Heterozygous Disruption of Gsα in Osteocytes Decreases Peripheral Fat without Affecting Bone Mass. Keertik Fulzele*[1], Kevin Barry[2], Sutada Lotinun[3], Roland Baron[4], Lynda Bonewald[5], Jian Feng[6], Min Chen[7], Lee Weinstein[8], Rajaram Manoharan[9], Mary Bouxsein[9], Paola Divieti Pajevic[10]. [1]Massachusetts General Hospital; Harvard Medical School, USA, [2]Endocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, [3]Harvard School of Dental Medicine, USA, [4]Harvard School of Medicine & of Dental Medicine, USA, [5]University of Missouri - Kansas City, USA, [6]Texas A&M Health Science Center, USA, [7]Metabolic Disease Branch, National Institute of Diabetes & Digestive & Kidney Diseases, National Institute of Health, USA, [8]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [9]Beth Israel Deaconess Medical Center, USA, [10]Massachusetts General Hospital, USA

The stimulatory α-subunit, Gsα, of a heterotrimeric G-protein is a ubiquitously expressed protein that mediates signals from various hormone and neurotransmitter receptors to the generation of cAMP. Gsα is a product of the *Gnas* gene, a complex imprinted gene with multiple products. Heterozygous loss-of-function mutations of Gsα lead to Albright hereditary osteodystrophy (AHO) characterized by skeletal defects and, in case of maternal mutation, results in obesity. To define Gsα actions in bone and specifically in osteocytes *in-vivo*, mice carrying floxed exon-1 alleles of *Gnas* were mated with mice expressing Cre-recombinase driven by 10kb dentin-matrix protein 1 (DMP-1) promoter to generate homozygous (DMP1-GsαKO) or heterozygous (DMP1-GsαHet) deletion of Gsα in osteocytes. Littermates lacking DMP1-Cre expression were used as controls. DXA analysis of 21-week old DMP1-GsαKO mice showed significantly decreased total body BMD (19%) and BMC (21%) ($p<0.01$, $n\geqslant6$). MicroCT analysis of the distal femur showed an 86% decrease in trabecular bone volume in DMP1-GsαKO mice compared to controls ($p<0.01$, $n=5$). Histomorphometry analysis of femurs from 7-week old DMP1-GsαKO mice showed a significant decrease in the number of osteoblasts, BFR, MAR, and the number of osteoclasts indicating a state of low turnover ($p<0.05$, $n\geqslant3$). Despite severe osteopenia in the DMP1-GsαKO mice, the osteocyte density was doubled as compared to controls ($p<0.01$, $n=4$), but resulted in dramatically disorganized canaliculi network as assessed by SEM. Immunohistochemical staining showed a 3-fold increase in sclerostin expression in tibia of DMP1-GsαKO mice indicating possible inhibition of Wnt signaling in osteoblasts. Additionally, DMP1-GsαKO, but not DMP1-GsαHet, mice showed hematopoietic abnormalities. Neither micro-CT nor DXA bone parameters differed between control and DMP1-GsαHet. Interestingly, both DMP1-GsαKO and DMP1-GsαHet mice showed a significant decrease (>40%) in peripheral fat at 21-weeks of age as analyzed by DXA ($p<0.01$, $n\geqslant6$). Preliminary analysis showed no change in fasting insulin and glucose in both DMP1-GsαKO and DMP1-GsαHet mice compared to controls. However, white adipose tissue histology from the mutant mice showed decreased adipocytes size and abnormal morphology suggesting a possible defect in lipid metabolism. These results suggest a possible direct role of Gsα signaling in osteocytes in regulating not only bone metabolism, but also peripheral adiposity.

Deletion of the Redox Amplifier p66^{shc} Decreases ROS Production in Murine Bone and Increases Osteoblast Resistance to Oxidative Stress in a Cell Autonomous Fashion: Causal Link with the Pro-survival Effects of Sex Steroid. Maria Jose Almeida*, Li Han, Elena Ambrogini, Shoshana Bartell, Aaron Warren, Randal Shelton, Stavros Manolagas. University of Arkansas for Medical Sciences, USA

The age- or gonadectomy-dependant decrease in osteoblast/osteocyte survival is associated with oxidative stress, as illustrated by increased levels of reactive oxygen species (ROS) and phosphorylation of p66^{shc} — an adapter protein that amplifies mitochondrial ROS generation and influences apoptosis and lifespan in mice. We have sought mechanistic evidence causally linking p66^{shc} to the adverse effects of oxidative stress and sex steroid deficiency on osteoblast survival. We report that p66^{shc} deletion in mice (a model provided to us by Dr. T. Prolla, Univ. Wisconsin) caused a decreased in ROS and an increase in the level of glutathione in the bone marrow. Moreover, calvaria-derived osteoblasts from these mice were resistant to H_2O_2-induced apoptosis. Consistent with these findings, silencing of p66^{shc} in established osteoblastic cell models (OB-6 or UAMS-32) abrogated the H_2O_2-, but not etoposide-, induced apoptosis. Silencing of p66^{shc} also reduced NF-kB activation in response to H_2O_2, as determined by the phosphorylation of IkB and the activity of an NF-kB reporter construct. Further, p66^{shc} silencing attenuated the H_2O_2-induced increase in the expression of the NF-kB-target genes IL-6 and TNFα. The H_2O_2-induced apoptosis and NF-kB activation were also attenuated by the specific PKCβ inhibitors hispidin or LY333531. On the other hand, the PKC inducer PMA had similar effects to H_2O_2 on both apoptosis and NF-kB activation. These effects of PMA were abrogated in the absence of p66^{shc} or in the presence of the PKCβ inhibitors, as was the case with H_2O_2, indicating that the effects of H_2O_2 or PMA are indeed dependent on PKCβ. 17β-estradiol (E2), a polymeric form of E2 that is not capable of stimulating the nuclear-initiated actions of ERα (EDC), or the non-aromatizable androgen DHT, prevented H_2O_2- or PMA-induced p66^{shc} phosphorylation, apoptosis, and NF-kB activation. Lastly, each of the three steroids prevented H_2O_2-induced PKCβ phosphorylation. These results demonstrate that p66^{shc} is an essential mediator of the effects of oxidative stress on apoptosis, NF-kB activation, and cytokine production by osteoblastic cells. Estrogens or androgens attenuate these effects by suppressing PKCβ-induced p66^{shc} phosphorylation via a mechanism that does not require the nuclear-initiated actions of the ERα. Thus, p66^{shc} is causally linked to the adverse effects of both aging and sex steroid deficiency on osteoblast survival.

Insulin Signaling in Osteoblasts Favors Whole Body Glucose Homeostasis by Activating Osteocalcin. Tatsuya Yoshizawa, Jianwen Wei*, Mathieu Ferron, Patricia Ducy, Gerard Karsenty. Columbia University, USA

Undercarboxylated osteocalcin has been shown recently to act as a hormone favoring b-cell proliferation in the pancreas, insulin secretion by b-cells, insulin sensitivity in peripheral tissues and energy expenditure. An implication of this array of functions is that insulin may, in a feedback loop, regulate osteocalcin expression, secretion and/or its carboxylation. To address these questions we generated, on the one hand, mice lacking the insulin receptor (InsR) only in differentiated osteoblasts and, on the other hand, a dual ELISA enabling us to measure selectively undercarboxylated osteocalcin in mouse serum. We show here that *InsR osb-/-* mice develop a glucose intolerance phenotype similar in severity to the one seen in mice lacking this receptor in liver and identical to the one reported in the literature in the *Osteocalcin -/-* mice. As such, this result underscores the importance of bone in the regulation of glucose metabolism. Three concurrent evidences indicate that insulin signaling in osteoblasts is in fact a major determinant of osteocalcin carboxylation status. First, the level of undercarboxylated osteocalcin was significantly decreased in the serum of *InsR osb-/-* mice compared to wildtype littermates while *Osteocalcin* expression was not affected. Second, continuous delivery of osteocalcin in the *InsR osb-/-* mice significantly improved glucose metabolism; third, compound heterozygous mice lacking one allele of the *InsR* in osteoblasts only and one allele of *Osteocalcin* develop a metabolic phenotype identical to the one reported in the *Osteocalcin-/-* mice and had lower levels of undercarboxylated osteocalcin. Taken collectively, these results demonstrate that insulin signaling in bone is a determinant of whole-body glucose homeostasis to the same extent as insulin signaling in liver is. They also demonstrate for the first time that insulin signaling in osteoblasts is a direct determinant of osteocalcin carboxylation. The unraveling of this feedback loop adds further support to the notion that bone, via osteocalcin, regulates glucose metabolism.

Osteoblast Ablation Compromises Glucose Homeostasis in Mice. Yoshihiro Yoshikawa[1], Lili Xu[2], Mathieu Ferron[2], Jayesh Shah[1], Charles Duncan[1], Aris Economides[3], Marie-Therese Rached[1], Stavroula Kousteni*[4]. [1]Department of Medicine, Division of Endocrinology, College of Physicians & Surgeons, Columbia University, USA, [2]Columbia University, USA, [3]Bone & Cartilage Biology Group, Genome Engineering Technologies Group Regeneron Pharmaceuticals, Inc, USA, [4]Columbia University Medical Center, USA

It has been proposed recently that the skeleton is a regulator of glucose metabolism. Osteoblasts would act through osteocalcin to favor β-cell proliferation, insulin secretion, insulin sensitivity and energy expenditure. This observation suggested that a decrease in osteoblast numbers would be sufficient to compromise glucose metabolism through decreased osteocalcin availability. We tested this hypothesis by inducibly ablating osteoblasts. We used compound mutant mice carrying an inactive form of the diphtheria toxin A chain (DTA) introduced into the ROSA26 locus (Gt(ROSA)26Sor) and a tamoxifen-regulated Cre under the control of the human osteocalcin promoter (DTA;CreERt2). DTA expression is prevented by a DNA sequence which terminates transcription flanked by two loxP sites while administration of tamoxifen activates Cre and allows DTA expression. Adult DTA;CreERt2 mice were injected intraperitoneally with vehicle or 0.07mg/g of tamoxifen daily for 10 days. At this time, mice were either left untreated or were treated intraperitoneally with 30 ng/g per day of recombinant osteocalcin for 4 weeks. We found that 50% of osteoblasts were ablated by DTA expression, as determined by bone histomorphometry in the lumbar vertebrae and by an equivalent 50% reduction in serum osteocalcin levels. Tamoxifen-treated DTA;CreERt2 mice had higher blood glucose and lower insulin levels in the fed state. Consistent with suppressed insulin production, islet numbers and β-cell area were all decreased in tamoxifen-treated DTA;CreERt2 animals. Glucose tolerance and insulin sensitivity were decreased in tamoxifen-treated DTA;CreERt2 mice. There was also a significant decrease in energy expenditure in the tamoxifen-treated mice as measured by heat production, oxygen and CO2 consumption and respiratory rate. In line with the decrease in insulin sensitivity, expression of resistin, an adipokine mediating insulin resistance, was increased by 2-fold in white adipose tissue of mice with osteoblast ablation. Expression and serum levels of adiponectin and leptin, two insulin sensitizing hormones, were not affected by the decrease in osteoblast numbers. Administration of osteocalcin reversed all the metabolic abnormalities resulting from osteoblast ablation and restored glucose metabolism. These observations demonstrate through genetic

means that osteoblasts are necessary for glucose homeostasis and this function occurs, at least in part, through osteocalcin.

FoxO1 Interacts with ATF4 in Osteoblasts to Affect Bone Remodeling and Glucose Homeostasis. Maria Theresa Rached*[1], Aruna Kode[1], Charles Duncan[2], Jayesh Shah[2], Stavroula Kousteni[3]. [1]Columbia University, USA, [2]Department of Medicine, Division of Endocrinology, College of Physicians & Surgeons, Columbia University, USA, [3]Columbia University Medical Center, USA

The Forkhead transcription factor, FoxO1 promotes osteoblast proliferation by maintaining redox balance. At the same time, osteoblastic FoxO1 inhibits β-cell proliferation, insulin secretion and sensitivity by suppressing the expression and activity of Osteocalcin. In searching for mechanisms mediating the bone and metabolic actions of FoxO1 we noticed that whereas type I collagen expression was not altered, its production was decreased in the bone of mice with osteoblast-specific deletion of FoxO1 (FoxO1ob-/-). This observation suggested the existence of a defect in amino acid import and protein synthesis in FoxO1-deficient osteoblasts. Supporting this notion, collagen content and osteoid surface was decreased in the bones of the FoxO1ob-/- mice. ATF4 is an osteoblast-enriched transcription factor that, among other functions, controls amino acid import in osteoblasts. Thus, we asked whether FoxO1 interacts with ATF4 to regulate protein synthesis in osteoblasts. We found that FoxO1 co-localizes with ATF4 in the osteoblast nucleus, and physically interacts with and promotes the transcriptional activity of ATF4 in osteoblasts. Consistent with the notion that FoxO1 is required for protein synthesis in osteoblasts and interacts with ATF4, high-protein diet rescued the low osteoblast number/low bone formation phenotype and the increase in oxidative stress in osteoblasts in FoxO1ob-/- mice. More importantly, compound mice lacking one allele of FoxO1 and ATF4 (FoxO1ob+/-;Atf4+/-) recapitulated the low bone formation phenotype of FoxO1ob-/- mice. Next, and because both factors affect glucose metabolism through their expression in osteoblasts we asked whether FoxO1-mediated regulation of glucose homeostasis also occurs through its interaction with ATF4. We found that insulin sensitivity and glucose tolerance were improved in FoxO1ob+/-;Atf4+/- mice. Specifically, FoxO1ob+/-;Atf4+/- mice showed increased β-cell area in the pancreas. Taken together these molecular, histological, metabolic and genetic experiments demonstrate that FoxO1 and ATF4 interact in vivo in osteoblasts to regulate bone remodeling and glucose homeostasis.

Decrease Bone Resorption in Mice Deprived of Peripheral Serotonin (Tph1-/-). Corinne Collet[1], Yasmine Chabbi Achengli*[2], Jacques Callebert[1], Francine Côté[3], Marie-Christine De Vernejoul[4]. [1]Laboratoire Biochimie Hopital Lariboisière, France, [2]INSERM U606, France, [3]Hopital Necker UMR 8147, France, [4]Fédération De Rhumatologie Et INSERM U606, France

Serotonin (5-HT or 5-Hydroxytryptamine) was previously shown to be involved in bone metabolism. As tryptophan hydroxylase 1 (Tph1) is the rate-limiting enzyme for peripheral 5-HT synthesis, we investigated the in vivo bone phenotype in Tph1 knock out (Tph1-/-) mice. The Tph1-/- male mice displayed increased bone density (whole body, femur, vertebrae) at the age of 6 and 10 weeks. Bone resorption markers (urinary deoxypyridinoline DPYR, plasma TRAP5b) were also decreased at 6 and 10 weeks (DPYR 6 weeks WT 23.6 $\pm$ 3.7 vs Tph1-/- 9.6 $\pm$ 0.8 $p<0.01$ and 10 weeks WT 22.6 $\pm$ 1.3 vs Tph1 -/- 13.1 $\pm$ 2.0 $p<0.01$) Histomorphometric analysis, carried out in 6 weeks old mice, indicated an increase of trabecular bone volume (+67%) associated with reduced trabecular number and trabecular separation in Tph1-/- mice. Bone formation rate was unchanged whereas osteoclast number and osteoclastic trabecular surfaces were markedly reduced (Oc.S/BS WT 21.4 $\pm$ 3.3 vs Tph1-/- 11.9 $\pm$ 3.2 $p<0.01$). To further study the osteoclast phenotype in Tph1-/- mice, we focused on ex-vivo spleen cells cultured with RANKL and MCSF. Spleen cells from Tph1-/- mice gave rise to both reduced numbers of osteoclasts (WT 3.5 $\pm$ 0.2 vs Tph1-/- 1.4 $\pm$ 0.004, $p<0.0001$) and decreased resorption pits on dentin slices in comparison with WT cells. The Tph1-/- osteoclast precursors displayed a reduced mRNA expression level of TRAP, cathepsin K and TRAF6. Moreover, osteoclastogenesis in Tph1-/- cell cultures was rescued following the addition of 5-HT (10-7 and 10-8M). Spleen cells of WT mice cultured with RANKL and MCSF synthetized 300 $\pm$ 21 ng of 5-HT/mg proteins that was undetectable in Tph1-/- cells. To define how 5-HT regulates osteoclast differentiation, we next focused on serotonergic components, namely the 5-HT transporter (SERT) and 5-HT receptors (5-HTRs). Using paroxetine, a SERT inhibitor, we observed a decrease in osteoclast number in WT but not in Tph1-/- cell cultures, as well as marked reduction in SERT mRNA expression level in Tph1-/- cell cultures. Finally, we observed a strong decrease in osteoclastogenesis in WT cells following the use of ketanserin, which is both a 5HT2AR antagonist and a vesicular monoamine transporter antagonist. In conclusion, murine osteoclasts synthetize minute amounts of 5-HT that appear to enhance osteoclastic differentiation. Our findings favour an autocrine/paracrine way of action for 5-HT and a role for SERT to support osteclastogenesis in presence of Tph1.

A Transcription Factor p63 Controls Extensive Steps of Endochondral Ossification through Distinct Functions of the Isoforms. Yuki Taniguchi*[1], Taku Saito[2], Toshiyuki Ikeda[3], Ung-Il Chung[4], Kozo Nakamura[5], Hiroshi Kawaguchi[6]. [1]University of Tokyo, Japan, [2]University of Tokyo, Graduate School of Medicine, Japan, [3]Information Technology Services, Inc., Japan, [4]University of Tokyo Graduate Schools of Engineering & Medicine, Japan, [5]The University of Tokyo, Japan, [6]University of Tokyo, Faculty of Medicine, Japan

Skeletal development and growth are achieved by the endochondral ossification process which starts with chondrogenic differentiation of mesenchymal cells by the signaling related to SOX9, SOX5 and SOX6. To examine the molecular network, we initially identified a novel core enhancer of the *SOX6* promoter (CES6) which was highly conserved among species. A screening of transcription factors using the CES6 as bait for cartilage-derived libraries identified p63, a p53 family member, as the most potent transactivator. p63 was extensively expressed in chondrocytes of various differentiation stages in mouse embryonic limb cartilage, as well as in cultured mouse chondrogenic ATDC5 cells and limb buds. The knockout ($p63-/-$) mouse embryos exhibited notably short limbs with decreased expressions of not only SOX6, but also SOX9, type II collagen (COL2A1), and COL10A1. Knockdown of p63 by siRNA in ATDC5 cells caused decreases in their expressions. Luciferase assay, electrophoresis mobility shift assay and chromatin immunoprecipitation assay identified respective core responsive elements of p63 in the promoters of *SOX9, COL2A1* and *COL10A1*, as well as the CES6 region in the *SOX6* promoter. Examination of expression profiles of six isoforms of p63 (TAp63α, β, γ, and ΔNp63α, β, γ) using isoform-specific primers and antibodies in the *in vivo* and *in vitro* systems above revealed that TAp63α and TAp63γ were the principal isoforms in chondrocytes, and TAp63α was predominantly expressed in the early differentiation stage while TAp63γ was in the late differentiation stage of chondrocytes. Overexpression of TAp63α in ATDC5 cells caused increases in the early markers like SOX9, SOX6, and COL2A1, while that of TAp63γ increased the late markers like COL10A1. Finally, we generated chondrocyte-specific *TAp63α* and *TAp63γ* transgenic mice driven by the *Col2a1* promoter (*Col2a1-TAp63α* TG and *Col2a1-TAp63γ* TG). Both proliferative and hypertrophic zones were elongated in the limb cartilage of *Col2a1-TAp63α* TG, while only hypertrophic zone was elongated in that of *Col2a1-TAp63γ* TG. We hereby conclude that p63 transcriptionally controls extensive steps of endochondral ossification through functions of TAp63α and TAp63γ in distinct differentiation stages of chondrocytes. Further understanding of the molecular network related to the p63 isoforms will unravel the molecular network underlying the endochondral ossification.

Chondrocyte-derived ß-catenin Expression Regulates Secondary Ossification Center and Growth Plate Development. Debbie Dao*[1], Matthew Hilton[2], Di Chen[3], Regis O'Keefe[4]. [1]University of Rochester School of Medicine & Dentistry, USA, [2]University of Rochester School of Medicine, USA, [3]University of Rochester Medical Center, USA, [4]University of Rochester, USA

This study addresses the central question of what role the chondrocyte-derived ß-catenin signal plays in regulating endochondral bone formation. The importance of Wnt/ß-catenin signaling during endochondral bone formation has been previously appreciated; however, the specific cellular contributors of this signal had not been identified prior to this work. Specifically, it was unknown what role the chondrocyte, the predominant cell type in early developing skeletal elements, played. This is partly due to the lack of targeting specificity and to the peri-natal lethality of previous genetic models used to address the question presented above. To overcome these limitations, this study employed the use of Tamoxifen-inducible genetic mouse models in which Cre-recombinase is conjugated to a mutant estrogen receptor and its expression is driven by the *Col2a1* promoter. This promoter is expressed specifically in chondrocytes after embryonic day 12.5 in mice. By injecting Tamoxifen into pregnant female mice after this time point, embryos expressing this enzyme and either *ß-catenin$^{fx(exon3)/wt}$* or *ß-catenin$^{fx/fx}$* alleles experience chondrocyte-specific *ß-catenin* gain- or loss-of-function, respectively.

In these models, *in situ* hybridization and immunohistochemistry studies revealed that ß-catenin in chondrocytes promotes chondrocyte maturation both in the growth plate and the secondary ossification center (SOC). In long bones, secondary ossification centers were present at E18.5 in gain-of-function animals; these centers normally do not appear until post-natal day five in mice. SOC development was delayed in loss-of-function animals. Chondrocyte-derived ß-catenin appeared to have non-cell-autonomous effects in that gain-of-function in chondrocytes promoted bone collar formation. Cartilage canals in developing epiphyses were observed prematurely in gain-of-function embryos, indicating an effect of chondrocyte-derived ß-catenin on vascularization processes. Both *in vivo* and *in vitro* studies revealed enhanced BMP, IHH, and MMP signaling with ß-catenin gain-of-function. These findings indicate that during development, ß-catenin in chondrocytes acts in conjunction with other positive regulators of bone formation to drive both cell-autonomous and non-cell-autonomous maturation. The overall effect of these interactions is accelerated endochondral bone formation as a result of the chondrocyte-derived ß-catenin signal.

Wntless is Required for the Secretion of Wnt5a to Promote Distal Limb Growth and Differentiation in Limb Development. Xuming Zhu*[1], Jingjing Cao[2], Lin He[1], Xizhi Guo[3]. [1]Bio-X Center, Shanghai Jiao Tong University, China, [2]Bio-X Center, Shanghai Jiao Tong University, Shanghai, China, [3]Shanghai Jiao Tong University, Peoples republic of china

Wntless is a conserved trans-membrane protein required for Wnt ligands secretion. Although the biochemical nature of Wntless-mediated intracellular transfer and secretion of Wnts has been intensively investigated in fly, its role during mammalian development is still poorly understood, owing to the early lethal effect of Wntless ablation. Here, we generated a conditional knockout mouse for Wntless carrying an exon3 floxed allele. Wntless in limb mesoderm was specifically removed by using *Prx1-Cre* mice. The *Prx1-Cre; Wls$^{c/c}$* mutant mice displayed digits-truncated limb with downsizing elements in stylopod, zeugopod and autopod. Embryonic limb in *Prx1-Cre; Wls$^{c/c}$* mutant exhibited downregulated proliferation and delayed differentiation of mesenchymal progenitor cells around PZ region underneath AER revealed by absence of Sox9 and Ihh expression in the tips of digit, as well as delayed ossification in long bones. However, normal expression of early PZ markers including Fgf10, Msx2 and Bmp4 in early limb patterning indicated that blocking Wnts secretion affected distal limb mesenchymal differentiation at later stage instead of early patterning. All these phenotypes mimicked that observed in *Wnt5a$^{-/-}$* mutants. Actually, immunohistological analysis revealed that Wnt5a protein was accumulated in their producing cells and its secretion was blocked in *Prx1-Cre; Wls$^{c/c}$* mutant. Taken together, our study demonstrated that Wntless was required for the secretion of non-canonical Wnt5a to exert its role in promoting distal limb growth and differentiation in mouse limb development.

Role of CCN2 in Matrix Secretion and Cellular Stress During Cartilage Development. Faith Hall-Glenn*[1], Andrea DeYoung[2], Karen Lyons[1]. [1]University of California, Los Angeles, USA, [2]Baxter, USA

Connective tissue Growth Factor (CCN2) has been described as a matricellular protein, functioning mainly on the cell surface to transduce signals between the extracellular and intracellular environment to regulate cell proliferation, migration and survival. Upon closer inspection of CCN2 knockout mice, defects in extracellular matrix (ECM) deposition were observed and it was hypothesized that CCN2 may play a direct role in chondrocyte ECM assembly and/or secretion. Using electron microscopy for ultrastructural analysis of Ccn2 mutant growth plates, enlarged Endoplasmic Reticulum (ER) and defects in matrix assembly in proliferating chondrocytes were observed (Fig. 1). Components of the Unfolded protein Response (UPR), GRP78 (BiP) and CHOP, visualized via immunoflorescence, were increased in CCN2 mutant growth plates (Fig. 2 A-C). Moreover, the loss of CCN2 leads to increased susceptibility to Thapsigargin (THG) induced ER stress in alginate chondron cultures. Conversely, inducible overexpression of CCN2 in cartilage reduced BiP levels in the growth plate, suggesting attenuation of UPR activation and subsequent ER stress (Fig. 2D,E). All previous examples of ER stress in the growth plate are caused by structural mutations in ECM proteins that lead to misfolding, or mutations in the ER secretory machinery. This is the first time that the absence of a matricellular protein has resulted in ER stress and highlights a novel protective role for CCN2 during ER stress, matrix assembly/secretion and chondrocyte differentiation. The ability of CCN2 to protect against ER stress may be a general feature of the CCN class of matricellular proteins, as mice lacking both CCN1 and CCN2 in cartilage exhibit a far more severe chondrodysplasia than do mice lacking either CCN1 or CCN2 alone.

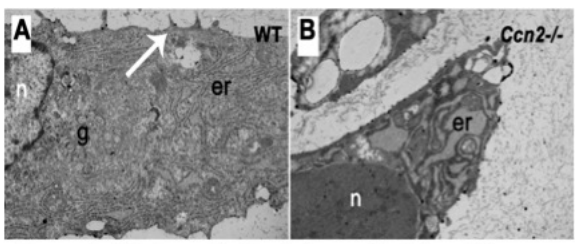

Figure 1. ER stress in *Ccn2-/-* growth plates. Ultrastructural images of chondrocytes in embryonic day (E)17.5 growth plates. Upper epiphyseal chondrocytes from WT and *Ccn2-/-* littermates. The endoplasmic reticulum (er) is grossly distended. The Golgi apparatus (g) in the mutant is vestigial. Arrows in A highlight lamellopodia-like extensions. These are absent in mutant chondrocytes.

Figure 1

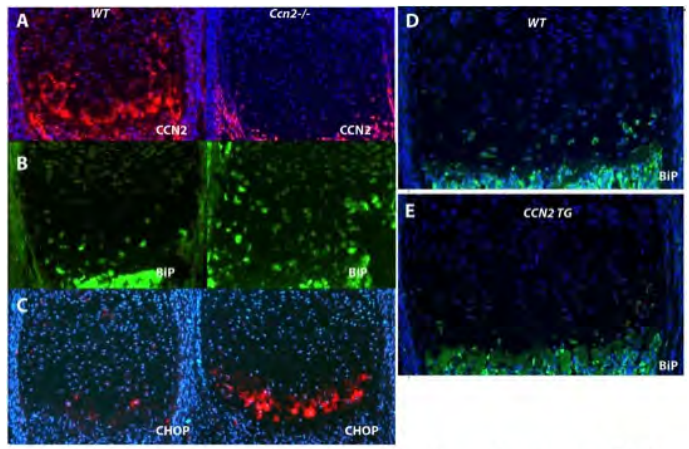

Figure 2: CCN2 mediates ER stress *in vivo*. Immunflorescence of ER stress pathway protein expression in hypertrophic chondrocytes (HC) of E16.5 growth plates. Loss of CCN2 (A) results in increased ER stress markers BiP (B) and CHOP (C) as compared to wildtype growth plates. Overexpression of CCN2 results in an attenuation of BiP (E) compared to wild type samples (D) in Postnatal day 0 growth plates. DAPI-nuclear stain.

The Function of Primary Cilia in Chondrocytes. Ching-Fang Chang*[1], Rosa Serra[2]. [1]University of Alabama at Birmingham, USA, [2]University of Alabama at Birmingham, USA

Primary cilia are microtubule-based non-motile cellular structures, which extend from the surface of almost all cells in our body. The assembly and maintenance of cilia are accomplished by intraflagella transport (IFT). Ift88/Tg737/Polaris is one of the subunits of the anterograde IFT complex. In our previous studies, we used conditional knockout mice Col2aCre;Ift88fl/fl, which had primary cilia specifically deleted in chondrocytes, to study the role of primary cilia in skeletal development. Primary cilia were deleted in mutant mice around e15.5 day. The mutant mice were viable but developed postnatal dwarfism. In histological analysis, the growth plate of mutant mice started to change around postnatal 7 days: the total length of epiphysis was reduced, the columnar organization and orientation of proliferating chondrocytes were altered, and growth plate chondrocytes exhibited reduced proliferation and accelerated hypertrophic differentiation. In order to find out the mechanism of columnar organization in the growth plate, we compared differences in gene expression in proliferating chondrocytes from postnatal 7 day wild type and Col2aCre;Ift88fl/fl mice by microarray analysis. The expression of Ptch1 and Gli-1 (downstream targets of hedgehog signaling), anti-apoptotic protein Bcl2, and several ion channels with ciliary localization, were down-regulated in mutant growth plate. Also, two Wnt signaling antagonists, Secreted frizzled-related protein 5 (Sfrp5) and Sfrp2 were down-regulated and up-regulated, respectively, in mutants. It is well known that primary cilia are required for hedgehog signaling. Based on recent studies implicating the Wnt/PCP pathway in growth plate columnar organization as well as studies suggesting Wnt/ß-catenin signaling can be suppressed by hedgehog through Sfrp-1, we hypothesized that alterations in Wnt signaling downstream of hedgehog could regulate growth plate organization. Our preliminary data showed that Sfrp5, but not Sfrp2 was altered by hedgehog treatment in cultured chondrocytes. Future studies will be focused on rescuing the growth plate phenotype in primary cilia mutants by supplying active Gli-1 or Sfrp5 viruses to metatarsal bones in culture.

Chondrocyte-Specific Inactivation of Forkhead Box O (FoxO) Transcription Factors Causes Severe Growth Plate Abnormalities and Increased Bone Volume. Guy Eelen*[1], Christa Maes[2], Conny Gysemans[3], Lieve Verlinden[3], Ji-Hye Paik[4], Ronald DePinho[4], Roger Bouillon[5], Geert Carmeliet[1], Annemieke Verstuyf[3]. [1]Katholieke Universiteit Leuven, Belgium, [2]Laboratory of Experimental Medicine & Endocrinology, K.U.Leuven, Belgium, [3]Laboratory for Experimental Medicine & Endocrinology, Katholieke Universiteit Leuven, Belgium, [4]Belfer Institute for Applied Cancer Science, Department of Medical Oncology, Medicine & Genetics, DFCI, Harvard Medical School, USA, [5]Laboratory for Experimental Medicine & Endocrinology, Belgium

The highly similar and functionally redundant Forkhead Box O (FoxO) transcription factors (TFs) FoxO1, FoxO3a and FoxO4 are ubiquitously expressed and drive diverse key cellular processes such as proliferation, apoptosis and control of intracellular levels of reactive oxygen species (ROS). During endochondral ossification, these processes are tightly controlled in growth plate chondrocytes to ensure adequate bone development and growth. The aim of this study was to determine the role of FoxOs in growth plate chondrocytes and endochondral ossification.

We generated mice lacking FoxO1, 3a and 4 in growth plate chondrocytes (chondrocyte specific triple knock-out; CTKO) by crossing $FoxO1^{L/L}FoxO3a^{L/L}FoxO4^{L/L}$ mice with mice expressing the Cre recombinase driven by the Col2a1 promoter. CTKO mice are viable and are born under normal Mendelian distribution. Histological analyses of the long bones of CTKO neonates (p2 to p10) revealed a significant increase in the length of the hypertrophic zone within the growth plate and this was most obvious in the distal growth plates of tibia and radius/ulna. Quantitative RT-PCR analyses of cultured neonatal growth plate chondrocytes showed a 2-fold decrease in the expression of the pro-apoptotic FoxO target gene bcl-2 interacting mediator of cell death (BIM), suggesting that decreased apoptosis could explain the increased length of the hypertrophic zone. At the age of 8 weeks, CTKO mice showed an increased kyphosis of the spine, increased body and tail length and larger ears. μCT-analyses of tibia at the same age revealed that CTKO mice had a 2-fold increased bone volume and trabecular number in comparison with control littermates. Both serum osteocalcin and serum TRAP5b levels were significantly increased in 8 week old CTKO mice *versus* control mice (osteocalcin: 86.4 ± 7.1 *vs* 53.4 ± 3.1 ng/ml; TRAP5b: 4.0 ± 0.3 *vs* 1.7 ± 0.1 U/L). Histological analyses confirmed the increase in trabecular bone in CTKO mice and in addition revealed a highly disorganized growth plate with complete loss of the columnar appearance of chondrocytes. Safranine O staining showed occasional remnants of chondrocytes within the cortex and trabeculae.

In conclusion, these data show that the expression of FoxO TFs in chondrocytes is indispensable for normal growth plate organization and control of skeletal growth and bone structure.

Circulating Osteogenic Cells in Periarticular Non-hereditary Heterotopic Ossification. Kevin Egan, Robert Pignolo*. University of Pennsylvania, USA

In the mature adult skeleton, new bone formation is normally restricted to regeneration of osseous tissue at sites of fracture. However, heterotopic ossification, or the formation of bone outside the normal skeleton, can occur within muscular, adipose, or non-muscle fibrous connective tissue. Periarticular non-hereditary heterotopic ossification (NHHO) may occur after musculoskeletal trauma, following CNS injury, with certain arthropathies, or following injury or surgery that is often sustained in the context of age-related pathology. Recently we identified a novel population of circulating osteogenic precursor (COP) cells which are derived from bone marrow and have the capability to form bone (Suda et al., Stem Cells 27:2209-2219, 2009). These cells are identified by the co-expression of the osteogenic marker type 1 collagen and the hematopoietic marker CD45. COP cells are strongly associated with HO in patients with fibrodyplasia ossificans progressiva, a genetic form of HO, and they can be found in early lesion formation in these individuals. We tested the hypothesis that COP cells may contribute to periarticular NHHO and examined their presence in surgically removed bony lesions after cerebrovascular accident, spinal cord injury, traumatic brain injury, non-neurologic trauma and post-arthroplasty. Using immunohistochemistry, we identified COP cells by co-expression of CD45 and type 1 collagen. There was a statistically significant association between the presence of COP cells and early fibroproliferative lesions of HO. COP cells were negligible or absent in regions of unaffected tissue (no HO). This study provides the first evidence that osteogenic cells in the blood home to distant sites where they are associated with formation of HO caused by diverse traumatic conditions.

The ACVR1 R206H Mutation Recapitulates the Clinical Phenotype of FOP in a Knock-in Mouse Model. Salin Chakkalakal*[1], Deyu Zhang[1], Andria Culbert[1], Alexander C. Wright[1], Andrew D. A. Maidment[1], Frederick Kaplan[2], Eileen Shore[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania Hospital, USA

Fibrodysplasia ossificans progressiva is a debilitating genetic disorder characterized by progressive endochondral heterotopic ossification within the soft connective tissues. Patients with classic clinical features of FOP have the identical heterozygous single nucleotide substitution (c.617G>A; R206H) in the gene encoding ACVR1/ALK2, a type I BMP receptor. A genetic knock-in recombineering strategy was used to replace ACVR1 codon 206 (CGC>CAC) in murine Acvr1 exon 5 to develop a mouse model for FOP. Chimeras obtained from knock-in ES cells blastocyst transfers were examined by microCT and X-ray analyses to reveal phenotypes consistent with the clinical features of malformed great toes and post-natal bone formation that characterize FOP. Histological analysis of the HO lesions in R206H chimera mouse displayed all stages of HO formation and paralleled the events in FOP lesion formation. Detailed analysis revealed stages of connective tissue degeneration through apoptosis and an immune response followed by fibroproliferation, chondrogenesis, and ultimately bone with marrow elements. Consistent with data from other models of heterotopic ossification, endothelial Tie-2+ abundantly contribute to heterotopic endochondral ossification in this knock-in mouse model. Further, heterotopic chondrocytes consist of both wild-type and mutant cells, suggesting that cells containing the mutation recruit both normal and mutant progenitor cells. The ACVR1 R206H knock-in mouse provides the first direct *in vivo* evidence that the FOP c.617G>A; R206H ACVR1 mutation induces the characteristic clinical phenotype of FOP and is responsible for the pathophysiology of FOP.

Hexa-D-Arginine Reversal of Osteoblast 7B2 Dysregulation in H*yp*-mice Normalizes the *HYP* Biochemical Phenotype. Baozhi Yuan*[1], Jennifer Meudt[2], Robert Blank[2], Jian Feng[3], Marc Drezner[2]. [1]University of Wisconsin, Madison, USA, [2]University of Wisconsin, USA, [3]Texas A&M Health Science Center, USA

Previously we have reported that decreased Phex-dependent osteoblast 7B2 production and diminished 7B2•SPC2 (subtilisin-like protein convertase 2) enzyme activity underlies the biochemical phenotype in hyp-mice. We showed that decreased 7B2•SPC2 function enhanced serum FGF-23 directly by inhibiting degradation of the protein in osteoblasts and indirectly by down-stream effects that stimulate FGF-23 mRNA transcription. As a result, we hypothesized successful therapy of the hypophosphatemic disorder in hyp-mice may depend upon increasing 7B2•SPC2 activity and normalizing FGF-23 degradation and production. Thus, in the present study, we treated normal and hyp-mice for 5 weeks with vehicle or Hexa-D-arginine (D6R [1.5 μmole/kg/day, ip]), a stimulant of 7B2•SPC2 activity and examined the effects on the characteristic biochemical abnormalities. D6R treatment of hyp-mice increased serum P to levels (3.2±0.2 vs 6.3±0.1mg/dl; $p<0.001$) no different than in vehicle or D6R treated normal mice (6.6±0.4 vs 6.8±0.6 mg/dl). Normalization occurred due to an increase of renal tubule Npt2 mRNA (0.7±0.1 vs 1.1±0.1 [relative expression]; $p<0.001$), to levels maintained in vehicle or D6R treated normal mice (1.1±0.1 vs 1.2±0.2). Moreover, in response to D6R treatment, increased renal 25(OH)D-1?-hydroxylase mRNA expression in hyp-mice decreased significantly (2.3±0.1 vs 1.3±0.3 [relative expression]; $p<0.001$) to a similar level as in vehicle and D6R treated normal mice (1.2±0.2 vs 1.3±0.2). These changes were due to resetting osteoblast FGF-23 production and degradation to normal levels. Accordingly, D6R treatment of hyp-mice normalized 7B2•SPC2 dependent intermediate steps in FGF-23 production, including osteoblast production of BMP1 and proteolytic degradation of DMP1 to its 57 kDa C-terminal product. Consequently, FGF-23 mRNA expression (1.2±0.2 vs 0.6±0.1; $p<0.05$) decreased to levels no different than in normal mice (0.5±0.1). Additionally, reduction of the intact FGF-23 to C-terminal fragment ratio in osteoblasts and the circulation indicated D6R treatment also normalized FGF-23 degradation. Thus, treated hyp-mice realized a significant reduction in serum FGF-23 levels (2126±281 vs 1682±191 pg/ml, $p<0.0001$). These observations not only indicate decreased 7B2•SPC2 activity abnormally regulates FGF-23 and P homeostasis, but provide seminal evidence that drug-induced enhancement of enzyme function may serve as a successful treatment for X-linked hypophosphatemia.

Hypophosphatasia: Enzyme Replacement Therapy for Children Using Bone-Targeted, Tissue-Nonspecific Alkaline Phosphatase. Michael Whyte*[1], Cheryl R. Greenberg[2], Deborah Wenkert[1], William H. McAlister[3], Katherine L. Madson[4], Amy L. Reeves[4], Karen E. Mack[4], Lise Bourrier[5], Alison M. Skrinar[6], Hal Landy[6]. [1]Shriners Hospital for Children, USA, [2]Univ of Manitoba, Canada, [3]Mallinckrodt Inst Radiology, USA, [4]Shriners Hospt for Children, USA, [5]Clinical Research Unit, Manitoba Institute of Child Health, Canada, [6]Enobia Pharma, Canada

Hypophosphatasia (HPP), the inborn-error-of-metabolism characterized by low serum alkaline phosphatase (ALP) activity, is caused by deactivating mutation(s) within the gene encoding the tissue nonspecific isoenzyme of ALP (TNSALP). Natural substrates for TNSALP accumulate extracellularly including inorganic pyrophosphate (PPi), an inhibitor of mineralization, and pyridoxal 5'-phosphate (PLP), the principal form of vitamin B6. Rickets and osteomalacia occur as PPi blocks hydroxyapatite crystal growth within the skeletal matrix. Deranged PLP metabolism reveals TNSALP to be an ectoenzyme. HPP severity spans stillbirth from profound skeletal hypomineralization to osteomalacia presenting late in adult life. There is no established medical treatment. ENB-0040 is a bone-targeted, human recombinant, TNSALP fusion protein that preserved skeletal mineralization and survival in a TNSALP knockout mouse model of severe HPP.[1]

Patient trials began in '08. In a 6-mo, open-label study initially of 6 pts (<3 yrs) with life-threatening HPP, substantial skeletal remineralization, weaning from respiratory support, and improved motor development occurred with ENB-0040 (IV infusion of 2 mg/kg, followed by 1-3 mg/kg SC 3x/wk).[2] Now, 11 patients have been recruited, with 9 (6 girls, 3 boys) having entered an extension study.

Here, we report a phase II, open-label, North American assessment of ENB-0040 in 13 HPP children, ages 5-12 yr (2 girls, 11 boys) randomized to receive either 2 or 3 mg/kg SC 3x/wk for 6 mo. To date, 11 pts have completed Wk 12, one of whom completed Wk 24. The completed study will be reported. Transient injection site erythema was common, but there were no drug-related SAEs. PLP diminished in all 12 patients reaching Wk 6, and was normal for the 9 patients with Wk 12 data. Increases in circulating PTH from enhanced skeletal mineralization occurred, but without hypocalcemia from 'hungry bones'. Skeletal radiographic improvement was observed in all pts by Wk 6 and persisted. All reported increased strength, endurance, and mobility within a few weeks of ENB-0040 treatment. The 9 pts assessed at baseline and at Wk 12 walked 29-121 meters further in a 6-minute walk test (+ 21% on average).

Bone-targeted, tissue-non-specific alkaline phosphatase is a promising enzyme replacement therapy for children with hypophosphatasia.

Non-redundant Functions of Alkaline Phosphatase and PHOSPHO1 During Endochondral Ossification. Manisha Yadav*[1], Ana Maria Sper Simao[1], Sonoko Narisawa[2], Carmen Huesa[3], Marc McKee[4], Colin Farquharson[3], Jose Luis Millan[1]. [1]Sanford Children's Health Research Center, Sanford-Burnham Medical Research Institute, USA, [2]Sanford-Burnham Medical Research Institute, USA, [3]Roslin Institute, University of Edinburgh, United Kingdom, [4]McGill University, Canada

Endochondral ossification is a carefully orchestrated process mediated by promoters and inhibitors of mineralization. Phosphatases are implicated in mineralization, but their identities and functions remain unclear. Alkaline phosphatase (TNAP) plays a crucial role promoting mineralization of the extracellular matrix by restricting the concentration of the inhibitor inorganic pyrophosphate (PPi). Mutations in the TNAP gene cause hypophosphatasia, a heritable form of rickets and osteomalacia. Here we show that PHOSPHO1, a phosphatase with specificity for phosphoethanolamine and phosphocholine, plays a functional role in the initiation of mineralization and that ablation of both PHOSPHO1 and TNAP prevents skeletal mineralization. Phospho1-/- mice are smaller that WT and heterozygote controls with evidence of spontaneous fractures, bowed long bones, osteomalacia and scoliosis in early life. The difference in weight gain is attributable to reduced food and water consumption by Phospho1-/- mice. Fracture callus and scoliosis are observed from 10 days of age onwards in Phospho1-/- mice and histological analysis revealed deformed growth plates, reduced secondary ossification centers, accumulation of osteoid in the long bones, reduced ash mineral content and bone mineral density of cortical bone in Phospho1-/- mice. qPCR of primary cultures of Phospho1-/- tibial growth plate chondrocytes show decreased Akp2 and increased Enpp1 and Ank expression explaining the increased output of PPi by these cells. A decrease in Col2a1, Mmp13, Aggrecan and Col10a1 gene expression was also observed in day 14 chondrocyte cultures pointing towards a growth plate defect. Chondrocyte cultures and chondrocytes-derived matrix vesicles (MVs) from Phospho1-/-mice also show reduced mineralizing ability. Plasma samples of Phospho1-/- mice have reduced levels of TNAP activity, increased NPP1 activity and elevated plasma PPi concentrations. Normalization of the plasma PPi levels by the transgenic overexpression of TNAP does not correct the bone phenotype in Phospho1-/- mice even at 7 months of age. In turn, deletion of a single TNAP allele (Akp2) onto the Phospho1-null background severely aggravated the phenotypic abnormalities of Phospho1-/- mice and no double homozygote knockout mouse survived past birth. Timed pregnancies revealed the presence of decreased mineralization of the vertebral bones and long bones of E16.5 Phospho1-/-embryos and the total absence of skeletal mineralization in [Phospho1-/-; Akp2-/-] double knockout embryos. We conclude that PHOSPHO1 has a functional role during endochondral ossification and, based on these data and a review of the current literature, we propose an inclusive model of skeletal mineralization that involves intravesicular PHOSPHO1 function and Pi-influx into MVs in the initiation of mineralization, with functions for TNAP, NPP1 and collagen in the extravesicular progression of mineralization in the extracellular matrix.

Teriparatide (Parathyroid Hormone 1-34) Promotes Osseous Regeneration in the Oral Cavity. Jill Bashutski*[1], Robert Eber[1], Janet Kinney[1], Erika Benavides[1], Samopriyo Maitra[1], Thomas Braun[1], William Giannobile[1], Laurie McCauley[2]. [1]University of Michigan, USA, [2]University of Michigan, School of Dentistry, USA

Teriparatide is an established and effective therapy for the treatment of osteoporosis and is currently under investigation for its systemic application to benefit localized osseous defect and fracture healing. The purpose of this study was to evaluate effects of teriparatide in conjunction with periodontal surgery on craniofacial osseous regeneration in patients with advanced periodontal disease. Methods: A double-masked, placebo-controlled study enrolled forty adult subjects with severe periodontal disease including a vertical infrabony defect. Patients received a traditional periodontal surgical procedure along with daily self-administered injections of teriparatide (20 μg) or placebo control, 1000 mg calcium and 800 IU of Vitamin D for 6 weeks. Clinical parameters (probing depth (PD), clinical attachment level (CAL), and bleeding on probing (BOP)), digital standardized radiographs, serum samples, gingival crevicular fluid (GCF) samples, and dual energy x-ray absorptiometry (DXA) scans were evaluated over 12 months. Patients with metabolic bone disease or co-morbid conditions were excluded. Statistical significance of post-treatment differences was determined via two-sample t-test, Wilcoxon, and chi-squared tests. Results: Periodontal surgery significantly improved surgical site clinical parameters in both groups. Teriparatide administration resulted in significantly greater clinical findings of PD reduction (2.42 mm vs. 1.32 mm; $p=0.02$) and CAL gain (1.58 mm vs. 0.42 mm; $p=0.02$) at 12 months. Radiographic alveolar bone defect resolution was significantly greater in the teriparatide group than in controls beginning at 6 months, with a 1.86 mm (29%) versus 0.16 mm (3%) linear defect resolution at 1 year ($p<0.0001$). Serum alkaline phosphatase was increased relative to baseline in teriparatide patients at 6 weeks, an indication of drug compliance ($p=0.003$). No significant differences were noted for other parameters. Conclusions: This is the first report of a prospective study using teriparatide

administration for an application of regenerating craniofacial bone and one of very few studies using teriparatide in a non-osteoporotic population. Teriparatide use for 6 weeks combined with a local surgical therapy resulted in improved clinical outcomes and better alveolar bone defect resolution. The use of a systemic anabolic agent like teriparatide provides an exciting new avenue of therapeutic potential for periodontitis patients.

Low Vitamin D is Related to Increased Risk of Death in Elderly Men. MrOS Sweden. Helena Johansson*[1], Anders Odén[2], John Kanis[3], Eugene McCloskey[4], Mattias Lorentzon[5], Osten Ljunggren[6], Magnus Karlsson[7], Åsa Tivesten[1], Elizabeth Barrett-Connor[8], Claes Ohlsson[9], Dan Mellström[1]. [1]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Institute of Medicine & Geriatrics, University of Gothenburg, Sweden, [2]WHO Collaborating Centre for Metabolic Bone Disease, University of Sheffield, United Kingdom, [3]University of Sheffield, Belgium, [4]University of Sheffield, United Kingdom, [5]Center for Bone Research at the Sahlgrenska Academy, Sweden, [6]Uppsala University Hospital, Sweden, [7]Skåne University Hospital Malmö, Lund University, Sweden, [8]University of California, San Diego, USA, [9]Centre for Bone & Arthritis Research, Sweden

Conflicting results have been presented regarding the association between serum vitamin D and risk of death. We therefore examined the association between serum 25-OH vitamin D (25-OHD) and the risk of death among elderly community dwelling men recruited to the MrOS Sweden study.

The study comprised a random, population-based sample of 3014 men aged 70-80 years. Baseline data included general health and life style questionnaires, femoral neck BMD and 25-OHD. Serum 25-OHD was measured by a competitive RIA (Diasorin, Stillwater, MN). Poisson regression model was used to investigate the association between 25-OHD and the hazard function of death, adjusting for age and time since baseline. A similar approach was used to examine other predictors of mortality and a final multivariate model was constructed to determine independent predictors.

The mean value of 25-OHD in the cohort was 69.7 nmol/l and 2% had 25-OHD <30 nmol/l. The average follow-up was 4.5 years, during which, 382 men died. Low 25-OHD was associated with increased mortality; the gradient of risk (GR) was 1.28 (95% CI, 1.15-1.43) for a 1 SD decrease in 25-OHD. For cardiovascular death the GR was 1.25 (95% CI, 1.04-1.50) and for cancer death the GR was 1.33 (95% CI, 1.11-1.59). Other significant predictors, in univariate analyses, included current smoking, self-estimated health, multiple medications, BMD and known comorbidities (cancer, stroke, myocardial infarction and angina). In multivariate analysis, low 25-OHD remained significantly associated with increased mortality (GR 1.20, 95%CI 1.07-1.34) and was independent of adjustments for a history of cancer, angina, diabetes, BMD, systolic blood pressure and self-estimated health. The Figure shows the relationship between 25-OHD and mortality derived from the multivariate model. Although the nonlinearity of the model was not significant, there appears to be a threshold value for 25-OHD above which survival is not further improved (77 nmol/l). If a causal relationship is assumed, raising 25-OHD levels to 77 nmol/l would decrease the overall mortality by 19% and provide on average 120 days of extended life in a 10 year perspective.

This study shows that low 25-OHD is associated with excess risk of death also when adjusted for comorbidities. These findings indicate that improved vitamin D nutrition has the potential to improve survival and should be examined in prospective trials.

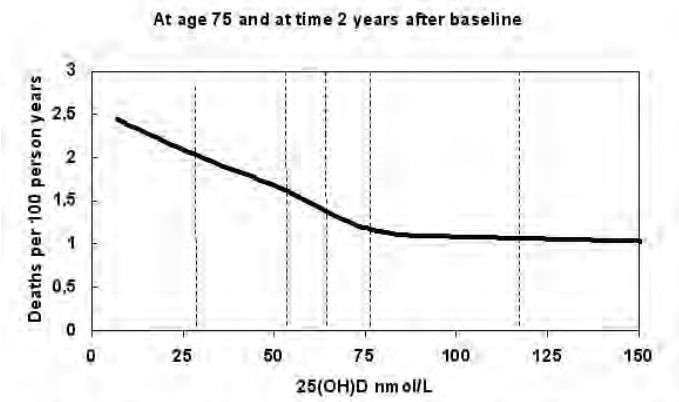

Figure The hazard function of death (momentary risk) according to 25-OHD for men aged 75 (2 years from baseline), with no history of cancer, angina or diabetes. The vertical dashed lines in the figure represent the 1st, 25th, 50th, 75th and the 99th percentiles of 25-OHD.

The Association of Concurrent Vitamin D and Sex Hormone Deficiency with Bone Loss and Fracture Risk in Older Men. Elizabeth Barrett-Connor*[1], Hong Li[2], Gail A Laughlin[3], Tien Dam[4], Jane Cauley[5], Kristine Ensrud[6], Marcia Stefanick[7], Edith Lau[8], Andrew R Hoffman[7], Eric Orwoll[2]. [1]University of California, San Diego, USA, [2]Oregon Health & Science University, USA, [3]University of California San Diego, USA, [4]Columbia University, USA, [5]University of Pittsburgh Graduate School of Public Health, USA, [6]University of Minnesota, USA, [7]Stanford University, USA, [8]Hong Kong Orthopaedic & Osteoporosis Center for Treatment & Research, Hong kong

Background: Low vitamin D (VitD), low sex hormones (SH), and high sex hormone binding globulin (SHBG) levels are common in older men. Using data from the Osteoporotic Fractures in Men study (MrOS), we tested the hypothesis that combinations of low VitD, low SH and high SHBG would have a synergistic effect on BMD, BMD loss and fracture risk in older men.

Methods: For the BMD analysis, 1468 men (mean age 74 yrs) were randomly selected from the MrOS cohort for baseline biochemical measures. Another 278 MrOS men with incident fractures were added for a case-cohort fracture analysis. Total hip BMD was measured by DXA at baseline and follow-up (median 4.6 years). VitD [25(OH)D], testosterone and estradiol were measured by mass spectrometry and SHBG by radioimmunoassay. Abnormal was defined as the lowest quartile for VitD (<20 ng/ml), bioavailable testosterone (BioT), and bioavailable estradiol (BioE), and as the highest quartile for SHBG. Associations with baseline BMD, annualized rate of change in BMD and time to fracture were examined using ANOVA and weighted proportional hazards regressions.

Results: Overall, 10% of participants had only VitD deficiency, 40% had only SH or SHBG abnormalities, and 15% had both. Table 1 presents results of multivariate analyses comparing men with specific combinations of VitD and/or SH/SHBG abnormalities to men with normal levels of all; groups are mutually exclusive. Men with low BioE only or high SHBG only tended to have lower baseline BMD, but did not differ by BMD loss. When combined with low VitD, low BioE (p=.01) and high SHBG (p=.09) were associated with 2-fold greater BMD loss than either low BioE or high SHBG alone. Bone loss was also greater in men with more than one SH/SHBG abnormality and concurrent VitD deficiency. The multivariate-adjusted hazard ratio (95% CI) for non-spine fracture was 1.2 (0.8-1.8) for low VitD alone (n=183); 1.3 (0.9-1.9) for low BioE and/or high SHBG alone (n=356) and 1.6 (1.1-2.5) for low BioE/high SHBG plus low VitD (n=293). Isolated VitD deficiency, and low BioT with or without low VitD, were not significantly related to any bone outcome.

Conclusions: The adverse effects of vitamin D deficiency on bone loss and non-spine fracture in older men were apparent only in the presence of low estradiol or high SHBG. Previous impressions of the effects of VitD or sex steroid abnormalities on bone health in the elderly should be re-examined in light of these findings.

Table 1. Association of Vitamin D and Sex Hormone Groups with Hip BMD & BMD Loss

VitD and SH Group	Baseline			%change/year	
	N	LSMEAN	P value	LSMEAN	P Value
Normal VitD and SH	518	0.97	Ref	-0.31	Ref
Low VitD only	152	0.96	0.40	-0.35	0.65
Low BioT only	121	0.97	0.68	-0.30	0.95
Low BioT + low VitD	52	0.94	0.12	-0.32	0.95
Low BioE only	112	0.95	0.09	-0.33	0.78

Bone-Muscle Indices as Risk Factors of Incident Fractures in Men. Andy Kin On Wong*[1], Kathy Wilt[2], Peggy Cawthon[3], Yahtyng Sheu[4], Joseph Zmuda[4], Christopher Gordon[1], Kristine Ensrud[5], Lynn Marshall[6], Moira Petit[7], Dennis Black[8], Steven Cummings[9], Jane Cauley[4]. [1]McMaster University, Canada, [2]San Francisco Coordinating Centre, USA, [3]California Pacific Medical Center Research Institute, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]Minneapolis VA Medical Center / University of Minnesota, USA, [6]Oregon Health & Science University, USA, [7]University of Minnesota, USA, [8]University of California, San Francisco, USA, [9]San Francisco Coordinating Center, USA

Background: Bone-muscle (BM) indices describe the interrelationship between bone and muscle strength, and were previously reported to vary with sex, aging and hormones. Objectives: The focus of this study was to examine whether BM indices can assess risk of incident fractures in men.

Methods: Participants in the Osteoporotic Fractures in Men (MrOS) Study completed a peripheral quantitative computed tomography (pQCT) scan of their 66% tibia (Pittsburgh, PA; Minneapolis, MN) in 2005-2006. Bone macrostructure, muscle cross-sectional area and volumetric (v) bone mineral density (BMD) were computed. Total hip and lumbar spine areal (a) BMD was obtained from dual-energy X-ray absorptiometry (DXA). Grip strength and walking speed tests were performed at study visit. Participants were followed prospectively for up to four years to obtain incident fracture data. All adjudicated fractures at any site were included. BM indices were expressed as the ratio of bone-to-muscle strength, mass and area (Table I). We examined the discriminative power of BM indices and aBMD on fractures, reported as a C statistic. Hazard ratios (HR) and 95% confidence intervals relating BM indices to incident fractures were obtained with Cox proportional hazards regression analyses.

Results: Of 1163 men (age: 77.2 $\pm$ 5.2 years, BMI: 28.0 $\pm$ 4.0 kg/m^2) who completed pQCT scans, 79 (6.75%) incident fractures were identified in follow-up. Fractured participants had weaker grip strength ($p<0.01$), and lower aBMD at both the total hip and lumbar spine ($p<0.01$). BM indices were smaller in fractured versus non-fractured groups except for density-weighted BM strength index ($BMSI_D$) and BM areal index (BMAI). One standard deviation decrease in BM indices was associated with increased fracture risk after accounting for age and body mass index. (Table II). After adjustment for functional capacity and lumbar spine aBMD, only BM bending indices ($BMBI_D$, $BMBI_U$) and BM mass index (BMMI) remained significant in identifying increased fracture risk. Discriminative power of BM indices on incident fractures did not improve when combined with aBMD.

Conclusions: Smaller BM indices were associated with increased risk of fractures but did not provide additional value to assessing fracture risk over aBMD. BMMI and BMBI were potential risk factors of fractures but more information is needed to assess whether they provide better sensitivity and specificity for detecting fractures over aBMD.

Table I. Definitions for bone-muscle (BM) indices. SSI = stress-strain index of the bone, MBM = muscle bending moment[a], MSS = muscle-specific strength[b], BMC = total body bone mineral content, LTM = total body lean tissue mass, BSI = bone bending strength index[c], MCSA = muscle cross-sectional area, CoA = cortical area. Subscript D = weighted by bone density, U = not adjusted for bone density.

Bone-Muscle indices	Equation	Units
$BMBI_D$ (density-weighted BM bending index)[a]	SSI/MBM	mm^2/N
$BMSI_D$ (density-weighted BM strength index)[a]	SSI/MSS	mm^5/N
$BMBI_U$ (unadjusted BM bending index)[a,c]	BSI/MBM	mm/N
$BMSI_U$ (unadjusted BM strength index)[c]	BSI/MSS	N^{-1}
BMMI (BM mass index)[d]	BMC/LTM	Index
BMAI (BM areal index)[c]	CoA/MCSA	Index

Clinical Vertebral Fracture Risk in Older Men Using Finite Element Analysis of CT Scans. Tony Keaveny*[1], Xiang Wang[2], Arnav Sanyal[2], Lynn Marshall[3], Peggy Cawthon[4], Lisa Palermo[5], Kristine Ensrud[6], Eric Orwoll[3], Dennis Black[5]. [1]University of California, Berkeley, USA, [2]Department of Mechanical Engineering, University of California, USA, [3]Oregon Health & Science University, USA, [4]San Francisco Coordinating Center, California Pacific Medical Center, USA, [5]University of California, San Francisco, USA, [6]Minneapolis VA Medical Center / University of Minnesota, USA

Finite element analysis of quantitative computed tomography (CT) scans is a promising technique for vertebral fracture risk assessment. While it may overcome some of the limitations associated with DXA, it has not yet been prospectively assessed. We used a case-cohort design to assess the ability of finite element analysis of CT scans to predict incident clinical vertebral fractures and to compare it to DXA-measured areal bone mineral density (BMD) at the femoral neck and total lumbar spine. From the MrOS study of 5995 men >65 years, 63 men who experienced incident clinical vertebral fracture (painful fractures presenting clinically and confirmed radiographically) and 242 no-fracture controls (confirmed radiographically) were identified from the approximately 3,500 subjects who had both quantitative computed tomography and DXA scans at baseline. Average follow-up time ($\pm$SD) was 6.5$\pm$2.2 years. Non-linear 3D finite element analysis of L1 (or L2 if L1 was not available for analysis) was performed to derive measures of vertebral strength (N) and volumetric BMD (g/cm^3), and hip and anterior-posterior spine DXA (Hologic 4500) was performed for areal BMD (g/cm^2). All analyses were performed blinded to fracture status. We found that (see Table) the hazard ratio per SD decrease in vertebral strength was 7.6 (95% CI: 4.9–11.9), over two-fold greater than for total spine areal BMD by DXA (3.5; 2.5–4.9). The hazard ratio for volumetric BMD of the whole vertebral body as measured by quantitative CT was comparable with that for strength. The strength-to-(volumetric)-density ratio was an independent predictor of fracture, indicating a significant risk associated with strength beyond that associated with volumetric BMD. The load-to-strength ratio (PHI) was also predictive of fracture. All finite element outcomes, as well as volumetric BMD, remained highly predictive even when LS areal BMD was included in the model and after accounting for the geographic study site. ROC analysis indicated that AUC values for vertebral strength (AUC=0.83) and volumetric BMD (AUC=0.82) were higher ($p=0.017$ and $p=0.038$, respectively) than for LS areal BMD (AUC=0.76). We conclude that, compared to areal BMD, vertebral volumetric BMD and finite element-based vertebral strength each improve prediction of clinical vertebral fracture in elderly men. Future studies should be conducted to confirm these findings in diverse cohorts of men and women.

Table 1: Relative Hazard per unit decrease† in SD (with 95% confidence intervals in parentheses) for each of the main predictor variables of new clinical vertebral fractures, with and without additional predictor variables in the model. N=63 clinical vertebral fractures; N=242 no-fracture controls.

Main Variable	Additional Variables in the Model: None	Age Race BMI	Age Race BMI Site	Age Race BMI Site LS aBMD
DXA:				
LS aBMD (g/cm^2)	3.5 (2.5–4.9)	3.4 (2.4–4.7)	3.4 (2.4–4.9)	
FN aBMD (g/cm^2)	2.1 (1.5–2.8)	2.1 (1.5–3.0)	2.0 (1.4–2.8)	0.9 (0.6–1.4)
QCT:				
Integral vBMD (g/cm^3)	6.1 (4.2–9.0)	5.8 (3.9–8.7)	9.9 (6.0–16.4)	9.4 (5.1–17.4)
FEA:				
Strength (N)	7.6 (4.9–11.9)	7.3 (4.6–11.4)	9.6 (5.7–16.2)	6.5 (4.5–16.2)
PHI (90° flexion with 10 kg)	3.1 (2.6–3.8)	3.0 (2.5–3.7)	3.5 (2.7–4.4)	2.9 (2.2–4.0)
Strength/vBMD (Ncm^3/g)	3.4 (2.5–4.6)	3.3 (2.5–4.5)	3.3 (2.4–4.6)	2.2 (1.6–3.2)

LS — Total lumbar spine; FN — femoral neck; BMI—Body Mass Index; Site — imaging center; integral vBMD is volumetric BMD for the entire vertebral body (without posterior elements but including cortical and trabecular bone); PHI — load-to-strength ratio (ratio of estimated *in vivo* force to vertebral strength; higher values indicate greater risk); † Hazard ratio is per unit *increase* in SD for PHI

Diagnosis of Vertebral Fracture in Men: What is the Best Agreement Between the Different Approaches? Jacques Fechtenbaum*, Karine Briot, Simon Paternotte, Sami Kolta, Christian Roux. Paris Descartes University, Rheumatology Department, Cochin Hospital, France

Introduction: Reduction in vertebral heights is common in men, because of traumatisms and degenerative spinal diseases. Methods used for vertebral fracture (VF) diagnosis may give different results in a population with high prevalence of vertebral deformities. The aim of the study was to compare the prevalence of VF in men according to 4 methods: 1- Algorithm-Based Qualitative (ABQ)[1], 2- Semi Quantitative with a threshold of 20% (SQ)[2], 3- Semi Quantitative with visual inspection and adjudication by an expert[2,3], 4- Semi Quantitative without grade 1 deformities at the thoracic level[4].

Material and methods: We analysed the X-rays of 261 osteoporotic (Tscore between -2.5 and -4 SD) caucasian men of at least 65 years old, performed with a standardized acquisition. All the methods were used by experienced rheumatologists; method 3 was performed by the same expert as method 2 but 6 months later. Agreement between methods was determined by K statistics and prevalence-adjusted bias-adjusted kappa (PABAK).

Results The prevalence of fractured patients (at least one vertebral fracture from T4 to L4) was 27.2%, 45.2%, 26.4% and 30.7% for the 4 methods. The best agreement for the classification: fractured yes/no, at the patient level was obtained for the methods 1 and 3 with 86.49 % and a PABAK score of 0.73. At the vertebral level, the percentage of agreement between these two approaches was 87.40% to 98.01% with the worse agreements for T8 and T12.

Conclusions. There is a good agreement in vertebral diagnosis in osteoporotic men between ABQ and SQ approach with expert judgement. Methods using only vertebral height reductions give completely different results.

Type I Collagen Isomerization (Alpha/Beta CTX Ratio) and Risk of Clinical Vertebral Fracture in Men: A Prospective Study. Douglas Bauer*[1], Patrick Garnero[2], Stephanie Litwack Harrison[3], Jane Cauley[4], Kristine Ensrud[5], Richard Eastell[6], Eric Orwoll[7]. [1]University of California, San Francisco, USA, [2]Molecular Diagnostics, Synarc, France, [3]Research Institute, California Pacific Medical Center, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]Minneapolis VA Medical Center / University of Minnesota, USA, [6]University of Sheffield, United Kingdom, [7]Oregon Health & Science University, USA

We have previously reported that the ratio of urinary alpha (native) to beta (isomerized) type I collagen C-telopeptide fragments (alpha/beta CTX ratio) may reflect bone matrix collagen maturation and is independently associated with hip fracture risk in older men, even after adjustment for hip BMD. The relationship between CTX isomers and vertebral fracture is unknown. We conducted a prospective nested case-cohort analysis in the Osteoporotic Fractures in Men Study (MrOS) to test the hypothesis that higher alpha/beta CTX ratio is associated with an increased risk of symptomatic (clinical) vertebral fracture. Among the 5,995 men enrolled at baseline (mean age: 73.7 $\pm$ 5.9), during a mean follow-up of 7.2 yr. 97 men had new symptomatic vertebral fractures documented on paired spine radiographs. Using fasting urine collected at baseline and stored at –80℃, alpha and beta CTX isomers and urine creatinine (Cr) were obtained on 93 fracture cases and 933 men without known vertebral fracture. Fracture outcomes were examined in logistic models adjusted for age, clinic and total hip BMD (Hologic QDR4500). Compared to men without vertebral fracture, those with incident symptomatic vertebral fracture during follow-up were older (76.5 yr. vs. 73.7) and had lower total hip BMD (0.87 gm/cm^2 vs. 0.96), but had similar BMI (26.9 kg/m^2 vs. 27.4). Higher levels of urine alpha CTX isomer/Cr were associated with a higher risk of clinical vertebral fractures (p trend=0.001), while higher levels of urine beta CTX isomer/Cr were associated with a lower risk (p trend=0.003). Greater alpha/beta CTX isomer ratio was associated with a substantially increased risk of incident clinical vertebral fracture (Figure), particularly in the highest quartile (OR= 9.5, 95% CI: 4.2, 21.6, compared to the lowest quartile). We conclude that the alpha/beta CTX isomer ratio is independently associated with clinical spine fracture risk in older men. These findings support the hypothesis that the alpha/beta CTX isomer ratio reflects some element of bone quality, such as collagen maturation, and may be useful to predict new symptomatic vertebral fractures in older men.

Four Years of Denosumab Exposure in Women With Postmenopausal Osteoporosis: Results from the First Year Extension of the FREEDOM Trial. Socrates Papapoulos*[1], Henry G. Bone[2], Maria Luisa Brandi[3], Jacques Brown[4], Roland Chapurlat[5], Edward Czerwinski[6], Nadia Daizadeh[7], Andreas Grauer[7], Christine Haller[7], Marc-Antoine Krieg[8], Cesar Libanati[7], Zulema Man[9], Dan Mellstrom[10], Sebastião C. Radominski[11], Jean-Yves Reginster[12], Heinrich Resch[13], José A Román Ivorra[14], Christian Roux[15], Steven Cummings[16]. The FREEDOM study established the efficacy and safety of denosumab for 3 years for the treatment of postmenopausal women with osteoporosis. The open-label extension of FREEDOM is evaluating the long-term (up to 10 years) efficacy and safety of denosumab. We report data from the 1st year of follow-up, representing up to 48 months of denosumab exposure.

All subjects who completed FREEDOM were eligible after providing consent to receive a sc injection of denosumab (60 mg) every 6 months during the extension study. For those assigned to the denosumab arm in FREEDOM (long-term group) the data reported here reflects a total of up to 8 injections of denosumab. For those previously assigned to placebo (de novo group) the data are from exposure of up to 2 doses of denosumab for 12 months. All subjects continued to take calcium (1 g) and vitamin D ($\geq$400 IU) supplements daily. Changes in BMD and bone turnover markers (BTM) over 48 months are reported for subjects enrolled in the extension. No formal statistical testing was planned for this interim report. *P*-values are descriptive.

Overall, 4550 (70.2%) eligible subjects from FREEDOM enrolled in the extension study: 2343 in the long-term and 2207 in the de novo group. During the 1st year of the extension study, lumbar spine BMD in the long-term group increased a further 2.0% to a total of 12.1% over FREEDOM baseline at 48 months, and total hip BMD increased an additional 0.8% from extension study baseline to 6.5% at 48 months ($P<0.0001$ for BMD gains during year 4; Figure 1). In the de novo group lumbar spine and total hip BMD increased by 6.0% and 1.7%, respectively (both $P<0.0001$). The magnitude of the rapid reduction in serum C-telopeptide (CTX) after denosumab initiation was similar for the long-term and de novo groups (Figure 2). Reductions in BTM continue to attenuate at the end of the dosing interval as previously reported. Adverse events (AEs) were reported by 70.4% of subjects in the long-term group and 67.9% of subjects in the de novo group. Serious AEs were reported by 9.8% of subjects in the long-term group and 11.2% of subjects in the de novo group. During the 4th year, 31 and 51 osteoporotic nonvertebral fractures were reported in the long-term and de-novo groups, respectively.

These results suggest that 48 months of denosumab continues to significantly increase BMD. Long-term treatment decreases BTM with a similar pattern and to a similar degree as observed with the 1st year of treatment.

The Value of Monitoring Hip BMD During Treatment with Denosumab: One Year Changes in BMD and Reductions in Fracture Risk. Steven Cummings*[1], Li-Yung Lui[2], Eric Vittinghoff[3], Richard Eastell[4], Matt Austin[5], Steven Boonen[6], Ian Reid[7], Andreas Grauer[8], Cesar Libanati[9], Douglas Bauer[3]. [1]San Francisco Coordinating Center, USA, [2]California Pacific Medical Center Research Institute, USA, [3]University of California, San Francisco, USA, [4]University of Sheffield, United Kingdom, [5]Amgen, Inc., USA, [6]Center for Metabolic Bone Disease, Belgium, [7]University of Auckland, New zealand, [8]Amgen Health Center, USA, [9]Amgen Inc, USA

Some patients lose BMD despite treatment with effective drugs; others gain more than expected. There are few data about whether BMD changes during treatment indicate lesser or greater reduction in risk of fracture, so the value of monitoring BMD is uncertain. If BMD change predicts reduction in risk, then monitoring may be useful. Methods: We studied the association between changes in total hip BMD at one year and reductions in risk of fractures during 3 years of denosumab. We included 5,969 women with osteoporosis who received all 6 planned doses of denosumab 60 mg or placebo subcutaneously every 6 months. We compared fracture rates in the 10% of women who lost hip BMD (≤ 0% change) during the 1st year of denosumab with the 10% who lost the most during the 1st year of placebo. We also compared fracture rates in the 10% of women who gained the most hip BMD (≥ 6.5% increase) on denosumab with the 10% who gained the most on placebo. We also compared fracture rates for the 80% of women whose BMD changes were in between. Logistic models adjusted for differences in baseline BMI and hip BMD; statistical significance was based on tests for interactions.

Results: Overall, denosumab reduced the risk of vertebral fracture by 76% (odds ratio=0.24, 95%CI 0.17-0.34). The decreased risk of vertebral fracture was greater for those who gained hip BMD during the 1st year - 81% (OR=0.19)-than for those who lost BMD (≤0% change): 48% (OR=0.52; interaction P=0.03). Overall, denosumab reduced the risk of nonvertebral fractures by 22% (OR=0.78, 0.64-0.96). The decreased risk appeared to be greater in those who gained the most hip BMD (≥6.5%) during the 1st year-47% (OR=0.53)-than for those who gained less or lost BMD: 18% (OR=0.82). The interaction between increasing BMD on denosumab and decreasing risk of nonvertebral fracture was not statistically significant (P=0.11).

Conclusion: For patients who fully comply with denosumab therapy, those who gain hip BMD during the first year have an 81% reduction in risk of vertebral fracture that is greater than the reduction for patients who lost BMD. Relatively large gains in BMD might indicate a greater reduction in risk of nonvertebral fracture, however additional study of the relationship between change in BMD during treatment with denosumab and risk of nonvertebral fracture is warranted. Our results suggest that monitoring BMD after 1 year of denosumab may give an indication of its antifracture efficacy.

Effect of Whole-Body Vibration on Bone Density and Structure in Postmenopausal Women with Osteopenia: A Randomized Controlled Trial. Lubomira Slatkovska*[1], Shabbir Alibhai[2], Joseph Beyene[3], Angela Cheung[2]. [1]University of Toronto, Canada, [2]University Health Network, Canada, [3]McMaster University, Canada

Purpose: Recent data suggest that whole-body vibration (WBV) may be beneficial to bone health. We conducted a 12-month randomized controlled trial (RCT) to examine WBV effects on bone mineral density (BMD) and bone structure.

Methods: Postmenopausal women with primary osteopenia not on bone medications were randomly assigned to one of three groups: 90 Hz WBV at 0.3*g* (90Hz), 30 Hz WBV at 0.3*g* (30Hz) and control (CON). Women in the 90Hz and 30Hz groups were asked to stand on their WBV platforms for 20mins a day at home. CON group did not receive WBV. Adequate calcium and vitamin D intakes were ensured through diet and supplementation. Bone outcomes were assessed at baseline and 12 months by DXA (dual-energy x-ray absorptiometry; Hologic Discovery A^{TM}, Hologic, Massachusetts) at the lumbar spine, total hip and femoral neck, and by HR-pQCT (high-resolution peripheral quantitative computed tomography; Xtreme CT$^{®}$, Scanco, Switzerland) at the distal tibia and distal radius. Our primary outcome was trabecular volumetric BMD (vBMD) in the distal tibia and secondary outcomes included all other DXA and HR-pQCT parameters. Adherence was recorded by each WBV platform. Between-group differences in absolute pre-post change in bone outcomes were examined using ANOVA. Contrast analyses, specified a priori, were used to study all single pair-wise comparisons and the combined effect of 90Hz and 30Hz versus CON. A priori subgroups were also examined.

Results: 202 women participated in the trial (90Hz: n=67, 30Hz: n=68, CON: n=67): 78% Caucasian, 16% Southeast Asian and 6% other. Mean age was 60 (44-79) years and mean mass was 63 (43-88) kg. Mean daily calcium and vitamin D intakes were 1448 mg and 872 IU. Mean percent adherence was 64% in 90Hz (median=79%) and 66% in 30Hz (median=77%). Using intention-to-treat approach, mean pre-post change in trabecular vBMD of the distal tibia was +0.4, -0.1, -0.2 mg·cm^{-3} in 90Hz, 30Hz, and CON, respectively (between-group differences: p=0.5) (Table 1). There were no statistically significant between-group differences in absolute pre-post change in any primary or secondary bone outcomes using ANOVA and contrast analyses. Subgroup analyses also did not show any effect in women ⩾80% adherent, <65 kg in mass, ≤60 years-old or ≤10 years since menopause.

Conclusions: WBV at 0.3*g* and 30 Hz or 90 Hz 20mins daily for a year did not alter BMD or bone structure in postmenopausal womens with osteopenia.

Reduction in the Risk of Clinical Fractures after a Single Dose of Zoledronic Acid 5 mg. Dennis Black*[1], Ian Reid[2], Kenneth Lyles[3], Christina Bucci-Rechtweg[4], Guoqin Su[5], Trisha Hue[1], Richard Eastell[6]. [1]University of California, San Francisco, USA, [2]University of Auckland, New zealand, [3]Duke University Medical Center, USA, [4]Novartis Pharmaceuticals Corporation, USA, [5]Novartis pharmaceuticals, USA, [6]University of Sheffield, United Kingdom

Purpose: Studies have shown that compared with placebo, annual infusions of zoledronic acid 5 mg (ZOL) significantly reduce fracture risk over 3 years. However, studies of ZOL, as well as other bisphosphonates, have shown residual effects on BMD and bone turnover over periods ranging from 1 to 5 years after treatment discontinuation. We therefore conducted this post-hoc analysis to investigate the impact of a single infusion of ZOL on fracture risk over a period up to 3 years. This analysis includes women and men from two randomized, double-blind, placebo-controlled trials of ZOL: the HORIZON Pivotal Fracture Trial (PFT) and Recurrent Fracture Trial (RFT). In PFT, 7736 women with osteoporosis were followed for 3 years, whereas, RFT was an event-driven trial in 2127 women and men with recent hip fracture who were followed for as many as 3 years.

Methods: We analyzed the impact of ZOL on fracture risk in a subset of subjects (n=1367) who received only a single, baseline infusion and who completed the respective study. They were followed for a mean of 1.5 years. For comparison, we also analyzed the impact of ZOL in the subset of subjects who received at least 3 infusions (n=6904). These subjects were followed for a mean of 3 years. In both subsets, the incidence rates of fracture were compared in ZOL vs placebo over 36 months using Kaplan–Meier estimates for three categories of fractures: all clinical, non-vertebral and clinical vertebral.

Results: At Month 36, in patients who only received a single ZOL infusion, there was a statistically significant 32% reduction in clinical fracture compared with placebo (p=0.039) and there was a trend toward reductions in clinical vertebral and non-vertebral fractures (p=NS). The magnitude of the risk reduction for the three fracture types in the group who received a single ZOL infusion are similar to those observed with three annual ZOL infusions (34%). Since the subgroup of single infusion patients is based on a post-randomization categorization, the ZOL and PBO groups are not necessarily comparable. However, even after adjustment for confounding variables including age and/or baseline FN BMD T-score (PFT *vs.* RFT), the results remained substantially the same (HR=0.67 [0.47, 0.97] adjusted for age *vs.* HR=0.70 [0.49, 1.01] adjusted for age and FN BMD).

Conclusion: This preliminary analysis demonstrates that a single dose of ZOL in patients with osteoporosis, can reduce the risk of clinical fractures at 3 years.

Divergent Trends between Typical and Atypical Hip Fractures and Prevalence of Bisphosphonate Use in the US Elderly, 1996-2007. John Wang*[1], Timothy Bhattacharyya[2]. [1]Intramural Research Program, NIAMS/NIH, USA, [2]Intramural Research Program, NIAMSNIH, USA

Context Though overall hip fracture incidences are declining, increasing numbers of atypical hip fractures have been reported, particularly among elderly patients with long-term use of bisphosphonates. Objective To compare trends between atypical and typical hip fractures and medication use between men and women 65 years or older. Design, Setting, and Patients Cross-sectional studies from 1996 to 2007 on 371 347 respondents to the annual Medical Expenditure Panel Survey and 619 044 hospitalizations in the Nationwide Inpatient Sample with a primary surgical procedure and a primary diagnosis of either a typical closed hip fracture in femoral neck and intertrochanteric regions or an atypical closed fracture in the subtrochanteric region. Main Outcome Measures National estimates and sex-specific, age-adjusted rates of hip fractures. Results Between 1996 and 2007, the annual national estimate for typical hip fractures decreased 12.8% from 263 623 to 229 942. Among women, age-adjusted rates of typical hip fractures decreased by 31.6% (from 1020.5 to 697.4 fractures per 100 000) and among men, by 20.5% (from 424.9 to 337.6 fractures per 100 000). In contrast, national estimates for atypical hip fractures increased 31.2 % from 8 273 to 10 853. Joinpoint regression analysis indicated that trends in age-adjusted rates for atypical hip fractures remained unchanged among men (p=0.34), but increased 20.4% among women from 28.4 (95% Confidence Interval [CI], 27.7-29.1) in 1999 to 34.2 (96% CI, 33.4-34.9) fractures per 100 000 in 2007. The annual percentage increase was 2.1% (95% CI, 1.3-2.8, p<0.001). Meanwhile, prevalence of bisphosphonate use increased more among women (from 3.5% in 1996 to 16.6% in 2007) than in men (2.3% in 2007). Conclusion Typical hip fractures are declining in the US elderly. Hospitalizations for atypical hip fractures, albeit rare, have increased annually since 1999 and were detected mostly among postmenopausal women, a group with prevalent use of bisphosphonates.

Atypical Subtrochanteric and Shaft of Femur Fractures - Are they related to Bisphosphonate Therapy? : Blinded radiological review. Christopher Warren[1], Nigel Gilchrist*[2], Mark Coates[3], Joy Helmore[4], John McKie[5], Gary Hooper[5]. [1]Department of Geriatrics, Princess Margaret Hospital, New zealand, [2]CGM Research Trust, New zealand, [3]Department of Radiology, Christchurch Hospital, New zealand, [4]CGM Research Trust, Christchurch, New zealand, [5]Department of Orthopaedic Medicine & Surgery, Christchurch Hospital, New zealand

Purpose: Recent reports have raised the possibility of a relationship between a subset of subtrochanteric and diaphyseal femoral fractures (atypical fractures) and bisphosphonate therapy. A recent review by Black did not show a statistically significant relationship. We undertook a retrospective study of male and female patients admitted with fractures to Christchurch Hospital between 2004 and 2008 to evaluate the relationship between bisphosphonates, this subset of fractures and typical subtrochanteric and diaphyseal femoral fractures.

Methods: The total number of fracture admissions during this period was 18,345. International Statistical Classification of Diseases and Related Health Problems 10th Revision discharge codes (S72.2 subtrochanteric and S72.3 fracture of shaft of femur) were used to identify cases. There were 538 cases identified. Exclusions were a history of motor vehicle accident; age less than 20, misclassification of fracture on x-ray report (intra trochanteric or neck of femur) and tumours identified on x-ray report. There were 336 cases excluded at this stage.

The remaining 202 cases were submitted for independent, blinded single radiologist review. Cases were excluded if they were periprosthetic, or neither subtrochanteric nor diaphyseal femoral fractures. Included fractures were sub classified into typical or atypical (transverse fractures with cortical thickening and beaking of the cortex) fractures. Also excluded were all of those with a history of Paget's disease, malignancy and significant trauma (a fall from greater than standing height). An additional 134 cases were excluded.

Results: There were 61 typical fractures with 9 on alendronate and 5 on etidronate. There were 12 atypical fractures with 4 on alendronate and 0 on etidronate. There was a trend towards alendronate being associated with atypical fractures (relative risk [RR] 2.3) but this did not reach statistical significance (p value 0.12 using chi-squared test). There was less suggestion that any bisphosphonate exposure was associated with atypical fractures, RR 1.7 (p value 0.45).

Conclusions: Atypical femoral fractures are uncommon (<0.1% of total fracture admissions during this study period). Independent radiological review of x-rays is important. This study does not show a statistically significant relationship between alendronate use and atypical subtrochanteric and femoral diaphyseal fractures compared with typical fractures.

Genome Wide Association Study Identifies Four Loci that Account for 76% of the Population Attributable Risk of Paget's Disease. Omar Albagha*[1], Micaela Visconti[1], Nerea Alonzo[1], Anne Langston[1], Tim Cundy[2], Rosmary Dargie[3], William Fraser[4], Michael Hooper[5], Giancarlo Isaia[6], Geoffrey Nicholson[7], Javier del Pino[8], Rogelio Gonzalez-Sarmiento[8], Marc di Stefano[6], John Walsh[9], Stuart Ralston[1]. [1]University of Edinburgh, United Kingdom, [2]Faculty of Medical & Health Sciences University of Auckland, New zealand, [3]Glasgow Royal infirmary, United Kingdom, [4]Royal Liverpool University Hospital, United Kingdom, [5]Sydney University & Sydney South West Area Health Service, Australia, [6]University of Torino, Italy, [7]University of Melbourne, Australia, [8]University of Salamanca, Spain, [9]Sir Charles Gairdner Hospital, Australia

Paget's disease of bone (PDB) is a common disorder with strong genetic component that affects up to 2% of Caucasians aged 55 years and above. Genetic factors are known to be important in PDB but so far *SQSTM1* is the only gene that has been confirmed to cause classical PDB. Whilst mutations of *SQSTM1* are found in about 10% of patients with PDB, the remaining genes that contribute to the disease are unclear. Here we report the results of an extended genome-wide association study involving a discovery sample of 750 PDB patients without *SQSTM1* mutations and 2699 controls from the Wellcome trust case control consortium and a replication

sample of 500 PDB cases and 535 controls. Following data cleaning and quality control measures, association testing was performed using the stratified Cochran-Mantel-Haenszel test and stepwise logistic regression. This resulted in the identification of four loci with genome wide significant evidence of association with PDB. These were close to *CSF1* (encoding M-CSF) on chromosome 1p13 ($p=2.1 \times 10^{-26}$; odds ratio (OR)=1.7), within *TM7SF4* (encoding DC-STAMP) on chromosome 8q22 ($p=9.2 \times 10^{-12}$; OR=1.4); within the *OPTN* gene on chromosome 10p13 ($p=1.5 \times 10^{-21}$; OR= 1.6) and close to *TNFRSF11A* (encoding RANK) on chromosome 18q21 ($p=2.4 \times 10^{-13}$; OR=1.4). The M-CSF, DC-STAMP and RANK, genes are strong candidates for PDB since they play key roles in osteoclast differentiation but the function of *OPTN* in bone is as yet unknown. Stepwise regression analysis showed that all four loci were independently associated with PDB and we therefore combined information from all variants to generate a risk allele score and estimate the population attributable risk for PDB. We found that remarkably, the associated SNPs accounted for 76% of the population attributable risk of PDB in the study population with a 16-fold variation in risk between carriers of protective and susceptibility alleles. This study has identified four novel genetic loci that contribute substantially to disease susceptibility. Further work is now required to define the molecular mechanisms responsible for these associations and to determine if predictive genetic testing for these susceptibility alleles might be of clinical value in identifying patients at risk of the disease or complications.

