with the progression of bone destruction. The MM-OC interaction appears to create a highly acidic milieu by proton produced by OCs and lactate by MM cells. Reveromycin A (RM-A), a novel anti-resorptive agent, permeates a cell membrane to induce apoptosis only in an acidic microenvironment. The present study was therefore undertaken to clarify the role of an acidic condition in MM tumor growth and drug resistance, and therapeutic effects of RM-A on tumor expansion and bone destruction in MM. Rabbit OCs on bone slices enhanced INA6 MM cell growth; however, blockade of acid release by the proton pump inhibitor concanamycin A partially but significantly reduced the enhancement of MM cell growth, suggesting the role of acid in MM growth. MM cell lines as well as primary MM cells constitutively express pH sensors including TDAG8, OGR1, G2A, and TRPV1 at various levels. MM cell growth was enhanced in media acidified by lactic acid to pH below 7.2. Interestingly, at pH7.0 or lower about a half of MM cells remained intact after treatment for 2 days with doxorubicin at 6 microM and the proteasome inhibitor bortezomib at 30 nM although intracellular accumulation of doxorubicin and subsequent generation of ROS in MM cells were not affected, whereas most cells quickly underwent apoptotic cell death at pH 7.4. Interestingly, MM cells showed up-regulation of Akt phosphorylation when cultured at pH 7.2 or lower, suggesting activation of Akt-mediated survival pathway. In contrast, RM-A marginally affected MM cell viability at pH 7.4, but potentially induced cell death along with caspase-3 activation in MM cells in acidic conditions. Furthermore, treatment with RM-A s.c. at 4 mg/kg twice daily or bortezomib s.c. at 0.5 mg/kg twice a week decreased the progression of tumor as well as osteolytic lesions in bones in human INA6 MM cell-bearing SCID-rab MM models. Of note, RM-A and bortezomib in combination almost completely eradicated MM cells and resumed bone formation. These results demonstrate that an acidic condition potentiates MM growth and confers resistance in MM cells to chemotherapeutic agents. RM-A is suggested to target not only OCs but also MM cells in a highly acidic milieu in MM bone lesions, and its anti-MM effects can be envisaged to be augmented in combination with bortezomib with anabolic actions which is active at non-acidic sites.

Characterization of Bioluminescent Osteosarcoma Orthotopic Model Using Bioluminescent Imaging, Micro-computed Tomography and Histopathology. Rama Garimella*, Jeff Eskew, Priyanka Bhamidi, George Vielhauer, Yan Hong, H Clarke Anderson, Ossama Tawfik, Peter Rowe. University of Kansas Medical Center, USA

Osteosarcoma (OS) is the most common malignancy of bone, mainly affecting children, adolescents and young adults. It is a highly aggressive tumor and typically metastasizes to lungs. Despite aggressive chemotherapy and surgical treatments, the current survival rate is 60-70%. Hence there is a need for clinically relevant models to understand OS pathobiology, and to develop more efficacious treatment strategies. Our long term goal is to apply the bioluminescent orthotopic OS model to screen potential therapeutic agents that enhance the survival rates (especially in patients with

metastasis) by increasing responsiveness to standard cytotoxic drugs or by altering tumor biology. Bioluminescent imaging allows non-invasive tracking of tumor progression in real time. In this study, we developed a bioluminescent orthotopic OS model using the 143 B- OS cell line. We engineered 143B cells to express luciferase using retrovirus transduction techniques. Positive cells were selected in puromycin, expanded and assayed for luciferase activity. Exponentially growing 143B-luc cells were injected into the tibia of Nu/Nu mice, and tumor progression was monitored weekly using the IVIS system. Following intra-tibial injection, the 143B-luc cells formed tumors in the bones and spontaneously metastasized to lungs and kidneys, within four weeks. We detected the presence of m-cherry (fluorescent marker) positive 143B luc cells in the bone and lung sections (Figure 1 A-B). Histological examination showed the presence of actively dividing OS cells in tibias and lungs (Figure 1 C-F). In a defined region of interest at 10X magnification, we observed that the presence of tumor decreased the total bone volume by 19.5%. Segmental micro-computed tomography (μ -CT) analyses revealed a reduction in bone volume/tissue volume (BV/TV) in tumor bearing tibia vs. control (non-tumor) tibia, which needs to be further validated in a larger sample. Micro-CT analyses revealed changes in the bone architecture due to cortical penetration of the tumor in tumor bearing tibia vs. control tibia (Figure 2). Goldner staining on non-decalcified tibial sections indicated the presence of more osteoid in the tumor tissue compared to control, thereby indicating the presence of active osteoid secreting osteosarcoma cells. In conclusion, we have successfully established and characterized a bioluminescent orthotopic model that can be used to study OS pathobiology, and to evaluate potential therapeutic agents.

Figure 1. Photomicrograph illustration showing the presence of m-cherry positive 143B luciferase transduced cells in OS of bone and lung tissue (A-B); evidence of primary tumor in tibia (C-D) and OS metastatic lesions in lungs (E-F)

Characterization of Dkk-1 Expression in an Orthotopic Murine Model of Human Osteosarcoma. Tessa Grabinski, Bart Williams, Kevin Kampfschulte, Matthew Steensma*. Van Andel Research Institute, USA

The identification of factors leading to adoption of a metastatic phenotype represents a key area of research in osteosarcoma, as patients afflicted with metastatic disease experience greatly diminished survival. Upregulated Wnt/ β -Catenin signaling is thought to play an important role in osteosarcoma disease progression. The role of secreted Wnt inhibitors in this process has not been thoroughly evaluated. Elevated serum levels of Dickkopf-1 (Dkk-1) have been detected in patients with osteosarcoma, and correlate with tumor involvement in skeletal and non-skeletal sites. As such, Dkk-1 has been proposed as a suitable biomarker of disease burden. Mechanistically, Dkk-1 is known to play a role in the uncoupling of bone formation in osteolytic cancer, such as myeloma. Dkk-1 expression is Wnt/ β -catenin inducible as part of a negative feedback loop that is presumed to be aberrantly upregulated in osteosarcoma. Our goal is to characterize an animal model that recapitulates Dkk-1 expression in human osteosarcoma. In this way, specific hypotheses regarding the role of Dkk-1 expression as it relates to Wnt signaling can be tested. This model will also be useful for evaluating emerging, Wnt-specific diagnostic and therapeutic reagents.

An orthotopic tibial injection model of osteosarcoma was developed using GFP-expressing human osteosarcoma cell lines (MHOS and 143B; ATCC) that were previously demonstrated by ELISA to produce Dkk-1 in culture media. Following successful tumor induction, Dkk-1 serum levels were correlated with tumor size, quantitative *in vivo* fluorescence, as well as the degree of histologic necrosis in the developing primary tumor. *In vitro* modeling of the effects of Dkk-1 on proliferation (MTT assay), motility (scratch motility assay), osteoblastic differentiation and osteoclastogenesis (qPCR) were performed using an siRNA knockdown strategy for reducing Dkk-1 expression (Qiagen®).

Dkk-1 was readily detectable in mouse sera, and directly correlated with tumor size, intensity of *in vivo* fluorescence, and pulmonary metastasis. Additionally, histologic necrosis was associated with a relative decrease in Dkk-1. Minimal effects on proliferation or motility were observed in the siRNA Dkk-1 hypomorphic cell lines. Knockdown of Dkk-1 increased Axin2 expression indicating possible loss of negative feedback control. These data confirm the relevance of the orthotopic murine model with respect to Dkk-1, Wnt signaling and osteosarcoma disease progression.

Genomic Promoter Occupancy of Runx2 Identifies Genes Involved in Cell Migration and Invasion in Osteosarcoma Cells. Margaretha van der Deen¹, David Lapointe¹, Sneha Gupta¹, Daniel Young¹, Martin Montecino², Jane Lian¹, Janet Stein¹, Gary Stein¹, Andre Van Wijnen^{*1}. ¹University of Massachusetts Medical School, USA, ²Universidad Andres Bello, Chile

Runx-related transcription factors (RUNX1, RUNX2 and RUNX3) are key lineage-specific regulators of progenitor cell growth and differentiation, but also function pathologically as cancer genes that contribute to tumorigenesis. RUNX2 attenuates growth and stimulates maturation of osteoblasts during bone formation, but is also robustly expressed in a subset of osteosarcomas, as well as in metastatic breast and prostate tumors. To assess the biological function of RUNX2 in tumorigenesis, we examined human genomic promoter interactions for RUNX2 using chromatin immunoprecipitation (ChIP)-microarray analysis in osteosarcoma cells (SAOS-2). Promoter binding of both RUNX2 and RNA Polymerase II (RNAPII) was compared with gene expression profiles of cells in which RUNX2 was depleted by RNA interference. The majority of RUNX2 bound loci (1550 of 2339 total) exhibit promoter occupancy by RNAPII and contain the RUNX consensus motif 5'[T/A/C]G[T/A/C]GG[T/G]. Gene ontology analysis indicates that RUNX2 controls components of multiple signaling pathways (e.g., WNT, TGF β , TNF α , and interleukins), as well as genes linked to cell adhesion, migration and/or invasion (e.g., the focal adhesion related genes FAK/PTK2 and TLN1). Trans-well studies reveal that RUNX2 depletion in osteosarcoma cells diminishes cellular invasion and migration. Hence, the metastatic potential of osteosarcomas and non-osseous tumors may be increased by pathological elevation of RUNX2.

Impairment of Osteoblast Differentiation and Activity in Multiple Myeloma Bone Disease: Role of Sclerostin. Silvia Colucci^{*1}, Giacomina Brunetti², Angela Oranger¹, Giorgio Mori³, Giorgina Specchia⁴, Erminia Rinaldi⁴, Paola Curci⁴, Giovanni Passeri⁵, Alberta Zallone⁶, Rita Rizzi⁴, Maria Grano². ¹Department of Human Anatomy & Histology, University of Bari, Italy, ²University of Bari, Italy, ³Department of Biomedical Science, University of Foggia, Italy, ⁴Hematology Section, Bari University, Medical School, Italy, ⁵Department of Internal Medicine & Biomedical Sciences, Center for Metabolic Bone Diseases, University of Parma, Italy, ⁶University of Bari Medical School, Italy

Wnt signalling through the secretion of Wnt inhibitors DKK1, sFRP-2 and -3 plays a key role in the decreased osteoblast activity associated with multiple myeloma (MM) bone disease. We provide evidence that another Wnt antagonist, sclerostin, an osteocyte-expressed negative regulator of bone formation, is expressed by myeloma cells, i.e. human myeloma cell lines (HMCLs) and plasma cells (CD138+ cells) obtained from the bone marrow of a large number of MM patients with bone disease. We demonstrated that bone marrow stromal cells (BMSCs), differentiated into osteoblasts and co-cultured with HMCLs showed, compared with BMSCs alone, reduced expression of major osteoblastic specific proteins, decreased mineralized nodule formation, and attenuated expression of members of the AP-1 transcription factor family (Fra-1, Fra-2 and Jun-D). Moreover, in the same co-culture system the addition of neutralizing anti-sclerostin antibodies restored osteoblast functions by inducing nuclear accumulation of β -catenin. We further demonstrated that the up-regulation of RANKL and the down-regulation of OPG in osteoblasts were also sclerostin mediated. Our data indicated that sclerostin secretion by myeloma cells contribute to the suppression of bone formation in the osteolytic bone disease associated to MM.

Longitudinal preclinical microCT scanning: Maintaining Biological Relevance in Non-Invasive Metastatic Burden and Osteolysis Monitoring. Ning Zhang¹, Jay Whalen¹, Anna Christensen^{*2}, Magdalena Bazalova³, Jeff Meganck¹, Ed Lim¹. ¹Caliper Life Sciences, USA, ²Caliper LifeSciences, USA, ³Stanford University, USA

Non-invasive imaging is commonly used in longitudinal studies of small animals. Biologically relevant models are essential in characterizing pathological processes and monitoring therapeutic responses. This has not been possible with earlier generation in vivo microCT systems that resulted in radiation doses high enough to potentially impact the underlying biology. New technologies in microCT have enabled true longitudinal assessment of disease with minimal radiation doses by minimizing the scan time. The following work will discuss the Gafchromic film dosimetry evaluation of the Quantum FX standalone microCT scanner for longitudinal monitoring of metastatic tumor burden and bone osteolysis non-invasively in biologically relevant conditions. Dosimetric evaluations showed a mean body dose starting at 8mGy per 17 second scan at 90KV. The dose range from the Quantum FX scanner allowed us to take multiple scanning time points to characterize the development of osteolysis without radiation artifact. The metastatic tumor burden of MDA-MB231 mammary carcinoma cells was concurrently monitored through bioluminescent optical imaging on an IVIS Spectrum validating the characteristic metastatic potential of this model for anatomical microCT assessment.

Novel Bis-Cyclic Thioureas, Identified from Combinatorial Libraries, Inhibit the Proliferation and PTHrP Expression of Pancreatic Cancer Cells. Douglas Burton^{*1}, Randolph Hastings², Adel Nefzi³, Su Tu², Leonard Defetos⁴. ¹VA San Diego Healthcare System / University of California, San Diego, USA, ²VA San Diego Healthcare System / University of California San Diego, USA, ³Torrey Pines Institute for Molecular Studies, USA, ⁴Veterans Administration San Diego Healthcare System & University of California, USA

Background: PTHrP (parathyroid hormone related protein) is commonly expressed by pancreatic cancer cells and this oncoprotein can influence the progression of this malignancy. Recently we discovered, through combinatorial library screening, bis-cyclic thioureas compounds that inhibit lung cancer cell PTHrP expression and retard the growth of PTHrP-expressing lung cancer cells. The focus of this study was to evaluate these compounds for their effects on pancreatic cancer PTHrP expression and growth.

Methods: In vitro studies were conducted using human pancreatic cancer cell lines (BxPC-3 and CFPAC-1) treated with 2 µg/ml bis-cyclic thiourea compounds (#2 and #17). We measured PTHrP expression and cell growth over 7 days by immunoassays and MTT assays and compared the bis-cyclic thiourea treatment groups to the vehicle control (DMSO) treatment group.

Results: The bis-cyclic thiourea compounds significantly inhibited PTHrP expression and cell proliferation compared to the vehicle control treatment and the effects were directly proportional to the pancreatic cell basal PTHrP expression. The most dramatic inhibitory effects were observed in the BxPC-3 cells (>65% inhibition of PTHrP and growth). Less inhibitory effects were demonstrated on the CFPAC-1 cells (approx. 20% inhibition of PTHrP and growth). Compound #2 was more potent in both cell lines compared to compound #17.

Conclusions: Bis-cyclic thiourea molecules inhibit PTHrP expression and growth of PTHrP-producing pancreatic cancers. Cyclic thioureas could find clinical utility either as anti-neoplastic agents for innovative treatments of PTHrP expressing cancers or as treatments for hypercalcemia of malignancy.

Opposing Survival Effects of Amino and Carboxyl-Terminal PTHrP in Non-Small Cell Lung Carcinoma Patients. Randolph Hastings^{*1}, Philippe Montgrain¹, Rick Quintana¹, Ann Tipps², Douglas Burton¹, Leonard Defetos³. ¹VA San Diego Healthcare System / University of California San Diego, USA, ²University of California San Diego, USA, ³Veterans Administration San Diego Healthcare System & University of California, USA

Introduction: From our previous work, we know that tumor expression of carboxyl-terminal PTHrP is a positive prognostic indicator in women with non-small

cell lung carcinoma (NSCLC). In contrast, a recent study suggests that amino-terminal PTHrP is associated with shorter survival in lung adenocarcinoma patients. The goal in this study was to tumor evaluate amino and carboxyl PTHrP immunoreactivity in the same group of NSCLC patients and investigate survival implications.

Methods: Amino PTHrP expression was assessed by immunohistochemistry in tumor samples from 165 patients with NSCLC. Carboxyl PTHrP had been determined previously in the same samples. A pathologist unaware of the clinical history classified specimens as PTHrP-positive or PTHrP-negative. The log-rank test and Cox regression were used to analyze survival as a function of PTHrP expression and other covariates.

Results: By odds of 6:1, lung carcinomas in males expressed amino and carboxyl PTHrP together rather than carboxyl PTHrP alone. A larger proportion of female carcinomas were solely carboxyl PTHrP positive. Amino PTHrP and carboxyl PTHrP were significant and independent negative and prognostic indicator with hazard ratios for death of 1.7 (P = 0.031) and 0.6 (P = 0.018), respectively. Patients with carboxyl PTHrP-positive/amino PTHrP-negative carcinoma had the longest survival overall and those that were amino positive/carboxyl negative had the shortest lifespans.

Conclusions: Amino and carboxyl PTHrP have independent and opposing associations with lung cancer patient survival. Dual expression of the two epitopes differs between male and female patients. This factor combined with the differing survival effects could explain the apparent restriction of a carboxyl PTHrP survival effect to females was associated with a survival advantage in female patients. Future work is indicated to determine whether the sex-based difference in lung cancer PTHrP peptide expression depends on variable processing of the prohormone and whether the effects could be targeted for therapeutic purposes

Specific Receptor Tyrosine Kinases (RTKs) are Novel Therapeutic Targets for Osteosarcoma. Ashley Rettew^{*}, Mee Jee Lee, Patrick Getty, Edward Greenfield. Case Western Reserve University, USA

One-third of osteosarcoma patients succumb to pulmonary metastasis despite high-dose neoadjuvant chemotherapy protocols. These survival rates have not improved over the last 30 years. Tyrosine kinases have emerged as targets for new cancer therapies. Using phosphoproteomic screening of 42 individual RTKs, we identified 10 RTKs that were phosphorylated and previously unstudied in 143B and/or LM7 metastatic human osteosarcoma cell lines. An siRNA screen using pools of 4 individual duplexes to target each of the 10 activated RTKs demonstrated that 9 siRNA pools inhibited the in vitro phenotype (invasion, motility, cell growth and/or colony formation) of one or both cell lines. Since the major caveat of siRNA is the possibility for off-target effects, we individually tested the four siRNA duplexes to validate the pooled results. In these experiments, the pattern of phenotype inhibition replicated the pattern of knockdown by the individual duplexes for 6 of the 9 RTKs, indicating that those effects are consistent with on-target silencing. For example, in LM7 cells, the FGFR2 pool and two duplexes knocked down FGFR2 expression by >80% and inhibited motility and colony formation by ≥35% whereas the other two duplexes only reduced expression levels by <60% and had little to no effect on phenotype. To further validate the individual duplex experiments, approaches other than siRNA were used to inhibit the RTKs. Antisense-mediated knockdown targeting EphB2 or Ret significantly inhibited colony formation and motility in LM7 cells (p<0.05) demonstrating that the effects of EphB2 and Ret inhibition are on-target. Antisense-mediated knockdown of EphA2 demonstrated off-target effects in 143B cells. The translationally relevant small molecule inhibitors (SMIs) PD173074 and R428 were used to inhibit FGFRs or Axl, respectively. PD173074 inhibited motility and colony formation in both cell lines (p<0.001) and invasion in LM7 cells (p=0.03) in a dose-dependent manner. R428 reduced motility and colony formation in a dose-dependent manner in 143B cells (p<0.001). Moreover, R428 or PD173074 caused pre-formed colonies to undergo rapid changes in cell morphology consistent with cell death. In conclusion, our results indicate that specific RTKs (Axl, EphB2, FGFR2, FGFR3 and Ret) contribute to the in vitro behavior of metastatic osteosarcoma cell lines and are novel therapeutic targets for osteosarcoma.

The Synthetic Inhibitor of ZZ Domain of Sequestosome-1/p62 Inhibits Both Stromal Cell Independent and Dependent Myeloma Cell Growth and Osteoclast Formation. Jumpei Teramachi^{*1}, Kyaw Ze Yar Myint², Rentian Feng², Xiang-Qun Xie², G. David Roodman³, Noriyoshi Kurihara⁴. ¹University of Pittsburgh & The Center for Bone Biology at UPMC, USA, ²University of Pittsburgh, Pharmaceutical Sciences, USA, ³University of Pittsburgh, The Center for Bone Biology at UPMC, & VA Pittsburgh Healthcare System, USA, ⁴University of Pittsburgh & The Center for Bone Biology, USA

The marrow microenvironment plays a critical supportive role in myeloma (MM), and enhances both tumor growth and bone destruction through MM cell derived TNFα activation of multiple signaling pathways in marrow stromal cells. We reported that sequestosome 1 (p62) plays a key role in the formation of signaling complexes

that result in NF- κ B, p38 MAPK and PI3K activation in the marrow stromal cells of patients with MM that result in enhanced MM growth and OCL formation. Recently, we generated deletion constructs of p62 that lacked specific p62 domains: PB1, ZZ, p38, TBS and UBA, to identify the domains of p62 responsible for increased MM cell growth and osteoclast (OCL) formation mediated by NF- κ B and p38 MAPK signaling, as a means to develop inhibitory peptides/molecules as potential therapeutic agents for MM. We transfected these constructs into a p62-knockout stromal cell-line and found that the ZZ domain is required for stromal cell support of increased MM cell growth, IL-6 production, VCAM-1 expression and OCL formation. These results suggest that dominant negative constructs or small molecules that target the ZZ domain of p62 should inhibit stromal cell support of MM cells and OCL formation by the marrow microenvironment. Therefore, we developed a p62-ZZ inhibitory small molecule (MW:363.5) and tested this compound for its capacity to block the enhanced myeloma cell growth, IL-6 production, VCAM-1 expression on stromal cells and OCL formation induced by TNF- α . TNF- α specifically induces PKC ζ phosphorylation that is activated via p62-ZZ. MM1.S myeloma cells or normal human CFU-GM, a source of OCL precursors, were co-cultured with human stromal cells in the presence or absence of the p62-ZZ inhibitor. The inhibitor (10 μ M) directly blocked MM cell growth by 90% compared to vehicle. VCAM-1 expression and IL-6 production by stromal cells induced by TNF- α was blocked by 30% and 90% respectively compared to vehicle controls. This compound at 10 μ M did not change the proliferation of stromal cells by the MTT assay. Further, the TNF- α induced PKC ζ phosphorylation in stromal cells and MM1.S was blocked when the cells were pre-treated with this p62-ZZ inhibitory compound for 3 hours. These results suggest that synthetic compounds that target the ZZ domain of p62 and can inhibit MM cell growth and OCL formation induced by the marrow microenvironment by blocking p62 function.

The Transcription Repressor Gfi1 Directly Interacts with the *Runx2* Gene In Osteoblast Precursors To Mediate Repression by Multiple Myeloma Cells Via TNF- α , Leading To Blocked Osteoblast Differentiation. Shunqian Jin^{*1}, Sonia D'Souza¹, Quanrong Sun¹, Benedicte Sammut¹, H. Leighton Grimes², G. David Roodman¹, Deborah L. Galson¹. ¹University of Pittsburgh, Medicine/Hematology-Oncology, The Center for Bone Biology of UPMC, & VA Pittsburgh Healthcare System, USA, ²University of Cincinnati College of Medicine/Division of Immunobiology, USA

Multiple myeloma (MM) is a plasma cell malignancy that is the most frequent cancer to involve the skeleton. MM bone disease is characterized by the formation of lytic bone lesions adjacent to MM cells that rarely heal even when patients are in long-term remission due to a persistent suppression of bone marrow stromal cell (BMSC) differentiation into osteoblasts (OB). We have previously reported that MM cells induce a long-lasting suppression of OB differentiation by repression of the *Runx2* gene, through elevated expression of the transcription repressor Gfi1. These changes were also mediated by TNF- α . Co-transfection reporter assays in MC-4 cells showed that the mouse *Runx2* promoter was repressed by MM cells and TNF- α , and was also repressed in a dose-dependent manner by cotransfection with wild-type (wt)-Gfi1 protein, and surprisingly, by the Gfi1N382S DNA-binding mutant, although not as efficiently as wt-Gfi1. We conducted detailed analyses to determine if Gfi1 directly represses the *Runx2* promoter and to identify the *Runx2* promoter sequences responsible for the Gfi1-mediated repression. Deletion analyses and biotin-oligonucleotide pull-down assays revealed that the -40~-1 region of the *Runx2* promoter is the main site of Gfi-1 binding, that the binding was specific by competition assays, and that the entire C-terminal Zn-finger region of Gfi1 is necessary and sufficient for binding. Importantly, these assays provided further proof that both wt-Gfi1 protein and the Gfi1N382S (albeit weaker) could bind directly to this region. The Gfi1 binding site was mapped within the -40~-1 region to an unusual palindromic double Gfi1 binding site, AAGCTT and confirmed by EMSA. Oligos with mutations of either AA or TT are still bound by wt-Gfi1, but not by Gfi1N382S, whereas mutation of both sides results in a complete lack of wt-Gfi1 binding. Luciferase assays with site-specific mutant *Runx2* promoter reporters demonstrated that this Gfi1 binding site is responsible for the Gfi1-mediated repression as well as part of the TNF- α -induced repression. Strikingly, chromatin immunoprecipitation revealed that Flag-Gfi1 binds within -111/+123 region of the endogenous *Runx2* promoter in MC-4 cells, confirming that Gfi1 binds the endogenous *Runx2* gene. Thus, these results indicate that MM cell secretion of TNF- α induces the transcription repressor Gfi1, which is directly involved in the repression of *Runx2* expression in OB precursor cells, thereby preventing OB differentiation.

Soft Tissue Postraumatic Calcifications Associated with a New *FGF23* Gene Mutation: Clinicopathological and Molecular Genetic Study. Maria Luisa Brandi¹, Deobra Strigoli², Caterina Fossi², Cristiana Casentini², Gigliola Leoncini², Sergio Fabbri², Francesco Franceschelli², Gemma Marcucci², Loredana Cavalli¹, Francesca Giusti², Laura Masi^{*1}. ¹University of Florence, Italy, ²Metabolic Bone Diseases Unit, Italy

Extraskelatal calcifications of soft tissues are not rare radiographic finding. However, parts of these constitute a rare familial condition indicated as Tumoral Calcinosis (TC). It is a familial disease characterized by a phosphate disorder due to mutations of one of the genes coding phosphatonins (FGF23, GALNT3 or KLOTHO gene). Localized trauma can be responsible of deposition of calcium and phosphate in soft tissues with small nodules that may ulcerate, extruding a chalky with material identified as hydroxyapatite similarly with TC. In the literature, no phosphatonins gene mutations have been so far described in these patients. In the present study we evaluated the role of phosphatonins in a patient with postraumatic soft tissue calcifications. The patient is a man 44 yrs old with a history of traumatic fracture of the right tibia. Fracture was follow by a hemorrhage around the bone and the formation of nodule 10 cm diameter in the peroneal muscle. The histopathological analysis of the mass showed the deposits of calcium. The patient exhibited a normophosphatemia [2.9 mg/dL (n.v.: 2.7-4.5)], normocalcemia [9.6 mg/dL (n.v.: 8.2-10.7)]. Urine calcium and phosphate were in the normal range. A very low level of 25 hydroxyvitamin D3 was observed [5.7 ng/ml (n.v.:30-70)] with PTH circulating levels slightly upper normal range [8.1 pmol/L (n.v.: 1.3-7.6)]. Genomic DNA was extracted from peripheral blood collected from patient using the microvolume extraction method QIAamp DNA Mini Kit (Qiagen GmbH, Hilden, Germany), according to the manufacturer's instructions. Intact FGF23 serum level and C-terminal fragment were determined by ELISA. We found a new heterozygous (GGC>AGC) codon 240 Gly/Ser substitution in exon 3 of FGF23 gene. No mutations of the GALNT3 and KLOTHO genes were detected. Circulating intact and C-terminal fragment measurement showed a high level of inactive C-terminal fragment (90 RU/ml) a low level of active FGF23 (10.2 pg/ml). In conclusion we described a new mutation of FGF23 associated with formation of extraskelatal calcifications. C-terminal FGF23 fragment is usually very high in the serum of the patient after a bone fracture. However, the levels return in the normal range after 15-20 days. In the present case C-terminal fragment was measure after 6 months from the injury. We could speculate the FGF23 gene mutation could alter the normal production of FGF2 and may be favor the deposition of calcification after an injury.

Vitamin D Status in Ireland: Post IOM Interpretation. Malachi McKenna^{*1}, Barbara Murray¹, Mark Kilbane². ¹St. Michael's Hospital, Ireland, ²St. Vincent's University Hospital, Ireland

Background: The Institute of Medicine (IOM) in a recent public health report on dietary requirements for calcium and vitamin D in North America contained three important findings for clinicians: (1) a serum 25-hydroxyvitamin D (S-25OHD) level above 50 nmol/L meets the needs of 97.5% of the population for all life stages, (2) a S-25OHD level above 125 nmol/L could indicate those at risk of harm from over-replacement, and (3) a simulated dose-response formula is given for estimating the expected S-25OHD based on total oral vitamin D intake. We and others over the past 30 years have identified high prevalence of poor vitamin D status in Ireland. So we reviewed our recent experience of vitamin D status in the light of the IOM report both in healthy subjects and those with illnesses.

Methods: S-25OHD was measured in a diverse group of Irish subjects (n=1254): healthy adults during winter, patients with multiple sclerosis during winter; mothers at term and cord samples from their offspring; preterm infants at about 3 weeks old and again at about 15 weeks old; osteoporosis patients on low-dose vitamin D supplementation; and cystic fibrosis patients on low-dose vitamin D supplementation.

Results: In healthy adults during winter 33% were \geq 50 nmol/L compared to 28% of MS patients. Mothers at birth (45%) were more likely than their offspring (13%) to have levels \geq 50 nmol/L. Preterm infants at about 3 weeks were less likely to have levels \geq 50 nmol/L compared to same infants after prolonged augmented vitamin D intake of 400 IU/d (13% vs 86%), but of the later 25% were $>$ 100 nmol/L and 8% were $>$ 125 nmol/L. Osteoporosis patients on supplementation (723200 IU/d) achieved level \geq 50 nmol/L in 91% but cystic fibrosis patients on supplementation (1380447 IU/d) were less successful (Table 1). Using data from a previous study we calculated the dose-response to low-dose vitamin D and noted an increase 8.4 nmol/L/100 IU that is over fourfold higher than the oft quoted expected rise of 1.8 nmol/L/100 IU, but was similar to the IOM simulated dose-response.

Conclusion: The IOM offers a standard and a gauge for guaranteeing adequate vitamin D status in the Irish population but in our more northerly latitude we have an even greater dependence on oral intake in ensuring optimal vitamin D status. We found a high prevalence of poor vitamin D status in our unsupplemented groups; however for many infants 400 IU/d is excessive.

Groups	N	S-25OHD nmol/L				
		<30	30-49	≥50	>100	>125
Healthy adults during winter	229	21%	46%	33%	0%	0%
Multiple sclerosis patients during winter	331	40%	32%	28%	2%	1%
Healthy pregnant women at term	39	21%	34%	45%	3%	0%
Umbilical cord samples at term	39	59%	28%	13%	0%	0%
Preterm infants at 3 weeks	272	21%	65%	14%	1%	0%
Preterm infants at 15 weeks (supplemented)	148	3%	11%	86%	25%	8%
Osteoporosis outpatients (supplemented)	91	1%	8%	91%	20%	2%

Epidemiology of Paget's Disease of Bone in the City of Recife, Brazil. Rainier Reis¹, MaÚra Poncell¹, Daniele Fontan², Erik Diniz², Francisco Bandeira³. ¹University of Pernambuco Medical School, Brazil, ²Division of Endocrinology, Agamenon Magalhaes Hospital, Brazil, ³UPE, Brazil

The aim of this study was to determine prevalence and incidence of Paget's disease of bone (PDB) between 2006 and 2009 in one institution in the city of Recife, Northeast Brazil. All patients aged 45 years and over attending the Pernambuco Osteoporosis Centre at the Endocrine and Diabetes Department were assessed. Serum alkaline phosphatase (SAP) was measured in all patients and pelvis X-rays taken previously for other medical reasons were also evaluated. When levels of SAP were elevated, bone scintigraphy was performed to identify possible affected sites. High bone turnover areas on scintigraphy were then examined using radiographies, which were used as gold standard for diagnosis of PDB. Period prevalence (PP) and incidence density (ID) were calculated for each year for males and females separately, with confidence intervals (CIs) and hypothesis test for difference between proportions. CIs for PP were estimated assuming a Binomial distribution, and expressed as percentage of every 1000 patients. Annual ID was computed as new cases arising from the beginning to the end of each year, divided by the assessed population and expressed as number per 10 000 person-years; CIs were calculated assuming a Poisson distribution. All statistical calculations were made using the MINITAB software Version 15. The present study was approved by the Research Ethics Committee of the Agamenon Magalhaes State Hospital.

A total of 7752 patients were assessed of which 53 presented with PDB. The age ranged from 53 to 90 years, with a mean of 69.53 ± 8.51 years. The total PP was 6.80/00 and a statistically significant increase from 4.20/00 in 2006 to 12.70/00 in 2009 was observed (p=0.013). The prevalence rates increased in both sexes during the period, although it did not reach statistical significance (p=0.058 for males and p=0.119 for females). Males were predominantly affected. The ID for PDB was 50.3 per 10 000 person-years for the period 2006-2009. A statistically significant increase from 34.6 in 2006 to 103.2 per 10 000 person-year in 2009 was observed (p=0.026). Males presented a statistically significant increase in the ID rates over this period (p=0.032). Such trend was not seen in females (p=0.307).

Our data show that prevalence and incidence rates of PDB in Recife are comparable to those from Southern Europe. No trends of decline either in prevalence or in incidence rates were observed. To our knowledge this is the first epidemiological study of PDB in South America.

Table 1. Period prevalence (PP) of Paget's disease of bone 2006-2009, in Recife, Brazil

Year	2006	2007	2008	2009	2006-2009
Total

Bone Mineral Density (BMD) Assessment in Patients with Primary Hyperparathyroidism (PHPT) before and one year after Parathyroidectomy (PTX). Eugénie Koumakis¹, Jean-Claude Souberbielle², Didier Borderie³, Emile Sarfati⁴, Soueda El Kettani¹, Andre Kahan¹, Catherine Cormier⁵.

¹Rheumatology Department A, Cochin Hospital, APHP, Paris Descartes University, France, ²Laboratoire d'exploration fonctionnelles, Hôpital Necker-Enfants Malades, France, ³Laboratoire de Biochimie générale et spécialisée, Cochin Hospital, APHP, Paris Descartes University, France, ⁴Department of endocrine Surgery, APHP, Hôpital Saint-Louis, France, ⁵AP-HP Groupe Hospitalier Cochin, France

PHPT is a frequent cause of secondary osteoporosis. Increase in BMD following PTX has been reported in numerous studies. Subclinical PHPT is increasingly diagnosed in osteoporosis patients. It is unclear whether patients with a milder phenotype might benefit from PTX. This study was to investigate BMD changes in PHPT patients before and one year after PTX, and to compare BMD changes between patients with classic PHPT and a milder phenotype of PHPT.

Patients and Methods: single center longitudinal study of 55 PHPT patients aged 63.10 ± 6.6 years with mean T-score at the spine, femoral neck and total hip of -2.51 ± 0.29, -2.34 ± 0.74 and -1.80 ± 0.82 respectively. A history of fracture and osteoporosis were reported in 41.8% and 90.7% of cases, respectively. 23 patients had both an elevated pre-PTX serum total and ionized calcium level (group 1), while the remaining 32 had normal pre-PTX total and/or ionized calcium (group 2). All patients were operated on with complete resolution of PHPT (normal serum total and ionized calcium, phosphate, and PTH 3 months after PTX). BMD was evaluated using QDR 4500 (Hologic) before and one year after PTX. Paired data were assessed with the Wilcoxon rank test, and unpaired data were assessed with the Mann-Whitney test.

Results. In the 55 PHPT patients, BMD increased significantly one year after PTX by 3.25.1% at the spine (p=0.0001), 3.05.6% at the femoral neck (p=0.0002) and 3.35.3% at the total hip (p=0.0001). In group 1 patients, BMD increased significantly by 4.84.5% at the spine (p=0.0001), 4.65.9% at the femoral neck (p=0.0019), and 2.94.5% at the total hip (p=0.0005). In group 2, BMD increased significantly by

1.85.1% at the femoral neck ($p=0.031$) and 2.76.1% at the total hip ($p=0.048$) but not at the spine (2.05.2% gain, $p=0.098$). The BMD gain was more important at the spine in group 1 than in group 2 patients ($p=0.0076$), but there was no difference in BMD gain between the 2 groups at the femoral neck and total hip ($p=0.15$ and $P=0.16$ respectively). In group 2 patients, hyperplasia and multiple adenomas tended to be more frequent than in group 1 patients, although not significantly.

Conclusion. In these PHPT patients, BMD increased significantly after PTX at the spine and hip. Even in patients with normal pre PTX serum total and/or ionized calcium, a significant increase was observed at the hip. This highlights the need for a biological exploration in osteoporosis patients to exclude secondary causes of low bone mass.

Carotid Plaque Calcification is Increased in Mild Primary Hyperparathyroidism. Marcella Walker^{*1}, Tatjana Rundek², James A. Lee³, Chiyuan Zhang¹, Donald J. McMahon¹, Ralph L. Sacco², Shonni J. Silverberg¹. ¹Columbia University, USA, ²University of Miami, USA

We have previously reported that patients with mild primary hyperparathyroidism (PHPT) have evidence of subclinical carotid atherosclerosis including increased carotid intima-media thickness and decreased vascular compliance. Although carotid plaque was no more common in PHPT compared to controls, recent advances in ultrasound imaging now allow for the determination of plaque morphologic composition including the degree of plaque calcification. Of 49 patients with mild PHPT, 20 (41%) had carotid plaque (age: 65.7; serum calcium 10.40.5 mg/dl; PTH 11358 pg/ml). We compared their plaque morphology with that in 27 age-, sex- and race-matched controls with plaque. Age, BMI, renal function, history of hypertension, diabetes, smoking, hypercholesterolemia, or myocardial infarction did not differ between the two groups. On carotid ultrasound, PHPT and controls had similar average plaque number (2.2 1.3 vs. 2.3 1.4, $p = 0.72$), maximal carotid plaque thickness (MCPT; 2.10.5 vs. 2.20.7 mm, $p=0.59$) and plaque area (17 14 vs. 19 16, $p = 0.70$), all estimates of the burden of atherosclerosis. Overall plaque composition (echogenicity, reflecting content of lipid-rich, calcified and mixed areas) was also similar (88 25 vs. 9229, $p=0.58$). However, within the echodense (calcified) portion of plaque, the degree of calcification was higher in PHPT (15891 vs. 10639, $p=0.02$). Degree of calcification did not correlate with PTH ($r = 0.23$, $p=0.35$) or serum calcium ($r=0.34$, $p=0.17$). Plaque did not become more echolucent (less calcified) after parathyroidectomy (PTX; $n=18$). Instead, echodensity increased (baseline 16064; 12 mo 21366, $p<0.005$; 24 mo 26378, $p<0.001$), as did maximum plaque thickness (baseline 2.10.2; 12 mo 2.20.2, $p=0.19$; 24 mo 2.30.3, $p=0.045$) and plaque area (baseline 18 7.7; 12 mo 22 7.9, $p=0.03$; 24 mo 269.2, $p=0.003$). In summary, although mild PHPT is not associated with a greater burden of carotid plaque, when plaque is present it is more highly calcified than plaque in controls. Since PTX did not prevent progression of plaque area, thickness, or calcification, surgery should not currently be recommended for the specific purpose of improving carotid plaque. Whether greater plaque calcification in PHPT patients represents plaque stabilization or is a marker for increased future cardiovascular risk requires further investigation.

Clinical and Biochemical Variables Determining BMD in Primary Hyperparathyroidism. Lars Rolighed^{*1}, Peter Vestergaard¹, Peer Christiansen², Lene Heickendorff³, Tanja Sikjaer¹, Lars Reinmark¹, Leif Mosekilde¹. ¹Aarhus University Hospital, Denmark, ²Department of Surgery P, Aarhus University Hospital, Denmark, ³Department of Biochemistry, Aarhus University Hospital, Denmark

Purpose: Primary hyperparathyroidism (PHPT) is a known cause of secondary osteoporosis. Decreased BMD is often present at the time of diagnosis especially at the hip and forearm. The purpose of this retrospective study was to analyze the association between different clinical and biochemical variables and BMD in a large series of PHPT patients.

Methods: We identified all 1391 consecutive patients undergoing parathyroid surgery at Aarhus University Hospital, Denmark in a 15 year period from 01.01.96 – 31.12.2009. We excluded patients operated for hyperparathyroidism secondary to renal disease and parathyroid implantation after thyroid surgery. With the unique Danish personal identification number we retrieved preoperative biochemical data including plasma levels of parathyroid hormone (PTH), ionized calcium (Ca^{2+}), creatinine and 25-hydroxyvitamin D (25OHD), height, weight and preoperative DXA measurements of the spine, hip and forearm. A complete set of biochemical data were available on 785 patients.

Results: Median age was 62 years (range 13-91) and 638 (81%) patients were women. PTH (mean SD) was 17.4 24.3 pmol/l and 25OHD was 56 30 nmol/l. Women had slightly lower Ca^{2+} (1.50 0.09 mmol/l) than men (1.53 0.12 mmol/l, $P < 0.001$) and also lower plasma creatinine compared with men ($P < 0.001$). Insufficient plasma 25OHD levels (< 50 nmol/l) were found in 365 (46%) patients. Associations with BMD were calculated in a multiple regression model. As expected BMD of the spine, hip and forearm were negatively associated with age ($P < 0.001$). PTH was inversely associated with BMD of the forearm ($P < 0.001$) but not associated with

total hip or spine BMD (NS). BMD of the spine, hip and forearm were not associated with 25OHD levels (NS). PTH was negatively associated with 25OHD ($P < 0.001$) and positively associated with creatinine ($P < 0.001$).

Conclusions: In PHPT patients, DXA of the forearm is recommended due to the negative association between PTH and BMD of the forearm and the higher prevalence of subnormal values. Plasma levels of 25OHD are inversely related to PTH. However, levels of 25OHD did not correlate to BMD of the spine, hip or forearm.

Co-morbid Medical Conditions Associated with Prevalent Hypoparathyroidism: A Population-based Study. Bart Clarke^{*1}, Cynthia Leibson², Jane Emerson², Jeanine Ransom², Hjalmar Lagast³. ¹Mayo Clinic College of Medicine, USA, ²Mayo Clinic, USA, ³NPS Pharmaceuticals, USA

Hypoparathyroidism (HypoPARA) is a rare condition with widespread consequences, ranging from asymptomatic presentation to fatal hypocalcemia. Population estimates of prevalence of HypoPARA across the full range of disease and associated patient characteristics are lacking. Using unique longitudinal, population-based Rochester Epidemiology Project (REP) medical records linkage resources, we 1) identified all persons residing in Olmsted County, MN, in 2009 with any diagnosis of HypoPARA assigned by a REP provider since 1945, 2) reviewed detailed medical records to confirm diagnosis of HypoPARA and assign etiology, 3) assigned 2 age- and sex-matched controls per confirmed case, and 4) obtained all medical diagnoses from 2006 through 2008 to compare cases with controls for percent with any diagnosis in each chapter and subchapter of the International Classification of Diseases, Version 9, Clinical Modification (ICD-9-CM). There were 54 confirmed cases (prevalence=37/100,000; 71% female; mean age 5820 years); etiology=78% post-surgical, 9% secondary, 7% familial, 6% idiopathic. Cases were more likely than controls ($p<0.05$) to have ≥ 1 diagnosis within 7 of 17 chapters and 15 subchapters. Details on specific chapter and subchapter differences are provided in the table. These population-based data on confirmed HypoPARA prevalence and case characteristics reveal that, compared to unaffected peers, persons with HypoPARA exhibit a substantial burden of comorbid disease across multiple dimensions.

Table: Increased likelihood that persons with vs. those without confirmed diagnosis of HPT had any diagnosed medical condition within each ICD-9-CM chapter/subchapter.

Development of a Bioactive PTH (1-84) Specific Assay on the IDS-iSYS System. Craig Dixon^{*1}, Emma King², Christopher Fox², Jackie Tran³, David Laurie², Alex Barnes², Martha Garrity². ¹Immunodiagnostic Systems Ltd, United Kingdom, ²IDS Ltd, United Kingdom, ³IDS Ltd, USA

Introduction: Measurement of Parathyroid Hormone (PTH) is essential for the management of hyperparathyroidism and metabolic bone disease associated with chronic kidney disease (CKD-MBD). Currently available assays recognise either full-length PTH and large C-terminal fragments (Intact PTH) or are specific for only the full-length 84 amino acid molecule (Bioactive PTH). The cross-reactivity to non PTH (1-84) fragments recognised by Intact PTH assays can vary considerably, leading to significant variation in overall PTH results between analytical platforms. The 2009 KDIGO Clinical Practice Guideline for the Diagnosis, Evaluation, and Treatment of CKD-MBD indicates PTH should be measured from Stage 3 for diagnoses of abnormalities and rate of progression of CKD. Recognising the inter-laboratory differences in PTH assays, the guideline suggests clinical laboratories inform clinicians of the actual assay method in use and report any changes in methods, sample source (plasma or) serum, and handling specifications to facilitate the appropriate interpretation of biochemistry data. Consistent and accurate measurement of PTH levels is therefore vital. There is much discussion regarding which PTH assay represents the most reliable and sensitive method for PTH monitoring. In particular, whether Intact PTH can be used given the undefined biological activity of non-(1-84) fragments, opposed with the opinion that Intact PTH is still a robust indicator of overall PTH levels. The Bioactive PTH (1-84) assay will allow specific measurement of full-length PTH on the IDS-iSYS system and in combination with the available panel of bone and calcium metabolism tests, such as 25-OH-D and BAP, will allow clinicians to select treatment modality and monitor therapy efficacy.

Methods: The measurement of Bioactive PTH (1-84) is a two-site chemiluminescent immunoassay. PTH (1-84) is bound by Biotinylated C-terminal and Acridinium-conjugated N-terminal-specific antibodies. These complexes are captured by streptavidin-coated magnetic particles. Bound PTH (1-84) is measured in a high sensitivity luminometer, where signal generated by the acridinium conjugate is directly proportional to the concentration of PTH (1-84) in the sample.

Results: The Bioactive PTH (1-84) assay has a range of 4-1800pg/ml. Time to first result is 33 minutes. Analytical sensitivity is 1.8 pg/mL. Correlation with the IDS-iSYS Intact PTH assay gives a relationship of Bioactive PTH = 0.6 x Intact PTH values in EDTA plasma (n=59). Cross-reactivity with non PTH (1-84) fragments is clinically insignificant. Recovery was measured at 95%. Excellent linearity was observed across the full clinical decision range of CKD-MBD with an observed/expected value of 101%.

Conclusion: This assay has potential to provide accurate data for the specific measurement of PTH (1-84) across the full clinical range required for CKD-MBD monitoring.

Genetic Analysis Of CDKN1B/p27^{Kip1} Gene in Familial Primary Hyperparathyroidism. Filomena Cetani^{*1}, Elena Pardi², Elena Paltrinieri², Simona Borsari², Benedetta Raspini², Federica Saponaro², Luisella Cianferotti¹, Antonella Picone², Chiara Banti², Edda Vignali², Claudio Marroccci¹. ¹University of Pisa, Italy, ²University of Pisa Department of Endocrinology & Metabolism, Italy

Primary hyperparathyroidism is usually a sporadic disorder, but in a minority of cases (<10%) occurs as part of hereditary syndromes, including multiple endocrine neoplasia types 1 and 2A (MEN1 and MEN2A), hyperparathyroidism-jaw tumor syndrome (HPT-JT), familial hypocalcemic hypercalcaemia (FHH) and familial isolated hyperparathyroidism (FIHP).

MEN 1 is an autosomal dominant disorder characterised by tumours in multiple endocrine glands, most commonly the parathyroid, enteropancreatic and anterior pituitary glands. To date over 1100 germline heterozygous mutations have been identified as the causative molecular defect of familial MEN1 disorders. However, there are no identifiable mutations in the menin coding sequence in approximately 20-30% of clinically proven MEN1 kindreds. FIHP can result either from incomplete expression of a syndromic form of familial primary hyperparathyroidism, or have still unrecognized causes. It has a heterogeneous molecular etiology, infact germline mutations of *MEN1* (25%); *HRPT2* (7%) and *CASR* (4%) genes were reported in a subset of FIHP families. Recently, a *cyclin dependent kinase inhibitor 1B* (*Cdkn1b*) germline frameshift mutation was identified in a rat colony as the cause of a recessive multiple endocrine neoplasia called MENX. Interestingly, germline mutations of the homologous human gene (*CDKN1B/p27^{Kip1}*) were identified in 6 kindreds with MEN1-like syndromes, clinical MEN1 without proven mutations in the MEN1 gene, thereby establishing a direct link between p27 alterations and tumor predisposition also in humans.

Our objective was to evaluate the role of *CDKN1B/p27^{Kip1}* gene in 11 MEN1 and 9 FIHP kindreds that were negative, respectively, for MEN1 gene and MEN1, HRPT2, CASR, genes germline mutations.

Genomic DNA from index cases was analyzed for germline mutations in the *CDKN1B/p27^{Kip1}* gene by PCR amplification and direct sequencing by a 16-capillaries automatic sequencer.

No mutations in the coding region of *CDKN1B/p27^{Kip1}* were detected. Our results indicate that *CDKN1B/p27^{Kip1}* mutations effectively happens in a small portion of MEN1 syndrome without known mutations in the MEN1 gene.

Subclinical Hypoparathyroidism: A New Variant Based Upon a Cohort from MrOS. Natalie Cusano^{*1}, Patty Wang², Serge Cremers³, Elizabeth Haney², Douglas Bauer⁴, Eric Orwoll², John Bilezikian¹. ¹Columbia University College of Physicians & Surgeons, USA, ²Oregon Health & Science University, USA, ³Columbia University, USA, ⁴University of California, San Francisco, USA

Hypoparathyroidism (HypoPT), characterized by hypocalcemia and reduced PTH levels, occurs primarily as an autoimmune disorder or after neck surgery. Progressive loss of parathyroid function may occur over months to years. It follows that there may be a phase of HypoPT in which the serum calcium (Ca) level is still maintained but the PTH level is low. This phase is not likely to be recognized because PTH levels are rarely measured when the serum Ca concentration is normal. Subclinical HypoPT has surfaced when such patients are given bisphosphonates. With a mild lowering effect of bisphosphonate on serum Ca, symptomatic hypocalcemia can develop with inadequate parathyroid reserve. We hypothesized that individuals with subclinical HypoPT could be identified in an unselected population such as in The Osteoporotic Fractures in Men study (MrOS). MrOS consists of a cohort of US community-dwelling men ≥ 65 years at enrollment. We measured PTH levels (Scantibodies IRMA, inter-assay CV 8.4%, intra-assay CV 5.6%) in a random subset of 1593 men. 89 did not have serum Ca values and were excluded, leaving 1504 men for these analyses. Subclinical HypoPT was defined as a serum PTH below the reference range of the assay (<14 pg/ml) along with a normal albumin-adjusted serum Ca concentration. In this cohort, 25 subjects met these criteria for subclinical HypoPT (prevalence, 1.7%). There were no men with overt HypoPT (low serum Ca and PTH levels). The men with subclinical HypoPT had significantly higher phosphorus levels (3.5 vs. 3.2 mg/dl; $p<0.0001$) and 25-hydroxyvitamin D levels (28.5 vs. 25.1 pg/ml; $p=0.04$) than the others in the cohort. Daily calcium supplementation was significantly higher in the men with low PTH levels compared to the other subjects (617.7 vs. 347.2 mg/day; $p=0.002$) with the majority taking $\geq 1,000$ mg/day (52% vs. 23%; $p=0.0007$). Since this level of Ca supplementation in the setting of normal serum Ca does not suppress PTH to levels below the reference range, it is likely that higher Ca intake in these men represents greater calcium needs in the context of subclinical HypoPT. There were no significant differences between subjects with and without subclinical HypoPT in terms of: age, height, weight, BMI, bone turnover markers (P1NP, β CTX, TRAP5b), testosterone, estradiol, SHBG, lumbar spine or femoral neck BMD. The results provide evidence for the existence of a cohort of free-living community-dwelling individuals who have subclinical HypoPT.

Vitamin D Status in Primary Hyperparathyroidism. Alfredo Scillitani^{*}. Casa Sollievo Della Sofferenza Scientific Institute, Italy

Hypovitaminosis D is common in patients with Primary Hyperparathyroidism (PHPT) and several mechanisms could theoretically predispose to vitamin D deficiency. Indeed the excess PTH induces an accelerated catabolism of 25 hydroxy-vitamin D (25OHD) by activating both renal 1 α -hydroxylase and liver 24 hydroxylase.

We evaluated vitamin D and DBP (vitamin D Binding Protein) serum levels in PHPT patients and compared them with 2 different groups of healthy family members: those sharing the same environment only—that are, in-law relatives (ILR) or those sharing genetic background and environment—namely, first degree relatives (FDR).

This study is part of a larger one in which an accurate evaluation of PHPT patients with matched FDR and ILR subjects is performed. Eighty-five PHPT subjects of 400 patients were initially collected because we had at least one FDR and one ILR subject (trios) for each patient. Subsequently 36 patients were excluded since they had reported taking vitamin D supplementations.

Finally we analyzed data on 49 families. Mean age SD of PHPT patients, FDR and ILR subjects was 59.6 9.9, 43.4 14.5 and 51.8 14.7 years, respectively. Serum 25OHD levels were 14.1 7.5, 21.5 11.4, 22.2 13.9 ng/ml, respectively and were significantly different between patients and either group of healthy subjects ($p<0.05$). Serum DBP levels were 347 64, 411 87, 408 88 ug/ml, respectively and were significantly different between patients and either group of healthy subjects ($p<0.05$).

Univariate analysis of variance by GLM was utilized in order to correct for other covariates (season, age and DBP). Serum 25OHD was lower in PHPT patients in respect the two groups of healthy subjects after adjustment for these covariates but the difference was not significant vs the FDR ($p=0.09$).

Our study confirms that, PHPT patients have lower 25OHDvitamin D levels than healthy subjects sharing the same environment and a similar genetic background.

Calcium Carbonate Supplement Produces Positive Calcium Balance in Stage 3/4 Chronic Kidney Disease. Kathleen Hill¹, Berdine Martin², Meryl Wastney³, Sharon Martin Moe⁴, George McCabe², Connie Weaver², Munro Peacock⁵. ¹Indiana University School of Medicine, USA, ²Purdue University, USA, ³Metabolic Modeling Services, USA, ⁴Indiana University, USA, ⁵Indiana University Medical Center, USA

Background: Patients with chronic kidney disease (CKD) are often given a calcium carbonate supplement (CaCO₃) with meals both to bind dietary phosphate (Pi) and prevent negative skeletal calcium (Ca) balance. However, there are limited data on Ca balance and kinetics in CKD patients with or without CaCO₃. Purpose: To determine the state of Ca balance in CKD patients on an adequate Ca diet with and without CaCO₃. Methods: Three patients, of a projected eight, with stage 3/4 CKD participated in two 3wk Ca balance and kinetic studies using a randomized crossover design. Patients received 500 mg elemental Ca as CaCO₃ or placebo with meals 3x/d. Controlled diets consisted of 957 mg Ca/d. Wk 1 of each balance study was outpatient and considered an equilibration period. During wk 2 & 3, patients were inpatients, where they consumed the controlled diet, and collected all urine and feces. An oral and IV tracer (45Ca) were given on days 8 & 9, and serial blood drawn on days 8-21 for Ca kinetics estimated using a multi-compartmental model. Repeated measures ANOVA for crossover designs was used to determine differences between CaCO₃ and placebo. Results: Mean lumbar spine & femoral neck BMD t-scores were each -0.7. Mean fasting biochemistries did not differ between placebo and CaCO₃: serum Ca 9.3 & 9.5 mg/dL, Pi 4.2 & 4.2 mg/dL, Cr 2.4 & 2.6 mg/dL, PTH 73 & 60 pg/mL, FGF23 73 & 79 pg/mL, bone alkaline phosphatase 34 & 37 U/L, 25(OH)D 21 & 20 ng/mL, 1,25(OH)2D 48 & 43 pg/mL, urine Ca:Cr ratio 0.05 & 0.06. Ca balance was negative on placebo and positive on CaCO₃ (-111.6 & +105.6 mg/d); bone formation was higher on CaCO₃ than placebo (359 & 282 mg/d), and bone resorption was lower on CaCO₃ than placebo (254 & 394 mg/d); urinary Ca excretion was higher on CaCO₃ than placebo (136 & 102 mg/d); endogenous fecal Ca excretion was lower on CaCO₃ than placebo (138 & 167 mg/d); absolute Ca absorption was higher with CaCO₃ than placebo (380 & 158 mg/d) and fractional Ca absorption was lower on CaCO₃ than placebo (0.15 & 0.17). Conclusions: These preliminary studies suggest that patients with stage 3/4 CKD are in negative Ca balance while consuming a diet of 957 mg/d Ca, but are in positive Ca balance when given 1500 mg/d elemental Ca with meals, due to increased net Ca absorption and retention. The beneficial or adverse effects of chronic positive Ca balance on bone mass, extraskeletal mineralization and phosphate balance and homeostasis need to be established.

Cortical Abnormalities are Associated with Prevalent Fractures in Postmenopausal Women with Chronic Kidney Disease. Emily Stein¹, Thomas Nickolas², Donald McMahon¹, Adi Cohen², Xiaowei Liu¹, Mafo Kamanda-Kosse³, X Guo³, Elizabeth Shane¹. ¹Columbia University College of Physicians & Surgeons, USA, ²Columbia University Medical Center, USA, ³Columbia University, USA

Chronic kidney disease (CKD) is associated with increased fracture risk in postmenopausal women. We hypothesized that women with CKD and fragility fractures would have more cortical abnormalities than those with no fracture history. Postmenopausal women with stage 3 and 4 CKD (eGFR by MDRD 15-60ml/min) were enrolled. Women with significant bisphosphonate use (>1 yr) or any teriparatide use were excluded. Women with (FX, n=20) and without (C, n=33) a history of low trauma fracture after menopause had aBMD of the lumbar spine (LS), total hip, femoral neck, 1/3 radius and ultradistal radius (UDR) measured by DXA. Trabecular (Tb) and cortical (Ct) volumetric BMD (vBMD) and Tb microarchitecture were measured by high resolution peripheral computed tomography (HRpQCT, voxel size ~82 µm) of the radius and tibia.

Of 53 women enrolled (57% Caucasian, 36% Latina, mean age 717 years), mean eGFR was 414 ml/min and did not differ by fracture status. There was no difference in age, race, BMI, prevalence of hypertension or diabetes, use of estrogen, loop diuretics, calcitriol or parent vitamin D intake. Calcium intake tended to be higher among women with FX (995299 vs. 786401 mg/d; p=0.08). In FX subjects, mean T-scores were significantly lower at the UDR (-1.60.2 vs -0.80.2; p<0.03) and tended to be lower at the LS (-1.20.4 vs -0.60.2; p=0.14), but did not differ elsewhere. In contrast, HRpQCT revealed substantial microarchitectural differences (Table). At the radius, total area did not differ, but FX subjects had smaller Ct and larger Tb regions. FX subjects also had lower total density, tended to have lower Ct density, and had lower Ct thickness. Although Tb density did not differ, sub-cortical (outer) Tb density was lower in FX subjects. Tb number, separation and network heterogeneity did not differ. Similarly at the tibia, FX subjects had smaller Ct and greater Tb area. Total, Tb, and sub-cortical density were lower among FX subjects. While cortical density was not significantly lower at this site, Ct and Tb thickness were lower in FX subjects.

In conclusion, postmenopausal women with CKD and fractures have lower vBMD, primarily due to deficits in cortical bone. The smaller cortical area and lower sub-cortical density observed are consistent with endocortical cancellization. These changes along with lower cortical density and thickness suggest that excess PTH may be an important mediator of skeletal fragility in this population.

Identification of Pathological Bone Mineralization in Diabetic Osteomyelitis.

Karen Esmonde-White¹, Francis Esmonde-White², Crystal Holmes¹, Michael Morris², Blake Roessler¹. ¹University of Michigan Medical School, USA, ²University of Michigan, USA

Introduction: Diabetic osteomyelitis occurs when non-healing and infected wounds of plantar soft tissue spread to the underlying bone. Clinical and imaging tests show that whole tissue properties of bone, including hardness and mineralization, are directly affected by diabetic osteomyelitis. The assumption is that bone chemistry is altered to induce observable changes in tissue, however, these changes have never been examined in osteomyelitic bone. The objective of our study is to measure osteomyelitis-induced changes in bone composition. We used an optical method (Raman spectroscopy) to show that abnormal calcium phosphate minerals are present in diabetic foot osteomyelitis. Methods: All aspects of the clinical protocol were reviewed and approved by the University of Michigan Medical School Institutional Review Board. After informed consent, fragments of affected bone were collected from 4 human patients (Male 3, Female 1, mean age of 69 y) undergoing surgical treatment for diabetic osteomyelitis. We also examined bone fragments from cadaveric specimens as controls. Near infrared Raman spectra were collected at the surface of the bone fragments using a Raman equipped microscope. Raman spectra were compared with pathology, microbiology and clinical imaging results. Results: Osteomyelitis was indicated by clinical imaging in all 4 patients. Raman spectra showed presence of two calcium phosphate minerals not observed in normal bone tissue: uncarbonated calcium hydroxyapatite and dicalcium phosphate dihydrate (brushite). No atypical results were observed in the controls. Because brushite is only formed under acidic conditions, we hypothesize that the acidic environment of a diabetic foot wound bed accelerates dissolution of carbonated apatite and favors formation of other calcium phosphate minerals. Conclusions: We present preliminary results from a continuing study to characterize the chemical composition of bone infected by diabetic osteomyelitis. Our first results suggest pathological mineralization occurs in diabetic osteomyelitis, and mineral chemistry is significantly altered. While this study has focused on diabetic osteomyelitis, we anticipate that these findings can be generalized to bloodborne or post-surgical osteomyelitis. Translating this technique to the clinic may provide a predictive measurement of osteomyelitis infections based on identification of pathological mineral species when patients are still asymptomatic.

ONO-5334, a Potent Cathepsin K Inhibitor, Suppresses Joint Destruction in the Monkey Collagen-induced Arthritis Model. Hiroshi Mori^{*}, Hiroyuki Yamada, Yasutomo Nakanishi, Akiko Kunishige, Satoshi Nishikawa, Yasuaki Hashimoto, Yasuo Ochi, Masafumi Sugitani, Kazuhito Kawabata. Ono Pharmaceutical Co., Ltd., Japan

Cathepsin K is highly expressed in osteoclasts, and plays a central role on bone degradation. It has been demonstrated that cathepsin K is also expressed in synovial fibroblasts and chondrocytes in rheumatoid arthritis (RA) patients that are implicated in cartilage degradation. Cathepsin K may be an attractive therapeutic target for joint

destruction in RA. In this study, we investigated the efficacy of ONO-5334, a novel small molecule inhibitor of cathepsin K, on joint destruction in the monkey collagen-induced arthritis model.

Arthritis was induced by immunizing with bovine type II collagen twice at 3-week intervals in female cynomolgus monkeys. Animals received either oral ONO-5334 (30 mg/kg, once daily), methotrexate (MTX, 10 mg/body, twice a week), combined treatment of ONO-5334 and MTX (ONO-5334/MTX) or vehicle (control) for 9 weeks from the day of the first immunization (4 groups, 9 animals/group).

In the control group, joint swelling score increased with time until week 7. Joint destruction was evaluated at week 9, and the findings such as joint space narrowing, bone atrophy, and bone erosion were observed at the phalangeal joints in X-ray examinations. ONO-5334 did not reduce joint swelling score. Joint swelling score in the MTX and ONO-5334/MTX was less than 50% of that in the control group at week 7 and 9, and the efficacy of these treatments was similar. ONO-5334 significantly decreased radiographic score, which indicates the affected joint number (48 joints per animal in total), by 65% compared to the control group ($p < 0.05$). MTX decreased radiographic score by 46%, but no significant difference compared to the control group. Radiographic score in the ONO-5334/MTX group showed further decrease and reached 74% suppression ($p < 0.05$ vs control). In the control group, the bone resorption marker, urinary CTX-I, and the cartilage degradation marker, urinary CTX-II, increased by 10-fold at week 7 and 7-fold at week 3 from baseline (median value), respectively. ONO-5334 and ONO-5334/MTX maintained both marker levels at near baseline (median value). CTX-I level in the MTX group was comparable at weeks 3, 5 and 9 or slightly lower at week 7 to the control group, but MTX maintained CTX-II levels at near baseline (median value).

These results suggest that ONO-5334 may be effective for the prevention of joint destruction. Concomitant use of ONO-5334 with MTX may help to reduce joint swelling and to augment suppressive effects on joint destruction in RA.

Relationship Between Periodontitis and Arthritis. Melissa Cantley*, David Haynes, Victor Marino, Peter Mark Bartold. University of Adelaide, Australia

Periodontitis (PD) and rheumatoid arthritis (RA) are similar chronic inflammatory diseases where bone loss is a major problem. Increasing evidence suggests that a relationship may exist between the two pathologies. Previous studies have demonstrated that PD is a risk factor for development of RA and it may also enhance RA severity. The aim was to investigate bone loss and the relationship between pre-existing PD and experimental arthritis similar to human disease in an animal model.

Periodontitis was induced in female balb/c mice by oral inoculations with live *P. gingivalis* bacteria (periodontal pathogen) over 36 days. Following this, collagen antibody induced arthritis (CAIA) was induced via intravenous injection of a mAb to type II collagen followed by injection of *E. coli* LPS two days later. These animals were compared to animals with PD alone, arthritis alone and no disease (controls) ($n=4$ per group). Visual changes in paw swelling were assessed for clinical development of arthritis. Alveolar bone and joint changes were assessed using live animal micro-CT analysis, histological analyses and immunohistochemistry. Serum levels of C-reactive protein (CRP) were used to monitor systemic inflammation.

Mice with pre-existing PD developed more severe arthritis at a markedly faster rate with significantly higher paw scores on days 6, 8, 9 and 10. There were also significantly higher CRP levels in the PD and arthritis group ($p < 0.05$). However, despite more rapid onset in animals with pre-existing PD there were no significant differences ($p > 0.05$) in bone loss in the radio carpal joints at day 10 (CT analysis). There was, however, more intense staining for RANKL in the PD and arthritis group compared to arthritis alone. Interestingly, mice with PD alone showed bone loss within the radio carpal joint and more intense RANKL staining than controls ($p < 0.01$). Similarly elevated RANKL expression and alveolar bone loss was seen in mice with arthritis alone in the gingival tissues.

Mice with pre-existing PD developed arthritis at a faster rate but bone loss was eventually similar to that seen in mice without PD. Interestingly, minor but significant bone loss was evident not only in the joints of PD mice but also in the alveolar bone of mice with arthritis. This demonstrates a relationship between PD and inflammatory joint disease. This unique model can be used to further investigate the relationship between PD and arthritis and test the effects of potential treatments.

Advanced Glycation End-Products-Induced Vascular Calcification Is Mediated By Oxidative Stress: Functional Roles of NAD(P)H-oxidase.

Yuko Tada*¹, Shozo Yano², Kyoko Okazaki¹, Noriko Ogawa¹, Miwa Morita¹, Ippei Kanazawa³, Toru Yamaguchi², Toshitsugu Sugimoto⁴. ¹Shimane University Faculty of Medicine, Japan, ²Shimane University Faculty of Medicine, Japan, ³McGill University, Canada, ⁴Shimane University School of Medicine, Japan

Background and aims: Vascular calcification is associated with increased morbidity and mortality in patients with diabetes mellitus and end-stage kidney disease. Especially, medial artery calcification, known as Monckeberg's type of calcification, is often detected in these patients. Growing evidence suggests that advanced glycation end-products (AGEs) are associated with vascular calcification, although their actions are still unclear. On the other hand, oxidative stress leads to vascular damage through diverse mechanisms. Thus, we investigated an *in vitro* study to elucidate the effects of AGEs and the roles of NAD(P)H oxidase in the pathogenesis of vascular calcification.

Materials and methods: Rat vascular smooth muscle cells (A7r5) were incubated in calcification medium with AGE3 to measure calcium deposition, to evaluate apoptosis (ELISA) and to determine mRNA expression levels of osteopontin (OPN), osteocalcin (OC), Runx2, Nox-1, Nox-4, and p22phox (real-time PCR).

Results: Calcium deposition was increased by AGE3 in a dose- and time-dependent manner in A7r5 cells. AGE3 was the most potent in calcium deposition among AGEs, which we had examined. Expression levels of the OPN, OC, and Runx2 mRNAs were significantly higher in AGE3 treatment than those in control BSA treatment, indicating the osteoblastic transdifferentiation of the vascular smooth muscle cells. In addition, apoptosis was enhanced within 24hrs in cells treated with AGE3, compared to that with control BSA. Increased expressions of Nox-1, Nox-4, and p22phox mRNAs (3 to 6 folds) were also observed in cells treated with AGE3, suggesting that AGEs most probably promote reactive oxidative species production resulting in the progression of calcium deposition. Therefore, we examined the effects of silencing of these mRNAs by using siRNA and found that AGE3-stimulated calcium deposition was significantly decreased in the cells transfected by either Nox-4 or p22phox siRNA. In contrast, no significant effect was shown in silencing of Nox-1.

Conclusion: The present findings indicate the involvement of osteoblastic transdifferentiation of the vascular smooth muscle cells and the apoptosis as well as oxidative stress in the pathogenesis of AGEs-induced vascular calcification. Activated NAD(P)H oxidase, which is induced by increased expression of Nox-4 and p22phox, may play important roles. These molecules could be a target of new strategy to prevent vascular calcification as well as vascular damage.

Aortic Arch Calcification Is Associated With Low Bone Mineral Density But Not Orthostatic Hypotension In Advanced Old Age. Jude Ryan*¹, Sheila Carew², Catriona O'Connell³, Teresa Donnelly², Catherine Peters², Aine Costelloe², Tina Sheehy², Declan Lyons².

¹Midwest Regional Hospital, Limerick, Ireland, ²Clinical Age Assessment Unit, Department of Medicine, Division of Ageing & Therapeutics, University of Limerick Medical School & Mid-West Regional Hospital, Ireland, ³Midwest regional Hospital, Ireland

Introduction

Vascular calcification has been associated with bone loss in previous epidemiological studies, suggesting a possible relationship between osteoporosis and age-related vascular stiffness. Orthostatic hypotension (OH) is a common age associated vasculopathic phenomenon. We investigated whether the presence of aortic arch calcification on chest x-ray may predict the co-existence of osteoporosis and orthostatic hypotension in advanced old age.

Methods

Patients who had a dual-energy-x-ray-absorptiometry (DEXA) scan, head up tilt test (HUT) and chest radiographs performed within a 1 year period were identified from our unit database. Radiographs were viewed by 2 experienced blinded clinicians to determine the presence/absence of aortic arch calcification. Results were correlated with bone mineral density (BMD) (hip) and blood pressure response to HUT.

Results

111 patients were studied, 88 female, mean age 85 years (range 80-95). 51/111 (45.9%) had aortic arch calcification. 70.6% of the total group had osteoporosis. 60.8% of the total group had a diagnosis of orthostatic hypotension on head-up tilt. Hip BMD was lower in the calcified compared to non calcified group (0.6830.02 V 0.7650.03g/cm²; $p=0.03$ unpaired t test). There was no difference in mean resting blood pressures between groups (144/764/2 V 148/784/2mmHg; $p=0.54$ unpaired t test). Change in systolic blood pressure in response to HUT was similar in both groups (-35.82.5 V -35.22.3 mmHg, $p=0.86$ unpaired t test).

Conclusion

The presence of aortic arch calcification is associated with a lower BMD, this lends support to a common mechanism for osteoporosis and large vessel calcification. In this study there doesn't appear to be any haemodynamic consequences associated with aortic arch calcification, specifically OH which would pose a significant risk of falling.

The lack of an association with OH is not surprising as the principal pathogenic site for this condition is the resistance vessel.

miRNA-125b is Involved in Calcification of Vascular Smooth Muscle Cells. Claudia Goettsch^{*1}, Martina Rauner², Lorenz Hofbauer³. ¹Brigham & Women's Hospital/Cardiovascular Division, USA, ²Medical Faculty of the TU Dresden, Germany, ³Dresden University Medical Center, Germany

Vascular calcification is a prominent feature of atherosclerosis and is closely linked to osteoporosis. Various microRNAs (miRNA) have been shown to regulate cell differentiation, including miR-125b, which is involved in osteoblast differentiation. However, no specific miRNA has been defined that modulates vascular calcification. Here, we assessed the impact of miR-125b in osteogenic transformation of vascular smooth muscle cells. Osteogenic transdifferentiation of human coronary artery smooth muscle cells (HCASMC) was induced by osteogenic medium (OM) and enhanced the formation of mineralized matrix resulting in a significantly higher mineral deposition after 21 days. The expression of miR-125b was time-dependently increased in HCASMC, and diminished during osteogenic transdifferentiation. At day 21, miR-125b was significantly reduced (-42%) compared to the untreated control. The miRNA processing enzymes DICER and DROSHA were also down-regulated. Furthermore, inhibition of endogenous miR-125b promoted osteogenic transdifferentiation as measured by an increased alkaline phosphatase activity and matrix mineralization. Expression analysis revealed the osteoblast transcription factor SP7 (osterix) as a target of miR-125b. In vivo, miR-125b was decreased in calcified aortas of ApoE knock out mice. In conclusion, our results suggest that miR-125b is involved in vascular calcification in vitro and in vivo at least partially by targeting SP7. Evaluating the role of miRNAs in arterial calcification in vivo may have important therapeutic implications.

Adaptation of Bone and Calcium Metabolism to Low Dietary Calcium (Ca) Intake is Affected by Genetic Background in Mice. Qiang Li^{*}, Rebecca McCreedy, James Fleet. Purdue University, USA

We tested the hypothesis that genetics control the ability of Ca and bone metabolism to adapt to low dietary Ca intake. Male mice from 11 inbred lines (129S1/SV1mJ, A/J, AKR/J, C3H/HeJ, C57BL/6J (B6), CAST/EiJ, CBA/J, DBA/2J, PWK/PhJ, SWR/J and WSB/EiJ) were fed AIN93G diets containing adequate (0.5%) or low (0.25%) Ca levels from weaning until 3 mo (n=8 mice from each line per diet group). Ca metabolism normally adapts to diet Ca restriction by increasing serum 1,25 dihydroxyvitamin D (1,25 D), causing upregulation of intestinal Ca absorption (Ca Abs), and protection of bone mass. Ca Abs was assessed using an oral gavage test (45Ca, 0.1 mM, 10 min) after an overnight fast. At sacrifice, serum was harvested for 1,25 D levels and femora were fixed for DEXA analysis of bone mineral density (BMD) and content (BMC). In mice fed the 0.5% Ca diet, significant differences were observed between the lines for all parameters measured (high 1,25 D in 129, A/J, C3H, CBA, SWR, WSB; high Ca Abs in A/J, C3H, CBA, SWR, WSB; high BMD/BMC in 129, AKR, C3H, CBA). This demonstrates that there is genetic control on these parameters. Ca restriction significantly increased 1,25 D in 129, C3H, B6, and SWR mice by 35-55%; increased Ca Abs in 129, B6, CAST, and SWR mice by 72-195%; reduced BMD in 6 lines of mice: A/J (-4.8%, p<0.1), AKR (-4.8%), CBA (-6.6%), C3H (-4.8%, p<0.1), CAST (-6.4%, p<0.1), and 129 (-9.0%). For A/J, AKR/J and CBA/J, the reduced BMD could be partly explained by their inability to increase serum 1,25 D and Ca absorption on low Ca intake. In contrast, the robust increase in Ca Abs in 129, CAST, and C3H mice did not protect them from bone loss, and PWK are able to protect BMD without a large increase in Ca absorption, suggesting mechanisms other than regulation of Ca absorption influence bone during low Ca intake. Collectively, these data show that genetic factors control a number of parameters relevant to Ca and bone metabolism and that there are genetic controls influencing the physiological adaptation of Ca metabolism to dietary Ca restriction that ultimately affect bone health. Future forward genetic approaches will be necessary to identify the genetic variation responsible for these physiological differences.

A Genome-wide Association Meta-analysis Identifies Two Loci for Cortical Thickness. Mattias Lorentzon^{*1}, Lavinia Paternoster², Terho Lehtimäki³, Mika Kahonen⁴, Olli Raitakari⁵, Marika Laaksonen⁶, Vera Mikkilä⁶, Jorma Viikari⁷, Leo-Pekka Lyytikäinen³, John P Kemp², Adrian Sayers⁸, Maria Nethander⁹, Liesbeth Vandenput¹⁰, Jon H Tobias², Claes Ohlsson¹, David M Evans². ¹Center for Bone Research at the Sahlgrenska Academy, Sweden, ²MRC CAiTE centre, School of Social & Community Medicine, University of Bristol, United Kingdom, ³Department of Clinical Chemistry, University of Tampere & Tampere University Hospital, Finland, ⁴Department of Clinical Physiology, University of Tampere & Tampere University Hospital, Finland, ⁵Research Centre of Applied & Preventive Cardiovascular Medicine, University of Turku & the Department of Clinical Physiology, Turku University Hospital, Finland, ⁶Department of Food & Environmental Sciences, University of Helsinki, Finland, ⁷Department of Medicine, University of Turku & Turku University Hospital, Finland, ⁸University of Bristol, United Kingdom, ⁹Center for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ¹⁰University of Gothenburg, Sweden

Several loci associated with areal bone mineral density (aBMD) (as measured by dual x-ray absorptiometry (DXA)) have previously been identified in large bone-related genome-wide association (GWA) studies. Though more direct measures of bone geometry and structure are related to fracture risk as strongly as aBMD, considerably less is known of their genetic determinants, and as of yet, no GWA studies have been performed searching for genetic signals for cortical thickness.

In order to determine genetic markers (Single Nucleotide Polymorphisms-SNPs) for cortical thickness, we performed a GWA study of this trait, as measured by peripheral quantitative computed tomography (pQCT) in the tibial diaphysis, among 5,952 Caucasian subjects from three cohorts (ALSPAC, aged ~15 years, n=3,456; GOOD, aged ~19 years, n=938 and YFS aged 31-46 years, n=1,558). We used an inverse variance weighted fixed-effect model meta-analysis of study-specific results. We identified genetic variants in two separate loci reaching genome wide significance ($p < 5 \times 10^{-8}$).

The top ranking SNP (rs9525638) was located in the *RANKL* (*TNFSF11*) locus on chromosome 13, had an effect size of 0.11 SD per allele and $p = 3.8 \times 10^{-10}$. In addition, we identified another genetic signal for cortical thickness in the *Wnt16* locus on chromosome 7 (rs2707466). This SNP had an effect size of 0.11 SD per allele and $p = 6.2 \times 10^{-9}$. *Wnt16* is a member of the wingless-type MMTV integration site family and has previously been shown to be involved in the regulation of bone turnover. Several previous GWA studies have identified the *RANKL* locus for aBMD and fracture, while only one previous study has implicated the locus near *Wnt16* as of importance for aBMD.

In conclusion, we identified two loci associated with cortical thickness. Our findings suggest that *RANKL* and *Wnt16* are involved in the regulation of cortical thickness.

Functionality of Bone-Specific Promoter SNPs in Human Bones In Vivo and Influence on the Phenotypic Variability of Osteogenesis Imperfecta (OI).