Measles Virus Nucleocapsid Gene Expression and the SQSTM1 Mutation Both Contribute to the Increased Osteoclast Activity in Paget's Disease. Noriyoshi Kurihara*[1], Hua Zhou[2], David Dempster[3], Jolene Windle[4], Jacques Brown[5], G. David Roodman[6]. [1]Center for Bone Biology, University of Pittsburgh, USA, [2]Helen Hayes Hospital, USA, [3]Columbia University, USA, [4]Virginia Commonwealth University, USA, [5]Laval University, Canada, [6]VA Pittsburgh Healthcare System (646), USA

The primary cellular abnormality in Paget's disease (PD) resides in the osteoclast (OCL). OCLs in PD are hyper-multinucleated and hyper-responsive to RANKL and 1,25-$(OH)_2D_3$, express increased levels of TAF-12, and secrete high levels of IL-6. Both measles virus and genetic causes have been proposed for the etiology for PD. However, their respective role in PD is unclear. To define the contributions of measles virus and the $p62^{P392L}$ mutation linked to PD to the abnormal OCL activity in PD, OCL precursors from involved and uninvolved bones of 12 PD patients harboring the $p62^{P392L}$ mutation and 6 normals were characterized by qPCR assays for measles virus nucleocapsid protein (MVNP) mRNA expression, OCL formation, and the effects of antisense-MVNP (AS-MVNP) on PCL formation/morphology, bone resorption capacity and 1,25-$(OH)_2D_3$ and RANK ligand (RANKL) responsivity were determined. OCL precursors from involved and uninvolved bones of 1/3 of PD patients expressed MVNP($MVNP^+$) and formed OCLs characteristic of PD in vitro. OCL formation by $MVNP^+$ cells was blocked by AS-MVNP. In contrast, 2/3 of PD patients and all normals which lacked MVNP formed normal OCLs, which were not affected by AS-MVNP. To further characterize the effects of $p62^{P392L}$ and MVNP on OCL activity in vitro and in vivo, we generated $p62^{P394L}$-knock-in ($p62^{P394L}$-KI) mice and crossed them with transgenic mice with targeted MVNP expression to the OCL lineage (T-MVNP mice). OCL precursors from $p62^{P394L}$ KI mice were hyper-responsive to RANKL but not to 1,25-$(OH)_2D_3$, did not form hyper-multinucleated OCLs and the mice developed progress osteopenia rather than PD bone lesions. In contrast, OCLs precursors from T-MVNP mice were hyper-responsive to RANKL and 1,25-$(OH)_2D_3$, expressed increased levels of TAF-12 and formed hyper-multinucleated OCLs in vitro. OCL precursors from $p62^{P394L}$-KI/MVNP were more hyper-responsive to both RANKL and 1,25-$(OH)_2D_3$, showed increased NF-κB, MAPK and PI3K signaling, increased TAF-12 expression, and formed hyper-multinucleated OCLs. These results suggest that both $p62^{P392L}$ and MVNP in vivo contribute to the abnormal OCL activity in PD with $p62^{P392L}$ enhancing the effects of MVNP in pagetic OCL compared to T-MVNP mice.

***TNFRSF11A* Gene Allelic Variants are Associated with Paget's Disease of Bone and Interact with *SQSTM1* Mutations to Cause the Severity of the Disorder.** Daniela Merlotti*[1], Fernando Gianfrancesco[2], Luigi Gennari[1], Domenico Rendina[3], Marco Di Stefano[4], Giuseppe Mossetti[3], Salvatore Gallone[5], Teresa Esposito[2], Sara Magliocca[2], Daniela Formicola[2], Alessandra Mingione[2], Pierpaola Fenoglio[5], Antonio Criasia[4], Riccardo Muscariello[3], Pasquale Strazzullo[3], Giancarlo Isaia[6], Ranuccio Nuti[1]. [1]Department of Internal Medicine, Endocrine-Metabolic Sciences & Biochemistry, University of Siena, Italy, [2]Institute of Genetics & Biophysics, CNR, Naples, Italy, [3]Department of Clinical & Experimental Medicine, Federico II University of Naples, Italy, [4]Department of Internal Medicine, University of Turin, Italy, [5]Department of Neuroscience, University of Turin, Italy, [6]University of Torino, Italy

Paget's disease of bone (PDB) is a chronic bone disease with a consistent genetic component. Despite mutations in *SQSTM1* gene have been detected in up to 50% of familial cases, phenocopy or incomplete penetrance were described and their prevalence is low in sporadic PDB, likely due to the presence of additional predisposition genes. Although the *TNFRSF11A* gene (encoding RANK, a key protein in osteoclastogenesis) has been associated with different PDB-like syndromes, no *TNFRSF11A* mutations have been reported in PDB patients. In this study we evaluated whether 2 non-synonymous *TNFRSF11A* single nucleotide polymorphisms (SNPs), rs35211496 (H141Y) and rs1805034 (A192V), are associated with PDB and the severity of phenotype in a large population of 580 unrelated consecutive patients that were previously screened for *SQSTM1* gene mutations. 496 age and sex-matched controls were also genotyped for comparison. Both SNPs were associated with PDB in the overall cohort as well as after the exclusion of patients with *SQSTM1* gene mutations (n=79). The largest effect was found for rs1805034, yielding an odds ratio of 1.3 (p=0.006), with the C allele as the risk allele. Moreover, an even more significant p-value (p=0.0009) was observed in the subgroup of patients with *SQSTM1* mutation, with an odds ratio of 1.6, again indicating the C allele to be the risk allele. Interestingly patients with the C allele also showed an increased prevalence of polyostotic disease (68%, 53%, and 51% in patients with CC, CT, and TT genotypes, respectively, p=0.01) as well as an increased number of affected skeletal sites (2.9, 2.5, and 2.0 in patients with CC, CT, and TT genotypes, respectively, p=0.008). These differences increased in magnitude when analyses were restricted to cases with *SQSTM1* mutation, both for the prevalence of polyostotic disease (91%, 77%, and 73% in patients with CC, CT, and TT genotypes, respectively, p=0.03) and the number of affected sites (4.4, 3.3, and 2.8 in patients with CC, CT, and TT genotypes, respectively, p=0.03). No significant differences in relation to *TNFRSF11A* genotypes were observed concerning age of diagnosis and the estimated age of onset of PDB. Haplotype analysis combining the 2 SNPs evidenced an odds ratio of 2.12 in subjects with C-C haplotype (p=0.02). In conclusion, this study provides evidence that *TNFRSF11A* SNPs are associated with the susceptibility to develop PDB and may interact with *SQSTM1* mutations to cause the severity of the disorder.

Both Hypersensitivity to 1,25-$(OH)_2D_3$ and High IL-6 Levels Are Required to Induce Pagetic Osteoclasts. Noriyoshi Kurihara*[1], Jolene Windle[2], G. David Roodman[3]. [1]Center for Bone Biology, University of Pittsburgh, USA, [2]Virginia Commonwealth University, USA, [3]VA Pittsburgh Healthcare System (646), USA

Our previous studies showed that measles virus nucleocapsid protein (MVNP) can induce development of Paget's disease (PD) osteoclasts (OCL) and pagetic lesions in vivo. MVNP induced hyper-responsivity of OCL precursors to 1,25-$(OH)_2D_3$ through increased expression of a novel VDR co-activator, TAF-12, as well as high levels of IL-6 in the local bone microenvironment. Further, knockdown of TAF-12 blocked formation of pagetic OCL in vitro, but overexpression of TAF-12 in normal OCL precursors did not induce pagetic OCL formation. These results suggest that high levels of IL-6 and hyper-responsivity to 1,25-$(OH)_2D_3$ are both required for development of PD-OCL. To test this hypothesis, TRAP-MVNP mice, which have MVNP targeted to the OCL lineage, using the TRAP promoter and develop pagetic-like bone lesions, were mated with $IL\text{-}6^{-/-}$ mice to generate TRAP-MVNP/$IL\text{-}6^{-/-}$ mice. Bone marrow cells from TRAP-MVNP and TRAP-MVNP/$IL\text{-}6^{-/-}$ mice were then tested for their capacity to form OCL that express a pagetic phenotype in vitro. OCL precursors from TRAP-MVNP but not TRAP-MVNP/$IL\text{-}6^{-/-}$ mice were hyper-responsive to 1,25-$(OH)_2D_3$ and expressed high levels of TAF-12. As expected, OCL precursors in marrow cultures from TRAP-MNVP were hyper-responsive to RANKL. In contrast, OCL precursors from $IL\text{-}6^{-/-}$, MVNP/$IL\text{-}6^{-/-}$ and WT mice were not hyper-responsive to RANKL. OCL from TRAP-MVNP/$IL\text{-}6^{-/-}$, $IL\text{-}6^{-/-}$ and WT were not hyper-responsive to 1,25-$(OH)_2D_3$, did not have increased nuclei per OCL and did not form PD-OCL. Further, in contrast to TRAP-MVNP mice, the bone resorption capacity of OCL formed from TRAP-MVNP/$IL\text{-}6^{-/-}$ was similar to WT. Loss of IL-6 in TRAP-MVNP mice (TRAP-MVNP/$IL\text{-}6^{-/-}$ mice) blunted the enhanced p38 and ERK signaling seen in TRAP-MVNP OCL precursors treated with 1,25-$(OH)_2D_3$. It had no affect on NF-κB and AKT signaling. Further, loss of $IL6^{-/-}$ decreased the enhanced NFATc-1 expression in OCL precursors from TRAP-MVNP

mice. Histomorphometric studies showed that loss of IL-6 significantly decreased osteoblast perimeter and bone formation rate compared to that in TRAP-MVNP mice. These results show that IL-6 is required for hypersensitivity of OCL precursors to 1,25-$(OH)_2D_3$ and that high levels of IL-6 combined with increased TAF-12 expression are necessary to induce PD-OCL and pagetic bone lesions in vivo.

Effects of Estrogen on Bone Marrow Cytokines/Bone-Regulatory Factors and Osteoprogenitor Cells In Vivo in Elderly Women. Ulrike Moedder*[1], Louise McCready[2], Kelley Hoey[2], Matthew Roforth[2], James Peterson[2], Sundeep Khosla[3]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic, USA, [3]College of Medicine, Mayo Clinic, USA

Decreases in estrogen (E) levels contribute not only to early postmenopausal bone loss but also to ongoing bone loss with aging in women. E is known to regulate bone turnover; however it is unclear whether E treatment alters peripheral blood (PB) or bone marrow (BM) plasma levels of inflammatory cytokines, sclerostin, or other candidate bone-regulatory factors. In addition, possible effects of E on proliferation or differentiation of human BM osteprogenitor (hematopoietic lineage [lin]-/Stro1+) cells in vivo have not been elucidated. Thus, we treated elderly postmenopausal women (mean age, 71 ± 1 yrs) either with transdermal E2 (0.05 mg/d) or placebo (Control, n=16 per group) for 4 months. PB serum and BM plasma was collected to determine levels of bone formation and resorption markers (P1NP, CTX, TRAP5b) as well as candidate cytokine and other bone-regulatory factors (TNFα, IL-1β, IL-6, RANKL, OPG, adiponectin, DKK1, oxytoxin, serotonin, and sclerostin). Lin-/Stro1+ cells were isolated from BM samples by magnetic activated cell sorting (MACS) for gene expression analysis. As expected, bone turnover markers (P1NP, CTX, TRAP5b) were significantly decreased following E treatment. None of the PB serum or BM plasma marker levels that were determined differed significantly between the two groups, with the notable exception of sclerostin levels, which were significantly lower in the E-treated compared to Control women both in PB (Control, 332 ± 6; E-treated, 207 ± 19 pg/ml, P=0.011) and in BM plasma (Control, 378 ± 41; E-treated, 249 ± 25 pg/ml, P=0.022). There was also a significant correlation between BM plasma and PB serum sclerostin levels (R=0.74, P<0.0001). Gene expression analysis of BM lin-/Stro1+ cells demonstrated a significant decrease in the expression of several proliferation markers (cyclin B1, cyclin E1, E2F1), the BMP target, lysyl oxidase, as well as the master-regulator of osteoblast differentiation, runx-2. In summary, of all the candidate cytokines and other proteins assessed, sclerostin was the only bone-regulatory factor clearly reduced in BM plasma and PB of postmenopausal women following E treatment. Moreover, consistent with the known anti-remodeling effects of E, we demonstrate for the first time in vivo that E suppresses proliferation and expression of runx-2 by early osteoprogenitor cells. Further studies are needed to define whether these effects of E are direct or indirect and whether they differ in early vs late osteoblastic cells.

Postmenopausal BMD Variation is Strongly Associated with Subsets of MicroRNAs and Other Non-coding RNAs (ncRNAs) Expression Levels. Sjur Reppe*[1], Marit Holden[2], Vigdis T. Gautvik[1], Harish Datta[3], Kaare M. Gautvik[4]. [1]Oslo University Hospital, Ullevaal, Norway, [2]Norwegian Computing Center, Norway, [3]Newcastle University, United Kingdom, [4]Oslo University Hospital, Ullevaal; University of Oslo; Lovisenberg Deacon Hospital, Oslo, Norway

Heritage determines 60-80% of the maximal obtainable bone mineral density (BMD) level in women, and BMD is closely associated with skeletal fractures occurring in about 40% of postmenopausal women in the western world. MicroRNAs are short (19-24) polynucleotides that bind to messenger RNAs of protein coding genes and confer genetic regulation at the post-transcriptional level, affecting a wide range of biological processes. We have identified novel determinants of bone remodeling through global profiling of mature microRNAs and other non-coding RNAs (ncRNAs) in bone biopsies from postmenopausal Caucasian females and calculated their associations to BMD variations. The unrelated women (n=84, 50-86 yr), had diverse BMDs (healthy, osteopenic or osteoporotic) with or without low energy fractures. Out of 667 tested, a set of 24 ncRNAs correlated strongly with total hip BMD adjusted for age and BMI (5% false discovery rate (FDR)). Lasso analysis was used as an alternative statistical method employing cross validations and identified a subset of 10 ncRNAs that explained 32% of the BMD variation in total hip BMD after adjustment for differences in age and BMI. The top ranked 9 Lasso ncRNAs were included among the 24 at 5% FDR level, thus adding strength to the results. High significant correlation between the Lasso ncRNAs and mRNAs previously shown to be highly associated with BMD (Reppe et al., Bone. 2010 46:604-12) suggested reciprocal or similar regulation between several of the RNAs in the two groups, emerging as a closely interconnected net. Target prediction software identified the Adherens Junction, TGFβ and Wnt signaling pathways to be the most implicated. While the TGFβ and Wnt pathways are well known to be important in bone remodeling, the Adherens junction comprising regulation of cell to cell contact via E-Cadherin is a less appreciated complementary system. The results provide novel insight in the functional association between distinct microRNAs / ncRNAs in bone cell metabolism and their possible roles in the pathogenesis of osteoporosis as the ultimate consequence of low BMD.

Inhibiting Cx43 Gap Junction Function in Osteocytes, but not Cx43 Hemichannel Function Results in Defects in Skeletal Structure and Bone Mass. Jean Jiang*[1], Sirisha Burra[2], Stephen Harris[1], Hong Zhao[3], Mark Johnson[4], Lynda Bonewald[5]. [1]University of Texas Health Science Center at San Antonio, USA, [2]University of Texas, USA, [3]School of Dentistry, University of Missouri, USA, [4]University of Missouri, Kansas City Dental School, USA, [5]University of Missouri - Kansas City, USA

Connexin (Cx) 43 plays an important role in maintaining normal bone function and development. Targeted deletion of Cx43 in osteoblasts using either 2.3Col or OC-Cre mice crossed with floxed Cx43 mice results in increased osteocyte apoptosis and osteoclast recruitment leading to reduced bone mass and strength. Cx43 forms both gap junctions and hemichannels. Whereas gap junctions play a role in cell signaling, hemichannels are thought to play a role in both signaling and cell viability. In order to begin to separate the role of gap junctions from hemichannels in osteocyte function, we generated a Cx43 (R76W) mutant construct predicted to block gap junction but not hemichannel function. This construct was expressed in Hela and osteocytic MLO-Y4 cells and tested for Cx43 function. Dye transfer experiments showed that Hela cells expressing Cx43 (R76W) failed to form functional gap junction channels. When co-expressed with wild-type Cx43, this mutant acted as dominant negative for gap junctions. This mutant also inhibited gap junctions formed by endogenous Cx43 when expressed in MLO-Y4 cells. Dye uptake analysis suggested that unlike gap junctions, hemichannel function was not affected by Cx43 (R76W) in both Hela and MLO-Y4 cells.

Next, in vivo studies were performed to determine relative contributions of Cx43 gap junctions to hemichannels in osteocytes by generating mice in which osteocyte specific expression of Cx43 (R76W) was driven by a 10 kb-DMP-1 promoter. At 1 day of age, no differences were observed between controls (C) and heterozygotes (Het) with regards to size, weight, BMD and BMC using x-ray and bone densitometry. To date, no homozygotes have been obtained suggesting lethality. By 4 weeks of age, the heterozygote mice showed a decrease in body weight (15.8/11.7 gm: C/Het) and a decrease in BMD (0.0491/0.0444 g/cm^2: C/Het), but a dramatic decrease in BMC (0.427/0.282; C/Het). By micro-CT analysis, significant increased porosity was observed especially in distal femora and vertebrae (Figure 1). These results suggest that gap junction channels formed by Cx43 in osteocytes are critical for maintaining normal bone density and architecture and potentially postnatal development. Gap junctions, by not hemichannels may be responsible for osteocyte signaling to initiate remodeling. Alternatively, excessive Cx43 hemichannel activity due to the over-expression could also attribute to impaired bone phenotypes exhibited by this transgenic model.

Resorption is an Essential Component of Bone Anabolism Induced by Active PTH Receptor Signaling in Osteocytes. Yumie Rhee*[1], Matthew Allen[2], Lilian Plotkin[2], Nicoletta Bivi[3], Racheal Lee[4], Jeffery Benson[4], Virginia Lezcano[5], Ana Ronda[5], Teresita Bellido[2]. [1]IUMS, Yonsei University, College of Medicine, South korea, [2]Indiana University School of Medicine, USA, [3]Indiana University, USA, [4]Department of Anatomy & Cell Biology, Indiana University School of Medicine, USA, [5]Department of Biochemistry, Biology, & Pharmacy, Universidad Nacional de Sur, Argentina

The contribution of remodeling-based bone formation (BF) coupled to osteoclast activity and modeling-based BF that occurs independently of resorption, to the anabolic effect of PTH remains unclear. Earlier work demonstrated that transgenic (TG) mice with constitutive activation of PTH receptor signaling in osteocytes (DMP1-caPTHR1 mice) display increased endosteal remodeling and enhanced periosteal BF. We dissected herein the contribution of resorption to formation induced by PTHR signaling in osteocytes by administering alendronate (ALN, 5.25 mg/kg/week) or vehicle for 2 weeks to 1-month-old DMP1-caPTHR1, DMP1-Sost, double TG, or wild type (WT) littermates. ALN reduced circulating CTX and OCN in all groups, except for OCN in double TG mice that was already low. The increased periosteal BF displayed by DMP1-caPTHR1 mice was reversed by Sost overexpression but still elevated in DMP1-caPTHR1 mice treated with ALN, demonstrating its dependence on the Wnt pathway but not on resorption. In contrast, the increased endocortical MAR of the DMP1-caPTHR1 mice was abolished by ALN indicating that osteoblast activity in this surface is driven by resorption. Moreover, MAR was further increased by Sost overexpression consistent with the higher resorption and low OPG expression exhibited by these double TG mice. However, the increased endocortical MS/BS displayed by DMP1-caPTHR1 mice was not affected by ALN but it was reduced by Sost overexpression, suggesting that the presence of osteoblasts on mineralizing surfaces induced by PTHR signaling is not driven by resorption but depends on the Wnt pathway. Because of the respective lower values of MAR and MS/BS, double TG mice treated with ALN exhibited endocortical BFR even lower than WT mice, demonstrating cooperation between resorption and Wnt activity on remodeling-based BF driven by PTHR signaling in osteocytes. Moreover, whereas Sost overexpression exacerbated the elevated intracortical porosity exhibited by DMP1-caPTHR1 mice, ALN reduced porosity in both DMP1-caPTHR1 and double TG mice. As a result of these combined effects on periosteal and endosteal (endo- and intra-cortical) surfaces, double TG mice treated with ALN exhibited similar bone area in the femoral mid-diaphysis (micro-CT) and femoral BMD (DXA) to WT mice. These findings demonstrate that, although dispensable for periosteal BF, resorption is essential for increasing BF in the endosteal surfaces driven by PTH receptor signaling in osteocytes.

Sclerostin Antibody Protects the Skeleton from Disuse-induced Bone Loss. Alexander Robling*[1], Stuart Warden[1], Chris Paszty[2], Charles Turner[3]. [1]Indiana University, USA, [2]Amgen, Inc., USA, [3]Indiana University, Purdue University Indianapolis, USA

The Wnt signaling pathway is a key modulator of bone metabolism, including responses to the mechanical environment. Soluble inhibitors of Wnt signaling are modulated by mechanical loading and unloading (disuse), and consequently, represent potential targets to alter the naturally occurring responses to those stimuli. We sought to determine whether inhibition of sclerostin, an osteocytic protein that inhibits Wnt signaling through the Lrp5/6 receptors, would protect bone from the bone-wasting effects of mechanical disuse. Adult female mice were subjected to one of two disuse models: tail suspension, or unilateral botox-induced muscle paralysis (Botox; 20 U/kg) of the right lower limb. The left lower limb was injected identically with saline (internal control). The mice underwent disuse for 3 wks in the presence or absence of twice-weekly dosing with a sclerostin neutralizing antibody (Scl-AbIII; 25 mg/kg) injection. In the ground control mice, femoral aBMD did not change significantly over the three week treatment period (+1.7%, p=0.41), but tail suspended mice exhibited a 7% reduction ($p<0.001$). Tail suspended mice treated with Scl-AbIII exhibited a 6.2% increase ($p<0.001$) in femoral aBMD after 3 wks. This increase was significantly greater than that noted for the ground control mice ($p<0.01$), suggesting that Scl-AbIII not only protected these suspended mice from bone loss, but actually increased bone mass over ground control mice, despite the weightless environment. The Botox studies produced similar results to those described for the tail suspension studies. Saline injection into the left lower limb musculature resulted in a slight but significant decrease in femoral aBMD (-2.6%, $p<0.01$) over the 3-wk treatment period, whereas Botox injection into the right limb musculature of these same animals resulted in an 8.4% decrease ($p<0.001$) in femoral aBMD. Mice given Scl-AbIII during the 3 wk period following Botox injection exhibited an 8.0% increase in femoral aBMD in the paralyzed limb. This increase was significantly different from the changes occurring in the saline-injected limbs of mice not receiving antibody ($p<0.001$), suggesting that Scl-AbIII not only protected these paralyzed limbs from bone loss, but actually increased bone mass over non-paralyzed, saline-injected limbs. In summary, these data suggest that sclerostin inhibition is a useful approach for overcoming the bone loss that normally occurs with disuse.

A Membrane-Targeted GFP Selectively Expressed in Osteocytes Reveals Cell and Membrane Dynamics in Living Osteocytes. Patricia Veno[1], Yongbo Lu[2], Suzan Kamel[1], Jian Feng[3], Lynda F. Bonewald[4], Sarah Dallas*[4]. [1]University of Missouri, Kansas City, USA, [2]Texas A&M University System Health Science Center, USA, [3]Texas A&M Health Science Center, USA, [4]University of Missouri - Kansas City, USA

Osteocytes, once viewed as quiescent cells, are now known to be capable of modifying their microenvironment, play a key role in phosphate homeostasis and may act to integrate mechanical and hormonal signals to regulate bone mass. We have previously shown in neonatal mouse calvaria that osteocytes within their lacunae may be highly dynamic and show motions of their cell body and dendrites. To further understand the dynamic properties of these cells, we have used live imaging approaches in conjunction with a new transgenic mouse line that selectively expresses a membrane targeted GFP construct in osteocytes.

Transgenic mice were generated expressing a membrane targeted AcGFP variant driven by a 10kb fragment of the Dmp1 promoter. This GFP variant contains the N-terminal 20 amino acids of neuromodulin (GAP-43), which targets the GFP to plasma and intracellular membranes. Living calvarial explants from 5-7 day old mice expressing the transgene were imaged by time lapse fluorescent microscopy. The transgene was expressed in partially and fully embedded osteocytes as well as a sub population of motile cells on the bone surface that we have previously proposed may represent an osteocyte precursor cell. Time lapse fluorescence imaging confirmed motions of the osteocyte cell body and dendrites and also suggested extensive ruffling of the osteocyte cell membrane within its lacuna. Live cell imaging was also performed on primary calvarial osteoblasts isolated from Dmp1-memGFP transgenic mice that were cultured under mineralizing conditions. Mineral deposition occurred exclusively in areas containing clusters of Dmp1-mem-GFP positive cells and was associated with extensive ruffling of the cell membrane of the GFP-positive cells, and apparent shedding of membrane bound vesicles. Confocal microscopy of neonatal Dmp1-memGFP calvaria and immunostaining for the membrane associated osteocyte marker protein, E11/gp38, showed vesicles in the ECM that are apparently shed from the osteocyte dendrites and cell body.

These data underscore the dynamic properties of osteocytes and further reveal their extensive membrane ruffling activity within their lacunae. The shedding of membrane bound vesicles by osteocytes may represent a mechanism for reduction of cytoplasmic volume, may be involved in regulation of mineral deposition and/or may be a mechanism for intercellular communication in the bone microenvironment.

Ablation of Mef2C in Osteocytes Increases Bone Formation and Bone Mass Through Transcriptional Repression of Sclerostin (SOST). Nicole Collette*[1], Aris Economides[2], Liqin Xie[3], Damian Genetos[4], Richard Harland[5], Gabriela Loots[6]. [1]Lawrence Livermore National Laboratory/ University of California, Berkeley, USA, [2]Regeneron Pharmaceuticals, Inc., USA, [3]Regeneron Pharmaceutical company, USA, [4]University of California, Davis, USA, [5]University of California, Berkeley, USA, [6]LLNLUC Merced, USA

Myocyte Enhancer Factors (Mefs) are a family of transcriptional regulators originally described for their key roles in cardiovascular development. In vertebrates there are four closely related Mef2 genes (A, B, C, D) -with overlapping expression patterns in muscle and vasculature. Since Mef2C null mice are embryonically lethal because of their failure to develop hearts, the role of Mef2C in bone metabolism has not yet been described. Recently, MEF2C has been shown to play a role in skeletal development by activating the gene program for chondrocyte hypertrophy. Concomitantly, we found Mef2C and D to be robustly expressed in mineralized bone, suggesting that Mef2 transcription factors may govern similar transcriptional regulatory networks in bone and muscle. Through functional characterization of a distal regulatory element (ECR5) that controls SOST expression specifically in osteocytes, we have previously reported the discovery of a MEF2 response element that is critical for the enhancer activity of this element, in vitro. Since loss of Sclerostin or SOST is responsible for two rare, autosomal recessive disorders characterized by generalized severe hyperostoses of the skeleton [sclerosteosis and Van Buchem Disease (VB)], we aimed to address whether deleting the SOST osteocyte enhancer, ECR5, or the putative upstream regulatory protein, Mef2C, would produce similar phenotypes, in vivo. We examined Mef2C conditional knockout mice in the context of Col1- and Dmp1-Cre in combination with ECR5-LacZ reporter transgenes or Sost-LacZ knock-in alleles. Whereas ECR5-LacZ and Sost-LacZ mice express β-galactosidase in osteocytes in a similar fashion to endogenous mouse Sost, when these reporters were examined in the Mef2C; Dmp1-Cre or Col1-Cre background, the osteocyte-specific ablation of Mef2C in these mice resulted in ECR5-dependent loss of Sost transcription (confirmed histologically and by qRT-PCR). In addition, the osteocyte-specific ablation of Mef2C also causes high bone mass, in these mice. Mef2C; Dmp1-Cre mice showed significant increase in trabecular microarchitecture in both distal femur and lumbar vertebrae relative to WT controls, and strikingly, this phenotype mimicked the bone overgrowth phenotype caused by the loss of ECR5, in vivo. Our results demonstrate that Mef2C is required for the transcriptional activation of Sost in osteocytes and loss of either ECR5 distal enhancer or Mef2C in osteocytes results in a bone phenotype similar to VB.

Bone Mass Increases in Osteocyte-specific Mef2c Knock-out Mice are Due to Decreased Bone Resorption. Stefan Baertschi*[1], Ina Kramer[2], Olivier Leupin[1], Hansjoerg Keller[1], Michaela Kneissel[1]. [1]Novartis Institutes for BioMedical Research, Switzerland, [2]Novartis Institutes for BioMedical Research, Che

We discovered previously that myocyte enhancer factor 2 (Mef2) a, c and d transcription factors are expressed in osteocytes and required for expression of the negative bone formation regulator Sost, implicating Mef2s in bone homeostasis. In order to analyze the role of Mef2c, which we found to be most highly expressed amongst the Mef2s in mineralized bone, we generated osteocyte-specific Mef2c deficient mice (Mef2cloxP/loxP;Dmp1-Cre). Previously presented results revealed cancellous and cortical bone mass increases in the axial and appendicular skeleton of male and female Mef2cloxP/loxP;Dmp1-Cre mice during growth and ageing (J Bone Miner Res 23, Suppl.). To gain further mechanistic insights into the observed phenotype we performed qPCR expression profiling utilizing osteocyte-enriched RNA from the femur diaphysis of 3-month-old mice and subjected the cancellous bone in the distal femur metaphysis to histomorphometric analysis.

Mef2c was decreased by 61% in male Mef2cloxP/loxP;Dmp1-Cre mice, consistent with an at least partial deletion of osteocytic Mef2c. Sost expression levels were reduced by 40%. In female mice Mef2c levels decreased by 50 %, while Sost expression decreases of 32 % did not reach significance. Mef2a and Mef2d expression levels were unaffected in both sexes. Despite partial decreases in Sost expression, fluorochrome label based bone formation rates and osteoblast number were largely unchanged in male and female Mef2cloxP/lox;Dmp1-Cre mice. In contrast, we found osteoclast surface to be reduced in male mice by 39 % compared to wildtype controls. Female knock-out animals presented with a decrease of osteoclast surface by 34%. Serum levels of the bone resorption biomarker Trap5b were decreased by 38 % in male mice, while they were not significantly altered in female mice. Expression analysis of bone marker and Wnt/beta catenin target genes revealed increases in expression of soluble RANKL decoy receptor osteoprotegerin (Opg) (70%) in male Mef2c deficient mice, while RANKL was unchanged. Female mice did not show a significant change in Opg expression compared to controls.

In summary, reduction of osteocytic Mef2c results in decreased bone resorption and increased bone mass. Reduced bone resorption is at least in male mice associated with increased Opg levels. Future studies will need to elucidate whether the modulation of Opg levels is dependent on repression of the presumed Wnt/beta-catenin signaling antagonist Sost or is independent of it.

Autophagy Related Proteins Mediate Osteoclast Function in vitro and in vivo. Carl DeSelm*[1], Brian Miller[1], Wei Zou[2], Herbert Virgin[1], Steven Teitelbaum[2]. [1]Washington University School of Medicine, USA, [2]Washington University in St. Louis School of Medicine, USA

Osteoclasts (OCs) degrade skeletal tissue by generating a polarized resorptive microenvironment, between themselves and the bone surface, isolated from the general extracellular space by a sealing zone. Ultimately bone degradation depends upon the cell's capacity to secrete protons, which mobilize mineral, and cathepsin K, which degrades organic matrix, into this sealed compartment. Transport of these molecules, in turn, is mediated by the OC's resorptive organelle, the ruffled border, which is encompassed within the actin ring. The ruffled border is the product of exocytosis of lysosmal vesicles containing the bone-degrading molecules. Thus, the mechanism by which lysosomal vesicles traffic to, and fuse with, the polarized plasma membrane is central to OC function. Autophagy is the process whereby cells degrade intracellular material within the lysosome. Because recent human GWAS data indicates a link between the autophagy pathway and bone density and as autophagy regulates survival and function of some secretory cells, we tested its importance in the OC. Activation of the autophagy pathway results in lipidation of the protein, LC3, which localizes to autophagosomes to promote their development and fusion with lysosomes. LC3 appears in punctate cytoplasmic structures in bone-residing OCs, but also localizes to the ruffled border. Furthermore, inhibition of the autophagy protein Atg4, which mediates lipidation of LC3, prevents LC3 transport to the ruffled border. Confirming this observation, LC3-G120A mutant, which cannot be lipidated, also fails to target to the resorptive organelle. We next turned to Atg5, an essential autophagy protein whose gene we conditionally deleted in OCs. We find Atg5 is also necessary for LC3 localization to the ruffled border and for efficient cathepsin K accumulation within the resporptive micoenvironement. These defects of Atg5-/- OCs are rescued by the WT gene but not its inactive K130R mutant. Establishing physiological relevance, Atg5 deficiency is attended by a ten fold reduction in ruffled border formation and failure to degrade bone slices in vitro, similarly rescued by the WT but not mutant gene. Lack of Atg5 also attenuates resorption in vivo resulting in diminished bone loss following ovariectomy. Thus, autophagy proteins target lysosomal vesicles to the bone-apposed plasma membrane to generate the ruffled border, thus facilitating bone resorption, providing insight into their genetic association with osteoporosis.

MHC Class II Transactivator: A Novel Estrogen-modulated In Vivo Regulator of Osteoclastogenesis and Bone Homeostasis Co-opted from Adaptive Immunity. Elisa Benasciutti*[1], Elisabetta Mariani[2], Egon Perilli[3], Emmanuele Barras[4], Roberta Faccio[5], Nick Fazzalari[6], Walter Reith[4], Simone Cenci[2]. [1]Division of Genetics & Cell Biology, San Raffaele Scentific Institute, Italy, [2]Division of Genetics & Cell Biology, San Raffaele Scientific Institute, Italy, [3]Department of Surgical Pathology, Institute of Medical & Veterinary Science, Australia, [4]Department of Pathology & Immunology, University of Geneva Medical School, Centre Médical Universitaire (CMU), Switzerland, [5]Washington University in St Louis School of Medicine, USA, [6]Institute of Medical & Veterinary Science, Australia

The integrated study of bone and immunity, two co-evolved systems, is greatly expanding our understanding of skeletal biology, with implications for the pathogenesis of bone-wasting diseases. Recent work in mouse models of postmenopausal osteoporosis unveiled an increased expression of the master switch of MHC Class II expression and antigen presentation, CIITA (MHC Class II Transactivator), in osteoclast (OC) precursors. We thus tested the role of CIITA in regulating OC differentiation and activity.

To this aim, we adopted three genetic mouse models, two overexpressing CIITA, either conditionally (CIITA promoter IV-/-) or systemically (CIITA transgenics, Tg) and one lacking CIITA (CIITA-/-). We observed that CIITA potently regulates OC differentiation and bone architecture. 3D microCT analyses on tibial epiphyses show a dramatically reduced trabecular structure in CIITA overexpressing models. Altered architecture is confirmed by histomorphometrical analyses on contralateral bones, that also show increased OC numbers and activity. In parallel, ex vivo OCgenesis from bone marrow monocytes (BMMs) is enhanced in CIITA pIV-/- and CIITA Tg mice, while CIITA-/- monocytes show reduced OC differentiation. Silencing CIITA in BMMs by RNA interference decreases OCgenesis, suggesting that endogenous CIITA levels control OC differentiation in a cell-autonomous fashion. A global increased activation of the signaling pathways downstream of RANK underlies the hyperOCgenic phenotype, indicating the common upstream adapter TRAF6 as a potential target of CIITA.

We also asked if CIITA is regulated by estrogen (E), the main osteotropic hormone whose deficiency represents the main causative factor of involutional osteoporosis. In vivo experiments on OC precursors from ovariectomized mice reveal profound suppressive effects of E on chromatin remodeling at the CIITA locus, reverted by inhibition of histone deacetylases, controlling the inducibility of CIITA target genes. In vitro experiments reveal that E directly regulates CIITA expression in monocytes.

Our study provides compelling genetic evidence that the master immune regulator CIITA controls OC differentiation and bone homeostasis, and is controlled by E in vivo. This work further links bone and adaptive immunity and promises to identify novel therapeutic targets against bone-wasting conditions, in primis osteoporosis.

Jmjd5, JmjC-domain-containing Protein, is an Osteoclastogenic Repressor. Min-Young Youn*[1], Ken-ichi Minehata[2], Ichiro Takada[1], Yuuki Imai[3], Takashi Nakamura[1], Takeshi Suzuki[2], Shigeaki Kato[4]. [1]IMCB, University of Tokyo, Japan, [2]Cancer Research Institute, Kanazawa University, Japan, [3]The University of Tokyo, Japan, [4]University of Tokyo, Japan

Osteoclastogenesis is highly regulated by various transcriptional factors, which play pivotal roles by reorganizing gene networks. Recently, epigenetic regulations, such as histone modifications and chromatin remodeling, have been thought to be essential for the regulation of gene expression by transcription factors. Especially, reversibly regulated histone methylation is regarded as the most important storage of epigenetic information that defines cell fate and identity. However, it remains still unknown epigenetic regulations including histone demethylation during osteoclastogenesis. To clarify the roles of epigenetic regulations during osteoclastogenesis, we focused on Jumonji C (JmjC)-domain-containing proteins which are known as histone demethylase family, because their physiological roles in bone are totally unknown. Firstly, we confirmed their significant expressions during RANKL induced osteoclastogenesis using Raw264 cells. Among detected ten kinds of JmjC-domain-containing proteins, we observed that the expression levels of JmjC-domain-containing protein 5 (Jmjd5) was reduced through osteoclastogenesis. To verify its functions in the osteoclast differentiation, a stable cell line constitutively expressing shRNAs against Jmjd5 was established, and then osteoclast formation was assayed by TRAP staining. Notably, down-regulation of Jmjd5 expression resulted in promotion of osteoclast formation with up-regulated expression of osteoclast-specific genes such as DC-STAMP and Cathepsin K (CtsK). These results indicated that Jmjd5 is a negative regulator for osteoclast differentiation. To define the physiological function of Jmjd5 in bone metabolism in vivo, we generated the osteoclast-specific Jmjd5 knockout (Jmjd5?Oc/?Oc) mice by crossing Jmjd5-flox mice with CtsK-Cre mice. Consistent with in vitro function, we could detect the reduced bone mineral density (BMD) of the femurs of 16-week-old Jmjd5?Oc/?Oc mice, when compared with BMD of wild type mice. Taken together, epigenetic regulations, at least methylation and/or demethylation of histone tale, might have an important role in osteoclastogenesis and bone metabolism.

Claudin 18 (Cldn-18), a Novel Bone Resorption (BR) Regulator, Interacts with Zona-occluden-2 (ZO-2) to Modulate RANKL Signaling in Osteoclasts. Gabriel Linares*[1], Robert Brommage[2], David Powell[3], Weirong Xing[4], Catrina Alarcon[1], Anil Kapoor[1], Shin-Tai Chen[1], Kin-Hing William Lau[5], Jon Wergedal[1], Subburaman Mohan[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]Lexicon Pharmaceuticals, USA, [3]Lexicon Pharmaceuticals Inc., USA, [4]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, [5]Jerry L Pettis Memorial VA Medical Center, USA

Cldn-18 is a member of a large family of transmembrane proteins that have been identified as important components of tight junction (TJ) strands. Targeted disruption of Cldn-18 function in mice decreased total body BMD by 18% ($P<0.01$) at 14 wks of age. μCT measurements at mid-diaphysis of femur revealed no significant change in size but a 20% reduction in cortical thickness ($P<0.01$) in knockout (KO) mice. Trabecular (Tb) bone volume at L5 vertebra was 50% less in KO mice ($P<0.001$) due to significant decreases in Tb number (50%) and thickness (20%) and increased Tb separation (50%). Histomorphometric analyses revealed that resorbing surface (87%) and osteoclast (OC) number (60%) were increased significantly in the KO mice without changes in bone formation parameters. Accordingly serum levels of TRAP5b and expression levels of TRAP and cathepsin K (Ctsk) were increased (60%-80%, $P<0.05$) in the femurs of KO mice. In vitro studies with bone marrow macrophages (BMM) revealed that Cldn-18 disruption significantly increased RANKL-induced OC differentiation (80%, $P<0.01$) but not MCSF-induced BMM proliferation. Consistent with a direct role for Cldn-18 in the regulation of OC differentiation are the findings that OCs express Cldn-18 and overexpression of Cldn-18 in RAW264.7 cells significantly inhibited RANKL-induced OC differentiation. We next tested whether Cldn-18 effects on RANKL signaling are mediated in part via interaction of C-terminal PDZ domain of Cldn-18 with PDZ domain containing protein, ZO-2, since certain Cldns interact with ZO proteins and since ZO-2 was highly expressed and regulated by RANKL in OCs. Accordingly, Cldn-18 interacted with ZO-2 by immunoprecipitation and knockdown of ZO-2 using lentiviral shRNA decreased RANKL induced OC differentiation by 50% ($P<0.001$) and expression of TRAP and Ctsk (43% and 58%, $P<0.05$) in RAW264.7 cells. Nuclear translocation of ZO-2 has been linked to increased gene expression. Accordingly, Cldn-18 overexpression decreased RANKL-induced nuclear levels of ZO-2 by 60% in RAW264.7 cells. Furthermore, knockdown of ZO-2 significantly reduced RANKL induced activation of p-NF-kB-Luc and p-NFATc1-Luc reporters. In conclusion, we demonstrate for the first time that Cldn-18 is a novel regulator of BR that acts by a previously undescribed mechanism involving sequestration of ZO-2 in the cytoplasm to prevent its translocation to the nucleus where it modulates the transcription of RANKL target genes.

The Rac1 Exchange Factor Dock5 Is Essential for Bone Resorption by Osteoclasts. Virginie Vives[1], Mélanie Laurin[2], Gaelle Cres[3], Pauline Larrousse[3], Zakia Morichaud[4], Daniele Noel[5], Jean-François Coté[2], Anne Blangy*[6]. [1]CNRS UMR 5535, France, [2]Clinical Research Institute of Montreal, Canada, [3]CNRS UMR 5237, France, [4]CNRS UMR 5236, France, [5]Inserm U844, France, [6]CNRS UMR 5237 CRBM, France

During bone resorption, actin cytoskeleton in osteoclasts undergoes extensive reorganization while these cells polarize and assemble the sealing zone, the actin based adhesion organelle essential for resorption, typical of osteoclasts. RhoGTPase signaling pathways, as major regulators of actin organization and then of cell adhesion and morphology, have essential functions in osteoclast biology. It is of particular importance when podosomes rearrange into the sealing zone, the osteoclast characteristic adhesion structure necessary for bone resorption.

We previously identified Dock5 as an activator of Rac1 whose expression is strongly induced during osteoclastogenesis (Brazier et al., JBMR, 2006). We found that RAW264.7-derived osteoclasts in which Dock5 expression had been suppressed by shRNAs exhibited an important drop in Rac1 activity accompanied by a low mineral matrix resorption activity.

We used transgenic mice with disrupted Dock5 gene (Dock5-/-) to further examine its function in osteoclasts and the incidence on bone in vivo. In line with our previous observations, bone marrow cells from Dock5-/- mice differentiate into osteoclasts that have highly reduced levels of Rac1 activity and are unable to assemble sealing zones. Dock5-/- osteoclasts result defective for bone resorption, shown by absence of pit formation on bone and reduced release of collagen degradation products into the medium. Osteoclasts lacking Dock5 have adhesion and spreading defects, linked to reduced Rac1 and p130Cas activities. Quantitative RT-PCR showed that osteoclast characteristic genes are expressed normally in Dock5-/- osteoclasts, suggesting the differentiation process is mostly unaltered. Furthermore, M-CSF signaling is normal in the absence of Dock5. Dock5-/- mice are osteopetrotic with normal osteoclast numbers, confirming in vivo that Dock5 is essential for bone resorption but not for osteoclast differentiation. We identified a chemical inhibitor of Rac1 activation by Dock5 and showed that it hinders osteoclast resorbing activity. We found that Dock5 expression is mainly restricted to osteoclasts. In particular, it is asbent in bone forming osteoblasts.

Our findings characterize Dock5 as a novel essential actor in bone degradation, predominantly expressed in osteoclasts. Osteoclast resorbing activity is reduced in the presence of chemical inhibitors of Dock5. Taken together, our observations characterize Dock5 as a novel target to develop antiosteoporotic treatments.

Gain of FoxO Function in Osteoclast Precursors and their Progeny Decreases Osteoclastogenesis and Increases BMD in Mice. Elena Ambrogini*, Shoshana Bartell, Li Han, Haibo Zhao, Aaron Warren, Randal Shelton, Xiaohua Qiu, Joseph Goellner, Charles O'Brien, Maria Jose Almeida, Stavros Manolagas. University of Arkansas for Medical Sciences, USA

Skeletal aging is characterized by a decrease in the number of both osteoblasts and osteoclasts and is associated with increased oxidative stress (OS) in mice. Work during the last few years has revealed that FoxO transcription factors are an important defense mechanism against OS and gain or loss of FoxO function in bone has been shown to dramatically alter skeletal homeostasis. Based on evidence that reactive oxygen species (ROS) are required for osteoclast generation and that global combined deletion of FoxO1, FoxO3 and FoxO4 in mice leads to an increase in ROS and osteoclast progenitor number, we investigated here whether FoxO activation in osteoclast progenitors is responsible for the age-related decrease in osteoclast number. To this end, we generated transgenic mice overexpressing FoxO3 in cells of the monocyte/macrophage lineage by crossing FoxO3-flox stop mice with LysM-Cre mice (FoxO3-FS;LysM-Cre). Expression of the FoxO3 transgene was demonstrated in whole vertebrae and bone marrow-derived mature osteoclasts from the FoxO3-FS;LysM-Cre mice; and it was absent in the liver or brain. Strikingly, these mice exhibited a significant increase in BMD, as well as an increase in cancellous bone volume at 3 month of age as determined by micro-CT, in both vertebrae and femora. FoxO3-FS;LysM-Cre mice also exhibited increased trabecular number and decreased trabecular separation. Consistent with the changes in bone, the serum levels of the resorption marker CTx decreased as compared to the controls. Moreover, the mRNA levels of the osteoclast markers TRAP and cathepsin K were decreased in vertebral bone while the osteoblast marker osteocalcin was unaffected. In line with these changes, bone marrow cultures established in the presence of RANKL and M-CSF from FoxO3-FS;LysM-Cre mice exhibited a 30% decrease in osteoclast progenitors and mature osteoclast formation, increased osteoclast apoptosis, but normal macrophage proliferation. Taken together with the results from several other models of genetic manipulation of ROS and FoxOs in cells of the osteoblast lineage, the demonstration of a suppressive effect of FoxOs on osteoclast generation and survival suggests that FoxO activation in response to OS plays a major role in the adverse effects of aging on both osteoblast and osteoclast number. Whether, FoxO3 overexpression interferes with the requirement of ROS for osteoclast generation, function, and survival or has ROS-independent effects requires future work.

Silencing of PTH Receptor 1 in T Cells Blocks the Bone Catabolic Activity of Continuous PTH Treatment Through a TNF and CD40 Dependent Mechanism. Hesham Tawfeek*[1], Brahmchetna Bedi[2], Jau-Yi Li[2], Jonathan Adams[1], Tatsuya Kobayashi[3], M. Neale Weitzmann[1], Henry Kronenberg[3], Roberto Pacifici[1]. [1]Emory University School of Medicine, USA, [2]Emory University, USA, [3]Massachusetts General Hospital, USA

Hyperparathyroidism in humans and continuous PTH treatment (cPTH) in mice cause bone loss by regulating RANKL/OPG production by stromal cells (SCs) and osteoblasts. Recently, it has been reported that T cells are required for cPTH to induce bone loss as the binding of CD40L T cell costimulatory molecule to CD40 in SCs augments the sensitivity of SCs to PTH. However it is unknown whether direct PTH stimulation of T cells is required for cPTH to induce bone loss. Therefore, PTHR1 (PPR) expression in T cells was conditionally silenced by crossing PPR floxed ($PPR^{fl/fl}$) mice with LCK-Cre mice, a strain that expresses Cre recombinase in the early stages (DN2-DN3) of T cell development. Our data revealed that cPTH infusion (80 μg/kg/day for 2 weeks) caused trabecular and cortical bone loss (as measured by μCT), increased biochemical (serum CTX) and histomorphometric indices of bone resorption, and increased in vitro OC formation in control mice ($PPR^{fl/fl}$ and $PPR^{fl/+}$/Lck-Cre mice). By contrast, in $PPR^{fl/fl}$/Lck-Cre mice cPTH induced a significant increase in trabecular bone volume, did not cause cortical bone loss, and induced a smaller increase in bone resorption and in vitro OC formation. The $PPR^{fl/fl}$/Lck-Cre mice, but not the control mice, were protected against the bone catabolic effect of in vivo cPTH treatment due to impaired production of RANKL to OPG by SCs as a result of blunted expression of CD40. Further studies demonstrated that TNF treatment of SC induces CD40 expression and that T cells produce TNF in a PPR activation dependent manner. Moreover, cPTH treatment was neither able to induce bone loss, nor to regulate SC CD40 expression and RANKL/OPG production in $TNF^{-/-}$ mice. These findings indicate that TNF is a downstream mediator of PPR action in T cells. In support of this hypothesis we found that specific silencing of T cell TNF production by adoptively transferring $TNF^{-/-}$ T cell into T cell deficient nude mice blocked the capacity of cPTH treatment to induce bone loss, stimulate bone resorption, and augment CD40 expression and the RANKL/OPG ratio in SCs.

Indeed, mice lacking T cell TNF production had the same altered response to cPTH as mice lacking functional PPR in T cells. Altogether, these findings demonstrate that PPR signaling in T cells plays an essential role in cPTH induced bone loss by promoting SC osteoclastogenic activity through TNF and CD40 signaling.

Deletion of *PTH* Prevents the Premature Aging Phenotype of the *Klotho*-Null Mice. Xiuying Bai*[1], Dinghong Qiu[2], David Goltzman[3], Andrew Karaplis[4]. [1]Lady Davis Institute, Canada, [2]LDI, Canada, [3]McGill University Health Centre, Canada, [4]McGill University, Canada

Mice homozygous for the hypomorphic *Klotho* allele have a short lifespan and show biochemical and morphological features consistent with premature aging. In this study, we have used a mouse genetic approach to investigate *in vivo* the role of PTH in the metabolic and skeletal derangements arising from the absence of *Klotho*. To this end, we crossed mice heterozygous for the hypomorphic *Klotho* allele ($Kl^{+/-}$) to mice heterozygous for the null *Pth* allele and obtained mice homozygous for both the *Kl*-hypomorphic and the *Pth*-null ($Pth^{-/-}/Kl^{-/-}$). Mice were sacrificed and serum and tissues were procured for analysis and comparison to *WT*, $Pth^{-/-}$ and $Kl^{-/-}$ controls.

From 4 weeks onward, $Pth^{-/-}/Kl^{-/-}$ mice were clearly distinguishable from *Klotho*-null mice and exhibited a striking phenotypic resemblance to the $Pth^{-/-}$ controls. The life span of the double mutants increased from 10 weeks to 6 months (as long as they have been observed) as did their body weight, in parallel to the wild type and $Pth^{-/-}$ mice. Serum analysis for calcium, phosphorus, ALP activity, $1.25(OH)_2D_3$, and creatinine confirmed the biochemical similarity between the $Pth^{-/-}/Kl^{-/-}$ and $Pth^{-/-}$ mice and their distinctness from the $Kl^{-/-}$ controls. Interestingly, the extremely high serum FGF23 levels observed in the *Klotho*-null mice were supressed in the double knock-out mice, similar to the serum levels in the wild type mice.The characteristic skeletal changes associated with the absence of *Klotho* were also dramatically converted by the concurrent deletion of *Pth*. Moreover, widespread soft tissue calcification characteristic of the $Kl^{-/-}$ mice was absent in the double mutants.

In summary, our findings substantiate *in vivo* the essential role of PTH in the *Klotho*-null phenotype as its ablation fully reverts the complete spectrum of biochemical and skeletal alternations arising from lack of *Klotho*.

Role of the Transcriptional Co-Activator CITED1 in Bone and its Effect on Anabolic Actions of PTH. Hila Bahar*[1], Jun Guo[2], Dehong Yang[3], Rajaram Manoharan[4], Toshi Shioda[5], Mary Bouxsein[6], F. Richard Bringhurst[2]. [1]MGH & HMS, USA, [2]Massachusetts General Hospital, USA, [3]Endocrine Unit, Massachusetts General Hospital, USA, [4]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, USA, [5]Molecular Profiling Laboratory (T.S.), Massachusetts General Hospital Cancer Center, USA, [6]Beth Israel Deaconess Medical Center, USA

CITED1 is a transcriptional co-activator that interacts directly with CBP/p300 and is capable of enhancing TGF-beta and estrogen-dependent transcription and inhibiting beta-catenin-dependent transcription. CITED1 mRNA expression is rapidly and transiently upregulated by PTH in cultured osteoblasts (Obs) in a manner dependent on cAMP-signaling. Also, the cAMP-mediated Ob-differentiating effect of PTH is selectively suppressed by CITED1 in vitro. Histological observations supported by DEXA measurements indicated that 8-week old CITED1 global knockout C57BL/6 mice (KO) exhibit mild osteopenia, mainly in the primary spongoisa. MicroCT analysis showed a significant reduction in trabecular (Tb) bone volume in KO vertebra, a similar tendency in the Tb bone of the femur and no difference in cortical bone compared to wild type mice (WT). Our is to study the role of CITED1 in PTH's anabolic action on bone. Eight week-old CITED1 KO and WT mice were injected daily with vehicle (VEH), 80 ug/kg of hPTH(1-34) (PTH) or 1600 ug/kg of cAMP-selective PTH analog [G1,R19]PTH(1–28) (GR) for 4 weeks before analysis of blood and bone. MicroCT analysis showed no differences between KO vs. WT VEH-treated controls. PTH significantly augmented both Tb bone at the distal femur (BV/TV, Tb.Th) and cortical thickness at the mid-femur in KO and WT mice, but the overall effect was reduced in KO mice. There was no effect of GR in either WT or KO. BMD of the total body and femur (measured by pDXA) were similar in vehicle-treated KO vs. WT mice. PTH significantly increased BMD in both KO (8%-total body, 10%-femur) and WT (9%, 20%) the increase was significantly less in KO than in WT. GR treatment had no effect on BMD in either WT or KO except for the distal femur that was significantly higher in WT mice (11%). Histological observations were consistent with microCT and pDXA results. Serum P1NP was significantly increased in PTH-treated mice and, to lesser extent, in GR-treated mice in both KO and WT vs. VEH. Serum level of CTX was increased similarly in PTH- and GR-treated WT mice and was not significantly altered in the PTH- and GR-treated KO mice. We conclude that the anabolic effect of PTH and particularly that of the cAMP-selective analog GR, seen in trabecular bone of WT mice is diminished in mice lacking CITED1. CITED1 may be required for a full anabolic response of trabecular bone to PTH.

Anabolic Effects of Intermittent PTH Are Impaired in MAP Kinase Phosphatase-1 Knockout Mice. Manshan Xu*, Li Ma, Shilpa Choudhary, Olga Voznesensky, Douglas Adams, Lawrence Raisz, Carol Pilbeam. University of Connecticut Health Center, USA

Mitogen activated protein (MAP) kinase phosphatase-1 (MKP-1) can dephosphorylate and inactivate MAP kinases, including ERK, p38, and JNK. *Mkp-1* is an immediate early gene, expressed in osteoblasts, and upregulated by many factors, including PTH. The aim of this study was to investigate the effect of *mkp-1* deletion on the anabolic responses to intermittent PTH. We used 4-mo old male mice in a C57BL/6 background with global knockout (KO) of MKP-1 developed by Lexicon Genetics. Mice (n=8-11) were injected subcutaneously with vehicle or PTH (80 µg/kg, 1-34 hPTH) daily for 22 days. Percent change in femoral bone mineral density (BMD) was measured by DXA *in vivo*. Mice were euthanized 3 h after the last injection. Trabecular morphometry within the metaphyseal region of the distal femur and cortex in the femoral shaft were measured by µCT. Blood was obtained by heart puncture at time of euthanasia. Tibiae were extracted for RNA. PTH significantly increased femoral BMD 11% in WT mice and 5% in KO mice, but the difference between WT and KO mice was not statistically significant. By µCT, PTH significantly increased trabecular bone volume per total volume (BV/TV) and trabecular thickness (TbTh) 59% and 33%, respectively, in WT mice compared to vehicle-treated controls. Trabecular spacing (TbSp) and trabecular number (TbN) were similar in vehicle- and PTH-treated WT mice. In MKP-1 KO mice, PTH did not increase BV/TV or TbTh relative to vehicle-treated controls. In addition, there was a trend for TbSp to be increased 10% and TbN to be decreased 10% in PTH-treated KO mice relative to vehicle-treated controls. Following PTH treatment, BV/TV, TbTh, and TbN were all significantly lower in KO compared to WT mice, whereas TbSp was significantly higher. Analysis by µCT also showed that PTH stimulated significant increases (20%) in femoral cortical bone thickness and area in WT but not KO mice. PTH increased serum markers of formation (P1NP) and resorption (TRAP 5b and CTX) and gene expression for alkaline phosphatase and RANKL / OPG similarly in WT and KO mice. These data indicate that the anabolic effects of intermittent PTH are impaired by the deletion of *mkp-1* and suggest an important role for MAP kinases in the anabolic effects of intermittent PTH.

Signaling Mechanisms Underlying Prolonged Calcemic Actions of Long-Acting PTH Analogs. Akira Maeda*[1], Makoto Okazaki[2], Jun Guo[1], Henry Kronenberg[1], John Potts[1], Thomas Gardella[1]. [1]Massachusetts General Hospital, USA, [2]Chugai Pharmaceutical. Co., Ltd., Japan

We recently reported that high-affinity, N-terminally modified PTH peptide analogs, e.g. and M-PTH(1-34) (M=Ala1,Aib3,Gln10,Har11,Ala12,Trp14,Arg19), produce prolonged calcemic responses in mice following single injection, as compared to PTH(1-34) (Okazaki et al. P.N.A.S. 2008). The unique feature appears to be a prolonged response at constant amplitude, rather than a brisk initial response that subsides over time. The analogs could thus be useful as treatments for hypoparathyroidism. The prolonged responses are not simply explainable by pharmacokinetics, but the underlying molecular and cellular mechanisms, and how they might differ from those mediating the calcemic actions of native PTH, are not well understood. To address these questions, we first compared the blood Ca++ responses induced in normal mice by M-PTH(1-34) at a dose of 10 nmole/kg to those induced by hPTH(1-34) at the higher dose of 100 nmole/kg. We found that the high dose of hPTH(1-34) produced a brisk calcium rise that peaked at two-hours post-injection, and declined to basal by six hours. The M-PTH(1-34) response showed a slightly lower maximum at two-hours, but the elevated levels were maintained for at least four hours, and did not return to basal until 24 hours post injection. To next address the signaling pathways involved, we compared the calcemic actions of M-PTH(1-28), which signals through both the cAMP/PKA and IP3/PKC pathways, to those of Trp1-M-PTH(1-28), which signals efficiently through the former, but not the latter pathway. To compensate for the three-fold lower binding affinity of the Trp1 analog versus that of M-PTH(1-28), the peptides were injected at doses of 20 nmole/kg and 60 nmole/kg, respectively. The resulting blood Ca++ response profiles were largely overlapping, and each was sustained, as compared to that of hPTH(1-34). We further utilized mice having the endogenous PTHR allele homozygously replaced by one encoding a PTHR mutant (DSEL) that is deficient for PLC signaling. These mice produced Ca++ responses to M-PTH(1-28) that were sustained, equivalently to those observed in wild-type mice. Overall, the results suggest that 1) the new long-acting PTH ligands induce increases in blood Ca++ by mechanisms which differ from those utilized by PTH(1-34); and 2) the sustained responses are achieved mainly via the cAMP/PKA signaling pathway. We hypothesize that the mechanisms differ at the level of receptor-interaction and signaling in target cells. In support of this, we found that cAMP levels in homogenates of kidneys obtained from wild-type mice at times after injection with M-PTH(1-34) were elevated for longer times, as compared to with PTH(1-34). Defining more precisely the PTHR signaling and trafficking pathways used by these long-acting PTH analogs in target tissues should further our capacity to treat PTH-related diseases.

Intact Neuropeptide Y Circuit Required for Full Anabolic Response to Parathyroid Hormone in Mice. Natalie Sims[1], Ingrid Poulton[2], Susanna Rossotti[3], Leah Worton[4], Rena Hirani[5], Herbert Herzog[6], Edith Gardiner*[4]. [1]St. Vincent's Institute of Medical Research, Australia, [2]St Vincent's Medical Research Institute, Australia, [3]UQ Diamantina Institute, Australia, [4]University of Washington, USA, [5]Australian Institute for Bioengineering & Nanotechnology, Australia, [6]Garvan Institute of Medical Research, Australia

Neuropeptide Y (NPY) suppresses bone formation via a neural circuit involving both hypothalamic Y2 receptors and osteoblastic Y1 receptors. Germline Y1 or Y2 gene deletion results in enhanced bone formation, and osteoblastic Y1 expression is absent in both Y1 and Y2 knockout (KO) mice. Parathyroid hormone (PTH), a potent anabolic agent for bone, can induce Y1 expression in cultured murine osteoblastic cells, indicating cross-talk between NPY and PTH receptors in bone-forming cells. The present study investigated the interaction between these two anabolic regulatory pathways in the Y2KO mouse model. Male 12 week-old mice were treated with hPTH(1-34) (0.05 mg/kg body weight, 5 days/week for 3 weeks, n=10/group) by subcutaneous injection, with intraperitoneal calcein (10 mg/kg) at days 10 and 19 for histomorphometric analysis of trabecular bone in proximal tibia. As anticipated, PTH exposure significantly increased trabecular bone volume and trabecular thickness in wild type (WT-PTH) mice compared to vehicle (WT-veh) controls; unexpectedly however, neither parameter was significantly affected by PTH treatment in Y2KO-PTH mice. Osteoblast, osteoid and osteoclast surfaces were significantly and similarly elevated in PTH-treated mice of both genotypes (3.1-, 2.9- and 1.8-fold, respectively). PTH treatment also increased single calcein-labeled surface 1.3- to 1.5-fold in WT and Y2KO mice. In contrast,double calcein-labeled surface was significantly reduced (by 53%) in Y2KO-PTH but was not significantly modified in WT-PTH mice. Furthermore, while mineral apposition rate and bone formation rate were significantly increased (1.5- and 1.4-fold) in WT-PTH, there was no change in this parameter in Y2KO-PTH. Y2KO-PTH mice also demonstrated a significant increase (1.7-fold) in osteoid thickness; a change that was not observed in WT-PTH mice. Consistent with these results, although mineralization lag time was significantly increased in both PTH-treated groups, the effect was significantly greater in the Y2KO mice (2.9-fold increase in Y2KO vs 1.8-fold in WT). In summary, genetic ablation of Y2 receptor impaired the response of bone to anabolic intermittent administration of hPTH(1-34), leading to an accumulation of osteoid and longer mineralization lag time in the Y2-deficient animals. The results suggest that in addition to modulating mesenchymal progenitor cell populations, disruption of NPY signaling may also inhibit PTH-stimulated mineralization by mature osteoblasts.

Greater Baseline Lean Mass is Associated With Increased Hip Fracture Risk in Elderly Women: The Framingham Study. Alyssa Dufour*[1], Marian Hannan[2], Kerry Broe[3], Xiaochun Zhang[1], Douglas Kiel[1], Robert McLean[4]. [1]Hebrew SeniorLife, USA, [2]HSL Institute for Aging Researchand Harvard Medical School, USA, [3]Hebrew Senior Life, USA, [4]Hebrew SeniorLife, Harvard Medical School, USA

Reduced muscle mass (sarcopenia) is associated with weakness and poor functioning in elders, yet few data exist on its relation with hip fracture. We previously showed that greater leg lean mass was unexpectedly associated with increased hip fracture risk among older women in the Framingham Original Cohort. Leg lean mass, however, does not account for other muscles that may influence fracture risk or account for body size, and thus may not reflect whether an individual has adequate muscle mass to prevent falls that lead to fracture. As no accepted criteria exist for sarcopenia, we examined whether several measures of sarcopenia predicted hip fracture in women of the Framingham Original Cohort. We hypothesized that higher muscle mass would be associated with lower hip fracture risk even after adjusting for confounders. 419 women with baseline (1992-93) whole body DXA scans (Lunar DPX-L) were followed for incident hip fractures through 12/31/2007. Continuous measures of sarcopenia (lower value=less mass) calculated from DXA scans included: total body lean mass (LM; kg), appendicular lean mass (aLM; arm + leg lean mass, kg); relative lean mass accounting for height (rLM; aLM/ht^2; kg/m^2) as well as the categorical low rLM (poor mass) as rLM£5.67 kg/m^2. Cox proportional hazards regression was used to calculate hazard ratios (HR) and 95% confidence intervals (CI) estimating the risk of hip fracture for each unit increase in LM, aLM and rLM, as well as the risk for those with low rLM vs. those without. Initial analyses adjusted for baseline age (y), weight (lbs), height (in), and physical activity, followed by adjustment for femoral neck bone mineral density (BMD, g/cm^2). Mean age at baseline was 78 y (range 70-92 y) and 59 hip fractures occurred over median follow-up of 10.4 y. Each kg increase in LM and aLM was associated with a 26 and 29% increased hip fracture risk, respectively (Table). The relation was a bit stronger for rLM, with a 1 unit increase associated with an 84% higher fracture risk, however low rLM was not associated with hip fracture risk. The CIs included the null after BMD adjustment, yet HRs were only slightly attenuated. These results confirm our previous unexpected findings of a direct association between lean mass and risk for hip fracture. Future studies should use more precise assessments of physical activity and consider the potential role of sarcopenic obesity in the relation between muscle mass and hip fracture.

Multivariable-adjusted HRs and 95% CIs for risk of hip fracture for different sarcopenia definitions in women from the Framingham Original Cohort

Sarcopenia measure	Mean (SD) or %	HR (95% CI)	
		Model 1*	Model 1 + BMD
LM (kg)	16.31 (2.28)	1.26 (1.02, 1.54)	1.20 (0.97, 1.48)
aLM (kg)	14.96 (2.01)	1.29 (1.03, 1.63)	1.23 (0.97, 1.56)
rLM (kg/m^2)	6.72 (0.77)	1.84 (1.11, 3.03)	1.62 (0.97, 2.72)
Low rLM (yes vs. no)	7.16%	0.99 (0.33, 3.0)	1.05 (0.35, 3.17)

Higher Total Protein Intake Associated With Greater Lean Mass and More Favorable Ratio of Low Lean-to-Fat Mass Ratio in Middle-Aged Men and Women: The Framingham Osteoporosis Study. Shivani Sahni*[1], Robert McLean[2], Douglas Kiel[3], Kerry Broe[4], Katherine Tucker[5], L Adrienne Cupples[6], Marian Hannan[7]. [1]Hebrew SeniorLife, Institute for Aging Research, Harvard Medical School, USA, [2]Hebrew SeniorLife, Harvard Medical School, USA, [3]Hebrew SeniorLife, USA, [4]Hebrew Senior Life, USA, [5]Northeastern University, USA, [6]Boston University School of Public Health, USA, [7]HSL Institute for Aging Researchand Harvard Medical School, USA

Protein intake influences muscle mass in younger persons and athletes. Aging is associated with body composition changes, including increases in fat mass (FM) and decreases in lean mass (LM). In one study, protein at RDA level appeared to preserve LM across 3-y in older adults (ages 70-79y). In another study protein was associated with reduced FM among obese subjects. It is unclear what the associations between protein intake and LM (as well as FM) may be in a population of middle-aged men and women. Therefore, we evaluated associations of total protein intake with measures of LM in the Framingham Offspring Cohort. 2,272 participants had a food frequency questionnaire (from either 1995-98 or 1998-2001) and a whole body DXA scan using a Lunar DPX-L (1996-2001). Quartiles of total protein intake (g/day) were created, adjusting for total energy intake (residual method). DXA scans were used to derive leg LM (both legs in kg) and total LM (kg). Participants were also classified (y/n) as having a low lean-to-fat mass ratio (low lean: fat; the lowest sex-specific quintile of total LM to FM ratio). Analysis of covariance was used to compare the least squares-mean leg LM and total LM among quartiles of protein intake and test for a linear trend. Logistic regression was performed to calculate the odds ratio (OR) and 95% confidence intervals (CI) for low lean:fat in each of the upper 3 protein quartiles compared to the lowest quartile (Q1). All models were adjusted for sex, age, height, and total energy intake. Models for leg LM and total LM were additionally adjusted for leg % fat and total % fat, respectively.

Mean age was 55 y (SD=9.6 y, range: 26-86y). Leg LM averaged 14.04 $\pm$ 3.4 kg and total LM averaged 43.28 $\pm$ 10.2 kg. Higher protein intake was associated with greater leg LM (P trend$<$0.001) and total LM (P trend= 0.03, table 1). Those in protein intake quartiles 3 and 4 had 30% (95%CI 0.51-0.96) and 46% (95%CI 0.40-0.73) lower odds of low lean:fat compared to those in Q1, and the trend across quartiles was statistically significant (P$<$0.01).

Our results suggest that higher protein intake is associated with greater leg and total LM in middle-aged men and women. Further, higher protein intake was associated with lower risk of having a low lean-to-fat mass ratio. Future studies should examine the effect of different types of protein intake on age-related loss of LM. As in the elderly participants of the Health ABC cohort, perhaps improving protein intake, even in middle-aged men and women, may help in preserving LM, across the adult age spectrum.

Table 1. Least squares-adjusted leg and total LM, and ORs (95% CIs) for low lean:fat[1], for quartiles of protein intake in middle-aged men and women of the Framingham Offspring Study.

	n	Protein Intake Quartile				*P* trend
		Q1 (low)	Q2	Q 3	Q 4 (high)	
Median protein intake (g/d)		60	66	75	96	
Lean Mass, Mean ± SE[2]						
Leg Lean Mass (Kg)	2791	14.07 ± 0.06[a]	14.31 ± 0.06[b]	14.30 ± 0.06[b]	14.40 ± 0.06[b]	0.0003
Total Lean Mass (Kg)	2266	44.51 ± 0.17	44.68 ± 0.17	44.79 ± 0.17	45.01 ± 0.17	0.03
Low Lean:Fat[1] (%)		15.9	17.6	21.2	25.1	
Low Lean:Fat, OR (95%CI)	1813	1.0	0.90 (0.66-1.23)	0.70 (0.51-0.96)	0.54 (0.40-0.73)	0.007

Association between Diabetes and QCT Measures of Bone Strength and Prevalent Vertebral Fracture: The Framingham Study. Elizabeth Samelson*[1], Mary Bouxsein[2], Serkalem Demissie[3], Blaine Christiansen[4], Kerry Broe[5], Xioachun Zhang[6], R. Manoharan[7], J. D'Agostino[8], Thomas Lang[9], L. Adrienne Cupples[3], Douglas Kiel[6]. [1]Hebrew SeniorLife, Harvard Medical School, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Boston University School of Public Health, USA, [4]University of California - Davis Medical Center, USA, [5]Hebrew Senior Life, USA, [6]Hebrew SeniorLife, USA, [7]Beth Israel Deaconness Medical Center, USA, [8]Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, USA, [9]University of California, San Francisco, USA

Older adults with type 2 diabetes mellitus (DM) have greater BMD yet increased risk of fracture, particularly at peripheral sites, compared to those without DM. At the spine, DM has been shown to increase, decrease or have no association with BMD and fracture. It is difficult to use DXA areal BMD (aBMD) to compare fragility at the spine in persons with and without DM as DXA overestimates aBMD in individuals with larger bones, degenerative conditions and aortic calcification. Moreover, DXA cannot distinguish trabecular bone, the compartment most affected by DM, from cortical bone, and does not allow measures of bone geometry that may be compromised in DM. Some previous studies relied on self-reported DM, clinically diagnosed VF, or were limited to highly selective populations. We compared volumetric QCT measures of the spine and vertebral fracture (VF) prevalence in community-dwelling adults by DM status.

Participants included all 209 individuals with DM (cases) and 418 individuals without DM (controls), selected by stratified random sampling by 5-yr age and sex groups, from 3,479 participants of the Framingham Study who had QCTs in 2002-06. DM was defined by fasting plasma glucose level >126 mg/dl or use of insulin or oral hypoglycemic agents. Custom software (T. Lang, UCSF) was used to measure trabecular, cortical, and integral vBMD, and average cross-sectional area (CSA) of L3. Compressive strength was estimated from CSA and integral vBMD. VF was defined as semi-quantitative grade >1 (mild) assessed from CT lateral scanograms. Regression models were used to compare mean bone measures and prevalence and severity of VF according to DM status, adjusted for age and weight.

Mean age was 64 years, range 40-87. Integral vBMD was 6% higher in women with DM, but trabecular and cortical vBMD, CSA, and compressive strength were similar in cases and controls (TABLE). In men, no differences in bone measures were seen by DM status. Prevalence, number, and severity of VF did not differ by DM status in women or men, however, frequency of persons with >2 VF (7%) or > grade 2 (moderate-severe) VF (3%) was low.

We did not find increased fracture at the spine in persons with DM, and QCT measures of bone strength were similar (or somewhat better) for those with DM. Increased fracture at peripheral sites previously reported for those with DM, but not at the spine in our study, suggests that DM may exert site-specific effects on skeletal fragility.

TABLE. Mean QCT measures of vBMD, cross-sectional area, and compressive strength and fracture prevalence at the spine, adjusted for age and weight, according to diabetes status in women and men in the Framingham Study

	Women			Men		
	Diabetes N=100	No Diabetes N=198	P	Diabetes N= 109	No Diabetes N=220	P
Cross-sectional area (cm^2)	10.181	10.371	0.31	12.389	12.625	0.13
Trabecular vBMD (g/cm^3)	0.140	0.130	0.11	0.137	0.137	0.96
Integral vBMD (g/cm^3)	0.186	0.174	0.04	0.184	0.182	0.71
Cortical vBMD (g/cm^3)	0.230	0.225	0.17	0.247	0.241	0.24
Compressive strength (Newtons)	3889	3705	0.20	4675	4722	0.78

Multi-Phenotype Genome-Wide Association Analysis (GWAS) on both BMD and Glycemic Traits Identified Novel Pleiotropic Genes that Affected Bone Metabolism and Glucose Homeostasis in Caucasian Populations. Yi-Hsiang Hsu*[1], Xing Chen[2], James Meigs[3], L. Adrienne Cupples[4], David Karasik[5], Douglas Kiel[5]. [1]Hebrew SeniorLife & Harvard Medical School, USA, [2]Harvard School of Public Health, USA, [3]Massachusetts General Hospital & Harvard Medical School, USA, [4]Boston University School of Public health, USA, [5]Hebrew SeniorLife, USA

Epidemiological studies suggest that T2DM patients are at increased risk of osteoporotic fractures. A recent rodent study showed that osteocalcin was involved in endocrine regulation of glucose homeostasis, which provided directly evidence linking the skeleton to the pathogenesis of diabetic complications. However, the underlying mechanisms of how the skeleton interacts with glucose homeostasis remain largely unclear. Significantly genetic correlations for BMD with fasting glucose and insulin in the Framingham Study indicates that shared genetic determinants may regulate both bone and energy metabolism. To identify pleiotropic genes associated with both BMD and glycemic traits, we performed a multiple-phenotypes genome-wide association analysis in the Framingham Study by modeling both BMD and glycemic phenotypes simultaneously using our newly developed approach, empirical-weighted linear-combined test statistics (eLC). eLC is a method to directly combine correlated test statistics with a weighted sum of univariate test statistics to maximize the heritability of the overall association tests. From simulation, our eLC approach has outperformed the simple look-up on the overlaps among uni-variate GWAS and traditional methods (such as GEE and PCA). BMD at the lumbar spine (LS) and femoral neck (FN) was measured by DXA. Fasting plasma insulin, proinsulin (radioimmunoassays) and glucose levels (hexokinase) were measured. Affymetrix 550K Gene chips were genotyped and 2.5 millions SNPs were imputed based on HapMap CEU phase II panel. A total of 3,569 Framingham participants (Caucasian with mean age of 61 years old; 1,531 Men and 2,038 women) were analyzed. We first performed univariate GWAS on these 5 phenotypes using linear mixed effects models with adjustment for age, sex, height, weight, ancestral genetic background and pedigree structure. We then applied the eLC method to combine test statistics from univariate analyses. P-values of the multi-phenotype association tests were estimated by permutation. Several associations achieved GWS level ($p < 5x10^{-8}$), i.e. SNPs in or near *TMEM16D, PGAP1, IQCJ* genes. Several suggestive GWS ($p < 5x10^{-6}$) loci were also found, i.e. *KLF14, CHIN, TNFRSF11B, TGFBI, ITGA1, and NPSR1*. Pathway analyses suggested significant clustering of genes involved in cell-cell connection and endocrine metabolism for T1DM. These top associated SNPs are being further evaluated in GEFOS (n=32,000) and MAGIC (n=36,610) consortia. In conclusion, our results reveal novel pleiotropic genes to further elucidate the link between the skeleton and energy metabolisms.

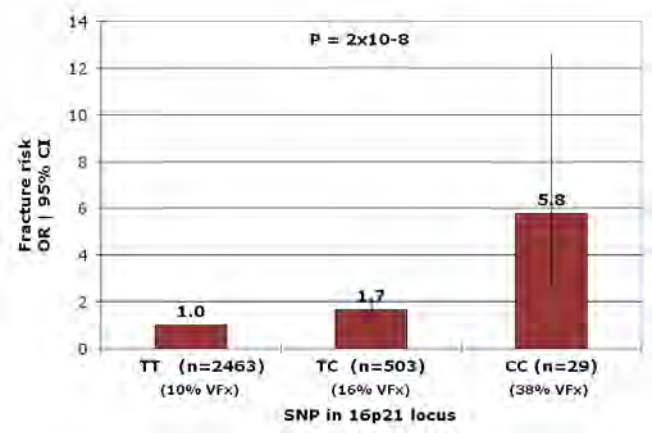
Genome-wide Association In the Rotterdam Study Implicates the 16p21 Locus As Determinant of Osteoporotic Vertebral Fractures. Ling Oei*[1], Karol Estrada[2], Martha C. Castano-Betancourt[3], Marjolein van der Klift[4], Hannneke Kerkhof[3], Albert Hofman[3], Huibert Pols[2], Lisette Stolk[3], Joyce B. van Meurs[3], M. Carola Zillikens[3], Andre Uitterlinden[5], Fernando Rivadeneira[2]. [1]Erasmus Medical Center, Nld, [2]Erasmus University Medical Center, The netherlands, [3]Erasmus MC, Netherlands, [4]Erasmus, Netherlands, [5]Rm Ee 575, Genetic Laboratory, The netherlands

Risk for vertebral fractures (VFx), the most common osteoporotic fractures, is a heritable complex trait. No genome-wide association studies (GWAS) searching for genetic susceptibility factors for VFx have been reported to date. The aim of this study was to perform a GWAS for VFx in a large population-based study of Dutch individuals (age >55 years). Radiographs of the thoracolumbar spine were scored for presence of osteoporotic VFx using the McCloskey/Kanis method. Genetic data was available in 329 VFx cases and 2666 controls. We tested 2,543,887 imputed (HapMap CEU release 22, build 36) SNPs for association with risk for VFx using a logistic regression model (MACH2DAT) adjusted for age, sex, and admixture principal components. At a genome-wide significant α-level (GWS) of $5x10^{-8}$, the design has 0.80 power to detect risk effect sizes (OR) of 1.7 to 2.4 for minor allele frequencies (MAF) of 0.20 to 0.05, respectively. A SNP on chromosome 16p21 (MAF=0.10) was associated at GWS level ($P=2x10^{-8}$) with an increased risk for VFx. Heterozygous carriers of the minor allele have 1.7-fold (95%CI: 1.3-2.2) and homozygous carriers 5.8-fold (95%CI: 2.6-12.6) increased risk compared to non-carriers. The VFx-associated SNP maps in a region previously found associated with lumbar spine BMD (LS-BMD) in a meta-analysis of 19,125 individuals, yet represents an independent signal from the reported BMD SNP (LD $r^2=0.002$). The VFx-associated SNP was not associated with LS-BMD. *FOXC2* is a strong candidate gene in the region mapping ~200 Kb upstream from the associated SNP. *FOXC2* is a transcription factor shown to be essential for axial skeletogenesis in mice, highly expressed in human bone tissue and involved in osteoblast differentiation through activation of canonical Wnt-β-catenin signals. Inactivating mutations affecting the FOX gene cluster cause severe vertebral malformations in humans. In conclusion, our findings implicate the 16p21 locus as a strong determinant for osteoporotic VFx. Pleiotropic effects of *FOXC2* are potentially driving these associations with LS-BMD and VFx. Replication within the GEFOS/GENOMOS consortia is currently underway to confirm this finding.



Vertebral fracture risk by 16p21 SNP genotype groups

Meta-analysis of Genome-Wide Association Study (GWAS) Identifies Several Genes for Hip Bone Geometry in Caucasians: The Genetic Factors for Osteoporosis (GEFOS) Consortium. Yi-Hsiang Hsu[1], Thomas Beck[2], Suzanne J Brown[3], Jane Cauley[4], Serkalem Demissie[5], Karol Estrada[6], Nicole Glazer[7], Stephen Kaptoge[8], Douglas Kiel[9], Brent Richards[10], Fernando Rivadeneira[6], John Robbins[11], Nicole Soranzo[12], Tim Spector[12], Elizabeth Streeten[13], Andre Uitterlinden[14], Scott Wilson[15], Laura Yerges-Armstrong[16], Carola Zillikens[17], David Karasik*[9]. [1]Hebrew SeniorLife & Harvard Medical School, USA, [2]Johns Hopkins Outpatient Center, USA, [3]Sir Charles Gairdner Hospital, Australia, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]Boston Univ. SPH, USA, [6]Erasmus University Medical Center, The netherlands, [7]University of Washington, USA, [8]University of Cambridge Bone Research Group, United Kingdom, [9]Hebrew SeniorLife, USA, [10]King's College London & McGill University, United Kingdom, [11]University of California, Davis Medical Center, USA, [12]King's College London, United Kingdom, [13]University of Maryland School of Medicine, USA, [14]Rm Ee 575, Genetic Laboratory, The netherlands, [15]Sir Charles Gardner Hospital, Australia, [16]University of Maryland, USA, [17]Erasmus MC, Netherlands

Hip geometry has been shown to be an important predictor of fracture. We performed meta-analysis in several large GWAS studies to identify genes associated with proximal femoral geometry phenotypes. We analyzed femoral neck length (FNL), neck-shaft angle (NSA), and narrow neck section modulus (NNZ) estimated by hip structure analysis (HSA) algorithms from DXA scans. GWAS results from the Rotterdam Study (RS, n=4102), Framingham Osteoporosis Study (FOS, n=3414), TwinsUK Study (TUK, n=3815 women), Amish Family Osteoporosis Study (n=806), Erasmus Rucphen Family Study (ERF, n=758), and Cardiovascular Health Study (n=337), were meta-analyzed, with a total of 9132 women and 4100 men (age range 16-93 years).

In each cohort, ~2.5 mil autosomal SNPs were imputed from the International HapMap Project CEU reference panel II, and sex-specific and sex-combined association analyses were performed under an additive model adjusted for age, age^2, height, and BMI. A weighted Z statistic-based fixed-effect meta-analysis implemented in METAL was performed. Since the genomic inflation factor λ_{GC} ranged from 0.996 to 1.049 across different traits, we applied a conservative double-genomic control correction. The genome-wide significance threshold was set at $p<5x10\text{-}8$.

Most significant associations - with FNL in both sexes - were observed over a long region on chromosome 10q24, where cytochrome P450 family member *CYP17A1* is mapped. As follows from the Table, suggestive associations were found between transmembrane proteins *TPRA1*/*GPR175* and NSA and *TMEM38B* and FNL. Also, several sex-specific associations were found, such as an association between forkhead box Q1 (*FOXQ1*) with NSA, and OR4K14 with NNZ, both in women.

In conclusion, we found associations between hip geometry measures and genes belonging to several pathways, most prominently *CYP17A1*, which is located in a previously reported QTL linked to femoral neck cross-sectional geometry. This enzyme catalyzes key steps in human adrenal steroid biosynthesis, therefore participates in sexual development earlier in life. Further replication in additional independent samples is underway to maximize power as well as to determine the relation with hip fractures.

Osteocyte-Independent Mechanotransduction of Interstitial Fluid Flow. Ronald Kwon*, Diana Meays, Alexander Meilan, Natalie Kardos, John Frangos. La Jolla Bioengineering Institute, USA

Skeletal adaptation to mechanical loading has long been hypothesized to involve the stimulation of osteocytes by interstitial fluid flow (IFF). Recently, Tatsumi et al. generated mice possessing a diphtheria toxin (DT) receptor transgene driven by the DMP1 promotor (DMP1-DTR), allowing for inducible osteocyte ablation by administration of DT [1]. While these authors found that osteocyte ablation conferred resistance to bone loss upon hindlimb suspension (HLS), mechanotransduction upon reloading was normal, giving rise to the intriguing possibility that loading-induced IFF may be sensed by cells other than osteocytes. We recently developed a microfluidic system for modulating femoral intramedullary pressure (ImP) in alert mice, and showed that the generation of dynamic ImP significantly increased IFF within lacunae and protected against bone loss in mice subjected to HLS [2]. Using this system, we investigated the effects of osteocyte ablation on IFF-induced adaptation. 16wk F wildtype (WT) and transgenic (Tg) DMP1-DTR mice were subjected to HLS for 14d. One limb was exposed to dynamic ImP/IFF (3min/d, 5Hz, peak flow rate: 5uL/s); the other limb served as a sham control. Mice were administered DT (10 or 50ug/kg) 1d prior to HLS and a booster 7d later. BMD and structural indices were quantified at the lesser trochanter using pQCT and uCT [2]. Osteocyte ablation was confirmed by observing empty lacunae (~30%) in H&E-stained sections from Tg mice. In both WT and Tg mice, we observed significant gains in BMD, trabecular volume fraction (BV/TV), cortical thickness (Ct.Th), and cortical area (Ct.Ar) in limbs exposed to flow compared to sham controls (Table 1). In addition, a significant increase in trabecular thickness (Tb.Th) was observed in Tg mice. Interestingly, relative gains (i.e., flow-no flow) in all parameters were greater in Tg mice, indicating that osteocyte ablation did not affect, or even enhanced skeletal adaptation to flow. In particular, rBMD and rTb.Th were significantly different between WT and Tg mice administered 10 or 50ug/kg DT (Table 1). Taken together, osteocyte ablation does not abrogate skeletal adaptation to dynamic ImP/IFF, suggesting that this response occurs independently of flow-induced stimulation of osteocytes. In addition, osteocyte ablation may enhance the response to dynamic ImP/IFF, perhaps by altering the function and/or number of other types of cells within bone.

Parameter (flow – no flow)		WT (n=15)	Tg+10ug/kg DT (n=11)	Tg+50ug/kg DT (n=5)	One-way ANOVA
	rBMD (mg/ccm)	15.7±4.0**	18.9±6.9*	48.2±17.0*	p<0.05
	rBV/TV (%)	5.8±1.0***	7.0±1.5***	7.0±1.3***	NS
	rTb.Th (um)	0.3±3.1	13.0±3.0**	19.2±1.6***	p<0.01
	rCt.Th (um)	10.9±3.7*	16.2±3.7**	17.3±6.5	NS
	rCt.Ar (mm^2)	0.07±0.02**	0.09±0.02**	0.09±0.03	NS

Table 1. Osteocyte ablation does not affect or enhances skeletal adaptation to dynamic IFF. Values (presented as mean±SE) are relative differences between limbs exposed to dynamic IFF vs. contralateral controls (i.e., flow – no flow) for WT and Tg mice administered 10 or 50ug/kg DT. For WT mice, no differences in relative values were observed for mice administered 10 or 50ug/kg DT, thus for statistical analysis these groups were combined. *,**, or *** indicate $p<0.05$, $p<0.01$, or $p<0.001$ obtained using a one-sample t-test with an assumed zero mean. One-way ANOVA revealed a statistically significant difference between groups (i.e., WT, Tg+10ug/kg DT, and Tg+50ug/kg DT) for rBMD and rTb.Th.

Beta-1 Adrenergic Administration Mitigates Negative Changes in Cancellous Bone Microarchitecture and Inhibits Osteocyte Apoptosis During Disuse. Joshua Swift*[1], Sibyl Swift[2], Matthew Allen[3], Florence Lima[2], Susan Bloomfield[2]. [1]United States Navy, USA, [2]Texas A&M University, USA, [3]Indiana University School of Medicine, USA

The sympathetic nervous system (SNS) plays a vital role in mediating bone remodeling. However, the exact role that beta-1 adrenergic (Adrb1) receptors have in this process has not been elucidated. We have previously demonstrated the ability of dobutamine (DOB), primarily an Adrb1 receptor agonist, to mitigate disuse-induced reductions of cancellous bone formation and bone mass at mixed bone sites. The purpose of this study was to characterize the independent and combined effects of DOB and hindlimb unloading (HU) on cancellous bone microarchitecture (by micro-CT), osteocyte apoptosis, and expression of pro- and anti-apoptotic proteins. Male Sprague-Dawley rats, aged 6-mos, were assigned to either normal cage activity (CC) or HU (n=18/group). Animals were given one daily bolus dose (4 mg/kg BW/d) of DOB (n=9) or an equal volume of saline (VEH; n=9). Unloading resulted in significantly lower distal femur BV/TV (-33%), Tb.Th (-11%), and Tb.N (-25%) compared to ambulatory controls (CC-VEH). DOB treatment during HU attenuated these changes, resulting in greater BV/TV (+29%), Tb.Th (+7%), and Tb.N (+21%) vs. HU-VEH. Distal femur cancellous vBMD (+11%) and total BMC (+8%) were significantly greater in DOB- vs. VEH-treated HU rats. Administration of DOB during HU resulted in significantly greater OS/BS (+158%) and Ob.S/BS (+110%) vs. HU-VEH group. Furthermore, Oc.S/BS was significantly greater in HU-DOB (+110%) vs. CC-VEH group. DOB treatment during unloading fully restored bone formation similar to cage control values, resulting in significantly greater BFR (+3-

fold) than in HU-VEH rats. HU resulted in increased prevalence of apoptotic cancellous osteocytes (+85%) vs. CC-VEH, and this increase was prevented with DOB treatment. Osteocyte apoptosis in HU-VEH was associated with greater Bax/Bcl-2 mRNA levels (resulting from increased Bax), and this ratio was not changed in HU-DOB group. Altogether, these data indicate that Adrb1 treatment during disuse mitigates negative changes in cancellous bone microarchitecture and bone mass by inhibiting increases in osteocyte apoptosis and maintaining bone formation. Our findings also suggest that, contrary to findings with Adrb2 receptor agonist treatment, there were no deleterious effects of Adrb1 agonist administration on cancellous bone in weightbearing controls.

Baseline Bone Turnover Declines with Age but Does Not Limit the Anabolic Response to Mechanical Loading in Mice. Michael Brodt[1], Michelle Lynch[1], Daniel Wood[1], Roberto Civitelli[2], Matthew Silva*[2]. [1]Washington University, USA, [2]Washington University in St. Louis School of Medicine, USA

With aging, the skeleton may become less responsive to mechanical stimuli. Yet we recently reported that aged (22-month old) mice do not have a diminished response to tibial compression compared to young-adult (7-month) mice. In the current study, we extended the age range to include younger, growing mice and asked if the anabolic response to loading depended on the baseline level of bone turnover. After approval from our Animal Studies Committee, female BALB/c mice were studied at 2, 4, 7 and 12 months of age. First, to establish baseline levels of systemic and local bone turnover, mice were euthanized without loading (n=8/age). Serum markers of bone turnover (osteocalcin, CTX) decreased significantly with age. Moreover, qPCR revealed age-related declines in bone turnover in the tibia. Expression of genes associated with bone formation (Alp, Osx, Bmp2) and resorption (Ctsk) were highest at 2 mo and lowest at 7-12 mo. These data confirmed that bone turnover is highest in young mice and declines with age. Next, we subjected the hindlimbs to axial tibial compression in vivo. Peak force values were chosen to produce an estimated peak endocortical strain of -1300 με at the mid-diaphysis. Under anesthesia, right legs were loaded 60 cycles/day, 3 days/wk; left legs were not loaded (control). Changes in bone structure due to loading were evaluated in a 6-week study (n=9/age). Tibias were scanned by in vivo microCT at 0, 3 and 6 weeks. Cortical bone size increased with tibial compression, independent of age (Fig. 1). Cortical bone volume (BV) increased from 0 to 6 weeks in loaded tibias from each age group ($p<0.05$), but did not change in control tibias ($p>0.05$). Cortical bone volume was greater in loaded tibias than controls at 6 wks. Changes in gene expression due to loading were evaluated in a 1-week study (n=4/age). Loading caused a significant upregulation of some genes related to bone turnover, but only in older animals. In particular, expression of Alp and Osx was not stimulated above control levels in the younger animals, yet was significantly increased in loaded limbs of 12 mo animals ($p< 0.05$). In summary, despite the decline in baseline bone formation with age, we found no evidence of an age-related loss of cortical mechanoresponsiveness. Taken together, our data indicate that loading overcomes the age-related decline in bone formation perhaps by increasing the number of committed osteoblasts to levels seen in growing animals.

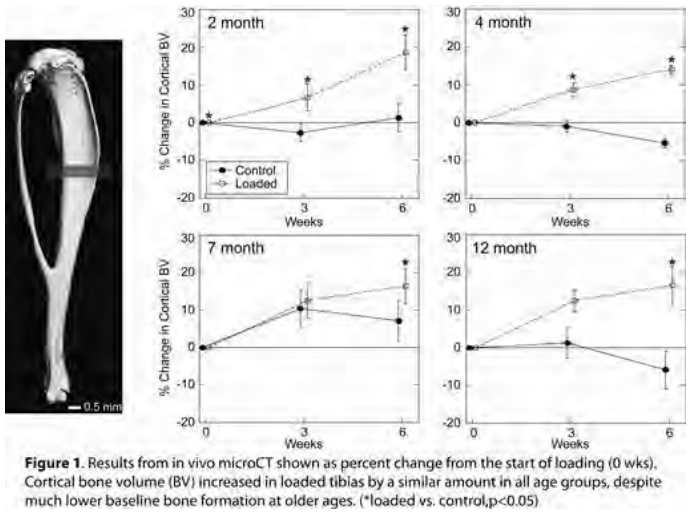

Figure 1. Results from in vivo microCT shown as percent change from the start of loading (0 wks). Cortical bone volume (BV) increased in loaded tibias by a similar amount in all age groups, despite much lower baseline bone formation at older ages. (*loaded vs. control,p<0.05)

HIF-1 Antagonizes Load-induced Bone Formation. Ryan Riddle*[1], Ted Gross[2], Thomas Clemens[3]. [1]Johns Hopkins University School of Medicine, USA, [2]University of Washington, USA, [3]Johns Hopkins University, USA

Mechanical loads induce profound anabolic effects in the skeleton but the molecular mechanisms that transduce such signals are still poorly understood. In many non-osseous tissues, mechanical signals induce the expression of hypoxia-inducible factor-1 (HIF-1), a transcription factor originally identified as a regulator of the cellular response to hypoxia. In this study we investigated the role of HIF-1 in skeletal mechanotransduction. Exposure of MLO-Y4 osteocyte-like cells and primary osteoblasts to either fluid shear stress or substrate strain induced the expression of HIF-1α, but not HIF-2α. In MLO-Y4 cells, HIF-1α expression was induced by PGE_2 treatment and prostanoid signaling was required for fluid shear to increase HIF-1α protein levels. Additionally, both PGE_2 and fluid shear activated the Akt/mTOR pathway and treatment with rapamycin abolished the expression of HIF-1α after either stimulus. To determine the role of HIF-1 in load-induced bone formation *in vivo,* we generated mice lacking HIF-1α in osteoblasts and osteocytes (OC-Cre; $HIF1\alpha^{flox/flox}$, ΔHIF1a) and exposed them to 3 weeks of mechanical loading via cantilever bending of the tibia. Compared to control littermates, ΔHIF1α mice were more responsive to mechanical loading. Despite receiving equivalent peak periosteal strain, bone formation rate after loading in ΔHIF1α mice was 2-fold higher than that observed in controls. Similarly, the load-induced increase in mineralizing surface per bone surface in ΔHIF1α mice was 86% higher than controls, which indicates that a greater number of osteoblasts were activated by loading in these mice. Since the Wnt/β-catenin pathway is believed to be critical for load-induced bone formation, and HIF-1 antagonizes this pathway, we investigated the interaction of these transcription factors. Co-immunoprecipitation studies showed that HIF-1α and β-catenin interacted six hours after exposure of MLO-Y4 cells to fluid shear stress. Moreover, osteoblasts over-expressing HIF-1α had reduced levels of the β-catenin target genes *Ccnd1* and *Axin2*. Taken together, these studies identify the hypoxia-inducible factor pathway as a novel regulator of skeletal mechanotransduction, and suggest that HIF-1 acts to suppress load-induced bone formation by altering the sensitivity of bone cells to mechanical signals.

IGF-1 Receptor in Mature Osteoblasts and Osteocytes is Involved in Skeletal Unloading Induced Bone Loss but not in Reloading Induced Bone Acquisition. Takuo Kubota*[1], Hashem Elalieh[1], Yongmei Wang[2], Daniel Bikle[2]. [1]University of California San Francisco/VA Medical Center, USA, [2]Endocrine Research Unit, Division of Endocrinology UCSF, USA

Mechanical loading has a profound influence on bone remodeling. Insulin-like growth factor 1 (IGF-1) signaling also plays a vital role in bone remodeling. IGF-1 production is increased in osteocytes and osteoblasts after mechanical load. Furthermore, skeletal unloading causes a decrease in bone mass with reduced bone formation and increased bone resorption associated with resistance to the anabolic effect of IGF-1. Therefore, we postulated that IGF-1 signaling mediates the skeletal response to unloading and reloading. In the present study, to determine whether the IGF-1 receptor in mature osteoblasts and osteocytes has a role in the skeletal response to unloading and reloading, we evaluated mice in which the IGF-1 receptor was deleted with osteocalcin-driven cre recombinase. These mice were subjected to skeletal unloading using tail suspension and reloading either after unloading or with cyclic axial loading of the right tibia during tail suspension. The micro CT analysis showed that BV/TV was decreased by 19% in the knockout mice compared with control mice at baseline and decreased to 56% below the control mice after two weeks of skeletal unloading. On the other hand, two weeks of reloading after the two-week unloading increased BV/TV in the distal femur by 148% in the knockout mice compared to that in the four-week unloaded knockout mice, a response comparable to the control mice (102% increase). In addition, cyclic loading increased BV/TV in the proximal right tibia of the unloaded knockout mice by 78% compared to the unloaded left tibia, again comparable to that in the control mice (72% increase). These results indicate that the IGF-1 receptor in mature osteoblasts and osteocytes plays a role in preventing bone loss induced by skeletal unloading but not in mediating bone acquisition induced by reloading. Moreover, these results are consistent with recent observations (Tatsumi S, et al. Cell Metab 2007;5:464.) that depletion of osteocytes does not prevent bone gain in response to reloading, and suggest that the IGF-1 receptor in mature osteoblasts and osteocytes helps maintain bone mass during skeletal unloading.

Mesenchymal Loss of BMP2 Primarily Impairs Cortical Bone Structure Causing Only a Modest Decrease in Tissue-Level Modulus. Jeffry Nyman*[1], Giuseppe Intini[2], Matthew R. Murry[1], Daniel Perrien[1], Erik G. Herbert[3], George M. Pharr[3], Gregory R. Mundy[4], Vicki Rosen[2]. [1]Vanderbilt University Medical Center, USA, [2]Harvard School of Dental Medicine, USA, [3]University of Tennessee at Knoxville, USA, [4]Vanderbilt Center for Bone Biology, USA

Mice lacking BMP2 in the cells of the mesenchymal lineage (BMP2fl/fl;Prx1-cre mice) experience spontaneous fractures in both the fore and hind limb by 10 weeks of age. This does not occur in control littermates, and rarely do spontaneous fractures occur in other genetic mouse models, suggesting that loss of BMP2 contributes to fracture risk. We hypothesized that fractures in the BMP2fl/fl;Prx1-cre mice are due to a structural deficit and reduced tissue-level properties. To examine this idea, the left femur was harvested from BMP2fl/fl;Prx1-cre mice and gender- and age-matched control littermates at 10 weeks and 15 weeks of age (n=9/genotype and n=8/genotype, respectively). Then, μCT scans were performed to quantify the structural properties of the diaphysis, trabecular bone architecture of the metaphysis, and mineralization density (mBMD) of both compartments. Next, femurs were embedded in plastic; a cross-section of the diaphysis was polished; and multiple sites throughout the cortex were analyzed by nanoindentation to characterize tissue-level properties. The effect of age and genotype on each bone property was tested for significance using a two-way ANOVA. While no differences were found in trabecular bone volume and architecture between the genotypes, cortical bone structure was vastly different in the absence of BMP2. BMP2fl/fl;Prx1-cre mice had slightly shorter femurs that were greatly reduced in cross-sectional area and moment of inertia when compared to control littermates. Effectively, the mutant diaphysis was more slender than the wild-type diaphysis (Fig. 1), creating a bone in which the mean ratio of body weight to bone slenderness was 4.5x less for mutant than for control mice. To a lesser degree, BMP2 activity appeared to influence tissue properties, with its deletion causing a modest reduction in nanoindentation modulus, and moreover, affecting the direct relationship between tissue modulus and mBMD, suggesting that BMP2 influences the micro-structural organization of the matrix, not just mBMD. Given that structural differences between the genotypes were vastly greater than the tissue-level differences, spontaneous fractures of BMP2fl/fl;Prx1-cre mice likely occur because the lack of BMP2 is preventing proper periosteal expansion of the diaphysis relative to longitudinal growth. Thus, BMP2 expression by cells of the mesenchymal lineage may be important to periosteal apposition and/or the functional adaptation of bone to mechanical loads.

Effect of the Cathepsin K Inhibitor, ONO-5334, on Biochemical Markers of Bone Turnover in the Treatment of Postmenopausal Osteopenia or Osteoporosis. Richard Eastell*[1], Shinichi Nagase[2], Maria Small[2], Michiyo Ohyama[3], Tomohiro Kuwayama[2], Junichiro Manako[3], Steve Deacon[2]. [1]University of Sheffield, United Kingdom, [2]ONO PHARMA UK LTD, United Kingdom, [3]Ono Pharmaceutical Co., Ltd., Japan

The effect of the Cathepsin K inhibitor, ONO-5334 (50mg bd, 100 or 300mg qd), on biochemical markers of bone turnover (BTM) was investigated in the randomised, placebo (PBO)-controlled, double-blind, parallel-group 1 year study enrolling 285 postmenopausal women. Alendronate (ALN, 70mg qw) was used as an active reference. Patients were equally randomised to 5 treatment arms. Calcium and vitamin D were given to all patients. Subjects were 55-75 years old and had osteoporosis (with no fragility fractures) or osteopenia (with a fragility vertebral fracture). We measured CTX, bone ALP, PINP, Osteocalcin, ICTP and TRACP5b in serum(s) and CTX, NTX, DPD in urine(u) throughout the study. Lumbar spine and hip BMD were also assessed.

ONO-5334 appeared to suppress bone resorption markers as potently as ALN (Table). However, the effect on bone formation markers bone ALP, PINP and OC appeared consistently less than ALN. 300mg qd ONO-5334 suppressed these formation markers by approximately 20% with no changes seen with either 50mg bd or 100mg qd ONO-5334. ONO-5334 increased ICTP and there were only small changes in TRACP5b.

All doses of ONO-5334 resulted in significant and dose-dependent increases in spine and total hip BMD vs. placebo (PBO). Mean +/- SE shown. At month 12, 300 mg ONO-5334 increased lumbar spine (LS) BMD by 5.1% (+/- 0.5) ($p<0.001$ vs. PBO 0.6% +/-0.5) and total hip BMD by 3.0% (+/-0.4) ($p<0.001$ vs. PBO 0.9%+/-0.4). ALN BMD results for LS and hip were 5.2% +/- 0.5 and 3.6% +/- 0.4, respectively ($p<0.001$ vs. PBO).

The effect of ONO-5334 on the BTM profile suggests a new mechanism of action vs. standard anti-resorptive agents such as ALN, with less suppression on bone formation markers and TRACP5b. Whether this might indicate a different long-term pattern of BMD change needs to be investigated with long term studies.

The Effects of Denosumab on Bone Mineral Density (BMD) and Fracture by Level of Renal Function. Sophie Jamal*[1], Osten Ljunggren[2], Catherine Stehman-Breen[3], Steven Cummings[4], Michael McClung[5], Stefan Goemaere[6], Peter Ebeling[7], Edward Franek[8], Yu-Ching Yang[3], Steven Boonen[9], Ogo Egbuna[10], Paul Miller[11]. [1]University of Toronto, Canada, [2]Uppsala University Hospital, Sweden, [3]Amgen, Inc., USA, [4]San Francisco Coordinating Center, USA, [5]Oregon Osteoporosis Center, USA, [6]University Hospital, Belgium, [7]University of Melbourne, Australia, [8]Central Clinical Hospital, Poland, [9]Center for Metabolic Bone Disease, Belgium, [10]Amgen, Incorporated, USA, [11]Colorado Center for Bone Research, USA

Purpose

The incidence of osteoporosis and chronic kidney disease (CKD) both increase with age yet there is a paucity of data on treatments for osteoporosis in the setting of impaired renal function. We examined the efficacy and safety of DMAb among subjects with varying level of renal function participating in the FREEDOM study; a 3 year, randomized phase 3 trial of 7808 postmenopausal women with osteoporosis.

Methods

We estimated creatinine clearance (eGFR) using the Cockcroft-Gault equation and defined stage of CKD using the National Kidney Foundation guidelines. We examined incident fracture rates, changes in BMD, serum calcium, creatinine and the incidence of adverse events after 36 months of follow up in subjects receiving DMAb and placebo, stratified by level of renal function using linear regression models adjusted for fracture since aged 45, prevalent vertebral fractures, self reported health status, baseline calcium intake, current smoking, femoral neck BMD T score and years since menopause. We used a subgroup interaction term to determine if there were differences in treatment effect by eGFR.

Results

Most (97%) women were Caucasian, the mean age was 72.3 $\pm$5.2 years, the mean weight was 63.8 $\pm$ 10.41 kg, mean serum creatinine was 70.8 $\pm$ 15.3 mmol/L and mean serum calcium was 2.44 $\pm$0.11mmol/L. 73 women had an eGFR between 15 to 29 ml/min (CKD stage 4); 2817 between 30 to 59 ml/min (CKD stage 3); 4069 between 60 to 89 ml/min (CKD stage 2) and 842 had an eGFR of $\geq$ 90ml/min (CKD stage 1/ normal).

Effects of DMAb, compared with placebo on incident vertebral and nonvertebral fractures and BMD over 36 months, by stage of renal function, are described in Table 1 and illustrated in Figure 1. The test for treatment by subgroup interaction was not statistically significant indicating that fracture risk reduction, as well as the difference in the mean % changes in BMD in subjects treated with DMAb compared to placebo did not differ by level of renal function. Changes in creatinine, calcium and the

incidence of adverse, serious adverse and fatal events were similar between the placebo and treatment groups and did not differ by level of renal function.

Conclusion

DMAb is effective at reducing fracture risk and increasing BMD in women with CKD participating in the FREEDOM trial. Further, the lack of differences in renal and non renal adverse events in the DMAb group compared with placebo suggests that, in this group, no dose adjustments need to be made.

Table 1. Effect of Denosumab, compared with placebo on incident vertebral and nonvertebral fractures and BMD over 36 months, by stage of renal function.

Outcome	Stage 4 CKD eGFR:15-29ml/min (N= 73)	Stage 3 CKD eGFR30-59ml/min (N= 2817)	Stage 2 CKD eGFR:60-89ml/min (N=4069)	Stage 1 CKD/Normal eGFR ? 90ml/min (N=842)
Vertebral Fractures; Odds Ratio (95%CI)	0.31 (0.02 to 5.08)	0.38 (0.26 to 0.57)	0.23 (0.15 to 0.34)	0.33 (0.16 to 0.66)
Nonvertebral Fractures; Odds Ratio (95%CI)	0.51 (0.04 to 7.26)	0.88 (0.66 to 1.16)	0.69 (0.54 to 0.89)	0.89 (0.51 to 1.52)
Lumbar Spine BMD; %change	5.0 (-0.8 to 10.8)	8.9 (8.4 to 9.3)	9.0 (8.6 to 9.4)	8.1 (7.2 to 8.9)
Femoral Neck BMD; %change	5.9 (3.3 to 8.5)	5.1 (4.7 to 5.5)	5.2 (4.9 to 5.5)	5.6 (4.9 to 6.3)
Total Hip BMD; % change	5.9 (3.0 to 8.7)	6.4 (6.1 to 6.7)	6.4 (6.2 to 6.7)	5.8 (5.2 to 6.3)

Note: Odds ratio < 1 in fracture risk or difference in BMD % change >0 in favor of denosumab.

Remodeling Status in Postmenopausal Women Who Discontinued Denosumab Treatment. Jacques Brown*[1], David Dempster[2], Beiying Ding[3], Ricardo Dent[4], Javier San Martin[5], Rachel B. Wagman[6], Jose Ruben Zanchetta[7]. [1]Laval University, Canada, [2]Columbia University, USA, [3]Amgen Inc, USA, [4]Amgen, USA, [5]Amgen, Inc., USA, [6]Amgen Inc. & Stanford University Scool of Medicine, USA, [7]Instituto de Investigaciones Metabolicas (IDIM), Argentina

Denosumab, a fully human monoclonal antibody to RANKL, reduces bone resorption, increases bone mineral density (BMD), and decreases risk for vertebral, nonvertebral, and hip fractures in postmenopausal women with osteoporosis.[1] Transiliac crest bone biopsies from subjects treated with denosumab for 1 to 3 years demonstrate low bone remodeling.[2] The effects of denosumab on biochemical markers of bone turnover (BTM) and BMD are reversible upon treatment discontinuation.[3,4] However, the effects of denosumab discontinuation on bone histology and histomorphometry are not known. Here we report interim results from a cross-sectional transiliac crest bone biopsy study designed to evaluate the effect of denosumab discontinuation on bone remodeling. Eligible subjects completed all denosumab doses in a phase 3 trial after which they received not more than 1 month of osteoporosis treatment. Transiliac crest bone biopsies were obtained for histology and histomorphometry evaluation ≥ 12 and < 36 months after subjects completed the original trial. Fasting serum samples were collected to assess BTM levels at the time of tetracycline (TC) labeling. This study is ongoing with an expected enrollment of approximately 15 subjects. Data from 5 subjects are currently available. Subjects' mean (SD) age at enrollment in the biopsy study was 59.6 (4.3) years. The 1st set of TC labeling occurred after a mean (SD) of 23.4 (2.7) months from denosumab discontinuation. All biopsies showed normal histology without evidence of pathology. Double TC labels were present in all biopsies, suggesting active remodeling. Static and dynamic histomorphometric variables for the 5 subjects are shown (Table). Most histomorphometric parameters of bone remodeling were within the reference values with the exception of an increase in osteoclast number. Both resorption (CTX) and formation (P1NP) markers were similar to the subjects' pretreatment baseline BTM levels. These data demonstrate that bone remodeling returned to pre-treatment levels upon denosumab discontinuation, confirming the reversibility effect of denosumab treatment on suppression of bone turnover.

The Effect of 3 Versus 6 Years of Zoledronic Acid Treatment in Osteoporosis: a Randomized Extension to the HORIZON-Pivotal Fracture Trial (PFT). Dennis Black*[1], Ian Reid[2], Jane Cauley[3], Steven Boonen[4], Felicia Cosman[5], P.C. Leung[6], Peter Lakatos[7], Zulema Man[8], Steven Cummings[9], Trisha Hue[1], MaryEllen Ruzycky[10], R Martinez[10], Guoqin Su[11], Christina Bucci-Rechtweg[10], Richard Eastell[12]. [1]University of California, San Francisco, USA, [2]University of Auckland, New zealand, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]Center for Metabolic Bone Disease, Belgium, [5]Helen Hayes Hospital, USA, [6]Chinese University of Hongkong, China, [7]Semmelweis University Medical School, Hungary, [8]Centro Médico TIEMPO, Argentina, [9]San Francisco Coordinating Center, USA, [10]Novartis Pharmaceuticals Corporation, USA, [11]Novartis pharmaceuticals, USA, [12]University of Sheffield, United Kingdom

Purpose: Zoledronic acid 5 mg (ZOL) used annually for 3 years has been shown to be effective in increasing BMD and decreasing fractures. However, it is unknown if increasing the duration of therapy beyond 3 years will maintain BMD and provide additional fracture protection. To address this question, we performed a 3-year extension of the HORIZON-PFT to 6 years.

Methods: A total of 1233 women who had received active ZOL for 3 years in the core study were randomly allocated to 3 additional years of ZOL (Z6, n=616) or 3 years of blinded placebo (Z3P3, n=617). The primary endpoint was percentage change in femoral neck (FN) BMD at Year 6 relative to Year 3 with secondary endpoints including other BMD sites, biochemical markers of bone turnover, fractures and safety. Additionally, a group who received placebo in the core was given 3 years of ZOL (n=1223) in order to retain the core study blind, but results will not be reported here.

Results: FN BMD results are shown in the figure below. In years 3-6, in the Z6 group, FN BMD remained constant while in the Z3P3 group, it dropped slightly (between treatment difference at year 6=1.04%, [95%CI: 0.4,1.7; p=0.0009]) but still remained well above pretreatment levels. Results for other sites of BMD were similar (total hip: 1.2%, $p<0.0001$, lumbar spine: 2.03, p=0.0018). Biochemical markers remained constant in the Z6 group but rose slightly in the Z3P3 group. However, 3 years after discontinuation of therapy in the Z3P3 group, P1NP remained about 47% below pretreatment values. New morphometric vertebral fractures were significantly lower in the Z6 vs. Z3P3 group (RR=0.48, p=0.04) while other categories of fractures including non-vertebral, hip and clinical vertebral were not different across study groups. The overall incidence of adverse events was comparable between groups. A numerical increase in atrial fibrillation SAEs (2.0% in Z6 vs. 1.1% in Z3P3) was not statistically significant (p=0.26). No long-term effect on renal function or difference in adjudicated ONJ events was observed between the two groups.

Conclusions: 6 years of ZOL maintained BMD while discontinuation after 3 years resulted in significant, although small, BMD losses. ZOL showed a comparable safety profile. The BMD results, together with the fracture results, suggest that patients at high risk of fracture, particularly vertebral fracture, should continue on annual ZOL therapy.

Atypical Femoral Fractures Are Associated With Bisphosphonate Use. Christian Girgis[1], Doron Sher[2], Markus Seibel*[3]. [1]Dept of Endocrinology & Metabolism, Concord Repatriation General Hospital, Australia, [2]Dept of Orthopaedic Surgery, Concord Repatriation General Hospital, Australia, [3]Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia

The association between the use of bisphosphonates and the occurrence of subtrochanteric (''atypical'') femur fractures remains controversial.

We reviewed 152 non-hip femoral fractures sustained by 152 patients (mean age 78 ± 5 years; 132 females) admitted to a large tertiary center between June 2003 and May 2008. A senior orthopedic surgeon reviewed the fracture radiographs of every patient in random sequence (Cohen's κ= 0.8) identifying fractures that displayed all criteria for an atypical fracture3,4 (i.e. a lateral transverse or <30 deg oblique fracture line in an area of cortical thickening with a medial unicortical beak).

Twenty of the 152 fractures were atypical. Following unblinding of the database, 17 patients in this group were found to be on current oral bisphosphonate treatment (15 on alendronate; 2 on risedronate; mean treatment duration 5.1 and 3yrs respectively). Of the 132 patients whose radiographs did not fulfill the atypical criteria, 2 were on alendronate (1.5%) and 1 was on risedronate (0.76%), with a mean treatment duration of 3.5yrs and 1yr, resp. Hence, the risk of an atypical vs. typical fracture in non-bisphosphonate-users (3/132, 2.3%) was increased 37.4 fold (95% CI 12.9-119, P<0.001) in bisphosphonate users (17/20, 85%). The atypical fracture pattern was 96.7% specific to bisphosphonate users.

Risk factors for atypical fractures included a history of low energy fractures (OR 3.2, 95%CI 2.1–17.1, P<0.001), glucocorticoid therapy for > 6 months (OR 5.2, 95%CI 1.3–31, P=0.01), active rheumatoid arthritis (OR 16.5, 95% 1.4–142.3, P<0.001) and 25-OH-vitamin D level <16ng/mL [40nmol/L] (OR 3.5, 95%CI 1.7–18.7, P<0.001).

Based on the center's catchment population (~174,448), the mean annual incidence of atypical femur fractures was calculated as 0.23/10,000 of the general population and 1.66/10,000 in people 65 years or older. According to dispensing data and using wide to narrow indices for the catchment locality, the mean annual incidence of atypical fractures was estimated to range from 11 to 33/10,000 amongst alendronate users, and from 2.5 to 7.4/10,000 amongst risedronate users.

We conclude that there is an apparent association between atypical subtrochanteric femur fractures and oral bisphosphonate use. However, the absolute frequency of these fractures is very low and on balance, the anti-fracture effects of bisphosphonates far outweigh their potential risks in patients with established osteoporosis.

Risk of Femoral Shaft and Subtrochanteric Fractures In Users of Bisphosphonates, Raloxifene and Strontium Ranelate. Peter Vestergaard*. Aarhus University Hospital, Denmark

Aim: To study the association between use of alendronate and other drugs against osteoporosis and the risk of femoral shaft and subtrochanteric fractures.

Methods: Nationwide cohort study from Denmark. All users of bisphosphonates and other drugs against osteoporosis between 1996 and 2006 (n=103,562) as exposed group and three age- and gender matched controls from the general population (n=310,683). Adjustments were made for prior fracture, use of systemic hormone therapy and use of systemic corticosteroids.

Results: An increased risk of subtrochanteric fractures were seen for alendronate (HR=2.41, 95% CI 1.78-3.27), etidronate (HR=1.96, 95% CI 1.62-2.36), and clodronate (HR=20.0, 95% CI 1.94-205) but not for etidronate (HR=1.06, 95% CI 0.34-3.32). However, an increased risk of subtrochanteric fractures was also present before start of alendronate (OR=2.36, 95% CI 2.05-2.72), etidronate (OR=3.05, 95% CI 2.59-3.58), clodronate (OR=10.8, 95% CI 1.14-103), raloxifene (OR=1.90, 95% CI 1.07-3.40), strontium ranelate (OR=2.97, 95% CI 1.07-8.27). Similar trends were seen for femoral shaft and overall fracture risk. Too few events were present to study subtrochanteric fracture risk after start of strontium ranelate and a number of other drugs against osteoporosis. After start of etidronate no dose-response relationship was present (p for trend 0.54). For alendronate a decreasing risk was present wit increasing dose (p for trend <0.01).

Conclusions: Although an increased risk of femoral shaft and subtrochanteric fractures are seen with use of several types of bisphosphonates, the increased risk before start of the drugs may point at an effect of the underlying disease being treated. The increased risk may thus perhaps be due to confounding by indication.

Deletion of the FoxO1, 3, and 4 Genes from Committed Osteoblast Progenitors Expressing Osterix Increases Wnt Signaling and Bone Mass. Elena Ambrogini*, Li Han, Shoshana Bartell, Aaron Warren, Randal Shelton, Kanan Vyas, Annick Deloose, Robert Weinstein, Charles O'Brien, Stavros Manolagas, Maria Jose Almeida. University of Arkansas for Medical Sciences, USA

Global deletion of FoxOs in 3 month old mice increases reactive oxygen species (ROS) and reproduces the effects of aging on bone; conversely, FoxO3 overexpression in mature osteoblasts decreases OS and increases bone mass. Nonetheless, diversion of the limited pool of β-catenin from Wnt/TCF- to FoxO-mediated transcription in the setting of increased oxidative stress suppresses osteoblastogenesis in vitro and is associated with the old age-dependant decrease in osteoblast number and bone formation in the murine skeleton. To elucidate the significance of the antagonism of Wnt signalling by FoxOs in skeletal homeostasis we deleted FoxO1, 3, and 4 from committed osteoblast progenitors by crossing mice with conditional alleles of FoxO1, 3, and 4 (FoxO1,3,4-flox) with mice expressing the Cre recombinase under the control of the murine osterix promoter (Osx-Cre). Female or male FoxO1,3,4-flox;Osx-Cre mice exhibited an increase in vertebral and femoral BMD (20%) by DEXA at 3, 5 and 8 month of age, as well as increased volumetric BMD, cancellous bone volume, trabecular number, connectivity, and BFR; but not osteoclast gene expression or resorption markers. These mice also exhibited a striking increase in femoral cortical thickness associated with an increase in the external, but not internal, diameter indicating augmented periosteal expansion. Consistent with the contention that FoxOs antagonize Wnt/TCF signaling, the expression of the β-catenin/TCF target genes axin2 and cyclin D1 was elevated, as was the expression of the osteoblast specific gene osteocalcin. In difference to the global deletion of FoxOs that caused a decrease in the number of colony forming unit osteoblasts (CFU-OB), deletion of FoxOs in Osx1 cells, did not affect CFU-OBs. These findings support the working hypothesis that an increase in ROS with advancing age decreases the number of osteoblasts by exhausting adult self-renewing mesenchymal progenitors; restraining the proliferation/differentiation of Osx1 expressing committed osteoblast precursors, at least in part by the diversion of β-catenin from Wnt/Tcf- to FoxO-mediated transcription; and by promoting the apoptosis of post-mitotic osteoblasts/osteocytes. Selective inactivation of FoxOs in Osx positive cells unleashes the restraining effects of FoxOs on Wnt signaling thereby increasing the number of osteoblasts to an extent that overcompensates for the adverse effects of ROS on mature osteoblast survival and causes bone anabolism.

Homozygous Deletion of Dickkopf1 Results in a High Bone Mass Phenotype. Michelle McDonald*[1], Alyson Morse[2], Paul Baldock[3], Lauren Peacock[2], Poh-Lynn Khoo[4], Patrick Tam[4], David Little[5]. [1]The Childrens Hospital Westmead, Australia, [2]Orthopaedic Research & Biotechnology Dept. The Kids Research Institute, The Children's Hospital Westmead, Australia, [3]Garvan Institute of Medical Research, Australia, [4]Developmental Embryology Dept. The Children's Medical Research Institute, Australia, [5]Orthopaedic Research & Biotechnology Dept, The Kids Research Institute, The Children's Hospital Westmead, Australia

Dickkopf-1 (DKK1), which antagonizes Wnt/β-catenin signaling activity via interaction with the Lrp5/6 co-receptor, is a negative regulator of osteoblast differentiation and bone formation. Complete deletion of *Dkk1* leads to early embryonic lethality and thereby precludes a proper investigation of its role in post natal bone. Recently, adult mice with complete absence of *Dkk1* function have been generated by genetically reducing the activity of Wnt3 during embryonic development. Over 50% of mice of the *Dkk1*-/-; *Wnt3*+/- genotype (HOM/HET) are found viable. We examined the bone phenotype associated with complete loss of *Dkk1* in comparison to *Dkk1*+/+;*Wnt3*+/+ (WT/WT), *Dkk1*+/-;*Wnt3*+/+ (HET/WT) and the *Dkk1*+/+;*Wnt3*+/- (WT/HET) mice.

Analysis of calvarial RNA showed no postnatal expression of Wnt3 in any genotype, as such this tissue in HOM/HET mice is functionally null only for *Dkk1*. Both male and female HOM/HET mice showed no change in body mass compared to WT/WT. Whole body BMC was increased 12% in male and 16% in female HOM/HET mice ($p<0.05$) and BMD was increased 14% in male HOM/HET mice ($p<0.01$) compared to WT/WT. QCT scans of metaphyseal bone revealed increases in trabecular BMC of 67% in female ($p<0.01$ vs WT/WT) and 64% in male HOM/HET mice ($p=0.053$ vs WT/WT). Diaphyseal cortical bone volume was increased by 31% and 27% in female and male HOM/HET mice respectively ($p<0.01$ vs WT/WT). Concurrently, cortical thickness was increased 22% in female ($p<0.01$ vs WT/WT) and 20% ($p<0.05$ vs WT/WT) in male HOM/HET mice. MicroCT scans of metaphyseal bone revealed a 3-fold increase in female and a 2-fold increase in male HOM/HET mice compared to WT/WT for 3D Bone volume/total volume (BV/TV) ($p<0.01$), which is associated with over 2-fold increases in trabecular number in both male and female HOM/HET mice ($p<0.05$). Furthermore, trabecular BMD was increased 83% in female and 104% in male HOM/HET mice compared to WT/WT ($p<0.05$).

Preliminary histological analysis showed a 48% increase in trabecular MAR in female HOM/HET mice compared to WT/WT ($p=0.06$, N=4) but no alterations in osteoclast parameters between genotypes.

In conclusion, our findings have revealed that absence of the WNT antagonist, DKK1, results in a robust phenotype of high bone mass with over 3-fold increase in metaphyseal bone volume. Histological analysis suggests these extensive increases in bone mass are a result of enhanced bone formation without any changes in bone resorption.

Postnatal Inactivation of Beta-catenin in the Cells of the Osteoblast Lineage Causes Progressive Bone Loss, Ectopic Cartilage Formation and Mesenchymal Cell Accumulation. Jun Guo*[1], Minlin Liu[1], Andrew P. McMahon[2], F. Richard Bringhurst[1], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]Harvard University, USA

Canonical wnt signaling plays an essential role in skeletogenesis and bone homeostasis. Previous reports have shown that inactivation of β-catenin, a key molecule of the canonical wnt signaling pathway, in mature osteoblasts leads to increased bone resorption through decreased expression of osteoprotegerin in osteoblasts, whereas constitutive deletion of β-catenin in skeletal progenitors or osteoblast precursors blocks osteoblast differentiation. To better understand the role of canonical wnt signaling in osteoblastic cells in postnatal bone homeostasis, we examined mice with postnatal inactivation of β-catenin in the cells of the osteoblast lineage by mating β-catenin floxed ($Ctnnb1^{f/f}$) mice with transgenic mice expressing osterix cre (osx-cre) that is suppressible by doxycycline (Dox) Upon stopping Dox administration, the osx-cre; $Ctnnb1^{f/f}$ mice showed a progressive bone loss, ectopic cartilage formation and "mesenchymal cell" accumulation in the metaphyseal trabecular regions of the tibia. In such accumulated mesenchymal tissue, some cells strongly express mRNAs encoding collagen types II and X and osteopontin, while many other cells express mRNAs encoding α1(I) collagen and Runx2 and to a lesser extent alkaline phosphatase and PTH/PTHrP receptors. However, no mesenchymal cells express osteocalcin. These observations suggest that postnatal inactivation of β-catenin in osteoblast progenitors blocks osteoblast differentiation but promotes chondrocyte differentiation. A dramatic increase in osteoclasts was also observed in both neonatal osx-cre; $Ctnnb1^{f/f}$ mice treated with a low dose of Dox (0.1 mg/ml) and postnatal osx-cre; $Ctnnb1^{f/f}$ mice after withdrawal of a high dose of Dox (1.5 mg/ml). Histologic analysis shows decreased cortical thickness and reduced endosteal osteoblasts in postnatal osx-cre; $Ctnnb1^{f/f}$ mice and the mutant mice showed a striking decrease in bone formation, assessed by double calcein labeling. Consistent with low bone mass and increased osteoclast activity, 12-wk old osx-cre; $Ctnnb1^{f/f}$ mice treated with Dox (1.5 mg/ml) until 7-wk old exhibited significantly decreased serum P1NP, a marker for bone formation and increased serum CTX, a marker of bone resorption. Serum total calcium and inorganic phosphorus were normal in the 12-wk old mutant mice. Taken together, these data indicate that canonical wnt signaling in the cells of the osteoblast lineage is essential for postnatal osteoblast differentiation, bone formation, and regulation of osteoclast-mediated bone resorption.

sFRP4 Regulates Bone Remodeling by Attenuating Both Wnt and BMP Signaling with Differential Effects on Trabecular- and Cortical Bone in Mice. Hiroaki Saito*[1], Key Yamana[2], Eric Hesse[3], Riku Kiviranta[4], Lynn Neff[1], Marta Hristova[5], Henry Kronenberg[6], Beate Lanske[1], Roland Baron[7]. [1]Harvard School of Dental Medicine, USA, [2]Teijin Institute for BioMedical Research, Teijin Pharma Limited, Japan, [3]Harvard Schools of Medicine & Dental Medicine, USA, [4]University of Turku, Finland, [5]Harvard School of Dental Medicine, Beth Israel Deacones Medical Center, USA, [6]Massachusetts General Hospital, USA, [7]Harvard School of Medicine & of Dental Medicine, USA

Wnt and BMP signaling regulate bone remodeling. Secreted Frizzled Related Protein 4 (sFRP4) is a member of a family of Wnt inhibitors that function as decoy Wnt receptors, thereby depleting Wnt ligands. Unlike Dickkopf 1 (Dkk1) and Sclerostin, sFRP4 suppresses activation of both canonical and non-canonical Wnt pathways. We previously showed that $Sfrp4^{+/-}$ and $Sfrp4^{-/-}$ mice have increased trabecular bone volume (BV) with a more than 2-fold increase in bone formation rate (BFR),due to increased osteoblast (OB) differentiation and activity as demonstrated by increases in OB surface, OB number, mineralizing surface, and mineral apposition rate (MAR), but no change in bone resorption. In contrast, cortical bone in $Sfrp4^{-/-}$ mice was significantly thinner with a decrease in periosteal and endosteal MAR. Thus, deletion of *Sfrp4* favored trabecular BFR and BV but had negative effects on cortical bone in adult mice. This contrasts with the effect of activation of canonical Wnt signaling due to allelic loss of Dkk1 or a lack of Sclerostin expression, but resembles the targeted transgenic *Bmp4* phenotype. We therefore determined whether the trabecular and cortical effects of *Sfrp4* deletion were due to Wnt or BMP signaling. Osteogenic differentiation of $Sfrp4^{-/-}$ calvarial cells was accelerated and analysis of BMP signaling showed increased pSmad protein and upregulation of the BMP target genes Id1, -2 and -3, suggesting that sFRP4 also inhibits endogenous BMP signaling.

To test whether canonical Wnt signaling also contributed to the cortical phenotype, we crossed $Sfrp4^{+/-}$ mice with mice that overexpress *Dkk1* driven by the collagen I-2.3Kb promoter (*Dkk1*-TG). In these mice, canonical Wnt signaling is antagonized whereas the non-canonical pathway is not expected to be affected. *Dkk1*-TG expression in $Sfrp4^{+/-}$ mice normalized the increased trabecular BFR, thereby correcting the high BV. However, the thin cortical bone in $Sfrp4^{+/-}$ mice was not worsened by high levels of Dkk1. These results suggest that activation of non-canonical Wnt and/or BMP signaling pathways when sFRP4 is absent may inhibit cortical bone formation. In conclusion, our results suggest that 1/ sFRP4 deletion activates not only Wnt signaling but also BMP signaling and 2/ while increased canonical Wnt signaling when sFRP4 is deleted has positive effects on trabecular bone formation, activation of non-canonical Wnt and/or BMP signaling may inhibit cortical bone formation.

Targeted Deletion of Gsα in Early Osteoblasts Leads to Decreased Wnt Signaling and Favors Adipogenic Differentiation of Mesenchymal Progenitors. Partha Sinha*[1], Piia Aarnisalo[2], Min Chen[3], Lee Weinstein[3], Henry Kronenberg[1], Joy Wu[1]. [1]Massachusetts General Hospital, USA, [2]University of Helsinki, Finland, [3]National Institute of Diabetes & Digestive & Kidney Diseases, USA

Progenitors of adipocytes and osteoblasts both arise from mesenchymal stem cells, and animal models and clinical observations suggest an inverse relationship between bone density and bone marrow adiposity. Gsα, a heterotrimeric G protein subunit, mediates cyclic AMP-dependent signaling of G protein-coupled receptors including the parathyroid hormone (PTH)/PTH-related peptide (PTHrP) receptor (PPR). Targeted deletion of Gsα early in the osteoblast lineage (Osterix-Cre:Gsα(fl/fl) mice) leads to osteoporosis and multiple fractures at birth. Histological analysis of bone marrow from mutant mice revealed increased adiposity as compared to wild-type bone marrow. To assess the differentiation potential of bone marrow stromal cells (BMSCs) from these mice and the mechanisms regulating this potential, we isolated BMSCs from Gsα conditional knockout mice and evaluated their differentiation in vitro. Such cells grown to confluence in vitro showed increased adipogenic differentiation as quantitated by oil red O staining. We found that BMSCs isolated from conditional knockout mice formed fewer Colony Forming Unit-Fibroblasts (CFU-F) compared to wild-type BMSCs. Furthermore, knockout BMSCs contained fewer CFU-alkaline phosphatase (CFU-ALP) osteoprogenitors, while the proportion of adipocyte progenitors (CFU-Adip) was increased as compared to wild-type. Loss of Gsα in early osteoblasts may favor adipocyte differentiation because of alterations in canonical Wnt signaling, which regulates the commitment of mesenchymal progenitors into the osteoblast versus adipocyte lineages. We have previously reported that osterix-Cre:Gsα(fl/fl) mice have increased expression of sclerostin, an inhibitor of canonical Wnt signaling secreted by osteocytes. Correspondingly, primary calvarial osteoblasts harvested from knockout mice had decreased mRNA levels of the Wnt targets Tcf1, Lef1, Axin2, and CycD1 as compared to wild-type calvarial osteoblasts. Taken together, these studies point to a key role for Gsα signaling in cells of the early osteoblast lineage in governing the balance of osteoblast and adipocyte progenitors, and suggest this may be mediated by alterations in Wnt signaling.

Lrp6 and Lrp5 Exert Distinct Roles in Regulating Bone Acquisition in the Mature Osteoblast. Cassandra R. Zylstra[1], Ryan Riddle*[2], Chao Wan[3], Daniel Robinson[1], Charlotta Lindvall[1], Thomas Clemens[4], Bart Williams[1]. [1]Van Andel Research Institute, USA, [2]Johns Hopkins University School of Medicine, USA, [3]University of Alabama, Birmingham, USA, [4]Johns Hopkins University, USA

Despite the well-accepted role of the canonical Wnt signaling pathway on skeletal development, the specific biological roles of the Wnt co-receptors Lrp5 and Lrp6 in bone have remained controversial. To define the individual contributions of Lrp5 and Lrp6 in skeletal development, we used Cre-LoxP recombination to create mice lacking each co-receptor selectively in osteoblasts. Mice lacking Lrp5 (ΔLrp5) or Lrp6 (ΔLrp6) in mature osteoblasts were generated by crossing Lrp6flox and Lrp6flox mice

with mice expressing cre-recombinase under the control of the human osteocalcin promoter (OC-CreTG) and were born at the expected Mendelian frequence and were viable. DEXA indicated reduced BMD at 3 months in both the ΔLrp6 and ΔLrp5 mice. Assessment of femoral bone morphology by microCT revealed significantly lower bone volume with decreased trabecular numbers in ΔLrp6 mice when compared to controls. Trabecular bone volume was not different from controls in ΔLrp5 mice. By contrast, cortical bone morphology was altered in Lrp5 mutants, which exhibited marked increases in cortical cross-sectional area. Mice deficient for both LRP5 and LRP6 had severely reduced cortical and trabecular bone volume similar in magnitude to that observed previously in mice lacking β-catenin (Holmen, et al, J Biol Chem 2005 280; 21162-8). Quantitative histomorphometric analysis disclosed a dramatically decreased number of osteoblasts in the ΔLrp5;ΔLRP6 mice. In vitro deletion of Lrp6 impaired the differentiation of primary osteoblasts as the expression of alkaline phosphatase, Runx2, and Osteocalcin were significantly reduced. These phenotypic markers were unaffected in Lrp5-deficient osteoblasts differentiated in vitro. Simultaneous disruption of both co-receptors in vitro altered fate-specification of calvarial cells which showed abundant alcian blue staining and increased expression of Sox9, Collagen II and Collagen X mRNA. These results suggest that Lrp5 and Lrp6 can serve overlapping functions in skeletal development, but that Lrp6 is required for normal trabecular bone acquisition, while Lrp5 appear to regulate cortical bone structure.

DAG Coordinates Polarized Secretion in Resorptive Osteoclasts through Activation of the PKCδ- MARCKS Pathway in Vitro and in Vivo. Viviana Cremasco*[1], Roberta Faccio[2]. [1]Washington University School of Medicine, USA, [2]Washington University in St Louis School of Medicine, USA

Both osteoclast (OC) development and bone resorption require the catalytic activity of the lipase PLCγ2, which generates the two second messengers IP3 and DAG. Despite the recognized importance of IP3 in calcium oscillations during OC development, little is known about the role of DAG in these cells. Novel PKC proteins are exclusively activated by DAG and, within this PKC family, we found that PKCδ is highly expressed in OCs. Moreover, consistent with the role of PLCγ2 in generating DAG, adhesion-dependent activation of PKCδ is dampened in PLCγ2-/- OCs. To study the role of DAG-mediated pathways in OCs, we examined the bone phenotype of mice congenitally lacking PKCδ. 6-week old, unmanipulated PKCδ-deficient animals exhibit increased bone mass as determined by histomorphometric analysis (26.9+/-3.2% increase in BV/TV vs WT mice). While OC differentiation is unperturbed, PKCδ-/- OCs are characterized by a flattened morphology in vitro and in vivo, indicative of defective polarization on bone. Despite presence of intact actin rings, genetic disruption of PKCδ significantly impairs OC bone resorption, as determined by collagen type I secretion in the media (CTX 32.7nm in WT and 6.3nm in KO, p=0.04). Strikingly, we observed that PKCδ is required for localization of cathepsin K within actin rings and for its polarized secretion in the resorptive lacunae. Mechanistically, we found that the actin bundling protein MARCKS becomes phosphorylated in a PKCδ-dependent manner upon OC adhesion. Furthermore, MARCKS localizes within the actin ring, implicating this protein in orchestrating polarized secretion during bone resorption. In support of this hypothesis, gene silencing of MARCKS, similarly to PKCδ-deficiency, reduces OC bone resorption (resorbed area/total area 23.5% in WT vs 10.6% in MARCKS knock-down, p=0.03) without affecting cell differentiation. Our results demonstrate a previously unknown role for DAG-PKCδ-MARCKS pathway as a critical regulator of OC polarized secretion during bone resorption, thus positioning this pathway as a possible anti-resorptive target.

TNF-α Induced Osteoclastogenesis and Inflammatory Bone Resorption are Negatively Regulated by the Notch-RBP-J Pathway. Baohong Zhao*, Xiaoyu Hu, Lionel Ivashkiv. Hospital for Special Surgery, USA

Notch receptors Notch1, 2 and 3 have been implicated in regulation of RANKL-induced osteoclastogenesis in vitro, but the effects are relatively modest, results obtained by different groups were not consistent, and mechanisms of regulation are not clear. The role of Notch signaling in pathologic inflammatory bone resorption is not known. In this study, we investigated the role of Notch signaling in osteoclastogenesis and bone resorption under inflammatory conditions. TNF-α did not detectably induce osteoclastogenesis in wild type (WT) bone marrow macrophages (BMMs). Deletion of RBP-J, the master transcription factor in Notch signaling, resulted in dramatic induction of osteoclastogenesis by TNF-α in the absence of exogenous RANKL, comparable to that induced by RANKL in WT cells. TNF-α-induced mouse osteoclasts derived from RBP-J deficient cells formed actin rings and resorbed dentin slices in vitro. Similar results were obtained using TNF-α-treated human osteoclast precursors in which RBP-J expression was knocked down using RNA interference. RBP-J deficiency had a much more modest augmenting effect on RANKL-induced osteoclastogenesis. TNF-α induced dramatically increased levels of the osteoclast master regulator NFATc1 and osteoclast marker genes including TRAP, cathepsin K, and integrin β3 in RBP-J deficient relative to WT cells. RBP-J deficiency resulted in increased TNF-α-induced NFATc1 transcription and RNA Pol II occupancy at the NFATc1 gene locus. These results show that RBP-J negatively regulates TNF-α-induced osteoclastogenesis by suppressing induction of NFATc1. Mechanisms by which RBP-J suppressed NFATc1 induction included decreasing NF-κB recruitment to the NFATc1 promoter while increasing expression of IRF8, a transcriptional repressor that suppresses osteoclastogenesis. Mice with a myeloid-specific deletion of RBP-J (RBP-J$^{f/f}$ LysM-Cre) did not exhibit a bone phenotype under physiological conditions. However, RBP-J$^{f/f}$ LysM-Cre mice showed dramatically increased osteoclast formation, severe bone destruction and increased serum TRAP levels relative to littermate controls in a TNF-α-induced model of pathological inflammatory bone resorption. These findings identify a key role for Notch component RBP-J in restraining inflammatory TNF-α-induced osteoclastogenesis and provide mechanisms by which RBP-J suppresses NFATc1 induction. Notch/RBP-J signaling plays a more prominent role in inhibiting osteoclastogenesis in inflammatory settings than under physiological conditions.

Itch, an E3 Ligase, Negatively Regulates Osteoclastogenesis by Promoting Deubiquitination of TRAF6 Through Interaction With the Deubiquitinating Enzyme, Cylindromatosis. Hengwei Zhang*[1], Chengyu Wu[2], Lydia Matesic[3], Brendan Boyce[4], Lianping Xing[2]. [1]Univeristy of Rochester, USA, [2]University of Rochester, USA, [3]University of South Carolina, USA, [4]University of Rochester Medical Center, USA

Osteoclastogenesis requires RANKL-induced signaling in osteoclast precursors (OCPs). RANKL binds to RANK leading to TRAF6 ubiquitin-mediated processing. TRAF6 ubiquitination then triggers downstream signaling, leading to osteoclast (OC) differentiation, but the mechanisms whereby this process is controlled have not been well investigated. Here, we report that the E3 ligase, itch, functions as a negative regulator of OC formation by promoting deubiquitination of TRAF6 and thereby limiting RANKL-induced OC formation. Itch is a HECT family E3 ligase, which affects cell function through the regulation of ubiquitination of target proteins, but its role in bone cell function is unknown. First, we demonstrated that Itch-/- cells formed more OCs than WT cells (#OCs/well: 360+24 vs 220+12) in response to RANKL, associated with a 3-4 fold increased expression of c-Fos and NFATc1. We then generated a retroviral expression vector for itch, infected WT and itch-/- OCPs with itch retrovirus, and cultured them with RANKL to form OCs. Itch over-expression significantly reduced RANKL-induced WT OC formation (#OCs/well: 120+12 vs 264+22 in GFP controls) but prevented increased OC formation of itch-/- cells (#OCs/well: 240+18 vs 400+32 in GFP-infected cells). We next used an ubiquitination assay to investigate the mechanism by which itch inhibits RANKL-induced OC formation. Two days of RANKL treatment induced TRAF6 ubiquitination in WT OCPs, the degree of RANKL-induced TRAF6 ubiquitination being similar in itch-/- and WT cells. However, ubiquitinated-(Ub-) TRAF6 disappeared after RANKL withdrawal in WT cells, while Ub-TRAF6 persisted in itch-/- cells, suggesting mis-regulation of TRAF6 ubiquitination in the absence of itch. A recent study reported that the deubiquitinating enzyme, cylindromatosis (CYLD), controls de-ubiquitination of TRAF6, thereby negatively regulating OC formation. We found that flag-tagged itch directly bound to HA-tagged CYLD in 293T cells. In OCPs, endogenous itch interacted with CYLD and TRAF6, but an itch mutant lacking ligase activity did not interact with CYLD. Finally, we found that RANKL increased itch mRNA expression starting at 4 hrs and peaking at 24 hr. RANKL-induced increased itch expression was confirmed by Western blot. Our findings suggest that itch is a new RANKL target gene, which is induced during osteoclastogenesis and functions as a deubiquitinating adaptor molecule to limit RANKL-induced OC formation.

PTHR1 in Osteocytes Plays a Major role in Perilacunar Remodeling through the Activation of "Osteoclastic" Genes in Osteocytes. Hai Qing*[1], Paola Divieti Pajevic[2], Kevin Barry[3], Vladimir Dusevich[4], John Wysolmerski[5], Lynda Bonewald[6]. [1]UMKC Dental School, USA, [2]Massachusetts General Hospital, USA, [3]Endocrine Unit, Massachusetts General Hospital, USA, [4]University of Missouri-Kansas city, USA, [5]Yale University School of Medicine, USA, [6]University of Missouri - Kansas City, USA

We have previously shown that during lactation, osteocytes directly remodel their perilacunar and pericanalicular matrix, thereby mobilizing calcium and contributing to maternal bone loss. It is known that osteocytes express the type 1 parathyroid-hormone (PTH)/ PTH related peptide (PTHrP) receptor (PTHR1) and that circulating levels of PTHrP are elevated during lactation. To determine if the PTHR1 is involved in perilacunar remodeling, mice lacking the PTHR1 in osteocytes (PTHR1-cKO) were generated by crossing DMP1-Cre mice with PTHR1 fl/fl mice. 12-wk old mice were allowed to become pregnant, deliver and lactate for 12 days before sacrifice. MicroCT analysis showed significant overall bone loss in wild-type lactating compared to wild-type virgin mice that was attenuated in lactating animals with PTHR1 deleted in osteocytes. Unlike control mice, no increase was observed in osteocyte lacunar size in PTHR1-cKO mice during lactation, either in cortical or trabecular bone, and there was no increase of osteocyte-specific TRAP activity. To identify genes potentially

responsible for perilacunar remodeling, microarray analysis was performed on tibiae from CD-1 virgin and lactating mice and mice sacrificed on day 7 post weaning. Periosteum and bone marrow were removed from the tibiae and the bone fragments underwent sequential collagenase/trypsin digestion and were examined histologically to ensure removal of all surface cells and confirm osteocyte enrichment prior to RNA extraction. Microarray data (Affy M430 arrays, n=3 per group) showed that PTHR1 was increased in lactating compared to virgin and post-lactation animals in addition to TRAP, Cathepsin K, ATP6V0D2, NFATc1 and other 'osteoclastic' genes (table). However, there was no significant change in expression of Rank and NF-kB, which are involved in osteoclast formation. These data were validated by qPCR showing a 5.7 ± 3.4 fold ($p<0.05$) increase of TRAP mRNA in lactating mice compared to virgin. A similar increase in TRAP and cathepsin K was also observed by immunostaining. Together these data suggest that osteocytes utilize some but not all of the molecular mechanisms used by osteoclasts to remove perilacunar bone matrix and that PTHR1 expression in osteocytes plays an essential role. These observations support the osteocyte as an important target for PTH/PTHrP actions in bone and suggest that the osteocyte may play a role in directly mobilizing calcium from bone ECM when there is a high calcium demand.

Table

Gene symbol	Gene name	Fold change Lac/virgin	Fold change Post/lac/lac
ATP6V0d2	ATPase, H+ transporting, lysosomal V0 subunit D2	3.6**	−2.9**
Car1	carbonic anhydrase 1	2.2*	−9.8**
Car2	carbonic anhydrase 2	1.8*	−12.7**
CTSK	Cathepsin K	3.6**	−2.5**
NFATc1	nuclear factor of activated T-cells, cytoplasmic, calcineurin-dependent 1	3.8*	−1.5
Nhede2	Na+/H+ exchanger domain containing 2	3.4**	−3.0**
ACP5	acid phosphatase 5, tartrate resistant	3.3**	−3.4*
PTHR1	parathyroid hormone receptor 1	1.5	−0.65

Values shown as fold changes; * P<0.05, ** P<0.01, Lac:lactation, P:p/lac: post lactation

Osteocyte Apoptosis Promotes Angiogenesis and Osteoclast Precursor Adhesion *In Vitro*. Wing-Yee Cheung*[1], Craig Simmons[1], Lidan You[2]. [1]University of Toronto, Canada, [2]Mechanical & Industrial Engineering, University of Toronto, Canada

In vivo studies have shown that osteocyte apoptosis precedes osteoclast resorption at the local remodelling site. Osteoclast precursors are transported from the bone marrow to the remodelling site via the circulation. However, the specific mechanisms by which osteoclast precursors are transported from the capillary in the Haversian canal to the adjacent bone lining surface are not clearly elucidated. We hypothesize that osteocyte apoptosis promotes angiogenic sprouting from the Haversian capillary to aid in osteoclast precursor recruitment, and activates the endothelium to allow for osteoclast precursor adhesion. We found that conditioned media from TNF-α induced apoptotic osteocytes induced a 90% increase in endothelial cell proliferation ($P<0.05$), a 70% increase in endothelial cell migration ($P < 0.05$), and more complex tubule network formation with longer ($P<0.01$) and more ($P < 0.001$) branches compared to treatment with non-apoptotic osteocyte conditioned media. Apoptotic osteocyte conditioned media contained 20% more VEGF than non-apoptotic osteocyte conditioned media ($P=0.01$). The VEGF concentration found in apoptotic osteocyte conditioned media formed endothelial tubule networks with longer ($p<0.05$) and more ($p<0.02$) branches than the VEGF concentration in non-apoptotic osteocyte conditioned media. Blocking VEGF in apoptotic osteocyte conditioned media abolished tubule formation effects ($p<0.001$). Endothelial cells treated with apoptotic osteocyte conditioned media had 130% greater osteoclast precursor adhesion than endothelial cells treated with non-apoptotic osteocyte conditioned media ($p<0.03$). Our results suggest that osteocyte apoptosis assists in osteoclast precursor recruitment by promoting angiogenesis (endothelial cell proliferation, migration and tubule formation) and enhancing osteoclast precursor adhesion to the endothelium.

Talin is Critical for Osteoclast Function by Mediating Inside-Out Integrin Activation. Wei Zou*[1], Brian Petrich[2], Susan J. Monkley[3], David R. Critchley[4], Mark H. Ginsberg[2], Steven Teitelbaum[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Department of Medicine, University of California, USA, [3]Department of Biochemistry, University of Leicester, United Kingdom, [4]University of Leicester, United Kingdom

Bone degradation by osteoclasts (OCs) depends upon their capacity to organize cytoskeleton, which is mediated by a signaling complex stimulated by the $\alpha v\beta 3$ integrin or the M-CSF receptor. Whether the two receptors activate this complex independently or collaboratively is unknown. We find M-CSF treatment of OCs transits $\alpha v\beta 3$ from a low affinity to a high affinity conformation suggesting M-CSF stimulates the cytoskeleletal signaling complex, indirectly via the integrin (inside-out activation). Talin (TLN) is a large cytosolic protein which by interacting with β cytoplasmic domains is a final step to integrin activation. We asked if TLN mediates M-CSF/$\alpha v\beta 3$-stimulated bone resorption. We find TLN constitutively expressed throughout osteoclastogenesis and M-CSF treatment promotes its association with the $\beta 3$. TLN activates $\alpha v\beta 3$ by associating with specific residues in the $\beta 3$ cytoplasmic domain, including Y747. OCs bearing the β3Y747A (YA) mutation fail to spread or normally resorb bone, in vitro. Affirming that the resorptive defect represents OC dysfunction and not arrested maturation, YA mutants normally express OCs differentiation markers. Furthermore, TLN fail to localize to the plasma membrane in YA OCs, underscoring the biological necessity of $\beta 3$/TLN recognition. Confirming this posture in vivo, YA mice have significantly more bone following OVX than do WT. Having established that mutating the TLN binding site in $\beta 3$ results in impaired OCs function, we asked whether the same obtains in TLN-/- mice. As the TLN-/- mouse is early embryonic lethal, we mated $TLN^{f/f}$ with cathepsin K-cre mice to delete TLN only in mature OCs ($TLN^{\Delta OC/\Delta OC}$) or Lys M-Cre mice to delete TLN in all OC lineage cells. Absence of TLN does not affect macrophage proliferation and apoptosis, it impairs their spreading and diminishes integrin induced cytoskeleton-organizing signals. Mn^{2+}, which directly activates integrins absent inside-out signals, partially rescues this defect. In keeping with inhibited resorption, bone mass is increased 3 fold ($p<0.01$) in $TLN^{\Delta OC/\Delta OC}$ mice as measured by μCT and DEXA. The presence of abundant OCs confirms the enhanced bone mass of $TLN^{\Delta OC/\Delta OC}$ mice reflects resorptive dysfunction and not diminished number. Indicating clinical relevance, $TLN^{\Delta OC/\Delta OC}$ mice are protected from OVX-induced bone loss and the periarticular osteolysis attending inflammatory athritis. Thus, TLN is critical for OC function and mediates M-CSF-induced $\alpha v\beta 3$ integrin activation in OC.

Increasing Adiponectin Via an Apolipoprotein Peptide Mimetic, L-4F, Reduces Tumor Burden and Increases Survival in a Murine Model of Myeloma. Jessica Fowler*, Seint Lwin, Gregory Mundy, Claire Edwards. Vanderbilt University, USA

Multiple myeloma (MM) remains a fatal malignancy associated with a destructive osteolytic bone disease, and it is essential to evaluate new therapeutic approaches. We have previously identified adiponectin (ADPN) as decreased in mice that are permissive for MM, suggesting a role for this adipokine in MM pathogenesis. *In vitro* studies revealed that ADPN had direct effects on MM cells to increase apoptosis. The aim of the current study was to determine the effect of increasing ADPN on MM development *in vivo*. Treatment of C57Bl/KaLwRij mice for 4 weeks with the apolipoprotein peptide mimetic L-4F (200ug/100g/day) resulted in increased serum ADPN ($p<0.01$, compared to vehicle-treated). Mice were treated with L-4F for 4 weeks prior to i.v. inoculation of 5TGM1 MM cells. Treatment was continued throughout the experiment to maintain the change in ADPN. Measurement of MM-specific IgG2b concentrations demonstrated that mice treated with L-4F had a significant decrease in the rate of MM development ($p<0.01$, compared to vehicle), evident as early as 7 days after tumor inoculation. FACS analysis of GFP-positive MM cells confirmed a significant reduction in tumor burden within the bone marrow (BM) of mice treated with L-4F ($p<0.01$). Immunohistochemical analysis of BM of MM-bearing mice treated with L-4F demonstrated a significant increase in TUNEL positive MM cells ($p<0.05$), indicative of apoptosis. There was also a significant decrease in Ki67 staining in the BM of L-4F-treated mice ($p<0.05$), compared to vehicle. In separate studies, MM-bearing mice treated with L-4F showed an overall increase in survival in comparison to vehicle ($p<0.0001$). In addition, L-4F-treated-mice had a significant increase in bone formation rates compared to vehicle-treated mice ($p<0.001$). *In vitro* studies demonstrated that L-4F had no direct effect on MM cell growth, but directly induced ADPN expression in BM stromal cells (BMSCs). Treatment of MM cells with conditioned media (CM) from L-4F-treated BMSCs increased MM cell apoptosis ($p<0.05$, compared to vehicle CM), suggesting L-4F may increase ADPN expression via the BM microenvironment and so induce MM cell apoptosis. Taken together, our results suggest that increasing ADPN with L-4F may reduce tumor burden via an effect on cells in the host microenvironment, so preventing MM bone disease and increasing survival. These studies identify both ADPN and L-4F as potential therapeutic approaches for the treatment of MM.

Host-derived MMP-7 Decreases Myeloma Progression *In Vivo*: An Unexpected Role for MMP-7 in Myeloma Pathogenesis. Seint Lwin*, Conor Lynch, Jessica Fowler, Gregory Mundy, Claire Edwards. Vanderbilt University, USA

Defining interactions within the bone marrow microenvironment that promote the development of multiple myeloma (MM) is essential to identify new therapeutic approaches. Matrix metalloproteinases (MMPs) are key regulators of tumor:host interactions due to their ability to alter activity of multiple substrates. Increasing evidence supports a critical role for host-derived MMPs in cancer progression and MMP7 has recently been implicated in breast and prostate cancer-mediated osteolysis. We hypothesized that host-derived MMP7 may play a role in MM bone disease *in vivo*. We have previously shown that inoculation of 5TGM1 MM cells into C57Bl/$RAG2^{-/-}$ mice resulted in MM development with osteolytic bone disease identical to that in the syngeneic C57Bl/KaLwRij strain. Our aim was to use Rag2/MMP7 null

($MMP7^{-/-}$) mice to investigate the role of host-derived MMP7 in MM *in vivo*. Inoculation of 5TGM1-GFP MM cells into $MMP7^{-/-}$ mice unexpectedly resulted in a significant increase in the rate of tumor growth, as measured by serum IgG2bk concentrations, when compared to MM-bearing $Rag2^{-/-}$ wild-type mice (WT). This surprising finding suggested that host MMP7 plays a protective rather than a contributory role in MM. FACS analysis of GFP-positive MM cells confirmed a 72% increase in tumor burden within bone in MM-bearing $MMP7^{-/-}$mice, as compared to MM-bearing WT mice ($p<0.01$). MicroCT analysis demonstrated a 47% decrease in BV/TV and 67% increase in osteolytic lesions in MM-bearing $MMP7^{-/-}$mice as compared with MM-bearing WT mice ($p<0.01$). No significant difference in osteoclast or osteoblast number was found. In support of an effect of host-derived MMP7 on tumor growth and/or survival, a 51% decrease in MM cell apoptosis was observed in MM-bearing $MMP7^{-/-}$ mice ($p<0.05$). Furthermore, in vitro studies found no MMP7 expression in MM cells, and no direct effect of MMP7 on MM cell proliferation or apoptosis. Using a candidate list of MMP7 substrates, we identified that $MMP7^{-/-}$mice had increased serum osteopontin (OPN), compared to WT (233 ± 5.7 ng/ml vs. 167 ± 12.3 ng/ml, $p<0.001$). OPN is a MM cell survival factor and we propose that processing of OPN by MMP7 may abrogate the survival effect of full-length OPN. Our studies suggest that host-derived MMP7 inhibits MM growth in vivo, demonstrating that MMPs can play differential roles in specific disease contexts and supporting the rationale for the design of selective MMP inhibitors for the treatment of MM bone disease.

Myeloid Derived Suppressor Cells (MDSC) are Responsible for Enhanced Bone Tumor Growth in Osteopetrotic *PLCγ2-/-* mice and are a Direct Target of Zoledronic Acid. Seokho Kim*[1], Deborah Novack[2], Roberta Faccio[3]. [1]Department of Orthopedics, Washington University, St. Louis MO, USA, [2]Washington University in St. Louis School of Medicine, USA, [3]Washington University in St Louis School of Medicine, USA

Despite the well established requirement of active osteoclasts (OC) to sustain tumor growth in bone, we found that PLCγ2-/- mice, with deficiency in OC formation, displayed a 3 fold increase in bone tumor burden compared to WT following intra-tibial (i.t.) and intra-cardiac inoculation of B16 melanoma cells. However, consistent with their OC defect, PLCγ2-/- mice had no tumor-associated bone loss. Even more intriguing, treatment with Zoledronic acid (ZOL), potent inhibitor of bone resorption, significantly suppressed tumor growth in PLCγ2-/- mice, suggesting that another bone-derived cell, targeted by ZOL, modulates tumor growth in these animals. MDSC, a heterogeneous cell population derived from bone marrow, are highly enriched in patients with cancer and potently suppress T-cell mediated anti-tumor responses. Based on the importance of PLCγ2 in myeloid cells, we hypothesized that PLCγ2 may negatively regulates MDSC expansion in tumor bearing mice. In support of this hypothesis, we found that PLCγ2-/- mice i.t. inoculated with B16 or LLC lung tumor cells had enhanced accumulation of MDSC (B16: $8.2 \pm 1.4\%$ in WT, $19 \pm 1.3\%$ in KO; LLC: $14 \pm 1.4\%$ in WT, $31 \pm 1.5\%$ in KO). Importantly, ZOL treatment (100μg/Kg) was sufficient to reverse the increase in MDSC number in vivo and promote apoptosis of MDSC in vitro at 10 and 25 μM, doses too low to directly kill cancer cells. Thus, ZOL may exert an anti-tumor effect in PLCγ2-/- mice by targeting MDSC, independent of its action on the OCs or cancer cells.

Further confirming the relevance of MDSC in tumor growth, WT mice subcutaneously co-injected with tumor cells and MDSC isolated from tumor bearing PLCγ2-/- animals displayed increased tumor burden compared to WT mice receiving tumor alone. Moreover, C57Bl/6 PLCγ2-/- mice, but not WT, allowed growth of the allogenic 4T1 tumor cells derived from BalB/C mice, and this was associated with increased MDSC ($20 \pm 2.7\%$ in WT, $51.6 \pm 3.3\%$ in KO). Taken together, these results indicate that expansion of MDSC is responsible for enhanced tumor burden in bone of osteopetrotic PLCγ2-/- mice. A better understanding of the mechanism leading to MDSC expansion and their targeting by ZOL will be useful for anti-tumor therapy in patients with bone metastases.

Multiple Myeloma Cell Induction of GFI-1 in Stromal Cells Suppresses Osteoblast Differentiation in Patients with Myeloma. Sonia D'Souza*[1], Shunqian Jin[1], Benedicte Sammut[1], Chinavenmeni S. Velu[2], Shibing Yu[3], Guozhi Xiao[4], H. Leighton Grimes[2], G. David Roodman[5], Deborah Galson[4]. [1]Center for Bone Biology, University of Pittsburgh, USA, [2]Cincinnati Children's Hospital Medical Center, USA, [3]School of Medicine/Hem-Onc,University of Pittsburgh, USA, [4]University of Pittsburgh School of Medicine, USA, [5]VA Pittsburgh Healthcare System (646), USA

Multiple Myeloma (MM) is a plasma cell malignancy characterized by formation of lytic bone lesions in approximately 90% of the patients which do not heal even after prolonged complete remission. The basis for this selective and protracted suppression of osteoblast (OBL) differentiation from immature bone marrow stromal cells (MSC) is unknown. However, we and others have reported the suppression of RUNX2, a critical transcription factor required for OBL differentiation in MM-altered MSC. The continued inability of MSC to differentiate into OBL even in the absence of MM cells in vivo and in vitro, suggests that the MM cells induced epigenetic changes in the MSC that result in RUNX2 suppression. We have developed a murine model of MM-induced OBL suppression using a murine myeloma cell line engineered to express GFP and thymidine kinase (5TGM1-GFP-TK MM cells). Injection of these 5TGM1-GFP-TK MM cells into SCID mice resulted in persistent and selective inhibition of OBL differentiation even when the MM cells were totally depleted by ganciclovir treatment in vitro. These MM-altered MSC demonstrated RUNX2 suppression and elevated levels of the transcriptional repressor, GFI-1, which can mediate chromatin remodeling. Further, addition of either MM cells in a transwell or TNF-α and IL-7 to MC4, a murine OBL precursor cell line, and to primary murine MSC resulted in inhibition of RUNX2 expression and increased GFI-1 expression. Additionally, neutralizing antibodies to TNF-α and IL-7 blocked MM-induced RUNX2 suppression and GFI-1 expression. Deletion analysis of the RUNX2 P1 promoter revealed that a 1103-bp region (992/+111) containing 29 putative GFI-1 binding sites was responsible for repression of RUNX2 expression by MM cells, TNF-α or by co-transfection with a GFI-1 expression plasmid. A histone deacetylase inhibitor (trichostatin A) abrogated GFI-1 inhibition of the Runx2 promoter reporter. Importantly, MSC from $GFI\text{-}1^{-/-}$ mice are partially resistant to MM-induced RUNX2 expression. In support of these results, we found decreased RUNX2 expression and elevated GFI-1 mRNA and protein levels in MSC from MM patients compared to normals. Significantly, siRNA knockdown of GFI-1 expression partially restored RUNX2, OCN, BSP and OSX expression in both MM exposed MC4 cells and in MSC from MM patients. These results support an important role for GFI-1 in repressing RUNX2 expression in MSC exposed to MM cells, thereby inhibiting osteoblastogenesis in MM.

Heparanase Promotes Osteoclastogenesis in Multiple Myeloma by Upregulating RANKL Expression. Yang Yang*[1], Yongsheng Ren[2], Li Nan[2], Vishnu C Ramani[2], Larry Suva[3], Ralph D Sanderson[4]. [1]The University of Alabama At Birmingham, USA, [2]Department of Pathology, University of Alabama at Birmingham, USA, [3]University of Arkansas for Medical Sciences, USA, [4]Department of Pathology, Comprehensive Cancer Center & the Center for Metabolic Bone Disease, University of Alabama at Birmingham, USA

Excessive bone destruction is a major cause of morbidity in myeloma patients. However, the biologic mechanisms involved in the pathogenesis of myeloma-induced bone disease are poorly understood. Heparanase, an enzyme that cleaves the heparan sulfate chains of proteoglycans, is upregulated in a variety of human cancers, including myeloma. Using SCID-hu and SCID-tibia animal models with the injection of CAG myeloma cells engineered to express either high or low levels of heparanase, we have demonstrated that heparanase expression promotes both local and systemic osteolysis. To investigate the underlying mechanism in heparanase induced bone destruction, the levels of human RANKL (a primary mediator of osteoclastogenesis) and OPG (a RANKL inhibitor) in these tumors were evaluated by immunohistolochemical staining and western blotting. A significant elevation of RANKL was observed in heparanase-high tumors compared to heparanase-low tumors, while the level of OPG was not affected. In vitro, RANKL levels were significantly elevated in both cell extracts and conditioned medium of CAG myeloma cells when heparanase expression was enhanced. In addition, the elevation of RANKL expression and secretion was also found in other myeloma cell lines (MM.1S and U266) when the cells were cultured in the presence of recombinant human heparanase for 48 hours. To examine the potential clinical significance of heparanase in myeloma bone disease, we investigated whether heparanase expression correlated with RANKL expression in myeloma patients. Heparanase, RANKL and OPG immunohistochemical staining was performed in 20 bone marrow core biopsy specimens of myeloma patients. The results showed a positive, highly significant correlation between the levels of expression of heparanase and RANKL in both myeloma cells and stromal cells in these patients ($p<0.0001$). The expression of OPG was detected in bone marrow cells but not in myeloma cells. However there was no significant correlation between the expression of heparanase and OPG within the bone marrow ($p=0.22$). In addition, increased heparanase expression in clinical samples was associated with an increased number of TRAP positive osteoclasts. These discoveries identify a novel role for heparanase in myeloma, provide new insights into the mechanisms of myeloma-induced bone disease and further validate the use of heparanase inhibitors in the treatment of myeloma bone disease.

Multiple myeloma (MM) develops and expands in the bone marrow, and causes devastating bone destruction by enhancing osteoclastic bone resorption in their close vicinity. In MM bone lesions, thus induced osteoclasts (OCs) in turn enhance MM cell growth and survival, thereby forming a vicious cycle between the progression bone destruction and MM tumor expansion. Reveromycin A (RM-A), a small microbial metabolite, preferentially induces apoptosis in acid-producing OCs, and draws considerable attention as a novel anti-resorptive agent. In the present study, we explored the effects of RM-A on bone resorption and tumor expansion in MM. INA6 and RPMI8226 MM cells potently enhanced osteoclastogenesis and osteoclastic pit formation when cocultured with rabbit bone marrow cells on bone slices. Notably, large multinucleated OCs were almost completely disappeared and pit formation on bone slices was abolished upon the treatment with RM-A at concentrations as low as 100nM. The cocultures with rabbit bone marrow cells stimulated INA6 MM cell growth; RM-A at 1μM was however able to substantially decrease the MM cell viability in the cocultures, although RM-A at this concentration did not affect MM cell growth when MM cells were cultured alone. The suppression of INA6 MM cell viability by RM-A was obviously more potent than that under bisphosphonate treatment in which mature OCs and pits on bone slices similarly decreased in number, suggesting that the anti-MM effects of RM-A is not merely due to depletion of mature OCs. Blockade of acid release from OCs by the proton pump inhibitor concanamycin A abolished such RM-A effects. Given that the acidic microenvironment increases cell permeability of RM-A to cause apoptosis, it is plausible that highly acidic milieu around OCs allows RM-A to act on nearby MM cells as well as OCs. In vivo RM-A effects were next studied using INA6 MM cell-bearing SCID-rab mice. We injected RM-A sc at 4mg/kg twice daily for 18 days to the mice after confirming MM cell growth at 4 weeks after the MM cell inoculation. The RM-A treatment substantially decreased osteolytic lesions in X-ray and μCT images and MM tumor area in bone sections along with a reduction of INA6 cell-derived human soluble IL-6 receptor levels in mouse sera as a marker of MM tumor burden. These results collectively suggest that RM-A may become a novel therapeutic agent against MM with extensive bone resorption.

Relation of Age, Gender, and Bone Mass to Circulating Sclerostin Levels in Women and Men. Ulrike Moedder*[1], Kelley Hoey[2], Shreyasee Amin[2], Louise McCready[2], L. Joseph Melton[2], Byron Riggs[3], Elizabeth Atkinson[2], Sundeep Khosla[4]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine,Rochester, MN, USA, [4]College of Medicine, Mayo Clinic, USA

Sclerostin is a potent inhibitor of Wnt signaling and bone formation. However, there is currently no information on the relation of circulating sclerostin levels to age, gender, or bone mass in humans. Thus, we used a recently developed ELISA (Biomedica) to measure serum sclerostin levels in a population-based sample of 365 women (123 premenopausal, 152 postmenopausal not on estrogen treatment [ET], and 87 postmenopausal on ET) and 318 men, age 21 to 97 yrs. In pre- and untreated postmenopausal women combined (n=275), serum sclerostin levels were positively associated with age (R=0.52, $P < 0.0001$); an even stronger association was present in men (R=0.64, $P < 0.0001$). Over life, serum sclerostin levels increased by 2.4- and 4.6-fold in the women and men, respectively. Sclerostin levels were significantly higher in men (mean $\pm$ SEM) (757 $\pm$ 22 pg/ml) versus women (538 $\pm$ 14 pg/ml, $P < 0.001$). In addition, sclerostin levels were significantly lower in postmenopausal women on ET (515 $\pm$ 28 pg/ml) versus untreated women (630 $\pm$ 19 pg/ml, $P < 0.001$). Because sclerostin is produced almost exclusively by osteocytes, we next examined the relation between serum sclerostin levels and total body (TB) bone mass, assessed as TB bone mineral content (TBBMC) by DXA. To reduce confounding by age, we separated the subjects into 3 groups: young (age 20-39 yrs), middle-aged (40-59 yrs), and elderly (60+ yrs). In young women (Figure, Panel A), there was no association between TBBMC and serum sclerostin levels; a modest association was present in middle-aged women (Panel B); the strongest, positive correlations were noted in elderly women (Panel C). As also evident, for a given level of bone mass (TBBMC), sclerostin levels were higher in elderly compared to young women (point 2 vs. 1 in the Figure). Identical findings were noted in men (not shown). In summary, our data demonstrate that (1) serum sclerostin levels increase markedly with age; (2) men have higher serum sclerostin levels compared to women; (3) ET reduces serum sclerostin levels; and (4) compared to young subjects, elderly individuals have higher serum sclerostin levels for a given amount of bone mass. These findings suggest that with aging, individual osteocytes may have increased sclerostin production. Further studies are needed to test this hypothesis as well as the potential role of increases in sclerostin production in mediating the age-related impairment in bone formation.

Recent studies suggest that mild hyponatremia may be associated with fractures due to increased risk of falling or a decreased bone mineral density (BMD). We investigated in the prospective, population-based, Rotterdam study whether mild hyponatremia at baseline is associated with fractures and studied a relation with recent falls and BMD. We examined 5208 individuals aged 55 years and over who had measurement of serum sodium levels at baseline. Incident non-vertebral fractures (n=926) were recorded during a mean follow-up period of 7.7 years and analyzed in Cox regression models. Vertebral fractures were assessed by X-rays at baseline (n=194) and during a mean follow-up period of 6.4 years (n=139) and analyzed in logistic regression models. Hyponatremia (serum sodium <136 mmol/l,) was detected in 399 subjects (7.7%), with the lowest values of 124 mmol/l. Subjects with hyponatremia were significantly older (73.5 $\pm$ 10.3 vs. 70.0 $\pm$ 9.0 years $P<0.001$), had more recent falls (23.8% vs. 16.4%, $P<0.01$) higher type 2 diabetes prevalence (22.2 vs. 10.3%, $P<0.001$), and used diuretics more often (36.9% vs. 21.3%, $P<0.001$). Hyponatremia was not related to femoral neck or lumbar spine BMD but was associated with increased risk of incident non-vertebral fractures (HR=1.39, 95% CI; 1.11-1.73, P=0.004) after adjustment for age, sex and BMI. Further adjustments for disability index, use of diuretics and psycholeptics, recent falls and prevalent diabetes did not modify the results. Subjects with hyponatremia also had an increased risk of vertebral fractures (combined prevalent and incident) after adjustment for all covariates (OR=1.61, 95% CI; 1.00-2.59, P=0.049). We conclude that mild hyponatremia in elderly subjects is associated with increased risk of recent falls, vertebral fractures and incident non-vertebral fractures but not with BMD. Since increased fracture risk was independent of recent falls and not associated with BMD, a relation with other determinants of bone quality should be studied. When our findings are replicated in an independent population, screening for hyponatremia should be advised for elderly patients with fractures.