Aline Domingues¹, Marc delepine², Anne Boland², Diana Zelenika², Didier Hannouche³, Marie-Christine De Vernejoul⁴, Frederic Jehan^{*5}. ¹Inserm UMR 606 & University Paris-Diderot, Hopital Lariboisiere, France, ²Centre National de Genotypage (CNG), CEA, France, ³Department of Orthopaedic Surgery & Traumatology, AP-HP & University Paris-Diderot, France, ⁴Federation De Rhumatologie Et INSERM U606, France, ⁵INSERM Unit 606, France

In the bone field single nucleotide polymorphisms (SNPs) have been extensively tested in association studies on bone mineral density (BMD) and fractures, but for most SNPs little is known about their functionality in human bones. We have investigated the functionality of promoter SNPs that may be directly responsible for change on promoter activity, and we have search for associations with gene expression in bone. Around 95% of cells in cancellous bone are of the osteoblasts lineage and we have used RT-qPCR and genotyping techniques on RNA and DNA samples to perform our experiments. We have analyzed a first set of 40 cancellous bone samples (Caucasian patients) that were obtained under the tibial plateau removed during Knee-replacement surgeries at the Department of Orthopaedic Surgery and Traumatology. For gene expression normalization, we have tested 6 different reference genes and have selected the 3 that have a stable expression in bone (geNorm algorithm). All tested genes had a measured PCR efficiency over 90%. Candidate genes have been selected in the bone field for having SNPs with frequent variations in their regulatory region and significant association with BMD and/or fractures in the literature.

Among the 8 candidate genes we have tested on the 40 different bone samples we have found significant associations between promoter variants and gene expression (delta CT meanSD):

SOST: (rs851054 G/A) 6.7041.168 (n=14) for G+ vs. 7.6470.788 for G- alleles (n=24, p=0.0110)

RUNX2: (rs12197755 G/T in the P2 promoter) 4.1170.590 (n=15) for G/T vs. 4.5740.619 for G/G genotype (n=24, p=0.0284)

SFRP1: (rs921142 A/G) 5.6630.725 (n=33) for A+ vs. 4.3900.614 for A- alleles (n=7, p=0.0001)

FZD1: (rs10953043 A/C) of 4.8850.621 (n=19) for A/A vs. 5.3690.772 for A/C genotype (n=17, p=0.0431)

We have tested associations between these SNPs and BMD or occurrence of fracture in a cohort of 136 patients with OI (with type I collagen genes tested for mutations at the CNG, Evry, France). Preliminary results have shown significant associations with the occurrence of fractures for the SOST, RUNX2 and SFRP1 SNPs, and with BMD for SFRP1. These effects don't depend on the presence or absence of type I collagen mutation and are regardless on gender and age.

Taken together, our results show that promoter polymorphisms may influence gene expression in human bones, and that these functional polymorphisms may explain some of the variability observed in OI.

Dullard Is a Novel Common Negative Regulator of BMP Signaling in Osteoblasts and Chondrocytes Acting at Smad1 Level Independently of Caveolae-Proteasome Pathway. Tadayoshi Hayata^{*1}, Yoichi Ezura², Makoto Asashima³, Ryuichi Nishinakamura⁴, Masaki Noda⁵. ¹Medical Reserach Institute, Tokyo Medical & Dental University, Japan, ²Tokyo Medical & Dental University, Medical Research Insititute, Japan, ³Graduate School of Arts & Sciences, The University of Tokyo, Japan, ⁴Department of Kidney Development, Institute of Molecular Embryology & Genetics (IMEG), Kumamoto University, Japan, ⁵Tokyo Medical & Dental University, Japan

Bone morphogenetic protein (BMP) plays crucial roles during skeletal development. BMP activity is regulated negatively by many tissue- or stage-specific BMP inhibitors to maintain proper signal levels. However, the mechanism underlying regulation of the signaling by these BMP inhibitors during osteoblastic differentiation is not fully understood. Dullard is the newest member of BMP inhibitors that dephosphorylates activated type I BMP receptor and promotes type II BMP receptor degradation via ubiquitin pathway after caveolae-mediated internalization based on animal cap and C2C12 cells. However, in osteoblasts, we have shown that Dullard suppresses BMP signaling further downstream at Smad1 level independently of its

phosphatase activity, suggesting the presence of tissue-specific signaling system. In the present study, we investigated whether Dullard suppresses BMP signaling via caveolae-proteasome pathway in skeletal osteoblastic cells. Dullard suppressed BMP signaling in the presence of caveolae disrupters, Nystatin and methyl- α -cyclodextrin, and a proteasome inhibitor MG132 by BRE-luciferase assay. Immunofluorescent staining revealed that signals for Dullard and caveolin-1 only partially co-localized. To determine functional domain of Dullard, we performed Dullard deletion analysis based on luciferase assay. We found that Dullard functional domain is located in C-terminal domain but not N-terminal domain where conserved phosphatase motif is present. The transmembrane domain at N-terminus is also required for Dullard function. Immunohistochemistry analysis revealed that Dullard protein is detected in osteoblasts as well as in chondrocytes at all stages in growth plate in newborn mice. In chondrogenic cell ATDC5, the baseline of the BRE-luciferase activity was higher than MC3T3-E1, and under this condition, Dullard suppressed such BRE-luciferase activity. These results suggest that in skeletal cell system, Dullard plays a role in regulation of BMP signaling independently of caveolae-proteasome pathway.

FGF23 Affects the Lineage Fate Determination of Mesenchymal Stem Cells.

Xu He^{*}, Tobias Larsson², Jiaxue He³, Urban Lindgren², Yan Li². ¹a Karolinska Institute; b Jilin University, Sweden, ²Karolinska Institute, Sweden, ³a Karolinska Institute; b Jilin University, Sweden

Fibroblast growth factor 23 (FGF23) is a newly identified hormone, which is supposed to be produced in bone and integral for phosphorus- and vitamin D homeostasis. It is currently recognized as a strong predictor for the disease progression in patients with chronic kidney disease and a biomarker for health status in general population. Knowledge about the clinical significance of FGF23 expanded quickly during the past decade; however, how FGF23 is secreted and whether it has a direct local action in bone remain largely unknown. Bone remodelling is organized by the deliberated balance between bone formation by osteoblasts and resorption by osteoclasts. The osteoblasts are derived from the mesenchymal stem cells. They conduct matrix production during proliferation/ differentiation and in the end undergo apoptosis or turn into osteocytes/bone lining cells, which are supposed to be the major producers of FGF23.

The present study aims to clarify whether FGF23 can affect the differentiation of cells in osteoblastic lineage. We produced functional FGF23 by transfecting hFGF23-PcDNA3.1-V5-His TOPO plasmid into COS-7 cells. The expression of Klotho was detected in mouse mechymal stem cell line C3H10 cells by Western Blot and Real time PCR. For differentiation study, the cells were cultured in osteoblast inducing medium (α -MEM medium supplement with 10%FBS, β -glycerophosphate, α -ascorbic acid and dexamethasone) for 2 weeks with different concentrations of FGF23. Osteogenic markers, including RunX2, Osteocalcin, RANKL and OPG, and adipogenic specific marker PPAR-g were measured by real time PCR. To detect FGF23 signalling, the phosphorylation of P44/42 MAPK (ERK1/2) was detected by Western blot.

We found that Klotho was expressed at both mRNA and protein level in C3H10 cells, however, at a rather lower level compared with the kidney (Fig.1). FGF23 stimulated the expression of the osteoblastic marker genes in a dose-dependent manner, but did not significantly affect the expression of the adipocyte marker gene PPAR-g (Fig.2). We also found apparent phosphorylation of the P44/42 MAPK (ERK1/2) after 10 minutes treatment of FGF23 (2000 ng/ml) (Fig.3).

In conclusion, our data indicates that FGF23 might be produced by mature bone forming cells in order to induce the osteoblastic differentiation of their progenitors. Therefore, a paracrine function of FGF23 might exist and the direct action of FGF23-klotho axis on bone remodelling demands further investigation.

HMWFGF2 Isoforms Regulate Bone Nodule Formation via Modulating FGFR/FGF23/ERK Signaling in BMSCs. Liping Xiao^{*1}, Alycia Eslinger¹, Marja Marie Hurley². ¹University of Connecticut Health Center, USA, ²University of Connecticut Health Center School of Medicine, USA

FGF23 is responsible for phosphate wasting and the phenotypic changes observed in human disease X-Linked Hypophosphatemia (XLH). However the mechanism(s) regulating FGF23 production by osteoblasts/osteocytes is not defined. Targeted over-expression of nuclear high molecular weight (HMW) FGF2 isoforms in osteoblasts resulted in a transgenic mouse with phenotypic changes similar to XLH including increased FGF23. HMWFGF2 also has phosphate independent effects on bone

formation in vitro mediated in part via FGF23. The goal of this study is to assess whether HMWFGF2 mediate effects on bone formation in vitro by modulating FGFR/FGF23/ERK signaling in bone marrow stromal cells (BMSCs).

To determine if decreased bone formation in cultures from HMW mice can be rescued by FGF23 neutralizing antibody, BMSCs harvested from Vector and HMWtg mice were cultured in osteogenic medium in the absence or presence of FGF23 neutralizing antibody (100 nM). Conditioned medium was collected on day 21 for FGF23 measurement by ELISA. To determine whether impaired mineralized nodule formation by HMWFGF2 over-expression can be abrogated by the FGF Receptor tyrosine kinase inhibitor SU5402 (25uM) or the MAP kinase inhibitor PD98059 (25uM), BMSCs from Vector and HMWtg were cultured in osteogenic medium and the inhibitors were added from day 14 to 21 of culture. The cells were harvested on day 21 to assess mineralized nodule formation by scanning of GFP and Xylenol Orange stained living cells and Alizarin Red staining to assess mineralized nodules. Parallel dishes were used for RNA and protein extraction. Gene and protein expression was assessed by qPCR and Western blot respectively.

FGF23 level in conditioned medium was dramatically increased in HMW-control IgG (229,6741.56 pg/mL) compared with Vector-control IgG (undetectable). In HMW-FGF23AB group FGF23 expression (close to zero) was comparable to Vector-control IgG. Mineralized nodule number was significantly decreased in HMW-control IgG compared with Vector-control IgG. The decreased nodule formation in HMW-control IgG was partially rescued by FGF23 neutralizing antibody. Decreased nodule formation in HMW cultures was also partially rescued by SU5402 and PD98059. Osteocalcin, RUNX2 and Osterix mRNA were also significantly decreased in HMW-Vehicle cultures compared with Vector-Vehicle and was partially rescued by SU5402 or PD98059 treatment.

We conclude that HMWFGF2 signals via FGFR/FGF23/MAPK to inhibit bone formation in vitro.

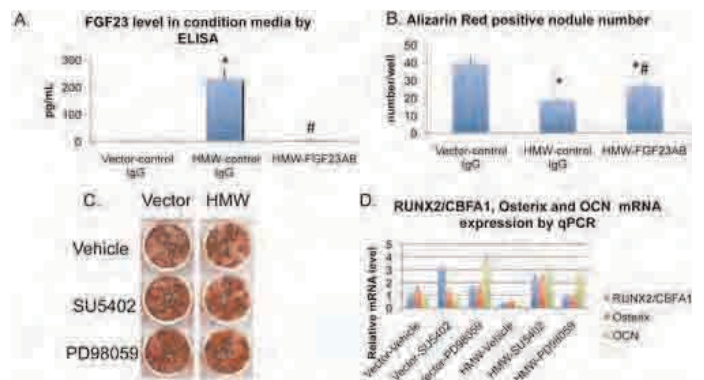

Figure 1. A) FGF23 level in condition media by ELISA. B) Alizarin Red positive nodule number per well. C) Alizarin Red stain. D) RUNX2/CBFA1, Osterix and OCN mRNA expression of BMSCs cultured for 21 days in osteogenic media. *: compared with Vector-control IgG p<0.05. #: compared with HMW-control IgG p<0.05.

EGFL6 Promotes Endothelial Cell Migration and Angiogenesis Through the Activation of ERK. Jennifer Tickner^{*1}, Shek Man Chim¹, Qin An¹, Ming Hao Zheng¹, Nathan Pavlos¹, Jiake Xu². ¹University of Western Australia, Australia, ²The University of Western Australia, Australia

Angiogenesis is required for bone development, growth, and repair. It is influenced by the local bone environment that involves cross-talk between endothelial cells and adjacent bone cells. However, data regarding factors that directly contribute to angiogenesis by bone cells remains poorly understood. Here, we report that EGFL6, a member of the epidermal growth factor (EGF) repeat superfamily proteins, induces angiogenesis by a paracrine mechanism in which EGFL6 is expressed in osteoblastic like cells but promotes migration and angiogenesis of endothelial cells. Co-immunoprecipitation assays revealed that EGFL6 is secreted in culture medium as a homodimer protein. Using scratch-wound healing and transwell assays, we found that conditioned medium containing EGFL6 potentiates SVEC endothelial cell migration. In addition, EGFL6 promotes the endothelial cell tubelike structure formation in Matrigel assays and angiogenesis in a chick embryo chorioallantoic membrane. Furthermore, we show that EGFL6 recombinant protein induces

phosphorylation of ERK in SVEC endothelial cells. Inhibition of ERK impaired EGFL6-induced ERK activation and endothelial cell migration. Together, these results demonstrate, for the first time, that osteoblastic like cells express EGFL6 that is capable of promoting endothelial cell migration and angiogenesis via ERK activation. Thus, the EGFL6 mediates a paracrine mechanism of cross-talk between vascular endothelial cells and osteoblastic like cells and might offer an important new target for the potential treatment of bone diseases, including osteonecrosis, osteoporosis and fracture healing.

Regucalcin Stimulates Osteoclastogenesis and Suppresses Osteoblastogenesis by NF- κ B Activation. Masayoshi Yamaguchi^{*1}, M. Neale Weitzmann². ¹Emory University School of Medicine, USA, ²Emory University School of Medicine & the Atlanta VA Medical Center, USA

Regucalcin plays a pivotal role in regulating intracellular calcium homeostasis and consequently has a profound effect on multiple intracellular signal transduction pathways. Regucalcin transgenic (RGN Tg) rat displays pronounced bone loss and bone marrow from these animals exhibits significantly elevated osteoclast formation. Consistent with these effects exogenous regucalcin promotes osteoclastogenesis in rat and mouse bone marrow cultures, but interestingly regucalcin suppresses the differentiation and mineralization of MC3T3 osteoblast precursors and down-regulates Runx2 and alkaline phosphatase expressions. However, the molecular mechanisms involved are presently unclear. As the NF- κ B signal transduction pathway is critical to osteoclastogenesis but inhibitory of osteoblastogenesis we hypothesized that regucalcin may promote osteoclastogenesis and suppresses osteoblastogenesis upregulating NF- κ B signal transduction. In this study we studied the effect of regucalcin on RANKL-induced osteoclast formation using RAW264.7 monocytic cell line and osteoblast formation using preosteoblastic cell line MC3T3.

As expected, culture with exogenous regucalcin was found to enhance RANKL-induced osteoclastogenesis. Consistent with this effect regucalcin increased basal and RANKL-induced NF- κ B activation as assessed by NF- κ B luciferase assay. The capacity of regucalcin to augment RANKL-induced NF- κ B activity was inhibited by menaquinone-7, a potent NF- κ B antagonist, while the Erk inhibitor PD98059 and staurosporine had no effect, demonstrating a specific effect on NF- κ B signaling.

By contrast, regucalcin inhibited mineralization in MC3T3 cells and enhanced TNF α -induced NF- κ B activation. As with NF- κ B induction in osteoclasts NF- κ B activation was abolished by addition of the NF- κ B antagonist menaquinone-7, but not PD98059 and staurosporine.

TGF- β and BMP-2 are potent early commitment and late osteoblast differentiation factors respectively and both mediate their actions through the Smad signal transduction pathway, a system that is extremely sensitive to and inhibited by TNF- α -induced NF- κ B. We consequently examined the effect of regucalcin on TGF- β - and BMP-2-induced Smad activation in the presence and absence of TNF- α . While regucalcin had no effect on basal Smad activation by TGF- β and BMP-2, it enhanced the suppressive effect of TNF- α on both TGF- β - and BMP-2-induced Smad activation.

Taken together our data suggest that regucalcin may induce bone loss in vivo by promoting osteoclasts and simultaneously suppressing osteoblasts through amplification of basal and/or cytokine-induced NF- κ B activation.

TGF β Dependent Repression of MMP13 in Chondrocytes Via a Smad3 and Runx2 Dependent Pathway. Daniel Thuillier^{*1}, Carol Chen², Emily Chin², Tamara Alliston². ¹UCSF, USA, ²University of California, San Francisco, USA

In osteoarthritis, articular chondrocyte homeostasis is disrupted such that chondrocytes terminally differentiate and undergo hypertrophy. TGF β prevents chondrocyte hypertrophy in the growth plate, in part through its role in the perichondrium. Aberrant signaling of TGF β , Runx2, and Smad3 have each been associated with chondrocyte hypertrophy and osteoarthritis. However, molecular interactions of these factors in cartilage and the chondrocyte-intrinsic role of TGF β in hypertrophy remain unclear. In osteoblasts, TGF β activated Smad3 inhibits Runx2-inducible gene expression and terminal osteoblast differentiation. Therefore, we hypothesized that TGF β also inhibits terminal chondrocyte differentiation in a cell-intrinsic manner by Smad3-mediated repression of Runx2.

In Col2a1-Cre^{+/+};Smad3^{fl/fl} mice, deficient in Smad3 in chondrocytes but not in perichondrial cells, MMP13 protein expression was increased in growth plate hypertrophic chondrocytes by immunohistochemistry. Using ATDC5 chondroprogenitor cells, we examined if TGF β -mediated repression of MMP13 was also observed in vitro. Consistent with prior reports, TGF β induced MMP13 mRNA expression at 24 hrs and beyond. However, TGF β reproducibly repressed MMP13 induction at 8 hrs and earlier. Both effects were nullified by addition of a TGF β type I receptor inhibitor. Leveraging the well-studied MMP13 gene, we investigated mechanisms by which TGF β inhibits expression of a hypertrophic gene using gain and loss of function approaches. While overexpression of Runx2 in ATDC5 cells increased activity of an MMP13 promoter reporter construct, cotransfection of Smad3 or TGF β treatment repressed reporter activity dose-dependently. Accordingly, siRNA ablation of Runx2 impaired both the TGF β -mediated induction and repression of MMP13. However, when Smad3 was ablated, the rapid repression of MMP13 at 8hrs of TGF β exposure was lost and was replaced with induction. While our results are consistent with previously reported induction of MMP13 through TGF β -activated MAPK-signaling, we show here that TGF β also represses MMP13 expression in vivo, and in vitro through a chondrocyte-intrinsic Smad3 and Runx2 dependent pathway. As in other tissues, TGF β signaling through Smad3 may oppose non-Smad signaling in cartilage. By understanding the molecular pathways by which TGF β regulates expression of MMP13, this work sheds light on cell-intrinsic mechanisms utilized by TGF β to inhibit chondrocyte hypertrophy in vivo.

FoxO1 is a Bimodal Transcriptional Modulator of Bone Formation. Aruna Kode^{*}, Ioanna Mosialou, Charles Duncan, Barbara Silva, Stavroula Kousteni. Columbia University Medical Center, USA

The Forkhead transcription factor FoxO1 is a known regulator of osteoblast function. Studies in mice with osteoblast specific deletion of FoxO1 have indicated that FoxO1 maintains osteoblast proliferation and bone formation by maintaining normal protein synthesis and redox balance in these cells. We show here that in spite of these proliferative effects, FoxO1 assumes a completely opposite role in the presence of high levels of serotonin, a hormone which when produced by the duodenum suppresses bone formation. Mouse models of high serotonin synthesis and cell culture experiments show that FoxO1 mediates the anti-proliferative actions of serotonin in osteoblasts. To understand this bimodal regulation we examined whether serotonin-activated FoxO1 interacts with a distinct set of proteins than those utilized under physiological conditions. We found that whereas both oxidative stress and serotonin induce nuclear localization of FoxO1, the first does so through AKT inactivation, whereas the latter suppresses PKA activity leading to an increase in the activity of JNK1. Activated JNK1 induces nuclear localization of FoxO1. In the nucleus FoxO1 can associate with either ATF4 or CREB. The association with ATF4 promotes FoxO1 transcriptional activity and thereby protein synthesis, it also maintains physiological oxidative stress levels. In contrast, association with CREB suppresses FoxO1 activity and does not affect protein synthesis or redox balance. Serotonin has no effect on the ATF4/FoxO1 complex but disrupts the FoxO1/CREB complex, an event which potentiates FoxO1 transcriptional activity. Enhancement of FoxO1 transcriptional activity is further reinforced by ATF4 and leads to suppression of cell cycle progression. These observations uncover a novel mechanism of regulation of osteoblast proliferation in which FoxO1 is the molecular node of an intricate transcriptional machinery in which different levels of FoxO1 transcriptional activity exert opposing effects on proliferation and bone formation.

Identification of Mechanisms of Lipopapoptosis in Normal Human Osteoblasts. Krishanthi Gunaratnam^{*1}, Christopher Vidal¹, Chris Thekkedam², Ross Boadle³, Gustavo Duque². ¹University of Sydney, Australia, ²Ageing Bone Research Program, University of Sydney, Australia, ³Millennium Research Institute, Australia

Although apoptosis plays an important role in the regulation of bone metabolism, the particular mechanisms of apoptosis in osteoblasts remain to be elucidated. We have previously demonstrated that osteoblasts undergo apoptosis after exposure to fatty acids suggesting a new model of lipopapoptosis in bone. In this study, we characterized the particular features and the mechanisms of lipopapoptosis in normal human osteoblasts (NHOs) after exposure to fatty acids. We hypothesized that, in contrast to "spontaneous" osteoblast apoptosis, lipopapoptosis is activated through a particular mechanism that should be identified in order to understand and prevent lipotoxicity in bone. NHOs were cultured in growth medium and induced to differentiate into osteoblast in the presence of either palmitic acid (100mM, 250mM and 500mM) or vehicle in the differentiation media for 24, 48 and 72h. Apoptosis was identified by TUNEL assay and electron microscopy. Additionally, the apoptotic pathways were identified using proteomic analysis of 43 apoptosis proteins (Human Apoptosis Array Kit, RayBiotech inc.). Finally, proteins showing a significant change were confirmed by western blot. TUNEL assay showed an increase in DNA fragmentation in palmitate-treated cells in a dose- and time-dependant manner. Electron microscopy showed predominantly early mitochondrial changes at 48h (Figure), which were more prevalent at higher concentration of palmitic acid. In addition, nuclear fragmentation was only observed at 72h. Later cellular changes (at 72h) included plasma membrane blebbing or budding and cell fragmentation into compact membrane-enclosed structures compatible with apoptotic bodies. Proteomic analysis identified 6 fold increase in Fas ligand ($p < 0.001$) and 2 fold increase in Bax and Cytochrome C ($p < 0.001$) expression in palmitate-treated cells (500 nM for 48 h) compared with untreated cells suggesting that, in agreement with the changes observed by electron microscopy, lipopapoptosis is induced through early activation of mitochondrial mechanisms following the activation of Fas-dependent pathways by palmitate, which in fact acts as a Fas-like compound. In summary, we have identified a previously unknown mitochondrial apoptotic pathway that is particular of lipotoxicity in osteoblasts. The regulation of fatty acid secretion and the inhibition of lipopapoptosis would protect osteoblasts against fat and could become a potential therapeutic target for osteoporosis in the future.

Alcohol Consumption Delays Bone Healing in Association with Reduced Osteocalcin Expression after Drill Hole Injury. Yoshinori Takeuchi^{*1}, Akinori Sakai¹, Toshiharu Mori², Takuto Tsuchiya¹, Shinkichi Kanoh¹, Toshitaka Nakamura¹. ¹University of Occupational & Environmental Health, Japan, ²University of Occupational & Environmental Health, Jpn

Background: Alcohol consumption has been reported to delay fracture healing because of inhibiting osteoblast differentiation and function. However the effect of alcohol in vivo still remains unclear. The aim of this study is to clarify the effect of alcohol consumption on bone healing after drill hole injury.

Method: 8-week-old male mice (C57BL6J) were divided into two treatment groups: A) free-ingested water for 4 weeks B) free-ingested 5% ethanol for 4 weeks. At the age of 12 weeks, we made drill-hole injury, 1mm in diameter, at the anterior portion of the diaphysis of bilateral femurs. The femurs of each group were harvested before injury (day0) and at days 3, 5, 7, 10, 14 after injury. We performed bone histomorphometry at days 7, 14 after surgery and mRNA expression at days 0, 3, 5, 7, 10, 14.

Result: In bone histomorphometry, bone volume (BV/TV), OBs/BS at day7 was significantly decreased in alcohol group compared with that in water group, but there was no significant difference in BV/TV, OBs/BS at day 14 between two groups. Quantitative RT-PCR revealed osteocalcin mRNA expression significantly decreased in alcohol group at days 3, 5, 7.

Conclusion: Alcohol consumption inhibited bone regeneration and delayed bone healing in association with reduced osteocalcin expression after drill hole injury.

Calcium Aluminate Scaffolds Covalently Linked with Melatonin Show Osteoconductivity and Osteoinductivity. William Clafshenkel¹, Rachelle Palchesko², Jared Romeo², James Rutkowski³, Kenneth McGowan⁴, Ellen Gawal², Paula Witt-Enderby^{*5}. ¹Duquesne University, Grad School of Pharmaceut Sci, USA, ²Duquesne University Bayer School of Natural & Environmental Sci, USA, ³Clarion Research Group, USA, ⁴Westmoreland Advanced Materials, LLC, USA, ⁵Duquesne University, School of Pharmacy, USA

One significant problem that the phosphate-based ceramic materials face is that they lack substantial mechanical integrity and are brittle and, as such, they require a high heat treatment so that they will develop the necessary strength. Another problem is that ceramic implants are only osteoconductive. Calcium aluminates (CAs) are composed of naturally hydratable mineral phases that form at room temperature. The objective of this study was to create novel CAs with regenerating and strength properties similar to natural bone that are moldable at room temperature and that display osteoconductive and osteoinductive properties. Recent evidence shows that melatonin enhances osteoblast differentiation, inhibits osteoclast-mediated bone resorption and is protective against bone loss. It was hypothesized that cooperative effects between calcium aluminate scaffolds (CAs) and melatonin occur to enhance bone regeneration in a model of calvarial (5x5mm²) defects. Our previous findings, in vivo, using female ovariectomized rats, show that melatonin-modified CA scaffolds (CA-Mel) are biocompatible and more osteoconductive compared to CA alone; the CA-Mel scaffolds showed greater bone remodeling within and around the CA-Mel scaffold/calvarial interface at 3 and 6 months as revealed by histochemistry and double fluorochrome labeling. To determine if the CA-Mel scaffolds were osteoinductive, in vitro studies were performed using human adult mesenchymal stem cells (hAMSCs) grown in culture. hAMSCs were plated over CA or CA-Mel scaffolds and then cultured in osteogenic medium for 7 days or 14 days; hAMSCs cultured under these conditions without scaffolds show differentiation into osteoblasts revealed by increases in alkaline phosphatase levels and alizarin red staining. The results from the in vitro studies reveal the presence of alkaline phosphatase within the CA-Mel scaffolds by 7 days in culture. These in vitro data show that hAMSCs grown on CA-Mel scaffolds induces their differentiation into osteoblasts, which is one indicator of osteoinductivity. These in vitro findings, showing increases in alkaline phosphatase levels within the CA-Mel scaffolds, also supports our in vivo findings about the osteoconductive nature of these scaffolds. These data support the hypothesis that CA-Mel scaffolds are both osteoconductive and osteoinductive. These findings are important and may lead to the development of a novel bioactive scaffold to enhance bone grating procedures.

Correction of the Haploinsufficient Hematopoietic Microenvironment is Sufficient to Normalize the Pathological Fracture Repair in Genetically Engineered Murine Model of Neurofibromatosis Type 1. Xiaohua Wu¹, Shi Chen¹, Yongzheng He¹, Steven Rhodes², Xiaohong Li¹, Xianlin Yang¹, Li Jiang¹, Grzegorz Nalepa¹, Khalid Mohammad², Alexander Robling², D. Wade Clapp¹, Simon Conway¹, Theresa Guise², Feng-Chun Yang².
¹Indiana University School of Medicine, USA, ²Indiana University, USA

Germline mutations in the NF1 tumor suppressor gene cause neurofibromatosis type 1 (NF1), a complex genetic disorder with a high predisposition to numerous skeletal dysplasias including short stature, osteoporosis and kyphoscoliosis. Understanding the pathogenesis of these sequelae has been difficult due to lack of appropriate orthologous genetic animal models.

In this study, Periostin promoter mediated Cre expression, which has been shown expressed in mesenchymal stem/progenitor cells (MSPCs) and osteoblasts, was introduced to the mouse model. PeriCre⁺ mice were intercrossed with mice bearing either systemic or conditional genetic targeting of the Nf1 allele (Nf1^{+/-} and Nf1flox/flox, respectively) to generate four experimental genotypes: PeriCre⁺;Nf1flox/flox (WT), PeriCre⁺;Nf1flox^{-/-} (Nf1^{+/-}), PeriCre⁺;Nf1flox/flox mice (Nf1 null in MSPCs and osteoblasts, otherwise systemically WT), and PeriCre⁺;Nf1flox^{-/-} mice (Nf1 null in MSPCs and osteoblasts, otherwise systemically Nf1 heterozygous). The skeletal phenotypes and fracture healing were evaluated by pDEXA, μ CT (for tibia or femur), TRACP staining, and McNeal's staining (for bone sections).

Our results showed that bone mineral density is significantly reduced in PeriCre⁺;Nf1flox^{-/-} mice as compared to other groups of mice. Furthermore, reduced trabecular bone formation and increased osteoclast activity in PeriCre⁺;Nf1flox^{-/-} mice are evidenced by μ CT analysis, McNeal's staining, and TRACP staining. PeriCre⁺;Nf1flox^{-/-} mice displayed an impaired fracture healing. These data suggest that the development of these skeletal manifestations requires a Nf1 haploinsufficient background in addition to nullizygous loss of Nf1 in MSPCs and their progenies. Moreover, the requirement of the hematopoietic bone marrow microenvironment is verified by adoptive transfer experiments. More importantly, transfer of WT bone marrow into PeriCre⁺;Nf1flox^{-/-} mice significantly improves fracture healing. These data provide the first evidence of a non-cell autonomous mechanism in non-malignant NF1 manifestations, specifically, skeletal manifestations.

Collectively, these data demonstrate a combinatory effect between nullizygous loss of Nf1 in osteoblast progenitors and haploinsufficiency in hematopoietic cells in the development of skeletal manifestations in NF1.

Forming Bone in Artificial Patterns Using Mother of Pearl. Ronke Olabisi*, Maude Rowland, Christy Franco, Joseph Hoffmann, Jennifer West. Rice University, USA

The purpose of this study was to direct osteoblast bone formation in specified patterns on surfaces of hydrogels using proteins extracted from mother of pearl (nacre). Neither biomimetics nor tissue engineering have yet produced a tissue biomechanically and structurally equivalent to authentic bone, and insights into developing better bone replacement materials may be obtained through studies of biomineralization. Water soluble proteins extracted from nacre initiated earlier biomineralization in MC3T3-E1 cells (1). Here we extract nacre proteins from the water soluble, urea soluble and EDTA soluble matrix (WSM, USM and ESM, respectively), then react them with poly(ethylene glycol)-succinimidyl valerate (PEG-SVA) to attach crosslinkable acrylated PEG polymers. Next, PEG hydrogels were formed containing PEGylated fibronectin to enable osteoblast attachment. PEGylated nacre proteins were combined with fluorescein o-acrylate (a fluorescent marker) and placed on the surface of hydrogels in all combinations of the 3 proteins (N=8: WSM, USM, ESM, WSM+USM, WSM+ESM, USM+ESM, WSM+USM+ESM, None). A patterned photomask was placed over the proteins and exposed to collimated white light in order to crosslink the PEGylated proteins to the hydrogel surface in the pattern. Murine osteoblasts (MC3T3-E1) were seeded on the surfaces of these hydrogels. On day 3, seeded hydrogels were imaged with phase and fluorescent microscopy and bone nodules were quantitated. On day 12, hydrogels were stained using the von Kossa method and imaged with phase microscopy. By day 3, mineralization occurred at a significantly greater rate ($p=0.019$) on the WSM hydrogel within or directly adjacent to areas containing WSM than areas devoid of the protein, as visualized by fluorescence of collocated fluorescein o-acrylate (Fig 1). von Kossa stains showed mineralized bone forming in the patterns on the surface of the WSM hydrogel (Fig 2). Hydrogels containing other proteins did not display this

phenomenon. While WSM proteins have been demonstrated to initiate bone formation by MC3T3-E1 cells, this is the first time this capacity has been demonstrated when the proteins have been covalently immobilized on a patterned hydrogel. Thus we have for the first time directed bone formation in a specified pattern. This may be the first step towards tissue engineering complex delicate bone structures, such as the stapes within the ear.

Impact of Omega-3 Polyunsaturated Fatty Acids on Bone During Chronic Simulated Resistance Training. Kaleigh Camp*, David Cunningham, Evelyn Yuen, Brandon Macias, Stuart Solomon, Harry Hogan, Susan Bloomfield. Texas A&M University, USA

Animals eating diets rich in omega-3 polyunsaturated fatty acids (n-3 PUFAs) exhibit enhanced bone formation. Eicosapentaenoic acid, an n-3 PUFA found in fish oil, competes with arachidonic acid, an omega-6 polyunsaturated fatty acid (n-6 PUFA), for the cyclooxygenase enzyme, modulating prostaglandin E2, a potent mediator of bone mechanotransduction. Whether this diet affects bone gains during chronic exercise is not well defined. The purpose of this study was to determine the impact of a diet rich in n-3 PUFAs on bone mass and geometry changes after simulated resistance training (SRT). We hypothesized rats consuming a high n-3 PUFA diet would gain more bone mass compared to the rats consuming a low n-3 PUFA diet in response to SRT. Virgin female Sprague-Dawley rats (5-mo-old, n=20) were assigned by body weight to one of two groups: diet with an n-6:n-3 dietary ratio of 23:1 (O6) or a diet rich in fish oil with an n-6:n-3 dietary ratio of 2:1 (O3) based on the AIN-93M purified diet. After 4 weeks' acclimation rats completed 9 SRT sessions on alternate days using stimulated muscle contractions under anesthesia at 75% peak isometric strength; each contraction included 1 sec isometric + 1 sec eccentric contraction. Cancellous and cortical density and geometric properties at the proximal and mid-shaft tibiae of both the exercised and non-exercised legs were quantified at

days -7 and 21 using *in vivo* peripheral quantitative CT. There were no significant differences in body weights among groups at baseline or after training. Rats on the O3 diet exhibited significant increases in total vBMD, total vBMC, and cortical BMD at the proximal tibia versus values in rats on the O6 diet ($p < 0.05$); however, the O3 diet had no effect on mid-shaft tibia cortical BMC, vBMD, or area. In both diet groups, SRT stimulated significant gains in total vBMD (6.3%) and cortical BMD (6.1%) at the proximal tibia, and cortical BMC (21.5%) and cortical area (19.8%) at the mid-shaft tibia. However, we could not detect any increased effect of the O3 diet on magnitude of these gains in bone mass or area with SRT. A diet high in n-3 PUFAs independently increases bone mass at the proximal tibia metaphysis; however, it does not further enhance gains in bone mass observed with simulated resistance training.

Maintenance of Human Osteoblasts, Mesenchymal Stem Cells, and Bone Explants In Vitro Without the Use of Animal Derived Materials. *Mrs Carole Elford, Deborah Mason, Dr Jim Ralphs, Professor John W. Gregory, Dr Alastair J. Sloan, Bronwen Evans**. Cardiff University, United Kingdom

It is important to advance and implement the 3Rs i.e. replacing, reducing and refining the use of animals in research and testing. Furthermore, musculoskeletal cell or tissue replacement therapies require the use of chemically defined media, which do not contain animal derived materials. We investigated the use of a range of non-fetal calf serum (FCS) containing media on cell number (3 days; MTS assay) in human osteoblast lines (MG63, SaOS2). We have compared the current gold standard of DMEM containing 10% FCS with a range of test media: 1) DMEM with 10% human serum (Lonza), 2) DMEM with 10% human serum AB (Lonza) 3) DMEM with K/O serum replacement (10%, 15%; Invitrogen), and 4) TheraPEAK (defined medium; Lonza). We also investigated the effects of these media on multipotent, marrow-derived, human mesenchymal stem cell (MSC; Promocell) numbers and differentiation (3 days; ALP activity). Cells were either i) set up in control media and test media added the next day, or ii) set up in the test media. Furthermore, similar work was undertaken with explants derived from human bone.

With MG63 cells, human serum and K/O decreased (50-60%; $p < 0.001$), whereas TheraPEAK increased numbers (~130%; $p < 0.001$). With the more differentiated SaOS2, however, human serum increased (120%; $p < 0.01$) or had no effect, depending on the set up methodology used, K/O (15%) decreased (~35%; $p < 0.01$), whereas TheraPEAK increased numbers by 200 to 300% ($p < 0.001$). With undifferentiated MSCs, results were similar to those with MG63 cells, although reductions with human serum and K/O were ~25% and ~75% respectively ($p < 0.001$). Human serum and TheraPEAK stimulated (~250%; $p < 0.001$) differentiation (ALP activity) in MSCs. Human bone chips set up in different media resulted in the establishment of osteoblast cultures in all media, although FCS containing cultures exhibited most proliferation, whereas osteoblasts in human serum containing medium were the most differentiated. Very few cells were observed with TheraPEAK.

The work shows that cells at different stages of the osteoblast differentiation pathway respond differently to non-FCS containing media, and that it is possible to establish primary, human osteoblast cultures without using FCS. The results will guide our planned studies to design successful human osteoblast and osteocyte culture methods using media which do not contain animal derived materials.

Mature Osteoclasts Produce S1P to Support Osteoblast Differentiation via S1P Receptor Engagement and RhoA Activation. *Patrick Quint**¹, *Moustapha Kassem*², *Jennifer Westendorf*³, *Sundeep Khosla*⁴, *Merry Jo Oursler*³. ¹Mayo Clinic Rochester, USA, ²Odense University Hospital, Denmark, ³Mayo Clinic, USA, ⁴College of Medicine, Mayo Clinic, USA

Bone is a dynamic tissue that continuously remodels and, under most conditions, resorbed bone is nearly precisely replaced in location and amount by new bone. It has long been recognized that bone resorption and formation are tightly coupled processes but the nature of the coupling factors remained unresolved. To study secreted osteoclast products that might recruit osteoblast lineage cells, we examined osteoclast precursor and mature osteoclast conditioned media (CM) influences on hMSC-TERT mesenchymal cells. A centrifuge filter unit with a nominal 10,000 dalton cut off was used to 10-fold concentrated conditioned media (CM) from mature osteoclasts. Osteoclast CM supported hMSC-TERT cell migration and mineralization compared to base media. The precursor CM also stimulated hMSC-TERT cells, but to a lesser extent than the mature osteoclast CM. Concentrated and unconcentrated CM stimulated hMSC-TERT cell migration and mineralization to nearly the same extent. These data indicated the possible presence of a low mass chemokine and we hypothesized that sphingosine-1-phosphate (S1P) was involved. There are two enzymes that produce S1P, Sphingosine-1-kinase (SPHK) 1 and SPHK2. During osteoclast differentiation, SPHK1 expression was up-regulated whereas SPHK2 expression remained constant. A luciferase reporter driven by the SPHK1 promoter confirmed promoter activation during osteoclast differentiation. Mass spectrometry

of the CM detected S1P in the CM from both osteoclast precursors and mature osteoclasts.

The hMSC-TERT cells expressed S1P receptors 1, 2 and 3 mRNAs. Targeted disruption of S1P interactions with S1P receptors 1 and 2, but not 3, blocked osteoclast precursor and mature osteoclast CM effects on mineralization and migration of hMSC-TERT cells. Combined blocking of receptors 1 and 2 was the most effective at blocking responses, supporting non-redundant roles for these receptors. To resolve the mechanisms by which S1P influences hMSC-TERT cells, we employed a pan-specific S1P receptor agonist to investigate influences of S1P on hMSC-TERT cells. Examination of Rho family GTPase activation revealed that Rho A, but not Rac1 or Cdc42, were activated following agonist treatment.