Bone Resorption and Fracture across the Menopausal Transition: The Study of Women's Health Across the Nation (SWAN). Jane Cauley*[1], Michelle Danielson[2], Gail Greendale[3], Joel Finkelstein[4], Yue-Fang Chang[2], Joan Lo[5], Carolyn Crandall[3], Jennifer Lee[6], Robert Neer[4], Mary Fran Sowers[7]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]University of Pittsburgh, USA, [3]University of California, Los Angeles, USA, [4]Massachusetts General Hospital, USA, [5]Kaiser Permanente, USA, [6]University of California, Davis, USA, [7]University of Michigan, USA

Bone turnover makers have been linked to fracture, independent of bone mineral density (BMD) but the majority of these studies have been carried out in older postmenopausal women. To test the hypothesis that bone turnover markers measured before the final menstrual period predict fracture risk across the menopausal transition and whether changes in bone resorption over the menopausal transition are associated with fractures, we studied 2090 multiethnic women enrolled in SWAN. Women attended up to 8 clinic visits an average of 7.6 ± 1.6 years. Women were pre- or early peri-menopausal at baseline. Self-reported fractures were assessed at each clinic visit. Osteocalcin and urinary cross-linked N-telopeptide of type 1 collagen (NTx) were measured at baseline; NTx was measured at each follow-up. Cox proportional hazards models were used to test whether baseline bone turnover markers predicted fracture; hazards ratios (HR) and 95% confidence intervals were calculated. Repeated measures analyses (generalized estimating equations) were used to test whether changes in NTx from baseline predicted fractures and are expressed as odds ratio (95% CI). Women who fractured (n=181) were more likely to be Caucasian, to report a previous fracture and had lower lumbar spine BMD but not total hip BMD at baseline than women who did not fracture. Baseline NTx was higher in women who fractured compared to women who did not fracture (37.6 vs 34.3 mm BCE/mm Cr, p=0.002) but there was no difference in osteocalcin. Baseline NTx was associated with a higher fracture risk (Table). Women with a baseline NTx greater than the median had a 44% higher risk of fracture over the follow-up period. Women who experienced an increase in NTx greater than the median had a 52% higher risk of fracture. In conclusion, bone resorption markers measured before or during the menopausal transition are associated with fracture risk.

Table: Bone resorption and fracture risk			
	Unit	**HR**	**95% CI**
Baseline NTx and Fracture*			
NTx (log transformed)	1	1.43	(0.99, 2.31)
NTx	>median, 31.9	1.44	(1.04, 2.22)

Association of Menopausal Vasomotor Symptoms with Increased Bone Turnover During the Menopausal Transition. Carolyn Crandall*[1], Chi-Hong Tseng[2], Sybil Crawford[3], Rebecca Thurston[4], Ellen Gold[5], Janet Johnston[6], Gail Greendale[1]. [1]University of California, Los Angeles, USA, [2]UCLA, USA, [3]University of Massachusetts Medical School, USA, [4]University of Pittsburgh School of Medicine, USA, [5]Division of Epidemiology, University of California, Davis, USA, [6]University of Alaska Anchorage Department of Health Sciences, USA

Purpose. To determine the longitudinal association between menopausal vasomotor symptoms (VMS) and urinary N-telopeptide level (Ntx) according to menopausal stage.

Methods. We analyzed data from 2283 participants of the Study of Women's Health Across the Nation, a longitudinal community-based cohort study of women aged 42 to 52 years at baseline. At baseline and annually through follow-up visit 8, participants provided questionnaire data, urine samples, serum samples, and anthropometric measurements. We used repeated measures mixed models to examine associations between annually-assessed VMS frequency and annual Ntx measurements.

Results. After controlling for age, smoking, race/ethnicity, physical activity, alcohol intake, vitamin D intake, calcium intake, body mass index, and study site, mean Ntx was 1.94 nM BCE/mM creatinine higher among early perimenopausal women with any VMS than among early perimenopausal women with no VMS (p< 0.0001). Mean Ntx was 2.44 nM BCE/mM creatinine higher among late perimenopausal women with any VMS than among late perimenopausal women with no VMS (p=0.03). When we compared women with frequent VMS (≥ 6 days in past 2 weeks) and women without frequent VMS, associations between VMS and Ntx additionally reached statistical significance among postmenopausal women. Among premenopausal women, VMS frequency was not significantly associated with Ntx level. Adjustment for serum follicle-stimulating hormone level greatly reduced the magnitudes of associations between VMS and Ntx level.

Conclusion. Among early perimenopausal and late perimenopausal women, those with VMS had higher bone turnover than those without VMS. Prior to the final menstrual period, VMS may be a marker for risk of adverse bone health. The Study of Women's Health Across the Nation (SWAN) and the SWAN Repository (AG017719) have grant support from the National Institutes of Health (NIH), DHHS, through the National Institute on Aging (NIA), the National Institute of Nursing Research (NINR) and the NIH Office of Research on Women's Health (ORWH) (Grants NR004061; AG012505, AG012535, AG012531, AG012539, AG012546, AG012553, AG012554, AG012495). The content of this presentation is solely the responsibility of the authors and does not necessarily represent the official views of the NIA, NINR, ORWH or the NIH.

Abdominal Body Composition and Risk of Non-spine Fracture among Elderly Men. Yahtyng Sheu*[1], Lynn Marshall[2], Kathleen Holton[3], Robert Boudreau[1], Peggy Cawthon[4], Jane Cauley[1]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]Oregon Health & Science University, USA, [3]Oregon Health & Sciences University, USA, [4]California Pacific Medical Center Research Institute, USA

The association of abdominal body composition with incident fracture is unclear. To examine the relationships between incident fracture and abdominal adipose tissue (AT), intermuscular AT (IMAT) and muscle, we performed a case-cohort study of 294 men with incident non-spine fractures confirmed from medical records and a random subcohort of 616 men from the Osteoporotic Fractures in Men study (MrOS). We measured volumes (cm^3) of abdominal subcutaneous AT, visceral AT, total muscle, total muscle IMAT, as well as total abdominal muscle density (HU) and percent total abdominal muscle IMAT, obtained from a single-slice (5-mm) quantitative computed tomography scan at the L4-L5 intervertebral space. Cox proportional hazards regression with a robust variance estimator was used to estimate the hazard ratio (HR) and 95% confidence intervals (CI) of non-spine fracture per standard deviation (SD) increase in the abdominal body composition measure of interest. Standard multivariable models included age, study site, BMI, and dual energy X-ray absorptiometry measure of femoral neck bone mineral density (BMD). The mean age among men in the random cohort was 74.2 ± 6.1 years and the average follow-up time was 5.2 years. Among the case-cohort study, men with incident fractures were older and more likely to have fracture after age 50, and had lower weight, body mass index (BMI), grip strength, and body lean and fat mass than men without fracture. Abdominal subcutaneous and visceral AT, and total abdominal muscle volume were not associated with incident fracture (Table 1). HRs for every SD increase in abdominal muscle density and percent abdominal muscle IMAT were 0.82 and 1.23 with borderline significance, respectively. However, total abdominal muscle IMAT volume was significantly associated with 29% greater fracture risk when the above multivariate model was further adjusted for total abdominal muscle volume. The findings suggest that adipose infiltration may decrease muscle quality and consequently lead to higher fracture risk in older men independent of BMD.

Abdominal measure	Mean±SD	HR per SD increase (95% CI)	p-value
Subcutaneous AT (cm^3)	92.8±32.5	0.99 (0.77, 1.26)	0.92
Visceral AT (cm^3)	67.8±28.4	0.90 (0.72, 1.12)	0.33
Total muscle (cm^3)	63.6±8.4	1.10 (0.88, 1.37)	0.41
Total muscle density (HU)	14.7±16.5	0.82 (0.65, 1.04)	0.10
Total muscle IMAT (cm^3)*	16.2±6.5	**1.29 (1.01, 1.65)**	**0.04**
Percent total muscle IMAT (%)	26.0±10.8	1.23 (0.97, 1.56)	0.09

Birth Weight Influences Peak Bone Mass In 25-Year Old Swedish Women. Kristina Akesson[1], Mattias Callréus*[2]. [1]Malmo University Hospital, Sweden, [2]Skåne University Hospital, Sweden

It has been postulated that accrual of bone mass in childhood and adolescence is related to birth weight, however it is not clear to what extent this effect persists to contribute to peak bone mass. The purpose of this study was to evaluate the potential influence of birth weight on peak bone mass, fat mass and lean mass.

Subjects and Methods

1061 young adult women, all 25 yrs old, participated in this population-based study, PEAK-25. DXA was used to assess bone mass and body composition. Bone mineral density (BMD) was determined for spine (LS) and femoral neck (FN). Total body (TB) measurement was used for bone mineral content (BMC), fat mass and lean mass. Information on lifestyle and other health factors were obtained through questionnaire. Birth data was available for 1047 women and obtained from the National Board of Health and Welfare. Pearson Correlation was used to identify correlations between birth weight and assessed parameters. ANCOVA analysis adjusted for current adult body weight, with Bonferroni correction, was applied after dividing subjects into tertiles of birth weight. *Results*

At baseline the women were 25.5 $\pm$ 0.2 yrs, height 167 $\pm$ 6 cm, body weight 65 $\pm$ 11 kg. Mean birth weight was 3 392 $\pm$ 537 gram, and length 50 $\pm$ 2.3 cm. Crude positive correlations with birth weight were identified for TB BMC (r=0.24; p<0.001), FN BMD (r=0.11; p<0.001), fat mass (r=0.10; p=0.001), and lean mass (r=0.29; p<0.001). There was no significant correlation for LS BMD. After adjustment, positive correlations remained for TB BMC (r=0.16; p<0.001), and lean mass (r=0.22; p<0.001). Correlation to fat mass became strongly negatively correlated (r=-0.21; p<0.001). Lean mass demonstrated the highest correlation, even after adjustment. ANCOVA confirmed these findings. Birth weight effects were most pronounced between the low-high birth weight tertiles (p<0.001), and between low-middle birth weight (BMC p=0.002; fat mass p=0.003; lean mass p=0.002). Fat mass changed direction between middle-high birth weight (p=0.013).

Conclusion

This study indicates that birth weight is predictive of peak bone mineral content in women and has a strong influence on future fat and lean mass. In general, the influence appeared more pronounced for women with lower birth weights.

Does the Benefit of Medication Adherence Relate More to a Drug Effect or the Behavior Itself? Quantifying the Effect of Adherence Behavior Using Data From the Placebo Arms of the WHI. Jeffrey Curtis*[1], Joseph Larson[2], Elizabeth Delzell[1], M. Alan Brookhart[3], Suzanne Cadarette[4], Rowan Chlebowski[5], Suzanne Judd[1], Monika Safford[1], Daniel Solomon[6], Andrea Lacroix[2]. [1]University of Alabama at Birmingham, USA, [2]Fred Hutchinson Cancer REsearch Center, USA, [3]UNC-Chapel Hill, USA, [4]Leslie Dan Faculty of Pharmacy, University of Toronto, Canada, [5]UCLA Medical Center, USA, [6]Harvard Medical School, USA

Purpose: The relationship between medication adherence and various outcomes including fracture is of substantial interest, particularly in the osteoporosis community. The extent to which adherence to medications as a behavior is a proxy for other healthy behaviors that affect outcomes is unclear. To better understand the magnitude of the effect of adherence as a behavior, we examined the relationship between adherence to placebo in the hormone therapy (HT) arm of the Women's Health Initiative (WHI) on the risk of fracture, cardiovascular events, malignancy and death.

Method: We used data from those randomized to placebo in the HT arm of the WHI. Adherence was represented as timevarying based upon pill counts and quantified as a medication possession ratio (MPR). Outcome events were identified and validated using medical records as per the original WHI protocol. Confounders were selected a-priori and based upon the ability to adjust the main exposure-outcome relationship by > 10%. Cox proportional hazards models were used to evaluate the relationship between adherence ($\leq$ 50%, 50-80%, $\geqslant$ 80%) and each of the various outcomes, with low adherence as referent. Analyses were censored at the first event specific to each outcome.

Results: A total of 13485 women were randomized to placebo in the HT arm of the WHI and were under observation for 86091 person-years (without respect to censoring). The median (IQR) cumulative adherence to placebo at the end of the trial was 91.3% (81.4, 96.0%). There was a consistent relationship between adherence to placebo and a protective effect of all outcomes that was strongest for death and hip fracture, although not all results were statistically significant (see table). Results were not substantially affected by multivariable adjusted for various confounders.

Conclusion: Medication adherence appears to be a proxy for other unmeasured behaviors and health habits that have important effects on numerous outcomes. The magnitude of this effect was greatest for hip fracture and death. Results of future studies evaluating outcomes related to adherence to specific medications should be interpreted cautiously in light of these results.

Relationship Between Adherence to Placebo and Various Events, High Compared to Low Adherence, WHI Clinical Trial Placebo Arm (N=13,444 Women)

Outcome	Adherence Category	Events	Ann %	Unadjusted Hazard Ratio (95% CI)	Fully Adjusted* Hazard Ratio (95% CI)

Utility of Serial BMD for Fracture Prediction After Discontinuation of Prolonged Alendronate Therapy: The FLEX Trial. Douglas Bauer*[1], Ann Schwartz[1], Lisa Palermo[1], Jane Cauley[2], Kristine Ensrud[3], Marc Hochberg[4], Arthur Santora[5], Dennis Black[1]. [1]University of California, San Francisco, USA, [2]University of Pittsburgh Graduate School of Public Health, USA, [3]Minneapolis VA Medical Center / University of Minnesota, USA, [4]University of Maryland School of Medicine, USA, [5]Merck Research Laboratories, USA

Some clinicians recommend a drug holiday after 5 or more years of bisphosphonate treatment. The utility of serial monitoring with DXA following discontinuation of bisphosphonates is unknown.

The FLEX trial randomized 1099 postmenopausal women previously treated with alendronate (ALN) for approximately 5 years to either continued ALN or placebo for an additional 5 years. Hip DXA (Hologic QDR2000) was obtained at baseline and at each annual visit. Self-reported clinical fractures (non-spine and vertebral) were centrally adjudicated. This analysis is limited to women randomized to placebo in FLEX (N=437). The relationship between FLEX baseline total hip BMD (BMD-BL) or 1-year or 2-year percent change in BMD (ΔBMD) and the risk of clinical fracture were analyzed using age-adjusted Cox models; BMD-BL and ΔBMD were analyzed as continuous variables and tertiles. Among the cohort of 437 women, 109 non-spine and 28 clinical vertebral fractures occurred in 94 women during nearly 5 years of follow-up. Fractures occurring after FLEX baseline but before the follow-up BMD measurement (22 fractures in 19 women during the first year) were excluded.

Compared to women without fracture during follow-up, those with clinical fracture were older (75.2 vs.73.0 yr., p<0.001) and had lower total hip BMD-BL (0.69 vs. 0.73 gm/cm^2, p<0.001), but 1-year ΔBMD was similar (-1.5 vs. -1.3% p=0.59). When analyzed as a continuous variable, or by tertiles (Figure), there were no significant associations between ΔBMD and clinical fracture risk during follow-up, even among the 21% of placebo-treated women in FLEX with >3% bone loss after 1 year (27.5 vs. 19.5%; RH 1.5, 95% CI: 0.9, 2.4, p=0.12). Conversely, BMD-BL was strongly related to the risk of fracture during follow-up (Figure). Results using 2-year ΔBMD gave similar results.

We conclude that among women stopping ALN after 5 years of therapy, hip BMD at the time of discontinuation strongly predicts the risk of clinical fracture over the next 5 years, but 1-year and 2-year changes in BMD after discontinuation of ALN are not associated with subsequent fracture risk. These data suggest repeat BMD

measurements 1-2 years after discontinuation of prolonged ALN therapy may not be useful.

Denosumab Improves Both Femoral and Vertebral Strength in Women With Osteoporosis: Results From the FREEDOM Trial. Tony Keaveny*[1], Michael McClung[2], Harry Genant[3], Jose Ruben Zanchetta[4], David L. Kendler[5], Jacques Brown[6], Stefan Goemaere[7], Christopher Recknor[8], Maria Luisa Brandi[9], Richard Eastell[10], Klaus Engelke[11], Thomas Fuerst[12], Hoi-Shen Radcliffe[13], Cesar Libanati[14]. [1]UC Berkeley, USA, [2]Oregon Osteoporosis Center, USA, [3]UCSF/Synarc, USA, [4]Instituto de Investigaciones Metabolicas (IDIM), Argentina, [5]University of British Columbia, Canada, [6]Laval University, Canada, [7]Ghent University Hospital, Belgium, [8]United Osteoporosis Center, USA, [9]University of Florence, Italy, [10]University of Sheffield, United Kingdom, [11]Synarc, Germany, [12]Synarc, Inc., USA, [13]Amgen Inc, United Kingdom, [14]Amgen Inc, USA

Denosumab (DMAb), a human monoclonal antibody to RANKL, increased bone mineral density (BMD), decreased bone resorption, and significantly reduced the risk of new vertebral, nonvertebral, and hip fractures in the FREEDOM trial (Cummings et al, NEJM, 2009:361:756). FREEDOM was a phase 3 trial in women 60-90 years old with postmenopausal osteoporosis randomized to 60mg DMAb or placebo (Pbo) every 6 months plus daily calcium and vitamin D supplementation. Patient-specific femoral strength for a simulated sideways fall and L2 vertebral strength for a simulated compression overload were estimated, blinded-to-treatment status, using non-linear 3D finite element analysis of the quantitative computed tomography scans obtained at baseline, 12, 24, and 36 months in a subset of participants (51 DMAb; 48 Pbo). All analyses were exploratory and posthoc. For women treated with DMAb, femoral strength increased significantly compared with baseline by 5.4% ($p<0.0001$) at 12 months, and this strength was augmented over time reaching 8.4% ($p<0.0001$) at 36 months (Table). In contrast, for women treated with Pbo, femoral strength did not change at 12 months and decreased at 36 months compared with baseline (–5.4%, $p<0.0001$). The same temporal trends were seen at the spine but the changes were much larger than at the hip: at 36 months, vertebral strength increased by 18.1% ($p<0.0001$) for the DMAb group and decreased by –4.1% ($p=0.004$) for the Pbo group. For both the hip and spine, DMAb subjects displayed mostly uniform increases in cortical strength, derived from the outer 3mm of bone at the hip and the outer 2mm at the spine, as well as in trabecular strength. Pbo subjects exhibited a preferential loss of trabecular strength. We also found that DMAb-related improvements in strength at the hip and spine were significantly correlated (r=0.38, $p=0.02$, Figure). At 36 months, all DMAb subjects had increased vertebral strength, and all but 2 had increased femoral strength; strength decreases were observed for the majority of Pbo subjects. These improvements in whole-bone strength support the vertebral and nonvertebral fracture efficacy observed with DMAb. We conclude from these findings that DMAb treatment significantly increases both hip and vertebral strength after 12 months compared with both baseline and Pbo, and positively influences both the trabecular and cortical compartments, and that these strength changes improve over 36 months of treatment.

Table.

		FEMUR			SPINE		
		Month 12	Month 24	Month 36	Month 12	Month 24	Month 36

Regulators of Bone Formation in Postmenopausal Osteoporosis: Effect of Bisphosphonate Treatment. Richard Eastell, Rosemary Hannon, Fatma Gossiel*. University of Sheffield, United Kingdom

The Wnt signalling pathway is essential for the regulation of bone formation. Serum based immunoassays have recently been developed to measure two key regulators of Wnt signalling, namely Dickkopf-1(Dkk-1) and sclerostin. Postmenopausal osteoporosis is associated with an increase in bone resorption and bone formation. Treatment with oral bisphosphonates results in a decrease in bone formation markers. It is not known whether levels of Dkk-1 and scelrostin are increased in postmenopausal osteoporosis and decrease with bisphosphonate treatment.

The aims were to determine whether 1) Dkk-1 and sclerostin are decreased in postmenopausal osteoporosis and 2) bisphosphonate treatment of postmenopausal osteoporosis results in an increase in these regulators of bone formation.

We recruited 50 postmenopausal women (mean age 68: range 55 to 85 years), with a BMD T-score of <2.5 or <1 and a fracture. They were randomised in to 3 treatment groups: ibandronate (n=15), alendronate (n=19) and risedronate (n=16). 50 healthy premenopausal women (mean age 38: range 35 to 40 years) were also recruited. We measured DKK-1 and sclerostin (Biomedica Gruppe, Austria), Total PINP, osteocalcin and CTX (Roche Diagnostics, Pensberg, Germany) and Intact PINP (IDS, Boldon, UK) in fasting serum samples at baseline and after 48 weeks of treatment in the post menopausal women and once in the premepausal control.

The median levels of total and intact PINP, osteocalcin and sCTX, and sclerostin were significantly higher in osteoporotic postmenenopausal women at baseline compared to the controls, P<0.001. There was no significant difference in median levels of Dkk-1. After 48 weeks of bisphosphonate treatment total and intact PINP, osteocalcin and sCTX decreased by 67%, 68%, 52% and 78% respectively, and no difference in the median levels of Dkk-1 and sclerostin.

We conclude that like bone turnover markers, sclerostin levels are higher in postmenopausal osteoporotic women compared to premenopausal women. This may reflect the impairment of bone formation relative to bone resorption in osteoporosis. Treatment of postmenopausal osteoporosis with oral bisphosphonates results in a decrease in bone turnover as expected. However, there was no increase in Dkk-1 and sclerostin.

The median and 95% confidence intervals for each bone marker and regulators of bone formation in the healthy premenopausal control group and the osteoporotic postmenopausal group at baseline and 48 weeks after bisphosphonates treatment

	Control group (N=50)	Mean B/line (N=50)	Week 48 (N=50)
Total PINP ng/ml	34.1 (30.6-38.4)	54.4 (47.7-62.3)	18.1 (14.3-22.7)
Intact PINP ng/ml	27.5 (25.7-31.9)	44.2 (38.8-53.8)	14.0 (11.7-18.3)
Osteocalcin ng/ml	15.2 (14.35-17.0)	28.8 (22.6-30.2)	13.6 (11.2-13.8)
sCTX ng/ml	0.22 (19.00-0.27)	0.47 (0.39-0.54)	0.10 (0.08-0.12)
Dkk-1 pmol/l	475.3 (436.0-512.8)	452.9 (418.6-487.3)	438.4 (388.4-492.9)
Sclerostin pmol/l	14.9 (11.4-16.6)	20.7 (16.2-24.1)	20.1 (14.7-22.7)

Risedronate Reduces Deterioration of Cortical Bone Microarchitecture Accompanying Menopause. Ego Seeman*[1], Babul Borah[2], Roland Chapurlat[3], Dieter Felsenberg[4], Lynn Darbie[5], Rene Rizzoli[6]. [1]Austin Health, University of Melbourne, Australia, [2]Procter & Gamble Pharmaceuticals, USA, [3]E. Herriot Hospital, France, [4]Charité - Campus Benjamin Franklin, Germany, [5]Warner Chilcott Pharmaceuticals, USA, [6]University Hospital, Switzerland

Increased remodeling with its negative bone balance contributes to structural deterioration of the skeleton after menopause. While accelerated trabecular bone loss contributes to bone fragility and has been the focus of attention, cortical bone, which constitutes 80% of the skeleton, is a critical but neglected determinant of bone strength because it is believed to remodel slowly. Moreover, most fractures are non-vertebral and arise in women with osteopenia. Risedronate (RIS) reduces the risk for non-vertebral and hip fracture and reduces intracortical porosity as assessed in iliac crest biopsies[1]. To better understand the structural basis of the anti-fracture efficacy of risedronate, particularly in women with osteopenia, we conducted a 12 month double-blind pilot study involving 159 osteopenic women aged 45-55 years within 36 months of menopause. Participants were assigned to oral RIS 35mg/week or placebo (PLB) in a 2:1 randomization. Using high resolution pQCT (XtremeCT, Scanco, 100 µm resolution) ,microstructural parameters were measured at baseline and 12 months at distal tibia (DT) and distal radius (DR). In PLB, DT total and cortical but not trabecular vBMD and cortical thickness decreased. RIS prevented the decline in cortical vBMD in DT (p=0.03); similar observations (not significant) were made for DT cortical thickness and DR cortical vBMD and thickness. No treatment differences were detected in trabecular vBMD, BV/TV or other trabecular bone indices in DT or DR. RIS decreased P1NP (-44.1%) and CTX (-39.4%) and increased aBMD in the lumbar spine (1.4%) and proximal femur (0.5%). The seeming lack of response in trabecular bone may be the result of trabecularization of cortex. Treatment with RIS reduces the deterioration of cortical microstructure, probably due to the reduction of intra-cortical porosity and may therefore protect against developing bone fragility.

Fracture Risk Reduction with Zoledronic Acid by Predicted Fracture Risk Score. Jane Cauley*[1], Steven Cummings[2], Lisa Palermo[3], Felicia Cosman[4], Richard Eastell[5], Steven Boonen[6], Trisha Hue[3], Christina Bucci-Rechtweg[7], Dennis Black[3]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]San Francisco Coordinating Center, USA, [3]University of California, San Francisco, USA, [4]Helen Hayes Hospital, USA, [5]University of Sheffield, United Kingdom, [6]Center for Metabolic Bone Disease, Belgium, [7]Novartis Pharmaceuticals Corporation, USA

Purpose: New NOF treatment guidelines for osteoporosis are based on analyses that assume the same level of drug efficacy regardless of the underlying absolute risk of fracture. In the Health Outcomes and Reduced incidence with Zoledronic Acid Once-Yearly Pivotal Fracture Trial (HORIZON_PFT), zoledronic acid (ZOL) 5mg significantly reduced the risk of vertebral, hip and other fractures by 70%, 41%, and 33%, respectively.

Methods: To test the hypothesis that the effect of ZOL on fracture reduction differs by predicted risk of fracture, we carried out a preplanned analysis in 7,736 women with postmenopausal osteoporosis who were randomized to receive a single annual infusion of ZOL 5mg or PBO over 3 years. Each participant was categorized for 5 year hip fracture risk by adapting a risk facture score developed by Black et al [1]. The assessment tool is comprised of a set of 7 variables: age, BMD T-score, fracture risk after age 50, maternal history of hip fracture, weight <125 lbs, smoking status and using arms to stand. The risk score ranged from 1 to 11. In continuous models, a one unit increase in the fracture score was associated with 1.29 (1.16, 1.44), and 1.11 (1.06, 1.17) increased odds (95% Confidence Intervals, CI) of hip fracture and any clinical fracture, respectively. For analyses, we divided the score into tertiles and calculated the relative risk (95% CI) of hip, all non-vertebral and all clinical fractures in ZOL versus PBO using Cox proportional hazards models and for incident morphometric vertebral fractures using logistic models. Interaction between treatment effect and absolute fracture risk was tested using continuous risk models.

Results: The effect of ZOL on reduction of vertebral, non-vertebral and all clinical fractures was similar regardless of the estimated risk of fracture (Table). However, for hip fractures, there was a trend toward greater reduction in women at the lowest risk, (p=0.056).

Conclusions: We conclude that the effect of ZOL on fracture reduction was consistent for vertebral, all non-vertebral and all clinical fractures across tertiles of absolute fracture risk. The observation that ZOL may have a greater effect on hip fracture among those at lower absolute risk of fracture is consistent with subgroup analyses showing greater benefit among younger women[2].

A Five Years Exercise Intervention Programme in 7-9 Year Old Children Improve Bone Mass and Bone Structure without Increasing the Fracture Incidence. Magnus Karlsson[1], Jan-Åke Nilsson[2], Fredrik Detter*[3]. [1]Skåne University Hospital Malmö, Lund University, Sweden, [2]Clinical & Molecular Osteoporosis Research Unit, Sweden, [3]Clinical & Molecular Osteoporosis Research UnitLund University, Sweden, Sweden

Purpose: Published pediatric exercise intervention studies that evaluate if exercise may be fracture preventive span at maximum 24 months and uses bone traits as surrogate endpoints for fractures. Furthermore, reports infer physical activity to be associated with more trauma and fractures. Therefore we designed a 5-years population based controlled exercise intervention study with also fracture as endpoint.

Method: The intervention group achieved 40 minutes/day of school physical education and the controls 60 minutes/week. Included were 2395 children aged 7-9 years, 362 girls and 446 boys in the intervention (3152 person-years) and 780 girls and 807 boys in the control group (6761person-years). Fractures were prospectively registered. In 54 girls and 83 boys in the intervention and 53 girls and 58 boys in the control group, skeletal development was followed annually by dual energy X-ray absorptiometry. Slopes and annual changes were calculated for bone mineral density (BMD; g/cm^2) in spine and femoral neck and bone width (mm) in femur. Peripheral computed tomography was applied in forearm and tibia at last measurement. Group

comparisons are reported as mean group difference with 95% CI within brackets and with p-value adjusted for Tanner stage at follow-up.

Results: There were 20.0 fractures/1000 person-years in the intervention and 18.5 fractures/1000 person-years in the control group, leading to a Rate Ratio (RR) of 1.08 (0.79, 1.47) (mean (95% CI)). The mean annual gain in spine BMD was larger in both intervention girls (0.01 g/cm^2 (0.007, 0.02) and intervention boys (0.006 g/cm^2 (0.003, 0.01) and in femoral neck BMD larger in intervention girls (0.007 g/cm^2 (0.00, 0.02) than in the control groups. The gain in femur width was larger in intervention girls (0.3 mm (0.0, 0.6)) and intervention boys (0.1 mm (0.0, 0.4) than in the control groups. The intervention girls had at study end larger mid radial area (11 mm^2 (0.6, 21); p=0.006), more tibia cortical bone mineral content (0.2 g (0.0, 0.4); p=0.01)), larger mid tibial area (17 mm^2 (-3, 36); p=0.03) and larger mid tibial cortical area (17 mm^2 (2, 31); p=0.009) than the control girls The intervention boys had larger mid radial area (7 mm^2 (-3, 18); p=0.04) than the control boys.

Conclusions: Increased duration of school physical education for 5 years in 7-9 year old children could population based be used to improve bone mass and bone structure without increasing the fracture risk.

Habitual Vigorous Physical Activity Increase Cortical Bone Mass In Adolescents, Unlike Light Or Moderate Activity Which Are Without Effect. Jon Tobias, Adrian Sayers*. University of Bristol, United Kingdom

Introduction

How intense habitual physical activity (PA) needs to be affect skeletal development in childhood is currently unclear. To examine this question, we compared the contributions of light, moderate and vigorous day-to-day PA as measured by Actigraph accelerometers, to pQCT-derived cortical bone mineral content (BMCC) of the mid-tibia, in 1748 16-year-old boys and girls from the Avon Longitudinal Study of Parents and Children (ALSPAC).

Methods

Multi-variable analyses were performed to identify independent influences of light, moderate and vigorous physical activity on BMCC. Light, moderate and vigorous physical activity was defined by 2, 4 or 6 METS (kcal.kg^{-1}.h^{-1}) which are associated slow walking, brisk walking and jogging respectively. Further analyses were performed to identify the influences of PA on BMC that were independent of concurrent changes in fat mass (FM) and lean mass (LM). Path analyses were also carried out to identify the relative effects of an increase in periosteal circumference (PC), endosteal circumference adjusted for PC (ECPC) and cortical BMD (BMDC) to associations between PA and BMCC which were present.

Results

In multivariable analyses, vigorous activity had a strong positive influence on BMCC [β 0.082 (95% CI: 0.037, 0.128), p=0.0004], whereas there was no evidence of an effect of light or moderate PA (both P > 0.7) (b represents SD change per doubling of vigorous activity). The effect of vigorous PA on BMCC was largely independent of associated changes in body composition [β 0.070 (95% CI: 0.026, 0.115), p=0. 002, adjusted for FM and LM]. The vigorous PA effect on BMCC was mediated by an increase in PC [β 0.049 (95% CI: 0.018, 0.080), p=0. 002], and a reduction in ECPC [β 0.018 (95% CI 0.010, 0.027), p<0.0001]. There was also evidence of a small negative effect on BMDC [β -0.010 (95% CI: -0.017, -0.003)]. There was no evidence of a differing effect between boys and girls, p=0.47.

Conclusion

The amount of vigorous day-to-day PA exerts important effects on cortical bone development, whereas less intense PA has little discernible effect. Changing the amount of physical activity in childhood is unlikely to benefit skeletal development unless more intense high impact activities such as jogging or running are also increased.

Positive Impact of Both Physical Activity and Protein Intake before Puberty on Biomechanical Strength at Weight Bearing Skeletal Sites 7.8 yrs Later in Healthy Boys. Thierry Chevalley*[1], Jean-Philippe Bonjour[2], Bert Rietbergen[3], Serge Ferrari[4], Rene Rizzoli[5]. [1]University Hospitals of Geneva Division of Bone Diseases, Switzerland, [2]University Hospital of Geneva, Switzerland, [3]Eindhoven University of Technology, The netherlands, [4]Geneva University Hospital & Faculty of Medicine, Switzerland, [5]University Hospital, Switzerland

The influence of environmental factors on adult bone mass and strength appears to be stronger before than after the onset of pubertal maturation. In keeping with this notion we reported in a prospective study in a cohort of 176 healthy boys that the positive impact of relatively high protein intake (superior to median=HProt) and high physical activity (superior to median=HPA) vs. both moderate protein intake (inferior to median=MProt) and physical activity (inferior to median=MPA) evaluated at 7.4±0.4 yrs (±SD) old on areal bone mineral density (aBMD), content (BMC) and width of the femoral neck (FN) measured by DXA before pubertal maturation was observed unabated at the age of 15.2±0.5 yrs. At this age the difference in FN BMD, BMC and width in the HProt-HPA vs MProt-MPA was combined with significant differences (P<0.001) in structural components of distal tibia including cross-sectional area (CSA, mm^2), trabecular number (Tb.N, mm-1), and trabecular space (Tb.Sp, µm) as assessed by high resolution peripheral computerized tomography (HR-pQCT). We now report the influence of HProt-HPA vs MProt-MPA on biomechanical properties of the distal tibia as assessed by micro-finite element analysis (µFEA) based on HR-pQCT measurements. µFEA derived variables reported here include the estimated failure load [N] and the stiffness (kN/mm) as well as the distinct contribution of trabecular and cortical compartments. An increase in PA from 168±40 to 303±54 (±SD) kcal/day under MProt (38.0±6.9 g/day) was associated with increased stiffness and failure load of +0.16 and +0.14 Z-score, respectively. In contrast an increase in PA of similar magnitude from 167±33 to 324±80 kcal/day under HProt (56.2±9.5 g/day) was associated with a larger increase in stiffness and failure load of +0.42 and +0.48 Z-score, respectively (Figure). No difference was observed among these 4 sub-groups in the percentage of load carried by cortical and trabecular bone of the distal tibia. In conclusion, the positive influence of relatively high protein intake on the impact of physical activity observed before puberty and 7.8 yrs later on femoral neck aBMD, BMC and width is also associated with enhanced mechanical resistance at weight bearing site. These results underscore the importance of nutrition and exercise in the early prevention of adult osteoporosis.

Loaded Physical Activity Predicts 12-month Change in Bone Strength and Bone Microstructure at the Distal Tibia in Adolescents. Melonie Burrows*, Danmei Liu, Deetria Egeli, Heather McKay. University of British Columbia, Canada

Randomized controlled intervention trials and long-term prospective studies using dual energy x-ray absorptiometry and peripheral quantitative computed tomography (pQCT) highlight the key role that physical activity (PA) plays to enhance bone mineral content and bone geometry in adolescents across growth. However, there are no high resolution (HR) pQCT studies that assess the effect of PA on bone strength and bone microstructure over time. We conducted a 12-month prospective study to address the following two objectives; 1) To describe 12-month changes in bone strength and bone microstructure in male and female participants, and, 2) To investigate the contribution of loaded physical activity to bone changes. We assessed PA (loaded, hours per week) using the PA Questionnaire for High School Students (1). Using HR-pQCT (Scanco Medical) we assessed the distal tibia (8% site) in 110 male and 80 female participants at baseline (T1) and 12-months (T2). We report the following bone parameters; total area (ToA, mm), total density (ToD, mg/cm^3), cortical density (CoD, mg/cm^3), cortical thickness (Cort.Th, µm), trabecular density (TrD, mg/cm^3) and trabecular number (TbN, 1/mm). Our primary outcome was bone strength index (BSI, mg^2/mm^4 = ToA x ToD^2) (2). We addressed our first objective using ANOVA (P<0.05) and our second objective using regression (adjusting for baseline values, changes in height (cm), weight (kg) and tibial length (cm); STATA, version 10.1). We found significant changes in BSI (12%; 4%), Cort.Th (14%; 2%), TbN (2%; 2%) and ToD (7%; 1%) for male and female participants, respectively. Change in CoD (1%) and TrD (2%) was significant for males only, and change in ToA (2%) was significant for females only (Table 1). A one hour per week increase in PA predicted significant increases in BSI (1%), CoD (1%) and Cort.Th (0.5%) in males only (P<0.05). This could be due to significant increases in PA across the 12-month period in male participants (2%) whereas female's PA decreased (-8%). Our results suggest that PA contributes significantly to bone strength and bone microstructure in adolescent males. It seems important to extend our prospective trial to track whether these relationships persist/change for young adult men and women.

Increased Physical Activity Is Associated with Augmented Cortical Bone Size in Young Men: a Five Year Longitudinal Study. Martin Nilsson*[1], Claes Ohlsson[2], Dan Mellstrom[3], Mattias Lorentzon[1]. [1]Center for Bone Research At the Sahlgrenska Academy, Sweden, [2]Centre for Bone & Arthritis Research, Sweden, [3]Sahlgrenska University Hospital, Sweden

Physical activity is believed to have positive effects on the development of cortical bone during growth, but the effects in young adult men has been insufficiently studied. The aim of this five year longitudinal study of young adult men was to determine whether an altered level of physical activity between 19 and 24 years of age was associated with changes in bone mass in general and in cortical geometry in particular. Men from the original Gothenburg Osteoporosis and Obesity (GOOD) Study (n=1068) were contacted by letter and telephone and invited to participate in this five year follow-up study, and a total of 833 men (78%), 24.1 ± 0.6 years of age (mean ± SD), were included. The mean follow-up time was 62.2 ± 2.3 months. A standardized self administered questionnaire was used to collect information about patterns of physical activity at both the baseline and five year follow-up visits. Men were categorized according to physical activity level (Low <4 hrs/wk and High ≥4 hrs/wk) at baseline and at follow up. Areal bone mineral density (aBMD) was measured using dual energy X-ray absorptiometry, whereas volumetric bone mineral density (vBMD) and bone geometry were measured by peripheral quantitative computed tomography. Men who increased their level of physical activity (Low to High), had a more favorable development of total hip aBMD (a yearly increase of 0.3% ± 0.15 (mean ± SEM)) than men who maintained a low level of physical activity (a yearly decrease of 0.4% ± 0.05) during the five year period ($p<0.0001$).

The yearly increase in cortical cross sectional area (CSA) at the tibial diaphysis was greater in men who increased their physical activity level (from Low to High) than the corresponding increase in men with consistently low physical activity level (Fig.1). Men who reduced their physical activity level (High to Low) did not have lesser yearly gains in cortical CSA than men who continued with a high level of physical activity (Fig. 1).

In conclusion, we found that an increased level of physical activity between 19 and 24 years of age was associated with greater increments in cortical bone size and with continued gains in total hip aBMD, indicating that increased physical activity can optimize bone development due to a favourable effect on cortical bone geometry in young adulthood.

Physical Activity Predicts Bone Mass throughout Childhood: Iowa Bone Development Study Eight-Year Longitudinal Results. Kathleen Janz*[1], Trudy Burns[1], James Torner[1], Julie Eichenberger Gilmore[1], Marcia Willing[2], Steven Levy[1]. [1]University of Iowa, USA, [2]Washington University, USA

Purpose: One strategy to decrease the risk of developing osteoporosis during old age is to ensure optimal bone mass accrual during the growing years. Weight-bearing physical activity (PA) during childhood is associated with bone mass accrual; although most studies examining these relationships have focused on older children (just prior to puberty). Using a longitudinal observational design spanning 8 years of growth, we examined associations between PA and bone mineral content (BMC) in a cohort of healthy young children (n=398, 5 yr at baseline).

Methods: PA and BMC were analyzed in 188 boys and 210 girls participating in the Iowa Bone Development Study at 5, 8, 11, and 13 yr. BMC (hip, spine, whole body) was measured using DXA. PA was measured by the Actigaph monitor and categorized into moderate and vigorous intensity PA (min/d) and total PA (counts/min/d). TV viewing and video gaming, markers of sedentary behaviors, were estimated from parent and child reports. Maturity was estimated using predictive equations by Mirwald. Data were analyzed using multilevel (random- and fixed-effects) regression models which included adjustment for centered age (yr), centered age-squared (yr), height (cm), maturity (0,1), TV viewing (1-5 scale), and video gaming (1-5 scale). Quadratic age was included to allow for non-linear growth. The first-level of the models described the child-specific developmental change of region-specific BMC or whole body BMC over the course of the study (random effect). Adjustment variables and PA variables were added in a stepwise fashion as fixed effects to the second-level of the models. Likelihood ratio statistics were used to determine whether the effects of PA were significant contributors to the models. All models were gender-specific and used a criterion of $p < 0.05$.

Results: Throughout childhood, boys and girls who were the most active had the greatest amount of BMC ($p< 0.05$ all models; all PA measures). Higher intensity PA was more strongly associated with BMC than other PA measures. The association was strongest between higher intensity PA and hip BMC for both boys and girls. In boys, video gaming was inversely associated with BMC in all models ($p < 0.05$).

Conclusions: These results provide evidence that greater amounts and higher intensities of PA are associated with bone mass accrual throughout childhood and during puberty. In boys, decreasing time spent playing video games may contribute to optimal bone development.

Rescue of Active Intestinal Calcium Absorption Reverses the Impaired Osteoblast Function in VDR Null Mice. Ritsuko Masuyama*[1], Liesbet Lieben[2], Ingrid Stockmans[2], Riet Van Looveren[2], Nico Smets[2], Roger Bouillon[2], Geert Carmeliet[2]. [1]Nagasaki University Graduate School of Biomedical Sciences, Japan, [2]Laboratory Experimental Medicine & Endocrinology, Katholieke Universiteit Leuven, Belgium

Systemic vitamin D receptor (VDR) inactivation is characterized by severe hypocalcemia associated with impaired bone mineralization. The normalization of calcium homeostasis by dietary treatment corrects these bone pathologies and strongly suggests that the major target of vitamin D (VD) genomic action is the active intestinal calcium absorption.

To verify this hypothesis, we generated mice expressing VDR exclusively in the intestine (VDR^{res}) by breeding VDR null mice ($VDR^{-/-}$) with transgenic mice expressing VDR under the control of the Calbindin-D9k promoter. After appropriate breeding, VDR^{res}, $VDR^{-/-}$ and wild-type (WT) littermates were phenotypically analyzed.

VDR was expressed in the duodenum of 8-week-old VDR^{res} mice. Although VDR mRNA levels were only 10% of WT levels, serum calcium levels were largely normalized (VDR^{res} 9.0 ± 0.2mg/dL) likely due to increased expression of *Trpv6* by reintroducing VDR expression in the intestine, and resulted in an increased bone volume. Despite the severe hyperparathyroidism in VDR^{res} mice, osteoclast surface was not increased in VDR^{res} compared to WT mice. A possible explanation is that efficient induction of osteoclastogenesis by PTH requires VDR signaling. To substantiate this hypothesis, *RANKL* expression in osteoblasts, derived from bone marrow, was analyzed after PTH and 1,25VD treatment. PTH treatment increased *RANKL* expression in all genotypes, though the induction was much larger in WT osteoblasts. Combinations of PTH with 1,25VD caused synergistic effects in WT cultures whereas these effects were not observed in the cells lacking VDR. These results suggest that VDR-mediate VD signaling is involved in the regulation of *RANKL* expression by PTH. Furthermore, the expanded osteoid surface, a typical finding in $VDR^{-/-}$ mice, returned to normal by correcting serum calcium in VDR^{res}, as did osteoblast differentiation shown by similar *Runx2*, *osteopontin* and *osteocalcin* expression in femur of VDR^{res} compared to WT. To assess whether serum calcium levels directly modulate osteoblast differentiation, mRNA levels of differentiation markers were quantified in WT osteoblasts cultured with different calcium concentrations. Although *Runx2* and *osteopontin* expression was not affected, *osteocalcin* expression dose-dependently increased by calcium concentration.

In conclusion, intestinal VD genomic action promotes active calcium absorption that is required for normocalcemia which on its turn supports local bone turnover directly.

Disruption of Pdia3, a Mediator of Rapid Membrane Responses to 1α,25-Dihydroxyvitamin D_3 Results in Embryonic Lethality in Homozygotes and Bone Abnormality in Heterozygotes. Yun Wang*[1], Alex Nizkorodov[2], Kelsie Riemenschneider[2], Chris Lee[2], David Martin[3], Sharon Hyzy[2], Zvi Schwartz[1], Barbara Boyan[1]. [1]Georgia Institute of Technology, USA, [2]Department of Biomedical Engineering & Institute of Bioengineering & Bioscience, Georgia Institute of Technology, USA, [3]Department of Medicine, Emory University School of Medicine, USA

1,25-dihydroxy vitamin D_3 [1α,25$(OH)_2D_3$] is a critical regulator of bone and cartilage development. Protein disulfide isomerase A3 (Pdia3) (also know as 1,25-MARRS, ERp60, ERp57 and Grp58), is a multifunctional protein and expressed in various adult tissues as well as in embryonic stem cells. Previous studies showed that it associates with caveolin-1 and mediates 1α,25$(OH)_2D_3$ initiated-rapid membrane signaling in several cell types. To understand the role of the Pdia3 in regulating skeletal development, we generated Pdia3-deficient mice and examined the physiologic consequence of Pdia3 disruption in embryos and Pdia3 heterozygotes at different ages using stereo confocal microscopy, high-resolution μCT imaging and histomorphometric measurements. No homozygous mice for the Pdia3 deletion were observed at birth nor were embryos after E12.5. Only two homozygous embryos with open neural tube defects and hemorrhage were identified at E10.5, indicating that the targeted disruption of the Pdia3 gene resulted in early embryonic lethality (Fig.1). Heterozygotes aged from 5-weeks-old to 30-weeks-old had 30-50% reduction in Pdia3 expression as shown by real-time PCR and Western blots; no difference in nVDR expression level was observed. Pdia3 heterozygotes of all ages displayed decreased body length (nose to rump) but increased leg length/body length and heart weight/body weight. Pdia3 deficiency also resulted in skeletal manifestations as revealed by μCT analysis. The heterozygous mice had decreased cortical bone area, lower BV/TV and trabecular number compared to wild type mice. In all cases, an increase in tibia growth plate thickness and a reduction in tether volume were observed in heterozygous mice (Fig.2A-D). Histomorphometry showed decreased cell numbers in the resting zone and proliferating zone of the heterozygote growth plate but increased cell numbers in hypertrophic zone compared to wild type mice (Fig.2E,F). Collectively, our findings provide for the first time the in vivo evidence that Pdia3 is essential for normal embryogenesis and play a crucial role in skeletal development. The fact that the Pdia3 heterozygous mice share a similar bone and growth plate phenotype to nVDR knockout mice, suggests that Pdia3 mediated-rapid membrane signaling might be an alternative signal pathway responsible for 1α,25$(OH)_2D_3$'s actions in regulating skeletal development.

Increased Trabecular Volume in a Novel Mouse Model Expressing a Bone-Specific CYP27B1 Transgene. Andrew Turner*[1], Juliette Tyson[1], Rebecca Sawyer[1], Peter O'Loughlin[1], Gerald Atkins[2], Masakazu Kogawa[2], David Findlay[2], Howard Morris[1], Paul Anderson[1]. [1]SA Pathology, Australia, [2]University of Adelaide, Australia

The endocrine hormone, 1a,25-dihydroxyvitamin D3 (1,25D) is a regulator of calcium homeostasis and bone health. We have shown that a major source of 1,25D within the skeleton are osteoblasts [1], osteocytes and osteoclasts [2] by virtue of their expression of the 25-hydroxyvitamin D 1alpha-hydroxylase (CYP27B1). While locally produced 1,25D in bone may mediate anabolic and/or catabolic activities within the skeleton, in osteoblasts, it is our hypothesis that the synthesis of 1,25D in bone performs autocrine functions that support bone remodelling. In in vitro experiments, we have silenced CYP27B1 mRNA expression in human osteosarcoma (HOS) cells by RNAi technology. In the presence of 100-400nM 25D, inhibition of CYP27B1 expression was accompanied by a marked decrease in the production of 1,25D and abolishment of osteocalcin mRNA levels, which was overcome by the addition of exogenous 1,25D. In in vivo studies, we have constructed a plasmid, in which transcription of the human CYP27B1 sequence is driven by the human osteocalcin promoter (hOcn-CYP27B1). Transient transfection of the hOcn-CYP27B1 construct into HOS cells treated with 25D (50nM), results in higher 1,25D production (63.5±14.8 pM) than control vector transfected HOS cells (7.6±2.1 pM), or transfected kidney 293T cells (3.5±0.7 pM). This construct was recently used to generate transgenic mice, of which two lines (OSC1 and OSC3) are undergoing detailed characterisation. Expression of human CYP27B1 mRNA in both mouse lines, as measured by qRT-PCR, is restricted to bone tissue where it is expressed at high levels (>50-fold higher than any other tissue). OSC mice maintain normal calcium and 1,25D levels in the circulation. Seven week old male OSC1 mice demonstrate a 12.4% increase in BV/TV of the distal femoral metaphysis (n=6/gp, $p<0.05$). This was associated with a 10.8% increase in trabecular number ($p<0.05$) with trabecular thickness unchanged. Dynamic histomorphometry and osteocyte measurements will further clarify the mechanism of increased trabecular bone volume in OSC mice. Our data further support the concept of the skeleton as an intracrine organ for vitamin D, with locally synthesized 1,25D exerting important actions for

bone remodeling and challenging the long-held notion that 1,25D is solely an endocrine hormone.

Mechanisms Underlying Anabolic Androgen Action in the Periosteum I*n Vivo* and I*n Vitro:* Disparate Response Mediated by Distinct Stem Cell Lineages. Kristine Wiren*[1], Anthony Semirale[2], Xiao-Wei Zhang[3]. [1]Veterans Affairs Medical Center, Oregon Health & Science University Research Ser, USA, [2]Oregon Health Sciences University, USA, [3]VA Medical Center & OHSU, USA

Although androgen is considered anabolic, the consequences of androgen receptor (AR) overexpression in skeletally-targeted AR-transgenic lines highlight the detrimental effect of enhanced androgen sensitivity on cortical bone quality. A compartment-specific anabolic response is observed only in male AR3.6-transgenic (tg) mice, with increased periosteal bone formation and calvarial thickening. Notably, anabolic thickening in vivo is not uniform across the calvaria, occurring only in frontal but not parietal bones. Calvaria provide a unique resource for isolation of multipotent stem cells derived from distinct embryological origins, with frontal bones originating from ectodermal neural crest cells while parietal bones originate from mesoderm mesenchymal cells. Stem-like cells from both sources are multipotent and can differentiate into osteoblasts or adipocytes. To define mechanisms that mediate bone anabolic responses, the consequences of enhanced androgen sensitivity in these distinct stem cell lineages were determined and compared to qPCR array analysis of periosteal vs cortical bone. Fraction 1 frontal bone neural crest stem cell (fNCSC) vs parietal bone mesenchymal cell (pMSC) cultures were isolated after collagenase digestion from AR3.6-tg or wildtype (WT) calvaria. Transgene expression was similar between fNCSC and pMSC cultures. Adipogenesis was significantly reduced in fNCSC cultures from AR3.6-tg compared to WT ($p < 0.05$ at d7; $p < 0.01$ at d10). In contrast, there was no significant difference in WT vs AR3.6-tg pMSC cultures. Notably, osteoblastogenesis was significantly increased in fNCSC cultures from AR3.6-tg compared to WT, with elevated alkaline phosphatase (AP) activity and induction of mineralization and nodule formation by alizarin red and von Kossa staining. Osteocalcin and AP mRNA levels were increased ($p < 0.05$ at d18) in fNCSC cultures from AR3.6-tg vs WT, with no significant difference between the genotypes in pMSC cultures. Expression profiles from AR3.6-tg vs WT long-bone periosteal tissue analyzed by array were recapitulated in fNCSC samples, while pMSCs reflected cortical expression. These observations confirm enhanced osteoblast lineage commitment by androgen in cells derived from neural crest. Combined, these results change our understanding of androgen action and reveal that androgen signaling results in osteogenic responses only in neural crest but not mesodermal lineages, and that the periosteum may have a neural crest origin.

ERα Deletion in Mesenchymal Progenitors or Mature Osteoblasts Decreases Cortical Bone Thickness and Increases Apoptosis, Respectively. Maria Jose Almeida*[1], Elena Ambrogini[1], Marta Martin Millan[2], Shoshana Bartell[1], Aaron Warron[1], Randal Shelton[1], Tony Chambers[1], Jinhu Xiong[1], Robert Weinstein[1], Robert Jilka[1], Charles O'Brien[1], Stavros Manolagas[1]. [1]University of Arkansas for Medical Sciences, USA, [2]University of Arkansas, Center for Osteoporosis & Metabolic Bone Diseases, USA

Estrogens attenuate osteoclast generation and life span via cell autonomous effects; and osteoclast ERα deletion causes loss of cancellous, but not cortical, bone indicating that osteoblasts, osteocytes, and perhaps other cell types are responsible for their protective effects on the cortical compartment. We sought genetic evidence for cell autonomous effects of estrogens at different stages of the osteoblast lineage progression by deleting a conditional ERα allele in early precursors of the mesenchymal lineage of the appendicular skeleton (ERα-flox;Prx1-Cre mice); or in osteoblasts expressing collagen type I (ERα-flox;2.3kbCol1a1-Cre mice). The efficiency of the deletion in these models was determined by measuring ERα mRNA in osteoblasts, generated by culturing adherent bone marrow cells with ascorbic acid, and other non-bone tissues by quantitative RT-PCR. ERα mRNA in osteoblasts from the ERα-flox;Prx1-Cre or ERα-flox;2.3kbCol1a1-Cre mice was decreased by about 60% as compared to the respective controls. Strikingly, cortical thickness in the femurs of 2 month old female ERα-flox;Prx1-Cre was decreased while cancellous bone volume was unaffected, as determined by micro-CT. Moreover, 6 month old ERα-flox;2.3kbCol1a1-Cre mice exhibited a 2-fold increase in osteoblast apoptosis, as determined by ISEL staining in vertebral cancellous bone sections but no changes in cancellous or cortical bone mass under basal conditions. Nonetheless, the number of CFU-OB in ex vivo bone marrow cultures from the ERα-flox;Prx1-Cre mice was 2-fold higher than those from control mice; but indistinguishable from the littermate controls in bone marrow cultures from the ERα-flox;2.3kbCol1a1-Cre mice. These results establish that estrogens acting though the ERα exert cell autonomous effects on osteoblasts; and that these actions are responsible for the protective effects of estrogens on the cortical compartment, as well as the survival of mature osteoblasts in cancellous bone. These findings also suggest that stimulation of differentiation or an increase in osteoblast progenitor survival, or both, may be more important for the effects of estrogens on bone mass than either suppression of progenitor self-renewal or prevention of apoptosis of mature cells. Nonetheless, it remains possible that prevention of osteocytes apoptosis by ERα-mediated effects of estrogens might contribute to strength independently of bone mass.

Estrogen Receptor-related Receptor Gamma (ERRg) is a Regulator of Skeletogenesis. Jane Aubin[1], Ralph Zirngibl[2], Marco Cardelli*[2], Ruolin Guo[3], Jonathan Boetto[4]. [1]University of Toronto Faculty of Medicine, Canada, [2]University of Toronto, Canada, [3]University of Rochester, USA, [4]University of Toronto - Molecular Genetics, Canada

Sex steroids, such as estrogen, play a role in the onset and severity of symptoms in arthritis and osteoporosis. Estrogen exerts its activity via its receptors, estrogen receptor alpha and beta, which are members of the nuclear receptor family. There are also members of the family for which ligands have not been identified, the so-called orphan receptors. Amongst these are the estrogen receptor-related receptors (ERRs), ERRα, ERRβ, and ERRγ. Previously, we showed that ERRγ is highly expressed in bone and cartilage and that it plays a functional role in osteogenesis and chondrogenesis *in vitro* (Bonnelye *et al*., 2001; Bonnelye *et al*., 2007). We have also found that ERRγ is expressed in skeletal cells and tissues, albeit at levels significantly lower than ERRα. Consistent with recent evidence from in vitro and ectopic bone formation experiments, suggesting that ERRγ is a negative regulator of osteogenesis, impinging on the BMP-Runx2 pathway (Jeong *et al*., 2009), we also found that knockdown of ERRγ in calvarial cell cultures increases osteoblast differentiation and bone nodule formation (unpublished data). To extend our *in vitro* findings to the whole animal level, we have utilized an ERRγ knockout line (Deltagen). Whole mount skeletal preparations of late embryonic/early postnatal stages revealed an increase in intramembranous bone formation, but no significant difference in long bone length. Preliminary μCT data from 14 week heterozygous mice reveal an increase in trabecular BMD and trabecular bone volume fraction, but no significant difference in cortical bone parameters. Further, *ERRγ* +/- calvaria bones were thicker than their WT counterparts but in a site-specific manner. To investigate the underlying cellular mechanisms, cells were isolated from neonatal knockout and heterozygous calvaria and cultured under osteoblast differentiation conditions. ALP and von Kossa positive staining (number and area) was increased in *ERRγ* +/- and *ERRγ* -/- cultures compared to WT. *In silico* analysis for ERRE consensus sequences identified *Msx2*, *Twist1* and *Alp* as putative ERRγ target genes. Collectively, our data indicate that ERRγ is a negative regulator of osteogenesis and further investigation into its putative target genes and interacting partners will shed light on its mechanism of action.

IGF-I Released during Osteoclastic Bone Resorption Induces Osteoblast Differentiation of BMSCs in the Coupling Process. Lijuan Pang*[1], Xiangwei Wu[2], Weiqi Lei[1], Tao Qiu[2], Feng Li[3], Mei Wan[2], Xu Cao[4]. [1]The Johns Hopkins University School of Medicine, USA, [2]Johns Hopkins University School of Medicine, USA, [3]Department of Pathology, Shihezi University School of Medicine, China, [4]Johns Hopkins University, USA

TGFβ1 has been shown to recruit bone marrow stromal cells (BMSCs) to the bone resorptive sites in response to osteoclastic bone resorption for coupled bone formation. It is, however, still unknown what factor(s) is responsible for the differentiation of BMSCs into osteoblasts during their recruitment. IGF-I is also one of the most abundant factors deposited in the bone matrix. We found that the conditioned medium (CM) from osteoclasts with bone slices induces osteoblast differentiation of BMSCs, and addition of an antibody against IGF-I inhibited the differentiation. Bone resorption CM contains high level of IGF-I, but the control CMs do not have detectable IGF-I, indicating release of IGF-I during osteoclastic bone resorption. To examine the effect of IGF-I on differentiation of BMSCs in the coupling process, we developed osteoprogenitor-specific IGF-IR deficiency mice (IGF-IR-/-) by using osterix promoter-Cre mice. The two-month-old female IGF-IR-/- mice exhibited smaller size with low trabecular bone volume and larger trabecular bone space as measured by μCT. Osteoblast number and area were significantly reduced in IGF-IR-/- mice relative to their WT littermates while osteoclast number and area did not change. Trabecular and endosteal mineral apposition rates were reduced in IGF-IR-/- mice measured by calcein double labeling. Suspensions of BMSCs isolated from the IGF-IR-/- mice and their WT littermates for CFU-F assay. The CFU-Fs were further induced in osteogenic media (CFU-Ob). The number of CFUs of IGF-IR-/- mice was equivalent to their WT littermates, but the number of CFU-Ob significantly decreased, indicating the osteogenic potential of the BMSCs is reduced in IGF-IR-/- mice.

To demonstrate that the role of IGF-I in vivo, GFP-labeled BMSCs isolated from IGF-IR-/- mice were injected into the femur cavity of the immuno-deficient Rag2-/- mice. At two weeks after injection, the GFP-labeled IGF-IR-/- and IGF-IR+/+

BMSCs were largely found at the trabecular bone surface. Importantly, some of the IGF-IR+/+ BMSCs, but no IGF-IR-/- BMSCs were embedded in the trabecular bone at four weeks after injection. Taken together, IGF-I released during bone resorption stimulates osteoblast differentiation of the BMSCs at bone resorptive sites recruited by TGFβ1. Thus, TGFβ1 induces migration of BMSCs to the bone surface in response to bone resorption and IGF-I further stimulates osteoblast differentiation of the recruited BMSCs.

Role of CCL-12 (a.k.a. MCP-5) in Joint Development and Need of TGF-β Signaling in Controlling its Expression. Lara Longobardi*, Tieshi Li, Timothy J. Myers, Froilan Granero-Molto, Yun Yan, Anna Spagnoli. University of North Carolina at Chapel Hill, USA

The Tgfbr2PRX-1KO mouse generated in our laboratory, which lacks the Tgfbr2 in developing limbs, fails joint interzone development. Combining laser-capture microscopy with gene expression microarrays, we found that the interzone is characterized by a down-regulation of the cytokine CCL-12 (a.k.a. MCP-5, homologous of the human MCP-1) compared to the adjacent growth plate, and such regulation is impaired in Tbr2PRX-1KO. Aberrant expressions of MCP-1/CCL12 and its unique receptor CCR2 are involved in OA and RA pathogenesis. Clinical studies aimed at blocking the system in patients with RA are on the way. Our ex-vivo and in vivo studies are aimed at determining whether: #1) an aberrant release of CCL-12 into developing digits disrupts the interzone; #2) the blockage of the CCR2 signaling rescues the Tbr2PRX-1KO phenotype. For purpose #1, using a micro-injector unit and glycol-chitosan-β-cholanic nanoparticles for sustained protein release, either CCL-12 protein or MC-21 antibody (against CCR2) were injected within the developing joints of dissected E13.5 WT or Tbr2PRX-1KO limbs respectively, that were cultured for 2 days. For purpose #2, pregnant females potentially generating Tbr2PRX-1KO, were treated PO with RS504393, a CCR2 inhibitor, starting at E11.5 (4mg/Kg/day). At E18.5 mice were sacrificed and dissected limbs from Tbr2PRX-1KO and control embryos subjected to histological and in-situ hybridization analyses (ISH). Using an immunomagnetic system, TGFβRII+ cells were isolated from E13.5 limb mesenchyme; and treated with increasing doses of CCL-12 The sustained release of CCL-12 into developing WT joints, blocked the interzone development, abolished specific joint marker (i.e. Gdf5) expressions and halted the growth plate segmentation, leading to a continuous pattern of Col2 expressing cells throughout the digit. In-vitro, CCL-12 treatment of TGFβRII+ cells, decreased joint marker (Gdf-5, Wnt9a and Sulf1) and increased Col2 expression. Blockage of the CCR2 signaling in Tbr2PRX-1KO either ex-vivo or in-vivo, led to a rescue of the Tbr2PRX-1KO phenotype restoring interzone and joint formation. In Tbr2PRX-1KO growth plate, CCR2 signaling blockage determined also a more organized pattern in Ihh, Sox9 and Col10 expressions. Our findings provide evidence for new roles for CCL-12 and TGFβRII signaling in joint development, opening novel prospective for their function in adult joint homeostasis and for the prevention and treatment of different forms of arthritis.

Peripheral Actions of the NPY System Regulate Bone Formation via Modulation of PYY. Iris Wong*, Ronaldo F. Enriquez, Amanda Sainsbury, Herbert Herzog, John Eisman, Paul Baldock. Garvan Institute of Medical Research, Australia

The neuropeptide Y (NPY) system regulates bone anabolism through hypothalamic Y2 and osteoblastic Y1 receptors. Hypothalamic NPY expression has a strong, negative relationship to bone anabolism. However, in addition to the central actions of NPY, the NPY system also contains peripheral components which may influence bone homeostasis. Another NPY receptor ligand, peptide YY (PYY) released from the gastrointestinal system, has recently been shown to have an inverse correlation with BMD. Given the critical role of diet in mineral homeostasis, and recent findings regarding serotonin action in bone, we hypothesize that PYY may be a link from gut to skeletal system.

To investigate, we examined bone cell activity and structure of 16 week female mice from two different mouse models – a PYY knockout ($PYY^{-/-}$) model and a model with tamoxifen-inducible PYY over-expression (PYYtg) in the periphery where the ubiquitous gene *ROSA26* is expressed.

Whole body BMD was greater in $PYY^{-/-}$ compared to wildtype (51.8 ±0.8 vs 47.9 ±0.9 mg/cm^2, $p<0.05$). $PYY^{-/-}$ exhibited greater cancellous bone volume (12.9 ±0.7 vs 9.6 ±0.5 %, $p<0.005$) and trabecular number (4.20 ±0.16 vs 3.21 ±0.15 /mm, $p<0.001$) in the distal femur, accompanied by greater mineral apposition rate (MAR) (1.96 ±0.02 vs 1.62 ±0.07 μm/d, $p<0.005$) with no change in osteoclast surface. Endocortical MAR of PYY-/- was also greater (1.70 ±0.20 vs 1.14 ±0.13 μm/d, $p<0.05$).

Importantly, bone cells activities of PYYtg were the opposite of those observed in $PYY^{-/-}$. PYYtg had reduced MAR (1.69 ±0.07 vs 2.01 ±0.05 μm/d, $p<0.005$) and increased osteoclast number (6.01 ±0.21 vs 4.71 ±0.18 /mm, $p<0.001$) and surface (11.43 ±0.42 vs 9.01 ±0.37 %, $p<0.005$) with lower trabecular number (2.98 ±0.18 vs 3.48 ±0.11 /mm, $p<0.05$) and a trend towards reduced cancellous bone volume ($p=0.07$). Endocortical MAR was also reduced in PYYtg (1.57 ±0.06 vs 1.79 ±0.06 μm/d, $p<0.05$).

The contrasting effect of the knockout and transgenic mouse models indicates that peripherally produced PYY regulates bone mass through suppression of osteoblast activity in cancellous and cortical bone. Greater understanding of the role of PYY signalling in bone may reveal novel links between the gut and bone homeostasis.

Oncostatin M Receptor Signaling Inhibits the Pro-osteoclastic Action of PTH in vivo and in vitro. Emma C Walker[1], Ingrid Poulton[1], Narelle McGregor[1], Elizabeth Allan[1], T John Martin[1], Natalie Sims*[2]. [1]St. Vincent's Institute, Australia, [2]St. Vincent's Institute of Medical Research, Australia

Parathyroid hormone (PTH) acts via osteoblasts to stimulate both osteoclast formation and bone formation. Studies using genetic manipulation and neutralizing antibodies identified that the influence of PTH on osteoclast formation is partially dependent on cytokines that act by binding to the gp130 signal transduction unit (e.g. IL-6, IL-11, oncostatin M (OSM)). Since these cytokines stimulate osteoclast and osteoblast differentiation they may also mediate anabolic effects of PTH.

Microarrays of murine stromal cells identified regulation of gp130-binding molecules by PTH including a 4 fold increase in OSM receptor (OSMR) expression. This was confirmed in primary calvarial osteoblasts, where OSMR expression was increased 12 fold in response to PTH.

To determine whether OSMR signaling is required for PTH anabolic action, 6 week old male OSMR knockout (KO) mice and wild type (WT) littermates were treated with 30μg/kg/day hPTH(1-34) for 3 weeks. In WT mice, PTH increased trabecular bone volume (BV/TV) by 40% ($p<0.05$ vs saline), and increased trabecular thickness by 17% ($p=0.001$). In contrast, the same treatment of OSMR KO mice reduced BV/TV by 22% ($p<0.05$ vs saline) and reduced trabecular number by 27% ($p=0.002$). This difference in response to PTH was not explained by a different bone formation response; osteoblast surface, osteoid surface and mineral apposition rate were increased to the same extent by PTH treatment in WT and OSMR KO mice. In contrast, PTH treatment doubled osteoclast surface in OSMR KO mice ($p=0.003$ vs. saline), an effect that was not observed in WT. This was surprising since OSM stimulates RANKL expression and osteoclast formation via OSMR.

When bone marrow macrophage osteoclast precursors were cultured in the presence of OSMR KO osteoblasts, >3 fold more osteoclasts were formed in response to PTH than when the same precursor population was cultured with WT osteoblasts. Furthermore, even though the cAMP response of OSMR KO osteoblasts to PTH was identical to that of WT osteoblasts, PTH-induced RANKL expression was 5-fold greater in OSMR KO osteoblasts compared to WT, and this high level of RANKL expression was retained at least until 24 hours after PTH exposure.

These data indicate that despite the known pro-osteoclastic and pro-RANKL influence of OSM, OSMR signaling suppresses the action of PTH that enhances RANKL expression in osteoblasts and stimulates osteoclast formation, indicating significant crosstalk between these pathways.

The In Vivo Effect of EGFR on Bone. Xianrong Zhang*[1], Ji Zhu[1], Haiyan Chen[2], Xiaoyan Tian[2], Barbara Kream[3], Nicola Partridge[4], Ling Qin[5]. [1]University of Pennsylvania, School of Medicine, USA, [2]University of Utah, USA, [3]University of Connecticut Health Center, USA, [4]New York University College of Dentistry, USA, [5]University of Pennsylvania, USA

The epidermal growth factor receptor (EGFR) has vital roles in developmental and pathological processes. However, its function in the skeletal system has not been well studied. Our previous research demonstrated that its ligands are potent mitogens for osteoprogenitors but strongly suppress osteoblast differentiation in vitro. To address the in vivo role of EGFR in bone, we constructed transgenic and pharmacological mouse models and used microCT and histomorphometry to analyze their bone phenotype. To eliminate the pre/osteoblastic EGFR activity, we generated 3.6 kb collagen1a1-Cre $Egfr^{Wa5flox}$ (Col-Cre $Egfr^{Wa5lf}$) mice harboring an EGFR dominant negative allele, Wa5. At 3-, 5- and 7-months old, these mice exhibited a remarkable 20-40% decrease in tibial trabecular bone volume (BV/TV) with a reduction in trabecular number (17-32%) and trabecular thickness (10%) in both genders. Histological analyses of 7-month old female mice revealed that bone formation and mineralization activities were reduced and bone resorption was elevated. These mice exhibited decreases in osteoblast surface (35%), osteoid surface (34%), mineral apposition rate (MAR, 15%), bone formation rate (BFR, 24%), and an increase in osteoclast surface (78%). Similarly, administration of an EGFR inhibitor into wild type mice caused a 25% reduction in trabecular BV/TV. Histomorphometric analyses suggested similar changes in bone formation and resorption parameters as Col-Cre $Egfr^{Wa5lf}$ mice. In contrast, 3-month old $Egfr^{Dsk5l/+}$ mice with an EGFR constitutively active allele displayed increases in trabecular BV/TV (36-43%) accompanied by an increase in trabecular number (28-35%) and a decrease in trabecular separation (9-17%) in both genders. These structural changes were due to increases in osteoblast surface (37%), osteoid surface (35%), MAR (18%) and BFR (34%) and a decrease in osteoclast surface (27%). Interestingly, we found that EGFR

inhibitor dramatically reduced the number of CFU-F (52%) derived from bone marrow, suggesting that EGFR functions in maintaining the osteoprogenitor pool. In conclusion, our data demonstrate that the EGFR signaling pathway affects both bone formation and bone resorption in vivo and therefore it acts as a novel anabolic regulator for bone metabolism.

Hypertrophic Chondrocytes and Osteocytes are Essential Sources of RANKL for Bone Growth and for Bone Remodeling, Respectively. Jinhu Xiong*, Melda Onal, Priscilla Cazer, Xinrong Chen, Robert Weinstein, Robert Jilka, Stavros Manolagas, Charles O'Brien. University of Arkansas for Medical Sciences, USA

RANKL is required for osteoclastogenesis and thought to be supplied by cells of the osteoblast lineage. However, ablation of matrix-synthesizing osteoblasts and their immediate replicating precursors does not alter RANKL expression or osteoclast number. Therefore, the identity of osteoclast support cells remains unclear. To address this issue, we created mice with a RANKL conditional allele (RF) and crossed them with mice expressing Cre recombinase under the control of osterix (Osx1-Cre), osteocalcin (OCN-Cre), or dentin matrix protein 1 (DMP1-Cre) gene regulatory elements. Deletion of RANKL using Osx1-Cre or OCN-Cre caused severe osteopetrosis associated with retention of mineralized cartilage in the long bones and spine of 5 wk old mice. Consistent with this, immunohistochemical analysis revealed that both Osx1-Cre and OCN-Cre deleted RANKL from hypertrophic chondrocytes. Osx1-Cre and OCN-Cre activity in hypertrophic chondrocytes was confirmed using the R26R Cre reporter strain. Deletion of RANKL with DMP1-Cre increased bone mass at 5 wk of age, compared to littermate controls, but this was not associated with retention of calcified cartilage. Bone mass continued to increase in DMP1-Cre;RF mice, relative to DMP1-Cre littermates, so that by 6 mo of age, there was a 30% difference in BMD in the spine, suggesting that osteocytes are an essential source of RANKL during bone remodeling. Consistent with this, RANKL mRNA levels were significantly lower in bones from DMP1-Cre;RF mice. However, analysis of DMP1-Cre expression with R26R mice revealed that, in addition to osteocytes, Cre activity was also present in cells on cancellous bone that may be osteoblasts. To confirm that the decrease in RANKL expression caused by DMP1-Cre occurred in osteocytes and not osteoblasts, adult RF mice were treated with OPG for 2 wk to suppress bone turnover, thereby reducing osteoblast number, and were then injected with vehicle or PTH, followed by quantification of RANKL expression. OPG treatment did not change basal or PTH-stimulated RANKL mRNA levels but did potently reduce osteocalcin mRNA. Both basal and PTH-stimulated RANKL were significantly reduced in DMP1-Cre;RF mice. These results, taken together with previous osteoblast ablation studies, demonstrate that hypertrophic chondrocytes are an essential source of RANKL during endochondral bone growth and that osteocytes, but not osteoblasts, are an essential source of RANKL for bone turnover during adulthood.

Gli2 is Essential for Postnatal Intervertebral Disc Growth and Maintenance. Fanjie Zeng*, Ming Xue, Xinping Zhang. University of Rochester Medical Center, USA

Deterioration of the intervertebral disc (IVD) is common in the elderly and has been shown to be the major cause for back pain. While studies have shown that age-related disc degeneration is associated with enhanced apoptosis and loss of normal extracellular matrix composition in IVD, mechanisms underlying the degeneration of the disc remain poorly understood. Hedgehog (Hh) pathway is critically involved in the vertebral column formation and skeletogenesis. However, due to embryonic lethality, its roles in postnatal IVD growth, maintenance and aging remain unknown. In this current study, we examined the expression of Hh-related genes in young and aged lumbar disc in mice. We found a progressive loss of both Shh and Ihh in aged IVD, associated with significant downregulation of the key transcriptional activator Gli2. Comparing to IVD harvested from the young, aged IVD exhibited loss of proteoglycan, rupture of annulus fibrosus as well as marked induction of apoptosis in endplate. To determine the role of Gli2 in postnatal IVD growth and maintenance, we generated a Gli2f/f;Col2CreER;RosaR mouse model, which permits deletion of Gli2 postnatally in annulus fibrosus, endplate and growth plate following treatment of Tamoxifen (TM). Deletion of Gli2 via Col2CreER led to rapid destruction of cartilaginous tissue in IVD just 3 days following TM injection at postnatal day 18. TUNEL assay showed a near 5-fold increase of apoptosis in endplate and a massive induction of apoptosis in hypertrophic chondrocytes in Gli2f/f;Col2CreER mice, coincided with the severe loss of Col2a1, ColX and MMP13 gene expression as determined by in situ hybridization. In addition to enhanced apoptosis, Brdu labeling showed a near 3 fold reduction of proliferation in growth plate chondrocytes. Deletion of Gli2 further led to disorganization of annulus fibrosus, as evidenced by the loss of Col2a1 expression in the inner layer of annulus but aberrant induction of Col 2a1 expression in the outer layer of the annulus, a phenomenon that was described in the mechanical injury-induced early disc degeneration. By 2 month of age, Gli2-mutant IVD displayed a nearly complete loss of cartilaginous tissue, disruption of endplate, rupture of annulus fibrosus, shrinkage and severe loss of nucleus pulpopus, and fusion of vertebral bodies. Taken together, we conclude that Gli2 plays a critical role in postnatal growth and maintenance of IVD and Hh deficiency could contribute to age-related disc degeneration.

Conditional Ablation of the Heparan Sulfate-synthesizing Enzyme Ext1 Leads to Dysregulation of BMP Signaling and Severe Skeletal Defects. Yukihide Iwamoto[1], Fumitoshi Irie[2], Yu Yamaguchi[2], Kazu Matsumoto[2], Yoshihiro Matsumoto*[3]. [1]Department of Orthopaedic Surgery kyushu Universtiy School of Medicine, Japan, [2]Sanford-Burnham Medical, Research Institute, USA, [3]Department of Orthopaedic Surgery Kyushu University School of Medicine, Japan

Increasing evidence indicates that heparan sulfate (HS) is an integral component of many morphogen signaling pathways. However, its mechanisms of action appear to be diverse, depending on the type of morphogen and the developmental contexts.

To define the functionof HS in skeletal development, we conditionally ablated Ext1, which encodes an essential glycosyltransferase for HS synthesis, in limb bud mesenchyme using the Prx1-Cre transgene. These conditional Ext1 mutant mice display severe limb skeletal defects, including shortened and malformed limb bones, oligodactily, and fusion of joints. In developing limb buds of mutant mice, chondrogenic differentiation of mesenchymal condensations is delayed and impaired, whereas the area of differentiation is diffusely expanded. Correspondingly, the distribution of both BMP signaling domains and BMP2 immunoreactivity in the mutant limb mesenchyme is broadened and diffuse. In micromass cultures, chondrogenic differentiation of mutant chondrocytes is delayed and the responsiveness to exogenous BMPs is attenuated. Moreover, the segregation of the pSmad1/5/8-expressing chondrocytes and fibronectin-expressing perichondrium-like cells surrounding chondrocyte nodules is totally disrupted in mutant micromass cultures. Together, our results show that HS is essential for patterning of limb skeletal elements, and that BMP signaling is one of the major targets for the regulatory role of HS in this developmental context.

Smad7 Mediates Stress Pathways in the Growth Plate. Kristine Estrada*, Fuad Elkhoury, Kelsey N. Retting, Karen Lyons. University of California, Los Angeles, USA

The bone morphogenetic protein (BMP) and transforming growth factor beta (TGF-beta) pathways are important regulators of endochondral bone formation. However, the in vivo regulation of these pathways by inhibitory Smad proteins, Smad6 and Smad7, is unclear. Gain and loss of function studies have revealed potential roles for I-Smads in chondrocytes in vitro, while in vivo studies are limited to demonstrations of prominent roles of Smad6 in the cardiovascular system and of Smad7 in immune responses. Therefore, we characterized the skeletal phenotypes of mice lacking either Smad6 or Smad7 to test the roles of these intracellular inhibitors in the growth plate in vivo. Mice deficient in Smad6 exhibit elevated BMP signaling in the growth plate, while mice deficient in Smad7 exhibit a unique growth plate phenotype. In particular, histological analysis of Smad7 mutant growth plates reveal a delay in chondrocyte hypertrophy. By late gestation, the core of the growth plate is hypocellular, which may be due, at least in part, to increased apoptosis as demonstrated by TUNEL staining. Moreover, Safranin-O staining reveals defective extracellular matrix deposition in this region, partly owing to impaired type II collagen secretion. Given the documented inhibitory effect of Smad7 on canonical BMP and TGF-beta signaling, we expected that effectors of these pathways would be increased in Smad7-/- growth plates. However, reduced levels of both pSmad1/5/8 (BMP signaling) and pSmad2 (TGF-beta signaling) were seen in the core of the neonatal growth plate; levels were unaffected in the hypertrophic zone. Interestingly, pSmad2/3 localization overlaps with that of the most hypoxic regions of the growth plate and with the location of the necrotic core in Smad7 mutants, suggesting a functional connection between TGF-beta signaling and the hypoxic response. This hypothesis is substantiated by the finding that treatment of either ATDC5 or rat chondrosarcoma cells with TGF-beta1 increased *HIF-1alpha* expression. In accordance, knockdown of Smad7 in ATDC5 cells via siRNA led to increased *HIF-1alpha* and *VEGF* expression. Moreover, Smad7-/- mutants exhibited elevated levels of HIF-1alpha throughout the growth plate, with the exception of the necrotic core. These results indicate that Smad7 mediates its effects on hypoxic signaling via increased TGF-beta signaling. More importantly, our results present a novel role for Smad7 in mediating hypoxic stress responses in the growth plate.

The Oxygen-sensor PHD2 in Chondrocytes Modifies Bone Mass by Regulating Cartilage Collagen Processing. Kjell Laperre*[1], Peter Fraisl[2], Maarten Depypere[3], Stefan Vinckier[2], Nico Smets[1], Roger Bouillon[4], Frederik Maes[3], Peter Carmeliet[2], Geert Carmeliet[5]. [1]Laboratory of Experimental Medicine & Endocrinology, K.U.Leuven, Belgium, [2]VIB Vesalius Research Center, K.U.Leuven, Belgium, [3]Medical image computing (ESAT/PSI), K.U.Leuven, Belgium, [4]Laboratory for Experimental Medicine & Endocrinology, Belgium, [5]Katholieke Universiteit Leuven, Belgium

A balanced supply of oxygen and nutrients is mandatory for bone metabolism. More precisely, an adequate response to hypoxia is critical for the expanding growth plate as lack of the hypoxia inducible factor α (HIFα) in the developing avascular and hypoxic growth plate leads to massive apoptosis. Oxygen sensing is considered to rely on three prolyl-hydroxylase-domain containing (PHD) proteins of which PHD2 seems to be the most important one. To assess the role of PHD2 in bone development, we genetically inactivated *Phd2* in chondrocytes by crossing *Phd2^{fl}* with collagen 2-Cre mice (*Phd2^{chon-}*). The efficient and cell-specific inactivation of *Phd2* resulted in highly increased HIF1α protein levels in growth plate chondrocytes.

Phenotypically, *Phd2^{chon-}* mice were growth retarded and unexpectedly, trabecular bone volume was almost doubled. Yet, *in vivo* and *in vitro* analyses did not reveal major differences in bone formation, resorption or vascularisation. Cartilage remnants were however present in the trabeculae and cortices of *Phd2^{chon-}* mice, suggesting that the cartilage matrix was modified and hence hampered remodeling by osteoclasts.

Mechanistically, *Phd2* null chondrocytes adjusted their energy metabolism in response to the increased HIF1α levels without jeopardizing cell viability: energy production as well as energy expenditure was reduced. Indeed, *Phd2* null chondrocytes displayed a shift towards anaerobic metabolism characterized by increased glycolysis and lactate production associated with decreased glucose oxidation. This adaptation resulted in decreased oxygen consumption and reduced ATP levels. To withstand this challenge, *Phd2* null chondrocytes reduced their energy expenditure by decreasing proliferation and activating the unfolded protein response. The synthesis of proteins and collagen in particular was reduced, but posttranslational processing of collagen was promoted, evidenced by increased mRNA levels of protein disulfide isomerase and lysyl oxidase and the presence of abundant collagen crosslinks. These changes resulted in a denser collagen network in *Phd2* null growth plates and likely rendered the collagen matrix less susceptible to degradation, ultimately leading to cartilage remnants.

In conclusion, deletion of PHD2 in growth plate chondrocytes lowers cellular energy metabolism and activates the unfolded protein response. Hence crosslinked collagens accumulate in the cartilage matrix, precluding remodeling and resulting in increased bone mass.

Role of Fibroblast Growth Factor Receptor 3 in bone formation. Emilie Mugniery*[1], Romain Dacquin[2], Caroline Marty[3], Catherine Benoist-Lasselin[1], Arnold Munnich[1], Marie-Christine De Vernejoul[4], Pierre Jurdic[5], Valerie Geoffroy[6], Laurence Legeai-Mallet[1]. [1]INSERM U781, France, [2]Institut de génomique fonctionnelle de Lyon - ENS Lyon, France, [3]INSERM U606, France, [4]Fédération De Rhumatologie Et INSERM U606, France, [5]Ecole Normale Superieure de Lyon, France, [6]INSERM Unit 606, France

Fibroblast Growth Factor receptor 3 (FGFR3) is involved in a family of chondrodysplasias. FGFR3 missense mutations, is associated with achondroplasia, the most frequent form of dwarfism, thanatophoric dysplasia, the lethal form and hypochondroplasia mild form. These mutations induce a constitutive activation of the receptor. To study the role of FGFR3 during bone formation, we first generated a Fgfr3 mouse model which ubiquitously expressed an activating mutation (Y367C). These mice (Fgfr3Y367C/+) exhibit a severe dwarfism, with macrocephaly, short limb and narrow trunk that mimics the human pathology. As in chondrodysplasias, growth plate was severely disorganized and long bones were broad and shortened. Micro-scanner, densitometric and histomorphometry studies revealed a severe primary ossification defect and a significant decrease of bone volume (94%, $p<0,01$), trabecular thickness (16%, $p<0,05$) and trabecular number (66%, $p<0,01$) in the secondary spongiosa in Fgfr3Y367C/+ 3-weeks-old mice. The proliferation and mineralization were decreased in primary cultures of osteoblasts isolated from Fgfr3Y367C/+ mouse calvaria. To highlight involvement of FGFR3 in bone formation, we have established a mouse model (ColI-Fgfr3Y367C/+) that expresses the mutation specifically in osteoblasts. At three weeks of age, these mice (ColI-Fgfr3Y367C/+) do not exhibit any obvious evidence of bone defect. Conversely, at 3 months of age, the mutant mice showed a bone phenotype characterized by a significant increase in bone area at the vertebrae and at the femora (16% and 10% respectively, $p<0.01$). Histomorphometric analysis of secondary spongiosa confirmed an increase in bone diameter (11%, $p<0.002$) and revealed an increase in trabecular thickness (12%, $p<0.003$). In addition, osteoblast number and bone formation rate were both increased in mutant mice. These results indicate that FGFR3 activated mutation disturbs endochondral ossification process. The disorganization of the growth plate induces a severe primary ossification defect. In contrast, when expression of activated FGFR3 was restricted to osteoblasts, the primary ossification process is unmodified. Surprisingly, we observed a significant positive effect on bone formation of activated FGFR3 in this mouse model at adult stage. In FGFR3-related chondrodysplasias, the abnormal bone formation could be due to independent effects of the activated receptor on chondrocytes and osteoblasts.

Cartilage-specific Notch Signaling Regulates Chondrocyte Maturation and Coordinates Osteoblast Differentiation. Anat Kohn*[1], Yufeng Dong[2], Alana Jesse[2], Tasuku Honjo[3], Regis O'Keefe[2], Matthew Hilton[1]. [1]University of Rochester School of Medicine, USA, [2]University of Rochester, USA, [3]Kyoto University Graduate School of Medicine, Japan

Recently, the Notch signaling pathway has been implicated in regulating cartilage maturation during skeletal development. While a strong argument for Notch regulation of these processes has been provided, it still remains unclear whether these processes are regulated via (1) RBPjκ-depended or –independent Notch pathways, and (2) specific Notch signaling in chondrocytes or within multiple mesenchymal cell lineages (chondrocytes, osteoblasts and surrounding connective tissues). Furthermore, it remains to be determined whether Notch signaling in one skeletal lineage can indirectly control the development of another lineage (i.e. – chondrocyte control of osteoblastic differentiation). To identify whether chondrocyte maturation is regulated via RBPjκ-depended or -independent Notch signaling, we first analyzed RBPjk loss-of-function (LOF) (*Prx1Cre;Rbpjκ$^{f/f}$*) and RBPjκ-independent Notch gain-of-function (*Prx1Cre;Rosa-NICD^{fl+};Rbpjκ$^{f/f}$*) mutant embryos at E14.5 and E18.5. Analysis of these embryos, using histology and *in situ* hybridization, revealed that delays in chondrocyte maturation seen in Notch LOF mutants is mediated solely by RBPjκ-dependent pathways. This finding was corroborated *in vitro* using primary chondrocyte cultures from RBPjκ-floxed mice. Finally, analysis of BrdU incorporation in vivo revealed an increase in the rate of chondrocyte proliferation in RBPjκ LOF mutants. Since the Prx1Cre transgene targets multiple cell lineages, we performed similar *in vivo* experiments using the tamoxifen inducible Col2Cre^{ERT2} transgene to ascertain whether the observed effects were due to Notch perturbations in cartilage versus surrounding mesenchymal tissues (*Col2-Cre^{ERT2};Rbpjκ$^{f/f}$, Col2Cre^{ERT2};Rosa-NICD^{fl+}, Col2Cre^{ERT2};Rosa-NICD^{fl+};Rbpjκ$^{f/f}$*). Tamoxifen induction in pregnant mice after E12.5 allows for cartilage-specific Notch

deletion and/or activation. Our results from analyzing these mutant embryos at E14.5 and E18.5 demonstrate conclusively that chondrocyte maturation is regulated via RBPjκ-dependent Notch signaling specifically within chondrocytes. Interestingly, our findings also suggest that Notch signaling specifically within chondrocytes regulates osteoblast differentiation in a cell non-autonomous manner. Continued analyses using both our *in vivo* and *in vitro* approaches will allow us to determine the underlying molecular mechanisms by which Notch signaling regulates chondrocyte proliferation and maturation, while coordinating osteoblast differentiation.

Reduced Bone Strength in Young Adult Women with Clinical Fractures During Childhood or Adolescence. Serge Ferrari*[1], Thierry Chevalley[2], Bert Van Rietbergen[3], Jean-Philippe Bonjour[4], Rene Rizzoli[5]. [1]Geneva University Hospital & Faculty of Medicine, Switzerland, [2]University Hospitals of Geneva Division of Bone Diseases, Switzerland, [3]Eindhoven University of Technology, Netherlands, [4]University Hospital of Geneva, Switzerland, [5]University Hospital, Switzerland

We previously reported that young adult women with clinical fractures during childhood/adolescence have decreased peak bone mass (aBMD) at radius and to a lesser extent at femur; lower volumetric bone density, and lower trabecular and/or cortical thickness at distal radius and tibia. These observations raised the possibility that fractures during growth, although most commonly associated with high-impact trauma, could actually be a hallmark of lifelong bone fragility. Whether young adults who experienced a fracture during childhood or adolescence have decreased bone strength, remains to be directly investigated.

We assessed 3D cortical and trabecular bone structure at distal radius and tibia by high-resolution peripheral QCT (HR-pQCT, XtremeCT, Scanco) in 125 women (mean age ±SD, 20.4 ±0.6 yrs) whose clinical fractures had been prospectively recorded since the age of 8 years. The volume of interest (VOI) spans over 1 cm, proximally to a point located at 1 cm and 2.2 cm from the endplate of the radius and tibia, respectively. Using the HR-pQCT measurements, finite element analysis (FEA) was conducted in 95 subjects (34 with fractures, 61 without), simulating an axial compression test to predict bone strength and stiffness, and also separating the contribution of trabecular and cortical compartments.

Adult weight and height were similar in the fracture (Fx) and no fracture (NoFx) groups. Within the VOI, the percentage of load carried by cortical bone decreased from 80-85% proximally to less than 50% more distally, at both radius and tibia. Although no significant differences in the distribution of load between the cortical and trabecular compartments were noted between fracture groups, the percentage of load carried by cortical bone in the distal VOI tended to be lower (-5 to -7%) in Fx compared to NoFx subjects. Bone estimated failure load, stiffness, and apparent modulus of the distal radius were 9-12% significantly lower in Fx than NoFx, both before and after adjustment for age, height, weight, pubertal stage, calcium and protein intakes, and physical activity. At distal tibia, the parameters of bone strength were also 5-9% significantly lower after adjustment for these confounding variables.

In conclusions, young adult women with clinical fractures during growth have decreased bone strength at distal radius and, to a lower extent, distal tibia. These observations further support the possibility that childhood fractures might be a hallmark of persistent bone fragility in adults. Whether these women will sustain more frequent wrist and/or other fractures later in life remains to be determined.

Central QCT Reveals Cortical and Trabecular Structural Deficits in Premenopausal Women With Idiopathic Osteoporosis Whether Diagnosis is Based on Fragility Fracture or Low Areal Bone Mineral Density. Adi Cohen*[1], Thomas Lang[2], Halley Rogers[1], Emily Stein[3], X Guo[4], Xiaowei Liu[4], David Dempster[4], Donald McMahon[3], Joan Lappe[5], Chiyuan Zhang[4], Robert Recker[5], Elizabeth Shane[3]. [1]Columbia University Medical Center, USA, [2]University of California, San Francisco, USA, [3]Columbia University College of Physicians & Surgeons, USA, [4]Columbia University, USA, [5]Creighton University Osteoporosis Research Center, USA

In idiopathic osteoporosis (IOP) in premenopausal women (PreM), young, otherwise healthy women with normal gonadal function present with fragility fractures (Fx). IOP may also be diagnosed on the basis of low areal bone mineral density (aBMD) by DXA in PreM without Fxs, but the clinical significance of isolated low aBMD in young women is controversial. By high-resolution peripheral quantitative tomography (HR-pQCT) of the distal radius and tibia and analysis of transilac bone biopsies, we reported that PreM with IOP (Fx; Low aBMD but no Fx) have low volumetric BMD (vBMD), thin cortices, fewer trabecular (Tb) plates, fewer, longer Tb rods, decreased Tb connectivity and stiffness compared to controls. To assess the central skeleton in PreM IOP, we measured vBMD and stiffness of the spine and hip by quantitative computed tomography (QCT) and finite element analysis (FEA) in 34 Controls (37+9 yrs) and 44 IOP (38+8 yrs; 32 Fx, 12 LowBMD). L1-L2 measures included vBMD of an integral (Int) compartment containing vertebral body and posterior elements (Int vBMD) and of the centrum containing only Tb bone (Tb vBMD). Hip measures included Int, Tb and cortical (Ct) vBMD of femoral neck (FN) and total hip (TH), FN cross-sectional area (FNCS), a measure of bone size, and a ratio of tissue volume in Ct regions of interest to total tissue volume within the periosteal boundaries (C/I), a measure of Ct thickness that correlates with hip Fx At spine and hip, IOPs had comparably lower aBMD by DXA (18-21%), Int vBMD by QCT (17-20%) and stiffness by FEA (19-21%). Tb vBMD was 26% lower at L1-L2 and 37-45% lower at FN and TH ($p<0.0001$). FNCS was 11% and 15% lower in IOP Fx and LowBMD respectively than Controls ($p<0.0001$). Ct vBMD of the hip regions did not differ between Controls and IOP, but C/I was 11-14% lower in IOPs ($p<0.0001$). This suggests that while intrinsic density of Ct bone is retained in IOP, Ct losses occur through thinning, consistent with lower Ct thickness seen on HR-pQCT and transiliac biopsy in these subjects. All differences were significant after controlling for age, height, BMI and FNCS. Moreover, IOP Fx and Low BMD subjects differed comparably from Controls and did not differ from each other. We conclude that in PreM with IOP, low aBMD by DXA is also associated with low vBMD of the central skeleton and is not explained by smaller bone size. We therefore conclude that a history of fragility Fx should not be required for the diagnosis of PreM IOP.

Is Screening BMD Testing in Older Women Effective for Fracture Prevention in Routine Clinical Practice? A Matched Case-Control Study. William Leslie*[1], Mahmoud Azimaee[1], Suzanne Morin[2], Colleen Metge[1], Patricia Caetano[1], Lisa Lix[3]. [1]University of Manitoba, Canada, [2]McGill University Health Centre, Canada, [3]University of Saskatchewan, Canada

BMD screening in healthy women after age 65 years, or younger post-menopausal women with additional risk factors, is widely used to identify those that may benefit from anti-osteoporotic therapy. Direct evidence of the effectiveness of this strategy for the prevention of subsequent fractures is limited. OBJECTIVE: To compare fracture rates in relatively healthy women undergoing screening BMD testing with a matched cohort of women that were not screened. METHODS: A database containing all clinical BMD tests for the Province of Manitoba, Canada, was accessed to identify women age 50 and older at the time of baseline (first ever) screening BMD testing (cases) performed during 1998-2007. We excluded women with: any anti-osteoporosis treatment in the prior 12 months; prolonged oral corticosteroid use in the prior 12 months; prior major fractures (hip, wrist, spine, humerus); loss to follow up from migration; use of homecare services or personal care home in the prior 12 months; any hospitalization in the prior 12 months. The index date for the screened cases was the date of BMD testing. Three women who were not screened (controls) were matched to each screened woman using the same exclusion criteria (matching variables age, area of residence, number of comorbid diagnoses). The index date assigned to each control was the date of BMD testing for the matched case. 17,912 screened cases were successfully matched with 53,736 non-screened controls. The outcomes of interest were major osteoporotic fractures (hip, wrist, spine, humerus) and hip fractures alone after the index date. Fractures at fixed intervals (1, 2, 3, 4, 5 years) and at final follow up date (March 31 2008) were established through linkage within a population-based provincial health data repository. RESULTS: No significant reduction in major osteoporotic fractures was seen in the screened women, but hip fractures rates were significantly lower in screened women at all time points after year 1. At final follow up, hip fractures had been diagnosed in 165 (0.9%) of the screened and 621 (1.2%) of the non-screened women ($p=.0091$). The number needed to screen to prevent one hip fracture was 426 (95% CI 249 to 1,472). CONCLUSION: A significantly lower hip fracture rate was seen among screened women. Inability to demonstrate a reduction for other major osteoporotic fractures may indicate residual confounding (referral bias) or greater tendency to diagnose fractures among screened women (ascertainment bias).

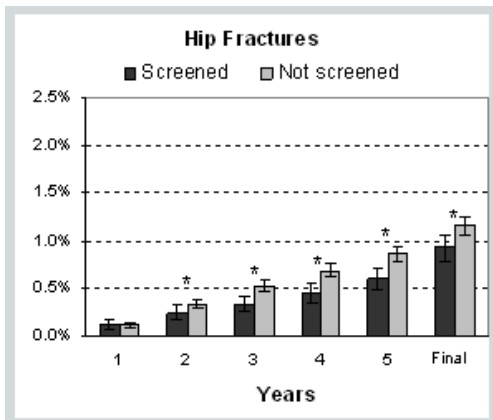

Figure: Percent of screened and non-screened women with hip fractures during follow up (*=p<.05).

Determination of an Osteoporosis Screening Interval for Women Aged 67 Years and Older. Margaret Gourlay*[1], John S. Preisser[2], Ryan C. May[2], Li-Yung Lui[3], Kristine Ensrud[4]. [1]University of North Carolina at Chapel Hill, USA, [2]University of North Carolina, USA, [3]California Pacific Medical Center Research Institute, USA, [4]Minneapolis VA Medical Center / University of Minnesota, USA

The US Preventive Services Task Force estimated that a 2-year osteoporosis screening interval for older postmenopausal women might be reasonable considering the precision error of bone densitometry. A bone density screening interval for postmenopausal women has not been determined based on US longitudinal data. We conducted time-to-event analyses of 5035 women aged 67 years and older from the Study of Osteoporotic Fractures to determine an optimal bone mineral density (BMD) testing interval according to baseline T-score category over a total of 15 years of prospective follow-up. We defined an optimal dual energy x-ray absorptiometry (DXA) testing interval as the estimated time during which 10% of women with normal BMD or osteopenia became osteoporotic. All participants underwent DXA and had BMD values at 2 to 5 visits during the study period. Osteoporosis, osteopenia and normal BMD were defined by WHO diagnostic criteria at the femoral neck or total hip. Parametric survival curves for the time to osteoporosis for baseline T-score subgroups were estimated from log logistic survival regression models for interval censored data adjusting for age, BMI, estrogen use, any fracture after age 50 years, current smoking, oral glucocorticoid use and alcohol use. Transitions from osteopenia (n=4278 women) and normal BMD (n=1275 women) were analyzed separately; 518 women who transitioned from normal to osteopenia prior to their last DXA contributed to both analyses. Participants were censored for incident hip fracture or use of bisphosphonate or calcitonin. Adjusting for the covariates, the estimated times for 10% of women to transition to osteoporosis were calculated for the following T-score subgroups: T-score >-2.5 and <=-2, 1.26 years; T-score >-2 and <=-1.5, 5.06 years; T-score >-1.5 and <-1.0, 16.1 years; T-score >=-1, 16.1 years (time conservatively estimated for the lowest BMD in the normal range). The unadjusted estimated times were similar to the adjusted times for the corresponding T-score subgroups (see table). These results suggest that baseline BMD is the most important determinant of a screening interval, and that an interval of 1 year should be considered for older postmenopausal women with a T-score <=-2. An interval of up to 5 years may be reasonable for osteopenia with T-score above -2. For women with normal BMD, repeat DXA before 10 years is unlikely to be informative.

Baseline T-score range	Time interval between DXA exams for 10% of participants to transition to osteoporosis	
	Unadjusted years (95% CI)	Adjusted* years (95% CI)
>-2.5 and <=-2	1.05 (0.93,1.20)	1.26 (1.09,1.44)
>-2 and <=-1.5	4.48 (4.07,4.92)	5.06 (4.54,5.65)
>-1.5 and <-1.0	14.9 (12.5,17.7)	16.1 (13.4,19.4)
>=-1	16.6 (11.3, 24.6)	16.1 (11.3, 23.1)

*adjusted for age, BMI, estrogen use, any fracture after age 50 years, current smoking, oral glucocorticoid use and alcohol use; model for T>=-1 includes continuous BMD and adjusts only for age as only 10 women transitioned from normal BMD to osteoporosis

Predictive value of FRAX® for the prediction of major osteoporotic fractures: The OPUS study. Karine Briot*[1], Simon Paternotte[2], Sami Kolta[3], Richard Eastell[4], Dieter Felsenberg[5], David M Reid[6], Claus C Gluër[7], Christian Roux[2]. [1]Cochin Hospital, France, [2]Paris Descartes University, Rheumatology Department, Cochin hospital, France, [3]Paris-Descartes University, Rheumatology Department, Cochin Hospital, Paris, France, France, [4]Department of Human Metabolism, University of Sheffield, United Kingdom, [5]Charité - Campus Benjamin Franklin, Germany, [6]Division of Applied Medicine, University of Aberdeen, United Kingdom, [7]Medizinische Physik, Klinik für Diagnostische Radiologie, Universitätsklinikum Schleswig-Holstein, Campus Kiel, Germany

Background and objectives: The validity of the WHO 10-yr probability of major osteoporotic fracture model (FRAX®) for prediction of fracture has been tested in few studies. We analyzed how well FRAX® predicted the risk of major osteoporotic fracture over 6 years in the prospective OPUS (Osteoporosis and Ultrasound) cohort.

Patients and methods: The OPUS study consisted of 2409 ambulatory European women aged above 55 years, recruited in 5 European centers from random population samples and followed over 6 years. For this study, we excluded women who didn't have follow-up for fracture assessment (n=670) and women who received an antiosteoporotic treatment (n=268). The population for analysis consisted of 1504 women (mean age of 65.7 years) with information on incident fractures. 607 (40.9%) of them had a prevalent low-trauma fracture (radiographic vertebral fracture included). We analyzed data of FRAX® with ORs and areas under receiver operating characteristics curves (AUC).

Results: 60 (4%) patients with incident major fractures and 9 (0.6%) with incident hip fractures were recorded. FRAX® predicted incident major osteoporotic fracture with an AUC of 0.58. History of low trauma fracture alone (AUC=0.63) predicted incident major osteoporotic as well as a combination of age + femoral neck (FN) BMD (AUC=0.60) and FRAX (AUC = 0.59). In this study, FRAX® did not predict incident hip fracture. In women without any prevalent fracture (n=897), FN BMD and FRAX® predicted incident major osteoporotic with an AUC of 0.63 and 0.55, respectively.

Conclusion: this study suggests that FRAX® predicts major osteoporotic fracture. However, once history of prevalent fracture, FN BMD and age are known, the additional risk factors in FRAX® do not significantly improve the prediction of incident fracture. A combination of history of fracture, age and FN BMD is the strongest predictor of major osteoporotic fractures.

Force Directions for Optimal Proximal Femoral Strength and Hip Fracture Risk Assessment in Men and Women: The AGES-Reykjavik Study. Joyce Keyak*[1], Agusta Sigmarsdottir[2], Gyda Karlsdottir[2], Sigurdur Sigurdsson[2], Kristin Siggeirsdottir[2], Gudny Eiriksdottir[2], Shoujun Zhao[1], Tamara Harris[3], Gunnar Sigurdsson[4], Vilmundur Gudnason[2], Thomas Lang[5]. [1]University of California, USA, [2]Icelandic Heart Association Research Institute, Iceland, [3]Intramural Research Program, National Institute on Aging, USA, [4]Landspitali, Iceland, [5]University of California, San Francisco, USA

Hip fracture risk is a composite of fall risk and bone strength, which is a function of bone density distribution and geometry, as well as force direction. Finite element (FE) modeling explicitly accounts for all of these factors. The goal of this study was to identify the force directions for which proximal femoral (hip) strength most strongly predicts hip fracture in elderly men and women.

5500 subjects from the AGES-Reykjavik study aged 65-90 years had quantitative computed tomography (QCT) scans of the hip (Siemens Somatom 4, 120 kVp, 150 mAs, 1 mm slice thickness increased to 3 mm). During 3 to 7 years follow-up, 51 men and 76 women sustained hip fractures. For each fracture subject, about 2 sex- and age-matched control subjects (97 men, 152 women) were randomly selected. FE models of the left hip were generated from the QCT scans of each subject, and hip strength was computed for single-limb stance loading (Stance) and fall loading onto the lateral (Lfall), posterior (Pfall), and posterolateral (PLfall) greater trochanter. Proximal femur areal bone mineral density (BMD) was also computed from the CT scans. Logistic regression was used to identify fracture predictors separately in men and women, and odds ratios (OR) per standard deviation were computed with adjustment for age, height and weight. Backward stepwise regression with all FE variables, BMD, age, height, and weight was used to identify the parameters that independently predict hip fracture.

All FE variables and BMD were associated with hip fracture ($p<0.001$; Table), but tended to be more strongly associated with fracture in men than in women. Stance and Pfall were the strongest predictors of fracture in men, and Pfall was the strongest in women. After backwards stepwise regression for men, Stance alone remained (OR=4.3, 95%CI:2.2–8.5), and for women, Pfall (OR=3.3, 95%CI:1.7–6.2) and height (OR=1.6, 95%CI:1.0–2.4) remained, indicating that Lfall, PLfall and BMD did not contribute additional information about fracture risk.

Stance in men and Pfall in women, followed by Pfall in men and Stance in women, most strongly predicted hip fracture, indicating that directly lateral loading may not be optimal for assessing fracture risk. Although a posterior fall is unlikely to impact the greater trochanter, a fall onto the greater trochanter can include a large posterior component. Therefore, hip strength under posterior loading should be considered an important factor for assessing hip fracture risk.

Table. Adjusted Odds Ratios per Standard Deviation from Univariate Analysis

Predictor	Men - OR (95% CI)	Women - OR (95% CI)
Stance	5.3 (2.6 – 10.9)	2.6 (1.5 – 4.3)
Lateral fall	4.0 (2.0 – 8.0)	2.1 (1.2 – 3.7)
Posterior fall	4.5 (2.2 – 9.3)	3.1 (1.8 – 5.4)
Posterolateral fall	2.7 (1.5 – 4.6)	2.2 (1.4 – 3.4)
BMD	3.3 (2.0 – 5.6)	2.5 (1.6 – 3.9)

Suppression of FSH Secretion in Postmenopausal Women has No Effect on Bone Resorption Markers. Matthew Drake*[1], Louise McCready[2], Kelley Hoey[1], Elizabeth Atkinson[1], Sundeep Khosla[3]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic, USA, [3]College of Medicine, Mayo Clinic, USA

It has recently been suggested that the increase in bone resorption following the menopause may not be due principally to estrogen (E) deficiency, but rather to the concomitant increase in circulating follicle stimulating hormone (FSH) levels. This hypothesis is based on in vitro studies demonstrating that FSH increases osteoclastogenesis and the observation that, despite having E deficiency, FSH-

receptor null mice may have normal bone mass, although different laboratories have obtained conflicting data on bone mass in these mice. Furthermore, serum FSH levels have been shown to correlate directly with rates of bone loss in postmenopausal women. However, effects of FSH on bone resorption may differ between rodents and humans, and correlation does not prove causality. Thus, to directly test for possible regulation of bone resorption by FSH in humans, we randomized healthy postmenopausal women to undergo suppression of endogenous FSH secretion using the gonadotropin releasing hormone (GnRH) agonist, leuprolide, 7.5 mg intramuscularly every 28 days (n = 22), or no FSH suppression (placebo injections [Control, n = 20]), for 4 months. To eliminate possible variations in residual E levels as a confounder, both groups were concomitantly treated with the aromatase inhibitor (AI), letrozole, 2.5 mg/d. Fasting (8 AM) serum samples were obtained at baseline (Bsl) and monthly thereafter. As shown in the Figure, Panel A, whereas Control women had a slight, transient increase in serum FSH levels (likely due to the AI-induced suppression of E production), the GnRH group had a marked (~90%) suppression of FSH levels, into the premenopausal range for this assay. Compared to Bsl, 4 month (endpoint, EP) levels of bone resorption markers (serum CTX and TRAP5b) increased slightly in the Control women (Panel B), again likely due to the AI-induced reduction in endogenous E levels. In the GnRH group (Panel C), suppression of FSH secretion did not reduce either CTX or TRAP5b levels; on the contrary, both bone resorption markers increased to a similar extent in the GnRH group as in the Control group. This direct interventional study thus demonstrates that FSH does not regulate bone resorption in postmenopausal women. As such, development of pharmacological antagonists of FSH secretion and/or action is unlikely to be a viable approach for limiting postmenopausal bone loss.

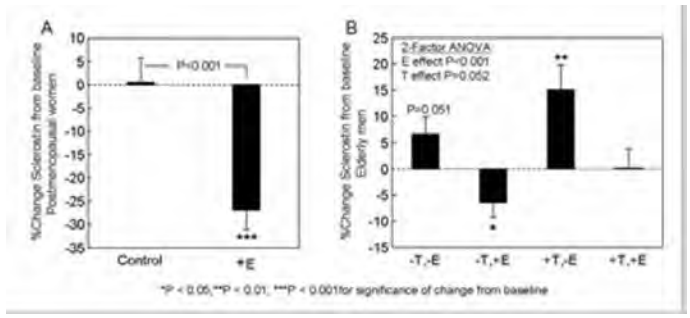
Estrogen, but not Testosterone, Suppresses Circulating Sclerostin Levels in Humans. Ulrike Moedder*[1], Jackie Clowes[1], Kelley Hoey[2], James Peterson[2], Louise McCready[2], Merry Jo Oursler[2], Byron Riggs[3], Sundeep Khosla[4]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine,Rochester, MN, USA, [4]College of Medicine, Mayo Clinic, USA

Sex hormones are important regulators of bone turnover, but the mechanisms of their effects remain unclear. Sclerostin is a major inhibitor of Wnt signaling, but whether sex steroids regulate sclerostin production and whether changes in sclerostin levels are associated with changes in bone formation and/or resorption markers is unknown. Thus, we examined effects of short term sex steroid treatment on serum sclerostin levels (measured by ELISA [Biomedica]) in E-treated postmenopausal women (Study A, n=34, mean age 54yrs) and in elderly men (Study B, n=59, 66yrs) made sex steroid deficient (using a GnRH agonist and an aromatase inhibitor) and on no replacement (-T,-E), E alone (-T,+E), T alone (+T,-E), or on both (+T,+E). E treatment of postmenopausal women for 4 weeks led to a significant decrease in serum sclerostin levels (-27%) compared to controls (+1%, P<0.001, Figure A). In addition, bone formation markers increased in E-treated women (+42% versus +12% in controls for PINP, P=0.012, and +7% versus -2% for osteocalcin, P=0.034) and bone resorption markers decreased (-37% versus -8% for CTX, P<0.001, and -25% versus -3% for TRAP5b, P<0.001). In Study B (men), using a 2-factor ANOVA model comparing the +E to the -E and +T to the -T groups, E, but not T, prevented increases in circulating sclerostin levels following induction of sex steroid deficiency (Figure B). Serum P1NP levels decreased (-13%) and bone resorption markers increased (+56% for CTX and +17% for TRAP5b, respectively, P < 0.05 for all) in the -T,-E group, and these increases were prevented by E (+14% for CTX and +6% for TRAP5b, respectively), but not T (+53% for CTX and +17% for TRAP5b, respectively) treatment. In both sexes, changes in sclerostin levels correlated with changes in bone resorption, but not formation, markers (R = 0.62, P < 0.001 and R = 0.33, P = 0.009 for correlations with changes in serum CTX in the women and men, respectively). Our studies thus establish that in humans, circulating sclerostin levels are reduced by E, but not T. Moreover, while the E-induced reduction in sclerostin production may play a role in the effects of E in maintaining bone formation, the associations we observed between changes in sclerostin levels and in bone resorption markers suggest that, consistent with recent data indicating important effects of Wnts on osteoclastic cells, at least part of the anti-resorptive effects of E may be mediated by changes in sclerostin production.



Sclerostin E and T

Altered Bone Microarchitecture and Decreased Local Runx2, RANKL and SOST Gene Expression in Men with Primary Idiopathic Osteoporosis. Janina Patsch*[1], Paul Roschger[2], Andrea Berzlanovich[1], Christian Muschitz[3], Thomas Woegerbauer[4], Thomas Kohler[5], Heinrich Resch[6], Peter Pietschmann[1]. [1]Medical University of Vienna, Austria, [2]L. Boltzmann Institute of Osteology, Austria, [3]St. Vincent's Hospital, Austria, [4]St. Vincent Hospital Vienna, Austria, [5]b-cube AG, Switzerland, [6]Medical University Vienna, Austria

While postmenopausal osteoporosis is considered to be a high bone turnover disease in the first years after menopause, idiopathic osteoporosis in both premenopausal women and men might be associated with a functional osteoblast defect and/or impaired osteoblast-osteoclast coupling. The aim of this study was to assess the expression of a predefined set of osteoblastic or osteoblast-influencing genes in transiliac bone biopsies of patients with primary male osteoporosis and to relate molecular-biological to micro-structural alterations at the tissue level. 11 men with untreated, primary male osteoporosis underwent a double transiliac bone biopsy. Age-matched control samples (n = 11) were obtained from forensic autopsies following sudden death. One biopsy per patient was used for gene expression analysis the second biopsy was-embedded in PMMA and used for structural characterization. Gene expression levels were analyzed by quantitative real time PCR to assess RANKL, OPG, osterix, runx2, SOST and wnt10b, normalized to GAPDH expression. For structural analysis embedded biopsies were measured by micro-computed tomography (micro-CT) and common morphometric indices were determined for the trabecular bone compartment using a direct 3D approach.The patients' mean age was 52 ±16 years. Their mean T-scores were -2,06 at the lumbar spine (L1-L4) and -2,18 at the (total) hip. Peripheral or vertebral fractures were prevalent in about 90%. 45% of patients had a positive family history for fractures. After normalization to GAPDH, the gene expression of runx2, RANKL and, somewhat surprisingly, SOST expression was significantly lower in osteoporotic patients than in non-osteoporotic controls. Trabecular separation (Tb.Sp) was significantly increased (p=0,012) whereas trabecular number (Tb.N) was (p=0,01) reduced in the patient group. A significant difference in the structure model index (SMI; p=0,014) further indicates a more rod-like appearance of trabeculae in men with primary osteoporosis. The decreased runx2 expression stresses the potential role of a functional osteoblast defect in the pathogenesis of male idiopathic osteoporosis. We speculate that the decreased RANKL and SOST expression reflect an osteoblast-osteoclast coupling effect as well as an indirect sign of osteoblast-osteocyte cross-talk, respectively.

Rosiglitazone Decreases Bone Mass and Bone Marrow Fat: A Randomized, Placebo-controlled Trial. Torben Harsloef*[1], Louise Wamberg[2], Louise Møller[3], Steffen Ringgaard[4], Hans Stødkilde-Jørgensen[4], Steen Bønløkke Pedersen[2], Bente Langdahl[5]. [1]Aarhus Amtssygehus, Aarhus University Hospital, Denmark, [2]Department of Endocrinology & Internal Medicine, THG, Aarhus University Hospital, Denmark, [3]Department of Endocrinology & Internal Medicine, NBG, Aarhus University Hospital, Denmark, [4]MR Research Centre, Aarhus University Hospital, Skejby, Denmark, [5]Aarhus Sygehus, Aarhus University Hospital, Denmark

Activation of peroxisome proliferator-activated receptor gamma (PPARγ) is believed to force mesenchymal stem cells of the bone marrow in an adipocyte direction at the expense of osteoblast leading to decreased BMD and increased marrow fat. Some studies, however, suggest that the two cell types can develop independently of

each other and might originate from different clones of stem cells. Rosiglitazone is a PPARγ agonist.

We examined the effect of rosiglitazone (8mg/day) for 14 weeks on BMD assessed by DXA and spine bone marrow fat assessed by magnetic resonance imaging proton spectroscopy (1H-MRS) in 53 healthy, postmenopausal women in a prospective, randomized placebo-controlled trial. Both types of scans were made before and after treatment but 1H-MRS only in a subgroup of 20 randomized participants. 1H-MRS provides a measure of fat content relative to water, the lipid to water ratio (LWR).

At the femoral neck, BMD decreased by 1.34 ± 0.60% (mean ± SEM) in the rosiglitazone group whereas BMD increased by 0.28 ± 0.56% in the placebo group (p=0.055). Changes in BMC were similar although not statistically significant (p=0.16).

At the lumbar spine, BMD decreased by 1.03 ± 0.34% in the rosiglitazone group and by 0.42 ± 0.35% in the placebo group (p=0.22). BMC decreased by 1.38 ± 0.42% in the rosiglitazone group and by 0.24 ± 0.41% in the placebo group (p=0.058).

Bone resorption marker CTx increased 20.4 ± 7.7% (mean ± SEM) in the rosiglitazone group and decreased by 7.1 ± 4.7% in the placebo group (p=0.003). Changes in the bone formation markers PINP, BAP, and osteocalcin were not significantly different between the groups.

In the rosiglitazone treated women spine LWR decreased by 13.5 ± 5.5% (mean ± SEM) whereas in the placebo group an increment of 6.8 ± 7.4% was found (p=0.056).

Our study is the first to examine the effect of rosiglitazone treatment on marrow fat in humans. Contrary to what was expected, spine LWR decreased during rosiglitazone treatment. Furthermore, rosiglitazone treatment results in uncoupling of bone resorption and formation leading to bone loss. Our data confirm that the bone marrow osteoblast/adipocyte relationship is more complex than originally assumed and that the two cell types can be independently affected.

The *Misty* mouse which has minimal brown adipose tissue (BAT) has markedly reduced bone mass and altered microarchitecture. Masanobu Kawai*[1], Sheila Bornstein[1], Sudatha Lotinen[2], Maureen Devlin[3], Mary Bouxsein[3], Mark Horowitz[4], Roland Baron[5], Clifford Rosen[1]. [1]Maine Medical Center, USA, [2]Harvard School of Dental Medicine, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]Yale University School of Medicine, USA, [5]Harvard School of Medicine & of Dental Medicine, USA

Brown adipose tissue (BAT) is critical for non-shivering thermogenesis in young mammals. Recent studies suggest that BAT is also found in adults, particularly in young and thin individuals. Little is known about the relationship between BAT and skeletal remodeling, although expression studies have demonstrated that uncoupling protein-1(UCP-1), a marker of BAT, is highly expressed in some forms of marrow adiposity. To test the hypothesis that alterations in BAT affect bone metabolism, we phenotyped the Misty mouse that has been reported to have minimal BAT and impaired BAT function. Misty has a gray coat color on the B6 background and was previously used as a marker for prediction of the Lepr (db) genotype because the db locus is tightly linked to the Misty mutation. Loss of function of Dock7, a Rho family guanidine exchange factor (GEF) belonging to the DOCK180 protein family has been reported in Misty mice. Initially we performed developmental analyses of body composition in Misty and age and gender-matched B6 control mice. Misty females exhibited decreased body temperature at 16-wks, with altered BAT morphology, and reduced body weight compared to B6 controls across several time points (4-16 wk old). Surprisingly, percent body fat was not different between Misty and B6 at 16-wk of age although Misty had reduced whole body bone mineral content and bone mineral density vs B6 at all ages. MicroCT analysis confirmed that at 16 wks Misty had markedly reduced mid-femoral cortical thickness and decreased trabecular BV/TV and number in both the distal femur and spine ($p<0.01$ for all). Histomorphometric analysis revealed a 3 fold increase in osteoclast number ($p<0.001$) associated with a doubling in eroded surfaces in Misty vs B6, whereas osteoblast number and bone formation were identical to B6. Bone marrow stromal cell cultures revealed that CFU-Fs and CFU-OBs were comparable between Misty and B6, suggesting that the low bone mass phenotype of Misty is not cell autonomous for osteoblasts, despite relatively high expression of Dock7 in those cells. In sum, Misty mice have low bone mass and deteriorated architecture that is likely due to increased bone resorption. While we can not exclude the possibility that the lack of Dock7 directly affects osteoclast function, our data suggest that alterations in BAT have a profound systemic effect on bone acquisition and maintenance.

PPARβ/δ-deficiency Impairs Muscle and Bone Mass and Worsens its Response to Estrogen-deprivation. Nicolas Bonnet*[1], Beatrice Desvergne[2], Serge Ferrari[3]. [1]Geneva University Hospital, Switzerland, [2]Center for integrative Genomics, Genopodes, Switzerland, [3]Geneva University Hospital & Faculty of Medicine, Switzerland

Ppar beta/delta (ß/δ) is ubiquitously expressed and its prime role is to promote fatty acids oxidation in skeletal muscle and adipose tissue. Pparß/δ-deficient mice have reduced muscle strength and capacity to perform physical activity, but their skeletal phenotype is unknown. We investigated the influence of Pparß/δ on the skeleton and its response to aging and ovariectomy (OVX).

Female Pparß/$\delta^{-/-}$ and Pparß/$\delta^{+/+}$ mice were monitored from 3 to 12 months of age. Another group was OVX or SHAM operated at 6 months and followed 8 wks.

Compared to Pparß/$\delta^{+/+}$, 3-month-old Pparß/$\delta^{-/-}$ mice had lower total body (TB) lean mass (17.9±0.4 vs 19.9±0.3 g, $p<0.001$), TB BMD (0.052±0.001 vs 0.054±0.001 g/cm^2, $p<0.05$), spine BMD (0.073±0.001 vs 0.080±0.002 g/cm^2, $p<0.01$), caudal vertebral BV/TV (8.6±0.3 vs 10.6±0.8 %, $p<0.05$) and tibial cortical (Ct) bone volume (BV, 0.34±0.01 vs 0.38±0.02 mm^3, $p<0.05$). Serum levels of TRAc5b were 20% higher in Pparß/$\delta^{-/-}$ vs PPARß/$\delta^{+/+}$ mice ($p<0.05$). At that age, no significant differences in TB fat mass, femoral BMD, tibial BV/TV or osteocalcin were observed. Between 3 and 12 months, Pparß/$\delta^{-/-}$ had significantly lesser % gain in femur BMD (+4.9% vs +13% in Pparß/$\delta^{+/+}$, $p<0.01$), tibial Ct BV (+9.8% vs +18.2% in Pparß/$\delta^{+/+}$, $p<0.05$), and Ct thickness (+6.0% vs +14.6% in Pparß/$\delta^{+/+}$, $p<0.05$). Lean mass and the other bone parameters also remained significantly lower in old Pparß/$\delta^{-/-}$ vs Pparß/$\delta^{+/+}$, which was associated with decreased bone formation at endocortical surfaces (BFR/BPm: 0.002±0.001 in Pparß/$\delta^{-/-}$ vs 0.005±0.002 µm2/µm/day in Pparß/$\delta^{+/+}$; MPm/BPm: 0.32±0.10 vs 0.74±0.15 % in Pparß/δ +/+, both $p<0.05$), but not at the periosteum. Compared to SHAM, OVX caused a greater loss in Pparß/δ-/- of muscle volume in the lower leg (-14.9% vs +3.8 in Pparß/$\delta^{+/+}$, $p<0.05$), TB BMD (-13.6% vs 0% in Pparß/$\delta^{+/+}$, $p<0.05$), and CtBV (-9 vs -5.3% in Pparß/$\delta^{+/+}$ ns), whereas changes in TB lean mass, spine and femur BMD, and trabecular BV/TV were similar in Pparß/$\delta^{-/-}$ and Pparß/$\delta^{+/+}$.

These results indicate that Pparß/δ plays an important role on the acquisition and maintenance of muscle and bone mass (particularly cortical) with aging and estrogen-deprivation. Whether Pparß/δ regulates bone remodeling through its effects on muscle and/or directly on bone cells, -as suggested by low bone formation at endocortical rather than periosteal surfaces-, is currently being investigated.

Males Recruits with Stress Reaction of the Tibia Exhibit Higher Density and Smaller Geometry than Uninjured Recruits. Rachel Evans*[1], Charles Negus[2], Amanda Antczak[3], Amir Hadid[4], Yael Arbel[4], Ran Yanovich[4], Daniel Moran[4]. [1]U.S. Army Research Institute of Environmental Medicine, USA, [2]L-3 Applied Technologies, USA, [3]US Army Research Institute of Environmental Medicine, USA, [4]Heller Institute of Medical Research, Israel

Susceptibility to bone stress reaction (SR), a painful, debilitating bone overuse injury, has been attributed to parameters of bone that include low BMD, smaller bones (geometry), or a combination of these attributes (bone strength). Specifically, the higher occurrence of SR in women than men during military training has often been attributed to lower BMD. Data supporting this, however, utilized 2-dimensional DXA imaging and may represent smaller bone size in women rather than lower BMD. The purpose of this study was to determine if men and women who sustained a SR over the course of a 4-mo recruit training program differed from uninjured recruits (NSR) in measures of volumetric cortical BMD (vBMD), bone size [total area (TtAr), cortical area (CA), cortical width (CW)], and a bone strength index (BSI). Peripheral QCT was used to obtain cross-sectional images of the tibia from 114 male and 68 female recruits upon entry into the Israeli Defense Forces. MATLAB software assessed whole bone and regional (60° sectors) parameters of the tibia shaft at fracture prone sites (38 and 66% of tibial length). Tibial SR was diagnosed using MRI, bone scan, radiography, and clinical examination.

28 men (24.6%) and 12 women (17.6%) were diagnosed with SR. Women exhibited greater vBMD than men, though their bones were smaller ($p<0.001$). At the 38% site men with SR had higher vBMD than NSR men (1160.7±17.5 vs 1150.9±21.7 mg/cm^3, $p=0.03$), narrower tibial shafts (TtAr 411.0±38.2 vs 451.2±45.1 mm^2, $p<0.001$), and lower BSI (69.7±14.4X106 vs 81.1±6.3X106 mm4, $p=0.001$); similar differences were apparent at the 66% site ($p\leq0.04$). No differences were observed between SR and NSR women. Regional analyses revealed that greater vBMD and smaller area in SR men was most prominent at the anterior and medial-anterior sectors of the tibia. We conclude that male recruits with higher vBMD and smaller tibial geometry, specifically at the anterior/medial-anterior aspect of the tibia (a frequent SR site) may be more susceptible to bone overuse injury. While similar results were not observed in among women, the tibiae of females compared to men exhibited higher vBMD and smaller tibial geometry. Whether the higher incidence of SR in both women and susceptible men is related to higher mineralization that may compensate for smaller bones warrants further exploration. Moreover, previous conclusions that "lower BMD" predisposes healthy women or men to bone overuse injuries should be reconsidered.

Reduced Matrix Heterogeneity with Bisphosphonate Treatment in Postmenopausal Women with Proximal Femoral Fractures. Adele Boskey[1], Joseph Lane[1], Brian Rebolledo[1], Brian Gladnick[2], Dennis Meredith[1], Eve Donnelly*[1]. [1]Hospital for Special Surgery, USA, [2]Cornell University, Weill Medical College, USA

Bisphosphonate (BIS) treatment is generally effective in reducing fracture incidence in osteoporotic patients. While no significant association between BIS use and subtrochanteric (ST) fracture risk was detected in analyses of datasets from large trials [Black+ 2010], identification of a rare atypical fracture pattern specifically associated with BIS treatment [Neviaser+ 2008] suggests that BIS use may alter bone quality in a subset of patients. Our objective was to examine the effect of BIS treatment on bone tissue composition near femoral fracture sites.

Bone cores were removed from the lateral aspect of the proximal femur, adjacent to the fracture site, of postmenopausal women admitted for repair of intertrochanteric (IT) and ST fractures in an IRB-approved study. Specimens were allocated to the -BIS group (n=12, age=87$\pm$7y; fracture morphology: 11 IT, 1 ST, 0 atypical) if the patient had never used BIS; all others were allocated to the +BIS group (n=14, age=82$\pm$11y, BIS duration 7.4$\pm$5y; fracture morphology: 9 IT, 1 ST, 4 atypical). Cortices were analyzed with Fourier transform infrared (FTIR) imaging to assess the mineral:matrix ratio, carbonate:phosphate ratio, collagen cross-link maturity (XLR), and mineral crystallinity (XST). Pixel histograms of each parameter were characterized by their mean and full width at half maximum to assess average composition and compositional heterogeneity, respectively.

The XLR distribution width was reduced 29% in the +BIS group vs. the -BIS group (Fig. 1). Trends toward treatment-based effects in the +BIS group were evident in the XST mean (+2%, p=0.055) and width (-22%, p=0.068) but did not reach statistical significance. All other FTIR parameters were similar across groups.

Bisphosphonate treatment was associated with narrowed distributions of collagen maturity in patients with femoral fractures. The average cortical composition was minimally changed. These data are consistent with previous reports of loss of heterogeneity with BIS treatment in perimenopausal women [Boskey+ 2009] and in normal beagles [Gourion+ 2009a]. Our approach comprised analysis of FTIR parameters that are independent predictors of fracture risk [Gourion+ 2009b]. Because reductions in tissue heterogeneity are associated with reduced resistance to crack propagation, our data preliminarily suggest that oversuppression of bone turnover may alter bone quality and contribute to the increased risk of fractures in a subset of patients.

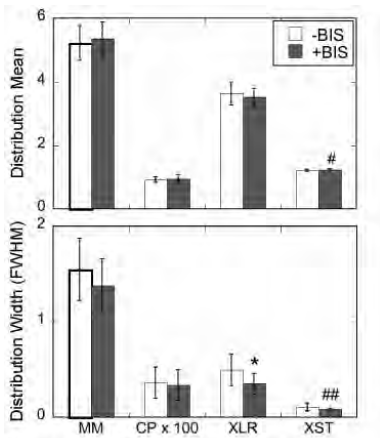

Figure 1: FTIR spectroscopic parameters for each treatment group reported as distribution means (top) and full widths at half maximum (FWHM) (bottom). (MM=mineral:matrix ratio; CP=carbonate:phosphate ratio; XLR= collagen maturity; XST=crystallinity; *p<0.05, #p=0.055, ##p=0.068 by t-test)

Bone Tissue Quality in the Years after Menopause: Micro-hardness is Decreased Independently of Changes in the Degree of Mineralization. Yohann Bala*[1], Susan Bare[2], Georges Boivin[1], Robert R. Recker[2]. [1]INSERM U831, Université de Lyon, France, [2]Osteoporosis Research Center, Creighton University, USA

Bone strength depends not only on bone mass and architecture but also on bone mineralization. The degree of mineralization of bone (DMB) depends on the age of bone structural unit which is influenced by the activity of bone remodeling[1]. Our purpose was to measure bone quality variables reflecting mineralization and microhardness in iliac bone biopsies from 20 women (49$\pm$2 yrs) before and 1 year after menopause (paired samples) and from 20 women (60$\pm$7 yrs) 14$\pm$9 yrs after menopause. DMB (g/cm^3), heterogeneity index (HI, g/cm^3) and Vickers microhardness were measured separately for cortical and cancellous bone[2]. Bone remodeling activity was evaluated with Activation Frequency (Ac.F, #/yr) measured in cancellous bone using tetracycline-based histomorphometry[3]. Ac.F was significantly (p=0.002) increased after 1 year of menopause vs before and was maintained at a high level after 14 yrs of menopause. Among the 3 groups, DMB was not significantly changed neither in cortical nor in cancellous bone. HI was also not significantly changed but lowest values of DMB (0.50-0.75 g/cm^3) were more frequent in bone tissue after 14 yrs of menopause than in other groups. Microhardness of cortical and cancellous bone tissue were significantly ($p<0.04$) decreased one year after menopause vs before. Measured after 14 years past menopause, microhardness of cancellous bone was significantly ($p<10^{-4}$) lower than after 1 year of menopause, this difference was borderline in cortical bone (p=0.07). Thus, menopause was associated with a low microhardness after both 1 and 14 years, independently of changes of DMB. This could be link with the changes in viscoelasticity of bone tissue showed after one year of menopause[4]. Results suggested that the substantial increase in bone remodeling modified the distribution of mineralization. Augmentation in bone formation led to an increase of hypomineralized bone tissue counterbalanced by the increase of resorption which led to an increased frequency of high DMB values. Consequently, DMB and HI were not changed despite of changes in Ac.F. In conclusion, the quality of organic matrix could influence bone strength independently of mineralization[5], and has to be taken into account in further analysis on bone quality.

Male Astronauts Have Greater Bone Loss and Risk of Hip Fracture following Long Duration Spaceflights than Females. Rachel Ellman*[1], Jean Sibonga[2], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]USRA Division of Space Life Sciences, USA

Despite an intense exercise regimen, excellent health, and relatively young age, astronauts experience dramatic bone loss in space. Yet it is not known how this decrement in bone mass influences the risk of fracture in the returning crewmember. Additionally, the sex-specific differences in the skeletal response to microgravity in astronauts have not been investigated, for lack of a sufficient sample size. Thus, our goal was to use a biomechanical approach to determine the risk for hip fracture following long-duration spaceflight in male and female astronauts based on their areal bone mineral density (aBMD) and body composition. To do so, we calculated the factor-of-risk (Φ), defined as the ratio of applied load to bone strength, in long duration astronauts before and after return from a mission on the International Space Station. All NASA long duration astronauts (n=25) from Expedition 1-18, with missions averaging 171 days (range 95-215), were included in the study. The load applied to the hip was calculated for a sideways fall from standing height based on each astronaut's height and weight, minus an attenuating contribution from the soft tissue overlying the greater trochanter. Femoral strength was estimated from trochanteric aBMD measurements by DXA, using a regression derived from a previous study of femoral strength in human cadaveric samples (Roberts et al, Bone 2010). Trochanteric aBMD measurements did not differ between male (n=20) and female crewmembers either at preflight or postflight. However, bone loss was twice as great in men, with 6.9% decrease in BMD ($p < 0.005$) versus 3.3% loss in women ($p = 0.09$). Male crewmembers had a significantly higher factor-of-risk for hip fracture than females, with postflight values of 0.88 $\pm$ 0.14 and 0.36 $\pm$ 0.05, respectively ($p <$

0.005). Three men, but no women, exceeded the theoretical fracture threshold of Φ=1 postflight, indicating that they would likely fracture if they were to fall sideways with impact to the greater trochanter. Altogether, these data indicate that male crewmembers may be at a higher risk for hip fracture than females following spaceflight, primarily due to a greater impact force from a fall. Moreover, the accelerated rate of microgravity-induced bone loss in men is in direct contrast to the greater risk of age-related osteoporosis in women. The mechanisms underlying these different responses warrant further investigation.

High Resolution Peripheral Quantitative CT (HRpQCT) Reveals Preferential Inner Trabecular Bone Loss in Lactating Women. Shannon Kokolus[1], Mary Beth Vrabel[1], Xiaowei Liu[1], Stephanie Boutroy[2], Halley Rogers[3], Donald McMahon[4], Carolyn Westhoff[1], Adi Cohen*[3]. [1]Columbia University, USA, [2]INSERM, Université De Lyon, France, [3]Columbia University Medical Center, USA, [4]Columbia University College of Physicians & Surgeons, USA

Lactation is associated with declines in bone mineral density (BMD) followed by recovery. Rodent studies show loss of trabecular (Tb) BMD with detectable changes in bone microarchitecture and decreases in bone strength. High resolution peripheral quantitative CT (HRpQCT; Xtreme CT, Scanco Medical AG; voxel size 82μm) can image bone microarchitecture *in vivo*, allowing us to examine longitudinal microarchitectural changes in the distal skeleton in lactating women for the first time. We measured BMD by DXA at the lumbar spine (LS), total hip (TH), femoral neck (FN), 1/3 radius (DR) and ultradistal radius (UD) and HRpQCT at the radius and tibia in 12 healthy, exclusively breastfeeding women at baseline and 6 months postpartum. At baseline (38±20 days postpartum), subjects (58% Caucasian) had (mean±SD) age of 34±4 yrs, weight of 62±7 kg, and BMI of 22.6±2.6 kg/m^2. Mean baseline BMD Z scores ranged from -0.68 to 0.28 at the 5 measured sites. By 6 months (190±11 days), subjects had lost 3.5±3.7 kg, a decrease of 5.1±5.0% (p=0.01). BMD also fell by 3.3±3.9% (p=0.01) at the LS, 1.6±3.3% (p=0.1) at the TH, 2.3 ± 4.8% (p=0.1) at the FN, and increased by 1.5±3.0% (p=0.1) at the DR and 0.3±4.1% (p=0.9) at the UD. Greater LS bone loss at 6 months correlated with lower baseline weight (R=-0.7;p=0.01) and greater decrease in weight (R=0.8;p=0.002), while age, baseline BMI and the number of days postpartum at baseline visit were not associated. By HRpQCT at the radius, no significant changes were found in cortical density or thickness, or in total Tb density (Dtrab), number, thickness or separation. However there was a 3.0±4.3% decrease in density of the inner Tb compartment (Dinn; p=0.04) and a 2.9±2.7% increase in the ratio of the outer (Meta) to inner Tb compartment density (Meta/Inn; p=0.004; Table). There were no significant changes in any HRpQCT measure at the tibia. Baseline weight was directly associated with the 6-month change in Dinn (radius: R=0.6; p=0.04; tibia: R=0.6; p=0.06) and inversely associated with the 6-month change in Meta/Inn (radius: R=-0.4; p=NS; tibia: R=-0.8; p=0.004). In summary, at 6 months postpartum, lactating women had expected decreases in LS BMD by DXA. HRpQCT at the radius revealed preferential bone loss in the inner trabecular compartment, similar to the pattern seen in rodent models. The lack of change at the tibia suggests that weightbearing may influence lactation-related bone loss.

	RADIUS		TIBIA	
	Mean % change	p (baseline vs 6mo)	Mean % change	p (baseline vs 6mo)

Finite Element Analysis of the Hip DXA Scans and Hip Fracture Risk in Older Men. Lang Yang*[1], Annabel Burton[2], Mike Bradburn[2], Eric Orwoll[3], Lynn Marshall[3], Carrie Nielson[3], Richard Eastell[2]. [1]Univesity of Sheffield, United Kingdom, [2]University of Sheffield, United Kingdom, [3]Oregon Health & Science University, USA

Low areal BMD (aBMD) is associated with increased risk of hip fracture, but many hip fractures occur in persons without low aBMD. Finite element (FE) analysis of QCT scans provides a measure of hip strength that predicted hip fractures independently of hip aBMD in MrOS. QCT scans are not widely available. We have developed an FE method for DXA scans of the hip and the aim of the study was to determine whether hip strength estimates predict hip fracture risk independent of aBMD.

This prospective case-cohort study included all first hip fractures (n = 40) and a random sample (n = 210) of non-fracture cases from 3549 community-dwelling men > or =65 yr of age, with a mean follow-up of 5.6 yr. We analyzed the baseline DXA scans of the hip using linear-elastic FE method. Stress and strain within the bone were calculated as a consequence of a sideways fall. A stress-based femoral strength S_s was defined as the impact force that caused the von Mises stress in 100 contiguous elements (24 mm^2) to exceed the element yield stress. A strain-based femoral strength S_e was also calculated similarly with the element yield strain being a constant of 1.45%. Cox regression with Prentice weighting was used to assess the association of the femoral strengths with hip fracture.

The mean femoral strengths S_s and S_e were 1287 (SD 612) and 4659 (SD 2107) N for fractured group, 2054 (SD 1170) and 8072 (SD 3699) N for non-fractured group, respectively. Between-group differences were highly significant ($p<0.0001$). Correlation of total hip (TH) aBMD with S_s: r=-0.44, $p<0.0001$ and with S_e: r=-0.64, $p<0.0001$. S_s and S_e were also positively correlated with one another (r=0.61, $p<0.0001$). The table shows the hazard ratio (HR) of hip fracture per standard deviation (SD) increase in age and decreases in TH aBMD, BMI, S_s and S_e in a variety of Cox regression models. The HRs of S_s and S_e were significant alone and after adjusting for age, BMI and site. When adjusted for age, BMI, site and TH aBMD, the HR of S_e was still significant. The HRs for BMI and site were not significant in any of the regression models.

These results demonstrated that FE analysis of DXA hip scans can provide strength estimates that predict hip fracture independent of aBMD. This finding is consistent with previous work in our group on women and with previous FE analysis using QCT in the same cohort of men.

Hazard ratio (95% CI) of hip fracture for 1 SD change in covariate values in various Cox models

Sirtuin1 (*Sirt1*) Regulates Osteoblastogenesis and Represses Sclerostin. Einav Cohen-Kfir*[1], Avi Levin[1], Hanna Artsi[1], Eva Abramowitz[1], Agustina D'Urso[2], Lei Zhong[2], Raul Mostoslavsky[2], Rivka Dresner-Pollak[1]. [1]Hadassah-Hebrew University Medical Center, Israel, [2]The Massachusetts General Hospital Harvard Medical School, USA

The sirtuins are NAD+-dependent enzymes with a prominent role in metabolism and age-related diseases. We have previously reported that *Sirt1*-haploinsuffient (*Sirt1*+/-) adult female mice exhibit a 30% reduction in bone mass (*Sirt1*-/- is lethal). The purpose of this study was to investigate the mechanisms of reduced bone mass in *Sirt1*+/- mice.

Bone formation and resorption were evaluated in vivo and in vitro. A decrease in bone formation was found in *Sirt1*+/- mice as indicated by a 20% reduction in mineral apposition rate and bone formation rate, decreased serum PINP, a 50% reduction in alkaline phosphatase activity in *Sirt1*-derived bone marrow mesenchymal stem cells (BM-MSC) induced to osteogenesis accompanied by fewer Von Kossa positive-stained nodules. On the other hand, no significant changes in bone resorption were observed as indicated by osteoclast number and serum TRAP5b. Osteoclastogenesis upon exposure of marrow machrophages to RANKL and M-CSF was reduced in *Sirt1*+/- mice, resulting in smaller osteoclasts with fewer nuclei. No differences in IGF-1, 25OHvitaminD3 and 17-β estradiol were detected.

To investigate the mechanism by which Sirt1 affects osteoblastogenesis, gene expression in *Sirt1*+/- and WT-BM-MSCs was compared. A 14-fold increase in SOST expression was found in *Sirt1*+/–BM-MSCs. Confirming the gene expression data, sclerostin was increased in *Sirt1*+/- -BM-MSCs and whole bone extracts, and was reduced in *Sirt1*-over-expressing C3HT101/2 cells. Moreover, beta-catenin was increased in *Sirt1*-over-expressing C3HT101/2 cells.

To study how *Sirt1* regulates SOST gene expression, a chromatin immunoprecipitation (ChIP) assay was performed with Sirt1 antibody in mouse embryonic stem (ES) cells. *Sirt1*-/- cells were used as negative control. PCR assay using primers that cover consecutive segments in the regulatory region of the SOST promoter, showed *Sirt1* binding to the 760-1940 region. No binding was detected in Sirt1-/- cells. Next we tested whether *Sirt1* affects the SOST promoter through modification of histone H3K9, a known *Sirt1* target, using a ChIP assay. H3K9 acetylation of the SOST promoter was dramatically increased in *Sirt1*-/- cells in the region of maximal *Sirt1* binding.

Conclusions: This study demonstrates a role for *Sirt1* in bone formation by repressing SOST expression via epigenetic modification of histone 3, and suggests that *Sirt1* is a potential novel target for anabolic therapy for osteoporosis.

Osteoblast-Specific Deletion of Neuropeptide Y1 Receptors Enhances Bone Formation. Nicola Lee, Ronaldo Enriquez, Amy Nguyen, Kharen Doyle, Amanda Sainsbury, Paul Baldock*, Herbert Herzog. Garvan Institute of Medical Research, Australia

Neuropeptide Y (NPY) has been shown to play a critical role in the central regulation of bone metabolism. However, the peripheral mechanism remains unknown. In-situ hybridisation on femur sections revealed the presence of the NPY, Y1 receptor mRNA in osteoblasts, consistent with a direct role for the Y1 receptor on bone cells.

To investigate the role of the Y1 receptor on osteoblastic cells, we generated mice with selective deletion of the Y1 receptor in osteoblasts ($Y1^{lox/lox,Cre/+}$) by crossing Y1 receptor floxed mice with mice expressing Cre specifically in osteoblasts under control of a 2.3kb fragment of the rat α_1(I)-collagen promoter.

In male mice at 16 weeks of age, osteoblast-specific Y1 receptor deletion resulted in a marked increase in femoral cancellous bone volume ($Y1^{lox/lox,Cre/+}$ 15.2 % $\pm$ 1.4, control 11.0 $\pm$ 0.6; $p<0.01$), trabecular thickness ($Y1^{lox/lox,Cre/+}$ 34.8 µm $\pm$ 2.4, control 29.4 $\pm$ 1.2; $p<0.05$) and trabecular number ($Y1^{lox/lox,Cre/+}$ 4.3 /mm $\pm$ 0.2, control 3.8 $\pm$ 0.1; $p<0.05$). This was the result of elevated osteoblast activity as shown by a significant increase in mineral apposition rate ($Y1^{lox/lox,Cre/+}$ 1.93 µm/day $\pm$ 0.02, control 1.64 $\pm$ 0.05; $p<0.001$) and bone formation rate ($Y1^{lox/lox,Cre/+}$ 0.52 $\mu m^2/\mu m^3$/day $\pm$ 0.02, control 0.41 $\pm$ 0.04; $p=0.01$) with no alterations in bone resorption as measured by osteoclast number and osteoclast surface area. Furthermore, osteoblastic Y1 receptor deletion also led to increased mineral apposition rate on both the endocortical ($Y1^{lox/lox,Cre/+}$ 1.72 µm/day $\pm$ 0.10, control 1.08 $\pm$ 0.08; $p<0.001$) and the periosteal surfaces ($Y1^{lox/lox,Cre/+}$ 1.33 µm/day $\pm$ 0.12, control 0.99 $\pm$ 0.07; $p<0.05$) resulting in significantly increased femoral diameter ($Y1^{lox/lox,Cre/+}$ 5.24 mm $\pm$ 0.10, control 5.00 $\pm$ 0.06; $p<0.05$) and a trend towards increased cortical bone strength as estimated by mean polar moment of inertia ($Y1^{lox/lox,Cre/+}$ 0.42 mm^4 $\pm$ 0.03, control 0.36 $\pm$ 0.02; $p=0.05$).

Together these data demonstrate a direct role for the Y1 receptor on osteoblasts in the regulation of osteoblast activity and bone formation in vivo and suggests that targeting Y1 receptor signalling directly in the bone may have potential powerful therapeutic implications for stimulating bone accrual in diseases such as osteoporosis.

Hedgehog Signaling Inhibits Differentiation of Osterix+ Progenitors to Mature Osteoblasts. Kyu Sang Joeng*[1], Fanxin Long[2]. [1]Washington University School of Medicine - St. Louis, USA, [2]Washington University School of Medicine, USA

Although a large number of genetic studies have shown that Indian hedgehog signaling is essential for endochondral bone development in the embryo, the function of Hedgehog (Hh) signaling in postnatal bone formation is not clear. In a previous study, we generated the R26-ΔNGli2 mouse strain which can express a constitutively activated form of Gli2 (termed ΔNGli2) in a CRE-dependent manner. To study the function of Hh signaling in postnatal bones, we initially generated *Col2-CRE; $R26^{\Delta NGli2/+}$* mice by crossing *$R26^{\Delta NGli2/+}$* mice with Col2-CRE mice which express Cre in both osteoblasts and chondrocytes. The *Col2-CRE; $R26^{\Delta NGli2/+}$* animals showed a disorganized growth plate and severe osteopenia at 2 and 4 months of age. However, the disorganized growth plate precluded the analysis of direct effects of Hh signaling on bone. To avoid the growth plate phenotype, we generated *Osx1-GFP::Cre; $R26^{\Delta NGli2/+}$* mice (termed OsxΔNGli2) by crossing *$R26^{\Delta NGli2/+}$* mice with *Osx1-GFP::Cre* mice which specifically express Cre in osteoblasts[1]. The OsxΔNGli2 animals exhibited a dramatic decrease (6-fold by uCT) in bone mass without any obvious growth plate phenotype at 4 and 6 weeks of age. Further analysis showed that the reduced bone mass in OsxΔNGli2 animals was due to decreased osteoblast number and activity. To study the molecular basis for the osteoblast phenotype, we performed in situ hybridization with osteoblast markers in neonatal OsxΔNGli2 animals. Whereas early osteoblast markers, *Runx2* and *Osterix (Osx)*, were expressed normally, the mature osteoblast marker, *Osteocalcin (Oc)*, was rarely detectable in OsxΔNGli2 animals. These data indicate that ectopic activation of Hh signaling by ΔNGli2 inhibits differentiation of Osx+ progenitors to Oc+ osteoblast. To examine the role of physiological Hh signaling in Osx+ progenitors, we generated *SP7-CRE; $Smo^{c/c}$* mice in which *Smoothened (Smo)*, the indispensable mediator for hedgehog signaling, was specifically knocked out in osteoblasts. Remarkably, *Osx1-GFP::Cre; $Smo^{c/c}$* animals showed a notable increase in bone mass (7-fold by uCT). Consistent with the notion that loss of Hh signaling promotes differentiation of Osx+ progenitors, in situ hybridization in neonatal *Osx1-GFP::Cre; $Smo^{c/c}$* animals detected a decrease in Osx signal in the primary spongiosa. Overall, through both gain- and loss-of-function studies, we have uncovered a new function for Hh signaling in osteoblast development. We speculate that the newly identified role of Hh signaling may be important for maintaining an adequate pool of progenitors for osteoblast.

Endogenous G_i Signaling in Osteoblasts Restricts Bone Formation in Adult Mice. Susan Millard*[1], Alyssa Louie[2], Nathalie Cotte[3], Bruce Conklin[3], Robert Nissenson[4]. [1]UCSF/VA Medical Center/Northern California Institute for Research & Training, USA, [2]VA Medical Center, USA, [3]Gladstone Institutes, USA, [4]University of California, San Francisco, USA

Blockade of endogenous Gi coupled signaling in osteoblasts throughout development, achieved by transgenic expression of pertussis toxin (PTX), results in increased cortical thickness and a female-specific increase in cancellous fractional bone volume (BV/TV) in femurs of 12wk old mice. Here we report on changes in bone formation rates (BFR) that underlie the Col1(2.3).PTX mouse phenotype and on the effects of blockade of Gi signaling in the adult mouse independent of developmental effects. Increased cortical thickness observed in Col1(2.3).PTX mice results from increased periosteal BFR (Male:1.3$\pm$0.3 vs 2.1$\pm$0.6µm/day $p<0.01$, Female:1.2$\pm$0.3 vs 2.0$\pm$0.8µm/day $p<0.05$). Mineralizing surface (MS) in control mice was primarily restricted to the lateral and anterior surfaces of the femoral midshaft, with little or no active bone formation on the medial and posterior surfaces. In contrast, Col1(2.3).PTX mice displayed an expanded MS with active bone formation evident around the entire circumference of the bone. There was no appreciable change in mineral apposition rate. In cancellous bone at the distal femur, expression of PTX produced no alteration of BFR in male mice (0.68$\pm$0.13 vs 0.77$\pm$0.12µm/day). However, BFR in female Col1(2.3).PTX bones could not be quantified due to the disorganized nature of bone formation which displayed a labeling pattern consistent with the rapid formation of woven bone. To examine the role of endogenous Gi coupled signaling in the adult skeleton we utilized the Tet-regulatable nature of our transgenic model. In these studies, expression of PTX in osteoblasts was delayed until 8wks of age, and the cohort was assessed by in vivo µCT of the distal femur and TFJ. Between 10wks and 6 mths of age, male and female control mice and Col1(2.3).PTX male mice all experienced a 30% decrease in cancellous BV/TV. Col1(2.3).PTX female mice displayed a striking 90% increase in BV/TV. Assessment of the TFJ showed that the percentage increase in cortical thickness to be greater in Col1(2.3).PTX than control mice (Male:5.6$\pm$2.6 vs 9.0$\pm$3.2% $p<0.05$, Female:6.8$\pm$4.1 vs 16.9$\pm$4.5% $p<0.001$). These results indicate that signaling by endogenous Gi coupled receptors in osteoblasts of adult mice: 1) restricts cortical bone formation in both genders; and 2)restricts cancellous bone formation in females. Inhibition of Gi coupled receptor signaling in osteoblasts represents a novel strategy for the development of new anabolic therapies for osteoporosis.

Intermittent PTH of Short Term can Activate Quiescent Lining Cells to Mature Osteoblasts: Unproven Mechanism of the Anabolic Action of Intermittent PTH. Sang Wan Kim*[1], Paola Divieti Pajevic[2], Martin Selig[3], Henry Kronenberg[2]. [1]Seoul National University Boramae Hospital, South korea, [2]Massachusetts General Hospital, USA, [3]Department of Pathology, Massachusetts General Hospital, USA

Intermittent administration of parathyroid hormone (PTH) increases bone mass, at least in part by increasing osteoblast number, but the molecular and cellular mechanism involved in the anabolic effects have not been completely elucidated. One possible source of osteoblasts might be conversion of inactive lining cells to osteoblasts, and indirect data are consistent with this hypothesis. To better understand the possible effect of PTH on lining cell activation, we conducted a lineage tracing study using an inducible gene system. We used the mouse 10kb DMP1 promoter to drive the expression of the inducible CreERt2 in transgenic mice; this gene is active, upon tamoxifen administration, in osteocytes and some osteoblasts, particularly in the calvarium. DMP1-CreERt2 mice were crossed with Rosa26R reporter mice that contain a conditional LacZ transgene downstream of a floxed stop-cassette inserted into the endogenous Rosa26 locus to render targeted mature osteoblasts and their descendents, lining cells or osteocytes, detectable by X-gal staining. Rosa26R:DMP1-Cre(+) mice were injected with 0.25mg of tamoxifen (TMX) at day 3, 5 and 7 postnatally and then injected with 0.1mg at day 14 and 21. They were sacrificed at day 23, 35 and 42 postnatally (2, 14 and 21 days after the last TMX, respectively). At day 42, some mice were challenged with anabolic injection of human PTH (1-34, 80µg/kg) or vehicle for 3 days, administered subcutaneously. In calvarial and tibia bones of Rosa26R:DMP1-Cre(+) mice at 23 days of age, many cuboidal osteoblasts and osteocytes were positive for X-gal staining. Twenty-one days after the last TMX injection, most of blue cells were found to be very flat on the periosteal surface of both calvaria and tibia. After 3 days of PTH injections, the thickness of blue cells on the inner surface of the calvaria and on the periosteal surface of tibia increased and the number of these cells did not fall as much as with vehicle. Moreover, new blue cells appeared on the outer surface of calvaria, which were not detected with routine light microscopy prior to PTH. Electron microscopy analysis revealed X-gal particles in both blue thin cells prior to PTH and cuboidal cells following PTH administration. PTH did not increased β-galactosidase activity in Rosa26R:DMP1-Cre(-) mice. These data support the hypothesis that short term treatment with intermittent PTH can contribute to the anabolic effect through activating lining cells to mature osteoblasts in vivo.

K-ras Generated Signals in Osteoblasts Increase Trabecular Bone Mass by Stimulating Osteoblast Proliferation and Inhibiting Osteoclastogenesis. Julie Leslie*[1], Ryan Riddle[2], Cassandra R. Zylstra[3], Katia Bruxvoort[3], Thomas Clemens[1], Bart Williams[3]. [1]Johns Hopkins University, USA, [2]Johns Hopkins University School of Medicine, USA, [3]Van Andel Research Institute, USA

K-ras is a GTPase that activates proteins necessary for the propagation of growth factor and receptor-initiated signals. Key among these is the mitogen-activated protein kinase (MAPK) pathway, which is required for osteoblast proliferation and optimal osteogenic gene expression. To directly investigate the role of K-ras signaling in skeletal development *in vivo*, we generated mice expressing a constitutively active form of K-ras in osteoblasts (OB $Kras^{G12D}$). Mice expressing the osteocalcin-Cre transgene were crossed with heterozygous Lox-Stop-Lox $K\text{-}ras^{G12D}$ mice, in which the expression of K-ras with an activating mutation at codon 12 (G12D) is controlled by a removable transcription termination element. Longitudinal analysis of whole body bone mineral density (BMD) by DEXA demonstrated a significant increase in BMD in OB $K\text{-}ras^{G12D}$ mice compared to controls, with the largest increase (14%) evident at 12 weeks of age. Micro-CT measurements of femoral bone structure in OB $K\text{-}ras^{G12D}$ mice revealed no change in cortical bone, but dramatically increased trabecular bone volume (109%). Histomorphometry revealed an increase in the total number of osteoblasts. Consistent with this observation, primary osteoblasts expressing $K\text{-}ras^{G12D}$ exhibited increased rates of proliferation and expression of cyclin D1. Osteoblast differentiation, however, was unaffected by increased activation of MAPK signaling, as alkaline phosphatase expression and matrix mineralization were equivalent in control and mutant osteoblasts. Surprisingly, the number of osteoclasts was reduced by more than 50% in OB $K\text{-}ras^{G12D}$ mice, which suggests that MAPK signaling in the osteoblast indirectly regulates osteoclast development. Indeed, osteoclast differentiation was impaired in co-cultures containing $K\text{-}ras^{G12D}$ expressing osteoblasts compared to cultures containing control osteoblasts, and these cells expressed lower levels of RANKL and higher levels of OPG. Taken together, these results indicate that K-ras-MAPK signaling in the osteoblast plays a dual role in regulating bone acquisition: signals downstream of K-ras directly stimulate osteoblast proliferation and promote additional signals which act in a cell non-autonomous fashion to inhibit osteoclast development. These results support the further development of novel bone anabolic therapies that target the MAPK pathway.

Targeted Overexpression of ADAMTS-7 in Chondrocytes Induces Chondrodysplasia in "young" Mice and Osteoarthritis-like Phenotype in "aged" Mice. Yongjie Lai*[1], Xiaohui Bai[1], Yuqing Chen[2], Brendan Lee[2], Chuanju Liu[1]. [1]New York University, USA, [2]Baylor College of Medicine, USA

We previously reported that ADAMTS-7, a metalloproteinase that belongs to ADAMTS family, associated with and degraded cartilage oligomeric matrix protein (COMP) and its level was significantly elevated in arthritis (Liu, et al, FASEB J. 2006; 20(7):988-999). In addition, our recent findings also revealed a physiological, developmental role for ADAMTS-7 in chondrogenesis in vitro (Bai, et al, Mol. Cell. Biol. 2009; 29(15):4201-4219). To define the role of ADAMTS-7 in cartilage development and arthritis in vivo, we generated Col2a1-TS7 transgenic mice overexpressing ADAMTS-7 under the control of a well-characterized Col II promoter. Newborn Col2a1-TS7 mice were significantly smaller. X-ray images revealed remarkable reductions of the skeletal length and bone volumes in transgenic (Tg) mice. Safranin O staining showed that the Tg growth plate was only half the size of that in WT. Staining with alcian blue and alizarin red S of whole body and forelimb skeleton revealed that Col2a1-TS7 mice had hypoplastic limb skeletons and dramatically delayed endochondral bone formation compared with control mice. However, Col2a1-TS7 mice reached to the normal size at about 6 weeks postpartum and no defects were observed in articular cartilage and joints. Interestingly, 8-month old Col2a1-TS7 mice spontaneously developed osteoarthritis (OA)-like phenotype. Micro-CT of the hind knees showed osteophyte formation in aged Tg mice. Safranin O staining demonstrated a remarkable loss of proteoglycan staining, and meniscus ossification in Tg mice. High power photograph revealed clear chondrocyte clustering, and migration of the irregular tide mark to the superficial zone. To further determine the role of ADAMTS-7 in OA development and progression, we established surgically-induced OA model by transecting MMTL (medial meniscotibial ligament) in Col2a1-TS7 and control WT mice. Histological analyses were performed in mice knee joints at 4, 8 and 12 weeks post-surgery. The operated knees of Col2a1-TS7 mice showed moderate loss of Safranin O staining as early as 4 weeks after surgery, while the control mice joints showed minor loss until 8 weeks. The destruction of knee cartilage increased along with time after surgery. Histological score grading indicated higher scores in the operated Col2a1-TS7 knees, with a significant reduction of cartilage thickness and loss of proteoglycan. In addition, COMP degradative fragments were increased in the operated Col2a1-TS7 mice. Collectively, targeted overexpression of ADAMTS-7 in chondrocytes results in defects in chondrogenesis in "young" mice and OA-like phenotypes in "aged" mice, and overexpression of ADAMTS-7 also accelerates surgically-induced OA. These findings not only provide novel insights into the role of ADAMTS-7 in cartilage and arthritis in vivo, but may also lead to the development of novel therapeutic intervention strategies for osteoarthritis.

Mechanisms of Exostosis Formation in Hereditary Multiple Exostoses Syndrome. Julianne Huegel*[1], Christina Mundy[1], Eiki Koyama[2], Yu Yamaguchi[3], Jeffrey Esko[4], Maurizio Pacifici[1]. [1]Thomas Jefferson University, USA, [2]Thomas Jefferson University College of Medicine, USA, [3]Sanford-Burnham Medical Research Institute, USA, [4]University of California, San Diego, USA

Hereditary Multiple Exostoses (HME) syndrome is caused by loss-of-function heterozygous mutations in *EXT1* or *EXT2* that encode glycosyltransferases responsible for synthesis of heparan sulfate (HS), but the *Ext*-dependent mechanisms causing exostosis formation and the origin of exostosis-forming cells remain largely unclear. Interestingly, HME patients produce less than the 50% HS expected of a heterozygous mutation, and heterozygous $Ext2^{+/-}$ mice form exostoses at a very low rate and with atypical characteristics. To test whether exostosis formation requires a steeper drop in HS production, we created double heterozygous $Ext1^{+/-};Ext2^{+/-}$ mice. These mutants did display stereotypic growth plate-like exostoses near their long bones and at high frequency. To identify the origin of exostosis-forming cells, we conditionally deleted *Ext1* in mesenchymal cells near the groove of Ranvier in long bones by mating $Ext1^{fl/fl}$ and *Gdf5Cre* mice. Indeed, this triggered local ectopic chondrogenesis and formation of exostosis-like tissue masses near the epiphyses. To determine whether the responses were cell-autonomous, we prepared micromass cultures of limb bud mesenchymal cells isolated from E11.5 wild type mouse embryos. Treatment of these cultures with the HS antagonist Surfen caused increases in expression in chondrogenic and cartilage matrix genes. As interestingly, Surfen treatment interfered with formation of individual cartilage nodules that became irregularly contoured and often fused with each other. In addition, Surfen-loaded beads placed near the cartilaginous epiphyses in cultured mouse embryo autopods caused similar disruption of the chondro-perichondrial border and formation of ectopic cartilage. Our data reveal that: (i) exostosis formation is inversely related to *Ext1* gene expression; (ii) a specific niche progenitor cell population may be responsible for exostosis formation in long bones; and (iii) exostosis formation involves disruption of mechanisms that control the chondro-perichondrial border. Together, our findings provide major new insights into, and a better understanding of, the pathogenesis of HME.

Schnurri2 Deficiency Increases all of 1,25(OH)2D3, Renal 25-hydroxyvitamin D 1-α Hydroxylase, PTH, FGF23, Serum Calcium and Phosphate in Association with Hypercalcification in Joints. Masashi Nagao*[1], Yoichi Ezura[2], Yoshitomo Saita[3], Kentaro Miyai[1], Ryo Hanyu[1], Tetsuya Nakamoto[1], Hiroaki Hemmi[1], Tadayoshi Hayata[4], Takuya Notomi[5], Shunsuke Ishii[6], Shigeaki Kato[7], Seiji Fukumoto[8], Hisashi Kurosawa[9], Kazuo Kaneko[10], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Juntendo University, Department of Ortopedics, Japan, [4]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [5]GCOE, Tokyo Medical & Dental University, Japan, [6]Laboratory of Molecular Genetics, RIKEN Tsukuba Institute, Japan, [7]University of Tokyo, Japan, [8]University of Tokyo Hospital, Japan, [9]Dept of Orthopedics, Juntendo University, School of Medicine, Japan, [10]Dept of Orthopedics, Juntendo University school of medicine, Japan

Schnurri (Shn)-2 is a zinc finger type transcription factor, regulating adipogenesis and lymphogenesis. In addition, we have shown recently that Shn2 plays an important role in bone remodeling through BMP signaling. Interestingly in that study, we noticed that Shn2 deficient mice exhibited periarticular calcification around the knee joint, as well as high serum phosphate and calcium levels causing high calcium-phosphate product. In this study, we aimed to analyze Shn2 functions in calcium and phosphate metabolism, focusing on the endocrine control. Serum FGF23, intact PTH and 1,25-(OH)2 vitamin D (1,25D) levels were determined in 12-weeks Shn2 deficient (KO) and control mice (WT) fed under the normal condition. Surprisingly, we found that all the hormone levels were significantly higher in KO mice compared to WT mice, indicating the disrupting feed-back systems of blood calcium and phosphate levels in KO mice. We also found that urinary phosphate level was higher in the mutants, as well as the increased serum BUN, and Creatinine levels. Since these clinical phenotypes are similar to human hyper-vitaminosis D, we hypothesized that the disruption of the mechanisms suppressing the 1,25D levels is the primary cause of the mutant phenotypes, and the increased levels of blood FGF23 and PTH are secondary observation caused by functional feed-back system against the hyperphosphatamia. In fact, we found that the 25 hydrodyvitamin D 1-alpha hydroxylase expression in KO mice was about 10 fold higher than those in WT mice, although that of renal 25 hydroxyvitamin D 24-alpha hydroxylase was not changed. Histological analysis revealed no remarkable changes in the parathyroid gland, supporting the notion that the serum PTH level was functionally increased against the increased serum phosphate level. To test this hypothesis, we applied the WT and KO mice under the 0.2% low-phosphate diet, and the endocrine status was followed up. Although a surprising finding was that all KO mice died within a few days due to severe

hypophosphatamia, we could confirm that the blood intact PTH and FGF23 levels are rapidly decreased both in the KO and the control mice, suggesting that the PTH and FGF23 levels are normally regulated for the lower phosphorous intake in these mice. Severe hypophosphatamia of the KO mice might be caused by slow response for declining the FGF23 because of the excessive level from the beginning. These observations indicate a novel function of the Shn2 in the renal tubular cells regulating the serum 1,25D level, that would be beneficial for understanding the mechanism of vitamin D metabolism, as well as understanding the human hypervitaminosis D, or unidentified human diseases caused by disrupting vitamin D regulation.

Proteoglycan-4: A Dynamic Regulator of PTH Actions in Skeletal Anabolism and Arthritic Joints. Chad Novince*[1], Megan Michalski[2], Amy Koh[2], Ben Sinder[2], Jan Berry[2], Kenneth Kozloff[3], Laurie McCauley[1]. [1]University of Michigan, School of Dentistry, USA, [2]University of Michigan, USA, [3]University of Michigan Department of Orthopaedic Surgery, USA

Intermittent parathyroid hormone (PTH) is anabolic via unclear mechanisms, and has been recently reported to protect against arthritic joint remodeling. Proteoglycan-4 (*prg*4) protein products are implicated in articular joint protection, hematopoiesis and megakaryopoiesis. *Prg*4 loss of function mutations result in the human condition camptodactyly-arthropathy-coxa vara-pericarditis syndrome, characterized by precocious joint failure and osteopenia. The purpose of this study was to investigate the role of *prg*4 in the anabolic actions of PTH, and to assess PTH actions on arthritic articular joints in *prg*4 deficient (KO) mice. *Prg*4 KO and wildtype (WT) mice were treated with intermittent PTH from 16-22wks of age and evaluated by histomorphometry and micro-CT. Bone marrow stromal cells (BMSCs) were analyzed for cell autonomous alterations, serum markers were assessed, peripheral blood cells enumerated, bone marrow cells analyzed via flow cytometry, and bone marrow gene expression evaluated by real-time PCR. *Prg*4 KO mice were osteopenic with a significantly blunted PTH anabolic response. BMSCs from *prg*4 KO mice had reduced cell numbers over time in culture, lower proliferation, and less mineralization than WT. KO mice had synovial tissue hyperplasia and arthritic remodeling in the knee joints that was further exacerbated by PTH. *Prg*4 KO mice had significantly lower serum PTH levels, yet serum calcium levels were similar in WT and KO mice. PTH significantly reduced serum FGF-23 in WT but not KO mice, suggesting an altered PTH impact on mineralization in KO mice. KO mice had increased peripheral blood neutrophils and decreased lymphocytes, which were normalized to WT levels with PTH. KO mice had reduced marrow B220+ (B-lymphocytic) cells, which were normalized with PTH. PTH increased hematopoietic progenitor ($Lin^-Sca\text{-}1^+c\text{-}Kit^+$) cells more significantly in WT vs. KO marrow. PTH decreased CD41+ (megakaryopoietic) cells in KO, and PTH increased ploidy status of CD41+ cells more significantly in KO vs. WT mice. KO mice had significantly higher IGF-1 mRNA levels in the marrow. PTH increased osteocalcin mRNA in WT marrow, and increased G-CSF mRNA in KO marrow. In summary, proteoglycan-4 intrinsically regulates BMSC proliferation and differentiation, and mediates PTH actions on immune and hematopoietic cell populations in a favorable physiologic manner. These studies identify proteoglycan-4 as a dynamic regulator of PTH actions in skeletal anabolism and arthritic joints.

β-Catenin Is A Key Mediator in the Development of Intervertebral Disc Degeneration in Humans and in a β-Catenin Conditional Activation Mouse Model. Bing Shu*[1], Meina Wang[2], Dezhi Tang[2], Baoli Wang[1], Edward Schwarz[2], Paul Rubery[3], Regis O'Keefe[2], Di Chen[1]. [1]University of Rochester Medical Center, USA, [2]University of Rochester, USA, [3]Medical center, University of Rochester, USA

Low back pain is a serious clinical problem that may be related to intervertebral disc (IVD) degeneration. The mechanism responsible for this disease remains unknown. In this study we found that β-catenin protein was up-regulated in IVD tissues from patients with disc degeneration (33 positive from a total of 36 samples analyzed). In contrast, β-catenin was undetectable in disc tissues from normal subjects (n=12). To assess the role of β-catenin on disc degeneration we generated a genetic mouse model in which β-catenin is constitutively expressed specifically in disc cells. These β-catenin conditional activation (cAct) mice expressed high levels of β-catenin in the annulus and endplate cartilage cells in their spine, which led to a 36% reduction in spine length, severe disc space narrowing, and extensive osteophyte formation within 3-months. These structural changes were associated with severe degenerative changes in the cells and extracellular matrix of the IVD. Expression of Mmp13 mRNA and protein was significantly up-regulated in β-catenin cAct mice. Activation of β-catenin with BIO, a GSK-3β inhibitor, enhanced Mmp13 and Runx2 expression in chondrocytes. A 3.4-kb human Mmp13 promoter was cloned and a conserved Runx2 binding site in the Mmp13 promoter (-138/-132) was identified. Mutation of the Runx2 binding site abolished the stimulatory effect of Runx2 as well as BIO on Mmp13 gene transcription. Runx2 siRNA also inhibited BIO-induced Mmp13 transcription. ChIP assay confirmed Runx2 binding to the Mmp13 promoter. These findings suggest that activation of β-catenin induces Mmp13 expression in a Runx2-dependent manner. We have then crossed β-catenin cAct mice with Mmp13-floxed mice and treated the β-catenin cAct mice with a MMP13-specific inhibitor. Micro-CT and histologic data showed that genetic ablation of the Mmp13 gene under β-catenin cAct background (n=8) or treatment of β-catenin cAct mice with the MMP13 inhibitor (n=5) significantly ameliorated the mutant phenotype observed in 3-month-old β-catenin cAct mice. Osteophyte formation was disappeared; disc space was returned to normal; and loss of endplate cartilage and proteoglycan protein was restored. Over 70% rescue was observed based on histomorphometric analysis after deletion of the Mmp13 gene or treatment with the MMP13 inhibitor in β-catenin cAct mice. These findings provide significant insights into the mechanism of disc degeneration.

Expression of BMP2 in Skeletal Progenitor Cells is Required for Bone Fracture Repair. Giuseppe Intini*, Karen Cox, Vicki Rosen. Harvard School of Dental Medicine, USA

Different from mice lacking Bmp4 or Bmp7, mice lacking Bmp2 are unable to repair fractures. To identify cells in which the expression of Bmp2 is important during fracture repair, we compared mice lacking Bmp2 in osteoblast-committed cells (Bmp2-2.3kbCol1cre mice) with mice lacking Bmp2 in skeletal progenitor cells (Bmp2-Prx1cre mice). We chose this comparison because localization studies using the Rosa26-2.3kbCol1cre mice showed β-gal staining restricted to osteoblast-committed cells whereas localization studies using the Rosa26-Prx1cre mice showed β-gal staining in skeletal progenitors as well as osteocytes, osteoblasts, and chondrocytes.

First, we analyzed the bone mass phenotype of 8-10 week old Bmp2-2.3kbCol1cre mice by μCT (n=7). This analysis showed no difference in terms of bone mass between the Bmp2-2.3kbCol1cre and the wild type mice. Subsequently, we created unilateral femur diaphysal fractures and evaluated the healing process by X-rays in 8-10 week old Bmp2-2.3kbCol1cre and Bmp2-Prx1cre mice (n=3). The X-rays obtained 3, 10, and 20 days after fracture showed normal healing process in Bmp2-2.3kbCol1cre mice and confirmed the lack of healing in Bmp2-Prx1cre mice. Finally, we compared the gene expression profile of the femur diaphyses of 8-10 week old Bmp2-Prx1cre mice to that of 8-10 week old wild type mice. The microarray data, validated by quantitative mRNA analysis, showed increased levels of BMP3, a BMP antagonist, and increased levels of Axin2, Dkk1, Sclerostin, Sfrp2, Sfrp4, and Wif1, inhibitors of the Wnt signaling, in diaphysal bones obtained from the Bmp2-Prx1cre mice (n=6, $p<0.05$).

Results indicate that when Bmp2 is inactivated only in osteoblast-committed cells expressing Col1, no alterations are seen in terms of bone metabolism and fracture healing. However, when Bmp2 is inactivated in skeletal progenitors by means of the Prx1cre recombinase, fracture healing does not occur and a BMP antagonist and Wnt inhibitors are up-regulated in cells of the diaphysal bones.

We conclude that during bone fracture repair expression of Bmp2 is required in the skeletal progenitor cells and that BMP3 and Wnt inhibitors may be responsible for the lack of differentiation of these cells.