We conclude from these data that osteoclast precursor and mature osteoclast CM promote mesenchymal cells at least in part through production of the chemokine S1P, which stimulates mesenchymal cell RhoA activation to promote recruitment and differentiation.

Mechanosensitivity of Osteoblasts Could Be Up-regulated by Inhibition of Cytoskeleton Reorganization. *Qiang Fu**, *Yun Shen*, *Yiping Zhang*, *Changjing Wu*, *Rui Chen*. School & Hospital of Stomatology, Sun Yat-sen University (present address is Shanghai Tenth People's Hospital, Shanghai), China

Evidence has proved that bone accommodates to steady mechanical loading by down-regulating its reaction induced by mechanical stimuli, inferring that bone cells can adapt their mechanosensitivity to a new mechanical environment. Cytoskeleton plays an important role in cellular mechanotransduction and would be reorganized in response to mechanical loading. In previous studies, we found that using RNAi against LIM domain kinase 2 (LIMK2) could inhibit the cytoskeleton reorganization induced by fluid shear stress in osteoblasts without structural or functional destruction of the cytoskeleton. Based on this, we proposed the hypothesis that the cytoskeleton reorganization of bone cells contributes to their adaptation to mechanical stimuli, and that the mechanosensitivity of bone cells would be manipulated by inhibition of the cytoskeleton reorganization.

In the present study, we chose two significant molecules of c-Fos and cox-2 as the representatives of osteoblasts activity, and studied their expression levels under loading when cytoskeleton reorganization was inhibited. Mouse primary osteoblasts were pretreated with RNAi against LIMK2 and loaded by fluid shear stress at 12 dyne/cm² for 1/1.5h. Negative RNAi and cytochalasin D were also used to pretreat the cells as two control methods. C-Fos and cox-2 expression levels were examined by Real-time PCR, immunofluorescence and Western-blot.

We found that loaded cells treated with LIMK2 RNAi had 2.4- and 3.1-fold higher expression levels of c-Fos and cox-2 mRNA, respectively, compared with the negative RNAi controls and 1.3- and 1.6-fold higher c-Fos and cox-2 protein levels, respectively. In contrast, c-Fos and cox-2 expression levels induced by fluid shear stress were significantly reduced by 32% and 37%, respectively, in Cytochalasin D-treated cells.

This study demonstrates that cytoskeleton integrity in osteoblasts is essential for the c-Fos and cox-2 genes expression induced by fluid shear stress, and when the cytoskeleton reorganization is inhibited their expression induced by fluid shear stress is promoted. So, from the point of view of these two important genes related with osteoblasts activity, it suggests that the mechanosensitivity of osteoblasts could be up-regulated by inhibition of cytoskeleton reorganization. The regulation of cytoskeleton should be a way to manipulate the mechanosensitivity of bone cells and even bone tissue.

OBs immunofluorescence Density of c-Fos in RNAi group was higher than NC group after loading

OBs immunofluorescence Density of COX-2 in RNAi group was higher than NC group after loading

c-Fos expression level induced by fluid shear stress was promoted through RNAi

COX-2 expression level induced by fluid shear stress was promoted through RNAi

Osteoblastic ephrinB2 Is Required for Normal Osteoblast Differentiation and Function *in vitro* and *in vivo*. Farzin Takyar¹, Stephen Tonna¹, Blessing Criméen-Irwin¹, T. John Martin¹, Natalie Sims². ¹St. Vincent's Institute of Medical Research, Australia, ²St. Vincent's Institute for Medical Research, Australia

Bidirectional signaling between EphB4 and ephrinB2 in osteoblasts leads to increased osteoblast differentiation *in vitro*, and interference with this interaction inhibits osteoblast differentiation. Furthermore, injection of PTH rapidly enhanced ephrinB2 expression in mouse and rat bone and isolated osteoblasts.

To determine the role of osteoblastic ephrinB2 in bone metabolism, we crossed *efnB2-flox* and osteoblast-specific tetracycline-regulatable *Osx1Cre* mice to delete *efnB2* from an early stage of osteoblast differentiation *in vivo*. Two groups of mice were studied: one where ephrinB2 was deleted constitutively, and one where mothers and pups were treated with doxycycline until 4 weeks of age, to allow ephrinB2 expression during

skeletal development. Tibiae from female 12 week old *Osx1Cre.efnB2^{fl/fl}* mice and controls (*Osx1Cre.efnB2^{wt/wt}*) were analyzed by histomorphometry.

No overt change in bone structure was observed in *Osx1Cre.efnB2^{fl/fl}* mice compared with *Osx1Cre.efnB2^{wt/wt}* regardless of whether ephrinB2 was deleted constitutively or after skeletal development. In *Osx1Cre.efnB2^{fl/fl}* mice treated with doxycycline until 4 weeks of age, we observed a significant (30%) increase in osteoblast number ($p=0.02$) compared to control animals, but osteoid and osteoclast parameters were unchanged. In *Osx1Cre.efnB2^{fl/fl}* mice with no exposure to doxycycline and therefore with ephrinB2 deletion throughout development, more dramatic alterations in bone formation were observed. With such lifetime deletion of ephrinB2, osteoblast surface, osteoblast number, and osteoid thickness were all significantly increased by ~30% in *Osx1Cre.efnB2^{fl/fl}* mice compared to controls ($p=0.03$, 0.003 , and 0.01 , respectively). Despite this, osteoid surface was not increased. Furthermore, in contrast to the increase in osteoblast number, a 30% decrease in mineralizing surface and 50% decrease in bone formation were observed in *Osx1Cre.efnB2^{fl/fl}* mice ($p=0.01$ and 0.03 , respectively). These data indicate that although their number is increased, ephrinB2-deficient osteoblasts have reduced mineralization ability. Osteoclast number was not significantly modified in *Osx1Cre.efnB2^{fl/fl}* mice.

These results provide *in vivo* evidence confirming *in vitro* findings indicating that ephrinB2 signaling within the osteoblast lineage is required for normal differentiation and function of osteoblasts in bone formation.

Time Course of Bone Response to Smoke Exposure in Cortical Bone. Diane Cullen^{*1}, Bryan Hackfort¹, Gwendolin Alvarez¹, Sara Rousch¹, Meredith Stein¹, Mohammed Akhter². ¹Creighton University, USA, ²Creighton University Osteoporosis Research Center, USA

Cigarette smoking is a risk factor for osteoporosis. In previous studies we have found bone loss, but inconsistent effects on bone formation in cortical bone. This may be due to the remodeling sequence and time frame for activation of osteoblasts and osteoclasts. We hypothesize that in mice, smoke exposure increases remodeling with early osteoclast activation and osteoblast suppression followed by an osteoblast increase secondary to osteoclast resorption. To test this, mice were divided into smoke exposure and control and then collected at baseline, after 3, 6, or 12 weeks treatment or after 12 wks treatment and 6 wks recovery. Mice were exposed for 3 hrs, 5 d/wk at an average smoke concentration of 103 mg/m³ TSP. To examine the interaction of smoking (catabolic treatment) with the Lrp5/Wnt pathway (anabolic pathway) we examined wild type C57Bl6 (W) mice, Lrp5 knockout (K) and HBM transgenic (H) mice. Differences were tested by three-way ANOVA for Time, Smoke, and Genotype (Figure). After 12 wks of treatment there was greater marrow area and lower bone strength in smoke exposed mice. In the control animals there was a decrease in bone formation rates with age. Periosteal bone formation rate (BFR) was further suppressed in all smoke groups at 3 and 6 wks of exposure and remained low at 12 wks. After smoke recovery, BFR was higher than in control. The endocortical BFR was suppressed at 3 wks and recovered to normal levels by 6 wks. At three weeks osteoblast activity is suppressed in all genotypes suggesting a negative effect of smoke on bone formation independent of Lrp5 expression. The recovery of formation by 6 wks, on the endocortical but not the periosteal surface is consistent with activation of osteoclasts and secondary osteoblast activation in remodeling. The periosteal surface in adult mice does not normally show remodeling and is perhaps the best indicator of direct smoke effects on the osteoblast which was consistent suppression. The periosteal recovery demonstrates the direct, acute effect of smoke exposure on osteoblasts. We conclude cigarette smoke suppresses osteoblast activity and that results from the endocortical surface are confounded by the coupling of osteoclasts and osteoblasts in remodeling.

A Program of MicroRNAs Controls Osteogenic Lineage Progression by Targeting Transcription Factor RUNX2. Ying Zhang^{*1}, Rong-lin Xie², Carlo Croce³, Janet Stein², Jane Lian², Andre Van Wijnen², Gary Stein². ¹Umass medical school, USA, ²University of Massachusetts Medical School, USA, ³The Ohio State University, USA

Lineage progression in osteoblasts and chondrocytes is stringently controlled by the cell-fate determining transcription factor Runx2. In this study we directly addressed whether small non-coding microRNAs (miRNAs), which inhibit mRNAs by binding to seed sites, control osteoblast maturation by modulating the osteogenic activity of Runx2. A panel of eleven Runx2-targeting miRNAs (miR-23a, miR-30c, miR-34c, miR-133a, miR-135a, miR-137, miR-204, miR-205, miR-217, miR-218 & miR-338) is expressed in a lineage-related pattern in mesenchymal cell types. During both osteogenic and chondrogenic differentiation, these miRNAs, in general, are inversely expressed relative to Runx2. Based on 3'UTR luciferase reporter and immuno-blot assays, each miRNA directly attenuates Runx2 protein accumulation. Runx2-targeting miRNAs differentially inhibit Runx2 protein expression in osteoblasts and chondrocytes and display different efficacies. Thus, cellular context contributes to miRNA mediated regulation of Runx2. All Runx2-targeting miRNAs (except miR-218) significantly impede osteoblast differentiation and their effects can be reversed by the corresponding anti-miRNAs. These findings demonstrate that osteoblastogenesis is limited by an elaborate network of functionally tested miRNAs that directly target the osteogenic master regulator Runx2.

Bone-specific Overexpression of NPY Modulates Osteogenic Differentiation. Igor Matic^{*1}, John Igwe², DARIO REPIC¹, SLAVICA PEJDA³, Tomislav Kizivat⁴, Douglas Adams¹, Ivo Kalajic¹. ¹University of Connecticut Health Center, USA, ²Department of Orthopedic Surgery, University of Connecticut Health Center, USA, ³University of Connecticut, USA, ⁴Croatia

Our previous work showed that neuropeptide Y (NPY) is expressed by osteoblast lineage cells and when administered in vitro can inhibit osteoblast lineage differentiation. We hypothesize that NPY, generated by mature osteoblast lineage cells, can control and modulate differentiation of osteoprogenitor cells. Therefore, in this study we have evaluated the effects of bone-specific overexpression by generating Col2.3NPY-ires GFP^{topaz} transgenic mice. As described in previous studies, this transgenic approach will direct NPY overexpression to mature osteoblasts and osteocytes. Real-time PCR analysis of bone-derived RNA showed increased expression of NPY in samples derived from Col2.3NPY mice compared to wild type. To characterize the Col2.3NPY mice phenotype in vivo, trabecular and cortical bone

morphometry was measured in three-month-old mice using µCT analysis. Lower trabecular and cortical bone mass and morphometric parameters were observed in both male and female mice, exhibiting 30-35% lower trabecular volume and 7-9% lower cortical volume, without differences in linear bone growth. Gene expression analysis in Col2.3NPY mice shows increased expression of OC when compared to wild type. No difference was detected in expression levels for BSP and DMP-1. Our preliminary data on dynamic histomorphometry has shown reduced mineral apposition rate in Col2.3NPY mice. This apparent discrepancy in bone mass and gene expression will be addressed by evaluating cellular parameters of bone lineage using histomorphometry and evaluation of the effects of NPY overexpression on proliferation and maturation of the osteoblast lineage cells in vivo. We have utilized primary culture to assess the effects of NPY overexpression. Markers of mature osteoblast lineage cells (BSP, OC, and DMP-1) in BMSCs derived from Col2.3NPY mice were enhanced compared to wild type. There was no difference in ALP activity or mineralization in MSC cultures derived from NPY versus wild type mice. In contrast to stromal cells, calvarial osteoblast derived from Col2.3NPY mice show a decrease in mineralization colonies. This difference between two culture models could be a result of the presence of more mature NPY producing cells driven by Col2.3 at the early days of calvarial osteoblast culture compared to BMSC. Further studies are required to clarify the bone phenotype of Col2.3NPY mice and to understand the mechanism by which bone derived NPY affects osteoprogenitor differentiation.

Collagen-Mimetic Peptide of Adiponectin Accelerates Osteoblastic Differentiation. Aiko Kamada^{*}, Takashi Ikee, Yoshihiro Yoshikawa, Eisuke Domae, Seiji Goda, Isao Tamura. Osaka Dental University, Japan

Adiponectin, a adipocyte-derived biologically active molecule, abundantly present as a plasma protein, and exhibits various biological functions, such as regulating energy homeostasis and increasing insulin sensitivity in the liver and skeletal muscle. It is ~30-kDa polypeptide containing N-terminal signal sequence, variable domain, collagen-like domain, and C-terminal globular domain. Recent studies have demonstrated both a positive and negative action of adiponectin on bone formation, and it was thought that these different actions might be attributed to its multifunctional domains. Previously we demonstrated that functional domains of adiponectin act on osteoblasts through different manners, and the collagen-like domain may be involved to osteoblast differentiation. In this study we synthesized collagen-mimetic peptide designed from adiponectin functional domains, and investigated its effect on osteoblast differentiation.

Recombinant murine adiponectin collagen-like domain was designed and produced. Osteoblastic differentiation of a murine pro-osteoblastic cell line, MC3T3-E1 cells, was induced by differential medium including ascorbic acid and beta-glycerophosphate with or without the peptide. Gene expression was determined by real time RT-PCR analysis.

The collagen-mimetic peptide induced expression of genes related to various signaling pathways and BMP family involved to osteoblastic differentiation.

Our study suggests the collagen-mimetic peptide from adiponectin collagen-like domain may be useful for regeneration of calcified tissues.

Differential Expression of Nuclear Receptors and Coregulators in Mouse Calvarial Osteoblast Differentiation and in Aged Mice. Matthew Roforth^{*1}, Sundeep Khosla², David Monroe³. ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA, ³Mayo Foundation, USA

A complex network of transcription factors contributes to the establishment and maintenance of the osteoblastic phenotype. Although relatively few transcription factors, such as Runx2 and osterix, are essential to the process of osteoblastic differentiation, others serve the purpose of fine-tuning in response to various environmental and hormonal cues. In this study we report the expression patterns of the entire nuclear receptor (NR) superfamily, select coregulator, and osteoblast marker genes during differentiation in a primary mouse calvarial cell model. Osteoblastic mineralization was visually apparent ten days following osteoblastic induction, as assessed by Alizarin red stain. Increases in the classical bone marker genes alkaline phosphatase, osteocalcin, Runx2 and osterix, were also observed. Interestingly, Sost, Dmp1, Fgf23, Phex and Mepe, all genes associated with osteocytic function, were increased suggesting the adoption of an osteocytic phenotype. Analysis of NR gene expression one day following induction revealed significant changes in a number of NR subfamilies and associated changes in select coregulators involved in NR signaling. Most notably upregulation of estrogen, retinoic acid and vitamin D receptors were observed within the first day of differentiation, supporting the role of these pathways in osteoblastic differentiation. Examination of NR and coregulator gene expression patterns at later stages of osteoblastic differentiation revealed that 78% of NRs and virtually all coregulators were downregulated. To place our findings in the context of age-related changes in bone metabolism, we next determined the NR and coregulator gene expression changes associated with age-related bone loss. Analysis of NR and coregulator gene expression in aged mice (18-22 month versus 6 month controls) revealed significant upregulation of Errα, Lxrα, Rorβ, Rev-erba/β and the p72 RNA helicase coactivator. Interestingly, all these NRs are associated with

either age-related bone loss or the support of adipogenesis. Collectively, these data demonstrate that large-scale changes in the nuclear receptor superfamily occur throughout osteoblastic differentiation and during the process of aging, leading to altered sensitivity to various hormonal cues. Whether these changes are prerequisite for osteoblast differentiation or a consequence of the induction of differentiation or the aging process remains an important area for further investigation.

Effect of Nanocoating with Rhamnogalacturonan-I on Surface Properties and Osteoblasts Response. Katarzyna Gurzawska^{*1}, Rikke Svava², Susanne Syberg³, Yu Yihua⁴, Kenneth Brian Haugshøj⁵, Iben Damager⁶, Leif Højislet Christensen⁵, Peter Ulvskov Ulvskov⁶, Klaus Gotfredsen⁷, Niklas Jørgensen⁸. ¹Research Center for Ageing & Osteoporosis, University of Copenhagen, Glostrup Hospital, Denmark, ²Copenhagen Center for Glycomisc, Faculty of Health Sciences, University of Copenhagen, Denmark, ³Glostrup Hospital, Denmark, ⁴Microtechnology & surface analysis, Danish Technological Institute, Gregersensvej 3, 2630 Taastrup, Denmark, Denmark, ⁵Microtechnology & surface analysis, Danish Technological Institute, Denmark, ⁶Department of Plant Biology, Faculty of Life Sciences, University of Copenhagen, Denmark, ⁷Institute of Odontology, Faculty of Health Sciences, University of Copenhagen, Denmark, ⁸Copenhagen University Hospital Glostrup, Denmark

Long-term stability of titanium implants are dependent on a variety of factors. Nanocoating with organic molecules is one of the methods used to improve osseointegration. Therefore, the aim of this study was to evaluate the in vitro effect of nanocoating with pectic rhamnogalacturonan-I (RG-I) on surface properties and osteoblasts response.

Three different RG-Is from apple and lupin pectins were modified and coated on amino-functionalized tissue culture polystyrene plates (aminated TCPS). Surface properties were evaluated by scanning electron microscopy, contact angle measurement, atomic force microscopy and X-ray photoelectron spectroscopy. The effects of nanocoating on proliferation, matrix formation and mineralization, and expression of genes (real-time PCR) related to osteoblast differentiation and activity, were tested using human osteoblast-like SaOS-2 cells.

It was shown that RG-I coatings affected the surface properties. All three RG-I induced bone matrix formation and mineralization, which was also supported by the finding that gene expression levels of alkaline phosphatase, osteocalcin and collagen type-I were increased in cells cultured on the RG-I coated surface, indicating a more differentiated osteoblastic phenotype. This makes RG-I coating a promising and novel candidate for nanocoatings of implants.

Identification of a Common BMP-responsive Element in the Id1, Id2 and Id3 Genes. Masashi Shin^{*1}, Satoshi Ohte¹, Katsumi Yoneyama¹, Hiroki Sasanuma¹, Shoichiro Kokabu², Toru Fukuda³, Eiji Jimi⁴, Takenobu Katagiri⁵. ¹Saitama Medical University, Japan, ²Harvard School of Dental Medicine, USA, ³Keio University School of Medicine, Japan, ⁴Kyushu Dental College, Japan, ⁵Saitama Medical University Research Center for Genomic Medicine, Japan

Bone morphogenetic protein (BMP) induces several common early responsive genes in various types of cells, suggesting that the mechanism of these genes expression plays a central role in BMP signal transduction. Id1 through Id4, which are negative regulators of basic helix-loop-helix transcription factors, have been reported to be involved in myogenesis and in skeletal development regulated by BMPs. Previously we and others independently identified a BMP-responsive element (BRE) in the Id1 gene, which is a GC-rich element and recognized by a complex of Smad1/5 and Smad4 in response to BMP stimulation. Here we report the BREs in the Id2 and Id3 genes. First, we cloned the

5' flanking regions of the murine Id2 and Id3 genes up to -3 kb and a -6 kb, respectively, into a luciferase reporter plasmid. Both reporter activity was stimulated in response to BMP-4. Series of deletion plasmids revealed that the Id2 and the Id3 genes contained the BREs at -2.9 kb and at -3.3 kb regions, respectively. Sequence alignment of the BREs in the Id1, Id2 and Id3 genes identified a core sequence, which consisted of a common 6 base GC sequence recognized by a Smad1/4 complex in EMSA. Chromatin immunoprecipitation assay confirmed the physiological binding of Smad1 to the elements. These findings indicated that the 6 base GC sequences found in the Id1, Id2 and Id3 genes are the functional BREs in them, and the transcription of the Id genes may be activated by Smad1/5 and Smad4 in response to an activation of BMP receptors.

Nanog Promotes Osteogenic Differentiation of Mesenchymal Cells By Modulating Bone Morphogenetic Protein (BMP) Signaling. Toru Ogasawara^{*1}, Shinsuke Ohba², Fumiko Yano³, Takahiro Abe¹, Hiroshi Kawaguchi⁴, Tsuyoshi Takato¹, Kazuto Hoshi¹. ¹University of Tokyo, Japan, ²The University of Tokyo Graduate School of Medicine, Japan, ³The University of Tokyo, Japan, ⁴University of Tokyo, Faculty of Medicine, Japan

How the pluripotency of stem cells is maintained and the role of transcription factors in this maintenance remain major questions. Nanog is a homeodomain transcription factor that maintains self-renewal of embryonic stem (ES) cells. In the present study, in order to clarify the mechanism underlying the pluripotency of somatic stem cells for the advancement of regenerative medicine, we examined the effect of forced Nanog expression in mesenchymal cells, with a particular focus on osteogenic differentiation. The human mesenchymal stromal cells (hMSCs) or mouse mesenchymal cell line C3H10T1/2 cells were transduced with the Nanog gene or control GFP gene by using retrovirus vectors. Short-term, forced Nanog gene expression had few effects on the terminal osteogenic differentiation of either hMSCs or C3H10T1/2 cells. To determine its long-term effects, we established C3H10T1/2 cells expressing Nanog constitutively. Constitutive Nanog expression strongly induced osteogenic differentiation of C3H10T1/2 cells. Nanog also enhanced osteocalcin and typeI collagen expression induced by the Runx2 or Osterix transfection. In regard to cell proliferation, constitutive Nanog expression promoted cell proliferation. However, Nanog repressed the proliferation of the cells treated with BMP-2. Western blot analysis revealed that constitutive Nanog expression enhanced phosphorylation of Smad1/5/8 and suppressed cyclinD1 and Cdk4. The promoter activities of both the osteocalcin and Id-1 genes were activated in cells expressing Nanog constitutively. These results indicate that Nanog functions as a modulator of BMP signaling in mesenchymal cells probably through a genome reprogramming process.

New AIS Candidate Gene Identification through Microarray Gene Expression Profiling. Khaled Fendri^{*1}, Shunmoogum Shunmoogum², Charlotte Zaouter³, Stefan Paent², Florina Moldovan⁴. ¹University of Montreal, Canada, ²University of Montreal, Canada, ³CHU Sainte-Justine, Canada, ⁴Montreal University, Canada

OBJECTIVES

We used a DNA microarray approach to evaluate gene expression profile of genes in Adolescent idiopathic scoliosis (AIS) individuals and identify genes that are differentially expressed (up- and down-regulated) as a result of estrogen exposure of non-AIS and AIS individuals.

METHODS

Gene expression profiling was investigated by microarray analysis in RNA samples isolated from osteoblasts derived from control (non-AIS) and AIS patients. We also evaluated gene expression levels in non-AIS and AIS osteoblasts following estrogen exposure: cells were cultured in absence or presence of 17 β -estradiol (E2) at different concentrations. Total RNA from osteoblasts were extracted, and then hybridized to DNA microarrays. Data analysis was performed. Genes that had at least 1.5-fold change in expression were considered differentially regulated relative to controls.

RESULTS

Microarray analysis revealed several genes that are differentially regulated in AIS osteoblasts compared to controls. Many of these genes are involved in different physiological pathways. We found that 2.6% of the examined genes were up-regulated in AIS osteoblasts, while 2.16% of them were down-regulated. We observed a roughly 3-fold increase in the transcripts of some genes in AIS osteoblasts. On the other hand, some genes were down-regulated by approximately 3-4-fold. When we compared the transcriptome profiling of estrogen-regulated genes between non-AIS and AIS osteoblasts, several genes were up- and down-regulated in response to estrogen. In presence of E2, we found a 3-4-fold increase in the expression of RBKS, OR8B4 and

RFC3 in AIS osteoblasts compared to non-AIS osteoblasts. Genes that were down-regulated by a considerable amount (3-4-fold) are MYT1, PSENEN and SCN1B.

CONCLUSION

More than one gene is likely responsible for AIS, and some of these genes are estrogen-regulated. In the absence of specific causative gene(s) for AIS, our study of gene expression by microarray pointed out putative biological pathways and genes to be carefully investigated.

Odd-skipped Related1 and Odd-skipped Related2 are Mutually Regulated.

Shinji Kawai*, Atsuo Amano. Osaka University Graduate School of Dentistry, Japan

Zinc finger transcription factor Odd-skipped related (Osr) forms the gene family of Osr1 and Osr2, and they have high homology in the zinc finger region mutually. We previously reported on the function of Osr2 by using the transgenic mice of dominant negative Osr2. In this transgenic mice, delayed mineralization in calvarial and cortical bone tissues, distinctly increased radiolucency in soft X-ray analysis, reduced staining intensities with alcian blue and alizarin red in the skull and skeletal elements, and markedly thinner parietal and cortical bones are observed. The proliferation and differentiation of calvarial osteoblast decreased. Moreover, Osr2-deficient mice revealed that Osr2 play a critical role in secondary palate and teeth development. On the other hand, abnormality was seen in heart, kidney, and gonad in Osr1 knockout mice. In addition, it is shown that Osr1 and Osr2 take part in the formation of synovial joint.

In the present study, it aimed to clarify the interrelation of Osr1 and Osr2, and mutual expression regulations of Osr1 and Osr2 were examined. As a result, the expression of Osr1 was higher than Osr2 in fibroblastic C3H10T1/2 cells and osteoblastic MC3T3-E1 cells. Moreover, Osr1 increased the expression of Osr2, and Osr2 promotes the expression of Osr1. In addition, Osr1 and Osr2 regulated their expression by the specific region of promoter with deletion analysis of promoter.

We propose that Osr1 and Osr2 mutually regulate Osr2 and Osr1 expression, respectively, and participate in cellular proliferation and cellular differentiation of osteoblast.

Osteoblast-specific Transcription Factor Osterix (Osx) Is an Upstream Regulator of Satb2 During Bone Formation. Chi Zhang*, Wanjin Tang, Yang Li, Lindsey Orsini. Bone Research Laboratory, Texas Scottish Rite Hospital, USA

Bone formation is a developmental process involving the differentiation of mesenchymal stem cells to osteoblasts. Osterix (Osx) is an osteoblast-specific transcription factor essential for osteoblast differentiation and bone formation. Osx knock-out mice lack bone completely. Satb2 is also critical for osteoblast differentiation as a special AT-rich binding transcription factor. It is not known how Satb2 is transcriptionally regulated during bone formation. In this study, microarray and real-time RT-PCR results demonstrated that Satb2 was dramatically downregulated in Osx-null calvaria. In stable C2C12 mesenchymal cells using Tet-off system, overexpression of Osx stimulated Satb2 expression. Moreover, inhibition of Osx by siRNA led to repression of Satb2 expression in osteoblasts. These results suggested that Osx controls Satb2 expression. Transient transfection assay showed that Osx activated 1kb Satb2 promoter reporter activity in a dose-dependent manner. To define the region of Satb2 promoter responsive to Osx activation, a series of deletion mutants of Satb2 constructs were made, and the minimal region was narrowed down to the proximal 130bp of Satb2 promoter. Further point mutation studies indicated that two GC-rich region mutations disrupted the Satb2 130bp promoter activation by Osx, suggesting that these GC-rich binding sites were responsible for Satb2 promoter activation by Osx. To examine physical association of Osx with Satb2 promoter in vivo, we performed Chromatin immunoprecipitation (ChIP) assays using primary osteoblasts from mouse calvaria. Endogenous Osx was shown to associate with native Satb2 promoter. Taken together, our findings conclude that Osx is an upstream regulator of Satb2 during bone formation. This reveals a new additional link of the transcriptional regulation mechanism that osteoblast-specific factor Osx controls bone formation.

Regulation by TNF- α of Beta 2 Adrenergic Receptor Expression in Osteoblasts. Kyunghwa Baek*, Hyorin Hwang, Hyerim Lee, Hyunjung Park, Arang Kwon, Jeonghwa Baek. Seoul national university, School of dentistry, South Korea

TNF- α is a multifunctional cytokine whose level is elevated in inflammatory diseases such as atherosclerosis, diabetes and osteoporosis. Recent evidence has suggested that beta adrenergic receptor activation in osteoblasts suppress osteogenic activity. In the present study, we explored whether TNF- α modulates beta adrenoreceptor expression in osteoblastic cells and whether such a modulation is associated with a decrement in osteogenesis. First, increased beta 2 adrenergic receptor expression with TNF- α treatment was observed in various cell types including MC4, C2C12 osteoblastic cells and primary rat bone marrow stromal cells. Moreover, increased intracellular cyclic AMP level observed in C2C12 cells treated with isoproterenol, a beta adrenergic agonist, was further elevated with simultaneous TNF- α treatment, which indicates that TNF- α induced increments in beta adrenoreceptor expression actually increases intracellular beta adrenergic signaling in osteoblasts. TNF- α treatment suppression of alkaline phosphatase (ALP) activity and osteomarker gene expression, including ALP and osteocalcin, in BMP2 stimulated C2C12 cells was aggravated by isoproterenol. However, such a decrement induced by TNF- α was mitigated with propranolol treatment. TNF- α treatment also increased expression of sclerostin, a molecule preventing Wnt signaling pathway, in BMP2 stimulated C2C12 cells. This increase was aggravated with isoproterenol. Taken together, TNF- α increased beta 2 adrenergic receptor expression in osteoblasts and beta adrenergic signaling blockade mitigated TNF- α induced suppression in osteomarker gene expression. These findings suggest a crosstalk mechanism between TNF- α and beta adrenergic signaling pathways occurs in osteoblasts to modulate osteogenesis.

In Vitro Hematopoiesis and osteoblastogenesis with Marrow from SAMP6 and SAMR1 mice. Regina O'Sullivan*, Joel Greenberger², Shaonan Cao³, Michael Epperly³, Julie Glowacki¹. ¹Brigham & Women's Hospital, USA, ²University of Pittsburgh School of Medicine, USA, ³University of Pittsburgh, USA

The SAM prone 6 (SAMP6) mouse develops osteoporosis with age and is an ideal model to investigate skeletal aging. The bone defect has been attributed to lower osteoblast potential in SAMP6. We compared *in vitro* hematopoiesis, proliferation, and osteoblastogenesis in marrow from SAMP6 and control SAMR1.

Methods: Long term bone marrow cultures (LTBMC) were established for hematopoiesis and for derivation of adherent Marrow Stromal Cells (MSCs). Growth curves were evaluated. Total RNA was extracted with Trizol reagent to determine constitutive expression. PCR products were separated by agarose gel electrophoresis and were quantified by densitometry. The MSCs were also grown in osteogenic media. The cells were grown to 90% confluence, the medium was changed from proliferation medium to osteogenic medium. Total RNA was extracted at intervals and was analyzed for expression of osteoblast markers Runx 2, Alkaline phosphatase (ALP), and Osteocalcin (Oc).

Results: SAMR1 LTBMC produce hematopoietic cells for a longer duration than the SAMP6 LTBMC. Cell expansion was slower in the SAMP6 cell line; cell population doubling time was 1.34-fold longer in cells from SAMP6 relative to SAMR1. This prolonged doubling time could be due, among other reasons, to prolonged G1 or G2 arrest. Consistent with age-related decreased proliferation the SAMP6 MSCs also exhibited induced expression of the inhibitors p16 and p19, and no significant differences in p53 and p21. There was constitutive expression of both ALP and Oc in the SAMP6 MSCs without osteogenic medium and there was up-regulation of PPAR γ in the SAMP6 cell line, compared with SAMR1. Runx 2

expression was similar in both cell lines. When cultured in osteogenic medium, there was greater Runx 2, ALP, and Oc expression in the SAMP6 cell line relative to the SAMR1 cell line

Conclusion: These *in vitro* results show that hematopoiesis in SAMP6 LTBMSC was shortened, compared with cells from SAMR1. The SAMP6 MSCs demonstrated constitutive expression of osteoblast signature genes relative to the SAMR1 cell line; both showed upregulation of osteoblast genes when cultured in osteoblastogenic medium. These unexpected findings suggest that *in vivo* factors may be important in suppressing osteoblast differentiation and function.

A Novel Role of PlexinA2 in Regulation of BMP-2 Signaling and Osteoblast Differentiation. Yong Deok Lee*, Ji-Eun Oh, Hyung Joon Kim, Woo-Shin Kim, Youngkyun Lee, Hong-Hee Kim. Seoul National University, South Korea

PlexinA2 (PlxnA2) is a molecule previously characterized mediate axon guidance in neural development. In an effort to find new molecules involved in osteoblast differentiation by DNA microarray analyses, we found that PlxnA2 up-regulated during differentiation of mouse preosteoblastic cells induced by BMP-2. PlxnA2 also increased during the osteoblastic differentiation of human mesenchymal stem cells. Gene knock-down of PlxnA2 by using specific siRNA resulted in decreased osteoblast differentiation and mineralization, and suppressed the expression of Runx2, the master transcription factor for osteoblast differentiation. The type I BMP receptor was found in association with PlxnA2, suggesting a direct modulation of BMP-2 signaling at the receptor level by PlxnA2. Indeed PlxnA2 regulated both Smad and Akt signaling pathways of BMP-2. In addition, *ex vivo* cultures of mice calvariae with PlxnA2 siRNA displayed reduced osteoblastogenesis compared to the control siRNA, supporting that PlxnA2 has an *in vivo* role in osteoblast differentiation. In conclusion, our study discovered PlxnA2 as a novel regulator of osteoblast differentiation.

Challenges in Identifying Human Bone Cell Differentiation in Murine Models of Skeletal Repair. Xiaonan Xin*, Xi Jiang, Liping Wang, Alexander Lichtler, David Rowe. University of Connecticut Health Center, USA

Developing reliable osteoprogenitor cells from human sources will be a critical step in the clinical application of cell based skeletal repair. While demonstrating osteoblast differentiation of murine derived progenitor cells in models of skeletal repair that utilize GFP reporters has been quite reliable, we have not been as sanguine of the outcome when human osteoprogenitor cells from either adult bone marrow stroma or hES/iPS sources are used. Specifically, while bone formation within the calvarial repair model does occur, we have not been able to distinguish human cells at a stage of active mineralizing osteoid formation from cells that are trapped in a poorly formed mineralized matrix that may have been formed by murine host cells. To better understand the histology of human bone formation that occurs in a murine environment, we have closely examined the bone and cartilage that is formed within a teratoma derived from either hES or iPS cells. Developmentally, the bone has the appearance of a cortical structure that resembles the initial stages of perichondrial ossification of a cartilage core. While there is blood vessel investment of the forming bone and osteoclasts are evident, no bone marrow develops. Distinct mineralization lines are present, but instead of a row of AP positive cells overlying the mineralizing lines (a reliable feature of murine osteoblasts), a broad band of elongated AP positive cells extend over the mineralizing bone. Cells within the teratoma bone can be identified as human in origin with human specific mitochondrial and nuclear antibodies. A BSP antibody identifies extracellular deposits surrounding the cells within the mineralized bone and regions containing hypertrophic chondrocytes. While these antibodies do identify human cells within the mineralized tissue of the repair defect, they do not identify BSP deposition around these cells. A particular concern is the necessity of bone-marrow-dependent bone remodeling to produce the morphological features of mature bone. Because the mouse does not appear to develop marrow at sites of human bone formation, the histological features of mature bone derived from a human source may be difficult to demonstrate. Further modifications to the NOD/Scid/IL2rg null host mouse line, such as in breeding of a bone specific GFP reporter and humanizing the bone marrow may be required to definitively assess the extent of bone formation produced from a human osteoprogenitor source.

Development of a Fluorescent High-throughput CFU-O assay for a High Content Imaging Platform. Jeffrey Kiernan*, Cheryl Cui, William Stanford. University of Toronto, Canada

Intervention strategies for the treatment of osteoporosis (both type I and type II) are largely based around anti-resorptive drug therapy using bisphosphonates to prevent excessive bone resorption. Currently, there are only a few treatments based on increasing bone formation, mainly due to a lack of pharmacological modulators of osteoblasts. Drugs capable of increasing the commitment of mesenchymal stromal cells (MSCs) to osteoblasts, or the output of committed osteoblasts, could benefit both type I and type II osteoporosis. In drug discovery, high-throughput screening processes are usually followed up by validation with a low-throughput functional assay such as the CFU-O (Colony Forming Unit Osteoblast). Ideally, a high-throughput functional assay could streamline this process. The CFU-O, used to quantify bone nodule formation, is widely used to investigate the osteogenic potential of a given cell population. This assay, based on Von Kossa staining to label alkaline phosphatase activity and calcium deposition, however, it is not adaptable to high-throughput screens. Here, we introduce two fluorescence based high-throughput (fHT) assays that characterize the osteogenic potential of MSCs on a high content imaging platform (Cellomics). The first assay (static fHT-CFU-O) stains endogenous ALP activity with enzyme labeled fluorescent 97 (E197) dye, while calcium is stained with the dye calcium orange. The ALP positive area (Target 1) identifies the Region of Interest (ROI) in Channel 1, while Channel 2 identifies calcium positive areas (Target 2). Only those objects positive for calcium that lay within the ROI were counted as a bone nodule. The static fHT-CFU-O successfully quantified a similar number of bone nodules as compared to manual counting of Von Kossa stained nodules. For the second assay (kinetic fHT-CFU-O), we utilized the fluorescent properties of the osteotropic antibiotic tetracycline to develop a kinetic osteogenic assay able to track the growth rate of bone nodules. Tetracycline stained nodules were imaged at various time points during the calcification process to measure nodule formation and to quantify their growth rates. Objects from different time points were identified and tracked based on their locations in a particular field and further analyzed based on the rate of nodule growth over the time course. We currently utilizing these assays to investigate possible compounds that increase the osteogenic potential of MSCs.

Immunohenotype and Functional Comparison of Osteoblast Progenitors from Human Embryonic Stem Cells and Bone Marrow. Melissa Stemig*, Mohammad Islam. University of Minnesota School of Dentistry, USA

Studies using human embryonic stem cells describe derivation of mesenchymal stem cells (hESMSC) based of CD73 expression. The purpose of our study is to compare immunophenotype and osteogenic potential of hESMSCs and human bone marrow derived mesenchymal stem cells (BMMSCs).

Materials and Methods: We isolated hESMSCs based on CD73 surface marker expression. Commercially available BMMSCs were used for comparison. We analyzed expression of cell surface markers CD73, CD90, CD105, CD31 and CD146 in hESMSC and BMMSCs. Osteogenesis was induced in both groups for 21 to 28 days. After this period, von Kossa staining for mineralized nodule formation and expression of osteogenic genes Runx2, bone sialoprotein (BSP), osteocalcin and collagen type I was compared. We also analyzed DNA methylation profile and lineage specific gene expression profile of hESMSCs using commercially available PCR arrays (SABiosciences). **Result:** Both hESMSCs and BMMSCs express MSC specific surface markers. They do not express endothelial marker CD31. Osteogenesis study showed that hESMSC form dark mineralized nodule in von Kossa staining. Osteogenic gene expression profile was also comparable. However, hESMSCs continue to proliferate during osteogenic differentiation, as demonstrated by cell count during differentiation. PCR array for stem cell transcription factor DNA methylation and lineage specific gene expression array showed differences in gene expression pattern between hESMSC and BMMSC. **Conclusion:** Standard methods for comparison of hESMSC and BMMSCs show that these two cell types are comparable. However, dissimilar DNA methylamine and lineage specific gene expression in these two groups suggests distinct character of hESMSCs.