Dentin Matrix Protein 1 Null Mice, a Model of Human Autosomal Recessive Hypophosphatemic Rickets, Exhibit Decreases in Cardiac, Skeletal, and Vascular Smooth Muscle Function. Michael Wacker*[1], Chris Elmore[1], Chad Touchberry[1], Leticia Brotto[2], Neerupma Silswal[1], Nikhil Parelkar[1], Hong Zhao[3], Todd Hall[2], Jon Andresen[4], Jian Feng[5], Marco Brotto[2], Lynda Bonewald[3]. [1]University of Missouri-Kansas City School of Medicine, USA, [2]University of Missouri-Kansas City School of Nursing, USA, [3]University of Missouri-Kansas City School of Dentistry, USA, [4]Universtity of Missouri-Kansas City School of Medicine, USA, [5]Texas A&M Health Science Center, USA

Currently there is little known about cardiac, skeletal, or smooth muscle function in Autosomal Recessive Hypophosphatemic Rickets (ARHR), a disease caused by mutations in Dentin Matrix Protein-1 (DMP1). Patients with Autosomal Dominant Hypophosphatemic Rickets (ADHR) and acquired hypophosphatemia report muscle weakness, while those with X-Linked Hypophosphatemia (XLH) do not. Fibroblast growth factor 23 is much higher in ADHR than XLH and ARHR patients even with phosphate treatment, suggesting that there could be other factors besides simply regulation of phosphate levels that could alter muscle function. As data from our laboratories suggest that a muscle-bone axis may exist in which muscle and bone influence each other in an endocrine manner, we hypothesized that muscle function would be reduced in Dmp1-/- mice. Dmp1-/- and wild-type (WT) mice (16-25 week old) were sacrificed and the heart, extensor digitorum longus muscle (EDL), soleus muscle (SOL), middle cerebral artery (MCA), and aorta were removed. Contractile responses to various stimulatory challenges were studied. Ca^{2+} imaging was also conducted on flexor digitorum brevis (FDB) in order to link ex-vivo contractility to Ca^{2+} homeostatic mechanisms. Dmp1-/- mice displayed an increased heart weight (HW)/body weight (BW) ratio (0.0038 ± 0.0002 vs 0.0045 ± 0.0005) and a decrease in relative maximum heart contraction as compared to WT mice (31.6 ± 11.3 vs 18.9 ± 2.5 mN/g) (n=4; $P<0.05$). The hearts of Dmp1-/- mice also generated weaker

contractions when challenged with high Ca^{2+} and caffeine. EDL and SOL muscles were atrophic. Relative and specific forces were significantly reduced in EDL and SOL muscles from Dmp1-/- mice, indicating that atrophy can only partially explain the force reduction in these muscles (n=4). Intriguingly, caffeine-induced fura-2 Ca^{2+} transients were larger in FDB muscle fibers from Dmp1-/- mice, indicating that the mechanisms for Ca^{2+}-induced Ca^{2+} release might be enhanced in Dmp1-/- mice. Contraction to serotonin was impaired in aortas of Dmp1-/- mice whereas in the MCA agonist induced constriction did not differ between Dmp1-/- and WT mice (n=3). Together, our data suggest that the contractile machinery is compromised in cardiac, skeletal, and vascular smooth muscles from Dmp1-/- mice. The mechanisms underlying the decreased muscle function remain to be elucidated, but may involve endocrine signaling mechanisms triggered by altered osteocyte function.

Klotho Lacks a Vitamin D Independent Physiological Role in Aging, Bone, and Glucose Homeostasis. Rene Anour*, Eva Ritter, Reinhold Erben. University of Veterinary Medicine, Austria

Lack of Klotho is known to shorten life span and to cause osteomalacia, hypercalcemia, hyperphosphatemia, elevated circulating vitamin D hormone, and increased peripheral insulin sensitivity in mice. The Klotho gene encodes for a transmembrane protein, acting as a co-receptor for fibroblast growth factor-23 (Fgf-23) which suppresses vitamin D hormone synthesis. In addition, the extracellular fraction of Klotho can be shed and released into circulation. Previous data suggest that circulating Klotho prolongs life span by inhibiting insulin and insulin-like growth factor-1 (IGF-1) signaling. To further explore the role of the vitamin D independent functions of Klotho in the regulation of aging, mineral, and glucose homeostasis, we mated *Klotho* deficient (*Klotho*$^{-/-}$) mice with vitamin D receptor (VDR) mutant mice characterized by a non-functioning VDR. All mice were kept on a rescue diet enriched with calcium, phosphorus, and lactose to prevent secondary hyperparathyroidism in *VDR* and compound mutants, and were killed at 4 weeks of age after double fluorochrome labeling. *Klotho*$^{-/-}$ mice displayed hypercalcemia, hyperphosphatemia, dwarfism, organ atrophy, azotemia, pulmonary emphysema, osteomalacia, and an elevated lumbar volumetric bone mineral density (BMD). In addition, glucose and insulin tolerance tests revealed profoundly increased peripheral insulin sensitivity in *Klotho* deficient mice. Compound mutants were normocalcemic and normophosphatemic, did not show premature aging or organ atrophy, and were phenocopies of *VDR* mutant mice in terms of body weight, BMD, and bone metabolism. Serum calcium and PTH levels as well as urinary calcium and phosphate excretion were not different between *VDR* and compound mutants. Furthermore, ablation of vitamin D signaling in double mutants completely normalized glucose and insulin tolerance, indicating that Klotho has no vitamin D independent effects on insulin and IGF-1 signaling. Histomorphometry of pancreas islets showed similar beta cell area per body weight in all groups of animals. In conclusion, we found no evidence for a physiologically relevant, vitamin D independent, function of Klotho in the regulation of carbohydrate and mineral metabolism in 4-week-old mice.

Prevention of Chemotherapy Induced Alopecia with a Novel Parathyroid Hormone Fusion Protein. Ranjitha Katikaneni*[1], Tulasi Ponnapakkam[1], Osamu Matsushita[2], Joshua Sakon[3], Robert Gensure[1]. [1]Ochsner Clinic Foundation, USA, [2]Kitasato University Medical School, Japan, [3]University of Arkansas, USA

Chemotherapy is a cancer treatment that causes many side effects, including alopecia, for which there is currently no therapy. Parathyroid hormone agonists and antagonists improve hair growth after chemotherapy; however, rapid clearance and systemic side-effects complicate their usage. To facilitate delivery and retention to the skin, we fused PTH agonists and antagonists to a bacterial collagen binding domain derived from clostridium histolyticum collagenase, and tested these compounds in-vitro and in-vivo. In vitro studies showed no differences in cAMP accumulation in SaOS cells with administration of PTH(1-33)-CBD vs. PTH(1-34). PTH(7-33)-CBD did not stimulate cAMP accumulation, and showed 27% inhibition of PTH(1-34) effect at 20x concentration. In-vivo studies were conducted in 5-week old C57BL/6J mice. 28 mice were divided into 4 groups (No Chemo, Chemo+Vehicle, Chemo+Agonist and Chemo+Antagonist) and depilated to synchronize the stage of the hair follicles. On day 7, No Chemo and Chemo+Vehicle groups received 320 ug/kg sq buffer solution, Chemo+Antagonist received 320 ug/kg sq PTH(7-33)-CBD, and Chemo+Agonist received 320 ug/kg sq PTH(1-33)-CBD. On day 9, cyclophosphamide (150 mg/kg ip) was administered to all animals except those in the No Chemo group. No Chemo mice showed rapid regrowth of hair after depilation. Histological examination showed normal anagen and telogen follicles. Chemo+Vehicle mice showed little hair regrowth and decreased pigmentation. Histological examination showed dystrophic anagen and catagen follicles. Chemo+Antagonist mice showed rapid but partial hair regrowth, only around the site of injection, with little change observed thereafter. Histological examination showed changes indistinguishable from those seen after chemotherapy alone. Chemo+Agonist mice showed regrowth and repigmentation of hair, approaching that seen in No Chemo mice. Histologically, normal follicles predominantly in the anagen phase were seen. Total number of hair follicles was significantly reduced in the Chemo+Vehicle (28+/-1, p=0.12) and Chemo+Antagonist groups (23+/-3, p=0.004) compared to that of the No Chemo group (49+/-7), while the Chemo+Agonist group (42+/-6, p>0.5, NS) showed no reduction in hair follicles. Staging of hair follicles for counts is being performed. Overall, the PTH agonist compounds had the most prominent effects in reducing the damage of chemotherapy on hair follicles, and produced the most cosmetically acceptable results.

Calcitonin Regulates Bone Formation by Reducing the Extracelluar Levels of Osteoclast-derived Sphingosine 1-phosphate. Thorsten Schinke*[1], Johannes Keller[2], Philip Catala-Lehnen[2], Antje K. Huebner[2], Robert P. Marshall[2], Jerold Chun[3], Michael Amling[2]. [1]University Hospital Hamburg, Eppendorf, Germany, [2]University Medical Center Hamburg-Eppendorf, Germany, [3]Scripps Research Institute, USA

The hormone calcitonin (CT) is long known for its pharmacologic action as an inhibitor of bone resorption, yet its physiologic functions are still not fully clarified. In this regard it was of hallmark importance that the recent analysis of mice lacking either CT or one allele of the CT receptor (CTR) demonstrated a high bone mass phenotype caused by excessive bone formation. Since the CTR is not expressed by bone-forming osteoblasts, these findings have raised the question, how the negative influence of CT on bone formation is explained at the cellular and molecular level. To address this issue we have applied the Cre/lox technology, which enabled us to delete the CTR in specific cell types. While the phenotype of mice with a ubiquitous CTR deletion resembled to one described for CT-deficient mice, we did not observe abnormalities of bone remodelling in mice lacking the CTR specifically in the hypothalamus. In contrast, an osteoclast-specific deletion of the CTR resulted an increased bone formation, thereby demonstrating that CT regulates the production of osteoclast-derived factors that influence osteoblast activities. To identify such factors, we treated wildtype and CTR-deficient osteoclasts with CT and performed a genome-wide expression analysis using Affymetrix Gene Chip hybridization. This approach led us to identify several CT-regulated genes, one of them being Spns2, which encodes a transporter for sphingosine 1-phosphate (S1P). Since others have previously shown that osteoclast-derived S1P promotes an osteoanabolic effect in vitro, we first confirmed that the negative regulation of Spns2 expression by CT resulted in decreased S1P levels in osteoclast-conditioned media. In addition, we were able to identify the serpentine receptor S1pr3 as a functionally relevant S1P receptor on osteoblasts, since S1pr3-deficient mice displayed decreased bone formation, and since the osteoanabolic effect of osteoclast-conditioned medium was fully abrogated, when the osteoblasts were derived from S1pr3-deficient mice. Taken together, our data have helped to identify one of the mechanisms coupling the activities of osteoclasts and osteoblasts. They further raise the possibility that S1P receptor agonists might be useful as osteoanabolic agents for the treatment of bone loss disorders.

FGF-23 Suppresses Renal 1,25(OH)$_2$D Production and Phosphate Reabsorption via MAP Kinase Activation in *Hyp* Mice. Daniel Ranch*[1], Martin Y.H. Zhang[1], Anthony Portale[1], Farzana Perwad[2]. [1]University of California, San Francisco, USA, [2]University of California San Francisco, USA

X-linked hypophosphatemia (XLH) is characterized by hypophosphatemia due to renal phosphate (Pi) wasting, inappropriately suppressed 1,25(OH)$_2$D production, rickets in children and is caused by a loss-of-function mutation in the *Phex* gene. In XLH and in its murine homologue, the *Hyp* mouse, increased circulating concentrations of fibroblast growth factor-23 (FGF-23) is responsible for the disordered metabolism of Pi and 1,25(OH)$_2$D. We previously showed in cultured renal proximal tubular cells that FGF-23 suppresses 1α-hydroxylase gene expression via activation of the mitogen-activated protein kinase (MAPK) signaling pathway, and such suppression is blocked when MAPK signaling is inhibited. In the present study, we tested the hypothesis that in *Hyp* mice, FGF-23-mediated suppression of renal 1,25(OH)$_2$D production and Pi reabsorption depend upon activation of the MAPK signaling pathway. We fed wild-type (WT) and *Hyp* mice a constant Pi diet (baseline), and then administered either vehicle or the MAPK inhibitor PD0325901 (12.5 mg/kg) orally daily for 4 days. At baseline, the renal abundance of early growth response-1 (egr-1) mRNA, a transcription factor downstream of MAPK pathway activation, was 3-fold greater in *Hyp* mice than in WT mice ($P<0.05$). After treatment with PD0325901, egr-1 mRNA abundance decreased by 94% in both WT and *Hyp* mice ($P<0.05$). In *Hyp* mice, PD0325901 induced a 19-fold increase in renal 1α-hydroxylase mRNA expression ($P<0.05$) and a 4-fold increase in serum 1,25(OH)$_2$D levels (350 ± 41 vs 89 ± 21 pg/ml, mean $\pm$ SEM, $P<0.05$) compared to values in vehicle-treated *Hyp* mice. Compared to WT mice, serum Pi levels in *Hyp* mice were significantly lower at baseline (10.5 ± 0.4 vs 5.8 ± 0.6 mg/dl, $P<0.05$), and increased significantly after treatment with PD0325901 (7.2 ± 0.3 mg/dl, $P<0.05$). The increase in serum Pi levels in *Hyp* mice was associated with increased renal Npt2a mRNA and brush-border membrane Npt2a protein expression. Serum PTH levels were higher in *Hyp* than in WT mice at baseline (54 ± 8 vs 7 ± 5 pg/ml, $P<0.05$) and did not change significantly after treatment. These findings provide evidence that in *Hyp* mice: a) the

MAPK signaling pathway is constitutively activated in the kidneys; and b) inhibition of MAPK signaling reverses FGF-23-dependent suppression of renal $1,25(OH)_2D$ production by up-regulation of renal 1α-hydroxylase gene expression, and partially corrects the hypophosphatemia by increasing renal Pi absorption via Npt2a.

The RANKL Distal Control Region is Required for Cancellous Bone Loss Due to Dietary Calcium Deficiency but not Lactation. Melda Onal*[1], Carlo Galli[2], Priscilla Cazer[1], Jinhu Xiong[1], Xinrong Chen[1], Robert Weinstein[1], Stavros Manolagas[1], Charles O'Brien[1]. [1]University of Arkansas for Medical Sciences, USA, [2]Università Degli Studi Di Parma, Italy

Parathyroid hormone (PTH) controls RANKL gene transcription in part via a distant enhancer, designated the distal control region (DCR). Importantly, deletion of this enhancer from the mouse genome blunts PTH-induced RANKL expression in vivo. Here we assessed the role of the DCR in the control of the bone resorption associated with secondary hyperparathyroidism or lactation, two situations in which the demand for calcium is met by an increase in osteoclastogenesis, at the expense of bone mass, through an increase in the expression of RANKL. In both conditions, activation of the PTH receptor (PTHR1), which binds both PTH (elevated during hyperparathyroidism) and PTH-related protein (PTHrP) (elevated during lactation), is thought to drive the increase in RANKL expression. Secondary hyperparathyroidism was induced by placing 5 month old wild-type (WT) and DCR knock-out (KO) mice on a calcium-deficient diet for 30 days. While secondary hyperparathyroidism led to loss of both cortical and cancellous bone in WT mice, as measured by microCT, only cortical bone was lost in DCR KO mice, demonstrating that the DCR is indispensable for cancellous bone loss in this model. Consistent with this, histological analysis showed that secondary hyperparathyroidism increased the percent of cancellous bone surface covered by osteoclasts in WT, but not KO mice. In contrast to these results, lactation-induced bone loss was not different between 5 month old WT and DCR KO mice, in either the cancellous or cortical compartment. Nonetheless, whereas lactation induced a striking increase in RANKL mRNA in bones from WT mice, as measured by quantitative RT-PCR, this change was abrogated in DCR KO mice. On the other hand, OPG mRNA expression was reduced during lactation in both WT and KO mice. These findings demonstrate that DCR-mediated control of RANKL expression is essential for the cancellous bone loss associated with secondary hyperparathyroidism, but not lactation. Moreover, they suggest that PTH uses different transcriptional enhancers to control RANKL expression in cancellous versus cortical bone. Lastly, the increase in RANKL during lactation also requires the DCR. However, because prevention of this increase does not blunt lactation-induced bone loss, other changes, such as decreases in OPG and estrogen, may be the predominant mechanisms underlying the increase in bone resorption during lactation.

Risk of Cardiovascular Events with Calcium/Vitamin D - a Re-Analysis of the Women's Health Initiative. Mark Bolland, Andrew Grey, Gregory Gamble, Ian Reid*. University of Auckland, New zealand

Recently, we reported that calcium supplementation was associated with an increased risk of cardiovascular events in the Auckland Calcium Study, and we have now confirmed this in a meta-analysis of studies of calcium monotherapy (IOF, 2010). Previously, the Women's Health Initiative (WHI) reported no effect of calcium/vitamin D supplementation (CaD) on cardiovascular events, but a significant interaction between BMI and the cardiovascular risk associated with CaD allocation. Also, >50% of WHI participants were using non-protocol calcium supplements, which might have obscured any effect of the intervention. Therefore, we re-analyzed the WHI limited access clinical trials dataset to determine whether adverse effects of CaD on cardiovascular events were seen in participants not taking non-protocol calcium supplements and who were not obese. We used Cox proportional hazards models to assess the effect of CaD on incidence of cardiovascular events in these subgroups. 44% of participants (n=15788) were not taking non-protocol calcium supplements at CaD randomisation. In these women, CaD was associated with increases in incidence of myocardial infarction (MI), coronary revascularisation, stroke, and related composite endpoints ranging from 11-19%. For the composite of MI and revascularization, this was significant. In women taking non-protocol calcium supplements, CaD was not associated with altered cardiovascular risk (hazard ratios 0.92-1.08). In non-obese women (BMI<30 kg/m^2), CaD was associated with statistically significant increases in incidence of coronary revascularisation and related composite endpoints ranging from 24-28%, and a non-significant 16% increase in myocardial infarction. In obese women, CaD was not associated with increased incidence of any cardiovascular endpoint. In non-obese women not using non-protocol calcium supplements, revascularizations and composite endpoints including MI were significantly increased, by 21-31% (Table). It is concluded that CaD in the WHI is associated with increased cardiovascular risk, and that this effect was confounded in the previous analysis by non-protocol calcium supplementation. The interaction with obesity might arise from the high incidence of vitamin D deficiency in the obese and a possible protective effect of the vitamin D component of the intervention on cardiovascular risk in those individuals.

Cardiovascular Events in Non-Obese Women Not using Non-Protocol Calcium Supplements

The Efficacy of High-Dose Oral Vitamin D_3 Administered Once a Year: A Randomised, Double-Blind, Placebo-Controlled trial (Vital D Study) for Falls and Fractures in Older Women. Kerrie Sanders[1], Amanda L Stuart[2], Elizabeth J Williamson[2], Julie A Simpson[2], Mark Kotowicz[2], Geoffrey Nicholson*[1]. [1]University of Melbourne, Australia, [2]The University of Melbourne, Australia

Objective

To determine whether a single annual dose of 500,000IU cholecalciferol administered orally to older women in fall or winter would reduce the risk of falls and fracture.

Methods

This single centre double-blind, placebo-controlled trial randomly assigned 2,256 community-dwelling women (median age 76 years, IQR 73, 80.0 years) to receive a single oral dose of cholecalciferol 500,000IU or placebo each autumn/winter for 3 to 5 years. Falls and fractures were ascertained for 4 to 6 years using monthly calendars and details confirmed by telephone interview. Fractures were radiologically confirmed. Biochemistry was done on a sub-study of 137 randomly-selected participants at baseline as well as 12-months post-dose (coinciding with immediate pre-dose for the current year). In 2006 and 2007 blood sampling was also done at one- and three-month post-dose. Serum 25-hydroxyvitamin D (25D) levels were measured in batches using DiaSorin immunoassay.

Results

The vitamin D group had more falls and fractures than the placebo group. The fall rate was 83.4 vs 72.7 per 100 person-years, vitamin D vs placebo groups, respectively and an Incidence Rate Ratio (IRR): 1.15; 95%CI 1.02, 1.30; p=0.025. The rate of fracture was 4.9 vs 3.9 per 100 p-y and the IRR: 1.26; 1.00, 1.59; p=0.047. The increased rate of falling in the vitamin D group was higher in the first three months following dosing (p=0.017). This temporal pattern was also apparent in fracture rates although not significance (interaction p=0.36). The cumulative incidence of first fall and first fracture were both increased in the vitamin D group (hazard ratios; 95% CI: Falls 1.16; 1.05, 1.28 p=0.003; Fractures 1.26; 0.99, 1.59 p=0.057). In the sub-study, the median baseline serum 25D was 49nmol/L. Less than 3% of the sub-study participants had baseline levels <25nmol/L. In the vitamin D group, one-, three- and 12-month median post dose levels were approximately 120nmol/L, 90 nmol/L and 70nmol/L, respectively.

Conclusions

The results indicate that high-dose vitamin D administered orally once yearly to older community-dwelling women increased the risk of falls and fractures.

A Higher Dose of Vitamin D is Required for Hip and Non-vertebral Fracture Prevention: A Pooled Participant-based Meta-analysis of 11 Double-blind RCTs. Heike Bischoff-Ferrari*[1], Endel J Orav[2], Walter Willett[2], Pierre Meunier[3], Ronan Lyons[4], Paul Lips[5], Michael Pfeifer[6], Leon Flicker[7], John Wark[8], Rebecca Jackson[9], Haakon Meyer[10], Jane Cauley[11], Hannes B Staehelin[12], Jana Henschkowski[13], Robert Theiler[14], Bess Dawson-Hughes[15]. [1]University of Zurich, Switzerland, [2]Harvard School of Public Health, USA, [3]Laennec University, France, [4]Swansea University, United Kingdom, [5]VU University Medical Center, The netherlands, [6]Medwiss Bad Pyrmont, Germany, [7]University of Western Australia, Australia, [8]Royal Melbourne Hospital, Australia, [9]The Ohio State University, USA, [10]Norwegian Institute of Public Health, Norway, [11]University of Pittsburgh Graduate School of Public Health, USA, [12]University of Basel, Switzerland, [13]University Hospital Zurich, Switzerland, [14]Triemli City Hospital, Switzerland, [15]Tufts University, USA

Background: Meta-analyses have reached conflicting results regarding vitamin D and fracture reduction, which may be explained by alternative criteria in the inclusion of trials. For efficacy, the focus is on double-blind RCTs.

Methods: Our meta-analysis pooled the individual participant data from 11 of 13 available double-blind RCTs with oral vitamin D supplementation and fracture assessment among seniors age 65 and older. Covariates available in all trials were age, gender, type of dwelling, calcium supplementation, and adherence to supplementation. We used Cox regression analysis to assess hip and any non-vertebral fracture risk by treatment (yes/no) and by quartiles of received dose of vitamin D in the treatment group (received dose = dose*adherence in the treatment group + additional supplement intake in the WHI trial). All analyses adjusted for age, gender, type of dwelling, and study. Due to significant co-linearity between received dose of vitamin D and received dose of calcium supplementation, the main model did not adjust for calcium supplement intake.

Results: The analysis included 29,893 seniors age 65 and older with 1111 hip fractures and 3771 non-vertebral fractures including those at the hip. Mean age was 76 years and 90% were women. For any dose of vitamin D (treatment yes/no), we found a non-significant 10% reduction in hip fracture risk (HR = 0.90; 95% CI: 0.80 -1.01), and a significant 7% reduction for any non-vertebral fracture (HR = 0.93; 95% CI: 0.87-0.99).

For quartiles of received vitamin D dose in the treatment group, fracture reduction was significant only at the highest intake quartile (735 IU+/day) compared to the control group, with a 28% fracture reduction at the hip (HR=0.72; 95% CI: 0.59-0.87) and a 14% fracture reduction at any non-vertebral site (HR = 0.86: 95% CI: 0.77-0.95). The effect of the highest intake quartile of vitamin D was consistent across studies (interaction p-value = 0.71 for hip and 0.35 for non-vertebral fractures). For the hip fracture endpoint, the effect at the highest vitamin D intake quartile stayed significant even when any individual study was removed from the analysis. For the non-vertebral fracture endpoint, statistical significance at the highest vitamin D intake quartile was only lost when the Chapuy 1992 study was removed from the analysis.

Conclusion: Based on this pooled analysis of 11 double-blind RCTs, a received dose of no less than 735 IU per day is required for hip and any non-vertebral fracture reduction.

Ergocalciferol and Cholecalciferol Induce Comparable Increases in Vitamin D Binding Protein and Free 25-hydroxy-itamin D with no Significant Change in Free 1,25-Dihydroxyvitamin D in Hip Fracture Patients. Gerard Chew[1], Charles Inderjeeth[2], Paul Glendenning*[3], Mario Taranto[4], Charles Inderjeeth[2]. [1]School of Medicine & Pharmacology, Australia, [2]Sir Charles Gardner Hospital, Australia, [3]Royal Perth Hospital, Australia, [4]PathWest, Royal Perth Hospital, Australia

Previous data indicate that ergocalciferol 1000 IU daily and cholecalciferol 1000 IU daily have comparable effects on PTH suppression, despite a greater increase in total 25-hydroxyvitamin D (25OHD) with cholecalciferol. The effects of either agent on vitamin D binding protein levels (VDBP), free 25-hydroxyvitamin D index (F25OHD) and free 1,25-dihydroxyvitamin D index (F125OHD) have not been previously examined.

We studied 95 hip fracture patients randomised to 3 months treatment with either cholecalciferol or ergocalciferol therapy. End study serum samples were available in 70 patients. All patients were vitamin D-deficient (25OHD < 50 nmol/L) at baseline. 25OHD was measured by HPLC, VDBP by immunonephelometry, and 1,25OHD by Diasorin radioimmunoassay. F25OHD and F125OHD were calculated from the molar ratios of 25OHD, 1,25OHD and VDBP. Baseline VDBP, F25OHD and F1,25OHD were comparable in the ergocalciferol-treated (n=48) and cholecalciferol-treated (n=47) patients. Mean VDBP increased from 4.4 to 5.1 umol/L with ergocalciferol ($P<0.01$) and 4.4 to 5.3 umol/L with cholecalciferol therapy ($P<0.001$). Mean F25OHD increased from 8.1 to 11.6 ($P<0.01$) with ergocalciferol and 9.7 to 14.2 with cholecalciferol therapy ($P<0.001$). Mean F12OHD declined from 15.1 to 12.8 with ergocalciferol (P= NS) and 18.5 to 15.2 with cholecalciferol therapy ($P<0.05$). Treatment effects were not significantly different between the groups for any of the three outcome parameters ($P>0.1$). There was no difference in outcome measures when the analysis was restricted to treatment-compliant (>80% compliance based on pill count) patients.

In vitamin D-deficient patients, supplementation with cholecalciferol 1000 IU daily produced similar effects on VDBP, F25OHD and F1,25OHD compared with ergocalciferol 1000 IU daily. These findings explain previous data showing no difference in the degree of PTH suppression between treatments.

CYP2R1 is a Potential Candidate for Predicting Serum 25(OH)D Variation as Suggested by Genetic and Epigenetic Studies. Yu Zhou*[1], Fengxiao Bu[1], Joan Lappe[2], Laura Armas[1], Robert Recker[2], Lanjuan Zhao[3]. [1]Creighton University, USA, [2]Creighton University Osteoporosis Research Center, USA, [3]Creighton University Medical Center, USA

Achieving and maintaining an optimal level of serum 25-hydroxyvitmain D [25(OH)D] are important for preventing rickets, osteoporosis and osteoporotic fracture. Oral vitamin D3 supplementation is the best approach to increase serum 25(OH)D levels. However, high variability of serum 25(OH)D in response to a given dose of vitamin D supplementation is widely observed. Factors contributing to the wide variability in serum 25(OH)D are largely unknown.

We first conducted a genetic epidemiology study to identify genes important for prevalent serum 25(OH)D variation. Nine candidate genes (ALPL, CYP24A1, CYP27A1, CYP27B1, CYP2R1, CYP3A4, GC, VDR, and PTH) important for vitamin D metabolism were comprehensively screened using 49 tag SNPs in 156 unrelated healthy Caucasian subjects. Evidence of association was observed at six SNPs in the CYP2R1 and GC gene. We further conducted a replication study for these six SNPs in an independent cohort with 340 unrelated healthy Caucasian subjects. Two SNPs in the promoter region of the CYP2R1 gene, rs10766197 (Pdiscovery = 0.007, Preplication = 0.019) and rs12794714 (Pdiscovery = 0.001, Preplication = 0.016), were confirmed to be significantly associated with prevalent serum 25(OH)D levels.

CYP2R1 was first identified in 2003 as a key vitamin D 25-hydroxylase that converts vitamin D into 25(OH)D. In order to test whether the gene contributes to serum 25(OH)D variability in response to vitamin D3 supplementation, we conducted an epigenetic study. In total, 446 non-Hispanic white postmenopausal women were treated with calcium (1500 mg/day) and vitamin D3 (1100 IU/day) for 12-months. We selected 18 responders and 18 non-responders from the 446 subjects, at the two extreme tails of the distribution of dose-adjusted 12-month increase of serum 25(OH)D. For each subject, genomic DNA before and after 12-month vitamin D3 intervention was extracted from frozen serum. The average methylation ratio of the CYP2R1 promoter in the non-responder group (30%) was significantly higher than that in the responder group (8%) (p=0.004). In both groups, the DNA methylation ratio was unaffected by vitamin D3 intervention. The hypermetylation in the non-responder group may contribute to gene silencing of CYP2R1, leading to lower increase of serum 25(OH)D levels.

These data suggest that CYP2R1 is a strong candidate for the variability in prevalent serum 25(OH)D, and variability in its response to vitamin D supplementation.

Effects of Vitamin D Deficiency and High Parathyroid Hormone on Mortality Risk in Elderly Men. Steven Frost[1], Tuan Nguyen[2], Dana Bliuc[2], John Eisman[2], Jacqueline Center[2], Nguyen Nguyen*[2]. [1]University of Western Sydney, Australia, [2]Garvan Institute of Medical Research, Australia

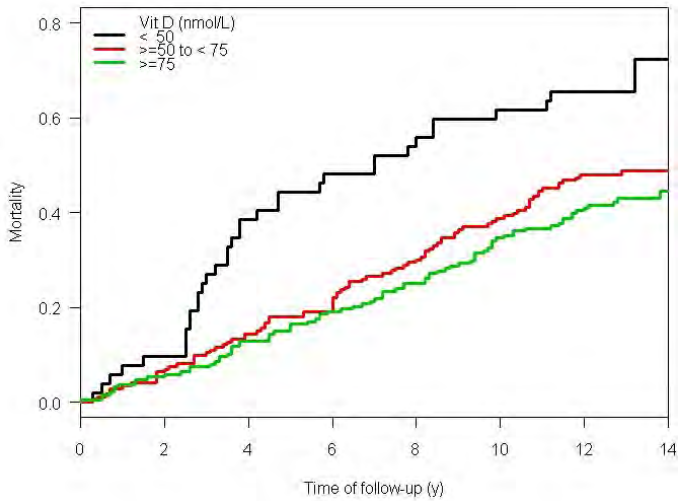
Vitamin D deficiency is common in the elderly. Recent data have suggested that mortality risk is elevated in men with low vitamin D levels; however, the relationship could be confounded by parathyroid hormone (PTH) which had previously been shown to be associated with mortality. Therefore, this study sought to examine the inter-relationship between vitamin D and PTH levels on the risk of mortality in men.

The study was part of the Dubbo Osteoporosis Epidemiology Study, which involved 413 men aged 60+ years as at 1989, whose health status had been continuously monitored for 14 years with biannual visits. During the follow-up period, mortality was ascertained. Vitamin D was measured by 25(OH)D using an in-house pre-extraction competitive binding protein assay with charcoal separation, with an inter-assay CV of 12%. Vitamin D status was classified in 3 groups: deficient (25(OH)D<50nmol/L), insufficient (50-75nmol/L) and sufficient (≥75nmol/L). PTH was measured by a solid phase two-site immunoenzymometric assay also from Diagnostics Products, with an inter-assay CV of 6%. The association between vitamin D and mortality was analyzed by the Cox's proportional hazards model with adjustment for covariates.

The overall prevalence of vitamin D deficiency was 12.6%. During the follow-up period of 4059 person-years, 200 men died, yielding an incidence of mortality of 4.9 per 100 person-years. The prevalence of vitamin D deficiency was 17.5% in the deceased and 8.0% in survivors. Men who died had lower baseline 25(OH)D levels

than those who survived (70.9 ± 22.9 vs. 77.3 ± 23.0 nmol/L, P=0.005), such that each SD (25nmol/L) decreased in 25(OH) D was associated with a 33% increase in the risk of mortality (RR 1.33, 95% CI: 1.12 – 1.57). Higher serum levels of PTH were associated with an increased risk of mortality (+0.5pmol/L, RR 1.16; 95% CI: 1.02-1.32). After adjusting for age and PTH, the association between 25(OH)D and mortality remained statistically significant (1.22; 1.02-1.46). Men with vitamin D deficiency and high levels of PTH were 1.63 (1.01-2.66) fold more likely to die from those with adequate vitamin D and low levels of PTH. Approximately 7% and 4% of mortality risk was attributable to vitamin D deficiency and vitamin D deficiency with high PTH, respectively.

The independent effects of vitamin D and PTH on mortality risk observed in this study suggests that men with vitamin D deficiency and hyperparathyroidism are at increased risk of all-cause mortality.



The association between vitamin D and mortality in men

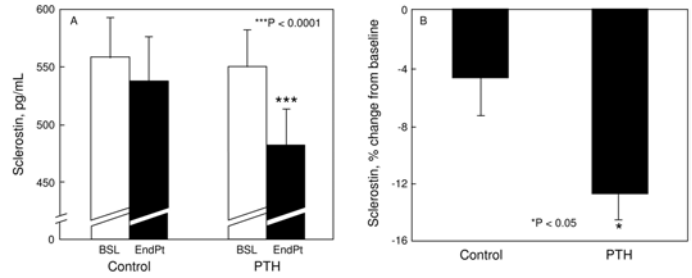
Intermittent PTH Treatment Decreases Circulating Sclerostin Levels in Postmenopausal Women. Matthew Drake*[1], Bhuma Srinivasan[1], Ulrike Moedder[1], James Peterson[1], Louise McCready[2], Byron Riggs[3], Denise Dwyer[4], Marina Stolina[4], Paul Kostenuik[5], Sundeep Khosla[6]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine,Rochester, MN, USA, [4]Amgen Inc, USA, [5]Amgen, Inc., USA, [6]College of Medicine, Mayo Clinic, USA

Intermittent PTH treatment stimulates bone formation (BF) more than bone resorption (BR), but the mechanisms of this stimulation remain unclear. Sclerostin is a recently identified inhibitor of Wnt signaling. Although animal studies have demonstrated that PTH decreases sclerostin production by osteocytes, there are currently no data regarding effects of intermittent PTH treatment on sclerostin production in humans. Thus, we studied 27 postmenopausal women treated with PTH 1-34 (40 μg/d) for 14 days and 28 control women and assessed changes in levels of serum sclerostin (Luminex assay), bone turnover markers, RANKL and OPG. The BF marker CICP increased (by 71%, $P < 0.001$) in PTH-treated women. Concomitant with the increase in BF, serum sclerostin levels decreased significantly in PTH-treated subjects, but did not change in control women (Figure A), and the percent change from baseline in serum sclerostin levels in PTH-treated women was significantly greater than that in control women (Figure B). Bone marrow plasma was obtained in a subset of control and PTH-treated subjects (n = 19 each) at the end of the treatment period, and marrow plasma and peripheral serum sclerostin levels were significantly correlated ($R = 0.64$, $P < 0.0001$). Although marrow plasma sclerostin levels were 24% lower in PTH-treated compared to control women, due to the smaller sample size this difference was not statistically significant ($P = 0.173$). The BR marker, serum CTX, also increased in PTH-treated women (by 59%, $P < 0.001$); while serum or marrow plasma RANKL levels were undetectable in the majority of subjects, marrow plasma (but not peripheral serum) levels of OPG were 33% lower in PTH-treated compared to control women ($P < 0.05$). These studies demonstrate that in humans, the stimulation of BF by intermittent PTH 1-34 treatment is accompanied by a decrease in circulating serum sclerostin levels, which correlate with bone marrow plasma sclerostin levels. Moreover, the observed increase in BR following PTH therapy is accompanied by decreases in bone marrow plasma (but not serum) OPG levels, suggesting that in contrast to circulating sclerostin levels, circulating OPG levels may not reflect changes in the bone microenvironment. Coupled with previous animal studies, our data thus indicate that decreases in bone levels of sclerostin and OPG, potent inhibitors of BF and BR respectively, may contribute to the observed increases in BF and BR following PTH therapy in humans.



PTH-Sclerostin

Absence of Gut Microbiota Leads to Increased Bone Mass Associated with Low Serum Serotonin Levels. Klara Sjögren*[1], Cecilia Engdahl[2], Marie Lagerquist[2], Fredrik Bäckhed[3], Claes Ohlsson[1]. [1]Centre for Bone & Arthritis Research, GU, Sauhlgrenska Academy, Medicine, Sweden, [2]Centre for Bone & Arthritis Researc, GU, Sauhlgrenska Academy, Medicine, Sweden, [3]The Wallenberg Laboratory, GU, Sahlgrenska Academy, Medicine, Sweden

The gut is inhabited by a microbial ecosystem, the gut microbiota, which consists of 10 times as many cells as our own eukaryotic cells. It is acquired at birth and its composition is modulated by a number of environmental factors throughout life and can thus be considered a dynamic organ that has endowed us with vital metabolic functions such as vitamin synthesis and xenobiotic metabolism. Furthermore, the gut microbiota is involved in the regulation of fat mass and can modulate expression of gut derived hormones[1]. Interestingly, gut-derived circulating serotonin reduces osteoblast proliferation and thereby bone mass, demonstrating that a gut bone connection exists [2,3] The possible impact of gut microbiota for bone metabolism is unknown and we, therefore, evaluated the skeletal phenotype of germ-free (GF)-mice and conventionally raised mice (CONV-R), having normal gut microbiota.

GF mice were kept in sterile flexible film isolators and colonized mice were kept in micro isolator cages in a specified pathogen-free state in a barrier facility. All mice were fed an autoclaved chow diet. At seven weeks of age GF mice had increased proximal tibial trabecular volumetric bone mineral density (vBMD) compared to CONV-R mice (+33%, $p \leq 0.01$) as measured by peripheral quantitative computed tomography (pQCT). To exclude developmental factors we had an extra control consisting of mice that were born germ-free and then colonized at three weeks of age. Colonization reduced the trabecular vBMD compared with GF counterparts (-21%, $p \leq 0.05$). More detailed investigation of the femur with microCT (μCT) showed an increased percent bone volume (BV/TV) in GF compared to CONV-R mice (49%, $p \leq 0.01$). This increase was due to an increased trabecular number (45%, $p \leq 0.01$) and decreased trabecular separation (-33%, $p \leq 0.01$) while trabecular thickness was unaffected in GF compared to CONV-R mice. Cortical thickness was also increased in GF compared to CONV-R mice (+6%, $p \leq 0.05$). Interestingly GF mice had decreased serum serotonin levels compared to CONV-R mice (-67%, $p \leq 0.01$).

In conclusion, absence of gut microbiota leads to increased bone mass associated with reduced serum serotonin. We propose that the gut microbiota modulates gut serotonin synthesis and thereby via an endocrine mechanism also bone metabolism.

Comparing the Effects of Odanacatib versus Alendronate on Bone Turnover of Transilial Biopsy in Adult Ovariectomized Rhesus Monkeys. Charles Chen*[1], Brenda Pennypacker[2], David Gilberto[3], Le Thi Duong[2]. [1]Merck & Co., Inc., USA, [2]Merck Research Laboratories, USA, [3]Merck & Co. Inc., USA

Cathepsin K (CatK) is a cysteine protease highly expressed in osteoclasts that degrades bone matrix proteins during resorption. Odanacatib (ODN) is a selective, potent and reversible CatK inhibitor in development for the treatment of osteoporosis. Here, we compared the effects of ODN and alendronate (ALN) on bone turnover in transilial biopsies collected from OVX-rhesus monkeys after 12-months treatment. Monkeys (age 10-22 yrs) were randomized post-OVX into 4 groups (N=16/group): (1) OVX+vehicle (Veh), (2) +ALN (30μg/kg/wk, sc), (3) +2mg/kg/d ODN (L-ODN; 11uM•24hr), or (4) +4mg/kg/d ODN (H-ODN; 49uM•24hr), as compared to estimated daily clinical exposure (~7uM•24hr) from the 50 mg weekly dose. A group of age- and aBMD-matched intact monkeys (Int, N=12) was included

as control. Prior to biopsy, calcein (8mg/kg, sc) was administered with a 15 day interval. Bone formation (BF) was determined in endocortical (Ec) and cancellous surface (Cn) with standard histomorphometric endpoints, including mineralizing surface (MS/BS, %), mineral apposition rate (MAR, μm/d), bone formation rate (BFR/BS). While ALN suppressed Ec BFR/BS ($p=0.01$) with significant reduction ($p<0.05$) of MS/BS and MAR. Neither L-ODN nor H-ODN changed these BF parameters. In the Cn surface, BF parameters tend to be lower in ALN group and were unaffected in ODN groups. In both Ec and Cn surfaces, ODN showed no effects on osteoid thickness (Os.Th, μm) or osteoid surface (OS/BS, %); and ALN treatment reduced Os.Th by 52% ($p<0.05$) and OS/BS by 65% ($p=0.05$). Our previous data indicated while fully blocking osteoclastic bone resorption, ODN increased osteoclast number in the lumbar vertebrae of OVX-monkeys. Here, osteoclast surface (OcS/BS,%) and osteoclast number (OcN/BS, #/mm) in Ec and Cn surfaces of ALN- and H-ODN treated groups were not different from Veh or Int controls. Interestingly, the L-ODN group showed significantly increased Ec OcS/BS and OcN/BS ($p<0.05$) vs. Int, as well as Cn OcS/BS and OcN/BS ($p<0.05$ vs. Veh and Int). In summary, ODN at dose levels exceeding the estimated daily clinical exposure, did not affect bone formation in transilial biopsy of OVX monkeys. This supports earlier findings that ODN differs from the bisphosphonates in sparing bone formation, potentially via uncoupling bone formation from resorption.

Inhibition of Active TGF-β1 Release by Anti-Resorptive Drugs Blunts PTH Anabolic Effects on Bone Remodeling. Xiangwei Wu*[1], Lijuan Pang[2], Weiqi Lei[2], William Lu[3], Jun Li[2], Zhaoyang Li[3], Frank Frassica[2], Xueling Chen[2], Mei Wan[1], Xu Cao[2]. [1]Johns Hopkins University School of Medicine, USA, [2]Johns Hopkins University, USA, [3]University of Hong Kong, China

Anabolic effects of PTH on bone formation are impaired with concurrent use of anti-resorptive drugs in clinic trials. Here we investigated the cellular mechanism how PTH-induced bone formation was inhibited by concurrent treatment of alendronate. The aged mice were injected with PTH, alendronate or both. PTH or alendronate alone stimulated an increase in bone mass, but additive effects were not observed with both drugs. Osteogenic potential of BMSCs was examined in a CFU-F assay. No significant difference was observed in the numbers of CFU-Fs formed by the bone marrow cells isolated from the different treatment groups, but osteoclast and osteoblast numbers were decreased in mice with concurrent treatment, indicating that reduction of osteoblasts is likely due to the interruption of the BMSCs recruitment.

Active TGF-β1 released during osteoclastic bone resorption induces migration of BMSCs to the bone remodeling sites. Indeed, the levels of active TGF-β1, as measured by ELISA, were significantly higher in the bone marrow of mice treated with PTH than those treated with vehicle or alendronate alone. Concurrent treatment resulted in a reduction in the PTH-stimulated levels of active TGF-β1. Higher numbers of p-Smad2/3-positive cells were found in the microenvironment of TRAP-positive osteoclasts in PTH treatment, but reduced significantly in those with concurrent use of alendronate, indicating that the release of active TGF-β1 from osteoclastic bone resorption sites was inhibited by alendronate. To investigate whether the alendronate-induced inhibition of release of active TGF-β1 impairs the anabolic action of PTH in bone, Tgfb1–/– mice and their wild-type littermates were injected intermittently with PTH or vehicle for 4 weeks. The anabolic effects of PTH on bone were diminished in the Tgfb1–/– mice as compared to their wild-type littermates, indicating that the release of active TGF-β1 during bone resorption is essential for the anabolic effects of PTH on bone formation. In a transplantation experiment, the recruitment of injected mouse Sca-1- and CD29-positive BMSCs stimulated by PTH was inhibited by alendronate. Thus, inhibition of active TGF-β1 release by alendronate reduces the recruitment of BMSCs to the bone sites and impairs PTH anabolic action in bone. Our finding suggests that the additive effects may be achieved by PTH stimulation followed by anti-resorptive drug therapy.

Selective knock out the membrane-bound Colony Stimulating Factor-1 (mCSF1) results in an increased anabolic response to PTH in mice. Gang-Qing Yao*[1], Jian Jun Wu[2], Karl Insogna[1]. [1]Yale University School of Medicine, USA, [2]Yale University, USA

CSF1 is absolutely required for osteoclastogenesis, and its genetic absence leads to osteopetrosis due to a failure of osteoclast formation. There are two isoforms of CSF1, soluble and membrane-bound (mCSF1), but their individual biological functions are unclear. To better define the role of mCSF1 in vivo, we have generated mCSF1 knock-out (k/o) mice. Bone density, as assessed by PIXImus, was increased by +15.9% ($p<0.01$), +6.8% ($p<0.05$) and +6.9% (NS) in the spine, total body and femur respectively in k/o animals compared to wild-type (wt) littermates. The number of osteoclasts on trabecular bone surfaces was significantly reduced as was the osteoclastogenic potential of bone marrow cells from the mCSF1 k/o mice.

PTH is the only anabolic therapy approved for use in human. However, the anabolic response to PTH is thought to be limited, in part, by the increase in bone resorption that follows the initial increase in bone formation. None-the-less, inhibiting osteoclasts with bisphosphonates does not improve the therapeutic response to teriparatide. Since osteoclasts are present in reduced numbers but phenotypically normal in mCSF1 k/o animals, we hypothesized that the reduced osteoclastogenesis in the genetic absence of mCSF1 would allow for a more robust response to PTH.

To test this idea, adult mCSF1 k/o mice and wt litmates were treated with either a single daily sc injection of human (1-34) PTH (80 ng/g body weight) or vehicle for 4 weeks, and BMD measured after 0 and 4 weeks of treatment. The PTH-treated k/o mice showed a greater increase both in spine and femur BMD compared to vehicle-treated k/o animals than did the PTH-treated wt animals compared to their vehicle-treated controls; $13.7 \pm 2.7\%$ vs. $4.9 \pm 3.3\%$ for the spine and $25 \pm 4.5\%$ vs. $14 \pm 2.2\%$, for the femur, ($M \pm SD$). Further, the PTH-treated mCSF1 k/o mice showed a greater increase in spine and femur BMD compared to baseline than did the wt mice (14.8% vs. 5.2% for the spine and 27.2 vs. 15.2 %; for femur respectively; $M \pm SD$).

Our findings indicate mCSF1 is essential for normal bone remodeling since, in its absence, bone density is increased. Interestingly, the anabolic response to PTH is augmented in mCSF1 k/o mice perhaps because of a reduced resorptive response to this treatment although other mechanisms cannot be excluded. Since the mCSF1 k/o mice do not have phenotypic abnormalities apart from an increase in bone mass, our data suggest that mCSF1 may be a reasonable drug target for low bone mass.

Tissue Level Mechanism of Increased Bone Formation by Sclerostin Antibody in Male Cynomolgus Monkeys. MS Ominsky*, Q-T Niu, P Kurimoto, HZ Ke. Amgen Inc, USA

Bone formation can occur with or without prior activation of resorption as part of the remodeling and modeling processes, respectively. In adult humans, the vast majority of bone formation occurs via remodeling, and the increases in histologic bone formation with the anabolic agent teriparatide have been primarily attributed to remodeling. Inhibition of sclerostin by sclerostin antibody (Scl-Ab) has demonstrated robust increases in bone formation and bone mineral density in rodents, monkeys, and humans. In the current study, we quantified the effects of Scl-Ab on modeling- and remodeling-based bone formation in male cynomolgus monkeys. Adolescent (4-5-year-old) monkeys were treated biweekly with subcutaneous vehicle (Veh) or 30 mg/kg Scl-Ab for 10 weeks, as part of a previously reported fibular osteotomy study. Tetracycline (25 mg/kg) was injected on days 14 and 24, and calcein (8 mg/kg) was injected on days 56 and 66. Histomorphometry was performed at the 2nd lumbar vertebra (L2). Calcein-based mineralizing surface (MS/BS) was 68% greater in the Scl-Ab group compared with Veh ($p<0.001$). MS/BS was separated into modeling- and remodeling-based surfaces. The Scl-Ab-mediated increases in MS/BS were almost entirely modeling-based, with an increase from 0.4% of the total bone surface in Veh to 27% in the Scl-Ab group ($p<0.001$). No significant change was observed in remodeling-based MS/BS between the Veh and Scl-Ab groups (17% vs 20%). Interestingly, we observed that mineral apposition rate (MAR) was slower on modeling versus remodeling surfaces in the Veh group (0.6 vs 1.3 μm/day, $p<0.05$), and no treatment-related changes were observed. However, the overall MAR in the Scl-Ab-treated group was lower than in controls (1.3 vs 0.9 μm/day, $p<0.05$), due to the increase in the proportion of modeling-based bone formation surfaces from 3% to 57% of total bone-forming surfaces. Scl-Ab also resulted in a significantly lower eroded surface (2.2% vs 4.6% in controls, $p<0.05$), and a greater proportion of remodeling-based MS/BS which had both underlying tetracycline labels (active from week 2; 52% vs 10% in the control group, $p<0.01$). These results demonstrate that Scl-Ab increased the duration of bone formation at remodeling sites and increased modeling-based bone formation, while reducing bone resorption. Through its unique tissue-level mechanism, sclerostin antibody may provide an efficient way to improve bone mass in conditions with low bone mass such as osteoporosis.

The Impact of Growth and Development on Bone Mineral Accretion of the Total Body (Less Head) and Lumbar Spine During Childhood and Adolescence; A Report from the Bone Mineral Density in Childhood Study Group. Babette Zemel*[1], Heidi Kalkwarf[2], Andrea Kelly[3], Joan Lappe[4], Mary B. Leonard[3], Struan Grant[3], Soroosh Mahboubi[3], Margaret Frederick[5], Sharon Oberfield[6], John Shepherd[7], Karen Winer[8]. [1]Children's Hospital of Philadelphia, USA, [2]Cincinnati Children's Hospital Medical Center, USA, [3]The Children's Hospital of Philadelphia, USA, [4]Creighton University, USA, [5]Clinical Trials & Survey Corporation, USA, [6]Columbia University Medical Center, USA, [7]University of California, San Francisco, USA, [8]NICHD, USA

Monitoring changes in bone health status to assess disease and/or treatment effects is important for at-risk children. Presently, there are no reference data on bone mass increments to assess adequacy of annual gains, and little is known about factors associated with bone mass increments. This study examined annual increments in bone mineral content (BMC) of the total body less head (TBLH) and lumbar spine

assessed by DXA (Hologic QDR densitometers), and explored the contribution of growth and development to bone accretion during childhood and adolescence.

Healthy subjects, ages 6 to 17years at enrollment, were participants who were measured annually for up to 3 years at 5 U.S. centers in the NICHD Bone Mineral Density in Childhood Study. Growth (initial height and weight, height and weight velocity) and puberty stage were assessed. Analyses were restricted to visits occurring 12 ± 1 month apart. Graphical inspection and backward stepwise multiple regression were used.

BMC accretion peaked at 14-15 and 12-13 y for males and females, respectively. Graphical representation showed strong sex and puberty dependent patterns of BMC accretion, so further analyses were stratified accordingly. For males and females, BMC accretion did not differ for Tanner stages 1 and 2, so they were combined for subsequent analyses. For both sexes and measurement sites, BMC accretion peaked during the year preceding Tanner stage 4, with median BMC accretion values for TBLH of 250 and 188 gm/y and for spine of 7.6 and 6.9 gm/y for males and females, respectively.

The combination of growth variables selected in the stepwise regression analyses varied by sex and puberty stage stratum. The level of explained variance (R2) was generally lower in Tanner 1-2 (0.09 to 0.38) and greater in Tanner 4 & 5 (0.46 to 0.65). Height velocity was significantly associated (all $p<0.001$) with BMC accretion for each stratum, but was the strongest predictor mainly in Tanner stages 4 & 5 for TBLH and spine. The effect of black race was significant mainly at the beginning and end of puberty in males.

These findings suggest that expected gains in BMC are only modestly growth-dependent in pre- and early pubertal children, but growth measures are important predictors during puberty, including children in Tanner stage 5 at follow-up. Evaluation of BMC accretion should be considered according to sex and puberty stage, and should account for growth during the period under examination.

Secular Trend for Earlier Skeletal Maturation in US Children. Dana Duren*[1], Ramzi Nahhas[1], Richard Sherwood[2], Miryoung Lee[3], Audrey Choh[1], Bradford Towne[1], Stefan Czerwinski[1], Roger Siervogel[3], Cameron Chumlea[1]. [1]Wright State University, USA, [2]Lifespan Health Research Center,Wright State University, USA, [3]Wright State University Boonshoft School of Medicine, USA

Secular trends have been noted in several markers for maturation in recent childhood cohorts. This is most notable in sexual maturity as indicated by earlier menarche in girls, which has been observed nearly world-wide in industrialized countries. Such trends may also be reflected in processes of skeletal maturation, as indicated by overall bone age and specific bone age endophenotypes such as fusion of the epiphyses of metacarpals and phalanges. The current study examined 1,271 children aged from birth to 18 years for 85 radiographic skeletal maturity indicators (155 maturity levels) in the bones of the hand and wrist. Two cohorts of children from the Fels Longitudinal Study were examined: 690 born 1929-1964 and 581 born 1965-2001. Maturity indicators were sorted into bone type (carpal/long bone) and categories of ossification, fusion, two types of shape change, and appearance of radiopaque densities. By sex, we modeled the proportion of children at a given maturity grade as a function of age using logistic regression, estimated the median age of maturity, and tested for the significance of differences in median age of maturity between the two cohorts ($\alpha=0.05$). The majority of indicator categories showed a general trend for earlier maturation, with some indicator types having both earlier and later maturity transitions in the recent cohort. In boys, 90% of fusion indicators matured significantly earlier in the more recent cohort. Ossification showed less of a tendency for earlier maturation in boys, with only 4.3% of carpal, and 10.2% of long bone, indicators maturing significantly earlier, and 10.2% of long bone ossification indicators maturing later. In girls, 96.7% of fusion indicators matured significantly earlier; ossification also occurred significantly earlier in 68.6% of the carpal and 33.9% of the long bone indicators, with none of the carpal ossification indicators occurring significantly later and only 5.1% of the long bone ossification indicators occurring later. These results demonstrate a significant secular trend for earlier skeletal maturity, especially fusion of the hand long bones, in post-baby-boom generations. The differences in frequency of earlier maturation observed in fusion versus ossification of the bones of the hand and wrist point to a potential shift in timing of pubertal hormone elevation, perhaps reflecting the secular trend in sexual maturity observed in other studies. Predictors of Skeletal Calcium Accretion in Adolescent Boys and Girls. Kathleen Hill*[1], Berdine Martin[2], Linda McCabe[2], George McCabe[2], Connie Weaver[2]. [1]Indiana University School of Medicine, USA, [2]Purdue University, USA

Purpose: Peak bone mass is a major determinant of osteoporosis risk; maximizing Ca retention during peak bone mineral accrual in adolescence is important for optimizing peak bone mass. The purpose of this study was to determine the relative contributions of diet and physiologic factors on Ca retention in adolescents. Method: A total of 487 observations on 265 10 – 15 y.o. white, black, and Asian boys and girls studied in a series of Ca balance studies were analyzed. Two-phase regression was used to model the relationship between Ca intake and Ca retention in boys and girls. Model building techniques including residual analysis were used to select potential variables for predicting Ca retention. These additional variables included race, BMI, height, weight, body composition, bone parameters, serum 25OHD, serum PTH, serum IGF-1, age, and sexual maturation. Bootstrap resampling was used to determine 95 % confidence intervals. Results: Ca intake explained 31 % and 11 % of the variation in Ca retention in boys and girls, respectively. A model that included Ca intake, BMI, serum 25OHD, and serum IGF-1 explained 40.5 % of the variation in Ca retention in boys. Ca intake, BMI, and serum IGF-1 were positively associated with Ca retention, whereas serum 25OHD was negatively associated with Ca retention. A model that included Ca intake, BMI, age, serum PTH, and race explained 27.9 % of the variation in Ca retention in girls. Ca intake, BMI, and serum PTH were positively associated with Ca retention and age was negatively associated with Ca retention. Black girls retained 147 mg/d Ca across compared to white and Asian girls across the range of Ca intakes studied. Conclusions: Ca intake is a major predictor of Ca retention in boys and girls, and represents a modifiable lifestyle factor. Measures of maturation and regulators of Ca metabolism are predictors of Ca retention in both boys and girls. In girls, the effect of race is evident even after accounting for other predictors of Ca retention, whereas in boys, the effect of race is eliminated by accounting for the other predictors of Ca retention. These results support that adequate dietary Ca during adolescent growth is important for skeletal Ca retention. Predictive models of Ca retention can be used to target interventions to those adolescents most at risk for suboptimal skeletal Ca retention, and lead us in the direction of personalized nutrition.

Gender Differences in Circulating Sclerostin Levels are Established During Puberty and Correlate with Cortical Porosity. Salman Kirmani*[1], Ulrike Moedder[2], Kelley Hoey[1], James Peterson[1], Louise McCready[1], Atkinson Elizabeth[1], Shreyasee Amin[1], L. Joseph Melton[1], Byron Riggs[3], Ralph Müller[4], Sundeep Khosla[5]. [1]Mayo Clinic, USA, [2]Mayo Clinic College of Medicine, USA, [3]Mayo Clinic College of Medicine,Rochester, MN, USA, [4]ETH Zurich, Switzerland, [5]College of Medicine, Mayo Clinic, USA

Sclerostin, produced by osteocytes, is a potent inhibitor of Wnt signaling and bone formation; a neutralizing antibody to sclerostin also reduces bone resorption. However, there is currently no information on possible changes in circulating sclerostin levels during growth in humans. Thus, we used a recently developed ELISA (Biomedica) to measure serum sclerostin levels in 6-21 yr-old girls (n = 62) and boys (n = 56) in whom high-resolution pQCT (XtremeCT, Scanco, voxel size 82 microns) imaging of the wrist was obtained. Markers of bone resorption (CTX) and formation (PINP) were also measured. Subjects were classified into 5 groups by bone age (BA): Group I (pre-puberty, BA 6-8 yrs), Group II (early puberty, BA 9-11 yrs), Group III (mid-puberty, BA 12-14 yrs), Group IV (late puberty, BA 15-17 yrs) and Group V (post-puberty, BA 18-21 yrs). As shown in the Figure, serum sclerostin levels were slightly higher in the girls prior to puberty, tended to decrease in both sexes during puberty, but remained significantly higher in the boys compared to the girls in Groups III-V. After adjusting for BA, sclerostin levels were positively correlated with bone turnover markers in girls ($r = 0.39$, $P = 0.002$ for CTX and $r = 0.29$, $P = 0.02$ for PINP) and in boys ($r = 0.39$, $P = 0.003$ for CTX and $r = 0.38$, $P = 0.004$ for PINP). Trabecular bone parameters showed little association with serum sclerostin levels in either sex; however, cortical thickness and volumetric BMD were inversely associated with sclerostin levels in girls ($r = -0.34$, $P = 0.007$ for both), but not in boys. Interestingly, the cortical porosity index (derived from the Xtreme CT scans), which has previously been shown to increase transiently during adolescent growth and to peak at the time of maximal forearm fracture incidence in both sexes, was positively correlated with serum sclerostin levels in both girls ($r = 0.30$, $P = 0.02$) and boys ($r = 0.41$, $P = 0.002$). We conclude that a gender difference in circulating sclerostin levels is established during puberty, with boys having higher sclerostin levels than girls. The observed associations of sclerostin levels in both sexes with bone turnover markers and with cortical porosity suggest a role for changes in sclerostin production during growth in regulating cortical structure.

Age At Onset Of Puberty Predicts Bone Mass In Young Adulthood. Vicente Gilsanz*[1], James Chalfant[2], Heidi Kalkwarf[3], Babette Zemel[4], Joan Lappe[5], Sharon Oberfield[6], John Shepherd[7], Thomas Hangartner[8], Margaret Frederick[9], Xiangke Huang[9], Soroosh Mahboubi[10], Jean-Claude Desmangles[5], Tishya Wren[2], Karen Winer[11]. [1]Children's Hospital of Los Angeles, USA, [2]Childrens Hospital Los Angeles, USA, [3]Cincinnati Children's Hospital Medical Center, USA, [4]Children's Hospital of Philadelphia, USA, [5]Creighton University Osteoporosis Research Center, USA, [6]Columbia University Medical Center, USA, [7]University of California, San Francisco, USA, [8]Wright State University, USA, [9]Clinical Trials & Surveys Corp., USA, [10]Hand Radiograph Core Laboratory, USA, [11]National Institutes of Health, NICHD, USA

Although the amount of bone gained during puberty is the main contributor to peak bone mass (PBM), the influence that normal variations in sexual development have on bone acquisition are yet to be clearly defined. The purpose of this prospective longitudinal multi-center study was to determine whether the timing of commencement and length of puberty in contemporary children in the United States influence dual x-ray absorptiometry (DXA) values of bone mineral content (BMC) and bone mineral density (BMD) in the axial and appendicular skeletons at skeletal maturity. We identified 78 girls and 85 boys who began puberty (Tanner 2 stage of breast development or greater than 4 mL testes) and completed skeletal maturity (physeal closure of the bones of the hand and wrist) during the duration of the study; 4.4 $\pm$ 0.8 and 4.5 $\pm$ 0.8 years later respectively. Multiple linear regression analyses indicated that the age of onset of puberty was a strong negative predictor of DXA bone measurements at skeletal maturity, independent of bone values at the beginning of puberty and the length of puberty. This negative relation was observed for all BMC and BMD measurements at all skeletal sites, in both boys and girls (all p's < 0.0001). On average, healthy girls starting puberty a year earlier had approximately 5% greater BMC measures and 2.5% greater BMD values at skeletal maturity, while those starting a year later had 5% and 2.5% less. Similar findings of a slightly smaller magnitude were observed in healthy boys. In contrast, length of puberty had no relation to any measures of bone. We conclude that the timing of pubertal commencement is a strong independent negative predictor of bone mass and bone density in healthy young males and females.

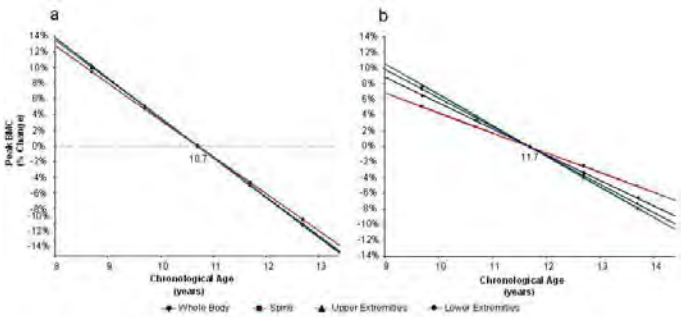

Figure 1. Predicted percent difference in peak BMC as a function of pubertal commencement for girls (a) and boys (b) as compared to the mean peak BMC at mean age of pubertal commencement (10.7 for girls and 11.7 for boys). Data points represent one and two standard deviations from the mean age of pubertal onset.

Predicted percent difference in peak BMC as a function of pubertal commencement

The Relationship Between Excess Adiposity and Bone Strength During Growth. Natalie Glass*, James Torner, Kathleen Janz, Elena Letuchy, Trudy Burns, Julie Gilmore, Barbara Broffitt, Steven Levy. University of Iowa, USA

Investigations of the relationship between excess adiposity and pediatric bone strength have yielded conflicting results. Because peak bone mass is attained in early adulthood, evaluation of this relationship may be important for the prevention of osteoporosis later in life. We conducted a longitudinal study in boys and girls to determine whether excess adiposity at age 9 was predictive of bone strength 2 and 4 years later.

Methods: Using peripheral quantitative computed tomography (pQCT), we measured trabecular bone mineral content (tBMC) and density (tBMD) at the 4% site of the distal radius and tibia; cortical bone mineral content (cBMC) density (cBMD), periosteal (peri) and endosteal (endo) circumference at the 20% and 38% distal radius and tibia, respectively; strength strain index (SSI) at the 38% distal tibia; and muscle cross-sectional area (mCSA) at the 66% site of the distal tibia. Data collection in 241 boys and 251 girls was completed at approximately ages 9, 11 and 13 years. Adiposity was ascertained using dual energy x-ray absorptiomety and expressed as fat mass index (FMI, total body fat mass/height^2). Multivariable regression analyses, adjusted for tanner stage, limb length, and mCSA (tibia only), evaluated whether FMI at age 9 predicted bone strength at age 11 and 13.

Results: Age 9 FMI predicted age 11 radial tBMC, tBMD, cBMC, endo, peri and SSI, but not cBMD in girls (p-values: $<$0.0001-0.0088); and radial tBMC, tBMD, endo, peri and SSI, but not cBMC or cBMD in boys (p-values: $<$0.0001-0.0091). Age 9 FMI was positively associated with all tibial bone measures at age 11, except cBMD, in both boys and girls (p-values: $<$0.0001-0.0153). Age 9 FMI was also positively associated with all radial bone measures for age 13 in girls, except cBMD (p-values: $<$0.0001-0.0015); and radial tBMC, cBMC, cBMD, peri, endo, and SSI at age 13 in boys (p-values: 0.0001-0.0495). At the tibia, there was a positive relationship between age 9 FMI and all age 13 bone measures, except cBMD in girls (p-values: $<$0.0001-0.0008), while all age 13 bone measures were positively associated in boys (p-values: $<$0.0001-0.049).

Conclusions: Excess adiposity was predictive of greater bone strength. This relationship was present at both weightbearing and non-weightbearing sites. This may suggest that the effects of excess adipose tissue on growing bone are not completely due to mechanical loading.

Osteopontin Plays a Pivotal Role in Sympathetic Control of Bone Mass. Masashi Nagao*[1], Yoichi Ezura[2], Yoshitomo Saita[3], Tetsuya Nakamoto[1], Tadayoshi Hayata[4], Yayoi Izu[1], Ryo Hanyu[1], Hiroaki Hemmi[1], Takuya Notomi[5], Susan Rittling[6], Hisashi Kurosawa[7], Kazuo Kaneko[8], David Denhardt[9], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Juntendo University, Department of Ortopedics, Japan, [4]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [5]GCOE, Tokyo Medical & Dental University, Japan, [6]The Forsyth Institute, USA, [7]Dept of Orthopedics, Juntendo Univ, School of medicine, Japan, [8]Dept of Orthopetics, Juntendo Univ school of medicine, Japan, [9]Department of Cell Biology & Neuroscience, Rutgers University, USA

Sympathetic tone suppresses bone mass levels. However, the link between sympathetic tone and bone metabolism remains obscure. One of the major causes of bone loss is unloading-induced event that is suppressed not only by beta blockers but also by the deficiency of osteopontin (OPN), a cytokine and one of the major components of non-collagenous extracellular matrix proteins of bone. We, therefore, examined whether OPN links sympathetic tone and bone metabolism. First, the activator of sympathetic tone isoproterenol (ISO) treatment increased the levels of plasma OPN. Furthermore, isoproterenol injection increased OPN expression in bone. To elucidate the role of OPN, the effects of OPN-deficiency on sympathetic tone-induced bone changes were examined. In contrast to wild type where isoproterenol treatment reduced the levels of bone volume, OPN-deficient mice were resistant to such isoproterenol-induced bone loss. Isoproterenol treatment suppressed bone formation parameters including mineral apposition rate (MAR) and bone formation rate (BFR) in wild type. However, OPN deficiency mitigated isoproterenol-induced reductions these bone formation parameters. Isoproterenol-treatment also increased the levels of bone resorption parameters such as osteoclast number and osteoclast surface as well as urinary deoxypyridinoline levels in wild type, while these parameters were unaffected by isoproterenol in OPN deficient mice. Isoproterenol treatment enhanced or reduced mRNA expression of osteoclastic or osteoblastic phenotype-related genes respectively, but not in bones from OPN-deficient mice. Though isoproterenol is catabolic and PTH is anabolic to bone, both enhance protein kinase A and CRE dependent luciferase activity. Osteopontin deficiency enhanced isoproterenol-induced CRE-luciferase activity as well as forskolin and IBMX-induced events and this enhancement was blocked by H89. OPN-deficiency enhanced phosphorylation of CRE-binding protein, CREB. Finally anti-OPN antibody treatment suppressed isoproterenol-induced bone loss. Thus, OPN plays a pivotal role in isoproterenol-induced bone loss at least in part via modulating CREB phosphorylation and transcription.

In Vivo Evidence for a Limiting Role of Bone Sialoprotein (BSP) in Primary Bone Formation and Resorption : The Marrow Ablation Model Under PTH Challenge. Ndéyé-Marième Wade-Gueye[1], Maya Boudiffa[2], Arnaud Vanden-Bossche[1], Farida Gueniche[1], Norbert Laroche[1], Jane Aubin[3], Laurence Vico[4], Marie-Helene Lafage-Proust[5], Luc Malaval*[6]. [1]Université de Lyon, INSERM U890, Université Jean Monnet, 42023 Saint-Etienne, France, [2]IRCM, Canada, [3]University of Toronto Faculty of Medicine, Canada, [4]University of St-Etienne, France, [5]INSERM Unit 890, France, [6]INSERM U890-Université de Lyon-Université Jean Monnet, Saint-Etienne, France

Bone sialoprotein (BSP) is highly expressed in early bone deposition and may be involved in primary bone mineralization. We previously showed that BSP-/- mice have

a mild secondary bone phenotype, and are responsive to mechanical and hormonal challenges. However, repair of a cortical bone defect, which involves primary bone deposition, is significantly delayed in these mice. To test whether the mutation more strongly affects newly layed bone, we investigated the role of BSP in a model of primary bone modeling.

Bone marrow was ablated by trans-epiphysis aspiration in the femora of BSP knockout (BSP-/-) and wild type (WT) mice. The femurs were analyzed through microtomography (μCT) and histomorphometry 7 (d7) and 14 days (d14) after ablation. At d7, μCT showed a vigorous new bone formation in the shaft of WT animals (BV/TV=30.2±5.0%, M±SEM, N=4), while medullary bone (MB) building was much reduced in mutants (10.0±0.9%, N=9, $p<0.001$ vs WT). At d14, MB volume was significantly decreased as expected in WT mice (9.8±2.1%, N=9, $p<0.001$), while it remained stable in the BSP-/-. Osteoid thickness and surface was higher in BSP-/- than in WT at d7 (OS/BS=3.6±0.8 vs 1.3±0.2%, N=4, $p<0.05$), suggesting delayed mineralization, while osteoclast surface et number was significantly lower in mutants (Oc.S/BS=8.4±0.8 vs 12.6±0.8%, N=4, $p<0.05$) at d14, during high MB resorption. At d7, mRNA expression of early osteoblast marker genes (runx2, osterix, alkaline phosphatase, osteopontin) did not differ between the two genotypes, while markers of terminal differentiation (MEPE, DMP1, osteocalcin) as well as RANKL and TRAP were significantly lower in mutants.

We investigated whether intermittent PTH treatment, which has been shown to stabilize MB volume in rats (Tissue Eng Part A, 14:237, 2008) could do the same in mice expressing or not BSP. MB volume in WT mice treated with PTH was 3x more abundant than in untreated controls at d8 (28.2±4.2 vs 11.4±2.7%, N=6, $p<0.01$), and 6X at d12 after ablation (39.3±7.6 vs 5.6±1.1%, N=7, $p<0.001$). In contrast, no significant difference between PTH-treated and controls was observed at either time-point in BSP-/- mice (d8: 9.9±3.0 vx 6.3±1.1% ; d12 : 13.7±3.4 vs 7.0±1.0%, N=7). At d12, the MB formed after marrow ablation is partly remodeled (presence of double labeled surfaces after tetracyclin injection). PTH significantly increased the bone formation rate of remodeled surfaces in both genotypes, while it reduced osteoclast numbers and surfaces in the MB of WT (Oc.S/BS=4.5±0.5 vs 10.3±1.2%, N=6, $p<0.001$, d12), but not BSP-/- mice (7.6± 1.0 vs 7.3±0.6%, N=7, d12).

In conclusion, mMB formation after marrow ablation, its subsequent resorption and its stabilization by PTH are blunted in BSP-/- mice. Overall, our findings demonstrate a crucial role for BSP in primary ossification, which has long been suspected for mineralization but here extends to bone deposition and modeling/remodeling.

Collagen Extracellular Matrix (ECM) Assembly Dynamics in Living Osteoblasts and Generation of a Collagen-GFP Transgenic Mouse. Suzan Kamel*[1], Yongbo Lu[2], Patricia Veno[1], Charlotte Phillips[3], Vladimir Dusevich[1], Sarah Dallas[4]. [1]University of Missouri, Kansas City, USA, [2]Texas A&M University System Health Science Center, USA, [3]University of Missouri-Columbia, USA, [4]University of Missouri - Kansas City, USA

Type I collagen is the major ECM protein in bone. It is a heterotrimer of two α1(I) and one α2(I) chains encoded by separate genes, mutations in which cause osteogenesis imperfecta (OI). Although much is known about post translational modification of collagen chains and their intracellular assembly into trimers, less is known of the hierarchical process by which collagen trimers are assembled into fibrils followed by larger collagen fibers. To further understand this process and its regulation, live imaging approaches were used to examine collagen assembly dynamics in living bone cells.

We have previously reported the generation of green and red fluorescent collagen probes, in which GFP or mCherry were placed in the pro-α2(I) N-terminus, as well as their stable expression in MLO-A5 late osteoblasts and MEF cells. Further validation of the GFP and mCherry probes confirmed that they are secreted and assembled into extracellular fibrils upon addition of ascorbate, they are localized by immunoEM in banded collagen fibrils and can be co-immunoprecipitated with α1(I) chains from conditioned media or salt extracts of the ECM, suggesting heterotrimer formation. Live imaging of stably expressing MLO-A5 cells showed that assembly of a well organized collagen fiber network is a highly dynamic process, involving migration of collagen to the cell periphery in vesicle-like structures, abundant cell and fibril motions and protrusions of cell processes that appear to align with forming fibers. Imaging of fiber assembly in co-cultures of red collagen and green collagen expressing cells showed co-deposition of red and green collagen within the same fibers, suggesting that multiple cells provide contributions to form fibers. Dual imaging of fibronectin and collagen showed initial deposition of collagen in association with fibronectin followed by turnover of fibronectin, leaving the collagen in place. To examine collagen dynamics in vivo, transgenic mice were generated expressing α2(I)-GFP-collagen driven by the 3.6kb Col1a1 promoter. These mice show GFP-collagen in bone ECM, tail tendon, and intervertebral discs and appear otherwise normal. These data underscore the dynamic nature of collagen assembly, the cooperation of multiple cells in assembly of complex fibril networks and the integration of collagen assembly with fibronectin, which acts as a temporary scaffold. Collagen-GFP mice will allow further delineation of collagen assembly dynamics in vivo and in models of OI.

PHOSPHO1 Is Essential for Mechanically Competent Mineralization and Avoidance of Greenstick Fractures. Carmen Huesa*[1], Manisha Yadav[2], Mikko Finnila[3], Simon Goodyear[4], Simon Robins[5], Katherine E. Tanner[6], Richard Aspden[5], Jose Luis Millan[2], Colin Farquharson[7]. [1]Roslin instituteUniversity of Edinburgh, United Kingdom, [2]Burnham Institute for Medical Research, USA, [3]Department of Medical Technology, University of Oulu, Finland, [4]University of Aberdeem, United Kingdom, [5]University of Aberdeen, United Kingdom, [6]Mechanical Engineering, University of Glasgow, United Kingdom, [7]Roslin Institute, University of Edinburgh, United Kingdom

Bone mineralization is mediated by promoters and inhibitors, of which tissue-nonspecific alkaline phosphatase (TNAP) is recognized to play a central role. TNAP promotes mineralization by restricting the concentration of the calcification inhibitor inorganic pyrophosphate (PPi). TNAP hydrolyses ATP to produce inorganic phosphate (Pi), but the generation of Pi and hydroxyapatite (HA) is unchanged in newborn $TNAP^{-/-}$ mice suggesting the involvement of other phosphatases. A bone specific phosphatase, PHOSPHO1, is hypothesized to be required for Pi generation and the formation of HA within matrix vesicles. $Phospho1^{-/-}$ mice present greenstick fractures in long bones and rib cages at birth. Fracture callus, curved long bones and scoliosis are observed from 10-days of age. Bones from $Phospho1^{-/-}$ mice are undermineralized as determined by BMD and ash weight measurements.

The aim of this study was to investigate the mechanical and material properties of $Phospho1^{-/-}$ bones to confirm the enzyme's specific role in HA formation.

Long bones from 7 wild-type (wt) and 9 $Phospho1^{-/-}$ 1 month old male mice were examined. $Phospho1^{-/-}$ bones did not fracture during 3- point bending but deformed plastically. With dynamic loading nanoindentation the elastic modulus and hardness of $Phospho1^{-/-}$ tibia were significantly lower than wt tibia ($P<0.005$). Raman microscopy showed significantly lower mineral:matrix ratios ($P<0.05$) and lower CO_3^{2-} substitutions ($P=0.005$) in $Phospho1^{-/-}$ tibia. The altered DHLNL:HLNL and PYD:DPD collagen crosslink ratios indicated possible changes in lysyl hydroxylase 1 activity and/or bone mineralization status. Histomorphometry revealed decreased alizarin red staining of trabecular bone and osteoidosis ($P=0.0001$) but no significant differences in the numbers of osteoblasts and osteoclasts. Bone formation (P1NP) and resorption (RatLaps™) markers measured in serum using ELISA were both increased in $Phospho1^{-/-}$ mice ($P<0.001$) indicating higher bone turnover.

In summary these data indicate that $Phospho1^{-/-}$ bones are hypomineralized and, consequently, are softer and more flexible. An inability to withstand physiological loading may explain the deformations noted. We hypothesize that this phenotype is due to the reduced availability of Pi to form HA during mineralization, creating an under-mineralized yet active bone. A higher bone turnover may indicate an attempt to remodel a mechanically competent bone capable of withstanding physiological load.

A Novel Mechanism for Modulation of Canonical Wnt Signaling by the ECM Component, Biglycan. Agnes Berendsen*[1], Tina Kilts[1], Marian Young[2]. [1]NIDCR, National Institutes of Health, USA, [2]National Institutes of Health, USA

Canonical Wnt signaling plays essential roles in the control of bone mass. So far, the role of ECM components of skeletal tissues in modulating Wnt signaling is largely unknown. The ECM of mineralized tissues is enriched in the proteoglycan biglycan (Bgn), which is composed of a core protein and two chondroitin sulfate chains. Previous studies showed that mice deficient in Bgn have a reduced growth rate and decreased bone mass. Considering that Bgn is usually localized in a pericellular space, we hypothesized that it could modulate Wnt availability and function at the cell surface where these proteins are co-localized. To test this possibility, we studied the effects of the canonical Wnt pathway activator, Wnt3a, on the activity of WT and Bgn-KO preosteoblasts obtained from the calvaria of newborn mice. Wnt3a induced nuclear localization of β-catenin in both cell types, indicating activation of the pathway in these cells. However, the Wnt3a-induced expression of several Wnt target genes, including Cyclin D1, Axin2, Myc, WISP1, and MMP14, was blunted in Bgn-KO cells. Bgn-KO cells treated with exogenous Wnt3a had less Wnt3a retained in the cell layer compared to WT cells. Furthermore, the Wnt3a-induced levels of phosphorylation of LRP6 (which is required for activation of β-catenin) appeared reduced in Bgn-KO cells. In addition to a loss of function analysis of Bgn, we studied the effect of adding recombinant Bgn protein on Wnt signaling in cells. Addition of Bgn to HEK cells stably transfected with a luciferase reporter of β-catenin-mediated transcriptional activity, dose-dependently increased the Wnt3a-induced reporter activity. In contrast, activation of the Wnt pathway by LiCl, an inhibitor of intracellular β-catenin degradation, was not affected in the presence of Bgn confirming that the proteoglycan's regulation of Wnt signaling works extracellularly. Bgn depleted of the two chondroitin sulfate chains was also effective in enhancing Wnt signaling indicating that the functional sites likely reside in the core protein and not in the GAG chains. IP analysis revealed that Bgn core protein can prevent the pull-down of Wnt3a, which suggests a direct interaction between these proteins. We propose that the core protein of Bgn may serve as a reservoir for Wnt in the pericellular space and modulate Wnt availability for activation of the Wnt signaling pathway. This study identifies a new role for the ECM protein Bgn in modulating canonical Wnt signaling.

Collagen XXIV Regulates Osteoblast Differentiation Through Crosstalk of STAT1/Smad7 and TGF-β/Smad3 Signal Pathways. Gang Liang, Shuying Yang*. State University of New York at Buffalo, USA

Collagen XXIV (*Col24α1*) is a new fibrillar collagen, which contains an amino-terminal domain closely related to those of the types V and XI collagen subunits. It is known that mouse col24α1 is predominantly expressed in the forming skeleton of the mouse embryo and the trabecular bone and periosteum of the newborn mouse. However, the role and mechanism of Col24α1 in bone development and formation remain largely unidentified. To gain insight into Col24α1 signaling in osteoblast differentiation, we analyzed expression pattern of Col24α1 gene by Northern blotting and found that col24α1 highly expresses in bone tissue. RT-PCR result further showed that Col24αl transcripts gradually increase during differentiation of osteoblast cells and are undetectable in BMMs induced osteoclast like cells. To demonstrate the importance of Col24α1 function in osteoblast differentiation, we used lentivirus-mediated RNA interference (RNAi) technology to silence (knockdown) Col24α1 expression in MC3T3-E1 clone 4 induced with ascorbic acid (AA)/ β-glycerol-phosphate (β-g-p). In contrast to wild-type cells, we found that the cells infected with Col24α1 shRNA lentivirus contain undetectable Col24α1 protein. Silence of Col24α1 expression significantly decreased ALP activity and cell mineralization at 7days and 14days after induced by AA/ β-g-p. RT-PCR results showed that Col24α1 silencing markedly inhibits expression of mature osteogenic marker such as osteocalcin and Runx2. Transcription of Smad3, the key transcription factor of TGF-β signal pathway, was dramatically decreased; on the contrary, Smad7, a TGFβ type 1 receptor antagonist with function of blocking access to SMAD3, was markedly increased in Col24α1 siRNA-treated MC3T3-E1 cells. Col24α1 contains KGD motifs. Previous reports have shown that KGD-containing peptides is specific and potent inhibitors of intergrin alpha IIb beta 3 function, which inhibits platelet activation and platelet PDGF-AB release via STAT1 signaling pathway, and STAT1 signaling negatively regulates Smad7 expression. Interestingly, we found that silence of Col24α1 increases PDGF-B and STαT1 expression in osteoblast cells. Thus, these results suggested that Col24α1 plays an important role in osteoblast differentiation and activation likely through crosstalk of STAT1/Smad7 and TGF-β/Smad3 signal pathways. Col24α1 knockout model is being generated for further analyzing the role and mechanism of Col24α1 bone development and formation *in vivo*.

Activation Function-1 in Estrogen Receptor-α but not Endogenous Estradiol is Required for the Osteogenic Response to Mechanical Loading in Female Mice. Sara Windahl*[1], Leanne Saxon[2], Anna Borjesson[1], Cecilia Engdahl[1], Klara Sjogren[1], M Christina Antal[3], Andrée Krust[3], Pierre Chambon[3], Lance Lanyon[2], Joanna Price[4], Claes Ohlsson[1]. [1]Centre for Bone & Arthritis Research, Sweden, [2]Royal Veterinary College, United Kingdom, [3]Institut de Génétique et de Biologie Moléculaire et Cellulaire, INSERM, France, [4]University of Bristol, United Kingdom

It is hypothesised that with the loss of estrogen, there is a decline in estrogen receptors (ERs) in bone cells, and it is these receptors that are partially responsible for signalling the bones' adaptive response to loading. We have previously shown a reduced response to loading in mice lacking ERα (Lee et al Nature, 2003, 424:389) however these mice still expressed a truncated ERα protein. The aims of the present study were to determine the relative roles of endogenous estradiol and different domains of ERα in the osteogenic response to mechanical loading.

At 17 weeks of age, the right tibia of 8-14 mice in each experimental group were subjected to short periods of cyclic compressive loading three times a week for two weeks (40 cycles, peak strain 1400με). Computed tomography was used to assess the osteogenic response in the cortex of the loaded (right) versus the non-loaded (left) tibia. To evaluate the role of endogenous estradiol, we compared the osteogenic response in intact (sham) and ovariectomized (ovx) mice. Loading increased cortical bone area to a similar extent in sham and ovx mice (sham 24.0±2.2%, ovx 25.7±2.3%). We next evaluated the role of ERα in the loading response using ERα-/- mice with a complete ERα inactivation (Dupont et al Development 2000, 127:4277). The ERα-/- mice displayed a 68±11% ($p<0.01$) lower loading-related increase in cortical area compared with wild type (WT) mice (WT 24.0±2.2%, ERα-/- 7.7±2.6%). The loading-related increase in cortical area was similarly reduced in OVX ERα-/- mice (-51%, $p<0.01$) mice compared with ovx WT mice. To characterize which domains of ERα are involved in this cortical bone response to mechanical loading, mice with specific inactivation of either activation function domain 1 (AF-1; ERαAF-1♂) or AF-2 (ERαAF-2♂) were evaluated. The ERαAF-1♂ mice displayed a 37±8% ($p<0.05$) lower response to mechanical loading in cortical area compared with WT mice while the cortical bone response was mainly unaffected in the ERαAF-2♂ mice compared with WT mice (-11±14%, non significant). These findings demonstrate that AF-1 in ERα but not endogenous ovarian-derived estradiol is required for the osteogenic response to mechanical loading in female mice. We propose that ERα modulates the osteogenic response to mechanical loading in cortical bone in a ligand-independent manner.