Ionizing Radiation-Induced Senescent Bone Marrow Stromal Cells Show Reduced Functions Essential for Hematopoietic Stem Cell Engraftment. Cynthia Carbonneau*, Christian Beausejour. Universite De Montreal - CHU Ste-Justine, Canada

The extent to which the integrity of the bone marrow stroma contributes to the success of hematopoietic cell transplantation is not well known. Alterations of the bone marrow microenvironment, which occur during aging or following genetic manipulations of telomere length, impair hematopoietic stem and progenitor cell (HSPC) engraftment and function. These results suggest that an increased number of senescent marrow stromal cells could affect niche function. We have shown that exposure to ionizing radiation (IR) impairs the bone marrow microenvironment by inducing senescence of the stromal cells, but the direct effects of such damage on transplantation is unknown. In this study, we investigated IR-induced alterations of bone marrow stromal cell functions susceptible to affect HSPC engraftment. High plasma levels of granulocyte colony-stimulating factor (G-CSF) were detected by ELISA in mice long-term post-IR. In vitro cultures of senescent bone marrow stromal cells with HSPC secrete more G-CSF compared to control cells. Migration assays showed that senescent stromal cells are less chemoattractive for HSPC in vitro. Also, less HSPC remained adhered to senescent stromal cells following a 3-hour co-culture compared to control cells. At the molecular level, we observed a down-regulation of N-cadherin mRNA and vascular cell adhesion molecule 1 (VCAM-1) protein in senescent stromal cells compared to control cells. In conclusion, senescent stromal cells could reduce HSPC engraftment (1) by mobilizing HSPC in blood due to G-CSF expression, (2) by limiting their recruitment to the bone marrow via reduced chemoattraction and (3) by limiting their retention in the niche via reduced adhesion molecules such as N-cadherin and VCAM-1.

Irradiation-induced DNA Damage Interferes with Mesenchymal Stem Cell Plasticity. Genevieve Despars*¹, Cynthia Carbonneau², Qanh Le³, Christian Beausejour³. ¹Centre De Recherche De L'Hopital St. Jus, Canada, ²Universite De Montreal - CHU Ste-Justine, Canada, ³Universite de Montreal, Canada

Mesenchymal stem cells (MSCs) give rise to chondrocytes, osteoblasts and adipocytes. Several transcription factors control lineage commitment in a cell-autonomous fashion, such as Runx2 and Osx/Sp7 in osteoblastogenesis and PPARγ for adipogenesis.

Exposure to ionizing irradiation (IR) can lead to the induction of cellular senescence, a process by which cells undergo permanent growth arrest and secrete a specific pattern of cytokines and inflammatory factors.

Here, we wanted to investigate whether the senescence phenotype could affect the differentiation potential of MSC. We found that IR-induced senescent MSCs were unable to form mineralised nodules *in vitro*, an effect we found could be due to their inability to adequately induce Runx2 and Osx/Sp7 following their culture with osteogenic factors. In contrast, IR-induced senescence of osteoblasts did not prevent the formation of mineralised nodules *in vitro*. Exposure to IR also prevented the differentiation of MSC into adipocytes despite that senescent MSC could upregulate PPARγ and SREBF1 at levels comparable to those observed in control non-irradiated MSC cultures. These results suggest a cell-autonomous defect in senescent MSC which cannot be bypassed by instructive differentiation factors.

Finally, we also investigated whether mineralisation of MSC could be affected in a paracrine manner by senescent cells. Unexpectedly, we found that mixed cultures of control and IR-induced senescent MSCs showed mineralisation. We hypothesize that IR-induced senescent MSC produce factors which increase mineralisation, or that irradiated MSC could revert to osteogenesis when in contact with control cells.

Overall, our results provide a rational on how exposure to IR could affect long-term bone formation; that is by preventing, in a specific manner, the differentiation and mineralisation of bone forming progenitor cells such as MSC.

Mitochondrial Superoxide Dismutase Regulates Proliferation and Differentiation of Osteoblasts. Keiji Kobayashi*¹, Yoshitomo Saita², Hidetoshi Nojiri², Daichi Morikawa¹, Kenji Watanabe³, Kouichi Nakasone¹, Kazuo Kaneko², Takahiko Shimizu¹. ¹Morecular Gerontology, Tokyo Metropolitan Institute of Gerontology, Japan, ²Department of Orthopaedics, Juntendo Univ., Japan, ³Morecular Gerontology, Tokyo Metropolitan Institute of Gerontology, Japan

Reactive oxygen species (ROS) are mainly produced from mitochondria as metabolic products in cells. In particular, ROS reacts to oxidize cellular components, such as DNA, proteins and lipids leading to oxidative stress. Mn-superoxide dismutase (Mn-SOD) is localized in mitochondria to convert superoxide to hydrogen peroxide. In this context, Mn-SOD is considered to protect from mitochondrial

oxidative stress. Mitochondrial Mn-SOD (SOD2)-deficient mice showed perinatal death with increased mitochondrial oxidative stress, indicating that Mn-SOD is essential for maintenance of mitochondrial redox balance and murine lifespan. However, the physiological role of Mn-SOD in bone was not fully understood yet. In the present study, to evaluate it, we generated the time-specific Mn-SOD-deficient mice by crossbreeding tamoxifen-inducible Cre recombinase transgenic mice with Mn-SOD floxed mice.

To examine the effects of mitochondrial oxidative stress on a cellular level, we used osteoblasts derived from neonatal calvarial bone from mutant and wild-type mice. At first, we evaluated gene ablation, protein content, and ROS production in the presence of 4-hydroxytamoxifen (4-OHT) in vitro. 4-OHT treatment effectively deleted Mn-SOD gene and down-regulated Mn-SOD protein in mutant osteoblasts, indicating that tamoxifen-inducible cre system was effectively worked to manipulate the expression of Mn-SOD in osteoblasts in vitro. 4-OHT treatment also significantly enhanced the levels of ROS production detected by fluorescence dye after 7 days in culture, suggesting that Mn-SOD depletion would diminish mitochondrial antioxidant capacity leading to increased oxidative stress in osteoblasts. In the growth analysis, we found that treatment of 4-OHT significantly delayed the cell proliferation by 50% after 7 days in culture. Interestingly, we failed to detect any signs of apoptotic phenotype in the mutant cells. In differentiation analyses, ALP activity was decreased to nearly 20% lower in the presence of 4-OHT after 14 days in culture. With respect to the nodule formation, 4-OHT treatment decreased the ability to form mineralized nodule after 21 days in culture. These results indicate that Mn-SOD insufficiency suppressed both cell proliferation and differentiation of osteoblasts, suggesting that Mn-SOD plays a pivotal role in cell proliferation and differentiation by regulating the mitochondrial ROS metabolism in osteoblasts.

Estrogen Treatment Early in Differentiation Promotes Osteoblastic Nodule Formation in Murine Cortical Bone Cells. Kumar Chokalingam*¹, Sundeep Khosla², David Monroe³. ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA, ³Mayo Foundation, USA

Both clinical and experimental observations have demonstrated the importance of 17β-estradiol (E2) in maintaining bone mass. Although E2 has been shown to protect bone by increasing differentiation and function of osteoblasts, the effects of E2 on osteoblast differentiation in vitro are unclear. Recent in vivo studies using deletion of ERα specifically in osteoblasts (Almeida et al ASBMR 2010, 1113) indicate that ERα mainly plays a role in regulating cortical osteoblasts and the effects of E2 on these cells occur early in differentiation. The goals of this study were to identify a murine E2-sensitive in vitro cell system and to determine when E2 elicits its pro-differentiative signal during osteoblastic differentiation. Cortical bone cells (CBCs) obtained by collagenase digestion of flushed long bones of 4 month old mice were grown to confluence and then cultured in osteoblast differentiation (OB) media with and without E2 for 18 days. Robust mineralization was observed in controls, which was further enhanced with the addition of E2. To address the temporal effects of E2 on osteoblastic nodule formation, E2 was added for 28 days or after 7, 14 and 21 days to CBCs continuously cultured in OB media. Mineralization was increased in CBCs receiving E2 for the entire 28 days as compared to all other CBCs. Mineralization was similar between CBCs receiving E2 after 7, 14 and 21 days of differentiation and control. These data suggest that exposure of E2 during early osteoblastic differentiation is necessary for the enhanced mineralization. To further demonstrate this early effect of E2 during differentiation, E2 was added throughout for 28 days or withdrawn after 7, 14 and 21 days to CBCs continuously cultured in OB media. Mineralization was increased in all CBCs receiving E2 as compared to control; however mineralization was the same between CBCs receiving E2 for 7, 14, 21 and 28 days (Figure). These results confirm that exposure of E2 early in osteoblastic differentiation alone is sufficient for enhanced mineralization. Combined with the in vivo results of Almeida et al, our findings suggest the beneficial effects of E2 on cortical osteoblast mineralization occur early in the course of differentiation. In summary, our findings demonstrate that cells originating from the cortical bone compartment are sensitized to the effects of E2 in vitro and that treatment early in differentiation promotes an increase in osteoblastic nodule formation.

Figure. Calcium concentration in E2 treated groups is significantly higher than control. No difference was seen between the E2 treated groups. * $p < 0.05$

Collagen as a Stop Signal for Osteoclastic Bone Resorption: an Extension of Chambers' Hypothesis. Kent Soe^{*1}, Ditte M.H. Merrild¹, Jean-Marie Delaisse². ¹Vejle Hospital, University of Southern Denmark, Denmark, ²Vejle Hospital, CSFU-IRS, University of Southern Denmark, Denmark

It is widely accepted that bone surface collagen prevents initiation of bone resorption activity of osteoclasts (OC), as first hypothesized by Chambers. Here we propose (i) that accumulation of undegraded demineralized collagen in the resorption pit itself similarly prevents continuation of ongoing OC resorption, (ii) so that the rate of collagenolysis relative to demineralization (C/D rate) determines arrest or continuation of resorption at a given resorption site.

We generated human OCs, and cultured them on cortical bone discs, in the presence or absence of inhibitors of collagenolysis (E64 and L873724) or demineralization (ethoxzolamide) in order to modulate C/D rates. Some assays were also performed on bone discs rendered anorganic through NaOCl. The efficiency of collagenolysis was monitored by assessing the thickness of the collagen fringes lining the excavations. Prevalence of continued vs. intermittent resorption (i.e. involving episodes of arrested resorption) was assessed as previously reported, by quantifying the number and surface of long continuous resorption "trenches" (i.e. continued resorption) vs. discrete round "pits" (i.e. intermittent resorption), as well as through assessment of resorption depths.

In all control culture conditions, pits were lined with a 3-5 μ m thick collagen fringe, whereas trenches did not show significant collagen leftovers. This suggests that the efficiency of collagen removal determines whether resorption stops or continues. Assays performed on anorganic bone showed a 2 to 5-fold increase in the trench surface/BS, supporting that resorption tends to continue in the absence of collagen. Furthermore, when we weakly inhibited demineralization, the trench surface/BS increased 2-fold and collagen leftovers decreased compared to controls. In contrast, when we inhibited collagenolysis, the trench surface/BS decreased 3-fold and 3-5 μ m thick fringes of demineralized collagen occurred at significantly lower resorption depths compared to controls. Thus, by modulating C/D rates through specific inhibition of demineralization or collagenolysis, we could push OC resorptive activity towards either continued or intermittent resorption.

We conclude that collagen may act as a stop signal for ongoing OC bone resorptive activity and that this signal is controlled by the balance between the rates of demineralization and collagenolysis.

Genetic Ablation of CD68 Results in Increased Bone in Mice and Abnormal Osteoclasts *in Vitro*. Jason Ashley^{*1}, Zhenqi Shi¹, Haibo Zhao², Robert Kesterson¹, Xu Feng¹. ¹University of Alabama at Birmingham, USA, ²University of Arkansas for Medical Sciences, USA

Firm adhesion of osteoclasts to the bone surface by way of the sealing zone is a critical feature of efficient bone resorption. While there has been much study into mechanisms of sealing zone formation, understanding of the mediators of this attachment remains incomplete. To identify putative bone adhesion molecules, we screened a bone marrow macrophage cDNA bacteriophage display library for

proteins with an affinity for bone. Using this screen, we identified CD68 (also known as macrophage scavenger receptor class B type 1) as a molecule with high bone affinity. CD68 is a heavily glycosylated Lysosome-Associated Membrane Protein (LAMP) family member. Unlike most LAMPs, however, CD68 contains an O-glycosylated mucin-like domain that may give it protective functions similar to those of mucins. CD68 is a commonly-used marker for macrophage lineages, and we have confirmed that, while mouse bone marrow macrophages express high levels of CD68, mouse osteoblasts do not express any detectable amount. We hypothesize that CD68 serves an important function in osteoclasts. Consistent with this, CD68 expression is up-regulated during osteoclastogenesis in an M-CSF-dependant manner, and confocal microscopy of osteoclasts cultured on bone slices revealed that CD68 can be found in and around the sealing zone of resorbing osteoclasts. We also found that, when CD68 was inhibited *in vitro* with either an antibody or shRNA, macrophage attachment to bone slices was reduced as was *in vitro* bone resorption. These preliminary findings drove us to generate mice lacking expression of CD68. These mice appear healthy and fertile, but when compared to age and sex matched wild type mice, femurs from six-month-old CD68-null mice have a 160% increase in BV/TV ($p < .05$), a 20% increase in trabecular number ($p < .01$), and a 20% decrease in trabecular spacing ($p < .01$) measured by micro-computed tomography. Osteoclasts generated *in vitro* from CD68-null precursors have intracellular accumulations of a large number of vesicle-like structures not seen to such an extent in CD68-expressing cells. Furthermore, following tartrate resistant acid phosphatase staining of *in vitro* generated osteoclasts, 14% of wild type osteoclasts demonstrated retractions in their plasma membrane whereas retractions can be seen in over 40% of CD68-null osteoclasts ($p < .001$). These data indicate that CD68 plays a role in the function of osteoclasts, and we suspect that role is potentially one related to adhesion or sealing zone function.

Spatiotemporal Dynamics of Cytosolic Calcium in Osteoclasts: Distinct Patterns Associated with Lamellipod Extension and Uropod Retraction. Benjamin D. Wheel^{*1}, Natsuko Tanabe², S. Jeffrey Dixon¹, Stephen Sims¹. ¹The University of Western Ontario, Canada, ²Nihon University School of Dentistry, Japan

Osteoclasts are specialized cells that mediate the resorption of bone and other mineralized tissues. These cells are highly motile, with bone remodeling involving alternating cycles of migration and resorption. Osteoclast migration is characterized by extension of lamellipodia at the leading edge, lamellipodial attachment to the substrate and release of the uropod at the trailing edge of the cell. However, little is known regarding the role of cytosolic calcium in coordinating these distinct cellular events in osteoclasts. The purpose of this study was to characterize the spatial and temporal patterns of calcium changes associated with motility in osteoclasts. Subcellular calcium was monitored by digital fluorescence imaging of fura-2-loaded osteoclasts using alternating excitation wavelengths of 345/380 nm, with emission ratio at 510 nm corresponding to cytosolic calcium concentration. We first observed that osteoclasts exhibited a pattern of spatially restricted, transient elevations of calcium localized predominantly at the cell periphery, a phenomenon temporally associated with lamellipodial extension. The intracellular calcium chelator BAPTA completely abolished these transient elevations of calcium. The extracellular calcium chelator EGTA also abolished these calcium transients, indicating channel-mediated influx of calcium from the extracellular milieu. Consistent with this observation, the phospholipase C (PLC) inhibitor U73122 had no discernable effect on these transient elevations of calcium. In contrast, U73122 effectively blocked UTP-induced elevations of calcium, confirming its ability to inhibit PLC-mediated release of calcium from intracellular stores. A second distinct spatiotemporal pattern of calcium changes was also observed in osteoclasts. This consisted of a localized elevation of calcium in the trailing edge of migrating cells that coincided with uropod retraction. Interestingly, BAPTA-treated cells exhibited an elongated morphology, consistent with the inability of uropods to detach from the substrate and undergo retraction. Taken together, these findings reveal novel spatiotemporal patterns of cytosolic calcium changes in osteoclasts, with spatially restricted, transient elevations being associated with lamellipodial extension and more sustained elevations being required for uropod retraction. These studies provide new insights into the subcellular mechanisms underlying the regulation of osteoclast migration.

Deletion of CD74, a Putative MIF Receptor, in Mice Enhances Osteoclastogenesis and Decreases Bone Mass. SE HWAN MUN^{*}, Paula Hernandez, Hector Aguila, Sun-Kyeong Lee. UNIVERSITY OF CONNECTICUT HEALTH CENTER, USA

CD74 is a type II transmembrane protein that can act as a receptor for macrophage migration inhibitory factor (MIF) and play a role in MIF-regulated responses. We have reported that MIF inhibited osteoclast formation and MIF KO

mice had decreased bone mass and increased osteoclasts. We therefore examined if CD74 was involved in the ability of MIF to alter osteoclastogenesis in cultured bone marrow (BM) from WT and CD74 deficient (KO) male mice. We also measured the bone phenotype of CD74 KO male mice. Osteoclast like cells (OCL) were identified as TRAP(+) multinucleated cells and granulocyte-macrophage colony-forming units (CFU-GM) were analyzed in semi-solid cultures. Bone mass in the femur of 8 week old mice was measured by micro-computed tomography and histomorphometry.

Bone marrow cells from CD74 KO mice formed 15% more OCL ($p<0.05$) with M-CSF and RANKL (both at 30 ng/ml) vs. WT. Addition of MIF to WT cultures inhibited OCL formation by 16% ($p<0.05$) but had no effect on CD74KO cultures. The number of CFU-GM in the bone marrow of CD74 KO mice was 26% greater ($P<0.05$) than in WT controls. However, flow cytometric analysis of bone marrow found no significant difference in the number of osteoclast precursors between WT and CD74 KO. Trabecular bone volume (TBV) in the femurs of CD74 KO male mice was decreased by 26% ($p=0.062$) compared to WT. In addition, cortical area and thickness were decreased by 14% and 11%, respectively ($p<0.05$ for both). Histomorphometric analysis demonstrated that TRAP (+) osteoclast number and osteoclast area were significantly increased ($p<0.05$) in CD74 KO by 35% and 43%, respectively compared to WT. We also measured serum CTX and osteocalcin levels in CD74KO mice. There was a trend for an increase in formation (osteocalcin) by 35% ($p=0.052$) while not significant changes in resorption (CTX). Finally, we examine the effect of MIF on RANKL-induced-signaling pathways in BMM cultures. MIF treatment decreased RANKL-induced NFATc1 and c-fos protein in BMM cultures by 44% and 32%, respectively ($p<0.05$).

Our data demonstrate that CD74 is required for MIF to affect in vitro osteoclastogenesis. Further, the bone phenotype of CD74 KO mice phenocopied that of MIF KO mice. MIF treatment of WT cultures suppressed RANKL-induced AP-1 expression, which resulted in decreased osteoclast differentiation in vitro. We speculate that CD74 play an important role in the effects of MIF on osteoclastogenesis.

IL-22 Promotes Osteoclastogenesis in Rheumatoid Arthritis Through Induction of RANKL from Synovial Fibroblasts. Kyoung-Woon Kim¹, Sang-Heon Lee^{*2}, Young-Il Seo³. ¹Konkuk University, South Korea, ²Konkuk University Medical Center, South Korea, ³Hallym University Medical Center, South Korea

This study aims to determine the regulatory role of IL-22 on the expression of receptor activator of NF- κ B ligand (RANKL) and the induction of osteoclastogenesis in rheumatoid arthritis (RA). The concentrations of IL-22 and RANKL in sera and synovial fluids (SF) of RA patients were measured using ELISA. After RA synovial fibroblasts were treated with rhIL-22, the expression of RANKL mRNA and protein was determined by real time PCR, western blot and intracellular immunostaining. IL-22 induced RANKL expression was also observed after inhibition of intracellular signaling molecules. Human monocytes were co-cultured with IL-22 pre-stimulated RA synovial fibroblasts and monocyte colony stimulating factor (M-CSF), and then osteoclastogenesis was determined by counting of TRAP-positive multinucleated cells. IL-22 concentration in RA SF was higher than that of OA patients. Serum IL-22 concentration was also higher in RA than that in OA patients and healthy subjects. Serum IL-22 concentration was correlated with serum rheumatoid factor titer, and SF IL-22 concentration was correlated with serum anti-cyclic citrullinated peptide antibody (anti-CCP) titer. When RA synovial fibroblasts were treated with rhIL-22, the expression of RANKL mRNA and protein were upregulated in a dose dependent manner. The IL-22 induced RANKL expression was significantly hampered by inhibition of p38 MAPK/NF- κ B and JAK-2/STAT3 signaling pathway. When human monocytes were cultured with IL-22 pre-stimulated RA synovial fibroblasts in the absence of RANKL, the monocytes were differentiated into osteoclasts, but this osteoclastogenesis was decreased after the inhibition of p38 MAPK/NF- κ B and JAK-2/STAT3. Our results reveal that IL-22 upregulates RANKL expression in RA synovial fibroblasts and it also induces osteoclastogenesis, which are mediated by p38 MAPK/NF- κ B and JAK-2/STAT3 pathways.

Primary human CCR6+ memory Th17 cells activate synovial fibroblasts leading to a proinflammatory profile with joint destructive capacity. Erik Lubberts^{*1}, Nadine Davelaar², Jan Piet van Hamburg², Edgar Colin², Patrick Asmawidjaja². ¹Erasmus MC University Medical Center, The Netherlands, ²Erasmus MC University Medical Center, Netherlands

IL-17 is a proinflammatory cytokine and is a stimulator of osteoclastogenesis in vitro. It has been shown in arthritis models that IL-17 is an inducer of RANKL expression leading to loss of the RANKL/OPG balance, stimulating osteoclastogenesis and bone erosion in arthritis. Furthermore, it has been reported that neutralizing IL-17A in collagen-induced arthritis (CIA) ameliorated CIA including joint damage and reduced numbers of osteoclasts in the joint. Moreover, mouse Th17 cells (a new T helper subset that produce IL-17A) function as an osteoclastogenic T helper subset that links T cell activation and bone destruction. However, although human Th17 cells have been found in rheumatoid arthritis (RA) the contribution of these cells to joint damage is still unknown.

Here, we report that in peripheral blood of treatment-naïve early RA patients, the numbers of IL-17A/TNF- α -producing CCR6+CD45RO+ memory CD4+ T cells are increased. Functional co culture experiments with early RA synovial fibroblasts (RASf) revealed that these Th17-enriched CCR6+ memory T cells were potent inducers of IL-6, IL-8 and matrix metalloproteinase (MMP)-1 and MMP-3 in RASf. Interestingly, IL-17A production by CCR6+ memory T cells was markedly increased through this Th17-RASf interaction. Elevated expression of cathepsin K (CTSK) was found in the co culture condition compared to CCR6+ memory Th17 cells alone. Furthermore, condition media of these activated Th17-RASf co cultures induced a higher degree of fusion compared to condition media of activated Th17 cells alone during osteoclastogenesis in vitro. These data show the potential of primary human Th17 cells to activate synovial fibroblast leading to a proinflammatory profile with joint destructive capacity. Targeting human Th17 cell activity may be beneficial to prevent joint destruction in Th17 mediated disorders potentially by suppressing cell fusion during osteoclastogenesis.

Regulatory Expression of Mitf-E as an Inducer of Osteoclastogenesis by the TGF- β family. Kumiko Asai¹, Masayuki Funaba², Ryo Ooishi¹, Masaru Murakami^{*1}. ¹Azabu University School of Veterinary Medicine, Japan, ²Kyoto University Graduate School of Agriculture, Japan

Microphthalmia-associated transcription factor (Mitf) is a tissue-specific transcription factor predominantly expressed in melanocytes, osteoclasts, mast cells, and heart. Mice with mutation of Mitf gene exhibit signs of osteopetrosis related to a lack of mature functional osteoclasts. Thus, Mitf is definitely involved in bone homeostasis, although the regulation of osteoclastogenesis by Mitf is not fully evaluated. There are at least nine Mitf isoforms differing in their transcriptional initiation site: Mitf-A, -B, -C, -D, -E, -H, -J, -M and -mc. Mitf isoforms are expressed in a cell type-specific manner, and their transcriptional activities are slightly but significantly different depending on the target gene. Here we specified Mitf isoform expressed during osteoclastogenesis induced by macrophage-colony stimulating factor (M-CSF) and receptor activator of NF- κ B ligand (RANKL), and explored the role of Mitf in the process. Expression of Mitf-E but not Mitf-A was induced in response to treatment with RANKL that stimulates osteoclast differentiation in primary bone marrow cells and RAW264.7 macrophage cells. Transfection with dsRNA for Mitf-E effectively inhibited the formation of osteoclasts and the expression of osteoclast-related genes, including tartrate-resistant acid phosphatase (Trap) and osteoclast-associated receptor (Oscar). Members of the transforming growth factor- β (TGF- β) family including TGF- β s, activins and bone morphogenetic proteins (BMPs) regulate a broad range of biological processes including osteoclastogenesis. TGF- β 1 and activin A but not BMP-2 enhanced RANKL-induced osteoclast formation in RAW264.7 cells; addition of TGF- β 1 or activin A to the culture medium containing RANKL increased the number of Trap-positive cells and expression of Trap and Oscar. TGF- β 1 and activin A also potentiated up-regulation of Mitf-E expression. The present results indicate that Mitf-E plays a crucial role in osteoclastogenesis, and that the expression of Mitf-E is positively regulated by the TGF- β family. Stimulatory activity of the TGF- β family on osteoclastogenesis may be partly elicited through up-regulation of Mitf-E.

Analysis of Regulatory Mechanism of Mouse RANK Gene Expression through AP-1 Response Element. Riko Kitazawa^{*1}, Satomi Kinto¹, Junko Ishii¹, Takeshi Kondo¹, Kiyoshi Mori¹, Sohei Kitazawa². ¹Kobe University Graduate School of Medicine, Japan, ²Ehime University, Japan

Receptor activator of NF- κ B (RANK) expressed on osteoclasts and their precursors is a receptor for RANK Ligand (RANKL). Signals transduced by RANKL-RANK interaction induce genes essential for the differentiation and function of osteoclasts partly through the direct binding of NFATc1 to target gene promoters. We have cloned a 6-kb fragment containing the 5'-flanking region of the mouse RANK gene and have analyzed the binding elements of transcription factors such as PU.1 (-480), NFATc1 (-370) and MTF (-100). Here, we examined the regulatory mechanism of RANK gene transcription through the putative CRE/AP-1 binding site (-240).

RANK mRNA expression in primary cultured-bone marrow cells and pre-osteoclastic RAW cells was induced by PMA and suppressed by PKC inhibitor Calphostin C. On the other hand, forskolin and H89 showed no effect on RANK mRNA expression, suggesting that PKC, not PKA, signaling regulates the RANK gene. We then assessed the involvement of the AP-1 transcription factor, c-fos, in RANK gene transcription. In RAW cells, c-fos knockdown by siRNA nullified the

inducible effect of PMA on RANK expression. Transfection with a c-fos expression vector into RAW cells increased RANK mRNA expression. By EMSA, an oligonucleotide (-246/-238) showed DNA protein binding, the specificity of which was confirmed by block-shift with an anti-c-fos antibody and by the addition of the excess of a cold consensus probe. Co-transfection with a c-fos expression vector and the RANK promoter construct showed that c-fos increased RANK promoter activity 2-fold in RAW cells. Mutagenesis of the putative AP-1 site (-240) nullified the inducible effect of c-fos on promoter activity.

Taken together, these results indicate that during differentiation of bone marrow mono-nucleated cells into osteoclast precursors, RANK transcription is positively regulated by c-fos/AP-1 through the binding element of its gene promoter.

Changes in Extracellular Calcium Concentration Affect Human Osteoclast Formation and Bone-Resorbing Activity. Francesca Hemingway¹, Xiaotong Cheng^{*2}, Nicholas Athanasou². ¹Nuffield Department of Orthopaedics, Rheumatology & Musculoskeletal Sciences, University of Oxford, United Kingdom, ²University of Oxford, United Kingdom

Osteoclasts are lysosome-rich multinucleated cells (MNCs) which resorb bone, releasing a large amount of calcium from the mineral component. The calcium concentration at the resorption site is very high, as much as 40 mM. Calcium in this region is removed into extracellular fluid by transcytosis. Previous studies in animals have shown variable effects of high extracellular calcium on osteoclast formation and activity, and no such studies have been carried out in man. Our study used human monocytes to examine the effect of high extracellular calcium and low extracellular calcium (in the case of hypocalcaemia) on osteoclast formation and osteoclast bone-resorbing activity.

CD14⁺ monocytes were isolated from human peripheral blood and cultured on glass coverslips or dentin slices with media containing 25ng/ml macrophage colony stimulating factor (M-CSF) and 50ng/ml receptor activator of nuclear factor kappa-B ligand (RANKL). Cells were cultured in media supplemented with CaCl₂ (final calcium concentrations in mM: 5, 7, 10, 15, 20), to study the effect of high extracellular calcium, or cultured in media with the calcium-chelating agent ethylene glycol tetraacetic acid (EGTA) (concentrations in mM: 0.5, 1.0, 1.5, 2.0) to study the effect of low extracellular calcium. CD14⁺ cells were cultured in above media for 12-14 days and osteoclast formation was assessed by counting the number of MNCs on tartrate resistant acid phosphatase (TRAP) staining. To study the effect on bone-resorbing activity, CD14⁺ monocytes were cultured with control media until osteoclasts formed then cells were cultured in high calcium media or media with EGTA for 3 days. The dentine slices were stained with toluidine blue to examine the extent of osteoclast resorption.

In 12-14 day cultures with high calcium media, the number of TRAP positive MNCs significantly decreased comparing to control (Figure 1). Similar results on osteoclast formation were found in 12-14 day cultures with EGTA, and the inhibition was recovered by adding the same amount of CaCl₂ in media (Figure 2). In 3-day cultures of mature osteoclast with high concentrations of calcium, the average area resorbed by MNCs increased comparing to control (Figure 3). Our findings indicate that both high and low concentrations of extracellular calcium inhibit human osteoclast formation, and that osteoclast bone-resorbing activity is enhanced in a high extracellular calcium environment.

Effects of Dietary Amino Acids on Expression Levels of Markers of Osteoclastic Differentiation/Activity. Qing Zhong^{*1}, Ke-Hong Ding¹, Wendy Bollag¹, Hugh Nadeau¹, Karl Insogna², Norman Chutkan¹, Mark Hamrick¹, Carlos Isales³. ¹Georgia Health Sciences University, USA, ²Yale University School of Medicine, USA, ³Medical College of Georgia, USA

Increased dietary protein in humans has been reported to increase both bone formation and bone breakdown. We have previously shown that individual amino-acids, particularly those of the aromatic family (Tyrosine, Tryptophan and Phenylalanine) increase bone formation. Thus, we were interested in whether individual amino-acids could also have direct effects on osteoclasts and affect bone breakdown. To evaluate this possibility we used primary osteoclasts isolated from the bone marrow of C57Bl6 mice and examined the effects of twenty of the common amino-acids on four markers of osteoclast differentiation/activity: Carbonic anhydrase 2; Calcitonin receptor; Matrix metalloproteinase 9 and Cathepsin K.

Individual amino-acid levels were increased two-fold in the osteoclast culture medium to mimic post-prandial levels. Changes in mRNA were quantified using Real Time PCR. We found that: (1) Arginine (4.6 fold), Asparagine (4.0 fold), Isoleucine (2.6 fold), Alanine (2.5 fold) and Threonine (2.2 fold) had the largest effects on Carbonic anhydrase 2 expression; (2) Arginine (2.3 fold), Isoleucine (2.1 fold), Threonine (2.1 fold), and Histidine (1.9 fold) had the largest effects on Calcitonin receptor expression; (3) Arginine (2.3 fold), Isoleucine (2.3 fold), and Threonine (2.1 fold) had the largest effects on MMP9 expression; and (4) Arginine (3.0 fold), Methionine (2.1 fold), and Threonine (1.9 fold) had the largest effects on Cathepsin K expression. Thus, Arginine, Threonine and Isoleucine seem to consistently increase expression of osteoclastic differentiation. These amino-acids are distinct from those found to increase osteoblastic differentiation (e.g., Tyrosine, Tryptophan and Phenylalanine), suggesting that bone formation or breakdown may be preferentially activated depending on the composition of the protein ingested.

Immunostimulatory Lipopeptides, Pam2CSK4 and Pam3CSK4, Enhance Osteoclast Differentiation. Jiseon Kim^{*1}, Jihyun Yang², Ok-Jin Park³, Cheol-Heui Yun⁴, Hong-Hee Kim¹, Seung Hyun Han³. ¹Seoul National University, South Korea, ²Department of Oral Microbiology & Immunology, DRI, & BK21 Program, School of Dentistry, Seoul National University, South Korea, ³School of Dentistry, Seoul National University, South Korea, ⁴Department of Agricultural Biotechnology & Research Institute for Agriculture & Life Sciences, Seoul National University, South Korea

Bacterial bone diseases including osteomyelitis and periodontitis are closely related with the excessive destruction of calcified matrix which is mainly caused by activation of osteoclasts. Since Gram-positive bacteria and Gram-negative bacteria preferentially express diacylated- and triacylated-lipoproteins, respectively, the immunostimulatory lipopeptides, Pam2CSK4 and Pam3CSK4, have been widely used as each of their lipoprotein models. In the present study, we investigated whether bacterial lipoproteins affect osteoclastogenesis in the committed osteoclasts using those two synthetic lipopeptides. Osteoclast precursors were prepared from C57BL/6 mouse bone marrow cells by treatment with macrophage colony stimulating factor (M-CSF) for three days. Then the cells were treated with M-CSF and receptor activator of nuclear factor κ B ligand (RANKL) for one additional day to differentiate them into the committed osteoclasts. When the committed osteoclasts were stimulated with the aforementioned lipopeptides in the presence of only M-CSF for two days, differentiation into mature osteoclasts was augmented concomitantly with an increase in the bone resorptive activity. When C57BL/6 mice were intraperitoneally administrated with Pam2CSK4 or Pam3CSK4, a decrease in the trabecular bone volume was also observed. Notably, such effects were not observed in the committed osteoclasts derived from TLR2- or MyD88-deficient mice. The lipopeptides also increased the expression of pro-inflammatory cytokines such as IL-6, IL-1 β and TNF- α . Furthermore, the lipopeptides enhanced phosphorylation of MAP kinases including ERK, p38 kinases, and JNK1, and the DNA-binding activity of AP-1, NF- κ B, and NF-AT in the committed osteoclasts. Collectively, these results suggest that the immunostimulatory lipopeptides enhance the osteoclast differentiation, which might at least partially contribute to the bone resorption.

The Alpha2 Integrin Minimally Impacts Osteoclast Differentiation and Adult Bone Homeostasis. Zhengyan Wang^{*1}, Grace Shin¹, Eric Everett², Xin Li³, Mary Zutter⁴, Laurie McCauley⁵. ¹University of Michigan, USA, ²University of North Carolina at Chapel Hill, USA, ³New York University, USA, ⁴Department of Pathology, Vanderbilt University Medical Center, USA, ⁵University of Michigan, School of Dentistry, USA

Collagen constitutes the most abundant protein in the bone extracellular matrix and triggers receptor mediated cell signaling. The α 2 β 1 integrin is a major collagen receptor on osteoblasts and osteoclasts and previous *in vitro* studies indicated that collagen- α 2 β 1 is essential for osteoblast differentiation. In osteoclasts, the α v β 3 integrin is known to mediate bone resorption; however, the role of α 2 β 1 integrin function is not known. The purpose of this study was to determine the role of α 2 β 1 integrin in osteoclastogenesis and function *in vitro* and *in vivo*. Bone marrow derived wild type osteoclasts showed increased cell surface expression of the α 2 integrin subunit during osteoclast differentiation *in vitro* as determined by flow cytometry and immunofluorescence. Stimulation of bone marrow derived osteoclasts with soluble type I collagen led to increased tyrosine phosphorylation, including src phosphorylation as detected via western blot analyses. This increased phosphorylation was reduced but not completely inhibited by α 2 β 1 blocking antibodies, suggesting that other collagen receptors may compensate in the absence of α 2 integrin signaling. Male C57BL/6 mice (10 wks) were examined via micro-computed tomography and bone histomorphometry. The α 2-/- mice had slight but significantly decreased femur length, diameter, and cortical bone density compared with wild-type littermates. There were no differences in other trabecular or cortical bone parameters including osteoclast number/perimeter evaluated in TRAP stained sections. Interestingly, α 2-/- osteoclasts had increased *in vitro* resorptive capacity as measured via resorption pit assay using Osteologic discs. Real time qPCR performed in cultures of differentiating osteoclasts revealed no differences in expression of osteoclast markers including β 3 integrin, calcitonin, cathepsin K, and *Nfatc-1*. There were no significant differences in serum TRAP levels in α 2-/- vs. wild type mice. In summary, these studies suggest that α 2-/- integrin is not essential for osteoclast differentiation or normal bone development and homeostasis. It is possible that other collagen receptors compensate for the lack of α 2, or the effects of α 2 integrin on osteoclasts are evident only in certain conditions.

Disclosures: Zhengyan Wang, None.

Thrombospondin-1 Regulates Bone Density Through Effects on Nitric Oxide Signaling in Osteoclasts. Sarah Amend^{*1}, Ozge Uluckan², Michelle Hurchla¹, Hongju Deng², William Frazier², Katherine Weilbaecher². ¹Washington University in St. Louis, USA, ²Washington University in St. Louis School of Medicine, USA

Thrombospondin-1 (TSP1), recognized primarily for its role in angiogenesis, is a secreted glycoprotein and a ligand for at least 9 different receptors including β 3 integrin and CD47, essential proteins for maintaining bone homeostasis. There is phenotypic overlap among mouse models deficient for CD47, β 3, and TSP1. Interestingly, mice with a targeted disruption of CD47 have increased bone mass and defective OCs, rescued *in vitro* by inhibition of nitric oxide synthase (NOS). In vascular cells and platelets, TSP1 binding is sufficient to block nitric oxide (NO) signaling. A cell autonomous role for TSP1 signaling in OCs has not been elucidated. We demonstrate that TSP1 deficient mice (TSP1-/-) have increased bone mass due to an OC defect. TSP1-/- mice have 7% more trabecular bone volume compared to wild type (WT) littermates at six weeks of age as measured by microCT analysis of tibiae, a defect that intensifies with age, with 6 month old mice having 25% higher bone volume than controls. These data, coupled with decreased serum collagen breakdown products in TSP1-/- mice compared to WT, indicates a role for TSP1 in mediating OC function to maintain healthy bone. MCSF and RANK-L induced differentiation of OCs from bone marrow macrophages is disrupted upon TSP1 blockade as indicated by TRAP stain. In addition, bone marrow macrophage proliferation, measured by BrdU incorporation, is abrogated, both in TSP1-/- macrophages compared to control and upon administration of TSP1 neutralizing antibody in WT cultures. NO signaling is known to exert a "Goldilocks effect" on macrophage proliferation and OC formation, with signaling at high and low extremes having an inhibitory effect. TSP1 antagonism in OC cultures causes 30-fold increased expression of inducible NOS by quantitative reverse transcription PCR. The cultures also display elevated NO signaling, indicated by increased concentration of nitrite in cell culture supernatant in a Griess reagent assay. Inhibition of NOS using the pan-NOS inhibitor L-NAME rescues both the macrophage proliferation and the OC differentiation defect in the absence of TSP1. Our data show a cell-autonomous role for TSP1 in regulating OC formation, in part through inhibition of NO signaling. This data suggest that clinical modulation of NO levels, common in the treatment of cardiovascular disease, may decrease levels of bone resorption.

Type I Phosphoinositide-4 Phosphate 5 Kinase γ Regulates Osteoclasts in a Bifunctional Manner. Tingting Zhu^{*1}, Robert Mecham², Pietro De Camilli³, Jean Chappel¹, Steven Teitelbaum¹, Wei Zou¹. ¹Washington University in St. Louis-School of Medicine, USA, ²Washington University School of Medicine, USA, ³Yale University School of Medicine, USA

As in all cells, phosphoinositides (PI), including PI(4,5)P₂ (PIP₂), impact osteoclast formation and function. We therefore asked if an enzyme central to PIP₂ synthesis, namely type 1 phosphoinositide-4 phosphate 5 kinase γ (PIP5K1 γ), regulates the bone-resorptive cell. We find that PIP5K1 γ -/- precursors are resistant to RANK ligand (RANKL) as regards both osteoclast differentiation ($p < 0.001$) and activation of signals controlling the event including NFATc1, β 3 integrin, Akt, p38 and JNK. Confirming physiological relevance, osteoclastogenesis is reduced by more than half ($p < 0.01$) in PIP5K1 γ -/- mice, *in vivo*. On the other hand, PIP5K1 γ -/- osteoclasts spread normally, form actin rings and individually resorb bone as effectively as their WT counterparts, establishing compromised formation but not function. Because like PLC γ -deficiency, which compromises osteoclast formation and function, excess PIP5K1 γ likely yields increased PIP₂, we overexpressed PIP5K1 γ in osteoclast precursors. In fact, overexpression of PIP5K1 γ delays osteoclast differentiation and reduces cell number. Unlike its absence, excess PIP5K1 γ also disrupts the cytoskeleton in that the cells fail to spread or dynamically form actin rings. Consistent with a PIP₂-mediated event, the cytoskeleton-disruptive effects of excess PIP5K1 γ reflect its kinase activity but appear independent of adaptor function as a similar phenotype develops in cells transduced with splice variants capable or incapable of binding talin. The combined arrested differentiation and disorganized cytoskeleton of PIP5K1 γ -transduced osteoclasts compromises their bone resorptive capacity ($p < 0.001$). Thus, likely reflecting PIP₂ generation, optimal PIP5K1 γ expression by osteoclasts is essential for skeletal homeostasis, *in vitro* and *in vivo*.

Calmodulin Interacts with Rab3D and Mediates Osteoclastic Bone Resorption. Jiaye Xu^{*1}, Taksum Cheng², Shek Man Chim², Jennifer Tickner², Estabelle Ang¹, Ming Hao Zheng², Nathan Pavlos². ¹The University of Western Australia, Australia, ²University of Western Australia, Australia

Calmodulin is a highly versatile protein that regulates intracellular calcium homeostasis and diverse cellular functions such as cardiac excitability, synaptic plasticity and signaling transduction. During osteoclastic bone resorption, calmodulin is concentrated at the ruffled border membrane of osteoclasts and has been implicated in the regulation of bone resorption. Here we show that calmodulin interacts with Rab3D, a molecule known to be important in osteoclast exocytic vesicle transport and bone homeostasis. By yeast two-hybrid screening, we identified a specific interaction between calmodulin and Rab3D, but not with other Rabs including Rab4, Rab5 and Rab6. This interaction was calcium-dependent as revealed by calmodulin sepharose pull-down assays *in vitro*. Consistently, expression of a calcium insensitive form of calmodulin (CaM1234) perturbed this interaction *in vivo* as monitored by bioluminescence resonance energy transfer (BRET) assays. Interestingly, the interaction of calmodulin and Rab3D was significantly enhanced when Rab3D was expressed and locked in its GTP-bound conformation (Rab3DQ81L) as compared to wild-type Rab3D, nucleotide lacking (Rab3DN135I) and prenylation deficient (Rab3DΔCXC) by BRET assays, suggesting that the interaction between calmodulin and Rab3D was nucleotide-dependent. During RANKL-induced osteoclast formation, calmodulin gene transcripts were constitutively expressed and paralleled with those of Rab3D. In mature osteoclasts, calmodulin co-fractionated with Rab3D at the plasma membrane during sucrose gradient sedimentation assays and colocalized with Rab3D in the ruffled border of bone-resorbing osteoclasts by confocal microscopy. Finally, functional blockade of this interaction by calmidazolium chloride resulted in a significant attenuation of osteoclastic bone resorption. Our data imply that calmodulin interacts with Rab3D at the ruffled border membrane to regulate efficient bone resorption by osteoclasts.

Does Ovariectomy in Non-Resorbing Adult Mice Cause Bone Gain? Christian Thudium^{*1}, Carmen Flores², Ilana Moscatelli², Jesper Thomsen³, Mie Bruel⁴, Natalie Sims⁵, Maria Askmyr⁵, Thomas Martin⁵, Anita Neutsky-Wulff⁶, Vicki Jensen⁷, Gerling Langenbach⁸, Claus Christiansen⁷, Vincent Everts⁸, Morten Karsdal⁷, Johan Richter², Kim Henriksen⁷. ¹Nordic Bioscience, Denmark, ²Lund University, Sweden, ³University of Aarhus, Denmark, ⁴Institute of Anatomy, University of Aarhus, Denmark, ⁵St. Vincent's Institute for Medical Research, Australia, ⁶Nordic Bioscience & University of Copenhagen, Denmark, ⁷Nordic Bioscience A/S, Denmark, ⁸Dept. Oral Cell Biology, (ACTA), Universiteit van Amsterdam & Vrije Universiteit, Netherlands

Patients and mice with mutations reducing the ability of the osteoclasts to secrete acid have osteopetrosis, characterized by defective bone resorption, increased osteoclast numbers, and normal or even increased bone formation.

This has suggested that osteoclasts have at least two distinct functions, bone resorption and coupling signals stimulating bone formation. To investigate this hypothesis, we used adult mice, transplanted with acidification deficient osteoclasts in a standard OVX bone loss model.

We hypothesized that 1) ovariectomy (OVX) induced bone turnover could be rescued by preventive transplantation of oc/oc fetal liver cells and most importantly 2) that OVX in these mice would result in more rather than less bone in the OVX model.

Adult mice were irradiated and transplanted with fetal liver cells from wt or oc/oc mice (Ly5.2 background) by IV injection into wt mice (Ly5.1 background). Engraftment levels were assessed using flow cytometry of the Ly5.2/Ly5.1 ratio. OVX was performed 2 weeks post transplantation. Serum samples were collected every 4-6 weeks for measurement of bone turnover markers (CTX-I, ALP and TRACP 5b). At week 17 the animals were euthanized and bones were collected for histomorphometry, μ CT and mechanical tests.

An engraftment level >95% was obtained. The resorption marker CTX-I was reduced in the oc/oc groups compared to wt/wt and wt/wt OVX, while TRACP 5b was increased in the oc/oc groups compared to wt/wt and wt/wt OVX. ALP levels were unchanged between groups.

μ CT analyses of femurs and vertebrae showed a 50% increase in bone volume in trabecular and 20% in cortical compartments of oc/oc mice compared to wt/wt in pilot studies without OVX. Bone histomorphometry confirms the increased bone volume found in μ CT analysis. Furthermore, mechanical tests showed a 35% increase in bone strength in the femoral neck and diaphysis of oc/oc mice compared to wt/wt in the pilot study. μ CT analyses of femurs and vertebrae in the OVX study, biomechanical tests on femur and vertebrae, and bone histomorphometry of vertebrae are ongoing.

In conclusion, we here present data indicating that that bone formation is uncoupled from bone resorption in adult mice, when the osteoclasts are unable to acidify the resorption lacunae and that ovariectomy increases bone gain in mice with non-resorbing osteoclasts. These data highlight the different functions of osteoclasts.

Lysophosphatidylinositol: Evidence for a Role in GPR55 Mediated Bone Resorption and Rheumatoid Arthritis. Lauren S. Whyte^{*}, Wendy R. Russell, Lynne Hocking, Michael Rogers, Ruth A. Ross, University of Aberdeen, United Kingdom

Male mice lacking the putative cannabinoid receptor GPR55 have a high bone mass phenotype due to a defect in osteoclast polarisation. Lysophosphatidylinositol (LPI), the endogenous ligand for GPR55, stimulates bone resorption *in vitro*, however it is not known whether osteoclasts produce LPI in response to GPR55 activation or whether levels of LPI are altered in response to cytokines known to modulate osteoclastic resorption. In addition, LPI is known to have a role in inflammation, but it remains to be determined whether levels of circulating LPI are altered in patients with rheumatoid arthritis (RA), an inflammatory condition associated with bone destruction.

Human osteoclasts were treated with the synthetic GPR55 agonist, O-1602, or the pro-inflammatory cytokines IL-1 or TNF α for 90 min. Cell pellets were extracted directly using acidified chloroform/methanol containing 1% acetic acid and prepared for LC-MS. The same LC-MS method was used to measure LPI in plasma collected from a cohort of patients with RA (n=14) and healthy controls (n = 6), with approval from the North of Scotland Research Ethics Committee. LPI was measured in triplicate for each sample.

Upon treatment of human osteoclasts with O-1602, levels of LPI were significantly increased relative to control cultures. Treatment of osteoclasts with IL-1, but not TNF α , resulted in a significant increase in LPI. These results suggest that activation of GPR55 results in an increase in production of the endogenous ligand. In

addition, LPI can also be produced in response to the pro-inflammatory cytokine IL-1 - most likely due to IL-1 induced activation of PLA2.

Having shown that LPI levels are altered upon treatment with IL-1, which is known to play an important role in bone erosion and cartilage destruction in arthritis models, we have also shown that plasma levels of LPI in a cohort of patients with RA were significantly higher than those measured in healthy controls. However, in the small number of patients studied so far, levels of LPI did not correlate with disease severity as assessed by DAS score.

These results suggest that LPI may play a role in IL-1 induced bone resorption via GPR55, further adding to the body of evidence that GPR55 antagonists may be of use in the treatment of bone diseases associated with excessive osteoclast activity. Furthermore, LPI may be a novel biomarker for RA.

Silicon Nanocrystal Tracer for Real-Time Activity Bioassay of Single Osteoclasts. Naif Alsharif, Mark Birch, Benjamin Horrocks, Harish Datta*. Newcastle University, United Kingdom

There is a lack of suitable in vitro techniques for assaying osteoclastic (OC) resorptive activity in real-time, and existing assays for osteoclast resorptive activity are cumbersome, insensitive and retrospective. A variety of real-time assays have also been used that measure one or more of the products generated by OC during resorptive activity, such as superoxide anion, proton pump activity, calcium generation or enzyme release. An important disadvantage of these assays is that they estimate only one aspect of OC activity, which may or may not relate to the overall resorptive activity of these cells. To address these problems, we have developed an assay, which we show is easy to use, rapid, precise and allows the real-time resorption assay of a single OC. The assay is based on an artificial hydroxyapatite / collagen matrix containing a luminescent tracer. As the OC resorbs the matrix, the tracer is released and internalised by the cell which can be observed in a fluorescence microscope. The assay therefore determines the overall resorption activity of the OC, as in the pit assay, but with the sensitivity speed and convenience of fluorescence microscopy. In principle, many fluorescent dyes could be employed as the tracer; however there are important criteria the dye must satisfy to ensure the quality of the assay. In our previous studies we have shown that alkyl-capped nanocrystals (SiNCs) have appropriate properties for such application (1), are insoluble in water and therefore do not leach from the matrix and they have bright luminescence that is proportional to their concentration without evidence of the aggregation or self-quenching effects typical of molecular dyes. Silicon nanocrystals have advantages over other types of quantum dot for long duration experiments because they cannot leach heavy metal ion. In this in vitro assay, OC is inhibited by calcitonin (CT), methyl- β -cyclodextrin (MCD) and filipin, and stimulated by RANKL in the expected manner, and stimulants and inhibitors of OC activity can be easily distinguished from the real-time fluorescence data over a period of about 30 min. The kinetics of the assay exhibit a lag phase followed by a growth of cell fluorescent intensity and the whole time course was satisfactorily described by the logistic equation.

Tctex-1, a Novel Interaction Partner of Rab3D, is Required for Osteoclastic Bone Resorption. Nathan Pavlos*, Taksum Cheng¹, An Qin¹, PeiYing Ng², Hao-Tian Feng², Estabelle Ang², Amerigo Carrello², Ching-Hwa Sung³, Reinhard Jahn⁴, Ming Hao Zheng¹, Jiak Xu². ¹University of Western Australia, Australia, ²The University of Western Australia, Australia, ³Cornell University, USA, ⁴Max-Planck-Institute for Biophysical Chemistry, Germany

Vesicular transport along microtubules must be strictly regulated to sustain the unique structural and functional polarisation of bone-resorbing osteoclasts. However, the molecular mechanisms bridging these vesicle-microtubule interactions remain largely obscure. Rab3D, a member of the Rab3 subfamily (Rab3A/B/C/D) of small exocytotic GTPases, represents a core component of the osteoclastic vesicle transport machinery. Here, we identify a new Rab3D-interacting partner, Tctex-1, a light chain of the cytoplasmic dynein microtubule motor complex by a yeast two-hybrid screen. We demonstrate that Tctex-1 binds specifically to Rab3D in a GTP-dependent manner and co-occupies Rab3D-bearing vesicles in bone-resorbing osteoclasts. Furthermore, we provide evidence that Tctex-1 and Rab3D intimately associate with the dynein motor complex and microtubules in osteoclasts. Finally, targeted disruption of Tctex-1 by RNA interference significantly impairs bone resorption capacity and mislocalizes Rab3D-vesicles in osteoclasts, attesting to the notion that components of the Rab3D-trafficking pathway contribute to the maintenance of osteoclastic resorptive function.

TRAF family member-associated Nf-kappa B activator (Tank), Induced by RANKL, Negatively Regulates Osteoclast Survival and Function. Mengrui Wu*, Lianfu Deng², Yiping Wang³, Wei Chen⁴, Xu Feng⁴, Yi-Ping Li⁴.

¹Institute of Genetics, Life Science College, Zhejiang University & Department of Pathology, University of Alabama at Birmingham, China, ²Shanghai Key laboratory, Shanghai Institute of Trauma & Orthopaedics, Ruijin Hospital, School of Medicine, Shanghai Jiao-Tong University, China, ³Institute of Genetics, Life Science College, Zhejiang University, China, ⁴University of Alabama at Birmingham, USA

Precise control of osteoclast activity is required for bone homeostasis, so bone resorption needs to be “turned off” when it is no longer needed (a negative feedback loop). However, little is known about the mechanism that regulates the negative feedback loop. To test our hypothesis that certain signaling proteins induced in osteoclast differentiation negatively control osteoclast activity, we characterized the expression and function of such signaling proteins.

ChIPArray was performed for genome-wide analysis of genes expression before and after osteoclast maturation. Bone marrow monocytes (BMMs) transduced with Tank-siRNA lentivirus were induced by RANKL and M-CSF. TRAF family member-associated Nf-kappa B activator (Tank) knockdown was validated 48 hours after lentivirus transduction by western blot analysis. TRAP staining, acridine orange staining, and a scanning electronic microscope were respectively used to assess osteoclast formation, acid production, and number of resorption pits. Osteoclast survival was examined by TRAP-stained osteoclast morphological analysis at different timepoints during prolonged culture on bone slides.

Our results show that Tank expression increased 10-fold from RANKL stimulation during osteoclastogenesis according to our ChIPArray data. Tank was identified as a candidate regulator of negative feedback. Western blot and RT-PCR confirmed upregulation of Tank in RANKL-stimulated BMMs. One siRNA (Tank-shRNA-1) was shown to knockdown Tank expression by 85.6% in osteoclasts. No obvious differences were observed in the degree of osteoclastogenesis. However, the Tank-knockdown group had increased acid production and a 200% increase in the number of bone resorption pits compared to the control group. The survival rate of mature osteoclasts in the Tank-knockdown group was 3.5 times higher than the control group.

In conclusion, our data indicates that Tank expression is highly induced by RANKL and that Tank inhibits osteoclast activity and reduces osteoclast survival, functioning in a negative feedback loop in RANKL-induced bone resorption. Tank may negatively regulate RANKL signaling in osteoclasts by inhibiting Nf-kappa B (Nf- κ B) activity. This is the first report of Tank's function as a negative regulator in osteoclast function. These results may provide means for therapeutic intervention in diseases of excessive bone resorption.

Both VEGF Receptor 2 (VEGFR2) and the Parathyroid Hormone Type 1 Receptor (PTH1R) Mediate the Early Antiapoptotic Response to Mechanical Stimulation in MLO-Y4 Cells. Marta Mavcas*, Luis Fernandez de Castro¹, Beatriz Bravo¹, Cira Garcia de Durango¹, Jose Manuel Pozuelo¹, Pedro Esbrit², Arancha Gortazar³. ¹Universidad San Pablo CEU, Spain, ²FUNDACION JIMENEZ DIAZ, Spain, ³Universidad San Pablo-CEU School of Medicine Madrid Spain, Spain

Mechanical loading plays a key role in bone formation and maintenance. While unloading induces osteocyte apoptosis and bone loss in vivo, mechanical stimuli prevents osteocyte apoptosis through a mechanism involving β -catenin accumulation and ERK nuclear translocation. Both vascular endothelial growth factor (VEGF) and parathyroid hormone-related protein (PTHrP) have a crucial role in bone formation,

but their interaction with osteocytes is not completely understood. VEGF receptor 2 (VEGFR2) has recently been shown to mediate, at least in part, the mechanical response of endothelial cells in a VEGF-independent manner. On the other hand, activation of the PTH type 1 receptor (PTH1R) in osteocytes has recently been shown to increase periosteal bone formation by targeting the Wnt pathway. Of interest, in osteoblasts, VEGF-independent VEGFR2 activation appears to be in part responsible for the antiapoptotic effect of PTHrP. In this work, we aimed to evaluate the putative roles of the VEGF and PTHrP systems in early (10 min-1h) osteocyte mechanosensing. To this end, MLO-Y4 cells were subjected to mechanical strain by laminar fluid flow (FF) or hypotonic shock. Mechanical stimuli, VEGF165 (6 ng/ml) or PTHrP (1-36) (100 nM) similarly stimulated cell viability and β -catenin stabilization related to an increased membrane localization (assessed by western blot and immunocytochemistry). A VEGFR2 antagonist (SU5416) or transfection of a dominant negative VEGFR2 plasmid -in contrast to a VEGF neutralizing antibody- and the PTH type 1 receptor (PTH1R) antagonist PTHrP (7-34) all decreased these events. In contrast, VEGFR2 overexpression in MLOY4 cells mimicked the effect of FF on β -catenin and also nuclear ERK relocalization. Interestingly, we also observed that mechanical stimulation increased PTH1R in membrane. In conclusion, our *in vitro* findings strongly support the role of both VEGFR2, in a VEGF-independent manner, and the PTH1R in the mechanism whereby mechanical stimuli promote osteocyte viability.

Regulation of Osteocyte Apoptosis and ECM by PTHrP. Leonard Defetos^{*1}, Cheryl Chalberg², Su Tu², Douglas Burton², Lynda Bonewald³. ¹Veterans Administration San Diego Healthcare System & University of California, USA, ²VA San Diego Healthcare System / University of California San Diego, USA, ³University of Missouri - Kansas City, USA

Background: Although osteocytes are the most abundant cell type in bone, much of their biology remains enigmatic. Recent data reveal that osteocytes themselves act as endocrine cells that synthesize growth regulating factors and respond to other regulatory hormones. The signaling pathways among bone cells are complex and involve many factors, including parathyroid hormone-related protein (PTHrP). In this study, we evaluated the effects of PTHrP on osteocyte genes related to apoptosis and extracellular matrix (ECM).

Methods: The MLO-Y4 cells, derived from mature mouse osteocytes, were transfected for 24 hours with a mouse-specific PTHrP 1-139 expression plasmid and compared to cells transfected with a vector control plasmid. The PTHrP expression was measured by immunoassay and total RNA was purified. The mRNA samples were analyzed for genes related to apoptosis and ECM using qPCR arrays. A GFP expression plasmid was used to assess transfection efficiency.

Results: Positive GFP expression was observed in over 85% of the cells by fluorescence microscopy. PTHrP overexpression was confirmed in the PTHrP 1-139 transfected cells (4205 pg PTHrP/ ml media) compared to vector control transfected cells (81 pg PTHrP / ml media), respectively. Significant differences in apoptosis and ECM related genes were observed between the PTHrP 1-139 and vector control transfected groups. In general, PTHrP 1-139 was pro-apoptotic, increasing over 1.5-fold TNF ligand and receptor (*FasII*, *Tnf*, *Cd40lg*, *Cd40*) and CARD (*Card10*) family related genes and decreasing some of the anti-apoptosis related genes. Greater effects of PTHrP were observed in the ECM array. PTHrP 1-139 transfection increased several cell adhesion and ECM related markers over 2-fold (*Itgax*, *Cntn1*, *Cntna2*, *Sele*, *Adams2*, *Mmp10*) and decreased > 50% other ECM related genes (*Fnl1*, *Vcan*, *Adamts1*, *Col1a1*, *Col3a1*, *Col6a1*).

Conclusions: In this study, we have demonstrated that PTHrP can regulate osteocyte markers for apoptosis and ECM. Apoptosis plays a critical role in normal biological processes requiring cell removal including differentiation, development, and homeostasis and ECM play critical roles in normal processes such as cell growth, division, differentiation, and migration. The modulation of osteocyte growth and function by PTHrP identifies additional pathways for bone homeostasis. Exploring these pathways in detail can identify both basic and clinical relevance for the effects of PTHrP on osteocytes.

Hypermineralization of Osteocyte Lacunae in the Aged Human Skeleton Leads to Underestimated Osteocyte Lacunar Densities. Vincent Carpentier, Jinquan Wong, Youwen Yeap, Cheryl Gan, Peter Sutton-Smith, Arash Badiei, Nicola Fazzalari, Julia Kuliwaba*. SA Pathology, Australia

Previous studies reporting on osteocyte density in the human skeleton (healthy vs pathological conditions) have underestimated 'true' osteocyte lacunar density, as hypermineralized osteocyte lacunae, a unique feature of the aging human skeleton, are not visible with standard histology. Therefore, the purpose of this study was to determine the extent of hypermineralized osteocyte lacunae in relation to bone mineralization for osteoporotic hip fracture (OP) and hip osteoarthritis (OA) patients, and non-pathological cadaveric controls (CTL). Intertrochanteric bone cores were obtained from patients at surgery for non-traumatic OP femoral neck fracture (10F, 4M, 65-94y) and for hip OA (7F, 8M, 62-87y), and femora at autopsy (CTL: 5F, 11M, 60-84y). Bone cores from the central region of L2 vertebrae were also obtained, from an independent cadaveric cohort (CVB: 3F, 6M, 53-83y). Bone samples were resin-embedded for quantitative backscattered electron imaging (qBEI). Bone tissue mineralization (wt %Ca) was not different between OP, OA, and CTL; but was greater in femoral CTL than in CVB (24.34 vs 22.95%; $p < 0.002$). Using a custom image-processing algorithm for qBEI images, lacunar, hypermineralized, and total lacunar densities were quantified. Percent hypermineralized lacunae relative to total number (HL/TL[%]) was greater in OP and OA than in CTL ($p < 0.005$). However, relative to bone mineral area, OP was characterized by increased hypermineralized lacunar density (HL.Dn[μm^{-2}]; $p < 0.02$); whereas OA was characterized by decreased lacunar density (L.Dn[μm^{-2}]; $p < 0.005$) and total lacunar density (TL.Dn[μm^{-2}]; $p < 0.02$). L.Dn was higher in CVB than in femoral CTL ($p < 0.04$). These study data suggest that even though the presence of hypermineralized lacunae is not specific to pathological bone, their proportionate number is increased in OP and OA. Further, these morphological data reiterate the fact that OP, OA, and CTL bone are different. Femoral trabecular bone was more mineralized with decreased lacunar density in comparison with vertebral trabecular bone, consistent with higher vertebral bone turnover. Further investigation is needed into whether the presence of hypermineralized lacunae in bone is detrimental to the quality of the osteocyte-canalicular cell network in terms of its mechanosensory role in bone adaptation, the ability to detect and repair microdamage, and its potential influence on bone material fracture strength and toughness.

PTH Regulation of SOST and FGF23 in Novel Osteocytic Cell Lines. Jordan Spatz^{*1}, J Martorell², KJ Barry³, ER Edelman⁴, M Balcells⁵, Paola Pajevic Divieti⁶. ¹Harvard-MIT Division of Health Sciences & Technology (HST), USA, ²Massachusetts Institute of Technology & Institut Quimic de Sarria, Barcelona, Spain, USA, ³Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, USA, ⁴Massachusetts Institute of Technology & Cardiovascular Division, Department of Medicine, Brigham & Women's Hospital, USA, ⁵Massachusetts Institute of Technology & Institut Quimic de Sarria, Barcelona, Spain, USA, ⁶MGH- Harvard Medical School, USA

To date, *in vitro* studies of osteocyte function and regulation have relied upon limited immortalized osteocyte-like cell lines that have some, but not all of the characteristic phenotype of *in vivo* osteocytes. Specifically, no osteocytic cell lines are available that truly model the end-state differentiation of osteocytes. To this end mice expressing the green-fluorescent protein (GFP) under the control of Dentin Matrix (8KbDMP1-GFP) were mated with Immortomouse (Charles River) and osteocytes were isolated from calvaria and long bone of double transgenic offsprings. Cells were subjected to sequential collagenase digestions followed by FACS sorting for GFP-positive cells. GFP-positive sorted cells displayed the dendritic morphology characteristic of an osteocytic population. Selected clones were further characterized for the expression of osteocytic genes (PheX, E11, SOST, Cnx43, FGF23) and proteins (Sclerostin and FGF23) using semiquantitative rt-PCR (qPCR) and western blot, respectively. Notably, several of the clones expressed detectable levels of sclerostin and FGF23. In addition, all osteocytic clones were negative for alkaline phosphatase staining. Next, we assessed PGE₂ and SOST regulation after 4 hours of laminar fluid flow (16 dynes/cm²) to allow for comparison of PGE₂ responsiveness in our cells to MLO-Y4. Osteocytic cells exposed to fluid flow showed a greater than 15-20-fold increase in PGE₂ production and a 2-fold reduction in SOST mRNA expression compared to static controls. DMP1-GFP expression, as assessed by fluorescent microscopy, was also significantly increased in cells exposed to fluid flow. Lastly, we evaluated functional regulation of SOST and FGF23 mRNAs. Osteocytic cell showed a 2-30 fold up regulation of FGF23 and two-fold decrease in SOST mRNA expression, as assessed by qPCR, after 4-hour treatment with 100nM hPTH(1-34). Moreover, FGF23 was also significantly upregulated after treatment with 100 nM 1,25(OH)₂D₃ for 16hr or with 10mM forskolin for 4 hr. Likewise, treatment with forskolin also decreased SOST expression in a manner similar to PTH. Treatment with 20mM phosphate, on the other hand, had no effect on FGF23 gene expression suggesting osteocytes might not regulate FGF-23 expression in response to phosphate changes. In conclusion, we have established novel osteocytic cell lines from DMP1-GFP positive calvarias and long bones that will be a tool to further investigate fundamental osteocytic research avenues.

The Formation and the Mineral Content of Hypermineralized Osteocyte Lacunae: the Phenomenon of Osteocyte Hypermineralization a Single State or a Matter of Degree?. Vincent T. Carpentier*, Jinquan Wong, Youwen Yeap, Cheryl Gan, Peter Sutton-Smith, Arash Badiei, Nicola L. Fazzalari, Julia S. Kuliwaba, SA Pathology & Hanson Institute, Australia

Hypermineralized osteocyte lacunae (HOL) have received little research attention as they are not visible with standard histologic techniques. No studies have investigated their formation or mineral content. Intertrochanteric trabecular bone cores were obtained from patients at surgery for osteoporotic (OP) femoral neck fracture (10F, 4M, 65-94y), and femora at autopsy (5F, 11M, 60-84y). Specimens were resin-embedded and carbon coated for quantitative backscattered electron imaging (qBEI) and energy dispersive X-Ray spectrometry (EDX). Using specimen observations under qBEI we describe different stages of intermediate HOL, between unmineralized black lacunae (grade I) and HOL (grade VII), which illustrate a phenomenon leading to HOL. The lacunae with a hypermineralized spherite (HS) (grade II; A) correspond to lacunae with a single HS. The lacunae with multiple HS (grade III; B) are characterised by the presence of several HS. The lacunae with wall-connected HS (grade IV; C) are lacunae with several HS where some merge with the lacunar wall. The partially HOL with HS (grade V; D) are lacunae with a hypermineralized lacunar ring associated with HS. The partially HOL (grade VI; E) are lacunae incompletely filled by hypermineralized substance, and without any presence of HS. The HOL (grade VII; F) are lacunae totally filled by hypermineralized substance. EDX analyses reveal that HOL are composed of Ca, P, Mg, and Na. Strikingly, the HOL mineral content ratios of Ca/Mg, P/Mg, and Na/Mg were higher than for the bone matrix in OP. Finally, in addition to the fact that one study reported that intermediate HOL are associated with the appearance of an apoptotic cell containing DNA under TEM (PMID:18615594), we report: 1) the fact that the osteocyte hypermineralization may be a multi-staged phenomenon; 2) the fact that HS look like "mineralized spheres" generated by osteoid-osteocytes (PMID:17115241). These findings strongly support the hypothesis that osteocyte hypermineralization is associated with osteocyte activity. We hypothesise that hypermineralization could happen in addition to osteocyte apoptosis. It appears that it is a possible specific osteocyte death which is different to apoptosis, necrosis or autophagy. Consequently, the relationship between hypermineralization and apoptosis needs to be further investigated. Unlike empty lacunae, HOL do not permit fluid circulation within the osteocyte network. Thus, their presence may modulate the quality of bone.

Stages of the phenomenon of osteocyte hypermineralization under qBEI at 400x.

Evidence of Fibroblast Growth Factor as a Physiological Regulator of Osteocyte Differentiation; Lessons from Wildtype and Hyp Mice. Carolyn Macica*¹, Adam Kaye², Guoying Liang². ¹Yale University School of Medicine, USA, ²Yale University, USA

The osteocyte is the most abundant cell type in bone and is involved in both phosphate homeostasis and as the mechanical sensor that regulates bone turnover. In addition to the extensive dendritic processes of osteocytes that function to sense physiological changes in the environment, osteocytes also produce FGF23, a phosphatonin that regulates renal phosphate transport and underlies the phosphate wasting of familial X-linked hypophosphatemia (XLH). Osteocytes are derived from a subset of osteoblasts that become buried in unmineralized matrix or osteoid. However, the physiological factors that regulate the transition from osteoblast to osteocyte are unknown. We sought to determine the putative role of fibroblast growth factors by examining the expression of FGF receptors in both wildtype and Hyp mice,

a murine model of XLH, using histological techniques in the tibia and femur. Bone-lining osteoblasts of wildtype mice showed strong FGFR1 membrane staining. In addition, we found evidence of FGFR1 expression in osteoblastic osteocytes and osteoid osteocytes associated with unmineralized osteoid. A complete downregulation of FGFR1 was revealed in all preosteocytes and osteocytes; however, they were associated with robust upregulation of a constitutively active tyrosine-phosphorylated FGF receptor (anti-Phospho-FGFR pY653/654). Staining was localized not only to the soma of osteocytes but heavily stained throughout the processes and did not stain for FGFR3. We then examined the tibia/femur of Hyp mice which characteristically display hypomineralized periosteocytic lesions. While osteocytes of Hyp mice were positive for tyrosine-phosphorylated FGFR, FGFR1 staining abnormally persisted and was particularly evident in the osteocytes embedded in lacunae of unmineralized osteoid. FGFR1 staining was normalized in Hyp mice treated with oral phosphate and vitamin D. These data confirm that mineralization is an important cue in the terminal differentiation of osteocytes with further studies aimed at determining the potential autocrine role of osteocyte-derived FGF23 in FGFR signaling.

Functional Heterogeneity of Osteocytes in FGF23 Production Revealed by 3-Dimensional Fluorescence Morphometry. Ayako Nakane*¹, Rieko Tanabe², Mayu Haraikawa³, Takashi Watanabe¹, Hiroshi Kamioka⁴, Masae Goseki-Sone⁵, Yuzo Takagi⁶, Akira Yamaguchi⁷, Tadahiro Iimura¹. ¹Tokyo Medical & Dental University, Global Center of Excellence Program, Japan, ²Department of Food & Nutrition, Faculty of Human Sciences & Design, Japan Women's University, Japan, ³Graduate School of Human Life Science, Japan Women's University, Japan, ⁴Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sc, Japan, ⁵Japan Women's University, Japan, ⁶Developmental Oral Health Sciences, Tokyo Medical & Dental University, Japan, ⁷Tokyo Medical & Dental University, Japan

Osteocytes are the most abundant cells in bone and play important roles in bone metabolism through sensing mechanical loading and endocrine regulation of the serum level of phosphate. Though morphological diversity of osteocytes depending on the sites of bone tissues and pathological changes has been described, it is not well documented whether these cells are functionally homogeneous or heterogeneous. To access this issue, we took advantages of 3-dimensional fluorescence morphometry. After conducting immuno-fluorescence with antibodies against FGF23 and DMP1 on bone sections, optical sections at different levels along z-axis were obtained by confocal microscopes. Three dimensional reconstitution and image processing were conducted in silico. Measurements of fluorescence intensity and its 3-dimensional distribution enabled to quantify relative expression level of FGF23 in an osteocyte lacuna in situ. Comparative analysis of osteocytes between trabecular and cortical bones in rat tibiae demonstrated that cortical osteocytes expressed higher level of FGF23 protein than trabecular osteocytes. To know whether these differences are functionally relevant, we compared tibiae in ovariectomized rats and sham-operated ones. In this experiment, the serum level of FGF23 in ovariectomized rats was significantly reduced to almost half level compared to that in the sham-operated group. The fluorescence morphometry analyses showed that the level of FGF23 protein in cortical osteocytes in the ovariectomized group was significantly lower than that in the sham-operated group, whereas those levels in trabecular osteocytes show no significant difference. These observations suggested that cortical osteocytes are more responsible for the production of FGF23 in response to estrogen deficiency than trabecular osteocytes. Further detailed analysis in cortical bone in both groups showed that FGF23 was heterogeneously produced among osteocytes. The level of FGF23 production in each osteocyte was reciprocally correlated with the DMP1 protein level in osteocyte lacuna. Our observation using 3-dimensional fluorescence morphometry suggested that cortical osteocytes are more responsible for regulation of the serum level of phosphate than trabecular osteocytes and that functional heterogeneity among osteocytes involves locally regulated reciprocal levels of FGF23 and DMP1.

Association Between Lipid Profile and Bone Turnover in Elderly Women and Men. Marija Tamulaitiene*¹, Rima Piliciauskiene², Vidmantas Alekna¹. ¹Vilnius University, Lithuania, ²State Research Institute Centre for Innovative Medicine, Lithuania

Background. Studies of bone markers and blood lipids are limited, and the results are conflicting.

Aim of study is to evaluate the relationship between the lipid profile and bone turnover markers.

Methods. This was a cross-sectional study on women and men aged 60 years and older who consecutively had visited the National Osteoporosis Center (Vilnius, Lithuania). Subjects who fractured during the last 12 months or have used medications known to affect bone metabolism were not included in this study. Blood samples were obtained between 9 and 11 am after overnight fasting. Total cholesterol, high-density lipoproteins (HDL), low-density lipoproteins (LDL) and triglycerides (TG) were analyzed. Serum bone resorption marker C-telopeptide of type I collagen crosslinks (s-CTX-I), type I procollagen amino-terminal propeptide (PINP) and parathyroid hormone (PTH) were measured by automated immunoassay (Cobas E411, Roche Diagnostic). Total body BMD was estimated by dual-energy X-ray absorptiometry (iDXA, GE Lunar). Mann-Whitney U test and Spearman's correlation methods were used for statistical analysis. Results. Participants included 69 men aged 71.236.85 y and 145 women aged 70.526.10 y. All the components of lipid profile were statistically significantly higher in women than in men. Total cholesterol was 6.071.23 mmol/l in women and 5.331.29 mmol/l in men ($p<0.001$), LDL - 3.831.07 mmol/l and 3.341.19 mmol/l ($p=0.001$), HDL - 1.660.44 mmol/l and 1.540.63 mmol/l ($p=0.011$) and TG - 1.370.61 mmol/l and 1.150.57 mmol/l ($p=0.002$), respectively. Total body BMD was higher in men than in women (1.1980.162 and 1.0320.132, respectively, $p<0.001$). PTH did not differ between genders: 49.9819.54 pg/ml in women and 47.9518.23 pg/ml in men. There was found weak correlation of HDL ($r=-0.20$, $p=0.022$) and LDL ($r=0.19$, $p=0.035$) with total body BMD in women. TG was statistically significantly negatively correlated to the s-CTX-I ($r=-0.23$, $p=0.007$) and PINP ($r=-0.25$, $p=0.002$) in women. No such relationship was found in men.

In conclusion we found that triglycerides negatively associated with bone turnover markers s-CTX-I and PINP only in women.

Evaluation of Undercarboxylated Osteocalcin (ucOC) in the Treatment for Osteoporosis: A Clinical Practice-Based Study. Yoichi Kishikawa*. Kishikawa Orthopedic Surgery, Japan

Purpose: Undercarboxylated osteocalcin (ucOC), which is a marker of deficiency of vitamin K2 (VK2), is an index of fracture risk independently on bone mineral density (BMD). The cut off values of serum ucOC for increased fractures risk have been determined as 4.5 ng/mL in patients without any medication for osteoporosis and 2.6 ng/mL in patients who are receiving bisphosphonate (BP) treatment. We evaluated serum ucOC levels in 255 patients (16 men and 239 women) with osteoporosis. Methods: The following information was obtained from all patients when serum ucOC levels were measured; age, sex, history of fractures, previous glucocorticoid use, BMD measured by a DXA, bone metabolism markers, and medication for osteoporosis for more than 3 months. Patients who were receiving glucocorticoid or BP treatment for more than 6 months were excluded from the analysis. Results: Serum ucOC levels were significantly lower in patients who were receiving BP treatment, but not raloxifene (RLX) or vitamin D (VD) treatment, than in those without any medication ($P<0.05$). In patients who were receiving BP or RLX treatment, but not VD treatment, ucOC levels were significantly correlated with serum NTX levels ($P<0.001$ and $P=0.007$, respectively). Among patients who were receiving BP treatment, the proportion of patients who showed serum ucOC levels less than 2.6 ng/mL was 51.3% despite lower serum NTX levels (<13.6 nmol BCE/L). A significant difference in serum ucOC levels was found between patients with lower serum NTX (<13.6 nmol BCE/L) and patients with higher serum NTX (13.6–16.5 nmol BCE/L). In patients who received combined treatment with BP or RLX and VK2, serum ucOC levels were significantly decreased than those with a single treatment with BP or RLX, and this reduction was greater in patients treated with BPs than those treated with RLX. Discussion: The present study showed that serum ucOC levels were significantly lower in patients who were receiving BP treatment than those without any medication for osteoporosis, and that serum ucOC was correlated with serum NTX in patients who were receiving BP or RLX treatment. We propose that when we use BPs, a two-step strategy utilizing bone metabolism markers is recommended. Firstly, the effect of BPs can be determined by measuring a bone resorption marker such as serum NTX. Secondly, fracture risk can also be determined measuring ucOC using a cut off value of 2.6 ng/mL.

Intravenous Zoledronate use in Adult Delayed Non-Union Fracture Healing. Nigel Gilchrist*, David Little², John McKie¹. ¹Department of Orthopaedic Medicine & Surgery, Christchurch Hospital, New Zealand, ²The Children's Hospital At Westmead, Australia

Introduction: Multiple surgical procedures are often required in patients with compound lower leg fractures with the result of either non-union or malunion with significant shortening and angulation.

Methods: We examined the effect of pulsed intravenous zoledronate, calcium and vitamin D supplements in such patients to assist bone healing. We included 7 patients who had malunion or non-union with shortening/angulation who required tibial revision surgery. Six males, age range between 42 – 68 years were included and 1

female aged 39. All subjects had undergone corrective revision surgery at least 2 – 3 years after their original compound fracture. All patients had been treated with an external fixator for deformity correction and lengthening but had failed to heal within 6 months of the revision surgery. All patients had biochemical/hormonal profile performed and technetium bone scans to assess ongoing local bone turnover. All patients except the 39 year old female had an active bone scan indicating ongoing local bone turnover and were therefore treated 6 weekly on 3 – 4 occasions with pulsed intravenous zoledronate and prior and post treatment with calcium and vitamin D. The dose of zoledronate 0.0125mg per Kg for the first dose and 0.025mg per Kg for subsequent dose and repeat doses were given on evidence of radiological healing.