The Role of Estrogen Receptor-α AF-1 and AF-2 for the Effects of Estradiol in Bone. Anna Borjesson*[1], Sara Windahl[1], Marie Lagerquist[2], Cecilia Engdahl[3], Baruch Frenkel[4], Klara Sjögren[1], Jenny Kindblom[2], Maria Cristina Antal[5], Andrée Krust[5], Pierre Chambon[5], Claes Ohlsson[1]. [1]Centre for Bone & Arthritis Research, Sweden, [2]Sahlgrenska University Hospital, Sweden, [3]Centre for Bone & Arthritis Researc, GU, Sauhlgrenska Academy, Medicine, Sweden, [4]University of Southern California, USA, [5]IGBMC, France

Estrogen exerts a variety of important physiological effects. The bone-sparing effect of estrogen is primarily mediated via estrogen receptor-α (ERα), which stimulates target gene transcription through two activation functions (AFs), AF-1 in the N-terminal and AF-2 in the C-terminal, ligand binding domain. We evaluated the involvement of ERα AF-1 and ERα AF-2 in the effects of estrogen in bone, as well as the immune system and the uterus. Mouse models with inactivation of total ERα (ERα-/-), AF-1 (ERαAF-10) or AF-2 (ERαAF-20) were ovariectomized (ovx) and then treated with either vehicle or estradiol (E2). Both ERαAF-10 and ERαAF-20 mice have a normal expression of ERα, except for the specific deletions of AF-1 and AF-2, respectively. Treatment of ovx mice with E2 increased the trabecular BMD by 334±36% and the cortical thickness (CT) by 27±2% ($p<0.01$). Neither the trabecular nor the cortical bone responded significantly to the E2 treatment in ERα-/- (Trabecular BMD 3±3%, CT -1±11%; of WT E2 response) or ERαAF-20 mice (Trabecular BMD 2±3%, CT -8±7%; of WT E2 response). ERαAF-10 mice displayed a normal estrogenic response in cortical bone (CT 76±11% of WT E2 response, $p<0.01$) but not in trabecular bone (Trabecular BMD 8±3% of WT E2 response, non significant). Although E2 treatment increased bone mass, uterine weight and liver weight, and reduced thymus weight and the frequency of CD19+ cells in bone marrow in ovx WT mice, no effect was seen on these parameters in ovx ERα-/- or ERαAF-20 mice. The effects of E2 in ovx ERαAF-10 mice were tissue dependent, with no response on thymus weight, a weak response on uterine weight (27% of WT E2 response), an intermediate response on bone marrow cellularity and the frequency of bone marrow CD19+ lymphocytes (30-60% of WT E2 response), and a normal response on liver weight (>75% of WT E2 response). In conclusion, ERα AF-2 is required for the estrogenic response in all the parameters evaluated, including the protection of both trabecular and cortical bone. The requirement for AF-1, on the other hand, is tissue specific, with an indispensable role for AF-1 in the E2 response in trabecular, but not cortical bone. These findings demonstrate that the role of ERα AF-1 is tissue dependent and selective ER modulators with minimal activation of ERαAF-1 could, therefore, exert tissue specific effects.

Physiological Impact of Osteoblastic Androgen Receptor in Androgen Anabolic Action. Yuuki Imai*[1], Shino Kondoh[1], Min Ni[2], Kazuki Inoue[1], Takahiro Matsumoto[1], Kunio Takaoka[3], Shigeyuki Wakitani[4], Myles Brown[2], Shigeaki Kato[5]. [1]The University of Tokyo, Japan, [2]Dana-Farber Cancer Institute, USA, [3]Osaka City University Medical School, Japan, [4]Osaka City University Graduate School of Medicine, Japan, [5]University of Tokyo, Japan

Sex steroid hormones play important roles to maintain bone tissues through various mechanisms. It has been clarified that estrogen exerts osteo-protective estrogen action by inducing osteoclast apoptosis through estrogen receptor α (ERα) in both osteoclast and osteoblast. On the other hand, it remains unclear whether androgen directly targets on bone tissue, since male androgen receptor (AR) knockout (KO) mice exhibited bone loss together with systemic endocrine defects. To clarify physiological impact of AR in bone, we generated and analyzed osteoblast specific KO (ObARKO) mice using Col1a1 2.3 kb Cre and AR flox mice. ObARKO did not exhibit systemic endocrine defect regardless of gender. However, male, but not female, ObARKO mice exhibited decreased bone mineral density (BMD) in diaphysis of long bones and calvaria. Micro CT analyses showed decreased cortical thickness in male ObARKO. Moreover, androgen deficiency induced by orchidectomy (ORX) decreased bone mass only in the AR wild-type, not in ObARKO mice. Likewise, ORX-induced bone loss could be recovered by a DHT treatment only in the wild-type mice. Furthermore, by a bone histomorphometry, no apparent change was found in static parameters, however, dynamic parameters such as MAR and BFR were reduced in both cortical and trabecular bone of ObARKO. These results indicated that AR in osteoblasts mediates androgen anabolic actions.

Therefore, to characterize the impact of AR in osteoblasts, a Chromatin Immunoprecipitation sequencing (ChIP-seq) was performed using a next generation single molecule high-throughput sequencer for an osteoblastic cell line, MC3T3E1, treated with DHT. ChIP-Seq analysis revealed 4018 AR binding sites in the mouse genome of MC3T3E1 cells with p value cut off of e-5. About 7.7% and 5.8% of binding sites were be mapped to within 10 kb upstream of the transcriptional start site and 10kb downstream of the transcriptional termination site. Moreover, when ChIP-seq data was merged with the results of gene expression microarray data sets, several genes were identified as candidates of AR direct target genes in osteoblasts.

Taken together, further characterization of AR target genes in osteoblasts to elucidate more precise molecular mechanisms of anabolic actions of androgen will be presented.

Increased Bone VDR Impairs Osteoclast and Osteoblast Activities with Low Dietary Calcium in a Mouse Model. Nga Lam*[1], Peter O'Loughlin[2], Rebecca Sawyer[1], Howard Morris[1], Paul Anderson[1]. [1]Endocrine Bone Research, SA Pathology, Australia, [2]Endocrine Bone Research, SA Pathology, Australia

The vitamin D receptor (VDR) in osteoblasts can mediate mineralization and signal osteoclastogenesis in vitro. While the role for osteoblast VDR in vivo is less clear, the osteoblast-specific VDR over-expressing transgenic mouse (OSVDR) has increased bone volume due to reduced RANKL-mediated osteoclastogenesis and increased bone formation. While the OSVDR bone phenotype can be diminished with reduced dietary calcium, the cellular and molecular mechanisms for this are unclear. Six week old female wild-type (WT) and OSVDR mice were fed either low (0.1%) (WT-LCa, OSVDR-LCa) or high (1%) calcium diet (WT-HCa, OSVDR-HCa) for 4 months, after which animals were killed for biochemical, molecular, histological and structural analyses. In OSVDR-HCa mice, both tibial trabecular and cortical bone volumes were approximately 20% and 15% greater respectively than WT-HCa levels ($P<0.001$). WT-LCa mice did not significantly reduce bone volume compared to WT-HCa mice. In contrast, OSVDR-LCa mice resulted in lower bone volume compared to OSVDR-HCa mice ($P<0.05$). The reduced bone volume in OSVDR-LCa mice occurred without increased serum PTH or induction of RANKL-mediated osteoclastogenesis. Furthermore, the osteoclast marker NFATc1 expression was lower than levels observed in WT-LCa mice ($P<0.001$), suggesting OSVDR mice are less capable of generating osteoclasts under low calcium stress. Importantly, reduced bone volume in OSVDR-LCa mice was also associated with reduced mineralising surface and markedly reduced Runx2, ALP, Col1, and osteocalcin mRNA levels compared to all other groups ($P<0.05$). Thus, unlike WT mice, when OSVDR mice were fed a low calcium diet, bone loss occurs due to a failure of mineralisation rather than increased bone resorption. Interestingly, OSVDR-LCa mice had markedly reduced serum 1,25D levels compared to WT-LCa mice ($P<0.001$), which, as serum PTH was unchanged is likely due to the observed higher serum FGF23 ($P<0.05$). Thus, inappropriately low 1,25D levels in OSVDR-LCa mice may lead to reduced induction of intestinal calcium absorption, reduced osteoclastogenesis and reduced bone mineralisation. In summary, under conditions of low dietary calcium, increased sensitivity to vitamin D in osteoblasts results in direct or indirect suppression of osteoclast and osteoblast activities, increased FGF23 levels and inhibition of renal 1,25D synthesis and possibly intestinal calcium absorption, reducing bone mineral volume.

Androgen Prevents Hypogonadal Bone Loss Primarily Through Osteocyte-mediated Inhibition of Resorption and is not Anabolic. Anthony Semirale[1], Xiao-Wei Zhang[2], Dawn Olson[3], Urszula Iwaniec[3], Russell Turner[3], Kristine Wiren*[4]. [1]Oregon Health Sciences University, USA, [2]VA Medical Center & OHSU, USA, [3]Oregon State University, USA, [4]Veterans Affairs Medical Center, Oregon Health & Science University Research Ser, USA

Androgen receptor (AR) is expressed throughout the osteoblast lineage, with the highest levels in osteocytes. Using AR-transgenic (tg) mice, we assessed the ability of enhanced androgen sensitivity in mature osteoblasts/osteocytes to ameliorate hypogonadal loss using two different paradigms of steroid replacement following orchidectomy (ORX) in male wild-type (WT) or AR-tg mice. ORX was performed at 3 months with DHT treatment delayed until 5 months (therapeutic, lower turnover), or at 5 months with immediate DHT replacement (preventive, higher turnover), both with treatment for 6 weeks. DXA, microCT and serum analysis were performed. In the preventive model, ORX significantly reduced BMD and BMC in both genotypes compared to sham and DHT was effective at prevention of loss only in AR-tg mice with overexpression in mature osteoblasts. In the therapeutic model, WT mice lost bone mass compared to sham while AR-tg mice lost less bone, and delayed DHT treatment provided no benefit in either genotype. MicroCT analysis of mid-shaft cortical bone in both genotypes generally showed reduced cortical volume and thickness after ORX in both paradigms, changes which were generally prevented with immediate DHT replacement in WT but not AR-tg mice, likely due to expansion of marrow volume. Delayed DHT was ineffective at restoring whole bone volume in either genotype. In cancellous bone, the effect of intevention was more robust. Consistent among 3 sites measured, ORX resulted in significant losses in bone volume/tissue volume (BV/TV) in both genotypes in both paradigms. With delayed treatment, there was no net effect of DHT to restore BV/TV, but when administered at the time of ORX, DHT completely prevented trabecular loss in both genotypes. In both paradigms, trabecular number was decreased with increased spacing with ORX, and improvement was seen with immediate DHT replacement but not after the 2 month delay in both genotypes. Serum osteocalcin and CTX levels revealed anti-resorptive effects of DHT when turnover was high, consistent with DXA and microCT results. In summary, androgen therapy is effective for the prevention of bone loss primarily through its antiresorptive properties, but shows little anabolic action as a therapeutic strategy to restore lost bone as only small improvements are seen. Increased sensitivity in mature osteoblasts/osteocytes does not increase anabolic activity and instead mediates antiresorptive responses.

The 1,25D3-MARRS Receptor/PDIA3/ERp57 is Required for Intestinal Cell Phosphate Uptake. Ilka Nemere*[1], Natalio Garbi[2], Gunter Hammerling[2]. [1]Utah State University, USA, [2]Division of Molecular Immunology, German Cancer Research Center DKFZ, Germany

We have crossed $ERp57^{lfx/flx}$ mice with commercially available mice expressing villin-driven cre-recombinase. Enterocytes isolated from 3-4 wk old littermate (LM) male mice responded to $1,25(OH)_2D_3$ with enhanced phosphate uptake, relative to corresponding controls within 1 min of addition, whereas in cells from targeted knockout (KO) mice the response was severely blunted.

Unlike chick enterocytes, mouse enterocytes did not respond to phorbol ester with enhanced phosphate uptake. However, forskolin, which does not stimulate phosphate uptake in chick intestinal cells did so in enterocytes isolated from either young male LM or KO mice. Intestinal cells isolated from young female LM mice also responded to $1,25(OH)_2D_3$ with enhanced phosphate uptake within 5 min of hormone addition, whereas cells from KO mice did not. Forskolin also stimulated phosphate uptake in enterocytes from either young female KO or LM mice. As with intestinal cells from adult male chickens or rats, cells from adult (8wk) male LM mice lost the ability to respond to $1,25(OH)_2D_3$ with enhanced phosphate uptake. In contrast, intestinal cells from adult female LM mice did respond with enhanced phosphate uptake within 1 min of steroid hormone addition, relative to corresponding controls, and the magnitude of the effect was greater than that observed in enterocytes of young females. Cells isolated from young or adult male or female LM mice failed to respond to $1,25(OH)_2D_3$ with enhanced PKC activity. Finally, we have previously reported that mouse enterocytes have cell surface VDR; however preincubation of such cells with anti-VDR antibodies demonstrated that the classical receptor is not involved in the rapid $1,25(OH)_2D_3$-stimulated uptake of phosphate.

FSH Markedly Increases Bone Mass in Mice via Ovary-dependent Mechanisms. Robert Kalak[1], Charles Allan[1], Kirsten McTavish[1], Colin Dunstan[2], Hong Zhou*[3], David Handelsman[1], Markus Seibel[3]. [1]ANZAC Research Institute, The University of Sydney, Australia, [2]University of Sydney, Australia, [3]Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia

We previously demonstrated that pituitary-independent, transgenic expression of human FSH (tgFSH) increased trabecular bone volume (BV/TV) in female mice (1), contrasting with previous claims that elevated FSH levels cause bone loss (2). Using the tgFSH model to further study the putative FSH actions on bone, we determined i) the dose-dependent effects of FSH in vivo; ii) tgFSH activity on bone in isolation of LH actions, using hypogonadal (hpg) female mice lacking endogenous GnRH and FSH/LH secretion, and iii) the dependence of FSH effects on the presence of intact ovaries, using ovariectomised tgFSH mice.

At circulating levels ranging between 6 and 44 IU/L, human tgFSH dose-dependently increased trabecular bone volume fraction as assessed by μCT. Higher tgFSH levels increased tibial BV/TV by 42-fold and 13-fold in tgFSH hpg and tgFSH non-hpg females (Fig 1), respectively, vs non-tg controls($p<0.001$ for both). Vertebral BV/TV was increased 4-fold ($p<0.001$) in tgFSH females regardless of the presence of LH. Osteoblast surface (Ob.S/BS) was increased in tibial trabecular bone by 1.7-fold ($p<0.001$) and 1.6-fold ($p<0.005$) in tgFSH non-hpg and tgFSH hpg vs control females, respectively. Very high tgFSH levels stimulated de novo bone formation, filling marrow spaces with woven rather than lamellar bone, resembling bone formation induced by strong systemic anabolic stimuli. Uterine weights indicated normal or reduced estradiol activity in tgFSH non-hpg or tgFSH hpg females compared to wildtype mice. However, positive correlations of tibia BV/TV with serum tgFSH ($r=0.65$, $p<0.001$), testosterone ($r=0.62$, $p<0.001$) and inhibin A ($r=0.43$, $p<0.005$) levels in tgFSH females suggests ovarian-derived factors are associated with altered bone dynamics. Ovariectomy completely abolished tgFSH-induced bone formation (Fig 1), proving an ovary-dependent FSH pathway. Furthermore, RT-PCR analysis did not detect any FSH receptor mRNA expression in bone or cultured osteoblast or osteoclast RNA preparations, suggesting FSH does not directly act on bone via local FSH receptor pathways.

Our results indicate that FSH has anabolic effects on bone independent of LH activity. The mechanism of action involves the ovary with no evidence of any direct FSH effects on bone cells.

Intestinal Calcium Absorption Regulates Serum Calcium by Compensatory Modifications in Bone Mass and Mineralization. Liesbet Lieben*[1], Ritsuko Masuyama[1], Karen Moermans[3], Jan Schrooten[4], Peter Baatsen[5], Roger Bouillon[1], Geert Carmeliet[1]. [1]Laboratory of Experimental Medicine & Endocrinology, Katholieke Universiteit Leuven, Belgium, [2]Department of Metallurgy & Materials Engineering, Katholieke Universiteit Leuven, Belgium, [3]Center for Human Genetics/VIB, Katholieke Universiteit Leuven, Belgium

Calcium is vital to multiple cellular functions and is a crucial component of the mineral phase of bone. Intestinal calcium absorption is critical for calcium acquisition and is mainly controlled by vitamin D [$1,25(OH)_2D_3$]. To genetically confirm the importance of active intestinal calcium absorption, we generated mice with a specific deletion of the vitamin D receptor (VDR) in the intestine (Vdr^{int-}) by mating *Vdr* floxed mice with Villin-Cre mice.

Intestinal calcium absorption was impaired in Vdr^{int-} mice, but serum calcium levels remained normal, which contrasts with the severe hypocalcemia observed in systemic *Vdr* null mice. This finding implies compensatory mechanisms in Vdr^{int-} mice, likely activated by the increase in serum parathyroid hormone (PTH) and $1,25(OH)_2D_3$. Indeed, renal calcium reabsorption was increased and the calcium content of bone was reduced to minimal levels. Hence, Vdr^{int-} mice showed normal skeletal growth, but bone gain was compromised from weaning on due to a hormonally-mediated increase in bone turnover. The high rate of bone modeling was accompanied by osteocyte maturation defects; scanning electron microscopic (SEM) and histological analyses showed that Vdr^{int-} osteocytes were larger with fewer processes and with impaired expression of differentiation markers. In addition to the reduced bone mass, bone mineralization was compromised: excess osteoid was present on all bone surfaces and surrounding the osteocytes. Moreover, the mineral content of the newly formed cortical bone was reduced in Vdr^{int-} mice shown by backscattered SEM. Given that serum calcium and phosphate levels were normal in Vdr^{int-} mice, the decrease in mineral content suggests that mineralization is inhibited. Indeed, increased mRNA levels of mineralization inhibitors, including *Osteopontin* and the pyrophosphate transporter *Ank*, were detected in bones of Vdr^{int-} mice, and *in vitro* data showed a direct regulation of these markers by $1,25(OH)_2D_3$. Bone mass accrual was thus compromised to preserve normocalcemia in Vdr^{int-} mice by increasing bone turnover and decreasing mineralization and these adaptations resulted in bone fractures.

In conclusion, intestinal *Vdr* inactivation impaired intestinal calcium absorption and triggered an increase in PTH and $1,25(OH)_2D_3$, which prevented hypocalcemia, but severely impaired calcium deposition in bone. These findings underline the importance of active intestinal calcium absorption for bone, even during normal calcium intake.

Resistance to Bone Loss Through Altered Stem Cell Physiology in CMKLR1-Deficient Mice. Christopher Sinal, Shanmugam Muruganandan*. Dalhousie University, Canada

Previously, we reported that decreasing the expression of chemokine like receptor-1 (CMKLR1) in bone marrow stromal stem cells increases osteoblastogenesis in vitro through the abrogation of adipogenesis (J. Bone Miner. Res. 22(2):222-234). In the present study, we examined bone formation in mice deficient for CMKLR1 expression in vivo. A significant increase in bone mineral densities of both homozygous and heterozygous CMKLR1-deficient mice was observed at 16 weeks of age. To induce bone loss, we utilized a diabetic osteopenia mouse model 60 days after the administration of streptozotocin (40 mg/kg, i.p. for 5 days). Bone loss was monitored by Dual-Energy X-Ray Absorptiometry (DEXA), microcomputed tomography (μCT), histological and biochemical analyses. Unexpectedly, heterozygous but not homozygous CMKLR1-deficient mice exhibited a significant and marked resistance to bone loss in both DEXA and μCT analyses. Consistent with this, bone marrow stromal stem cells (BMSCs) derived from heterozygous but not homozygous CMKLR1-deficient mice exhibited a shift to osteoblast phenotype characterized by spontaneous osteoblast differentiation, formation of mineralized nodules and markedly elevated secretion of osteocalcin into the media even in the absence of any differentiation inducer. Furthermore, the osteoblast transcription factors including osterix and runx2 and the osteoblast marker genes, alkaline phosphatase and type I collagen were found to be highly expressed in stem cells from heterozygous CMKLR1-deficient mice. A potentiation of IGF signaling through IGFBP3 was observed in the stem cells derived from heterozygous CMKLR1-deficient mice. Histological analysis revealed a marked induction of bone marrow adipogenesis in homozygous but not heterozygous CMKLR1-deficient animals possibly as a compensatory response to the loss of CMKLR1. These findings of differential stem cell phenotypes with enhanced bone formation in heterozygous vs. homozygous CMKLR1 deficiency suggest a role for CMKLR1 in bone marrow stem cell physiology. Complete loss of CMKLR1 could initiate compensatory adipogenic mechanisms for induced adipogenesis in the homozygous CMKLR1 knockout animals.

Membrane-type MMPs MT1-MMP and MT3-MMP are Essential for Postnatal Skeletal Homeostasis. Joanne Shi*, Mi-Young Son, Susan Yamada, Pamela Gehron Robey, Kenn Holmbeck. NIDCR, USA

Purpose: The membrane-type matrix metalloproteinases MT1-MMP and MT3-MMP are expressed at high levels in skeletal tissues, including skeletal stem cells, where they facilitate remodeling of unmineralized collagenous matrices such and type I, II and III collagen. Loss of MT1-MMP leads to a severe and progressive disease affecting remodeling of certain unmineralized cartilages and connective tissues associated with the bone and ultimately leads to premature death from fibrosis. In contrast, ablation of MT3-MMP affects skeletal development less severely, although deficient mice display reduced skeletal growth. However, the significance of MT3-MMP function is highlighted by the perinatal demise of MT1-MMP/MT3-MMP double-deficient mice, which display severe skeletal dysmorphism with cleft palate.

Methods: Due to the premature death of MT1-MMP deficient and MT1-MMP/MT3-MMP deficient mice, the role of these proteinases in skeletal homeostasis cannot be assessed. To overcome this impediment, we have generated mice amenable to conditional ablation of MT1-MMP in conjunction with MT3-MMP deficiency using a tamoxifen sensitive ablation strategy.

Results: We report here that postnatal ablation of MT1-MMP and MT3-MMP is compatible with sustained survival. The principal function of MT-MMP activity is therefore associated with proteinase substrate interactions in development and early postnatal growth. Loss of MT-MMP activity in adulthood does however lead to rampant loss of bone mass associated with vigorous osteoclastic activity and a severe progressive fibrosis due to collagen accumulation in skeletal and peri-skeletal tissues.

Conclusion: The results of our analyses demonstrate that MT-MMP activity is essential for viability and development of the skeleton. In addition, sustained postnatal MT-MMP activity is required for fibrosis surveillance and regulation of osteoclast activity in skeletal homeostasis in adulthood. These observations demonstrate the central role of MT-MMPs in pericellular matrix remodeling and signaling modulation in skeletal stem cells and their progeny.

Transgenic Over-expression of Human TRPV6 in Intestine Increases Calcium Absorption Efficiency and Improves Bone Mass in Mice. Min Cui*, James Fleet. Purdue University, USA

TRPV6 is a calcium (Ca) channel proposed to mediate basal and 1,25 dihydroxyvitamin D-induced Ca absorption but recent findings in TRPV6 knockout mice suggest this may not be true. To further examine the role of TRPV6 in intestinal Ca absorption we generated transgenic (TG) mice with intestine-specific expression of flag-tagged human TRPV6 driven by the villin promoter. Two TG lines, FT1 (65

copies) and FT2 (6 copies), were characterized; TG mRNA expression was detected from duodenum to distal colon. FT1 mice developed hypercalcemia (15.2 mg/dl), hypercalciuria, bladder stones and systemic soft tissue calcification by 3 mo when fed a chow diet (0.9% Ca). To prevent hypercalcemia in FT1 mice, both FT1 and wild type (WT) mice were fed a 0.25% Ca diet from weaning to 8 wks. TG expression was still elevated in intestine (duodenal total TRPV6 mRNA 2000-fold higher, TRPV6 protein > 300-fold than WT) but serum Ca was only slightly elevated (10.8 mg/dl in FT1 vs. 9.1 mg/dl in WT). Active intestinal Ca absorption (serum $45Ca^{2+}$ accumulation 10 minutes after oral gavage) was increased by > 3-fold in FT1 mice while femur BMD was 26% higher than WT by DEXA. In addition, renal CYP24 mRNA was increased 16-fold and CYP27B1 mRNA was decreased by >95% while high TG expression reduced expression of the transcript for the natural mouse TRPV6 gene in all intestinal segments (<10% WT level). These effects indicate molecular attempts to compensate for high Ca absorption by suppressing vitamin D-regulated calcium absorption. High TG expression was also accompanied by an increase in calbindin-D9K mRNA in duodenum (14-fold) and jejunum (251-fold), suggesting an adaptation to buffer intracellular Ca levels resulting from high calcium absorption efficiency in FT1 mice. FT2 (low TG copy #) mice were indistinguishable from WT in phenotype when fed chow diet. To suppress natural TRPV6 expression, both FT2 and WT mice were fed a 2% Ca diet from weaning to 8 wks. Duodenal total TRPV6 mRNA was 30-fold higher than WT in FT2 mice. This was accompanied by increased serum Ca (11.8 mg/dl vs. 9.0 mg/dl in WT) and 9% higher femur BMD in FT2 mice. Our models demonstrate that TRPV6 is a functional calcium channel important for active intestinal Ca absorption.

***Lrp5* is Required for *Sost* Deficiency Induced Mineral Apposition Rate Increases.** Jonathan Gooi*[1], Ina Kramer[2], Christine Halleux[1], Michaela Kneissel[1]. [1]Novartis Institutes for Biomedical Research, Switzerland, [2]Novartis Institutes for BioMedical Research, Che

Sclerostin, the osteocyte secreted Sost gene product, binds in vitro to Lrp5 and 6 Wnt co-receptors thereby inhibiting canonical Wnt signaling and thus providing a putative molecular mechanism for sclerostin action as a negative regulator of bone formation. To determine whether Sost and Lrp5 interact in vivo we generated Sost;Lrp5 double knockout (KO) mice. We reported previously that bone mass gain was blunted in the long-bones of Sost;Lrp5 double compared to Sost single mutant mice (Kramer et al., J Bone Miner Res 24 Suppl. 1). Here we analyzed the vertebral cancellous bone of 6.5-month-old mutant and wildtype mice by micro computed tomography and histomorphometry.

Sost deficient mice displayed increased cancellous bone volume (females (F): +224%, males (M): +93%) compared to wildtype (WT) mice. Consistently, trabecular number and thickness were dramatically increased. Aged Lrp5 deficient mice showed a moderate reduction in bone volume (Lrp5-/- F: -7%, M: -10%) and other structural parameters compared to WT controls. In heterozygous Sost KO mice bone volume was mildly increased indicating a gene dosage effect (Sost+/- F: +25%, M: +26%). Heterozygous Lrp5 KO mice presented with non-significant changes in bone volume (Lrp5+/- F: -10%, M: +3%). Yet, heterozygous loss of Lrp5 was sufficient to blunt the increase in bone mass induced by Sost deficiency (Lrp5+/-;Sost-/- F: -20% M: -21% compared to Sost-/-). Consistently, homozygous loss of Lrp5 further blunted the bone volume increases of Sost mutants (Lrp5-/-;Sost-/- F: -33%, M: -25% compared to Sost-/-). Evaluation of bone formation dynamics revealed that the blunting of the high bone mass phenotype of Sost deficient mice due to Lrp5 loss-of-function was related to abrogation of mineral apposition rate (MAR) increases. Sost deficient mice displayed a marked increase in MAR (Sost-/- F: +30%, M: +37%) compared to WT controls. Lrp5 single mutant mice had slightly decreased MAR (Lrp5-/- F: -13%, M: -6%). While heterozygous loss of Lrp5 only partially reduced Sost deficiency induced MAR increases (Lrp5+/-;Sost-/- F +24%, M: +17%), homozygous loss of Lrp5 completely abolished MAR increases (Lrp5-/-;Sost-/- F: -16%, M: -4%).

Together, our data demonstrate that Lrp5 is required for Sost deficiency induced increases in mineral apposition rates, reflecting indirectly osteoblastic matrix deposition and hence performance. Thus, Sost targets in part Lrp5 dependent bone anabolic pathways to control bone formation in vivo.

Does Osteoporosis Therapy Invalidate FRAX® for Fracture Prediction? William Leslie*[1], Lisa Lix[2], Helena Johansson[3], Anders Oden[4], Eugene McCloskey[5], John Kanis[6]. [1]University of Manitoba, Canada, [2]University of Saskatchewan, Canada, [3]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [4]Consulting statistician, Sweden, [5]University of Sheffield, United Kingdom, [6]University of Sheffield, Belgium

Ten-year fracture risk assessment with FRAX® is increasingly used to guide treatment decisions. Osteoporosis pharmacotherapy (OTX) reduces fracture risk, but the antifracture effect is greater than can be explained from the increase in BMD. Whether this invalidates predictions from FRAX is uncertain. METHODS: All women age 50 y or older at the time of baseline BMD testing performed during 1996-2008 with retrospectively calculated FRAX probability were included in the analysis (N=35,764). A provincial pharmacy database was used to identify OTX prior to BMD (mean 7.5 y of OTX information) and in the first year after BMD testing (OTX use after the first year was not available). The medication possession (MPR) was calculated for OTX use in the year after BMD testing. Women were categorized as untreated (no OTX in the year after BMD testing, no OTX in the year before BMD testing and <6 m cumulative earlier OTX use), high adherence current OTX users (MPR 0.80 or greater in the year after BMD testing), low adherence current OTX users (MPR < 0.80 in the year after BMD testing), and past users (no OTX in the year after BMD testing with OTX in the year prior to BMD or > 6 months earlier exposure). Ten year major osteoporotic fracture probability from FRAX (Canadian tool) was categorized as low (< 10%), moderate (10-20%), or high (> 20%) in accordance with national guidelines. Fractures outcomes to 10 y (mean 5.3) were established through linkage within a population-based provincial health data repository. For each risk category and OTX subgroup, observed ten year fracture risk was estimated using the Kaplan-Meier (KM) method. Calibration plots (predicted versus observed) were constructed for each OTX group. RESULTS: FRAX stratified major osteoporotic fracture risk in all OTX subgroups (all p<.001) with similar ROC area under curve (untreated 0.66, current OTX [MPR >80%] 0.67, current OTX [MPR <80%] 0.71, prior OTX 0.69; overall 0.70; all p<.001). There was a significant linear trend for higher major osteoporotic and hip fracture rates according to FRAX risk category for all OTX subgroups (all Cochran-Armitage p<.001). Calibration plots did not show significant differences for the four OTX subgroups (see Figure). In particular, there was close agreement in FRAX calibration for the untreated and most highly adherent current OTX users. CONCLUSION: FRAX continues to predict fracture risk in women currently or previously receiving OTX.

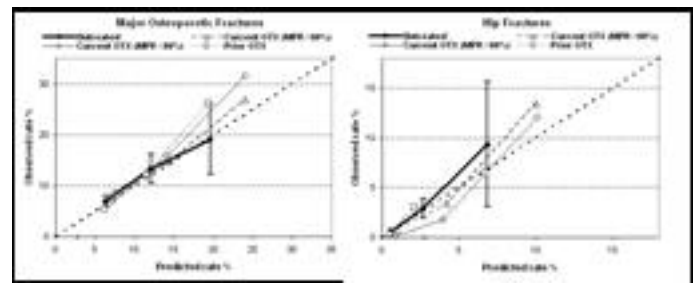

Figure. Predicted 10y fracture risk from FRAX (X-axis) vs observed 10y fracture rates (Y-axis).

Non-Hip Femoral Fractures in Patients on Bisphosphonate Therapy: a Population-Based Study from Olmsted County, Minnesota. Alvin Ng*[1], Matthew Drake[2], Stephen Sems[2], Sara Achenbach[3], Elizabeth Atkinson[4], L. Joseph Melton[5], Bart Clarke[2]. [1]Mayo Clinic Division of Endocrinology, Diabetes, Metabolism, & Nutrition, USA, [2]Mayo Clinic College of Medicine, USA, [3]Mayo Clinic Divsion of Biostatistics, Department of Health Sciences Research, USA, [4]Mayo Clinic Division of Biostatistics, Department of Health Sciences Research, USA, [5]Mayo Clinic Division of Epidemiology, Department of Health Sciences Research, USA

Purpose Long-term bisphosphonate (BP) therapy may be associated with increased risk of minimally traumatic non-hip femoral fractures (NHFF). This study was done to determine incidence rates of NHFF in Olmsted County, MN, before and after introduction of alendronate into clinical practice.

Methods All NHFF events among Olmsted County, Minnesota, residents in 1984-2007 were identified. Incidence rates were assessed before and after 1996, when the oral BP alendronate was approved for clinical practice, and compared to historical incidence rates in Olmsted County from 1965-1984.

Results From 1984-2007, 730 NHFF were observed in 691 residents. Affected residents were 50.8% female, with mean age at first fracture of 59.7 years; and 49.2% male, with mean age 31.5 years. Of the 691 subjects with NHFF, 653 had one, 37 had two, and 1 had 3 fractures. Of these fractures, 20.4% were subtrochanteric, 51.7% were mid-diaphyseal, and 27.9% involved the distal femur. Fractures were due to severe trauma in 51.1%, minimal to moderate trauma in 34.2%, and pathologic causes in 14.8%.

Among 691 residents with a first-ever NHFF, the total cumulative age- and sex-adjusted incidence (ASAI) from 1984-2007 was 26.8 ± 1.0/100,000 person-years, with age-adjusted incidence (AAI) for women 25.0 ± 1.4/100,000 person-years, and AAI for men 26.8 ± 1.6/100,000 person-years. Incidence rates of first-ever NHFF for women increased between 1984 and 1995, and between 1996-2007 (p=0.001), but did not change for men (p=0.125). For 1984-1995, the cumulative ASAI was 21.9 ± 1.4/100,000 person-years, with AAI for women 20.2 ± 1.9/100,000 person-years, and AAI for men 22.0 ± 2.0/100,000 person-years. For 1996-2007, the cumulative ASAI was 30.4 ± 1.5/100,000 person-years, with AAI for women 28.9 ± 2.0/100,000 person-

years, and AAI for men 30.0 ± 2.2/100,000 person-years. The incidence rate of first-ever NHFF from 1984-1995 was lower than the rate of first-ever NHFF from 1965-1984 (37.1/100,000 person-years). Three males and 27 females were taking a bisphosphonate at the time of first-ever NHFF. If patients using bisphosphonates from 1996-2007 were removed from consideration, the AAI rate for first-ever NHFF from 1996-2007 was 25.3/100,000 person-years for females, and 29.5/100,000 person-years for males, with both rates higher than in 1984-1995.

Conclusion The incidence rate of first-ever NHFF increased between 1984-1995 and 1996-2007, driven by a small increase in the rate for women after the introduction of alendronate into clinical practice in 1996.

A Retrospective Analysis of all Atypical Femur Fractures Seen in a Large California HMO from the Years 2007 to 2009. Richard Dell[1], Denise Greene[1], Susan Ott*[2], Stuart Silverman[3], Eric Eisemon[4], Tadashi Funahashi[1], Annette Adams[1]. [1]Kaiser, USA, [2]University of Washington, USA, [3]Cedars Sinai, USA, [4]Maimonides Medical Center, USA

Nontraumatic fractures of the femoral diaphysis with an unusual appearance have been recently reported in patients on long term oral bisphosphonates. These case series have not been able to enumerate the population at risk and the incidence of these atypical fractures has not been defined. We therefore conducted a study in a defined population to characterize these fractures and estimate their incidence. Using electronic data sources from a large California health maintenance organization, we identified all subtrochanteric and femur shaft fractures that occurred in patients aged 45 years or older between 1/1/2007 and 12/31/2009. All fractures above the subtrochanteric femur

region and below the distal femoral flair were excluded, as were periprosthetic fractures, pathologic fractures secondary to tumor, and high energy fractures.

The HMO serves 2.6 million patients 45 years or older. Records on over 15,000 femur fractures cases were screened and over 600 radiographs were then reviewed that meet inclusion criteria. We identified those with atypical features that included lateral cortical thickening, a transverse fracture with short oblique extension medially, and flaring of the lateral cortex. For all patients with qualifying fractures, demographic, clinical, and pharmacy data were gathered. 102 patients (99 women, 3 men) had the characteristic radiographic findings. 61% of the fractures occurred in the shaft region and 39% in the subtrochanteric region. 25% of the patients had either a complete fracture or stress fractures on the contralateral femur. The average age was 72 years old (range 45 to 92). Prodromal pain was reported by 70% of the patients. Five patients had not taken a bisphosphonate and 97 patients were on oral bisphosphonates with an average duration of use of 5.5 years. There was no correlation between the duration of bisphosphonate use and the patient age. Based on the number of patients receiving oral bisphosphonate treatment in our HMO (300,000 filled at least one prescription since 2002), preliminary estimates of atypical femur fracture incidence show a progressive increase with longer duration of treatment, from 2:100,000 per year to 78:100,000 cases per year as the duration of treatment went from 2 years to 8 years of oral bisphosphonate treatment.

These preliminary incidence estimates suggest that atypical femur fractures are rare in the general population, but may be more common among patients with longer-term oral bisphosphonate use.

Long-term Mortality after Low-energy Fractures at Middle-age - a Study of 22 000 Men and 11 000 Women. Anna H Holmberg*[1], Jan-Åke Nilsson[1], Peter M Nilsson[2], Kristina Åkesson[3]. [1]Dpt of Orthopedics, Skåne University Hospital, Malmö, Sweden, [2]Dpt of Internal Medicine, Skåne University Hospital, Malmö, Sweden, [3]Dpt of Clinical Sciences, Malmö, Clinical & Molecular Osteoporosis Research Unit, dpt of orthopedics, Skane University Hospital, Malmö, Sweden

The aim of this study was to examine long-term effects of a low-energy fracture on mortality rates in an urban middle-aged population. How long does the increased mortality risk persist? What types of fractures influence mortality risk? Are there any sex differences in mortality rates?

Methods: The Malmö Preventive Project consists of 10902 women and 22444 men, mean age at inclusion 50 and 44 years respectively.The subjects were followed prospectively regarding fractures and mortality up to 32 years. The subjects were subdivided according to sex and age at first fracture; <50, 50-59, 60-69 and ⩾70 yrs of age and further subdivided according to type of first fracture; forearm, shoulder, hip, clinical vertebral, ankle or other fracture. Standardised mortality rates (SMR), adjusted for age, sex and calendar year, were calculated per 100 person-years (p-yrs) with data from Statistics, Sweden, using the southern region (approx. 1 000 000 inhab) as background population. Dates of death was obtained from the National Board of Health and Welfare, Sweden.

Results: 2069 women and 1800 men sustained fractures and of these 332(16%) women and 648(36%) men died. In women, sustaining any type of fracture increased the 25-yr mortality risk in all ⩾50 yrs (SMR 126-237/100 p-yrs, CI 95% 102-295). A hip fracture at age 60 or more increased the 25-yr mortality risk up to 6 times (SMR 293-601/100 p-yrs, CI 95% 184-852). Vertebral fractures increased the 25-yr mortality risk in women 60-69 yrs (SMR 233/100 p-yrs, CI 95% 101-364).

In men, sustaining any type of fracture increased the mortality risk in all age groups up to 25 yrs (202-284/100 p-yrs, CI 95% 174-329). A hip fracture at age 50 or more increased the 25-yr mortality risk up to 4 times (391-463/100 p-yrs, CI 95% 249-598). Vertebral fractures increased the mortality risk up to 25 yrs post-fracture in all age-groups (SMR 260-375/100 P-yrs, CI 95% 133-607).

In both women and men, shoulder fractures were associated with an increased mortality risk up to 25 yrs, but the effect was small. Ankle fractures did not affect mortality in women, but almost doubled the risk in men aged 50-59 yrs at the fracture event (SMR192/100 p-yrs, CI 95% 126-259).

Conclusions: Any type of low-energy fracture in middle-age significantly influence long-term mortality in both women and men, with a higher impact in men. Hip fractures have the most pronounced effect, but any low-energy fracture in middle-age should be considered a sign of frailty.

Bone Age- a Novel Index of Age Based on Bone Mineral Density: A Multi-cohort Analysis. Yahtyng Sheu*[1], Anne Newman[1], Peggy Cawthon[2], Tamara Harris[3], Frances Tylavsky[4], Kristine Ensrud[5], Eric Orwoll[6], Jane Cauley[1]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]California Pacific Medical Center Research Institute, USA, [3]Intramural Research Program, National Institute on Aging, USA, [4]University of Tennessee, Memphis, USA, [5]Minneapolis VA Medical Center / University of Minnesota, USA, [6]Oregon Health & Science University, USA

Bone mineral density (BMD) and chronological age are strong risk factors for osteoporotic fractures. We investigated "bone age" as an alternative means to understand an individual's biologic age. Data from the Health Aging and Body Composition (HABC, n=3043, aged 68-80 yrs) study, the Osteoporotic Fractures in Men (MrOS, n=5600, aged 65+ yrs) study, and the Study of Osteoporotic Fracture (SOF, n=7546, aged 65+ yrs) was used. To calculate study-specific bone age, we modeled incident risk of non-traumatic and non-spine fracture as a function of chronological age "$h(t|age)=exp(\beta_0+ \beta_1 age)$" and then as a function of femoral neck BMD "$h(t|BMD)=exp(\gamma_0+ \gamma_1 BMD)$" separately using the exponential survival model. We then equated the hazards and solved for age to yield the following estimate of bone age by using in the maximum likelihood estimates for each parameter: $(\gamma_0-\beta_0)+\gamma_1 BMD)/\beta_0$. Bone age is then the risk-equivalent of femoral neck BMD. Results from the Cox regression model (adjusted for race, gender, and/or clinic sites when applicable) showed, in all three studies, that individuals with bone age greater than their chronological age were more likely to experience incident non-spine fracture (Table). Hazard ratios (HRs) for fractures among individuals with bone age 5 yrs older than their chronological age, compared to those with a bone age and chronological age difference within +/- 5 yrs, were 16-36% more likely to have fracture, while the risk was 13-61% lower among individuals with bone age 5 yrs younger than their chronological age (Table). All findings were statistically significant for HABC and SOF, except MrOS studies. Results remained similar when models were further adjusted for weight, height, current smoking status and fracture history. Older adults with younger bone age may have a reduced risk of fracture. Unlike other subclinical measures such as glucose and blood pressure, general public does not comprehend values of BMD or T-score until later in their life. The concept of bone age may provide an easily understandable translation of fracture risk to patients in order to tailor preventive treatments.

	HABC	MrOS	SOF
Follow-up time (yr)	7.7	7.5	13.2
Number of fracture cases	308 (10%)	579 (10%)	3115 (41%)
HR and 95% confidence interval for fractures for "bone age minus chronological age"			
Every +5 yrs difference	1.36 (1.26, 1.47)	1.09 (1.04, 1.14)	1.13 (1.10, 1.16)
< -5 yrs v.s. within ± 5 yrs	0.36 (0.28, 0.54)	0.87 (0.72, 1.06)	0.80 (0.73, 0.87)
> 5 yrs v.s within ± 5 yrs	1.36 (1.06, 1.75)	1.16 (0.95, 1.41)	1.24 (1.14, 1.35)

Direct Comparison of Four National FRAX® Tools for Fracture Prediction. William Leslie*[1], Lisa Lix[2], Helena Johansson[3], Anders Oden[4], Eugene McCloskey[5], John Kanis[6]. [1]University of Manitoba, Canada, [2]University of Saskatchewan, Canada, [3]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [4]Consulting statistician, Sweden, [5]University of Sheffield, United Kingdom, [6]University of Sheffield, Belgium

A FRAX® model for Canada was constructed for prediction of osteoporotic and hip fracture risk using national hip fracture data (2005) and mortality data (2004), with and without use of femoral neck BMD. Performance of this model was compared

with FRAX tools from the US (white), UK and Sweden. METHODS: We identified 36,730 women age 50+ with baseline BMD testing in the Manitoba BMD Program database which captures all clinical DXA results for the Province of Manitoba, Canada. FRAX probabilities were calculated based upon age, BMD, BMI and additional clinical risk factors (proxies used for smoking and high alcohol intake, adjustments were made for incomplete parental hip fracture information). Linkage with other provincial health databases allowed for the direct comparison of fracture risk estimates from the FRAX tools with observed fractures up to ten years (506 women with incident hip fractures and 2,380 with major osteoporotic fractures). Kaplan-Meier (KM) estimates of 10 year fracture risk were compared with predicted probabilities in subgroups defined by quintiles in fracture probability to assess fracture discrimination and calibration. RESULTS: The ten year KM estimate of major osteoporotic fractures for all women was 12.1% (95% CI 10.8-13.4%) and for hip fractures was 2.7% (95% CI 2.1-3.4%). The average FRAX probabilities from the Canadian tool were 11.1% and 2.8% respectively, which were within the observed CIs. FRAX estimates with the UK tool were similar to Canada (ratios for major osteoporotic 0.98 and for hip 1.07), were slightly higher with the US tool (ratios 1.11 and 1.09), and were much higher with the Swedish tool (ratios 1.27 and 1.78). The calibration plots (Figure) showed no significant difference in hip fracture discrimination/calibration with the Canada, US or UK tools but poor calibration with the Swedish tool (observed rates lower than predicted). Prediction of major osteoporotic fractures showed clinically insignificant differences between the Canada, US, and UK tools, but again the Swedish tool showed poor calibration (observed rates lower than predicted). CONCLUSION: Although the US and UK FRAX models gave predictions close to the Canadian FRAX model, the Swedish FRAX model significantly overestimated risk in Canadian women. This analysis supports the need for country-specific FRAX models based upon national fracture epidemiology.

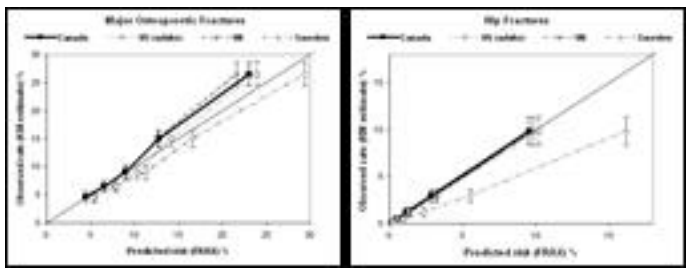

Figure: Predicted 10y fracture risk from FRAX (X-axis) vs observed K-M 10y fracture rates (Y-axis).

Lipoxygenase Alox15 is a Cell Autonomous Amplifier of Oxidative Stress in Osteoblasts and the Skeleton of Estrogen Deficient and Aged Mice. Robert Jilka*, Maria Jose Almeida, Elena Ambrogini, Leslie Climer, Stavros Manolagas. University of Arkansas for Medical Sciences, USA

Loss of bone with advancing age in C57BL/6 mice is accompanied by a progressive increase in reactive oxygen species (ROS) and osteoblast apoptosis, as well as a decrease in osteoblast number and bone formation rate. The increase in ROS is associated with a 5-fold rise in the expression of Alox15, a lipoxygenase that contributes to oxidative stress (OS) in the skeleton by oxidizing polyunsaturated fatty acids to produce the strong pro-oxidant 4-hydroxynonenal. However, the cause of the increased Alox15 expression with age is unknown. Prompted by evidence for high expression of Alox15 in embryonic fibroblasts with increased ROS due to deletion of glutathione peroxidase (Seiler et al, Cell Metab 8:237, 2008), we examined the possibility that ROS stimulate the expression of Alox15. We report that OS caused by addition of H_2O_2, or a xanthine/xanthine oxidase system that generates H_2O_2 continuously, increased the expression of Alox15 by 2-4 fold in murine bone marrow-derived osteoblastic cells. OS also increased Alox15 expression in the vertebrae. Thus, 4 month old mice lacking FoxOs1,3 and 4 (transcription factors that stimulate the expression of anti-oxidant enzymes) exhibited an increase in both OS and Alox15 compared to their control littermates; whereas expression of other lipoxygenases, including Alox12, Alox12b, Alox12e and Alox15b, was unaffected by FoxO deletion. Similar to FoxO1,3,4 deletion, the increased OS caused by ovariectomy in 6 month old mice increased Alox15 expression, and estrogen replacement prevented the increase of both OS and Alox15. On the other hand, suppression of OS by administration of the anti-oxidants N-acetyl cysteine or catalase to 24 month old C57BL/6 mice reduced expression of Alox15 to the level seen in 6 month old mice. Finally, as reported elsewhere in this meeting, the enhanced anabolic efficacy of intermittent PTH in 26 month old mice was associated with a reduction in both OS and Alox15 expression to the levels seen in 6 month old mice. We conclude that ROS stimulates the expression of Alox15 in cells of the osteoblast lineage in a cell autonomous fashion. Because Alox15-mediated lipid oxidation and generation of 4-hydroxynonenal further increases OS, we hypothesize that Alox15 is part of a positive feedback loop that both amplifies and perpetuates OS in the skeleton, thereby contributing to bone loss caused by estrogen deficiency or advancing age.

Tissue-Specific Knock-in of Constitutively Active IKKβ Leads to Bone Loss in Mice. Kaihua Zhang*[1], Jesse Otero[1], Muhammad Alhawagri[1], Isra Darwech[1], Yousef Abu-Amer[2]. [1]Washington University, USA, [2]Washington University in St. Louis School of Medicine, USA

Osteoclast differentiation requires stimulation of monocytes/macrophages with receptor activator of NF-κB (RANK) ligand. The ensuing signaling cascade results with activation of multiple pathways, primarily NF-κB. We have reported recently that constitutively active IKKβ ($IKK\beta^{SSEE}$), but not other forms of IKKβ or IKKα, stimulates differentiation of monocytes into *bona fide* functional osteoclasts in a RANK-independent fashion. To validate the physiological relevance of these findings, we generated a tissue-specific knock-in of $IKK\beta^{SSEE}$. Specifically, we utilized the R26Stop$IKK\beta^{SSEE}$ mice in which a cDNA encoding IKKβ containing two serine to glutamate substitutions in the activation loop of the kinase domain, preceded by a loxP-flanked STOP cassette, into the ubiquitously expressed ROSA26 locus. We crossed mice carrying this allele with the CD11b-cre mice in order to express $IKK\beta^{SSEE}$ exclusively in myeloid cells, including osteoclasts. Macrophages and osteoclasts derived from CD11bCre/R26Stop$IKK\beta^{SSEE}$ (Cre+/$IKK\beta^{SSEE}$) express Flag-tagged $IKK\beta^{SSEE}$ detected by Western blot. Real-time PCR showed that $IKK\beta^{SSEE}$ upregulates NFATc1 expression in macrophage/osteoclast lineage (p=0.008). $IKK\beta^{SSEE}$ also significantly enhanced TRAP (p=0.003) and CTR expression (p=0.007) compared to control. Noticeably, heterozygotes and homozygotes Cre+/$IKK\beta^{SSEE}$ mice displayed severe osteopenia due to hyperactive and increased number of osteoclasts which was also reflected by two-fold increase of serum TRACP 5b activity (10.59 U/L vs 4.93 U/L). Micro-CT and histological analyses showed that Cre+/$IKK\beta^{SSEE}$ mice lost half of the trabecular bone compared with control littermates, while marginal reduction of cortical bone was observed. To explore the mechanism underlying enhanced osteoclast activity in Cre+/$IKK\beta^{SSEE}$ mice, we further analyzed the expression and secretion of osteoclastogenic (RANKL and OPG) and inflammatory factors (TNFα and IL1β) in these mice. Serum levels of RANKL and TNFα remain normal, however serum IL1β increased significantly (p=0.018) compared to WT. Interestingly, serum level of OPG also increased dramatically (p=0.019), probably reflecting a negative feedback mechanism in Cre+/$IKK\beta^{SSEE}$ mice. Taken together, our findings indicate that in vivo expression of active IKKβ causes accelerated bone loss and leads to osteopenia in mice. Thus, we surmise that active IKKβ is a key culprit of bone erosion and as such is a promising target for therapeutic intervention.

Neuropeptide Y, Y6 Receptor, a Novel Regulator of Bone Mass and Energy Homeostasis. Frank Driessler*[1], Ernie Yulyaningshi[2], Ronaldo Enriquez[2], Amanda Sainsbury[2], Herbert Herzog[2], John Eisman[1], Paul Baldock[1]. [1]Garvan Institute of Medical Research, Australia, [2]Garvan Institute, Australia

The view of bone remodelling as an endocrine-paracrine-regulated process is rapidly changing with new evidence demonstrating that neuronal factors also potently modify the activity of bone cells. Neuropeptide Y (NPY) is the most abundant peptides in mammalian brain, inducing a variety of effects through 5 distinct NPY receptors. Hypothalamic Y2 and osteoblastic Y1 receptors are reported to be critical in the regulation of bone homeostasis. However, to date, the role of Y6 receptors is poorly defined. Y6 shares 60% sequence identity with the Y1 receptor, which, in addition to bone effects, is also involved in energy homeostasis. To understand the functional role of Y6 receptors in energy and bone homeostasis we generated Y6 null mice and characterised their phenotype.

$Y6^{-/-}$ mice are viable with equal gender distribution. Deletion of Y6 receptors significantly reduced body weight (11%) through reduced lean (8.6%) and fat mass (32.5%). This is associated with increased in energy expenditure and an elevated respiratory quotient, indicative of decreased preference for lipid as fuel. These metabolic phenotypes are accompanied by significant reduction in BMD (mg/cm^2) and BMC (mg) on a whole body level as well as for isolated femurs (femur BMD: 47.10 ± 1.1 vs. 57.94 ± 2.4, $p<0.01$; femur BMC: 18.58 ± 0.1 vs. 23.71 ± 1.0, $p<0.05$). Importantly, these changes were evident despite no change in femur length.

μCT analyses indicted that cancellous BV/TV (%) was significantly decreased in $Y6^{-/-}$ compared to wt values (7.30 ± 0.5 vs. 10.13 ± 0.7, $p<0.01$), with a significant loss of trabecular number (mm^{-1}) (1.36 ± 0.1 vs. 1.81 ± 0.1, $p<0.01$) albeit no change in trabecular thickness (μm) (wt $55.6. \pm 1$ vs. $Y6^{-/-}$ 53.5 ± 1, ns). A significant loss of cortical thickness (μm) was found in $Y6^{-/-}$ (18.37 ± 1.6 vs. 21.29 ± 6.2, $p<0.01$) accompanied by significant reduction in periosteal surface (mm) (wt: 5.45 ± 0.1 vs. $Y6^{-/-}$ 5.13 ± 0.1, $p<0.05$) with no change in endosteal (mm) surface of the bones (wt: 4.12 ± 0.1 vs. $Y6^{-/-}$ 4.02 ± 0.1, ns).

Together these results suggest an important role of the Y6 receptors in energy and bone homeostasis. The reduction bone mass evident in $Y6^{-/-}$ mice is in contrast to other NPY-mediated models, indicating the potential for a counter regulatory role if Y6 within the NPY system.

Brain-derived Neurotrophic Factor Regulates Bone Mass and Energy Homeostasis via the Central Nervous System. Claudia Camerino*[1], Peter Hauschka[2], Majd Zayzafoon[3], Maribel Rios[4]. [1]Center for Advanced Orthopaedic Beth Israel Deaconess Medical Center Boston, USA, [2]Children's Hospital Boston, USA, [3]University of Alabama at Birmingham, USA, [4]Tufts University school of medicine, Department of Neuroscience, USA

Brain-derived Neurotrophic Factor (BDNF) is a member of the neurotrophin family which includes nerve growth factor, neurotrophin-3 and neurotrophin-4/5. BDNF promotes neurite outgrowth and provides trophic support to certain neurons during development and in adulthood. BDNF, and the functional full-length form of its receptor, TrkB, are expressed in various hypothalamic nuclei associated with eating behavior and obesity, which makes it plausible that BDNF may act via the hypothalamic neuronal system. Further, the pharmacological profile of BDNF is strikingly similar to that of leptin, an adipocyte-derived satiety hormone that regulates body adiposity and bone mass in part through activation of the sympathetic nervous system. To determine the effect of BDNF on bone mass and metabolism we evaluated BDNF conditional knock out (KO) mice, in which BDNF expression was deleted from the brain through the use of the Cre-loxP recombination system (Rios et al, 2001). In both males and females, at 3 and 6 mo of age, central BDNF deletion leads to a metabolic phenotype characterized by hyperphagia, increased body weight, elevated serum levels of insulin and glucose, and leptin resistance. The mice are hyperactive with upregulation of UCP1 in brown adipose tissue at older ages. The BDNF conditional KO mice also have 40% greater fat pad weight than wild type littermates, and show evidence of liver steatosis at older ages, thus confirming diabetic status. Regarding the skeletal phenotype, BDNF KO mice have increased femur length (+6%, $p<0.01$) and greater femoral BMD (+30%, $p<0.001$) and BMC (+50%, $p<0.001$). μCT analysis of the femurs and vertebrae of 3 mo old BDNF KO mice reveal significantly greater trabecular BV/TV (+50% for distal femur, $p<0.001$ +35% for vertebral body, $p<0.001$) and mid-femoral cortical thickness (+11 to 17%, $p<0.05$). Bone microarchitecture was also enhanced at 6 mo of age, with more pronounced effect in females than males. Taken together these data identify a novel non-neurotrophic function for neurotrophins and provide evidence that the BDNF-to-TrkB signaling plays a role in the central regulation of bone homeostasis.

PTH Attenuates H_2O_2- and Glucocorticoid-induced Suppression of Wnt Signaling via an Akt-dependent Mechanism: a Mechanistic Explanation for the Efficacy of Intermittent PTH in Old Age- and Glucocorticoid-induced Osteoporosis. Maria Jose Almeida*, Shoshana Bartell, Stavros Manolagas, Robert Weinstein, Robert Jilka. University of Arkansas for Medical Sciences, USA

Intermittent PTH administration is an effective regimen for increasing bone mass and reducing the incidence of fractures in the osteoporosis that occurs with advancing age or with glucocorticoid administration, but the underlying mechanisms are unclear. Studies in mice show that age-related bone loss is due to increased oxidative stress (OS) and a rise in endogenous glucocorticoids, and is associated with reduced Wnt signaling. OS inhibits Wnt signaling by activating FoxOs and diverting β-catenin from Tcf- to FoxO-mediated transcription, whereas glucocorticoids attenuate Wnt signaling in part by inhibiting Akt phosphorylation leading to activation of GSK3β, a negative regulator of β-catenin. Interestingly, PTH activates Akt, and in studies reported elsewhere at this meeting, we show that the increased efficacy of intermittent PTH in old mice is associated with a reduction in oxidative stress and increased Wnt signaling. Therefore, we investigated here whether PTH reverses the negative effects of OS or glucocorticoids on Wnt signaling, and if so whether such effects are mediated by Akt. PTH stimulated β-catenin/Tcf transcriptional activity in UAMS-32P (expressing high levels of PTH receptor) and UMR-106 osteoblastic cells, as measured by a Tcf-luciferase (Tcf-luc) reporter construct. More important, pre-incubation with PTH prevented the H_2O_2- and dexamethasone-induced suppression of basal and Wnt3a-stimulated β-catenin/Tcf transcriptional activity. Moreover, PTH stimulated the phosphorylation of Akt, and attenuated the negative effect of dexamethasone on Akt phosphorylation. Consistent with a role of Akt in this effect of PTH, a dominant negative mutant of Akt abrogated the stimulatory effect of PTH on Tcf-luc activity, and also prevented the protective effect of PTH on H_2O_2-induced suppression of Wnt signaling. Like PTH, overexpression of Akt attenuated the dexamethasone-induced decrease in Wnt signaling. Akt could have promoted β-catenin/Tcf transcriptional activity by phosphorylating and thereby inactivating FoxOs, which would increase levels of β-catenin. Supporting this contention, PTH prevented H_2O_2-induced FoxO activation as measured by a FoxO-luciferase reporter. These findings support the hypothesis that the ability of PTH to attenuate old age- and glucocorticoid-induced bone loss is due at least in part to an Akt-mediated reversal of oxidative stress- and glucocorticoid-induced suppression of Wnt signaling.

RAD140: A Novel Non-steroidal SARM with Anabolic Activity in Rats and Non-human Primates. Gary Hattersley*[1], Maysoun Shomali[1], Kyla Gallacher[2], C. Richard Lyttle[3], Chris Miller[2]. [1]Radius, USA, [2]Radius Health, Inc, USA, [3]Radius Health Inc, USA

RAD140 is a novel nonsteroidal selective androgen receptor modulator (SARM) selected for potent oral anabolic activity, tissue selectivity and safety profile. RAD140 binds to the androgen receptor with nanomolar affinity and demonstrates good binding selectivity against a broad panel of molecular targets including nuclear hormone receptors. Muscle anabolism and tissue selectivity were initially evaluated in castrated and intact immature rats by assessing the effects on the levator ani muscle and prostate. In immature rats, castrated 7 days before initiation of treatment, daily oral dosing with 0.3 mg/kg RAD140 resulted in a significant increase in levator ani weight (wt), which was comparable to the wt of intact controls. In contrast, 10 mg/kg was required to restore prostate wt. Treatment with testosterone proprionate at 1 mg/kg resulted in a greater increase in prostate wt than 10 mg/kg RAD140, yet increased levator ani wt less than the maximal stimulation with RAD140. Similar experiments in intact immature rats revealed significant increases in levator ani wt with 0.1 mg/kg RAD140, while prostate wt was significantly increased only at 30 mg/kg. The effects of RAD140 on the male reproductive system were further assessed in a 12-week study in adult intact rats, where RAD140 up to 3 mg/kg did not stimulate but rather reduced prostate size, while maintaining the levator ani. In contrast, DHT administration markedly increased both prostate and levator ani wt. Using ovariectomized (OVX) rats, RAD140 showed positive effects on both trabecular and cortical bone, preventing OVX-induced BMD decrease in both the femur and lumbar spine at doses as low as 0.3 mg/kg. The increase in BMD was associated with improvements in trabecular and cortical bone microarchitecture, including increased cortical thickness in the femoral diaphysis. Consistent with these changes, several parameters of bone quality were also significantly enhanced as shown in femur 3-point bending and lumbar spine compression analysis. The anabolic activity of RAD140 was also demonstrated in male Cynomolgus monkeys, where daily treatment with RAD140 for 28 days at 0.1 mg/kg resulted in an 11% increase in body wt, which was predominantly associated with increased lean tissue mass. These results show potent muscle and bone activity of RAD140 with a low impact on reproductive tissues and could represent a valuable new therapeutic agent for treatment of conditions such as frailty and cachexia.

Oral Contraceptive Use and Change in Bone Density among Adolescent and Young Adult Women: Results from a Prospective Study. Delia Scholes*[1], Laura Ichikawa[2], Rebecca Hubbard[2], Andrea LaCroix[3], Leslie Spangler[2], Jeannette Beasley[2], Susan Ott[4]. [1]Group Health CooperativeGroup Health Research Institute, USA, [2]Group Health Cooperative, USA, [3]Women's Health Initiative, Fred Hutchinson Cancer Research Ctr, USA, [4]University of Washington, USA

Although an estimated 12 million US women use combined oral contraceptives (OCs), the possible adverse impacts of current OC formulations on bone mass gains remain unclear. Particularly needed are evaluations of bone changes that incorporate age, OC dose, duration of use, and potential reversibility of any impacts with discontinuation. The purpose of this study was to compare bone mineral density (BMD) changes in adolescent (14-18) and young adult (19-30) OC users and non-users, examining OC estrogen dose and duration, anatomic site, and changes following OC discontinuation.

In a population-based prospective cohort study, 606 women enrollees of Group Health Cooperative (WA state) were recruited using the plan's computerized databases: 389 were initiating and prevalent OC users (62% were using 30-35 mcg ethinyl estradiol (EE) OCs, 38% were using <30 mcg EE); and 217 were age-similar non-users. Just over half (51%) of the cohort was 14-18 years of age. BMD was measured every 6 months for at least 24 months. We collected data on OC use and other important covariates via interview and survey. Cohort retention was 78% at 24 months of follow-up. Linear regression models were used to compare 24-month mean BMD percent change for OC users vs. non-users by age (14-18 and 19-30 years) and OC dose (30-35 mcg EE and <30 mcg EE) at the hip, spine, and whole body. The models were adjusted for age, race, current smoking, BMI, period regularity, calcium intake, physical activity, baseline BMD, and duration of OC use at baseline.

In these analyses, 14-18 year-olds using 30-35 mcg EE OCs, but not those using <30 mcg EE OCs, had smaller adjusted 24-month mean BMD percent gains than non-users at the spine (0.54% vs. 1.81%, p=0.02) and whole body (1.22% vs. 1.89%, p=0.08) (Fig. A). Differences from non-users increased significantly with increasing duration of 30-35 mcg EE OC use at all anatomic sites. In 19-30 year-olds, mean 24-month percent changes in OC users did not differ from non-users at any anatomic site, regardless of OC EE dose (Fig. B).

These results suggest that use of 30-35 mcg EE OC formulations, particularly longer-term use, is associated with reduced bone accrual in adolescents. In young adult women with more complete bone accrual, bone changes were similar between OC users and non-users.

Effect of Gonadal and Adrenal Steroid Replacement on Bone Cross-Sectional Geometry in Young Women with Anorexia Nervosa: A Hip Structural Analysis Study. Amy DiVasta*[1], Henry Feldman[1], Meryl Leboff[2], Thomas Beck[3], Catherine Gordon[4]. [1]Children's Hospital Boston, USA, [2]Brigham & Women's Hospital, USA, [3]Johns Hopkins Outpatient Center, USA, [4]Children's Hospital Boston & Harvard Medical School, USA

Purpose: Young women with anorexia nervosa (AN) have suppressed concentrations of dehydroepiandrosterone (DHEA) and estrogen that may contribute to the low bone mineral density (BMD) and skeletal fragility seen commonly in these patients. Previous studies have shown that HRT alone does not prevent bone loss in AN. We previously reported that DHEA led to increased areal bone density Z-scores (aBMD-Z), but the effects were offset by accompanied weight gain. In the current study, we aimed to determine the effects of an 18-mo regimen of oral DHEA + hormone replacement therapy (HRT) vs. placebo on bone cross-sectional geometry in young women with AN.

Methods: Eighty women with AN, aged 13-27 yr, received a random, double-blinded assignment to micronized DHEA (50 mg/d) + HRT (20μg ethinyl estradiol/ 0.1mg levonorgestrel) or placebo for 18 mo. Measurements of aBMD at the total hip, lumbar spine, and whole body were obtained by dual-energy X-ray absorptiometry at 0, 6, 12, and 18 mo. We used the Hip Structural Analysis (HSA) Program to determine BMD, cross-sectional area (CSA), and section modulus (Z) at the femoral neck and femoral shaft regions.

Results: Over 18 mo of DHEA+HRT therapy, femoral shaft BMD increased in the treatment group (+3.4% change over 18 mo) while simultaneously dropping in the placebo group (-2.1%) (time x treatment p-value <0.01). Changes in femoral shaft CSA were also significantly different between groups (DHEA+HRT: +2.5% vs. placebo: -1.8%, p<0.01). No difference in shaft section modulus was noted. Shaft buckling ratio, a measure of fracture risk, decreased in the treatment arm, but increased in the placebo arm over 18 mo (-5.9% vs. +2.7%, p=0.02)No difference in hip geometry at the femoral narrow neck was noted between groups.

Conclusions: In young women with AN, a combination regimen of oral DHEA+HRT for 18 mo led to increases in estimates of bone cross-sectional geometry and a decrease in estimated fracture risk compared to placebo therapy. Positive results of treatment were seen at the femoral shaft but not at the femoral narrow neck. Our results indicate that this combination treatment has a beneficial impact on skeletal health in young women with AN.

Altered Bone Composition in Fracture Prone Children With Vertebral Fracture. Inari Tamminen*[1], Mervi K Mäyränpää[2], Mikael Turunen[3], Hanna Isaksson[3], Outi Makitie[4], Jukka S Jurvelin[3], Heikki Kroger[5]. [1]Bone & Cartilage research Unit (BCRU), University of Eastern Finland, Finland, [2]Department of Pediatric Surgery & Department of Pediatrics, Hospital for Children & Adolescents, Helsinki University Hospital, Finland, [3]Department of Physics & Mathematics, University of Eastern Finland, Finland, [4]Hospital for Children & Adolescents, University of Helsinki, Finland, [5]Kuopio University Hospital, Finland

In pediatrics, primary osteoporosis (OP) often leads to vertebral fractures. However, it remains unknown whether these fractures associate with changes in bone composition. This study aimed to determine if the bone composition is different in fracture prone children with and without vertebral fractures, as assessed using Fourier transform infrared spectroscopic imaging (FTIRI) and bone histomorphometry.

Iliac crest biopsies (n=24) were obtained from children with suspected primary osteoporosis based on fracture history and/or low bone mineral density (BMD) in DXA (Table 1) [1]. Samples were analyzed using FTIRI and bone histomorphometry. Phosphate-to-amide I (mineral-to-matrix ratio), carbonate-to-phosphate, carbonate-to-amide I, and cross-link ratios (collagen maturity) were quantified by FTIRI [2]. Additionally, samples were classified into groups based on histomorphometric findings (normal bone volume vs. OP). Mann Whitney U-test was used for statistical comparison.

OP was diagnosed by histomorphometry in 50% of the children with vertebral fracture, and the bone turnover rate was abnormal in 71% of these cases (Table 1). Children with vertebral fractures had lower carbonate-to-phosphate ratio (p<0.05) and higher collagen maturity (p<0.05) than children without vertebral fracture. The children with histomorphometrically diagnosed OP showed lower carbonate-to-phosphate (p<0.05) and carbonate-to-amide I ratios (p<0.05) than the children with normal bone volume.

Our results suggest that the fracture prone children with vertebral fracture history have more frequently osteoporotic trabecular bone and altered bone turnover rate. OP was found in 30 % of cases without vertebral fracture and these children had sustained peripheral fractures (Table 1). The observed changes in bone composition in children with vertebral fracture might explain their greater propensity to develop vertebral fractures.

Fractures in Healthy Adolescent Boys are Associated with Reduced Bone Strength as Assessed by Finite Element Analysis at Weight-Bearing Skeletal Site. Thierry Chevalley*[1], Jean-Philippe Bonjour[2], Bert Rietbergen[3], Serge Ferrari[4], Rene Rizzoli[5]. [1]University Hospitals of Geneva Division of Bone Diseases, Switzerland, [2]University Hospital of Geneva, Switzerland, [3]Eindhoven University of Technology, The netherlands, [4]Geneva University Hospital & Faculty of Medicine, Switzerland, [5]University Hospital, Switzerland

In healthy children and adolescent boys, fractures result from trauma of various severity. Whether these fractures are characterized by an intrinsic bone biomechanical fragility remains to be demonstrated. In a cohort of 176 healthy adolescent boys prospectively followed from age 7.5±0.5 to 15.2±0.5 yrs we reported that fracture history (156 fractures recorded in 87/176 boys) was associated with decreased femoral neck (FN) areal (a) bone mineral density (BMD) (-6.0%, p=0.005) measured by dual-energy x-ray absorptiometry (DXA) and lower distal tibia trabecular volumetric (v) density (-5.5%, p=0.029) and number (-4.2%, p=0.040) as determined by high resolution peripheral computerized tomography (HR-pQCT). In the present study we

assessed to what extent this lower trabecular microstructure in the distal tibial among boys with previous fractures was associated with reduced bone strength variables evaluated by micro-finite element analysis (μFEA) based on HR-pQCT measurements. Associations between FN aBMD, distal tibia microstructure and bone strength estimates, and fracture status were evaluated by univariate logistic regression and expressed as odds ratio (OR [95%CI]) per 1 SD decrease. As compared to those without fractures, boys with fractures had a 5.8% lower bone strength of the distal tibia as estimated by stiffness (245 vs. 260 kN/mm, P=0.024) and failure load (11706 vs. 12430 N, P=0.016), after adjustment for age, standing height, body weight, pubertal stage, calcium and protein intakes, physical activity, and calcium supplement or calcium randomization between age 7.5 and 8.5 yrs. As shown in the distal tibia (Figure), the adjusted ORs [95% CI] for fracture per 1 SD decrease were as follows: Stiffness 1.42 [0.96-2.44, P=0.072]; Failure Load 1.60 [0.99-2.60, P=0.056]; Trabecular Density 1.46 [1.02-2.09, P=0.038]; Trabecular Number 1.59 [1.04-2.42, P=0.031]. The corresponding fracture OR for FN aBMD was: 1.80 [95% CI 1.18-2.76, P=0.006]. In conclusion, although trauma plays a non-negligeable role in the occurrence of fractures in healthy children and adolescent boys, our study provides evidence for an intrinsic component of skeletal fragility as assessed by μFEA at weight-bearing site. The measured biomechanical deficit at distal tibia corroborates indirect estimates of fracture risk by assessing macro- and microstructural components of bone mineral density and architecture.

High-Resolution pQCT Assessed Trabecular Bone Volume Fraction Is Independently Associated with X-ray Verified Forearm Fractures in Young Men. Robert Rudäng*[1], Anna Darelid[2], Dan Mellstrom[3], Claes Ohlsson[4], Mattias Lorentzon[5]. [1]Center for Bone Research at the Sahlgrenska Academy, Dept. of Internal Medicine, University of Gothenburg, Sweden, Sweden, [2]Gothenburg University, Sweden, [3]Sahlgrenska University Hospital, Sweden, [4]Centre for Bone & Arthritis Research, Sweden, [5]Center for Bone Research at the Sahlgrenska Academy, Sweden

Areal bone mineral density (aBMD) is a well established predictor of fracture risk in adults as well as in children and adolescents. Whether or not measures of trabecular microarchitecture are related to fracture risk in young adults remains unclear. The purpose of this study was to investigate whether indices of trabecular microarchitecture or aBMD, both measured in the forearm, was most strongly associated with distal forearm x-ray verified fractures in young men.

In total, 756 young adult men (age 24.1±0.6 years) were included in this cross-sectional population-based study. The non-dominant radius was measured with dual-energy x-ray absorptiometry (DXA) to obtain aBMD and with an XtremeCT device to measure the trabecular bone volume fraction (BV/TV), trabecular number (Tb.N.), and trabecular thickness (Tb.Th.), cortical volumetric BMD, and cortical thickness. A standardized questionnaire was used to collect information regarding calcium intake, smoking and physical activity. Reported fractures were verified through local hospital X-ray records and national health care registers. In total, 290 (38.4%) men had suffered at least one prevalent fracture and 466 (61.6%) men had no prevalent fractures. There were 395 fractures. The most common fracture sites were at the distal forearm (27.6%, 109/395), the phalangs of the hand (15.7%, 62/395), and the carpals or metacarpals of the hand (13.2%, 52/395). Men with at least one prevalent distal forearm fracture (n=94) had lower radius aBMD (2.1%, p=0.04), and substantially lower trabecular BV/TV (6.9%, $p<0.001$), as a result of reduced Tb.N. (4.1%, $p<0.01$) than men without any fracture. No differences in cortical thickness or cortical volumetric BMD were seen between the groups. Using a logistic regression model (with age, height, weight, calcium intake, smoking and physical activity as covariates), we found that the prevalence of distal forearm fracture was increased for every SD decrease in trabecular BV/TV of the radius (Odds Ratio (OR) 1.47 (1.15-1.88)) but not with aBMD (OR 1.23 (0.96-1.58)) of the same bone. When both aBMD and trabecular BV/TV were included simultaneously, trabecular BV/TV was associated with prevalent radius fracture (OR 1.52 (1.12-2.1) while aBMD was not (OR 0.94 (0.69-1.29). We conclude that trabecular bone volume fraction as measured with high resolution pQCT is more strongly associated with X-ray verified prevalent forearm fractures than aBMD is in a large cohort of young adult men.

Cortical Consolidation Due to Increased Mineralization and Endosteal Contraction in Young Adult Men - a Five Year Longitudinal Study. Anna Darelid*[1], Claes Ohlsson[2], Johanna Melin[1], Dan Mellstrom[3], Mattias Lorentzon[4]. [1]Center for Bone Research at the Sahlgrenska Academy, Dept. of Internal Medicine, University of Gothenburg, Gothenburg, Sweden, [2]Centre for Bone & Arthritis Research, Sweden, [3]Sahlgrenska University Hospital, Sweden, [4]Center for Bone Research at the Sahlgrenska Academy, Sweden

Peak bone mass (PBM) is an important factor for the lifetime risk of developing osteoporosis. Large, longitudinal studies investigating the age of attainment of site specific PBM are lacking.

The aim of the present study was to determine the site specific development of peak bone mass in appendicular and axial skeletal sites, and in the trabecular and cortical bone compartments, using both Dual X-ray Absorptiometry (DXA) and peripheral computed tomography (pQCT). In total, 833 men (aged 24.1±0.6 years (mean±SD)) from the original population-based Gothenburg Osteoporosis and Obesity Determinants (GOOD) Study (n=1068), were included in this follow-up examination at 62.2±2.3 months. Areal bone mineral density (aBMD) was measured with DXA, whereas cortical and trabecular volumetric BMD (vBMD) and bone size were measured by pQCT at baseline and at the five year follow-up. During the five-year follow-up, areal BMD of the total body, lumbar spine, and radius, increased yearly with 0.74%, 0.85%, and 1.55%, respectively ($p<0.0001$). PQCT measurements were used to explore vBMD and bone geometry alterations in the long bones. Yearly increments of 0.43% and 0.13% were seen for cortical vBMD of the radius and tibia, respectively ($p<0.0001$), while cortical thickness gained 0.77% at the radius and 1.30% at the tibia yearly, due to diminished endosteal circumference (radius 0.47% and tibia 0.92% yearly, $p<0.0001$). As a result, the polar stress strain index, a measure of bone strength, increased 0.99% and 1.36% yearly ($p<0.0001$) at the radius and tibia, respectively. During the whole study period, the accumulated increase in polar SSI was 5.0% for the radius and 6.9% for the tibia.

In conclusion, our results indicate that peak aBMD has not yet been attained at the spine and in the long bones between 19 and 24 years of age in men. We demonstrate that between these ages there is a considerable cortical consolidation, that is due to increased mineralization and augmented cortical thickness with endosteal contraction (Figure 1).

microRNA-29 Modulates WNT Signaling in Human Osteoblasts Through a Positive Feedback Loop. Kristina Kapinas*, Catherine Kessler, Gloria Gronowicz, Anne Delany. University of Connecticut Health Center, USA

Our goal was to define the relationship between the microRNA miR-29 and canonical Wnt signaling during the differentiation of human osteoblasts. Wnt signaling is important for the differentiation of human mesenchymal stem cells to osteoblasts and for the maintenance of bone mass in humans. Post-transcriptional regulation of gene expression, mediated by microRNAs, plays an essential role in these processes. Previously we found that miR-29 family members are induced by

canonical Wnt signaling in murine osteoblasts. Here, we first showed by qRT-PCR that miR-29a expression is increased during osteoblastic differentiation of human FOB1.19 mesenchymal precursors and in primary cultures of human osteoblasts derived from bone chips. Knockdown of miR-29a reduced expression of alkaline phosphatase and osteocalcin mRNA, suggesting a role in differentiation, and miR-29a was rapidly induced by Wnt3A. We cloned up to 2 kb of the promoter region of the expressed sequence tag containing the human miR-29a gene into a promoterless luciferase reporter vector. The -982 to -1 region of the promoter contains 2 potential TCF/LEF binding sites. Promoter activity of this region was increased in cells treated with Wnt3A. Mutation of one or both TCF/LEF sites abolished responsiveness to Wnt3A. However, mutagenesis of both TCF/LEF sites increased basal promoter activity, likely due to the repressor function of TCF/LEF, which occurs when nuclear beta catenin is limited.

Since the expression of several antagonists of Wnt signaling are decreased during differentiation, we hypothesized that miR-29a may target these molecules. Based on the potential for miR-29a interaction with the 3' untranslated region (UTR), Dkk1, Kremen2, and sFRP2 emerged as candidates. We generated reporter constructs in which the 3'UTR for Dkk1, sFRP2 or Kremen2 act as the 3'UTR for the luciferase gene, and confirmed repression of these UTRs by miR-29a. Transfection of cells with miR-29a inhibitor increased Dkk1, sFRP2 and Kremen2 protein levels, confirming their regulation by miR-29. Overall, we demonstrate that miR-29 and Wnt signaling are involved in a regulatory circuit that modulates osteoblast differentiation. Canonical Wnt signaling induces miR-29a transcription. The subsequent down regulation of key Wnt signaling antagonists Dkk1, Kremen2, and sFRP2 by miR-29a could potentiate Wnt signaling and further promote a gene expression program necessary for osteoblast differentiation.

A Regulatory Loop of Runx2 Downregulates Expression of the miR-23a~27a~24-2 Cluster which Targets SATB2 for Control of the Osteoblast Differentiation Program. Mohammad Hassan*[1], Jonathan Gordon[1], Marcio M. Beloti[2], Carlo M. Croce[3], Andre Van Wijnen[1], Janet L. Stein[1], Gary Stein[1], Jane Lian[1]. [1]University of Massachusetts Medical School, USA, [2]University of Massachusetts Medical Schools, USA, [3]Ohio State University, USA

Regulation of osteogenesis includes a program of microRNAs (miRs) to repress the translation of genes that act as inhibitors of bone formation. Yet, how expression of these bone-related miRs is regulated remains a compelling question. Here we report that expression of the miR cluster -23a~27a~24-2 increases continuously during osteogenic differentiation and is directly regulated by Runx2, a transcription factor essential for osteoblastogenesis. Overexpression, reporter and ChIP assays established a functional Runx binding element that mediates downregulation of all 3 miRs (miR-23a, 27a and 24-2) present in the cluster. Consistent with this finding, each of the miRs suppresses osteoblast differentiation, suggesting a role for this cluster in attenuating the late stages of osteoblast differentiation. The biological significance of Runx2 repression of this miR cluster is that each miR directly targets the 3' UTR of SATB2, which is known to synergize with Runx2 to facilitate osteoblast differentiation. These results suggest a Runx2 feed-forward mechanism for negative regulation of multiple miRs in order to cause de-repression of SATB2. Additionally, we find that miR-23a directly targets the 3' UTR of Runx2 and represses its translation, which allows for upregulation of the miR cluster during late differentiation because Runx2 has been downregulated. Thus, this finding defines a miR-mediated negative regulatory loop for attenuation of bone formation at the termination of differentiation. Taken together, we have established a regulatory network with a central role of the miR cluster 23a~27a~24-2 in regulating both progression and attenuation of osteoblast differentiation.

Exploring Structural and Instructional Features of *CYP24A1* Distal Enhancers. Paul Goetsch*[1], Mark Meyer[2], John Stamatoyannopoulos[3], J. Pike[2]. [1]University of Wisconsin - Madison, USA, [2]University of Wisconsin-Madison, USA, [3]University of Washington, USA

1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) actions are negatively regulated in target cells via induction of CYP24A1, a cytochrome P450 enzyme that inactivates the hormone and thus limits its transcriptional potential. While early studies suggested that induction of this gene by $1,25(OH)_2D_3$ was controlled by two proximal promoter regulatory elements, our recent studies identified a downstream enhancer cluster that contributes to *CYP24A1* upregulation as well. This region together with the promoter contain functional vitamin D response elements, bind the VDR/RXR heterodimer in response to $1,25(OH)_2D_3$, recruit a series of coregulators and collectively mediate changes necessary for gene activation. However, virtually nothing is known about the origins of such enhancers or what draws the heterodimer to these specific regions. To begin to address these issues, we first asked whether the *CYP24A1* enhancers could be uniquely identified through specific epigenetic marks that may act as beacons for incoming regulatory proteins. To this end, we conducted an extensive ChIP-chip analysis across the *CYP24A1* locus using antibodies specific for various histone acetylation or methylation marks. In the absence of $1,25(OH)_2D_3$, strong H3K4me1 marks were evident at virtually all the *CYP24A1* enhancers but not at the *CYP24A1* promoter. H4K5ac, H4K8ac, H4K12ac and H4K16ac marks were only evident at subsets of these enhancers while H4K12ac and H4K16ac marks could also be seen at the promoter. In contrast, H3K4me3 and H3K36me3 marks were undetectable across the locus. Thus, H3K4me1 and various H4ac marks may highlight enhancers at the *CYP24A1* locus that play a role in *CYP24A1* regulation. We next asked whether these regions were uniquely accessible to entry by regulatory proteins such as VDR/RXR. Accordingly, we examined the patterns of DNaseI hypersensitivity (DHS) generated across an extended series of diverse cell types through deep sequencing analysis as an integral part of the ongoing ENCODE project. Both the *CYP24A1* promoter and virtually all of the gene's enhancers manifested increased hypersensitivity to DNAse I digestion, suggesting that these enhancers maintain structural properties that increase accessibility to incoming VDR. Importantly, these sites are not evident in cells that do not represent targets of vitamin D action. These studies suggest that *CYP24A1* responsiveness to $1,25(OH)_2D_3$ is determined by both preformed regulatory enhancers and a ligand-inducible VDR.

SIRT2 is a Protein Deacetylase Involved in the Regulation of Osteoblastogenesis by Inhibiting Adipogenesis. Jonathan Gordon*, Mohammad Hassan, Hai Wu, Andre Van Wijnen, Janet Stein, Gary Stein, Jane Lian. University of Massachusetts Medical School, USA

Sirtuins are NAD^+-dependent protein deacetylases (HDACs) and are strongly associated with age-related degeneration including decreases in bone mineral density and osteoporosis. Sirt2 is constitutively expressed in mesenchymal cells (C3H10T1/2 fibroblasts, bone marrow stromal cells) and osteoblasts (primary calvarial osteoblasts) during differentiation. Interestingly, shRNA-mediated knockdown of Sirt2 alone had a negative effect on osteogenesis, by significantly increasing adipogenic markers (PPAR gamma) and commitment of mesenchymal progenitor cells to adipocytes. Chromatin immunoprecipitation and co-immunoprecipitation experiments in progenitor cells show that Sirt2 directly interacts with Pbx1, a homeodomain protein that is a negative co-regulator of Hoxa10 mediated transcription. When co-expressed Pbx1 increases the nuclear localization of Sirt2 resulting in increased repression of osteoblast marker genes. Pbx1 and Sirt2 co-localize on osteoblast-related gene promoters (osterix (sp7), osteocalcin (bglap2), bone sialoprotein (ibsp)) while cells are actively proliferating resulting in suppression of these genes. There is a functional relationship between Pbx1 and Sirt2 as knockdown of Sirt2 in Pbx1 overexpressing cells resulted in increased histone acetylation at osteoblast gene promoters and subsequent increased expression of osteoblast-related genes suggesting that Sirt2 is required for Pbx1-mediated repression of osteoblast related genes. These results suggest that cellular levels of Pbx1 and Sirt2 are involved in specifying mesenchymal commitment to the adipocyte or osteoblast lineages and may represent a mechanism regulating age-related changes in osteoblastogenesis and bone formation.

Contributions of PTH-mediator CREB to Postnatal Bone Mass in Human and Mouse Through Regulation of Osteoblast Function. Hongbin Liu*[1], Rongrong Zhang[1], Shanshan Dong[2], James Edwards[3], Seon-Yle Ko[4], Hong-Wen Deng[5], Ming Zhao[2]. [1]Department of Basic Medical Sciences, UMKC School of Medicine, USA, [2]University of Missouri - Kansas City, USA, [3]Vanderbilt University Medical Center, USA, [4]Dankook University, School of Dentistry, South korea, [5]University of Missouri, Kansas City Medical School, USA

Transcription factor CREB (cAMP-response element binding protein) plays an essential role in osteoblasts to mediate the anabolic signaling of intermittent dosage of PTH in bone. To further investigate the precise physiological role of CREB in maintenance of postnatal bone mass, we have performed human genome-wide association and mouse functional studies. Data from 1000 unrelated US Caucasian subjects have shown that the polymorphisms at multiple positions of CREB gene were significantly associated with bone mineral density (BMD) of spine and ultradistal radius ($p<0.011$~0.042, suggesting that CREB is essential for postnatal bone mass in humans. To validate this relevance of CREB to bone, we created osteoblast-specific CREB knockout mice by crossing CREB floxed mice with Col1a1(3.6)-Cre mice. μCT and histological characterizations have shown that trabecular bone volume of limb bones of two-month-old CREB KO mice was substantially reduced, along with decreased trabecular number and trabecular thickness but increased trabecular separation, compared with those of the control mice. These results validate that normal CREB function in bone is critical for postnatal bone homeostasis. Next, we were interested in exploring the molecular mechanisms by which CREB functions in bone. We found that expression of BMP2, an important growth factor that induces osteoblastogenesis and bone formation, was substantially decreased in the primary CREB-deficient calvarial cells, compared with the control cells. Furthermore, we found that overexpression of CREB up-regulated BMP2 levels in osteoblast MC3T3/E1 cells stably transfected with CREB. DNA sequence analysis has shown that BMP2 promoter contains multiple cAMP response elements (CREs). The subsequent

promoter deletion, EMSA and mutation studies have confirmed that CREB transactivates BMP2 gene expression through these specific CREs in the BMP2 promoter. These results suggest that CREB is a powerful activator of BMP2 transcription in osteoblasts. As expected, we found that transfection of CREB increased ALP activity in various osteoblast cell lines and this action was blocked by noggin, a BMP antagonist, demonstrating that CREB stimulates osteoblast differentiation through BMP pathway. Lastly, we determined the effects of pharmacological manipulation of CREB phosphorylation on CREB activity in osteoblasts. We found that treatment of osteoblast cells with cAMP/PKA activator IBMX or inhibitor KT5720 markedly affected CREB transactivation of the BMP2 expression. Since PTH phosphorylates CREB in osteoblasts, we further examined whether PTH regulates BMP2 transcription. The results showed that BMP2 promoter activity was significantly enhanced when treated with PTH. Together, all the results of these human and mouse studies suggest that PTH-mediator CREB plays an important role in controlling postnatal bone mass by regulating BMP2 production and consequent osteoblast differentiation.