Results: In all cases the fracture deficit healed allowing early (2 - 8 months) removal of the Taylor spatial frame. There were no adverse effects and no continuation of non-union at 6 month review.

Conclusion: It appears that pulsed low dose intravenous Zoledronate with Calcium and Vitamin D may aid healing of non-union fractures.

Serum Sclerostin Level and its Association with Bone Turn-over Markers in Type 2 Diabetes. Megumi Shibata*, Atsushi Suzuki¹, Sahoko Sekiguchi-Ueda², Shogo Asano³, Yasumasa Yoshino², Masaki Makino², Nobuki Hayakawa³, Mitsuvasu Itoh³. ¹Fujita Health University, Division of Endocrinology, Japan, ²Fujita Health University, Japan, ³Toyokawa city hospital, Japan

Background: Accumulating evidences suggest that type 2 diabetes mellitus have an increased risk of fractures even with higher bone mineral density. In bone metabolism in diabetes patients, low bone formation seems to contribute to deteriorate so-called bone quality. Higher baseline levels of pentosidine and homocysteine are potential risk factors for osteoporotic fractures, but precise assessment of bone fragility in diabetes patients with a specific surrogate marker is still difficult. In the present study, we explored serum level of sclerostin, an inhibitor of bone formation, to assess its possible role to reflect bone metabolic disorder in diabetes patients.

Subjects and methods: We enrolled 49 patients (M/F= 26/23; age, 63.2 11.6 years) who visited our hospital for the treatment of type 2 diabetes mellitus. Mean HbA1c level was 6.8 0.9%. Serum sclerostin concentration was measured by ELISA (Biomedica GmbH, Wien, Austria).

Results: Mean serum sclerostin level was 28.1 21.1 pmol/l. Mean serum concentrations of iPTH, 25-OHD, serum NTx, BAP, homosistein, osteocalcin and pentosidine were 45.7 18.2 pg/ml, 25.1 7.5 ng/ml, 11.5 4.6nmolBCE/mmol, 22.3 6.3U/L, 11.3 5.8μmol/l, 3.8 1.9ng/ml and 0.06 0.06μg/ml, respectively. Sclerostin was not related to either iPTH, 25-OHD, serum NTx, BAP, homosistein or osteocalcin. On the other hand, serum sclerostin level was significantly associated with serum pentosidine concentration ($r=0.72$, $n=49$, $p<0.001$).

Conclusion: These results suggest that serum sclerostin could be another candidate to evaluate metabolic disorder in bone in type 2 diabetes.

Bone Loss in Ambulatory Patients with Multiple Sclerosis. Vit Zikan*, Michaela Tyblová², Ivan Raska¹, Eva Havrdová², Dana Michalská¹, Zdenek Telicka¹. ¹Department of Internal Medicine 3, Charles University Faculty of Medicine 1, Czech Republic, ²Department of Neurology, Charles University Faculty of Medicine 1, Czech Republic

Patients with multiple sclerosis (MS) have multiple risk factors for osteoporotic fractures, such as progressive immobilization, long-term glucocorticoids (GC) treatment or vitamin D deficiency. The aim of the present study was to investigate the relationships among the level of disability, GC use, vitamin D status, body composition and bone mineral density (BMD) in ambulatory patients with MS. Methods: We studied 90 men and 120 premenopausal ambulatory women with MS. Dual-energy X-ray absorptiometry was used to analyze body composition and BMD. Motor function of the patients was evaluated using the Kurtzke Expanded Disability Status Scale (EDSS). GC use was determined from medical records. Results: Our results showed that high proportion of patients with MS have low levels of 25-hydroxyvitamin D. Multiple regression analysis indicated that EDSS and Lean Mass were the most significant parameters associated with BMD in the proximal portions of the femur. Conclusion: In MS patients, both in men and premenopausal women, the level of disability and Lean Mass were the most significant parameters which correlated with the BMD at the proximal femur. Vitamin D insufficiency is common in patients with MS.

Estimation of Fracture Probability of Glucocorticoid-Induced Osteoporosis by a Logistic Regression Model. Ikuko Tanaka^{*1}, Shigenori Tamaki², Hisaji Oshima³. ¹National Center for Geriatrics & Gerontology, Japan, ²Nagoya Rheumatology Clinic, Japan, ³Tokyo Medical Center, Japan

[Background and purpose] FRAX made by WHO is a useful tool and is utilized all over the world. Input parameters for FRAX includes exposure to glucocorticoids but not dose of glucocorticoids which increases fracture risk. FRAX underestimates the possibility of fracture by glucocorticoid induced osteoporosis. The purpose of this study is to make a formula to calculate probability of fracture with BMD and dose of glucocorticoids. [Methods] Subjects were 220 patients with connective tissue diseases recruited in two years cohort study. Morphological incident fracture of the spine was measured with X-ray. A formula to calculate the two year probability of fracture was induced from the results of logistic regression analysis. Predictive accuracy of the fracture with this formula was compared to that with Japanese treatment guideline of glucocorticoid induced osteoporosis (JTG-GIOP). [Results] (1) Logistic regression analysis identified previous fracture, mean dose of glucocorticoids, %YAM, age, and sex as fracture risks. (2) A formula to calculate fracture probability was made. (3) Predictive accuracy of the formula and JTG-GIOP were 83.2% and 60.9%, respectively. [Conclusion] The probability formula is useful to predict fracture by glucocorticoid induced osteoporosis.

Intra-rater Reliability of Dual Energy X-ray Absorptiometry-based Measures of Vertebral Height and Consistency of Vertebral Deformity Classification in Postmenopausal Women. Alison M. Bonnyman¹, Colin Webber², Paul W. Stratford¹, Norma MacIntyre^{*3}. ¹School of Rehabilitation Science, McMaster University, Canada, ²Hamilton Health Sciences, Canada, ³McMaster University, Canada

Purpose: Bone geometry adapts to site-specific mechanical forces. Few methods exist to assess change in mineral distribution in the spine. Dual-energy X-ray absorptiometry (DXA) can provide measures of vertebral height, in mm, however the reliability is unclear. The commercial software uses the ratios of vertebral height measures to grade each vertebral body shape in terms of deformity. The primary purpose of this study was to estimate intra-rater reliability of DXA-based vertebral height measures in postmenopausal women. A secondary purpose was to determine the consistency in vertebral deformity grade on duplicate analyses.

Methods: Vertebral fracture assessment images of spinal levels L4 to T4 were acquired for 32 postmenopausal women (mean(SD) age: 70.4(7)y) using DXA (Hologic Discovery A). Each image was analyzed twice (4 weeks apart) by a single rater. Hologic's semi-automated software and a pre-determined protocol were used to landmark superior and inferior endplates of each visible vertebral body in order to derive measures of anterior, middle, and posterior vertebral heights. A minimum sample size of 22 images was required given a desired reliability (intraclass correlation coefficient, ICC) ≥ 0.80 with a lower 95% confidence interval (CI) of 0.70. Grades of vertebral deformity (normal, mild fracture, moderate fracture, severe fracture) were generated in duplicate for 192 vertebrae. Level of agreement across all grades was characterized using Cohen's unweighted kappa (κ) and the observed proportion of agreement (Pobs). Pobs was also used to characterize agreement for each grade separately. For both statistics, perfect agreement = 1.

Results: Above T9, endplates were visible in ≤ 21 images (66%). For measures of vertebral height at L4 to T9, reliability was acceptable [0.87(95%CI: 0.74, 0.94) \leq ICC \leq 0.98(95%CI: 0.95, 0.99)] except for posterior vertebral height at T9 [ICC = 0.62 (95%CI: 0.15, 0.84)]. Table 1 compares the grade of vertebral deformity obtained on each analysis. Overall, κ (95%CI) = 0.50(0.28, 0.72) and Pobs(95%CI) = 0.91(0.85, 0.94). For normal, mild, moderate, and severe grades, Pobs(95%CI) = 0.92(0.86, 0.95), 0.24(0.08, 0.50), 0.36(0.12, 0.68) and 0.50(0.03, 0.97), respectively.

Conclusions: Excellent intra-rater reliability was achieved for vertebral height measures from T9 (excluding T9 posterior vertebral height) to L4 in postmenopausal women using the pre-determined protocol. Consistency in grading fracture deformities was poor.

		Analysis 2				Total
		Normal	Mild	Moderate	Severe	
Analysis 1	Normal	165	7	3	0	175
	Mild	4	4	0	0	8
	Moderate	1	2	4	0	7
	Severe	0	0	1	1	2
Total		170	13	8	1	192

Quantitative Morphometry on Spinal X-Rays: Long-Term Precision of a New Workflow Tool for Measuring Vertebral Body Height in Non-Fractured Vertebrae. Klaus Engelke^{*1}, Bernd Stampa¹, Peter Steiger², Thomas Fuerst³, Harry Genant⁴. ¹Synarc Inc, Germany, ²Optasia Medical, USA, ³Synarc, Inc., USA, ⁴UCSF/Synarc, USA

Vertebral body height assessed by 6-point quantitative morphometry (QM) provides useful information for the diagnosis of prevalent and incident vertebral fractures. The aim of this study was to evaluate the long-term longitudinal precision of a new QM tool (SpineAnalyzer, Optasia Medical Ltd, Cheadle, UK) in a research setting for the measurement of vertebral body height in non-fractured vertebrae.

In this study the default automatic placement provided by SpineAnalyzer was compared with a standard manual 6-point placement, which was used as a reference standard. In contrast to clinical routine, default automatic placements were not corrected by the reader even if they were obviously incorrect. Lateral lumbar and thoracic x-rays from 48 osteoporotic postmenopausal women (73.85.2 y, femoral neck T-score = -2.70.6) were retrospectively evaluated at two visits 3 years apart. None of the subjects had prevalent or incident fractures as evaluated by SQ reading. For each patient T4 to L4 levels were analyzed except for 8 vertebrae judged unreadable at one of the visits due to poor image quality. Standard QM was done by different operators and the automatic analysis was done by the same operator. Baseline and year 3 data were analyzed in separate sessions. Anterior (HA), mid (HM) and posterior (HP) heights were calculated from the 6 points using standard algorithms. The root mean square coefficient of variation (rmsCV) between the two visits was calculated independently for the automatic SpineAnalyzer and the standard QM analysis for each of the 3 heights and for each vertebral level.

Long-term mean rmsCV SD values (averaged over all vertebral levels) for standard QM were 4.40.8 % (HA), 4.00.7% (HM) and 4.70.7% (HP) compared to 3.9 0.9% (HA), 3.40.7% (HM) and 3.51.0% (HP) for the automatic analysis. Significant differences (paired T-tests) were found for all three heights of T10 and T8, and in addition for HP of T9, T11 and T12 and for HM of T11.

Overall the longitudinal precision of the automated analysis over a period of 3 years was slightly superior in some but not in all thoracic vertebrae in particular for the posterior heights. Precision was comparable in the lumbar vertebrae. The results show that the automated analysis using SpineAnalyzer works well in non-fractured vertebrae. However, the performance of the tool on fractured vertebrae has not been tested here.

Reproducibility of High Resolution Peripheral Quantitative Computed Tomography (HR-pQCT): Influence of Examination Site and Age on Measurement Variability. Margaret Paggiosi¹, Richard Eastell², Jennifer Walsh^{*1}. ¹Sheffield Teaching Hospitals NHS Foundation Trust, United Kingdom, ²University of Sheffield, United Kingdom

High resolution peripheral quantitative computed tomography (HR-pQCT) is a powerful tool for the assessment of densitometric and micro-architectural properties of trabecular and cortical bone. However, further evaluation of the measurement variability, for the variables obtained with this technique, is required.

The aims of this study were to i) assess the reproducibility of HR-pQCT measurement variables and ii) investigate differences in measurement variability with a) examination site and b) age.

We conducted a cross-sectional observational study of healthy men and women ages 30-32 years ('younger', n=60) and 70+ years ('older', n=60). Duplicate HR-pQCT examinations of the distal radius and distal tibia, with re-positioning, were performed using the XtremeCT (Scanco Medical AG, Zurich, Switzerland). All HR-pQCT images were processed using standard and extended cortical bone analysis techniques (Burghardt et al. 2010. Bone 47: 519-528). Measures of trabecular and cortical bone density, trabecular number and thickness, and cortical porosity were acquired. Percent short-term root mean square coefficient of variation (%RMSCV) for each of these variables was calculated. The influence of a) site and b) age, on variability was investigated by examining differences in the measurement variable SDs using variance ratio tests (F-tests), with P<0.05 indicating statistical significance.

Lower %RMSCVs were observed for the tibia rather than the radius measurement variables. Age-dependent differences in measurement variable SDs were detected for cortical bone density, and cortical porosity (P=0.023 to P=0.001), with greater measurement variability being observed for the older group. There were also site-dependent differences in measurement variable SDs for cortical measurements. Variability at the radius was greater than at the tibia for cortical bone density and cortical porosity (P<0.001 to P=0.001).

We conclude that differences in measurement variability in the cortex relate to examination site and age. Measurements for the tibia were less variable, than those for the radius, and this may be explained by the larger cortical bone volumes being examined. The greater measurement variability observed for older volunteers may be due to the loss of bone micro-architectural integrity with age.

Percent short-term root mean square coefficients of variation (%RMSCVs), for densitometric and micro-architectural measurement variables determined by high resolution peripheral computed tomography (HR-pQCT), in younger (30-32 years) and older (>70 years) men and women.

Measurement Variable	Examination Site	%RMSCV for younger volunteers	%RMSCV for older volunteers
Trabecular bone density	Radius	1.0	1.2
Trabecular number		5.8	5.8
Trabecular thickness		5.5	5.1
Cortical bone density †		1.9	2.4
Cortical porosity †*		13.3	13.4
Trabecular bone density	Tibia	0.5	0.5
Trabecular number		3.6	5.3
Trabecular thickness		3.6	5.2
Cortical bone density †*		0.3	0.4
Cortical porosity †*		5.2	6.3

† and * denote significant differences in measurement variable SDs when examining the effect of a) site and b) age, respectively. Significance testing was based on the variance ratio test (F test).

Reproducibility of HR-pQCT measurements of the distal radius: influence of casting. Martijn de Kooter¹, Sandrine Bours^{*2}, Tineke Van Geel³, Chris Arts⁴, Paul Willems⁴, Joop Van Den Bergh⁵, Piet Geusens⁶, Bert Rietbergen⁷. ¹Eindhoven University of Technology, Netherlands, ²Maastricht University Medical Centre, The Netherlands, ³Maastricht University, The Netherlands, ⁴Maastricht University, Dept. of Orthopaedic Surgery, Netherlands, ⁵VieCuri MC Noord-Limburg & Maastricht UMC, USA, ⁶University Hasselt, Belgium, ⁷Eindhoven University of Technology, The Netherlands

Background: By using high resolution peripheral quantitative computed tomography (HR-pQCT), it is possible to obtain information of the cortical and trabecular microarchitecture of the bone. The reproducibility of HRpQCT measurements of the human radius in vitro is <3%. Subject motion is an important artifact affecting HRpQCT measurements. No data are available about the reproducibility with a synthetic cast.

Methods: The dominant radii of 15 healthy volunteers aged 20-40 year were scanned with the HRpQCT scanner (XtremeCT, Scanco) using the default in vivo settings given by the manufacturer, resulting in a voxel size of 82 µm. The length of the scan was extended to two stacks (220 slices), with a total duration of 5.8 minutes. Each volunteer had four scans, two with a synthetic cast and two without cast. CT Carpal X1 performed by Pearltec was used for fixation. In order to calculate short-term

precision, we used root-mean-square (RMS) averages of standard deviations of repeated measurements (SD). Precision errors were also expressed in coefficient of variation (CV). The data were tested to be normally distributed and a Pearson correlation test was applied, resulting in a coefficient of determination (R²). Reproducibility was assessed in two "groups": measurements without a cast (group 1) and measurements with a cast (group 2).

Results: In group 1, we found a RMS-CV of 0.98% (R² 0.99) for bone density and a RMS-CV of 3.77% (R² 0.90) and 3.49% (R² 0.94) for trabecular number (Tb.N) and trabecular thickness (Tb.Th), respectively. In group 2 the RMS-CV was 0.75% (R² 0.99), 2.56% (R² 0.95), 2.47% (R² 0.97) for density, Tb.N and Tb.Th, respectively. Linear regression analysis was performed to compare group 2 (with cast) with group 1 (without cast). The slope is 0.95 for density (R² 0.99), 0.91 for Ct.Th (R² 0.99), 0.87 for Tb.N (R² 0.92), 0.80 for Tb.Th (R² 0.96) respectively. Motion artifacts were found in 2 subjects without cast and in none with a cast.

Conclusions: The variation in each group was lower than 4%. With a synthetic cast we saw less variation, which is possibly due to better fixation with less movement artefacts than in the group without a cast. Motion artefacts occurred in 7% of measurements. A high correlation was found between measurements with and without a cast in young healthy volunteers.

Calcaneal Quantitative Ultrasound Compared to Hip and Femoral Neck DXA in People with Spinal Cord Injury. Danielle Barkema^{*1}, Nicole Wysocki², Lisa Streff², Sheena Bhuvu³, Rachel Welbel⁴, Lisa Ruppert², Sarah Linn², Dorian Samuels², Keith Gordon¹, Thomas Schnitzer¹. ¹Northwestern University, USA, ²Rehabilitation Institute of Chicago, USA, ³Texas A&M Health Science Center, USA, ⁴Chicago Medical School, USA

Purpose: Obtaining DXA data in people with spinal cord injury (SCI) is difficult; use of calcaneal quantitative ultrasound (QUS) measurements could provide a useful means to screen if found to have acceptable sensitivity and specificity. This study was performed to compare calcaneal QUS measurements to those obtained by DXA at the hip and femoral neck in people with SCI and evaluate the utility of these measurements to screen for osteoporosis in this population.

Methods: A convenience sample of 36 individuals (age: 38.1 ± 15.2 yrs) with a mean duration since SCI of 4.8 ± 8.4 years underwent bone density evaluation using a Hologic QDR-4500A densitometer and a GE Lunar Achilles Express ultrasonometer. BMD T-scores were measured at the right and left total hip and femoral neck by DXA, whereas T-scores were measured at the right and left calcaneus by QUS.

Results: Mean BMD T-scores by DXA for the right and left total hip were -1.0 ± 1.6 and -1.3 ± 1.6, respectively. Mean QUS T-scores were -1.2 ± 2.1 for the right calcaneus and -1.1 ± 2.1 for the left calcaneus. Right and left hip DXA T-scores were strongly associated with corresponding right and left calcaneal QUS T-scores (Right: r=0.78, p<0.001; Left: r=0.75, p<0.001; Figure 1). Right and left femoral neck DXA T-scores also showed a fairly strong relationship with right and left calcaneal QUS T-scores (Right: r=0.70, p<0.001; Left: r=0.67, p<0.001). 14 individuals had calcaneal QUS T-score ≤ -2.5, whereas 12 individuals had hip or femoral neck DXA T-scores ≤ -2.5. Using a QUS T-score cut-off of -2.5, the sensitivity of calcaneal QUS to detect osteoporosis (DXA BMD T-score ≤ -2.5) at the hip or femoral neck was 0.93 with a specificity of 0.88; the positive predictive value of calcaneal QUS was 0.79; negative predictive value was 0.96; and the area under the ROC curve was 0.895.

Conclusions: Strong correlation exists between measurement of T-scores by QUS at the calcaneus and measurement of T-scores by DXA at the hip and femoral neck in people with SCI. Calcaneal QUS measurement has favorable characteristics for use as a screening tool for osteoporosis in SCI.

Quantitative Ultrasound Measurements at the Heel Predict the Risk of Fragility Fractures in Postmenopausal Women and would Save the use of Densitometry. María Jesus Gomez de Tejada¹, Pedro Saavedra¹, Diego Hernandez², Esther Gonzalez-Padilla², Manuel Sosa-Henriquez^{*3}.

¹Professor, Spain, ²Dr., Spain, ³University of Las Palmas de Gran Canaria, Spain

Introduction: Heel QUS have been used for screening patients to evaluate risk of osteoporotic fractures. The aim of this study was to evaluate the ability of QUS to identify women with low risk of osteoporotic fractures and to avoid them the performance of a densitometry with low possibility of error.

Methods: We studied 1,132 postmenopausal women. A previously validated questionnaire about risk factors for osteoporosis was filled and we also performed on them QUS heel measurements, DXA at the lumbar spine and proximal femur, X-Ray of the dorsal and lumbar spine and also registered the non-vertebral fractures. OC curve, sensibility, specificity, predictive values and likelihood ratios were estimated.

Results: A QUI value higher than 88.5 in postmenopausal women with an age higher than 58 years old would permit to avoid the performance of a DXA in 43.1% of our population. The area under ROC curve is high, 0.8363 (95% CI 0.8249; 0.8477). This provides a sensitivity of 88.8 (95% CI: 81.4; 93.5) with a negative predictive value of 93.8 (95% CI: 89.4; 96.4) with a high specificity: 70.4 (95% CI 64.6; 75.7).

Conclusion: A value of QUI higher than 88.5 in women aged more than 58 years old is associated to a very low risk of all fragility fractures, with a sensitivity that could reach to 93.5% and a negative predictive value as high as 96.4%. This could avoid the measurement of DXA in 43.1% of postmenopausal women.

Area under ROC curve (AUC)	0.8363 (0.8249; 0.8477)
Sensitivity	88.8 (81.4; 93.5)
Specificity	70.4 (64.6; 75.7)
Positive predictive value	55.6 (48.7; 62.6)
Negative predictive value	93.8 (89.4; 96.4)
Positive likelihood ratio	3.00 (2.45; 3.68)
Negative likelihood ratio	0.15 (0.08; 0.27)
Error rate	24.18 (20.56; 28.83)

A Relationship Between Bone Mineral Density and Metabolic Syndrome in Koreans : The Chungju Metabolic Disease Cohort Study. Eun Hee Jang¹, Moo-Il Kang², Sun Hee Ko^{*3}, Ki-Hyun Baek¹. ¹Division of Endocrinology & Metabolism, Department of Internal Medicine, The Catholic University of Korea, South Korea, ²Seoul St. Mary's Hospital, South Korea, ³The Catholic University of Korea, South Korea

BACKGROUND Many studies have showed that the metabolic syndrome (MS) is associated with low-grade inflammation. In respect of bone, low-grade systemic inflammation activates bone resorption and may lead to reduce bone mineral density (BMD). The relationship between metabolic syndrome and bone mineral density has been actively investigated, but the results are inconsistent. This study aimed at identifying association between bone mineral density and metabolic syndrome in a community-based cohort in Korea. **MATERIALS AND METHODS** We evaluated a population-based, cross-sectional analysis of 2729 postmenopausal women and 1701 men aged 40 years and older in rural area of Chungju, Korea. Information on sociodemographic characteristics and diet intake were collected by an interviewer-administered standardized questionnaire. Bone mineral density was measured by central bone densitometry (Hologic QDR4500). MS was defined by American Heart Association/National Heart, Lung, and Blood Institute (AHA/NHLBI). **RESULTS** The prevalence of metabolic syndrome 36.5% in men and 55.2% in postmenopausal women. Men over 40 years and postmenopausal women with metabolic syndrome had higher femur and Lumbar spine BMD in the age-adjusted model. After multivariable adjustment, femur total BMD and femur neck were significantly lower among men with metabolic syndrome (0.746 g/cm², 0.891 g/cm²) than those without (0.759 g/cm²; p=0.035, 0.905 g/cm²; p=0.023). However, in postmenopausal women, there was no significant association between MS and bone mineral density. **CONCLUSION** In a community-based cohort in Korea, men older than 40 years with metabolic syndrome had lower femoral BMD, but there was no association between bone mineral density and MS in postmenopausal women.

Association of Bone Mineral Density with Insulin Sensitivity Indices in Normoglycemic Men and Women in the Fels Longitudinal Study. Naila Khalil^{*1}, Miryoung Lee², Audrey Choh¹, Keith Wurzbacher¹, Dana Duren¹, Cameron Wm Chumlea¹, Bradford Towne¹, Roger Siervogel², Stefan Czerwinski². ¹Wright State University, USA, ²Wright State University Boonshoft School of Medicine, USA

Purpose of the study: Insulin promotes collagen synthesis in osteoblasts in vitro, but it is not clear if this effect is impaired with the insulin resistance that often occurs prior to the onset of hyperglycemia. Few studies have examined the association between insulin resistance and bone mineral density (BMD) in healthy men and

women. The aim of our study was to explore relationships between BMD and insulin sensitivity, controlling for age and body composition.

Methods: We analyzed cross-sectional data from 673 apparently healthy adults (311 men; 362 women) aged ≥ 30 years (mean = 50 years) participating in the Fels Longitudinal Study. BMD (g/cm²) of the lumbar spine and femoral neck was measured using dual-energy x-ray absorptiometry. Fasting insulin and glucose were assayed using standard laboratory procedures. Insulin resistance was estimated by calculating both the glucose/insulin ratio and the Homeostasis Model Assessment-Insulin Resistance score (HOMA-IR). General linear models were used to evaluate the relationship between insulin resistance indices and BMD in each sex adjusting for age, weight, and stature. Each insulin resistance trait was divided into tertiles for analysis.

Results: In women, higher insulin levels were associated with significantly lower BMD in both the lumbar spine ($p=0.038$) and the femoral neck ($p<0.001$). A lower glucose/insulin ratio was also associated with lower BMD at both sites ($p<0.01$). For example, lumbar spine BMD was 0.980.01g/cm² in the lowest glucose/insulin ratio group compared to 1.030.01g/cm² in the highest group. Further, higher HOMA-IR levels were significantly associated with lower BMD in the femoral neck (0.760.1 vs. 0.790.01 vs. 0.800.01 g/cm², $p=0.007$). Among men, there were significant relationships between insulin resistance traits and BMD at the lumbar spine; both lower insulin levels and lower HOMA-IR scores were associated with increased BMD respectively.

Conclusions: These results suggest that even sub-clinical differences in insulin resistance are associated with BMD at different skeletal sites in a healthy sample of normoglycemic men and women.

Disclosures: Naila Khalil, None.

Body Composition and Serum Cholesterol Play the Most Relevant Role on High Bone Mineral Density in Healthy Women, Regardless Physical Activity, Dietary Intake, Bone Remodeling and Menopausal and Vitamin D Status. Karin Sarkis*¹, Marcelo Pinheiro², Vera Szeinfeld³, Ligia Martini¹. ¹University of Sao Paulo, Brazil, ²Sao Paulo Federal University/ Unifesp/ Escola Paulista De Medicina, Brazil, ³UNIFESP/EPM, Brazil

Objective: The aim of this study was to evaluate the main aspects related to high bone mineral density (HBMD) in healthy women. **Patients and Methods:** From June 2005 to October 2010, all women that performed BMD measurements, from metropolitan area of Sao Paulo, Brazil, were enrolled in this cross-sectional study. After database review, almost 22000 bone scans were identified, of whom 421 (1.96%) had HBMD, defined as above 1.400 g/cm² at spine or above 1.200 g/cm² at femur and T-score above 2 SD in both sites. The exclusion criteria were aged 60 years or more, black background, pregnant, obesity and osteoarthritis at any site. Women with concomitant diseases or drugs that affect bone tissue were excluded. A total of 40 women with HBMD were included and matched to 40 healthy women with normal BMD, paired to age, ethnicity, BMI and menopausal status. All women answered a clinical questionnaire based on risk factors related to bone mass, including details about lifestyle and medical history. Dietary intake was assessed by a validated food frequency questionnaire. Besides, they performed body composition by DXA (DPX MD+, GE-Lunar) and thoracic and lumbar radiographs to better define spine's degenerative changes as well as exclude other causes of spine HBMD, including metastasis and Paget disease. Biochemical parameters included serum lipids, hormone and mineral profile, vitamin D status, bone markers and calcium metabolism. Using a forward selective linear regression model, the main variables associated with HBMD were investigated. Significant P value was set as 0.05. **Results:** There were not significant differences between groups regarding to physical activity, smoking, calcium and vitamin D intake, and lab exams, including serum CTx and hormone parameters. Nonetheless, HBMD women had higher intake of protein, phosphorus and zinc, adjusted to energy. Moreover, they had higher fat free mass ($p=0.03$) and skeletal lean mass (SLM) ($p<0.01$) than controls. After statistical adjustments, total fat mass (TFM) and LDL-cholesterol plays a negative role on BMD. On the other hand, SLM was considered as protective on bone mass, according the equation: [Femoral neck = 1.096 - 0.272 (TFM) - 0.396 (LDL-C) + 0.337 (SLM); R²adjusted = 34.7; $p<0.001$]. **Conclusion:** Our data demonstrate that the body composition and serum cholesterol are the main aspects related to HBMD, regardless physical activity, dietary intake, bone remodeling and menopausal and vitamin D status.

Correlates of Higher Bone Mineral Density in Inuit Preschoolers Living in the Arctic. Jessy Havek*, Hope Weiler, Grace Egeland. McGill University, Canada

Introduction: Aboriginal adults, but not newborns, have lower bone mineral density (BMD) compared to their white counterparts. Although 60-80% of peak bone mass is determined by genetics, nutrition and lifestyle factors can be modified to improve bone status, particularly in the first 2 or 3 decades of life.

Purpose: Investigate the effects of anthropometric, dietary, biochemical and lifestyle factors associated with higher BMD among Inuit preschoolers (3- 5 y) living in Arctic communities (56° 32'-72° 40'N).

Methods: Children were selected randomly in summer and early fall ($n = 282$). Dietary intake was assessed through the administration of a 24-h dietary recall and a food frequency questionnaire (FFQ). Anthropometry (height, weight) was measured using standardized procedures. Plasma 25-hydroxy vitamin D (25(OH)D) and parathyroid hormone was measured using a chemiluminescent assay (Liaison, Diasorin). Plasma alkaline phosphatase and total calcium were measured by Beckman Coulter. Heel BMD (g/cm²) was estimated using ultrasound (Sahara Sonometer, Hologic Inc.). Pearson's correlations, t-tests, ANOVA followed by Bonferroni and logistic regression were used to identify associations between BMD and its correlates.

Results: Heel BMD was not different by age groups (y), sex (M/F), calcium intake above or below the median (mg/d), vitamin D intake above or below the median ($\mu\text{g/d}$), number of milk servings (250 ml) above or below the median and plasma 25(OH)D concentration above or below the median (nmol/L). Higher BMD was observed among children in the third tertile of body mass index (BMI) percentiles using WHO categories and having intakes of monounsaturated fat and saturated fat above the median. However, when accounting for age, only saturated fat intake for 5 y children, and BMI categories across all age groups remained significant. Using logistic regression, BMD predictors among Inuit preschoolers were higher BMI, calcium intake above the adequate intake and lower latitude.

Conclusions: These data suggest that factors in support of bone mineral acquisition in young Inuit children are calcium intake, BMI and latitude as a proxy for year endogenous synthesis of vitamin D. Since the dietary data was mainly derived from the 24 h recall data, further investigation assessing usual intakes of traditional foods and nutrients affecting BMD using multiple 24 h recalls and FFQ along with serial assessment of vitamin D status of Inuit children across seasons is required.

High Prevalence of Osteoporosis in Female Patients Undergoing Total Knee Arthroplasty for Advanced Knee Osteoarthritis. Ja-Young Choi¹, Chong Bum Chang*², Tae Kyun Kim³, Eun Seok Seo³. ¹Seoul National University Hospital, South Korea, ²Seoul National University Bundang Hospital, Rok, ³Seoul National University Bundang Hospital, South Korea

Purpose: This study sought to determine whether elderly female patients with advanced knee osteoarthritis (OA) warranting total knee arthroplasty (TKA) differ in terms of bone mineral density (BMD) from community-based females without significant knee OA, and to determine whether preoperative clinical statuses are associated with BMD in females with advanced knee OA warranting TKA.

Methods: Study subjects were matched for age (486 subjects; 243 in each group), and separately for age and body mass index (424 subjects; 212 in each group). BMD T-scores of lumbar and proximal femurs were compared using the Student's t-test. Prevalences of osteoporosis (T score ≤ -2.5 SD) were compared using the chi-square test. In patients with advanced knee OA, regression analyses were performed to determine whether preoperative clinical statuses were associated with BMD.

Results: The prevalence of osteoporosis in the age-matched advanced knee OA group was significantly lower than that in age-matched controls (28% vs. 42%, $p=0.002$). However, the prevalences of osteoporosis in the age and body mass-matched advanced knee OA and control groups were not significantly different (40% vs. 41%, $p=0.629$). Advanced knee OA patients with poorer preoperative clinical scores were more likely to have lower BMD T-scores in the proximal femur and overall BMD T-scores.

Conclusions: This study documents that a considerable proportion of elderly female patients with advanced knee OA have osteoporosis. We found that advanced knee OA per se does not have a marked protective effect against osteoporosis. In addition, this study indicates that functional deteriorations in advanced knee OA adversely affect BMD. Based on our findings, we propose that knee surgeons should pay more attention to the identification and treatment of osteoporosis in elderly female patients with advanced knee OA warranting TKA.

Osteoporosis: Still A Neglected Condition Among Elderly Individuals Living In Nursing Homes. Ana Lirani-Galvao*¹, Patricia Zach¹, Adriana Silva¹, Gilmar Teixeira¹, Orivaldo Silva², Marise Lazaretti Castro³. ¹Universidade Federal de Sao Paulo, Brazil, ²Universidade de Sao Paulo, Brazil, ³Federal University of Sao Paulo, Brazil

Osteoporosis diagnosis and treatment are still neglected in patients living in nursing homes, despite their known high risk of fractures. The aim of the present study was to assess functional capacity and bone mass in ambulating elderly institutionalized individuals. Ninety seven aged (60 years or older) patients (47 women (age 79.39) and 50 men (age 73.67)) capable of deambulating, with or without walking devices, never diagnosed of bone metabolic diseases, residents of three long permanence institutions in the metropolitan area of Sao Paulo, Brazil, were submitted to bone densitometry exam and functional capacity assessment. Bone mineral density

(BMD, g/cm²) (lumbar spine, proximal femur and distal forearm) and body composition were measured by dual energy X-ray absorptiometry (Hologic, Discovery A). Timed-up-and-go test (TUG), Health Assessment Questionnaire Disability Index (HAQ-DI), pain diagram and general health related questions were also performed. In women, weight was correlated to L1-L4 ($r=0.51$), total femur ($r=0.48$) and femoral neck ($r=0.30$) BMD; age was correlated to distal forearm BMD ($r=-0.32$) and HAQ-DI score ($r=0.38$); and TUG was correlated to HAQ-DI score ($r=0.70$). In men, weight was correlated to L1-L4 ($r=0.34$), total femur ($r=0.47$) and femoral neck BMD ($r=0.57$); age was correlated to distal forearm BMD ($r=-0.34$); HAQ-DI score was correlated to number of pain regions ($r=0.52$) and TUG ($r=0.55$) (Spearman test, $p<0.05$). Osteoporosis was diagnosed in 69.9% of the women (T scores of respectively most prevalent sites: distal forearm -3.21; total femur -2.70.8; femoral neck -2.51.5; L1-L4 -2.41) and 42% of the men (T scores of respectively most prevalent sites: femoral neck -2.80.6; total femur -2.70.5; L1-L4 -2.81; distal forearm -2.62). Besides, 23.4% of the women and 48% of the men were diagnosed of osteopenia. None was receiving any treatment for osteoporosis. Among the individuals with low bone mass, 22.2% of men and 21.1% of women had at least one fall incident in the last six months; 26.6% of men and 44.7% of women reported back pain, 29% of men and women use walking devices, 26.6% of men and 42.1% of the women are sedentary and 42.2% of men and 21% of women smoke. The high prevalence of osteopenia and osteoporosis in this population should raise concern about fractures, considering the greater risk of falls and chronic reduction of mobility in institutionalized elderly patients.

Chronic Exposure to Natural Uranium Affects Bone Cortical Parameters and Both Osteoblast and Osteoclast Gene Expression in Growing Rats. Ndeye Marieme Wade-Gueye^{*1}, Olivia Delissen², Isabelle Dublaineau³, Patrick Gourmelon⁴, Maamar Souidi³. ¹IRSN, France, ²Institut de Radioprotection et de Surete Nucleaire (IRSN), DRPH, SRBE, LRTOX, Pierrelate, France, ³Institut de Radioprotection et de Surete Nucleaire (IRSN), DRPH, SRBE, LRTOX, Fontenay-aux-Roses, France, ⁴Institut de Radioprotection et de Surete Nucleaire (IRSN), DRPH, Fontenay aux roses, France

The presence of uranium in environment, either natural or due to civil and military use, may lead to life-long contamination of the public. Uranium is a natural radioactive heavy metal and its accumulation after a chronic contamination was reported in various organs. Bone is its most important site of accumulation. We previously showed that a chronic exposure to uranium has a biological effect on Vitamin D metabolism (Tissandie et al., BBA, 2007, 1770:266), a crucial hormone in mineral and bone homeostasis. In this context, we hypothesised that uranium contamination may have consequences on bone metabolism. We investigated the effects of a chronic exposure to natural uranium (NU) on bone quality and remodeling. Male Rats ($n=8$ /group) were exposed to NU at a concentration of 40mg.l⁻¹ (1 mg/rat/day), a non-nephrotoxic supra-environmental dose, in drinking water for 9 months, starting at 3 months of age (adult model: NU-Ad) or just after birth (post-natal model: NU-postnat) and compared to them to age-matched controls (CT). Data are given as meanSEM. We used Three-dimensional Microtomography (μ CT), bone histomorphometry of femur and RT-PCR to analyze gene expression involved in bone metabolism. After 9 months of contamination μ CT analysis showed that cortical morphometric and trabecular microarchitecture parameters, histomorphometric bone cell activity as well as gene expression did not differ between NU-Ad and controls. In contrast, in NU-Postnat, contamination decreased significantly by 13% cortical Bone Area (CT: 9.20.3mm² vs NU-Postnat: 8.00.2mm², $p=0.01$) and by 16% Cross sectional Area (CT: 15.30.3 mm² vs NU-Postnat: 12.70.5mm², $p=0.002$). Trabecular bone morphometric parameters, bone resorption parameters and osteoid surfaces were not affected by NU, while osteoid thickness (CT: 1.80.1 vs NU-Postnat: 2.40.1 μ m, $p=0.01$) was increased significantly by 25% by NU. Moreover expression of genes involved in bone turnover (OCN, TRAP), in osteoblast differentiation (Runx2, Osterix, BMP2), in the mineralization of the bone matrix (BSP, OPN, DMP1), and of Vitamin D receptor and TRPV5 were significantly decreased by NU. While the expression of genes involved in the regulation of bone resorption (OPG, RANKL), in the regulation of phosphate homeostasis (MEPE, FGF23), of calcium transport were not affected. In conclusion, we showed for the first time that a chronic exposure to NU at a supra-environmental dose for 9 months significantly affects the skeleton in the young rats while it has no detectable effects in older animals.

Effects of Kale Supplementation on Bone Mineral Density and Bone Metabolic Markers in Postmenopausal Women. Noriaki Yamamoto*. Niigata rehabilitation hospital, Japan

Background: Kale contains a large amount of highly soluble calcium (Ca) and abundant vitamin K1. Its absorbability of Ca was equal to or better than that of milk, and it is expected to have efficacy on bone metabolism.

The purpose of this study is to determine the effects of oral intake of Kale in postmenopausal women for 1 year.

Methods: We conducted an open-label study with 13 postmenopausal women. All subjects take a beverage containing 9.5g of a powdered kale product (Ca: 126.6 \pm 5.4 mg/packet), 2 or 3 times a day for 12 months.

Serum Ca and bone metabolic markers (serum NTX, urinary NTX, serum OC, and serum BAP) are assessed at beginning, 3, 6, and 12 months of this study. Also bone mineral density in the lumbar spine (L2-4) and femoral neck are measured by dual-energy x-ray absorptiometry (DXA) at beginning, 6 and 12 months of this study.

Results: According to daily record of subjects, average Ca intake was 227.9~354.5 mg and vitamin K1 intake was 241.6~375.8 μ g.

Comparing to the baseline data, the serum NTX level had significantly decreased after 3 months ($p<0.05$), and maintained after 6 months and 12 months ($p<0.05$) of this study. The serum BAP level at 12 months had also significantly decreased ($p<0.05$). The urinary NTX had decreased .not significantly. The bone mineral density measurements showed a tendency of increase in the lumbar spine .

Conclusion: Improvement in both bone metabolic markers and bone mineral density was observed by oral intake of kale in postmenopausal women, which contains highly absorbable Ca and abundant vitamin K1.

Socioeconomic Status Over the Lifecourse and Adult Bone Mineral Density: The Midlife in the U.S. Study. Carolyn Crandall^{*1}, Sharon Stein Merkin¹, Neil Binkley², Gail Greendale¹, Teresa Seeman¹, Arun Karlamangla¹. ¹University of California, Los Angeles, USA, ²University of Wisconsin, USA

Purpose. To examine independent associations of adult and childhood socioeconomic status with bone mineral density (BMD) in participants of the MIDUS II Biomarker project, a sub-study of the Midlife in the U.S. Study of adults aged 25 to 74 years at baseline.

Methods. We used generalized linear mixed effects models to examine cross-sectional associations between socioeconomic advantage (from self-administered questionnaire) and BMD (by dual energy x-ray absorptiometry), adjusting for race, body weight, research center site, smoking, physical activity, menopausal transition stage (for women), and age (for men). Childhood socioeconomic advantage score was the sum of 3 items (total possible range 0 to 6): being on welfare in childhood (0 = yes, 2 = no) + childhood socioeconomic status relative to others (0 = worse off, 1 = same, 2 = better) + parent education (0 if < high school, 1 if high school or high school equivalent, 2 if some college or more). Adult socioeconomic advantage score was the sum of 5 items (total possible range 0 -10): participant education (high school or high school equivalent = 0, 1 = some college or associate's degree, 2 = college degree or more) + family-adjusted poverty to income ratio (0 if <300%, 1 if 300%-599%, 2 if \geq 600%) + self-assessed financial situation now (0 = worst, 1 = average, 2 = best) + money to meet needs (0 = not enough, 1 = just enough, 2 = more than enough) + difficulty paying bills (0 = very, 1 = not very, 2 = not at all).

Results. Data regarding socioeconomic advantage scores and BMD (lumbar spine and/or femoral neck) were available for 729 participants. Mean age of participants was 56.9 years, 51.6% were female, and 28% were non-White. After adjustment for race, body weight, menopause transition stage/age, smoking, and physical activity, childhood socioeconomic advantage score, but not adult socioeconomic advantage score, was statistically significantly associated with adult lumbar spine BMD. Independent of adult socioeconomic advantage score, for every point higher childhood socioeconomic advantage score, lumbar spine BMD was 0.011 g/cm² higher ($P=0.02$). Neither childhood nor adult disadvantage score were statistically significantly associated with adult femoral neck BMD.

Conclusions. Favorable childhood socioeconomic status is associated with higher adult lumbar spine BMD, independent of adult socioeconomic status. Childhood socioeconomic factors may influence attainment of peak trabecular BMD.

A Systematic Approach to Fragility Fracture Care and Prevention: Achieving a Consensus. Paul Mitchell¹, Alastair McLellan², Stephen Gallacher³, Andrew Gallagher⁴, Eamonn Brankin⁵, Alun Cooper⁶, Graham Davenport⁷, James Cooper⁸, Anne Thurston⁸, Femi Adekunle⁹, Emma Gilbert¹⁰. ¹University of Derby, United Kingdom, ²Western Infirmary, United Kingdom, ³Southern General Hospital, United Kingdom, ⁴Victoria Infirmary, United Kingdom, ⁵University of Glasgow, United Kingdom, ⁶Bridge Medical Centre, United Kingdom, ⁷Wrenbury Medical Centre, United Kingdom, ⁸National Osteoporosis Society, United Kingdom, ⁹Novartis Pharmaceuticals UK Ltd, United Kingdom, ¹⁰Amgen Limited, United Kingdom

Purpose: To describe development in the UK of a consensus shared by professional organisations, patient societies, policy makers and pharmaceutical manufacturers, and steps taken to implement a systematic approach to fragility fracture care and prevention of secondary fractures.

Methods: In 1999, professionals established an exemplar service, the Fracture Liaison Service (FLS), a new standard of care for fracture secondary prevention. In 2000, Scottish national audit found FLS achieves 7-9x higher rates of assessment/treatment for fracture secondary prevention than usual models of care. Key contributions from each group from 2000-2010 included:

Professional organisations: BOA-BGS Blue Book on the care of patients with fragility fracture, National Hip Fracture Database (NHFD) and Royal College of Physicians (RCP) National Audit of Falls and Bone Health

Patient societies: National Osteoporosis Society (NOS) Manifestoes and "Fighting for FLS" campaign

Policy makers: Falls and fracture section of Department of Health (DH) Prevention Package for Older People, Best Practice Tariff for hip fracture and Commissioning for Quality and Innovation payment framework

Pharmaceutical (and devices) manufacturers: FLS Resource Pack, FLS web modelling tool and unrestricted grants to support initial development of NHFD

Collaborative initiatives: NOS educational workshops to support local implementation of FLS in collaboration with DH in England, Amgen, Novartis and

Servier; Glasgow 'Preceptorships' (national education programme dedicated to sharing best practice on implementation of FLS and outcomes for clinicians and service managers); and Breaking Point Report (for parliamentarians, clinicians and service commissioners on the need and means to close the secondary prevention management gap).

Results: The 2008 RCP audit reported 29% of localities had established an FLS (update to be published in mid-2011). The 2010 NHFD Report identified progress in implementation of standards advocated in Blue Book and DH Prevention Package. On hospital admission, 10% of hip fracture patients received osteoporosis treatment; on discharge 75% were in process of receiving secondary preventive care.

Conclusions: Consensus has emerged on the need for a universal systematic approach to fragility fracture care and prevention in the UK. This provides an illustration of collaborative working across multiple specialities and sectors intended to improve healthcare quality and reduce associated costs.

Accuracy of ICD-9 codes to identify Malunion and Nonunion & Developing an Algorithm to Improve Automated Case-Finding of Nonunion and Malunion. Denise Boudreau^{*1}, Onchee Yu¹, Leslie Spangler², Thy Do³, Monica Fujii¹, Susan Ott⁴, Cathy Critchlow⁵, Delia Scholes⁶. ¹Group Health Research Institute, USA, ²Group Health Cooperative, USA, ³Amgen Inc., USA, ⁴University of Washington, USA, ⁵Amgen, USA, ⁶Group Health Cooperative Group Health Research Institute, USA

Background/Aims: Automated health plan data are a potential source for observational studies of the prevalence and risk of fracture healing complications. However, misclassification of cases is possible since these codes may be used to rule out, follow up, or note delays or complications in healing. Our aims were: 1) evaluate the accuracy of using automated claims data to identify nonunions (NU) and malunions (MU) and; 2) explore a classification algorithm to improve the accuracy of case finding through use of additional automated data.

Methods: Using health plan data, we identified potential cases of NU (ICD-9 code 733.82; N=300) and MU (ICD-9 code 733.81; N=288) occurring during 2004-2008. Medical charts for all potential cases were reviewed. True NU cases were defined as evidence of NU and no evidence of MU in the chart (and vice versa for MUs) or clinician confirmed when chart evidence was unclear. To validate NU and MU status, positive predictive values (PPV) were calculated for each ICD-9 code compared to true cases. Using additional automated data on fracture site, subsequent diagnostic codes of NU or MU, procedures, place of ICD-9 code origin (ambulatory vs. inpatient), and type of provider, we conducted a classification and regression tree (CART) analysis to create case-finding algorithms for NU and MU.

Results: Compared to "true cases", the PPV of ICD-9 codes for identifying NU and MU was 77% and 37%. The best case-finding algorithm for NU contained three predictors: number of NU visits in the 12-months after the first NU code; fracture location; and provider specialty for the first NU code (Figure 1). Sensitivity of the algorithm was 74%, specificity 81%, PPV 93%, NPV 49%, and misclassification rate 24% (versus 30% using ICD-9 only). For the MU algorithm, fracture location and number of NU visits (predictor of non MU case) were the best predictors (Figure 2). Sensitivity of the MU case finding algorithm was 81%, specificity 60%, PPV 54%, NPV 84%, and misclassification rate 32% (versus 63% using ICD-9 only).

Conclusions: Identifying fracture healing complications in automated data with only ICD-9 codes is better for NU than MU, although algorithms incorporating additional data are needed for both to improve case-finding. Further research validating these algorithms in datasets from different populations is needed as well as further exploration of case-finding algorithms in a larger sample.

Medical Care Resource Utilization and Costs Associated with Teriparatide Therapy in U.S. Patients. Russel Burge^{*1}, T. Kim Le¹, Yang Zhao¹, Jeffrey Curtis². ¹Eli Lilly & Company, USA, ²University of Alabama at Birmingham, USA

Objective: To examine all-cause healthcare utilization and costs among US patients during teriparatide (TPTD) usage. **Methods:** Employing a retrospective cohort study design on a large U.S. national healthcare claims database, patients aged 18+ who initiated TPTD in 2007 were identified. Initiation was defined as no prior TPTD use over the previous 12 months, where index date was first TPTD dispense date. All patients selected were required to have 12 months pre-index and minimum 12 to maximum 24 months post-index data. Four cohorts were constructed according to duration of TPTD therapy: <6 months, 6-11 months, 12-17 months, and 18-24 months. Descriptive statistics were summarized for patient demographics, comorbid medical conditions, prior medication use, and all-cause healthcare utilization and costs. Chi-square and Wilcoxon tests were used to make statistical comparisons between <6 months and ≥ 6 months of TPTD therapy. **Results:** The analysis included 2,461 TPTD patients. TPTD persistence for the four cohorts was: 21% (<6 months), 13% (6-11 months), 18% (12-17 months), and 48% (18-24 months). TPTD patients with <6 months of therapy were older (71 vs. 68 vs. 68 vs. 69 years, all p<0.05) compared to the other 3 cohorts. In the pre-index period, 31-33% of patients had a prevalent fracture, and 6-10% had rheumatoid arthritis. Patients with <6 months of TPTD therapy had more medical visits than those in the other cohorts over the 12 months pre-index period, and also had the highest prior 12-month total costs. Annualized mean number of medical visits per patient were lower after treatment initiation among all TPTD patients after 12 months of TPTD treatment vs. the pre-index period (26.0 vs. 23.8 for 12-17 months, 25.3 vs. 22.3 for 18-24 months, both p<0.05). In the TPTD cohort with <6 months of treatment, medical care costs (outpatient, emergency room, inpatient admission) per patient were higher than the pre-index costs. After 6 months of TPTD use, inpatient costs per patient decreased; and in the 18-24 month cohort the mean per patient costs were lower compared to the corresponding pre-index costs (inpatient: \$12,178 vs. \$22,826; outpatient: \$6,536 vs. \$7,280; emergency room: \$377 vs. \$635, all p<0.05). **Conclusion:** In this descriptive retrospective study, annualized total healthcare costs increased over time; however, lower inpatient costs were associated with longer TPTD exposure when compared to pre TPTD initiation levels.

The Incidence of Femur Fractures Below Trochanter Increases Exponentially with Age. Lisa Strahm^{*1}, Albrecht Popp¹, Patrick Schwab², Christoph Senn¹, Romain Perrelet¹, Kurt Lippuner¹. ¹Osteoporosis Policlinic, University of Bern, Switzerland, ²Swiss Federal Statistical Office, Switzerland

Purpose:The incidence of femoral neck and pertrochanteric fractures increases exponentially with age. Little is known about the epidemiological characteristics of femoral fractures below trochanter.

Methods:The incidence of femoral fractures hospitalized in year 2008 was determined by ICD-10 code, sex, and 10-year age categories using the medical database and the Swiss population statistics of the Swiss Federal Statistical Office (SFSO) which encompassed 98.8% of all hospitalizations. Raw data were extrapolated to 100% and the age-specific incidence calculated per 100000 women or men aged 45 years or more.

Results:Femoral fractures below trochanter represented 13.1% and 13.9% of all femur fractures in women and men, respectively. The age-specific fracture incidences in women and men are shown in the table below.

Conclusions:The incidence of femoral fractures below trochanter increased exponentially with age both in women and men, following a pattern similar to that of femoral neck and pertrochanteric fractures. This observation suggests that femur fractures below trochanter should be regarded as osteoporotic fractures.

Women

Age (years)	45-54	55-64	65-74	75-84	85+
Femoral neck (S72.0) and pertrochanteric (S72.1) fractures	20.3	75.5	214.7	1007.6	2759.2
Subtrochanteric fractures (S72.2)	0.9	2.6	10.5	62.1	128.0
Fractures of the femoral shaft (S72.3)	3.4	6.3	18.6	44.2	129.7

The Profile of Diseases Had Previous Fractures of the Femur By Failing Into a Group of 40 Elderly Patients at the Hospital Public, Sao Paulo, Brazil. Roberto Queiroz¹, Ursula Karsch¹, Bianca Segantin¹, Fabiana Fonseca^{*2}, Thais Braga¹, Ana Elisa Rosa¹, Manuela Santos¹. ¹PUC - SP, Brazil, ²PUC Sp, Brazil

This article reveals the prevalence of existing diseases found in a search field with a group of 40 patients, from 60 years of age being 31 females and 9 males who suffered the fracture of femur treated in Hospital Public Server in Sao Paulo State with indication of surgical treatment. Patients from fall of own height, defined by Studensk, (2002): an unintentional displacement of the body to a level lower than the starting position, with inability to fix in a timely manner, as determined by various causes circumstances which compromise stability. According to studies carried out in Brazil by the Ministry of health (2010) the annual incidence of fractures in the country is 1 million and the single health system, spent about \$ 81 million with fractures in elderly in year 2009. Determine the profile of old pathologies fracture by fall is vital to try to prevent them, because some diseases can affect cognitive and motor coordination, is of fundamental importance provide contemplation by the quality of life of elderly people in Brazil.

Trends in Hip Fracture Rates in Canada: An Age-Period-Cohort Analysis. Sonia Jean^{*1}, Siobhan O'Donnell², Claudia Lagace², Peter Walsh², Christina Bancej², Suzanne Morin³, Jacques Brown⁴, William Leslie⁵. ¹Institut National De Sante Publique Du Quebec, Canada, ²Public Health Agency of Canada, Canada, ³McGill University Health Centre, Canada, ⁴Laval University, Canada, ⁵University of Manitoba, Canada

Purpose: In Canada, age-standardized hip fracture rates have declined for males and females. This study explores whether these observed trends can be explained by period or cohort effects in order to identify the factors underlying these changes.

Methods: All hospitalizations during the study period 1985-2005 with a primary diagnosis of hip fracture (ICD-9-CM 820.x and ICD-10-CA S72.0-.2) were identified in a national database. Age- and sex-specific hip fracture rates (per 100 000 person-years) were calculated for nineteen age groups (from 0-4 to >85 years) and four calendar periods (from 1985 to 2004). This stratification resulted in twenty birth cohorts from 1905-09 through 2000-2004. Age-period-cohort (APC) models were fitted to the hip fracture rates using Poisson regression models.

Results: A total of 570,872 hospitalizations for hip fracture were identified (72.3% females and 27.7% males). Age-standardized hip fracture rates have progressively declined from 118.6 in 1985 to 80.9 in 2005 for females and from 68.2 to 51.1 for males. The annual linear decrease in rates per 5 year period were 12% for females and 7% for males (both $p < 0.0001$). Significant cohort effects were also observed for both sexes ($p < 0.0001$). Cohorts born prior to 1950 had a higher risk for hip fracture, while those born after 1954 had a lower risk. Table 1 shows a significant birth cohort effect, after adjustment for age and linear change (drift) for males ($p = 0.0126$) but not for females ($p = 0.9960$). In contrast, the period effect, after adjustment for age and linear change (drift) was significant for females ($p = 0.0373$) but not for males ($p = 0.2515$). For males, we observed no additional period effect after adjusting for age and cohort. For females, we observed no additional cohort effect after adjusting for age and period.

Conclusions: Although hip fractures rates have decreased in males and females, different factors may be contributing to these changes. In recent years, there have been more widespread preventive measures, diagnosis and treatment for osteoporosis. In addition to the linear decrease in rates, there is evidence of significant period effects in females and cohort effects in males. The causal factors underlying these changes remains uncertain.

CIITA Polymorphisms Affecting Expression of MHCII are Associated to BMD, Bone Loss and Fracture. Maria Swanberg^{*1}, Fiona McGuigan², Mattias Callreus¹, Paul Gerdhem³, Kristina Akesson⁴. ¹Lund University, Sweden, ²University of Lund, Malmo, Skane University Hospital, Malmo, Sweden, ³Karolinska Institutet, Sweden, ⁴Skane University Hospital, Malmo, Sweden

Inflammatory factors such as cytokines, surface molecules and T lymphocytes affect osteoclast activity and thereby the fine balance between bone formation and resorption. After menopause, levels of the pro-inflammatory cytokine interferon-gamma (IFN γ) increase. IFN γ promotes T lymphocyte survival and stimulates their activity by inducing expression of MHCII molecules on antigen-presenting cells. This process is mediated by the MHC class II transactivator, encoded by the CIITA gene.

We investigated the effect of polymorphisms in CIITA previously associated with reduced expression of MHCII (rs3087456(G) and rs4774(C)) on BMD, bone loss and fracture risk in young and elderly Swedish women. In addition, 3 SNPs in CLEC-16A, reported to be in linkage disequilibrium (LD) with CIITA, and 3 SNPs in IFNG were analyzed. Phenotypes included BMD in 25- and 75 year-old women (PEAK-25 n=999, OPRA n=1003) and serum bone resorption markers, bone loss and fractures between age 75 and 80 (OPRA n=753 at age 80).

CIITA was not associated to BMD at peak bone mass, but at age 75 (lumbar spine, femoral neck, total hip, $p = 0.01-0.04$) and age 80 ($p = 0.02-0.04$). BMD was 1.8-3.4% higher in rs3087456(G)-carriers ($p = 0.009-0.02$), suggesting an increasing effect on BMD by reduced MHCII expression.

CIITA was also associated with increased rate of bone loss (femoral neck $p = 0.01$, total hip $p = 0.03$, total body $p = 4E-5$), but not serum bone resorption markers between age 75 and 80. Despite increased bone loss, rs3087456(G) was protective against

fracture comparing carriers and non-carriers (any fracture sustained in 28% vs 39%, $p=0.002$; osteoporotic fracture 23% vs 31%, $p=0.02$).

Polymorphisms in IFNG were weakly associated to lower total hip- ($p=0.04$) and lumbar spine BMD ($p=0.03$) at baseline, but not to bone loss or fracture.

CLEC16A, in partial LD with CITA, was associated to lower lumbar spine BMD at age 75 ($p=0.04$) and lower total body, total hip, and femoral neck BMD at age 80 ($p=0.04$ for all). CLEC16A was also associated to fractures between age 75 and 80, 31% of the rs725613(G) carriers had a fracture compared to 39% of the non-carriers ($p=0.02$).

In conclusion, CITA alleles inducing lower MHCII expression were associated to higher BMD and decreased fracture risk in elderly women. These results support the importance of MHCII expression levels and T lymphocyte activation in postmenopausal bone health and identify the CITA gene as a risk factor for osteoporosis and fracture.

Bivariate Linkage Analysis Identifies a Genomic Region with Potential Pleiotropic Effects on Bone Mineral Density and Subclinical Cardiovascular Disease Indices. Allison Kuipers^{*1}, Candace Kammerer¹, Iva Miljkovic², Clareann H. Bunker², Alan L. Patrick³, Victor W. Wheeler³, Kim Sutton-Tyrrell², Joseph Zmuda¹. ¹University of Pittsburgh Graduate School of Public Health, USA, ²University of Pittsburgh, USA, ³Tobago Health Studies Office, Trinidad & Tobago

Subclinical measures of osteoporosis and cardiovascular disease are correlated in many populations, such that indices of adverse vascular health are associated with lower bone mineral density (BMD). We have recently demonstrated a significant genetic correlation between BMD and measures of vascular health in families suggesting that shared loci may explain in part the link between osteoporosis and CVD. To expand upon these findings, we performed bivariate genome-wide linkage analysis of subclinical CVD measures and BMD in 461 African ancestry individuals aged ≥ 18 years who belonged to 7 large, multigenerational families (mean family size 66; 3,414 relative pairs). Participants underwent carotid ultrasound scans to determine adventitial diameter (AD) and intima-media thickness (IMT). Dual-energy X-ray absorptiometry and peripheral quantitative computed tomography were used to determine BMD. Genotyping was completed by fluorescence-based methods using the Infinium HumanLinkage-12 BeadChip consisting of 6,090 single-nucleotide polymorphisms with average spacing of 0.58 cM across the genome. We conducted univariate and bivariate, multipoint quantitative trait linkage analyses using pedigree-based maximum likelihood methods. Models were adjusted for age, sex, weight, height, menopausal status, current smoking, alcohol intake and walking for exercise. Univariate linkage analysis identified a region on chromosome 14 linked to AD (LOD: 4.7) and another on chromosome 11 linked to trabecular BMD at the radius (LOD: 3.4). Bivariate analysis yielded strong evidence that the region on chromosome 14 might have pleiotropic effects on AD and cortical BMD at the tibia (LOD: 5.2). Our results suggest that the link between indices of CVD and osteoporosis may be due in part to genes with pleiotropic effects.

Heritability of Prevalent Vertebral Fracture and Vertebral Volumetric Bone Mineral Density in Three Generations of the Framingham Heart Study. Ching-Ti Liu^{*1}, Yanhua Zhou², Mary Bouxsein³, Harry Genant⁴, Yi-Hsiang Hsu⁵, Kerry Broe⁶, Thomas Lang⁷, Serkalem Demissie¹, David Karasik⁸, Adrienne Cupples¹, Douglas Kiel⁸. ¹Boston University School of Public Health, USA, ²Boston University, USA, ³Beth Israel Deaconess Medical Center, USA, ⁴UCSF/Synarc, USA, ⁵Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ⁶Hebrew Senior Life, USA, ⁷University of California, San Francisco, USA, ⁸Hebrew SeniorLife, USA

Background: Bone mineral density is an important risk factor for vertebral fractures, the most common osteoporotic fracture. Both environmental and genetic factors are suspected to contribute to the risk for vertebral fractures; however, there is a paucity of previous studies on the genetic contribution to vertebral volumetric bone mineral density (vBMD) and vertebral fracture. In fact the heritability (h^2) for vertebral fracture is not well established.

Objective: We aimed to estimate the h^2 of vertebral fracture and vBMD in Caucasian adult members of the Framingham Heart Study (FHS) families.

Methods: Members of the Original Framingham Cohort were assessed by lateral radiographs at 13 vertebral levels (T4-T12, L1-L4) in 1992-1993. In the Offspring and Generation 3, lateral QCT scout views were obtained in 2002-2005. In all cohorts, vertebral fracture status was measured using Genant's semi-quantitative (SQ) scale (grades 0-3). Fracture was defined as a SQ grade of 1 or higher at any vertebral level, in each participant. QCT scans from the Offspring and Generation 3 cohorts were also analyzed at the L3 level for integral (IBMD) and trabecular (TBMD) using custom

software developed by T. Lang. Heritability estimates were then calculated in SOLAR with and without adjustment for age, gender and cohort.

Results: For vertebral fracture, we analyzed 4,099 individuals including 2,082 women and 2,017 men with age ranging from 31 to 96 yrs. Among 665 vertebral fracture cases, 342 were present in men and 323 in women with age ranging from 32 to 96 yrs. Estimates of both crude and multivariable-adjusted h^2 were 0.205 ($p<0.0019$). For vBMD, we analyzed 3,129 individuals including 1,631 men and 1,498 women age ranging from 31 to 89 yrs. Estimates of crude h^2 ranged from 0.22 to 0.29 and multivariable-adjusted, ranged from 0.38 to 0.47 (all statistically significant).

Conclusion: Our study suggests both vertebral fracture and vertebral vBMD in Caucasian adults are heritable, although vertebral fracture heritability is not as high as related traits such as vBMD, underscoring the importance of further work to identify the specific variants underlying genetic susceptibility to vertebral fracture and its risk factors.

Phenotype	Model ^a	Heritability	SE	p-value

Menopausal, but not Ethnic or Seasonal Differences in Serum C-telopeptide in UK Caucasian and South Asian Women. Andrea Darling^{*1}, Fatma Gossiel², Rosemary Hannon², Richard Eastell², Susan Lanham-New¹.

¹University of Surrey, United Kingdom, ²University of Sheffield, United Kingdom

Bone turnover is a well studied phenomenon, however it is still unclear as to whether bone shows a season driven rhythm over the course of the year, particularly in ethnic groups, such as South Asians. Indeed, some studies in Caucasian populations have found a significant seasonal variation in bone resorption markers¹ but others have not². This study aimed to establish if in younger or older women, bone turnover shows significant seasonal variation. The study also aimed to assess whether there are differences in bone resorption between South Asian and Caucasian women. This has practical implications in terms of the use of bone markers in diagnostics. The D-FINES study investigated 373 Surrey Caucasian (C) and Asian (A) women every season over a 12 month period (2006-2007). A random sub-sample of premenopausal C (n 18) and postmenopausal C (n 17); premenopausal A (n 13) and postmenopausal A (n 17) with blood samples for all seasons were selected. Serum C-telopeptide (sCTX) was determined by electrochemiluminescent immunoassay on a cobas e411 automated analyser on a cobas e411 automated analyser. A mixed between-within subjects ANOVA showed there was no significant main effect of season $F(3,59.0) = 1.467$, $p=0.233$. However, there was a significant between subjects effect of group $F(3,61) = 3.099$, $p=0.033$, with post hoc tests showing significant differences between the two C groups ($p=0.007$) and between the postmenopausal A and premenopausal C groups ($p=0.042$) but no significant differences between the other groups. Last, there was no significant interaction between season and group $F(9,143.741) = 0.540$, $p=0.843$. The lower sCTX in the younger premenopausal groups is as would be expected. However, unexpectedly, there was a non-significant trend in the postmenopausal groups for the A women to have a lower mean sCTX than the C women. In contrast, in the premenopausal women, the sCTX was lower in the C group. Therefore it appears that it is menopausal status, not ethnicity which is likely

the main reason for the group differences. Overall, no evidence for a seasonal variation in bone resorption was found here but there was evidence for a menopausal difference in bone resorption. However, numbers of participants in this preliminary analysis was small and further analysis with a larger sample is planned.

A Study of the Risk Factors and Prevalence of Osteoporosis in Guayaquil, Ecuador. Augusto Focil*. California Hispanic Osteoporosis Foundation (CHOF), USA

This study aims to assess the incidence and risk factors of osteoporosis in Hispanics. A population-based cross-sectional study was conducted during November 2008 - November 2009 in Guayaquil, Ecuador. A total of 978 Ecuadorians (82% females, 18% males) underwent quantitative ultrasonography and were interviewed to find out the risk factors for osteoporosis. 456 (47%) were reported to be normal, 421 (43%) were osteopenic and 100 (10%) were osteoporotic. The mean age and standard deviation of the participants were 56 years +/- 12.0 years. In the univariate analysis, factors that were associated with osteoporosis/osteopenia included age, education, weight, marital status, use of cortisone/prednisone, and previous history of broken bone (p-value is less than 0.05). Using binary logistic regression, age, weight, sex, and education level were found to be independent predictors for osteoporosis/osteopenia as compared to normal individuals. The prevalence of osteoporosis and osteopenia is high among the study population of Guayaquil yet the understanding of the actual disease is shown to be low from our interviews and surveys.

Disclosures: Augusto Focil, None.

Analysis of Clinical Risk Factors for Post-menopausal Osteoporosis Based on WHO Fracture Risk Assessment (FRAX) Tool. Sudhir Unni¹, Yiwen Yao¹, Karen Gunning¹, Jeffrey Curtis², Joanne LaFleur*. ¹University of Utah, USA, ²University of Alabama at Birmingham, USA

Purpose: Osteoporosis is highly under-diagnosed and under-treated. The development of the fracture risk assessment tool (FRAX) by WHO makes it possible to calculate the 10-year fracture risk in men and women using individual and clinical risk factors. The objective of this study was to determine whether FRAX scores could be calculated from risk factors captured from patient electronic medical record (EMR) data.

Methods: We conducted a cross-sectional analysis using data from the University of Utah Health Care System EPIC Electronic Medical Record. The database contains inpatient, outpatient, clinical and financial information for about 1.4 million patients. The study sample included female patients age 50 years and older between January 1, 2007 and December 31, 2008. Patient data related to FRAX risk factor constructs were identified and patients were categorized into four groups based on risk factor availability. FRAX scores were calculated using an automated program that directly queried the FRAX server. Sensitivity analyses were performed for cases where risk factor information was not available. Means, standard deviations, and ranges of FRAX scores were reported for each group as were the proportions of patients exceeding treatment thresholds defined by the National Osteoporosis Foundation. FRAX scores were estimated separately for patients that did and did not receive bisphosphonate therapy prior to study inclusion.

Results: There were 345 patients with all risk factors available of which 175 were bisphosphonate naive. The mean 10-year risk of any major fracture was 11.2% for the overall group and 10.4% for the untreated subset. The mean 10-year risk was 11.1% similar for the overall group and 9.1% for the untreated subset when bone mineral density (BMD) was used instead of body mass index (BMI) to estimate the FRAX score. The corresponding mean 10-year risk of hip fracture was 3.3% and 2.7% using BMI and 3% and 1.7% using BMD to estimate the FRAX score. FRAX treatment thresholds for major fracture were exceeded in approximately 14% of all patients and 9% of untreated patients in the two groups when scores were calculated using BMI

and 10% and 5% when using BMD. For hip fracture, the percentages were 37% and 31% using BMI and 33% and 17% using BMD.

Conclusion: Osteoporosis is undertreated and more than 25% of the patients in the study cohort were eligible for osteoporosis treatment.

Anticonvulsant and Opioid Use and Fractures in Veterans with Spinal Cord Injury. Laura Carbone*, Amy Chin², Todd Lee², Stephen Burns³, Jelena Svircev⁴, Helen Hoenig⁵, Titilola Akhigbe¹, Frances Weaver². ¹University of Tennessee Health Science Center, USA, ²Edward J. Hines, Jr. VA Hospital, USA, ³VA Puget Sound Healthcare System, USA, ⁴VA Puget Sound, USA, ⁵VA Medical Center, USA

Purpose: Anticonvulsant and opioid use are associated with an increased risk for fracture in the general population. However, whether this also is true for patients with Spinal Cord Injury (SCI) has not been determined.

Methods: We utilized the Veterans Affairs Spinal Cord Disease Registry to identify all male Veterans with a traumatic SCI >two years duration from 2002-2007. Incident lower extremity fractures over during this time period and anticonvulsant and opioid use within five years prior to the fracture were identified. The association of anticonvulsant use overall, by type (enzyme inducing, non-enzyme inducing or both), by number (monotherapy vs. polytherapy) and by individual medication was determined. The relationship of benzodiazepine (BZD) use with overall fracture risk was determined. The relationship of opioid use to lower extremity fracture risk was also analyzed.

Results: There were 2964 anticonvulsant users and 4490 non users of these medications and 892 opioid users and 6562 non users of these medications. 892 Veterans developed an incident lower extremity fracture during this time period. After adjustment for covariates, there was no significant association between anticonvulsant use and lower extremity fractures (OR 0.96 (95% CI 0.82-1.11)). There was no significant association between type (p=0.79) or number of anticonvulsants (p=0.22) used and incident fractures. BZD use was not associated with fracture risk (OR 1.04 (95% CI 0.89-1.22)). Among individual anticonvulsants, topiramate (OR 1.93 (95% CI 1.18-3.18)) and temazepam (OR 1.44 (95% CI 1.12-1.85)) were positively and gabapentin (OR 0.83 (95% CI 0.69-0.99)) was negatively associated with fracture risk. After adjustment for covariates, there was no significant association between opioid use and lower extremity fractures (OR 1.01 (95% CI 0.86-1.17)). However, there was a significant positive association between hydromorphone (OR 1.91 (95% CI 1.12-3.26)), meperidine (OR 1.83 (95% CI 1.04-3.24)) and morphine use (OR 1.28 (95% CI 1.01-1.61)) and risk for lower extremity fractures.

Conclusions: The classes of anticonvulsant and opioid drugs are not associated with an increased risk for lower extremity fractures in males with SCI. However, the risk of fracture varies by individual anticonvulsant and opioid used. The selection of an anticonvulsant or an opioid for use in SCI patients at increased risk for fracture should be guided by the fracture risk associated with that particular drug.

Elevated Coronary Artery Calcium Scores Might be Related to Low Bone Mineral Density in Korean Women. Beom-hee Choi*, Kyu-nam Kim, Sang hyeon Je, Sang-man Kim, Nam-seok Joo, Duck-Joo Lee, Kwang-min Kim. Family Medicine, South Korea

Background; Decline of bone mineral density (BMD) is a character of aged women and coronary artery calcium deposit may be a risk factor of coronary artery diseases. However, little is known for the relationship between coronary artery calcium score (CACS) and BMD. The aim of this study was to evaluate that relationship in Korean women. **Methods;** We used the data of 634 Korean women who checked in a health promotion center of Cha and Ajou University, Republic of Korea, after excluding chronic diseases (kidney diseases, thyroid & parathyroid diseases, other autoimmune diseases), any cancers, history of coronary artery diseases. BMD was measured by the Dual Energy X-ray Absorptiometry (DEXA) and compared by CACS. CACS data was divided into two groups of group A (CACS=0) and group B (CACS>0). **Results;** Age, body mass index (BMI) and waist circumference were higher in group B than in group A. CACS showed positive correlation with age, BMI, and waist circumference. Lumbar, hip and neck BMD in group A was higher than in group B (p<0.05). After adjusting age, BMI, and waist circumference, group A still showed significantly higher BMD than group B (p<0.05). **Conclusions;** These results suggest that CACS may have inverse correlation with BMD and elevation of CACS may result from abnormal bone metabolism.

SA0376**Fat Mass Is Negatively Associated with Bone Mineral Content in Korean.**

Jung Hee Kim^{*1}, Hyung Jin Choi², Min Joo Kim², Jee Hyun An², Sang Wan Kim³, Seong Yeon Kim¹, Nam H. Cho⁴, Chan Soo Shin². ¹Seoul National University College of Medicine, South Korea, ²Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ³Seoul National University Boramae Hospital, South Korea, ⁴Ajou University School of Medicine, South Korea

Obesity and osteoporosis, two disorders of body composition, have become increasingly important public health problems throughout the world. However, the effect of fat mass on bone mass remains controversial. This study investigates the effect of fat mass and regional fat distribution on bone mass within a community-dwelling cohort.

A total of 3042 subjects (1284 men, 362 premenopausal women, and 1396 postmenopausal women) were studied. Fat mass, percent fat mass, lean mass, percent lean mass, and bone mineral content (BMC) were measured by dual energy X-ray absorptiometry.

Fat mass and percent fat mass decreased significantly across increasing tertiles of BMC in all 3 subgroups (men, pre- and postmenopausal women). In contrast, lean mass and percent lean mass increased significantly across tertiles of BMC in men, and a similar trend was also identified in postmenopausal women. Interestingly, although correlation analysis showed a positive association between fat mass and BMC ($P < 0.05$), this association became negative after controlling for age and weight ($P < 0.05$). Finally, in pre- and postmenopausal women, subjects with the lowest waist circumference had the highest BMC in the higher three quartiles of percent fat mass after adjusting for age and weight ($P < 0.05$), indicating that abdominal obesity is associated with BMC independent of total fat mass.

This study demonstrated that fat mass was inversely related to BMC after removing the mechanical loading effect in Korean men and women. Moreover, abdominal obesity as measured by waist circumference was significantly associated with BMC independent of total fat mass.

SA0378**High Serum Adiponectin Predicts Incident Fractures in Elderly Men. Mr OS**

Sweden. Helena Johansson^{*1}, Anders Oden², Ulf Lerner³, HANS JUTBERGER⁴, Mattias Lorentzon⁵, Elizabeth Barrett-Connor⁶, Magnus Karlsson⁷, Osten Ljunggren⁸, Ulf Smith⁹, Eugene McCloskey¹⁰, John Kanis¹¹, Claes Ohlsson⁵, Dan Mellstrom¹². ¹Swe, ²Centre for Bone & Arthritis Research (CBAR), Sahlgrenska Academy, University of Gothenburg, Sweden, Sweden, ³University of Umea, Sweden, ⁴UNIVERSITY HOSPITAL SAHLGRENSKA, Sweden, ⁵Center for Bone Research at the Sahlgrenska Academy, Sweden, ⁶University of California, San Diego, USA, ⁷Skane University Hospital Malmo, Lund University, Sweden, ⁸Uppsala University Hospital, Sweden, ⁹Lundberg Laboratory for Diabetes Research, University of Gothenburg, Sweden, ¹⁰University of Sheffield, United Kingdom, ¹¹University of Sheffield, Belgium, ¹²Sahlgrenska University Hospital, Sweden

An association between high serum adiponectin and increased risk of fracture in men is reported in a few studies. The aim of the present study was to determine whether high serum adiponectin was associated with an increase in the risk of fracture in elderly men, and if so, whether the relationship was non-linear in a multivariate analysis.

The relationship between serum adiponectin and the subsequent risk of fracture was examined in 999 elderly men drawn from the population recruited to the MrOS study in Gothenburg, Sweden. Baseline data included personal general health and life style questionnaires, BMI, BMD, serum adiponectin, osteocalcin, insulin and leptin. Serum adiponectin was analysed with an ELISA-kit (Linco Research, Missouri USA). Men were followed for up to 7.4 years (average 5.2 years). Poisson regression was used to investigate the relationship between serum adiponectin, other risk variables and the hazard function of fracture.

During follow up, 150 men sustained one or more fracture. The risk of fracture (adjusted for BMI, BMD, osteocalcin and insulin) increased by 32% for each SD increase in serum adiponectin (Gradient of risk = 1.32; 95% confidence interval = 1.15-1.52). When BMD was not adjusted for, the gradient of risk was 1.41 (95% confidence

interval = 1.23-1.61). The association between serum adiponectin and fracture risk did not significantly differ from linearity (Figure).

High serum adiponectin is associated with a significant excess risk of fracture in elderly men.

Figure. The hazard function of fracture (momentary risk) and 95% confidence intervals according to baseline serum adiponectin for a man where age was set to 75 years, the time since baseline was set to 2 years of follow up. Previous fracture was set to no and BMD and general health were set to the average value of the cohort. The vertical dashed lines represent the 1st, 10th, 50th, 90th and 99th percentile.

SA0379**Inverse Associations between Abdominal Visceral Adipose Tissue and Bone**

Density. Miryoung Lee^{*1}, Audrey Choh¹, Keith Wurzbacher¹, Ellen Demerath², Richard Sherwood³, Dana Duren⁴, Roger Siervogel¹, Bradford Towne¹, Stefan Czerwinski¹. ¹Wright State University Boonshoft School of Medicine, USA, ²University of Minnesota School of Public Health Division of Epidemiology & Community Health, USA, ³Lifespan Health Research Center, Wright State University, USA, ⁴Wright State University, USA

Introduction and aim: Obesity is thought to beneficially influence bone density through mechanisms such as increased mechanical loading. A few recent studies, however, have inconsistently shown abdominal obesity, especially visceral adipose tissue (VAT), to be negatively associated with bone mineral density (BMD). The aim of this study was to determine whether VAT and abdominal subcutaneous adipose tissue (SAT) mass are related to BMD in healthy white adults, independent of total body adiposity and osteoporosis-related risk factors.