MicroRNA-138 Targets Focal Adhesion Kinase and Regulates I*n Vivo* Bone Formation. Hanna Taipaleenmaki*[1], Tilde Eskildsen[1], Jan Stenvang[2], Basem Abdallah[3], Nicholas Ditzel[4], Sakari Kauppinen[5], Moustapha Kassem[6]. [1]Endocrine Research Laboratory (KMEB), Odense University Hospital, Denmark, [2]MicroRNA Research Unit, Department of Cellular & Molecular Medicine, University of Copenhagen, Denmark, [3]Odense University Hospital, University of South Denmark, Denmark, [4]Endocrine Research Laboratory (KMEB), Department of Endocrinology & Metabolism, Denmark, [5]Santaris Pharma, Denmark, [6]Odense University Hospital, Denmark

MicroRNAs (miRNAs) are short non-coding RNAs that interfere with translation of specific target genes acting as key regulators of diverse cellular processes. Elucidating the mechanisms regulating human mesenchymal stem cell (hMSC) differentiation into osteogenic lineage is of importance to identify novel targets for anabolic therapy of osteoporosis. Through comprehensive analysis of miRNAs expressed during hMSC differentiation into osteoblast we identified miR-138 as a potential modulator of osteoblast differentiation. Microarray analysis and further validation of miRNA expression by qRT-PCR revealed significant down-regulation of miR-138 during osteoblast differentiation of hMSCs. Overexpression of miR-138 inhibited osteoblast differentiation capacity of hMSCs *in vitro*, while silencing miR-138 by anti-miR-138 promoted ALP activity, matrix mineralization and expression of osteoblast specific genes. Furthermore, overexpression of miR-138 reduced ectopic in *vivo* bone formation by 85 % and, conversely, *in vivo* bone formation was enhanced by 60 % when miR-138 was silenced. Target prediction analysis and further experimental validation confirmed focal adhesion kinase (FAK/Ptk2), a kinase playing a role in promoting osteoblast differentiation, as a target of miR-138.

In conclusion, our data demonstrate that miR-138 attenuates *in vivo* bone formation possibly through inhibition of FAK signalling pathway. Inhibition of miR-138 is a potential new strategy for enhancing osteoblast differentiation and bone formation of MSC *in vivo*.

Long-Term Lack of Fgf-23 Induces Severe Secondary Hyperparathyroidism in Vitamin D Receptor-Ablated Mice. Carmen Streicher*[1], Olena Andrukhova[1], Ute Zeitz[1], Beate Lanske[2], Reinhold Erben[1]. [1]University of Veterinary Medicine, Austria, [2]Harvard School of Dental Medicine, USA

Fibroblast growth factor-23 (Fgf-23) is an endocrine signal originating from osteocytes which downregulates renal tubular phosphate reabsorption and vitamin D hormone synthesis. Previous studies in 4-week-old *Fgf-23* deficient mice crossed to vitamin D receptor (VDR) mutant mice suggested that the main physiological function of Fgf-23 is the suppression of renal 1α-hydroxlase, the key enzyme in vitamin D metabolism. Due to the short life span of *Fgf-23*$^{-/-}$ mice, data in skeletally more mature mice are lacking. Here, we examined the effects of long-term *Fgf-23* deficiency on mineral and bone homeostasis in 9-month-old wild-type (WT) mice, *VDR* mutant mice, and *Fgf-23*/*VDR* compound mutant mice on both a standard rodent chow and a rescue diet (RD) enriched with calcium, phosphorus, and lactose. As expected, *VDR* and compound mutants on the normal diet showed hypocalcemia and severe secondary hyperparathyroidism (sHPT). *VDR* mutants on RD were normophosphatemic and had normal tibial bone mineral density, but showed slightly reduced ionized blood calcium and increased serum intact PTH (106 ± 87 vs. 15 ± 5 pg/ml in WT). Circulating Fgf-23 was lower in *VDR* mutants relative to WT animals on RD. Relative to *VDR* mutants, compound mutants on RD were characterized by hyperphosphatemia and very high serum PTH (1,432 ± 286 pg/ml). sHPT in compound mutants was associated with bone loss and cortical thinning at the tibial shaft. Analysis of renal handling of minerals revealed additional calcium wasting but unchanged urinary phosphate excretion in compound relative to *VDR* mutants on RD. Quantitative RT-PCR showed that renal calcium wasting in compound mutants was associated with lower expression of calbindin D28k and D9k, but unchanged expression of PTH receptor and up-regulated expression of epithelial calcium channels TRPV5 and 6 mRNA, relative to *VDR* mutants. Collectively, our data suggest that the driving force behind the development of sHPT in compound mutants was hyperphosphatemia and renal calcium wasting. Interestingly, compared with *VDR* mutants, compound mutants showed hyperphosphatemia, renal calcium loss, and unchanged tubular reabsorption of phosphate in the presence of ~13-fold higher serum PTH. Hence, *Fgf-23* deficiency blunts the phosphaturic and calcium-conserving actions of PTH in vivo, suggesting that Fgf-23 and PTH signaling interact in renal tubular cells in a vitamin D independent fashion.

PHEX Has Distinct Roles in Regulating Cancellous and Cortical Bone Mineralization. Peter Rowe*[1], Anne-Marie Hedge[1], Yan Hong[1], Aline Martin[2], Lesya Zelenchuk[1], Valentin David[2]. [1]University of Kansas Medical Center, USA, [2]UTHSC, USA

Mutations in PHEX or DMP1 cause X-linked hypophosphatemic rickets (HYP) and Autosomal Recessive Hypophosphatemic Rickets (ARHR) respectively. Both diseases result in increased FGF23 levels with rickets and hypophosphatemia. DMP1 and MEPE derived ASARM-peptides are physiological substrates for PHEX and are strong inhibitors of mineralization. We described previously a competitive inhibitor of PHEX (SPR4) that binds specifically to ASARM-peptides and reverses the HYP mineralization defect *in vitro*. Here we describe the bone-mineral *in vivo* effects of 28 day osmotic pump infusion of SPR4 peptide in wild type and HYP mice

Wild type and HYP mice (C57BL/6; n=5, male) were infused with vehicle (0.9% NaCl) or peptide (276 nmoles/hr/kg) for 28 days (Alzet Osmotic pumps). Bone mineral Density (BMD) was measured by DEXA at day 0 and 28. Animals were sacrificed on day 28 after overnight metabolic cage housing. Femurs were removed and scanned by micro computed tomography (μCT).

SPR4 peptide treatment significantly reduced the percentage change in total Bone Mineral Density (Δ-BMD) in wild type mice (-22%; $p<0.05$) and this was more marked in femur epiphyses (-60%; $p<0.05$). Detailed μCT analysis revealed a dynamic change in Δ-BV/TV, bone mineral distribution and trabecular structure over the 28 days. Specifically in wild-type mice, segmental analyses of the distal femur head, (epiphyseal region) showed a significant drop in Δ-BV/TV in SPR4 treated animals. In contrast the cortical diaphyseal region contained a 20% increase in Δ-BV/TV (Figure 1A). Treated wild type mice also showed a significant drop in trabecular number, spacing and connectivity as measured by μCT (Figure 1B).

We conclude PHEX plays a major role in maintaining a normal cancellous bone structure. SPR4 disrupts this process by inhibiting competitively PHEX activity. In cortical bone, SPR4 peptide neutralizes free ASARM-peptides and thus positively alters the bone mineralization dynamic. This suggests PHEX plays distinct roles in regulating cancellous and cortical bone. Finally, we speculate SPR4-peptide may be of use in treating the endocortical-osteomalacia that occurs in patients with HYP, ARHR and perhaps ADHR.

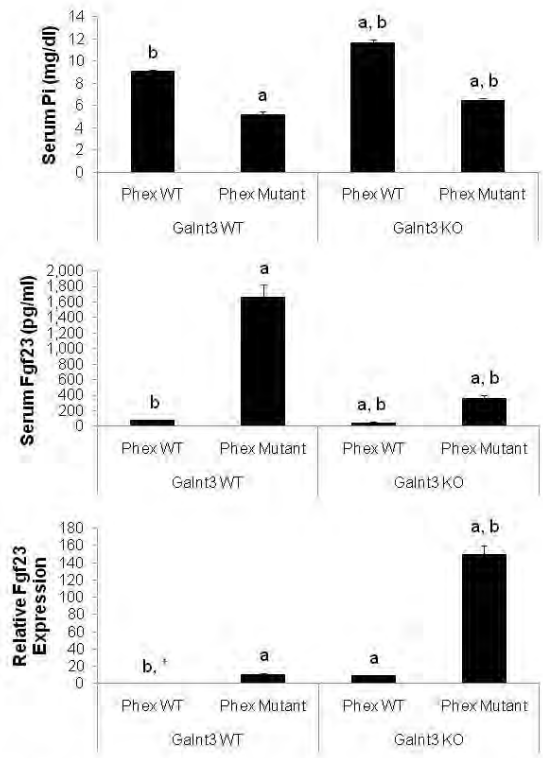
Phex Mutations in a Murine Model of X-linked Hypophosphatemia Result in Impaired Phosphate Sensing. Shoji Ichikawa*[1], Anthony M. Austin[2], Amie K. Gray[2], Michael Econs[2]. [1]Indiana University-Purdue University Indianapolis, USA, [2]Indiana University School of Medicine, USA

Fibroblast growth factor 23 (FGF23) is a critical regulator of phosphate homeostasis, which inhibits renal phosphate reabsorption and 1,25-dihydroxyvitamin D (calcitriol) synthesis. Elevated circulating FGF23 concentrations are the main cause of hypophosphatemia in various phosphate wasting disorders, including X-linked hypophosphatemia (XLH). The current standard therapy for XLH is high dose phosphate and calcitriol; however, this therapy further aggravates FGF23 concentrations. This observation suggested that FGF23-producing cells (osteoblasts and osteocytes) in XLH likely have an altered set point for phosphate sensing.

To test this hypothesis, we compared serum biochemistries and femoral Fgf23 mRNA expression between murine models of XLH ($Phex^{K496X}$) and hyperphosphatemic tumoral calcinosis ($Galnt3^{-/-}$), as well as Phex/Galnt3 double mutant mice. Phex mutant mice had increased Fgf23 expression in bone, resulting in markedly elevated serum Fgf23 levels and consequent hypophosphatemia. In contrast, because the secretion of intact, biologically active Fgf23 protein depends on O-glycosylation of Fgf23 by GalNAc transferase 3 (Galnt3), Galnt3 knockout mice had significantly lower circulating concentrations of intact Fgf23, despite markedly increased Fgf23 expression. As a result, Galnt3 knockout mice had hyperphosphatemia.

In the absence of a phosphate sensing defect, Phex/Galnt3 double mutant mice should express Fgf23 mRNA at the similar level as $Phex^{K196X}$ mice, but level of circulating intact Fgf23 protein should be markedly reduced or even normal compared to the single $Phex^{K196X}$ mutant animal and serum phosphate concentrations should be increased compared to $Phex^{K496X}$ mice. Although the double mutant had lower intact Fgf23 concentrations compared to the Phex mutant, these levels were still elevated compared to littermate controls, resulting in hypophosphatemia in the double mutant. Importantly, despite the presence of the marked hypophosphatemia, Fgf23 mRNA expression in the double mutant was 14 fold higher than the Phex mutant and 150 fold higher than controls, consistent with impaired phosphate sensing. In conclusion, these data suggest that Phex mutations lead to intrinsic defects in osteoblasts and osteocytes, which alter their phosphate sensing mechanism.



Number of six-week-old mice per group: 6-10. T-test p-values less than 0.01, compared to wild-type controls (a) and to Phex mutant with wild-type Galnt3 (b). *Wild-type controls arbitrarily set at 1.0.

Evidence that the Mineralization Defect in *hyp*-mice Results from the Uncoupled Effects of SOST/sclerostin on Osteoblast Mineralization and Proliferation. Baozhi Yuan*[1], Jennifer Meudt[2], Robert Blank[2], Jian Feng[3], Marc Drezner[2]. [1]University of Wisconsin, Madison, USA, [2]University of Wisconsin, USA, [3]Texas A&M Health Science Center, USA

Hyp-mice manifest hypophosphatemia and severe osteomalacia due to a loss of function Phex mutation. Recent studies revealed targeted Phex deletion in osteoblasts (*OC-Cre-*$Phex^{\Delta floxly}$) results in the typical *Hyp* phenotype. However, Phex deletion in osteocytes (*DMP1-Cre-*$Phex^{\Delta floxly}$), while creating *Hyp* biochemical abnormalities, results in a far less severe osteomalacia than in *hyp*- or *OC-Cre-*$Phex^{\Delta floxly}$*-mice*. The less profound mineralization defect in *DMP1-Cre-*$Phex^{\Delta floxly}$-mice occurred despite comparable hypophosphatemia and equal increments in circulating FGF-23, suggesting loss of Phex function in osteocytes causes abnormal mineralization independent of P and FGF-23. Thus, *DMP1-Cre-*$Phex^{\Delta floxly}$-mice provide a model that dissociates increased serum FGF-23 levels and hypophosphatemia from a profound defect in bone mineralization, indicating that Phex may have other unique actions impacting bone calcification. In accord with this hypothesis, we found Sost mRNA expression was significantly increased in the the *hyp*- and *OC-Cre-*$Phex^{\Delta floxly}$-mice with severe osteomalacia, but not in *DMP1-Cre-*$Phex^{\Delta floxly}$-mice with mildly aberrant bone mineralization, consistent with a regulatory effect of Sost on bone mineralization under hypophosphatemic conditions. To create the severe osteomalacia, evident in the *hyp*- and *OC-Cre-*$Phex^{\Delta floxly}$-mice, however, bone remodeling must reflect decreased bone mineralization without a coupled decrement in osteoblast proliferation. To examine if the Sost protein product exhibits such activity, we incubated cultured osteoblasts (TMOB) with sclerostin (0.625 μg/ml) for 14 days. We observed that sclerostin reduced TMOB mineralization (Alizarin stain/destain) compared to that in untreated cells (2.3 ± 0.2 vs 3.2 ± 0.1; $p<0.05$), demonstrating an inhibitory effect of the protein on calcification. Moreover, study of sclerostin action on osteoblast proliferation revealed uncoupled effects. Thus, TMOB cells, cultured with sclerostin (0.625 or 1.25 μg/ml) and harvested at 5, 24, 36, 48, 64, 72, and 82 hrs revealed no changes in cell proliferation (Cyquant assay, Invitrogen). These observations demonstrate sclerostin effects on bone mineralization are uncoupled from actions on osteoblast proliferation. Hence, abnormal bone mineralization evident in *hyp*- and in *OC-Cre-*$Phex^{\Delta floxly}$- mice may manifest due to increased Sost mRNA expression. Studies resulting in inhibition of Sost expression in *hyp*-mice are critical to elucidate this possibility.

Lrp5 G171V and A214V Knock-in Mice are Protected from the Osteopenic Effects of Sost Overexpression. Alexander Robling*[1], Matt Warman[2], Teresita Bellido[3], Paul Niziolek[3]. [1]Indiana University, USA, [2]Children's Hospital Boston, USA, [3]Indiana University School of Medicine, USA

Several missense mutations in the LRP5 receptor are associated with high bone mass (HBM) in humans. Based on *in vitro* evidence, the HBM mutations are thought to exert their effects on bone mass by providing resistance to binding/inhibition of the soluble LRP5 inhibitor sclerostin, among others. We previously reported the creation of two HBM mouse models, in which we knocked-in the A214V or G171V HBM mutation into the endogenous Lrp5 locus. To determine whether HBM knock-in mice are immune to sclerostin-induced osteopenia, we cross-bred these mice with transgenic mice overexpressing Sost in osteocytes (Dmp1::Sost).

We generated mice that were homozygous for the wild-type Lrp5 allele ($Lrp5^{+/+}$), A214V allele ($Lrp5^{A/A}$), and G171V allele ($Lrp5^{G/G}$). Within each Lrp5 genotype, mice were generated that were positive or negative for the Dmp1::Sost transgene. 8 male and 8 female mice were analyzed in each of the 6 genotype combinations created. Whole body DEXA scans were collected bi-weekly from 4.5 wks to 16.5 wks. At sacrifice (17 wks) the 5th lumbar vertebra was harvested for μCT measurements of trabecular bone properties. Comparisons were made between Dmp1::Sost transgenic and nontransgenic mice within each Lrp5 genotype.

Among $Lrp5^{+/+}$ mice, the Dmp1::Sost transgene lowered L5 vertebral BV/TV by 48-50% ($p<0.05$), compared to non-transgenic $Lrp5^{+/+}$ littermates. The same transgene, expressed in $Lrp5^{A/A}$ mutants resulted in a more mild reduction (10-16% decrease; $p<0.05$) in BV/TV, compared to nontransgenic $Lrp5^{A/A}$ mutants. Conversely, when expressed in the Lrp5 G171V mutants, the Dmp1::Sost transgene produced no significant effect on vertebral BV/TV (2-7% decrease, p=NS), when compared to nontransgenic $Lrp5^{G/G}$ mutants. Whole-body BMC was significantly reduced by the Dmp1::Sost transgene in male but not female $Lrp5^{+/+}$ mice. Among the male mice (where a significant Dmp1::Sost effect was detected), the transgene did not significantly reduce BMC in the $Lrp5^{A/A}$ or $Lrp5^{G/G}$ mutants.

In summary, the HBM mutation G171V imparted immunity to sclerostin-mediated osteopenia in mice. The Lrp5 A214V mutants exhibited immunity to sclerostin in some, but not all measures, suggesting that these two HBM mutations might affect in vivo sclerostin binding and inhibition differently.

Augmentation of cAMP Signaling in the Mouse Renal Proximal Tubule by Targeted in vivo Expression of the Extra-large Gsα Variant XLαs. Zun Liu[1], Hiroko Segawa[1], Cumhur Aydin[2], Reinhold Erben[3], Lee Weinstein[4], Vladimir Marshansky[1], Leopold Frohlich[5], Murat Bastepe*[1]. [1]Massachusetts General Hospital, Harvard Medical School, USA, [2]Gulhane School of MedicineAnkara, TURKEY, Turkey, [3]University of Veterinary Medicine, Austria, [4]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [5]Medical University of Graz, Austria

The α-subunit of the stimulatory G protein (Gsα) and its variant XLαs are both encoded by *GNAS*. XLαs, like Gsα, can mediate receptor-activated cAMP generation and, thus, is able to replace the latter in transfected cells. However, it remains unknown whether XLαs can mediate cAMP signaling in vivo. To address this question, we have employed rat type-I γ-glutamyltranspeptidase promoter and generated transgenic mice in which XLαs expression is targeted ectopically to the renal proximal tubule (rptXLαs mice). The transgenic mice were examined regarding renal proximal tubular responses that typically rely on cAMP signaling. Western blots indicated elevated protein kinase A (PKA) activity in renal proximal tubules of rptXLαs mice compared to littermate controls. Quantitative RT-PCR experiments showed that 25-hydroxyvitamin D3 1α-hydroxylase (Cyp27b1) mRNA, a downstream target of cAMP-PKA signaling, was ~2-fold higher in rptXLαs mice than wild-type littermates. In addition, Western blots showed that the expression of sodium-phosphate co-transporter type 2a, which is downregulated upon PKA-mediated mechanisms, was diminished in renal brush border membranes of the transgenic mice. In contrast, Gsα protein and mRNA levels in renal proximal tubules were unaltered, as determined by Western blots and quantitative RT-PCR. Serum calcium and phosphorus in rptXLαs mice were within the normal range, but serum PTH was ~40% lower than in wild-type littermates, consistent with increased PTH sensitivity in rptXLαs mice. When the transgenic mice were crossed to mice heterozygous for maternal ablation of *Gnas* exon 1, a model of pseudohypoparathyroidism, offspring with maternal *Gnas* exon 1 ablation alone had lower levels of 25-hydroxyvitamin D3 1α-hydroxylase mRNA in renal proximal tubules than wild-type mice, whereas offspring carrying both the XLαs transgene and maternal *Gnas* exon 1 ablation showed nearly normal levels of this transcript. These data demonstrate that transgenic XLαs expression in the renal proximal tubule leads to enhanced cAMP signaling, supporting the idea that XLαs can mimic the function of Gsα in vivo. Hence, XLαs may contribute to cAMP signaling and, thereby, play a role in a wide range of biological responses. Changes in XLαs activity may also be involved in the pathogenesis of diseases caused by *GNAS* mutations, including pseudohypoparathyroidism, Albright's hereditary osteodystrophy, and fibrous dysplasia of bone.

Parathyroid Hormone -Related Protein (PTHrP) Gene Ablation in Breast Cancer Cells Inhibits Invasion in vitro and Metastasis in vivo: Role of Akt and CXCR4. Richard Kremer[1], William Muller[2], Peter Siegel[3], Anne Camirand[4], Andrew Karaplis[5], Jiarong Li*[5]. [1]McGill University, Royal Victoria Hospital, Canada, [2]Rosalind & Morris Goodman Cancer Research Centre, Department of Biochemistry, Canada, [3]Goodman Cancer Research Centre, McGill University, Canada, [4]Sir Mortimer B. Davis Jewish General Hospital, McGill University, Canada, [5]McGill University, Canada

An increase in PTHrP circulating levels is associated with breast cancer recurrence and reduced survival. However, a mechanistic link between PTHrP and metastatic spread outside the skeleton has not yet been established. In this study, mice carrying a conditional PTHrP allele were crossed with the PyVMT transgenic mouse mammary tumor model and then with a separate transgenic strain expressing Cre in the mammary epithelium (MMTV/Cre). Tumors from PyVMT-PTHrP$^{flox/flox}$ Cre^{-} animals were harvested, minced, trypsinized and transfected with adeno-Cre GFP (experimental) or adeno-GFP (control) and selected by cell sorting. Cells were analyzed in vitro for invasion by Matrigel assays or reimplanted in vivo into the mammary fat pad (0.5X106 cells) of syngeneic 5-week old FVB mice non-tumor bearing mice of the same strain for analysis of metastatic spread to lung. The invasive ability in vitro of PyVMT-PTHrP$^{flox/flox}$-Cre^{+}cells was reduced by over 80% ($P<0.001$) as compared to control cells (PyVMT-PTHrP $^{flox/flox}$-Cre^{-}).Circulating tumor cells (CTCs) were detectable in animals transplanted into the mammary fat pad with PyVMT-PTHrPflox/flox-Cre-cells but not in animals transplanted with PyVMT-PTHrP $^{flox/flox}$-Cre^{+}cells. Metastatic spread to lungs was seen in 100% of animals transplanted with PyVMT-PTHrP $^{flox/flox}$-Cre^{-} cells when tumor size reached around 1.5cm^{3}. In contrast none of the animals transplanted with PyVMT-PTHrP $^{flox/flox}$-Cre^{+}cells had any evidence of metastatic spread in lungs at the same tumor size. We next assessed AKT1 and CXCR4 expression by Western blot and confocal microscope in both isolated cells and tumors from both genotypes. Akt 1 and CXCR4 expression by Western blot were markedly reduced(over 80% $P<0.001$)in PyVMT-PTHrP$^{flox/flox}$-Cre^{+}cells and tumors as compared to PyVMT-PTHrP $^{flox/flox}$-Cre^{-}cells and tumors. Akt1 and CXCR4 fluorescence intensity was high in PyVMT-PTHrPflox/flox-Cre-cells but almost absent in PyVMT-PTHrPflox/flox-Cre+cells. Furthermore, siRNA knockdown of AKt1 reduced invasion in vitro significantly more in PyVMT-PTHrP$^{flox/flox}$-Cre^{+}cells than in PyVMT-PTHrP$^{flox/flox}$-Cre^{-} cells($P<0.05$) suggesting that PTHrP has Akt dependent and independent effects. Overall, our study demonstrates that PTHrP plays a crucial role in metastatic spread possibly by altering critical checkpoint of cancer progression and suggest its potential usefulness to prevent progression and recurrence of breast cancer.

Unveiling Dual Functions of p53 in Preventing Breast Cancer Bone Metastasis by Simvastatin Targeting CD44 and PTEN. Chandi Mandal*[1], Nayana Ghosh-Choudhury[2], Toshiyuki Yoneda[3], Goutam G Choudhury[4], Nandini Ghosh-Choudhury[1]. [1]University of Texas Health Science Center at San Antonio, USA, [2]University of Texas Health Science Center, USA, [3]Osaka University Graduate School of Dentistry, Japan, [4]University of Texas Health Science Center & South Texas Veterans Administration, USA

Metastasis to skeleton is an ominous feature of malignant breast cancer. We used heart injection model to test the effect of simvastatin on breast cancer bone metastasis. Simvastatin prevented osteolytic lesions in mice injected with MDA-MB-231 (MDA) human breast cancer cells, indicating that statin attenuates breast cancer metastasis to bone. To investigate the mechanism, MDA cells were used in an *in vitro* wound healing assay. Simvastatin significantly inhibited the migration of MDA cells. Transwell invasion assay using collagen-coated discs confirmed the inhibitory effect of simvastatin on breast cancer cell invasion. We have recently shown that simvastatin inhibits primary tumor growth in mice by upregulating the tumor suppressor PTEN. Overexpression of PTEN in MDA cells significantly blocked their ability to migrate and invade. To determine the mechanism of PTEN upregulation, we considered the tumor suppressor protein p53, which is known to regulate PTEN expression. Simvastatin-treated mice tumors showed significantly increased levels of p53. Similarly, simvastatin enhanced the expression of p53 in MDA cells. Additionally, simvastatin increased transcription of the reporter plasmids containing the consensus p53-binding element (p53-Luc) or the PTEN promoter (PTEN-Luc). Cotransfection of p53 with these reporter constructs resulted in similar increase in transcription, indicating a role of p53 in PTEN expression by simvastatin. Recent reports indicate a direct correlation between expression of CD44 in breast cancer and their metastasis to other organs including bone. Levels of CD44 were significantly reduced in the tumors of mice treated with simvastatin. In MDA cells, simvastatin decreased the expression of CD44 protein and its transcription, as determined by CD44 promoter-driven luciferase construct (CD44-Luc). p53 acts as transcriptional activator or transcriptional repressor in a cell-type and context-dependent manner. Presence of non-canonical p53-binding elements has been reported in the CD44 promoter. Cotransfection of p53 with CD44-Luc significantly suppressed the transcription of CD44. Furthermore, expression of p53 markedly reduced the expression of CD44 protein. Finally, downregulation of endogenous CD44 by specific shRNA decreased migration of MDA cells. Together these results uncover a novel action of simvastatin, which targets p53 expression to simultaneously increase PTEN and decrease CD44 thus blocking migration and preventing bone metastasis of the human breast cancer cells.

Bone remodeling is based on a virtuous cycle in which osteoblasts and osteoclasts cross-talk and renovate the bone. Cancer cells are able to interfere with this process establishing the so called vicious cycle, in which osteoclasts are over-activated to resorb bone and release tumor-seeking growth factors stored in the bone matrix. Chondroadherin (CHAD) is an integrin binding protein. We observed that a cyclic peptide representing its integrin binding sequence (cyclicCHAD) reduced the mRNA expression of the osteoclastogenic cytokines RANKL IL-1beta and IL-6 by osteoblasts, without affecting their differentiation and function. It also directly inhibited osteoclast formation, adhesion and bone resorption and impaired invasion and migration of the human breast cancer cells, MDA-MB-231. Based on this in vitro evidence that cyclicCHAD targets all the players of the vicious cycle, we tested the efficacy of this peptide in the treatment of bone metastases in an animal model. We first investigated the safety of cyclicCHAD by injecting i.p. Balb-c nu/nu mice with vehicle or with 1 and 10 mg/kg body weight of cyclicCHAD, 5 days/week for 8 weeks. Treatment did not induce macroscopic organ injury, microscopic alteration of liver, kidney and spleen, or derangement of serum markers of tissue damage. Moreover, histomorphometric analysis of tibiae indicated the ability of cyclicCHAD to dose-dependently increase the bone structural parameters. Next we injected the left ventricle of Balb-c nu/nu mice with MDA-MB-231 cells and, starting the day after injection, we treated the animals daily with vehicle, 10 mg/Kg of control peptide, 1 mg/Kg of the reference drug, alendronate, or with 10 mg/kg of cyclicCHAD. Mice

receiving cyclicCHAD showed reduced cachexia (17% incidence) which, in contrast, affected 65% of control and alendronate-treated mice. Similar to alendronate, cyclicCHAD also dramatically reduced the incidence of bone metastases relative to vehicle (18.5% for alendronate and 18% for cyclicCHAD vs. 50% for control). At variance with alendronate, which increased the mean visceral metastasis volume by 2.9 fold vs. control, cyclicCHAD did not induce such adverse effect, thus leading to reduced morbidity and improved quality of life of treated animals. In conclusion, our data indicate that a cyclic peptide representing the integrin binding domain of CHAD could be a potential new drug for the treatment of bone metastases, targeting tumor cells as well as bone cells.

Bone-Targeted Therapy With Zoledronic Acid Combined With Adjuvant Ovarian Suppression Plus Tamoxifen or Anastrozole: 62-Month Outcomes From the ABCSG-12 Trial in Premenopausal Women With Endocrine-Responsive Early Breast Cancer. Michael Gnant*[1], P. Dubsky[1], C. Singer[1], R. Greil[2], B. Mlineritsch[2], H. Stoeger[3], H. Eidtmann[4], R. Jakesz[1], S. Poestlberger[5], G. Luschin-Ebengreuth[3]. [1]Medical University of Vienna, Austria, [2]Paracelsus Medical University Salzburg, Austria, [3]Medical University of Graz, Austria, [4]Universitäts Frauenklinik Kiel, Germany, [5]Hospital of the Sisters of Mercy, Austria

Purpose: The ABCSG-12 trial examined the efficacy of bone-targeted therapy with zoledronic acid (ZOL) in combination with ovarian suppression using goserelin plus anastrozole (ANA) or tamoxifen (TAM) in premenopausal patients (pts) with endocrine-responsive early breast cancer (EBC). The 48-month efficacy analysis presented at ASCO 2008 showed no difference between TAM and ANA; however, adding ZOL significantly reduced the risk of disease-free survival (DFS) events by 36% (P = .01). Longer follow-up is now available.

Methods: 1,803 premenopausal pts with EBC were randomized to goserelin (3.6 mg q28d) and TAM (20 mg/d) or ANA (1 mg/d) ± ZOL (4 mg q6m). The study was approved by each institution's human research committee. Endpoints were DFS and overall survival (OS); both were analyzed using log-rank test and Cox models. Compared with 2008 data, we now report on 34% more DFS events and 55% more deaths, based on data cutoff of December 1, 2009.

Results: With a median follow-up of 62 mo, 183 DFS events and 65 deaths were reported. Overall, adding ZOL reduced the risk of DFS events by 32% (hazard ratio [HR] = 0.68 [95% CI = 0.51-0.91]; P = .009). The risk reduction by ZOL was consistent in the TAM and ANA strata (HR = 0.68 [0.44-1.05] for TAM, HR = 0.68 [0.45-1.02] for ANA), and for N– and N+ pts. ZOL reduced the risk of death by 34% (HR = 0.66 [0.41-1.09]; P = .10), with a trend toward reduced risk of death in the N+ subgroup (HR = 0.61; P = not significant). There was no difference in DFS between pts who received TAM alone vs ANA alone (HR = 1.11 [0.84-1.50]; P = .44). However, ANA pts did worse with respect to OS (HR = 1.74 [1.05-2.87]; P = .03) vs TAM, probably due to differences in postrelapse treatment. Treatments were generally well tolerated. There were no cases of renal failure or osteonecrosis of the jaw.

Conclusions: With longer follow-up of ABCSG-12, adding ZOL (4 mg q6m) consistently improved DFS in the ANA and TAM subgroups, and in N+ and N– pts, with a trend toward better OS. There was no DFS difference between ANA and TAM, but ANA pts had inferior OS vs TAM, probably because ANA pts received second-line therapy off study. Based on these results and the known anticancer activity of ZOL demonstrated in preclinical and clinical studies, adding ZOL to adjuvant therapy should be considered for premenopausal pts with EBC.

Up-regulation of CGRP Expression by Acid-activated Calcium Channel Nociceptor Trpv1 is Involved in Bone Pain. Masako Nakanishi*[1], Kenji Hata[1], Tomotaka Nagayama[1], Toshihiko Nishisho[2], Toshiyuki Yoneda[1]. [1]Osaka University Graduate School of Dentistry, Japan, [2]BIGLOBE NEC, Japan

Bone pain is one of the most common complications in bone metastases, causing increased morbidity and undermining QOL in cancer patients. The mechanism of bone pain is poorly understood. We reasoned acidic conditions play a role in causing bone pain, since the microenvironment of bone metastases is acidic due to the presence of cancer cells, inflammatory cells and bone-resorbing osteoclasts and acid is a well-known algesic substance. To dissect the role of acid in bone pain, we studied calcitonin gene-related peptide (CGRP) which has been proposed to be critical in pain transmission. Immunohistochemical examination revealed CGRP expression in dorsal root ganglions (DRG), which are cell bodies of the sensory neurons. Moreover, transient receptor potential vanilloid subtype 1 (Trpv1), an acid-sensing calcium channel nociceptor, was co-expressed with CGRP in DRG. In organ cultures of DRG, acidic medium (pH 5.5) increased CGRP mRNA expression and this increase was significantly reduced by the selective Trpv1 antagonist I-RTX. Furthermore, CGRP mRNA elevation by acid was markedly decreased in DRG isolated from Trpv1-null mice. Conversely, Trpv1 introduction increased Ca^{2+} influx and CGRP expression upon acid stimulation in the F11 neuronal cells that are deficient in Trpv1. These results collectively suggest CGRP expression is regulated by acid-activated Trpv1 in the sensory neurons. We next studied the intracellular events that were involved in the up-regulation of CGRP expression by acid-activated Trpv1 with a special focus on CREB. CREB is a pivotal transcription factor in neuronal functions. We found phosphorylated CREB co-expressed with CGRP and Trpv1 in DRG. Acid stimulation increased CREB phosphorylation in the primary neuronal cells, which was inhibited by I-RTX. Knockdown of CREB expression by siRNA and blockade of CREB signaling by A-CREB, a dominant negative form of CREB, diminished acid-induced CGRP mRNA expression. Using the reporter assay and chromatin immunoprecipitation assay, we found acid elevated the transcriptional activity of CREB, thereby directly stimulating CGRP promoter activity. In conclusion, our results suggest that acidic microenvironments created in bone metastases activate Trpv1 in the sensory neurons, which in turn leads to up-regulation of CGRP mRNA expression via activation of CREB transcription activity. These series of events may be involved in the pathophysiology of bone pain.

Subnuclear Targeting Deficient Mutations of Runx2 Abrogate Cellular Migration and Metastasis in Prostate Cancer Cells. Jacqueline Akech*[1], John J. Wixted[1], Krystin Bedard[1], Margaretha van der Deen[1], Sadiq Hussain[1], Karthiga Gokul[1], Andre Van Wijnen[1], Janet L. Stein[1], Lucia R. Languino[1], Dario C. Altieri[1], Jitesh Pratap[1], Evan Keller[2], Gary Stein[1], Jane Lian[1]. [1]University of Massachusetts Medical School, USA, [2]University of Michigan, USA

The Runx2 bone-specific transcription factor is abnormally expressed in highly metastatic prostate cancer cells (PC3). Human tissue microarray studies of prostate tumors at stages of cancer progression show Runx2 is expressed in both adenocarcinomas and metastatic tumors (*Oncogene, 2010*). Previous studies identified functional activities of Runx2 in facilitating tumor growth and osteolysis in PC3 sublines observing a strong positive correlation between Runx2 cellular levels and increases expression of growth and metastasis-related genes (Survivin, MMP9, MMP13, OP), secreted bone-resorbing factors that promote osteolytic disease (PTHrP, IHH, VEGF) and more aggressive osteolytic bone disease in the intra-tibial metastasis model. Further, shRunx2 expression in PC3 cells blocked their ability to survive in the bone. In these studies, we further analyze the mechanisms by which Runx2 facilitates tumor growth and metastasis in prostate cancer cells. Runx2 is a scaffolding protein that interacts with numerous co-regulatory factors that mediate physiological signaling upregulated in tumor cells including canonical Wnt (TCF/LEF), Src (Yap) and growth factor (TGF, BMP, Smad) pathway responses. Runx2 protein-protein complexes are targeted to subnuclear domains for Runx2 functional activity through these pathways. We characterized PC3 cells knockdown by siRNA and showed decreased cell migration, invasion through Matrigel and downregulated metastasis-related genes. We then analyzed PC3 lines overexpressing functional mutations of Runx2 deficient in subnuclear targeting (C-terminus deletion) and point mutants that disrupted Src and BMP signaling. Runx2 target gene expression by qRT-PCR revealed that mutations of Runx2 abrogated the expression of MMP2, 9 and 13 as well as tumor growth and angiogenesis related markers; survivin, histone H4 and VEGF. In complementary studies, the effects of Runx2 mutations in abrogating tumor metastasis were further verified by invasion and migration assays showing a significant reduction of cellular migration analogous to a complete knockdown. These studies show that Runx2 is a key regulator of events associated with prostate cancer metastatic bone disease. Thus, subnuclear localization and organization of Runx2 is essential in promoting these metastasis events suggesting Runx2 as a molecular target for prostate cancer therapy.

Evaluation of Blood Flow and Skeletal Kinetics during Loading Induced Osteogenesis using PET Imaging. Ryan Tomlinson*, Kooresh Shoghi, Matthew Silva. Washington University in St. Louis School of Medicine, USA

Mechanical loading of the skeleton stimulates osteogenesis. Angiogenesis is essential to osteogenesis, although its role in loading induced osteogenesis is unknown. Previous studies show loading induced woven bone formation is associated with the production of new blood vessels, whereas lamellar bone formation is not. Our goal was to use positron emission tomography (PET) to examine blood flow and mineral kinetics at the site of loading induced bone formation. Lamellar or woven bone formation was induced by forelimb compression in adult rats using established methods. Right limbs were loaded, and left limbs were used as controls. PET scans were obtained 0, 1, 3, 7, and 14 days after loading and analyzed at the mid-forelimb.

^{15}O water, a freely diffusible radioisotope, was used to evaluate blood flow. Summed images (Fig 1A) show that loaded forelimbs in the lamellar group were not different from control limbs on days 0-7, but had 15% higher uptake on day 14 (after new bone formation). In contrast, loaded forelimbs in the woven group exhibited 30% higher uptake than controls on days 0-7, and remained 15% increased on day 14. Since ^{15}O water diffuses freely throughout the body, this radioisotope was modeled using a one-compartment, two-parameter model (Fig 1B). Modeling results confirm the static analysis.

^{18}F fluoride, a bone-seeking radioisotope, was used to evaluate skeletal kinetics. Summed images (Fig 2A) show no difference between loaded forelimbs in the lamellar group versus control at any time point. In contrast, loaded forelimbs from the woven group had 40-80% increased uptake compared to control limbs. A two-compartment,

three-parameter model was used to model ^{18}F kinetics near the site of bone formation (Fig 2B). At all time points, the macroparameter (K_1) as well as the microparameters (K_1, k_2, k_3) show significant differences in limbs producing woven bone versus lamellar bone (k_2 not significant at day 0 and 14).

In summary, PET imaging provided novel insight into the vascular response and mineral kinetics of osteogenic mechanical loading. There is an immediate and persistent increase in flow rate to the limbs producing woven bone, but only a small, late increase in limbs producing lamellar bone. Modeling of ^{18}F-fluoride indicated decreased vascular clearance during days 1-7, as well as increased incorporation of ^{18}F-fluoride into bone at all time points. We conclude that a strong vascular response precedes woven but not lamellar bone formation.

The Effect of Age on the Biomechanical Properties of Cortical Bone as a Function of Loading Rate. Daniel Nicolella*[1], Sidney Chocron[1], Arthur Nicholls[1], Don Moravits[1], Travis Eliason[1], Ryan Potter[1], Todd Bredbenner[1], Lorena Havill[2]. [1]Southwest Research Institute, USA, [2]Southwest Foundation for Biomedical Research, USA

The substantial increase in fracture risk with aging is a major clinical problem. With a growing elderly population, much effort has been given to understanding the mechanistic causes of the age-related decline in bone properties. However, the majority of these studies used very slow (e.g. quasi-static) loading rates, contrary to loading rates that are expected in a traumatic event such as a fall, where strain rates can be several orders of magnitudes higher. The objective of this investigation was to determine the effect of age on the biomechanical properties of cortical bone as a function of loading rate.

Cortical bone tensile mechanical properties were determined using specimens from the right femurs of 12 female baboons, part of a breeding colony at the Southwest National Primate Center/Southwest Foundation for Biomedical Research in San Antonio, TX. Animals were divided into two age groups: a young group (n=6, 6.63 ± 0.6 years) and an old group (n=6, 26.96 ± 1.3 years), corresponding to ages of ~20 human years and ~81 human years for young and old baboons, respectively. Two specimens from each femur were used in this study: one for quasi-static testing and one for dynamic testing. Quasi-static specimens were loaded to failure using an electro-mechanical test machine under displacement control at a strain rate of 0.0001 strain/sec to determine their quasi-static mechanical properties. Dynamic tensile tests were performed to failure on a custom built tensile Split Hopkinson Pressure Bar (SHPB) at an average strain rate of 194 strain/sec.

At quasi static strain rates, the mean elastic modulus (EM) for old bone was significantly greater than the mean EM for young bone. However, at dynamic rates, mean EM was greater for young bone compared to old bone. There was no difference in mean yield stress or failure stress between young and old bone at quasi-static loading rates, but at dynamic rates, both mean failure and yield stress were significantly lower in old bone. In contrast, mean failure strain in young bone was significantly greater than in old bone at low rates, but at high rates, there was no difference.

These results indicate that loading rate is a critical factor in determining aging affects on bone biomechanics and fracture risk suggesting that bone quality factors such as microdamage, microstructure, and physicochemical properties of the bone matrix contribute differently when bone is loaded at high strain rates compared to quasi-static strain rates.

Age-Related Changes in Bone Microarchitecture and Strength of the Distal Radius May Explain Sex Differences in Forearm Fracture Risk. Heather Macdonald*, Kyle Nishiyama, Jane Kang, David Hanley, Steven Boyd. University of Calgary, Canada

High-resolution pQCT (HR-pQCT) provides a non-invasive assessment of bone microarchitecture; however, few population-based data currently exist. In this cross-sectional study, we examined age-related changes in bone microarchitecture and strength at the distal radius (DR) and tibia (DT) in a population-based sample. Participants included 644 adults aged 20-99 yrs recruited from the Calgary, AB cohort of the Canadian Multicentre Osteoporosis Study (n=284 women, 140 men) or randomly selected from the general Calgary population (n=158 women, 62 men). We performed a standard morphological analysis of the DR and DT with HR-pQCT (Scanco Medical, AG), applied a customized segmentation algorithm to quantify cortical porosity (Ct.Po) and used finite element (FE) analysis to estimate bone strength (failure load) and the percentage of load carried by the cortex. In addition, we calculated a DR load-to-strength ratio as the ratio of estimated fall force to bone strength. We used t-tests to compare bone outcomes between young adult (20-29 yrs) women and men, and linear regression to predict change in bone outcomes between 20 and 90 yrs. Bone area, which was 33% larger in young men at both sites, changed similarly with age in women and men at the DT, but increased 22% more in men at the DR ($p<0.001$). Trabecular number and thickness (Tb.Th) were 7-20% higher in young men at both sites, but Tb.Th at the DR declined more with age in men (-16%) than women (-2%, p=0.004). Ct.Po was 31-44% lower in young women than young men at both sites, but women demonstrated 92-176% larger age-related increases in Ct.Po than men at both sites ($p<0.001$, Figure). The cortex carried 13-14% more load in young women at both sites, and the percentage of load carried by the DR cortex did not change with age in women, but declined by 17% in men (p=0.007). FE-estimated bone strength was 34-47% greater in young men at both sites, but the change with age was similar in women and men. In contrast, the load-to-strength ratio, an estimate of forearm fracture risk, was 41% lower in young men and increased more in women (+74%) than men (+47%) with age (p=0.009, Figure). Our results highlight important site- and sex-specific differences in patterns of age-related bone loss. In particular, less periosteal expansion, more porous cortices and a greater percentage of load carried by the cortex at the distal radius in women may underpin the well-documented sex differences in forearm fracture risk.

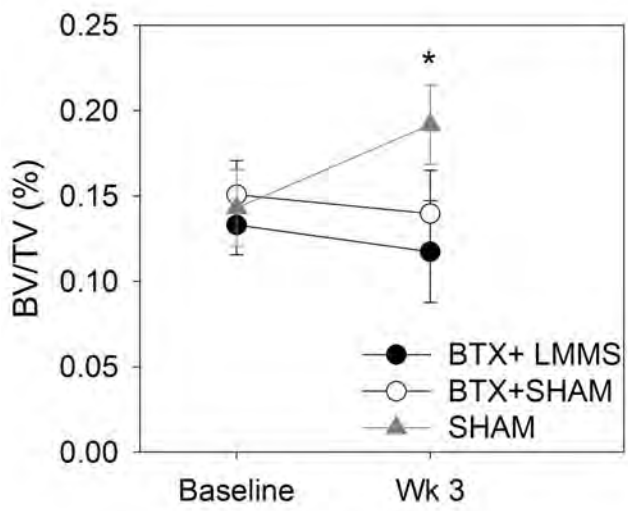
High-Frequency, Low-Magnitude Mechanical Signals Do Not Prevent Bone Loss in the Absence of Muscle Activity. Sarah Manske*[1], Steven Boyd[1], Craig A. Good[1], Ronald Zernicke[2]. [1]University of Calgary, Canada, [2]University of Michigan, USA

Muscles play a role in transmitting mechanical stimuli to bone, and exogenous high-frequency, low-magnitude mechanical signals (LMMS) may promote bone adaptation by mimicking postural muscle activity. We hypothesized that daily exposure to LMMS would maintain bone structure despite muscle disuse following injection with botulinum toxin type A (BTX). Female 16 wk old BALB/c mice (N = 25) were assigned to (a) BTX + LMMS, (b) BTX + Sham, or (c) Sham. BTX mice were injected with BTX (20 μL; 1 U/100 g body mass) into the posterior musculature of the left hindlimb. For 20 min/d, 5 d/wk, for 3 wk, all mice were anaesthetized and placed on a bed with the left leg strapped to a holder (tibiofemoral angle ~120°). Through the holder, the LMMS group received 45 Hz, 0.6 g acceleration with ~20 με without weight bearing. The sham groups received no mechanical input. The right leg served as an internal control. At baseline and 3 wk, muscle cross-sectional area (MCSA) and tibial bone properties (at metaphysis and diaphysis) were assessed with in vivo microCT (vivaCT40, Scanco Medical). Mice were sacrificed at 3 wk, and muscles were dissected and weighed. MCSA decreased in the BTX + LMMS leg (-47% from baseline) and the BTX + Sham leg (-46% from baseline). The change in MCSA in these groups was different from the Sham (0% from baseline, $p < 0.001$). Similarly, bone volume fraction (BV/TV) decreased in the BTX + LMMS leg (-12% from baseline) and BTX + Sham leg (-7% from baseline) (Figure). The change in BV/TV in these groups was different from the Sham (+34% from baseline, $p < 0.001$). Trends for gastrocnemius mass, soleus mass, trabecular thickness, and diaphyseal cortical area were similar. For all outcomes examined, there were no significant differences between the BTX + LMMS and BTX + Sham groups, nor between-group differences in the contralateral control leg. Our results suggest that LMMS did not prevent bone loss induced by a rapid decline in muscle activity. LMMS, which appears to operate primarily by increasing osteoblastic activity, did not overcome the osteoclastic action triggered by disuse. The daily loading duration was shorter than would be expected from postural muscle activity, and longer exposure may prevent bone loss. However, if LMMS were mimicking postural muscle activity, we would expect a diminished magnitude of bone loss. Understanding the mechanism by which LMMS stimulates bone adaptation will maximize its therapeutic potential.



Changes in bone volume fraction (BV/TV) after BTX injection and LMMS or sham in BALB/c mice

Increased Cortical Porosity during Puberty May Increase Distal Radius Fracture Risk in Boys: A HR-pQCT Study. Kyle Nishiyama*[1], Heather Macdonald[1], Melonie Burrows[2], Heather McKay[2], Steven Boyd[1]. [1]University of Calgary, Canada, [2]University of British Columbia, Canada

Distal radius fractures peak during puberty and are more common in boys than girls (Cooper et al. JBMR, 2004). A deficiency in cortical bone may underpin the high incidence of forearm fractures in boys (Kirmani et al. JBMR, 2009). For example, cortical density is lower in boys than girls during puberty (Wang et al. JBMR, In Press); however, little is known about the role of cortical porosity. Thus, we aimed to determine the maturity- and sex-related differences in cortical parameters and bone strength, estimated using finite element (FE) analysis and high-resolution pQCT (HR-pQCT). Subjects were healthy girls (N = 174, Age: 14.6 ± 3.9 yrs) and boys (N = 151, Age: 15.6 ± 3.4 yrs) who self-reported their maturity status using the method of Tanner. We grouped the subjects into prepubertal (Tanner I, n=49), pubertal (Tanner II, III, IV, n=155) and postpubertal (Tanner V, n=121) categories. To avoid the growth plate, we scanned the 7% site of the non-dominant distal radius using HR-pQCT (XtremeCT, Scanco Medical AG). We applied a validated automatic segmentation procedure (Buie et al. Bone, 2007; Nishiyama et al., JBMR, In Press) to determine cortical porosity (Ct.Po, %), cortical thickness (Ct.Th, mm) and cortical area (Ct.Ar, mm^2). We used FE analysis to estimate bone strength (ultimate stress, MPa) and determine the percentage of load carried by the cortex. A General Linear Model was applied to determine differences between sexes and across maturity groups. Cortical parameters and bone strength were not significantly different between prepubertal boys and girls (Figure 1). In the pubertal and postpubertal groups, Ct.Po and Ct.Ar were 18-65% lower in girls than boys ($p<0.001$). However, Ct.Th, bone strength, and the load distribution were similar in pubertal and postpubertal boys and girls. Within-sex comparisons indicated that Ct.Po was 35% and 76% lower in pubertal and postpubertal girls compared with prepubertal girls, respectively ($p<0.001$). In contrast, Ct.Po was similar in prepubertal and pubertal boys, but was 35% lower in postpubertal boys compared with prepubertal boys ($p<0.01$). Our results suggest that despite similar bone strength (size adjusted) across puberty, Ct.Po remains higher in boys during puberty, which corresponds to the time of peak forearm fracture incidence. Further investigation may determine whether regional variation in Ct.Po contributes to sex differences in forearm fracture risk during puberty.

Effects of Non-Enzymatic Glycation on Trabecular Bone Fragility May be Mediated Through Changes in Bone Matrix Quality and Microarchitecture. Deepak Vashishth, Lamya Karim*. Rensselaer Polytechnic Institute, USA

Factors other than reduced bone mass, such as changes in bone quality, may contribute to fracture risk. In addition to changes in the extracellular matrix, alterations in bone quality may be induced by changes in trabecular microarchitecture and microdamage (MDx), which also influence each other. Non-enzymatic glycation (NEG) creates crosslinks known as advanced glycation end products (AGEs) that accumulate and increase bone fragility [1]. The goal of this study was to investigate the interrelationships between NEG, microarchitecture, and MDx, and to determine the dominant factors influencing bone's mechanical integrity. 23 cancellous bone cores from tibiae of human donors (Ages 18 to 97) were imaged with microcomputed tomography to obtain microarchitectural information. Cores were mechanically tested via compression tests, and were subsequently stained with lead-uranyl acetate in order to quantify MDx [2]. From a hydrolyzed bone slice, total AGE content was measured via a fluorometric assay and pentosidine was measured through ultra-high performance liquid chromatography for each specimen. Crosslink content was normalized to collagen content where collagen was calculated based on hydroxyproline quantity measured [3]. Spearman correlations were run for crosslink quantities with microarchitecture, MDx, and mechanical parameters. Forward stepwise regression analysis was used to determine the most significant variables influencing mechanical properties. Mechanical measures related to bone fracture resistance including yield strain, ultimate strain and toughness all decreased with increase in NEG crosslinks (AGEs and PEN). Similarly these variables decreased with transition

to a rod-like from a plate-like structure and increase in microdamage. Stepwise regression, however, yielded only NEG crosslinks (AGEs or PEN) as the significant predictor of bone fragility because NEG crosslinks were also correlated to microarchitectural indexes and microdamage. Our results indicated that NEG depreciates trabecular bone's mechanical integrity and its effects on trabecular bone may be mediated by changes in microarchitecture and bone matrix quality.

Contributions of Cortical and Trabecular Bone to Age-related Declines in Vertebral Strength are not the Same for Men and Women. Blaine Christiansen*[1], David Kopperdahl[2], Douglas Kiel[3], Tony Keaveny[4], Mary Bouxsein[5]. [1]University of California - Davis Medical Center, USA, [2]O.N. Diagnostics, USA, [3]Hebrew SeniorLife, USA, [4]University of California, Berkeley, USA, [5]Beth Israel Deaconess Medical Center, USA

Women have a higher incidence of osteoporotic fractures than men, with over 25% of these being vertebral fractures. While this higher incidence of fractures in women is likely partially due to women having a greater decline in vertebral bone density than men, much less is known about compartment-specific changes in vertebral strength. We hypothesize that age-related changes to vertebral structure and strength in the cortical and trabecular compartments differentially affect men and women, ultimately making women more susceptible to vertebral fractures. To investigate these compartment-specific changes, we used finite element analysis of quantitative computed tomography (QCT) scans of the lumbar (L3) and thoracic (T10) vertebral bodies of young and old men and women to characterize bone structure, compressive strength, and bending stiffness. Subjects were selected from participants in the Framingham Heart Study Multidetector CT Study, and consisted of 30 men age 35-42, 30 women age 36-41, 30 men age 73-82, and 30 women age 74-83. We found larger age-related differences in vertebral compressive strength at both vertebral levels for women than for men (Table 1). This was associated with significant age-related differences in trabecular compressive strength in both sexes (with larger differences in women), but cortical strength declined only in women. Bending stiffness behaved similarly, with significant age-related declines at both vertebral levels in women, but no age-related changes in men. Similar changes were also seen for volumetric BMD, which, for women, declined with age in both trabecular and cortical compartments, whereas in men differences were primarily observed in trabecular bone only. This compartment-specific sexual dimorphism is of particular interest since a higher percentage of the total compressive strength of the vertebral body is attributable to the cortical compartment in old vs. young subjects. Altogether, these data point to a differential age-related loss of bone between men and women that is compartment specific — information that provides unique insight into vertebral fracture etiology and which may have relevance for improved sex-specific vertebral fracture risk assessment.

Men and Women With Similar Spine aBMD Have Different Bone Size, Volumetric Density, and Strength: The Framingham Study. Kerry Broe*[1], Douglas Kiel[2], Xiaochun Zhang[2], Elizabeth Samelson[3], Blaine Christiansen[4], Ching-An Meng[5], R Manoharan[6], J D'Agostino[6], Thomas Lang[7], Serkalem Demissie[8], LA Cupples[8], Mary Bouxsein[6]. [1]Hebrew Senior Life, USA, [2]Hebrew SeniorLife, USA, [3]Hebrew SeniorLife, Harvard Medical School, USA, [4]University of California - Davis Medical Center, USA, [5]Hebrew SeniorLife, Institute for Aging Research, USA, [6]Beth Israel Deaconess Medical Center, USA, [7]University of California, San Francisco, USA, [8]Boston University School of Public Health, Department of Biostatistics, USA

Areal BMD (aBMD) is commonly used to diagnose osteoporosis and predict fracture risk. However, bone strength depends on bone size, morphology and density – characteristics that aBMD does not distinguish. Thus, the mechanisms underlying sex-specific differences in skeletal fragility may be obscured by aBMD measures. In particular, we hypothesized that men and women with similar spine aBMD would have different vertebral size and volumetric BMD (vBMD). To test this, we compared 3D QCT bone measures among pairs of men and women matched for age and spine aBMD.

Subjects were selected from 1,138 men and 1,086 women from the Framingham Heart Study Multidetector Computed Tomography Study, who had volumetric QCT scans of the thoracic and lumbar spine. QCT scans were analyzed using custom software to measure simulated aBMD (g/cm^2), vertebral body cross sectional area (CSA, cm^2), trabecular volumetric BMD (Tb.vBMD, g/cm^3), integral volumetric BMD (Int.vBMD, g/cm^3), and to calculate the cortical volume ratio (cortex volume/vertebral volume), trabecular volume ratio (trabecular volume/vertebral volume), and compressive strength (Newtons) at L3. From these subjects, we identified 629 male/female pairs (1:1 match) matched on age ($\pm$ 1 yr) and QCT-derived aBMD of L3 ($\pm$ 1%), with an average age of 53 yrs (range: 34-83 yrs), and aBMD of 1.21 $\pm$ 0.58 g/cm^2 (range: 0.57-1.79 g/cm^2). Paired t-tests and multivariate regression were used to assess the sex-specific differences in bone measures.

All QCT bone measures differed significantly between men and women matched for aBMD (see Table, all $p<0.0001$). Differences remained significant after adjusting for height and weight. Matched for aBMD, men had 20% larger vertebral CSA, but lower Int.vBMD (-7%) and Tr.vBMD (-8.6%) than women. Their bigger vertebral bodies compensated for lower density, though, as men had 11% higher predicted compressive strength than women. Further, men had greater trabecular ratios but smaller cortical ratios compared to aBMD-matched women.

In conclusion, vertebral size, morphology, and density differ significantly between men and women matched for spine aBMD, suggesting that men and women attain the same aBMD by different mechanisms, namely a larger vertebral body in men and higher volumetric density in women. These results provide novel information regarding sex-specific differences in mechanisms that underlie skeletal fragility.

Mean spine QCT measures and p-values for paired t-tests for 629 men and women from the Framingham Study matched on age and QCT-derived aBMD

QCT Measures for L3	Men	Women	P-value
Cross-sectional area (cm^2)	12.37 ±1.19	10.29 ±1.31	<0001
Trabecular vBMD (g/cm^3)	0.139 ±0.037	0.152 ± 0.043	<0001
Integral vBMD (g/cm^3)	0.183 ±0.035	0.197 ±0.039	<0001
Cortical volume ratio	0.140 ±0.009	0.156 ±0.009	<0001

BMD is a heritable ($h^2 \asymp 0.60$) complex trait used for the assessment of fracture risk. Genome-wide association studies (GWAS) have identified 22 loci associated with BMD at genome-wide significant (GWS) level. As part of the Genetic Factors of OSteoporosis (GEFOS) Consortium we performed inverse-variance fixed-effects meta-analysis of 17 GWAS for LS-BMD and FN-BMD investigating 2.7 million single nucleotide polymorphism (SNPs) in individuals of Caucasian (n=32,000) and Han Chinese (n=800) ancestry. Traits were analyzed as sex-specific age- and weight-adjusted standardized residuals. Associations were declared GWS at $P<5x10^{-8}$ and suggestive at $5x10^{-6} < P < 5x10^{-8}$ after a conservative double-genomic control correction with an inflation factor of 1.1. In total, we detected 34 GWS and 49 suggestive associated loci. Of the GWS hits, 20 loci replicate previous findings and 14 represent novel loci. Two previously reported loci were significant ($P< 1x10^{-7}$) but not at GWS level (*DCDC5, ARHGAP1*). These 34 GWS hits map within or nearby genes involved in pathways relevant to bone biology; i.e. genes in WNT pathway (*WNT16, AXIN1, WNT4, LRP5, CTNNB1, GPR177, FOXC2*), NF-kB pathway (*AKAP11, TNSFR11B, RANK, OPG*) and/or part of the SOX family of transcription factors (*SOX4, SOX6, SOX9*). Site specificity was observed in six loci based on significant evidence for heterogeneity (Phet): four had significantly stronger effect on LS-BMD (*AKAP11, STARD3NL, KCNMA1, MPP7* with Phet<0.0002) and two loci on FN-BMD (*MEF2C, XKR9* with Phet<0.0006). Such site specificity in ~18% of the GWS loci is consistent with the ~70±6% genetic correlation observed between BMD sites. The 34 GWS loci accounted for ~5% of the phenotypic (~8% of the genetic) variance in BMD. All 83 identified loci will be followed-up by de-novo genotyping in ~50,000 additional samples in association with BMD and with fracture risk including more than 10,000 cases and 40,000 controls. In conclusion, we identified 34 GWS loci associated with LS-BMD and/or FN-BMD. We expect to at least double the number of GWS hits by follow-up replication genotyping and to examine their influence on fracture risk. These findings provide novel insight into relevant factors and biological pathways underlying the complex genetic architecture of BMD variation.

Contribution of Genetic Profiling to Individualized Prognosis of Fracture. Bich Tran*[1], Nguyen Nguyen[1], Vinh Nguyen[2], Jacqueline Center[1], John Eisman[1], Tuan Nguyen[1]. [1]Garvan Institute of Medical Research, Australia, [2]School of Electrical Engineering & Telecommunications, University of New South Wales, Australia

While it is well recognized that the fracture risk is determined by multiple genes, each with moderate effect, it is contentious whether a combination of many genes can help the prognosis of fracture for an individual. The present study was designed to examine the contribution of genetic profiling to fracture prognosis. The study was built on the on-going Dubbo Osteoporosis Epidemiology Study, in which fracture and risk factors of 858 men and 1358 women had continuously been monitored from 1989 and 2008. Fragility fracture was ascertained by radiological reports. Bone mineral density at the femoral neck was measured by DXA (GE-Lunar, Madison, WI, USA). Using the actual clinical data, we simulated 50 independent genes with allele frequencies ranging from 0.01 to 0.60 and relative risk from 1.01 to 3.0, such that genes with large effect sizes have lower allelic frequency. Three predictive models were then fitted to the data in which fracture was a function of (I) clinical risk factors only (age, BMD, prior fracture, and falls); (II) genes only; and (III) clinical risk factors and 50 genes. The area under the receiver operating characteristic curve (AUC) was used to assess the degree of discrimination; and reclassification analysis to assess the incremental prognostic value of model with genes. During the follow-up, 17% (n = 149) men and 31% (n = 426) women had sustained a fragility fracture. The distribution of simulated genetic risk score had a median genetic risk score of 13 (range: 4 to 25). Approximately 10% of individuals had <10 risk genotypes; while other 10% had more than 16 risk genotypes. Compared to those with <10 risk genotypes, those with 10-16 risk genotypes had their odds of fracture increased by 5.47 (95% CI: 3.03 – 9.90). Those with >16 risk genotypes had the highest risk of fracture (OR 43.6; 95% CI 22.8 – 83.2). The AUC for model I (clinical risk factors) was 0.77, lower than that of model II with 50 genes (AUC 0.82). Adding genes into the clinical risk factors model (model III) increased the AUC to 0.88, and improved the accuracy of fracture classification by 45%, with most (41%) was the improvement in specificity. In the presence of clinical risk factors, the number of genes required to achieve an AUC of 0.85 was around 25. These results suggest that genetic profiling could enhance the predictive accuracy of fracture prognosis, and help identify high-risk individuals for intervention to appropriate management of osteoporosis.

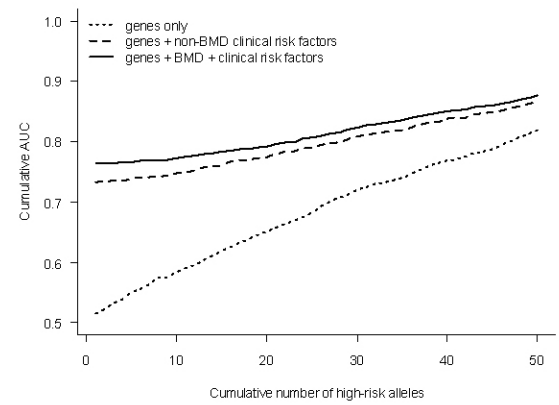

Figure 1. Cumulative AUC as a function of number of genes only (dotted line), with genes + non-BMD clinical risk factors (dashed line), and with genes + BMD + clinical risk factors (solid line).

Figure 1. Cumulative AUC

Systems Genetics Identifies *Bicc1* as a Regulator of Bone Mineral Density. Charles Farber*[1], Ana Lira[1], Yi-Hsiang Hsu[2], Brian Bennett[3], Luz Orozco[3], Gregory Hong[1], Atila van Nas[3], Hyun Kang[3], Eleazar Eskin[3], Elizabeth Bryda[4], Douglas Kiel[5], Thomas Drake[3], Clifford Rosen[6], Aldons Lusis[3]. [1]University of Virginia, USA, [2]Hebrew SeniorLife & Harvard Medical School, USA, [3]University of California, Los Angeles, USA, [4]University of Missouri, USA, [5]Hebrew SeniorLife, USA, [6]Maine Medical Center, USA

Systems genetics is an approach that combines the genetic analysis of clinical and molecular phenotypes. The advantage of systems genetics is that in addition to discovering genes affecting complex bone traits, it can also provide information on the function of newly identified genes. In the current study, we used systems genetics to identify bicaudal C homolog 1 (*Bicc1*) as a candidate regulator of BMD and predict that it plays a role in osteoblastogenesis. In an F2 mouse cross derived from the C57BL6/J and C3H/HeJ strains, we demonstrated that *Bicc1* transcript levels were regulated by a local expression quantitative trait locus (eQTL). In addition, the *Bicc1* eQTL was

coincident with the BMD QTL, *Bmd42.1*, and based on a causality modeling analysis we predicted that *Bicc1* was responsible for the effects of this locus. In support of this hypothesis, *jcpk*$^{+/-}$ mice which are heterozygous for a null mutation in *Bicc1* had reductions of 4.9% in femoral areal BMD. Moreover, using genome-wide association data from the Framingham Osteoporosis Study we identified a single nucleotide polymorphism in the first intron of human BICC1 that was associated (Bonferroni adjusted P=0.04) with total body BMD. To investigate the function of *Bicc1* we evaluated its expression in a panel of 96 mouse tissues and cell lines and found it to be the most highly expressed in mature osteoblasts. Furthermore, transcriptional network analysis of cortical bone microarray profiles generated in a panel of 97 mouse inbred strains indicated that *Bicc1* was associated with genes involved in osteoblast differentiation. Consistent with these findings the siRNA knockdown of *Bicc1* in primary calvarial osteoblasts resulted in reductions in alkaline phosphatase activity and *in vitro* mineralization in a dose-dependent manner. Similar deficiencies in osteoblast differentiation phenotypes were observed in primary calvarial osteoblasts isolated from *jcpk*$^{+/-}$ mice. These data identify *Bicc1* as a novel BMD gene and suggest that it influences BMD via a role in osteoblast-mediated bone formation. Additionally, our results highlight the strengths of systems genetics for gene discovery and annotating genes of unknown function.

Lean body mass is a highly heritable trait yet few underlying genes have been identified. The fat and lean soft-tissue compartments of the body can be assessed by relatively simple, accurate methods like DXA and bioelectrical impedance analysis (BIA). Large cohort studies have accumulated such phenotypic information on body composition that permits large-scale GWAS. We performed a meta-analysis of GWAS for total body (TBLM) and appendicular (arms and legs) (aLM) lean mass. In each cohort, ~ 2.5 mil autosomal SNPs were imputed from the International HapMap Project CEU ref panel II. The sample included 39,030 individuals (55% women) of Caucasian ancestry (ages 18 to 100 years) from 20 cohort studies. Lean soft-tissue mass from DXA or BIA were available for the TBLM in all cohorts, while aLM was available in 15 studies (n~28,000) aLM was determined from BIA using a published and validated equation. All cohorts performed GWA analyses on imputed data adjusting for age, age^2, sex, height and total body fat mass. Inverse variance meta-analysis of study-specific results was performed using METAL with fixed effects models. Evidence of genome-wide significance (GWS) was set at $P<5x10^{-8}$ and suggestive evidence (sGWS) at $P<2.3x10^{-6}$ after a conservative double genomic control correction (λ_{GC} 1.03 to 1.06). For TBLM, one locus was associated at GWS (VCAN) and seven at sGWS level (with markers mapping in *PIK3C2B*, *NPSR1*, *RHOC*, and *FTO* and close to the *DCBLD2*, *FRK*, and *ARHGEF4* gene regions). For aLM, one locus was associated at GWS (*PKIB*) while five at sGWS level (with markers mapping in *SERINC1*, *VCAN*, *TNRC6B*, *and HSF2*, and near *ZNF804A*). There was no evidence for significant heterogeneity of results across cohorts. This is the largest GWAS meta-analysis conducted to date for lean body mass identifying novel loci that contribute to this quantitative trait, although only *VCAN*, a large chondroitin sulfate proteoglycan that is a major component of the extracellular matrix, was common to both lean mass phenotypes. Several of the loci were in or near genes that are expressed in skeletal muscle. Further replication by de-novo genotyping is underway for the GWS and sGWS findings. Given the intimate biologic relation between muscle and bone mass, the influence of these loci on fracture risk will also be examined.

Effect of Odanacatib on Bone Density and Bone Turnover Markers in Postmenopausal Women with Low Bone Mineral Density: Year 4 Results. Neil Binkley*[1], Henry Bone[2], John Eisman[3], David Hosking[4], Bente Langdahl[5], Ian Reid[6], Heinrich Resch[7], Jose Rodriguez Portales[8], Romana Petrovic[9], Carolyn Hustad[10], Carolyn DaSilva[10], Arthur Santora[11], Antonio Lombardi[12]. [1]University of Wisconsin, USA, [2]Michigan Bone & Mineral Clinic, USA, [3]Garvan Institute of Medical Research, Australia, [4]Nottingham City Hospital, United Kingdom, [5]Aarhus Sygehus, Aarhus University Hospital, Denmark, [6]University of Auckland, New zealand, [7]Medical University Vienna, Austria, [8]Pontificia Universidad Católica de Chile, Chile, [9]Merck Sharpe & Dohme, Belgium, [10]Merck, USA, [11]Merck Research Laboratories, USA, [12]Merck & Co., Inc., USA

The selective cathepsin K inhibitor odanacatib (ODN) reduced bone resorption markers and progressively increased bone mineral density (BMD) during 3 years of treatment in a Phase 2b study. This study was extended for 2 additional years to further assess ODN efficacy and long-term safety.

In the 2-year base study, postmenopausal women with BMD T-scores between -2.0 and -3.5 at the lumbar spine, femoral neck, trochanter or total hip received placebo or ODN at 3, 10, 25 or 50 mg weekly. In Year 3, participants were re-randomized to ODN 50 mg weekly or placebo. In Years 4/5, women who received placebo or 3 mg ODN in Years 1/2 and placebo in Year 3 were switched to 50 mg ODN for Years 4/5; all others continued with their Year 3 regimen. 141 women entered the extension, and 133 completed 4 years. Endpoints were BMD at the lumbar spine (primary), total hip and hip subregions, and 1/3 radius; levels of biochemical bone turnover markers; and assessments of safety.

Overall, 100 women received 50 mg ODN during Year 4 and 41 received placebo. Continuous treatment with 50 mg ODN for 4 years induced significant BMD increases from baseline at the spine (10.7%), total hip (8.3%), femoral neck (8.9%), and trochanter (10.3%) and maintained BMD (-0.1%) at the 1/3 radius; BMD changes from Year 3 were 2.8% (spine), 2.5% (total hip), 3.9% (femoral neck), and 2.9% (trochanter). Serum CTx remained low at Year 4 (-41%), whereas BSAP was relatively unchanged (-2%) from baseline. Women who received active treatment for 2 years and switched to placebo for 2 years experienced bone loss, with BMD near baseline for most sites and decreased by 4.5% at the 1/3 radius at the end of Year 4. Levels of bone turnover markers in women who discontinued active treatment after 2 years rose in the first month off-treatment, but all levels returned to baseline by the end of Year 4. ODN was generally well tolerated.

In summary, 4 years of ODN treatment increased lumbar spine and hip BMD and was generally well-tolerated in postmenopausal women with low bone mass. Bone formation markers remained relatively unaffected. Discontinuation of ODN after 2 years of treatment was promptly followed by resolution of effects on bone turnover and density such that BMD and bone biomarker levels at Year 4 were at or near baseline.

A New Active Vitamin D Compound, Eldecalcitol, Is Superior to Alfacalcidol in Preventing Fractures in Osteoporotic Patients. Toshio Matsumoto*[1], Masako Ito[2], Yasufumi Hayashi[3], Takako Hirota[4], Yusuke Tanigawara[5], Teruki Sone[6], Masao Fukunaga[7], Masataka Shiraki[8], Toshitaka Nakamura[9]. [1]University of Tokushima Graduate School of Medical Sciences, Japan, [2]Nagasaki University Hospital, Japan, [3]Tokyo Metropolitan Rehabilitation Hospital, Japan, [4]Kyoto Koka Women's University, Japan, [5]Keio University, Japan, [6]Kawasaki Medical School, Jpn, [7]Kawasaki Medical School, Japan, [8]Research Institute & Practice for Involutional Diseases, Japan, [9]University of Occupational & Environmental Health, Japan

Eldecalcitol, a new active vitamin D compound, has been shown to have superior effects to alfacalcidol in suppressing bone resorption and increasing BMD of the spine and the hip with similar safety profile to alfacalcidol in osteoporotic patients. However, the effect of eldecalcitol on the prevention of osteoporotic fractures has not been evaluated in randomized trials. This randomized, active comparator, double-blind study was undertaken to examine whether eldecalcitol has a superior effect to alfacalcidol in preventing osteoporotic fractures. We assigned 1054 subjects (1030 females and 24 males) with osteoporosis aged from 46 to 92 years to receive either 0.75 μg eldecalcitol or 1.0 μg alfacalcidol once a day for 36 months. Subjects with serum 25-hydroxyvitamin D below 50 nmol/L were supplemented with 400 IU/day vitamin D_3. Vertebral fracture in eldecalcitol group decreased with time, and was significantly less than that in alfacalcidol group during the third year (odds ratio, 0.51; 95% confidence interval [CI], 0.27-0.97), with a reduction in overall vertebral fracture at 36 months (13.4 vs. 17.5%; hazard ratio, 0.74; predefined 90% CI, 0.56-0.97). The anti-fracture effect of eldecalcitol compared with alfacalcidol was more pronounced in patients with BMD T-score -2.5 or less (15.1 vs. 26.6%; hazard ratio 0.56; 95% CI, 0.34-0.90), and in patients with 2 or more prevalent vertebral fractures (23.7 vs. 36.8%; hazard ratio 0.61, 95% CI, 0.40-0.93). Eldecalcitol showed no significant effect on the total non-vertebral fractures, but markedly reduced the incidence of wrist fractures (1.1 vs. 3.6%; hazard ratio 0.29; 95%CI, 0.11-0.77). Eldecalcitol exhibited stronger effects on both serum BALP and urinary NTX, as well as hip (0.4 vs. -2.3%; $p<0.001$) and lumbar BMD (3.4 vs. 0.1%; $p<0.001$) compared with alfacalcidol after 36 month of treatment. Two subjects in eldecalcitol group but no one in alfacalcidol group experienced hypercalcemia over 11.5 mg/dL. Mean postprandial urinary Ca excretion at 36 months was 0.242 and 0.209 mg/dLGF in eldecalcitol and alfacalcidol groups, respectively. It is concluded that eldecalcitol has superior effect over alfacalcidol in preventing vertebral and wrist fractures in osteoporotic patients with sufficient vitamin D supply, with similar safety profiles to alfacalcidol.

Effects of Weight Loss, Exercise, or Combined on Bone Mineral Density and Markers of Bone Turnover in Frail Obese Older Adults. Krupa Shah*[1], Nehu Parimi[2], Suresh Chode[2], David Sinacore[2], Nicola Napoli[3], Reina Armamento-Villarea[4], Dennis Villareal[4]. [1]University of Rochester School of Medicine, USA, [2]Washington University School of Medicine, USA, [3]University Campus Biomedico, Italy, [4]University of New Mexico School of Medicine, USA

Background. Although weight loss therapy ameliorates frailty and improves metabolic coronary heart disease risk factors in obese older adults, weight loss can cause bone loss and increased fracture risk. It is not known whether exercise training can prevent bone loss and increased bone turnover when obese older adults undergo voluntary weight loss.

Methods. We conducted a 1-year randomized-controlled trial to evaluate the independent and combined effects of weight loss and exercise on bone mineral density and markers of bone turnover in 107 obese (BMI≥30 kg/m^2) older (≥65 yrs) adults. They were randomized to one of four groups: Diet-induced weight loss (DIET), Exercise training (EXER), Diet-induced weight loss + exercise training (DIET+EXER) and Healthy-lifestyle (CONTROL). All groups received calcium and vitamin D supplementation to adjust intake to 1200-1500 mg and 1000 IU per day, respectively.

Results. Ninety-four (87%) participants completed the study; adherence was 82 ± 9% for diet and 83 ± 16% for exercise interventions. After one year, body weight decreased in the DIET (-10 ± 5%) and DIET+EXER groups (-9 ± 5%) whereas weight was maintained in the EXER (-1 ± 4%) and CONTROL groups (between-group $P<.05$). Compared with the CONTROL group, total hip BMD decreased in the DIET group (-2.3 ± 0.4%) while it increased in the EXER group (1.3 ± 0.3%) (between-group $P<.05$). Hip BMD did not change in the DIET+EXER group (-0.8 ± 0.5) similar to the CONTROL group (-0.4 ± 0.3%) (between-group $P>.05$). Compared with the CONTROL group, serum markers of bone resorption and formation increased in the DIET group (CTX: 31± 11%, PINP; 9 ± 7%, osteocalcin: 26 ± 9%) while they decreased in the EXER group (serum CTX: -14 ± 7%, and PINP; -13 ± 6%, osteocalcin: -15 ± 7%) (between-group $P<.05$). Markers of bone turnover did not change in the DIET+EXER group (CTX: 15 ± 9%, PINP; 3 ± 8%, osteocalcin:-8 ± .5%) similar to the CONTROL group (CTX: 4 ± 8%, PINP; 1 ± 5%, osteocalcin:-0.4 ± .3%) (between-group $P>.05$).

Conclusions. Regular exercise is effective in preventing bone loss and increase in bone turnover during dietary-induced weight loss in obese older adults with adequate calcium and vitamin D intake. Therefore, exercise should be included as part of a comprehensive weight loss program to offset the adverse effects of dietary-induced weight loss on bone.

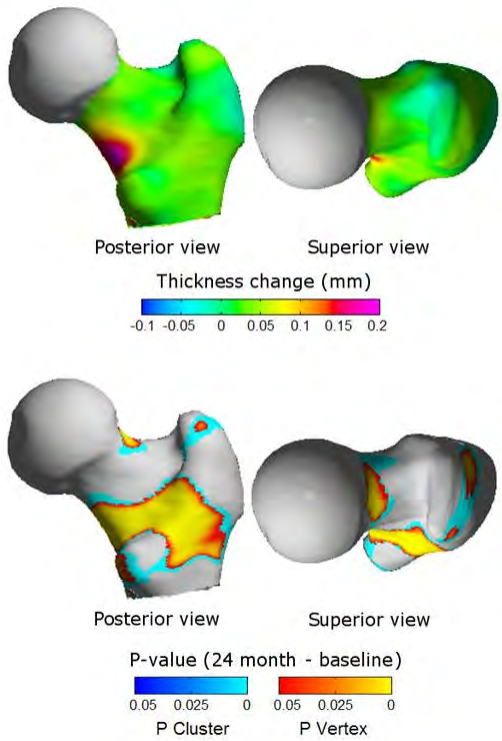
Teriparatide Treatment of Osteoporotic Women Increases Cortical Bone at Critical Sites in the Proximal Femur: An In Vivo Study using High Resolution Cortical Thickness Mapping. Andrew H Gee[1], Graham M Treece[1], Paul Mayhew[1], Jan Borggrefe[2], Kenneth Poole*[1]. [1]University of Cambridge, United Kingdom, [2]University of Schleswig-Holstein, Germany

Teriparatide treatment of osteoporotic women improved hip bone structure, most likely due to endocortical apposition of new bone since there was no associated increase in periosteal size (Borggrefe et al, JBMR in press). Teriparatide may enhance bone strength by increasing the sensitivity to load stimuli, but evidence for this effect in humans is lacking. In this study, we sought to identify the precise location of teriparatide-stimulated cortical bone growth in the human proximal femur. Women with severe osteoporosis were treated with teriparatide (the EUROFORS study) for 24 months, with QCT scans of the hips performed at baseline, 12 and 24 months. A novel cortical thickness mapping technique (Treece et al, Medical Image Analysis in press) was used to evaluate both proximal femurs of 65 qualifying QCT participants at baseline and 24 months. The surface of each femur was segmented from the CT scans using a semi-automated technique (119 femurs in total, 11 excluded mainly due to metalwork artefacts). This surface was used to automatically guide approximately 7,000 independent measurements of cortical thickness over the femur. Cortical thickness estimates were mapped to a canonical femur surface by non-rigid registration of the 119 femurs. Statistical parametric mapping (SPM) was used to identify significant changes in cortical thickness over time, displayed as a colour map over the canonical femur surface (figure, which shows statistically significant vertices and clusters). Cortical thickness increased significantly at several sites but did not decrease significantly anywhere. Zones that receive a high compressive stress during normal locomotion demonstrated a significant ($p<0.01$) increase in cortical thickness (0.05-0.2mm): the infero-medial cortex, and a posterior inter-trochanteric site where the calcar femorale transmits load from the trabeculae to the cortex. Several sites thought to be under tensile stress during locomotion were significantly thicker after teriparatide: on the greater and lesser trochanters near the attachment sites of the gluteus medius and psoas respectively. Thickness also increased at the head-neck junction of the superior cortex. We conclude that teriparatide treatment for 24 months increases cortical bone thickness at sites of compressive stress during locomotion, near key muscle attachments and in the superior cortex, considered critical for hip fracture susceptibility.



Maps of cortical thickness change (excluding the femoral head) and significance

The Effect of Teriparatide on Bone Material Properties is Not Different in Postmenopausal Women Who Were Previously Treatment-naive or Treated With Alendronate. Birgit Buchinger*[1], Sonja Gamsjaeger[1], Harald Dobnig[2], Jan J. Stepan[3], David B. Burr[4], Helmut Petto[5], Imre Pavo[6], Klaus Klaushofer[1], Eleftherios P. Paschalis[1]. [1]Ludwig Boltzmann Institute of Osteology at Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, 4th Med. Dept. Hanusch Hospital, Austria, [2]Division of Endocrinology & Nuclear Medicine, Medical University of Graz, Austria, [3]Institute of Rheumatology, Faculty of Medicine, Czech republic, [4]Dept of Anatomy & Cell Biology, Indiana University School of Medicine, USA, [5]Eli Lilly & Company Austria, Austria, [6]Eli Lilly & Company, Austria

Bone material properties are important contributors to bone strength. The purpose of the present study was to investigate the effects of teriparatide (TPTD) treatment on bone material properties (mineral/matrix ratio, carbonate substitution in the apatite lattice, mineral maturity, and relative proteoglycan content), in iliac crest biopsies.

Sixty-six postmenopausal women with osteoporosis (62% with previous fractures) either pre-treated with alendronate (ALN; N=38, mean treatment duration: 64 months) or osteoporosis treatment-naïve (TN, N=28) were treated with daily TPTD for 24 months in a prospective, single-arm, non-randomized study. For 33 patients (ALN, N=18, TN, N=15), valid, paired biopsies (before and after TPTD treatment; double-labelled by tetracycline) were analyzed by Raman microspectroscopy with a spatial resolution of ~1 µm. Spectra were obtained in the area between the second label and the mineralization front (youngest tissue age). Mann-Whitney test were used for between group comparisons and Wilcoxon signed-rank test for within group change in this exploratory analysis. The indices, mineral/matrix ratio, carbonate substitution and proteoglycan/mineral content at baseline and the change from baseline were not significantly different between the two groups (ALN, TN). However, at endpoint, the mineral/matrix ratio was significantly higher in the ALN pre-treated group (0.27 ± 0.2 vs. 0.12 ± 0.08, p=0.03) compared with TN. There was no other significant difference between the two groups (ALN, TN) at endpoint. In the pooled analysis (ALN, TN combined), mineral/matrix ratio, representing ash weight, increased from baseline. The amount of carbonate substitution, indicating mineral maturity, shape, and solubility decreased and relative proteoglycan content expressed as proteoglycan/mineral content decreased significantly (Table).

In conclusion, the observations in the present study indicate that TPTD treatment was associated with increased mineralization (based on mineral/matrix ratio), in formation of less mature crystals and in the formation of more favourable matrix for mineralization commencement (based on proteoglycan content).

	Baseline			Change from baseline

Nitroglycerin Improves Bone Mineral Density, Bone Geometry, and Bone Strength: Results from a Two-Year Randomized Controlled Trial. Sophie Jamal*[1], Celeste Hamilton[2], Dennis Black[3], Angela Cheung[4], Steven Cummings[5]. [1]The University of Toronto, Canada, [2]Women's College Hospital/University of Toronto, Canada, [3]University of California, San Francisco, USA, [4]University Health Network, Canada, [5]San Francisco Coordinating Center, USA

Purpose: Nitric oxide stimulates bone formation and inhibits bone resorption. Organic nitrates (such as nitroglycerin; NTG) can act as nitric oxide donors. Observational studies suggest use of organic nitrates is associated with increased bone mineral density (BMD) and decreased fracture risk. However, the effects of nitrates on BMD, geometry and strength have not been tested in a randomized trial. Methods: In a 24 month randomized, blinded trial, we compared the effects of once daily administration of NTG ointment (15mg/day applied at bedtime instead of every 6 to 8 hours as prescribed for angina) or matching placebo in postmenopausal women who had BMD T-scores between 0 and -2.0 at the lumbar spine and above -2.0 at the hip. Participants enrolled if they completed a 1-week run-in period taking the active NTG ointment. All women took at least 1200mg of elemental calcium and 800IU of vitamin D3 daily. We measured BMD at the lumbar spine, femoral neck and total hip at baseline, year 1 and year 2 (GE Lunar Prodigy). We used peripheral quantitative computed tomography (pQCT; Norland/Stratect XCT 2000) to measure bone density, geometry and strength at the radius. We analyzed the data with a modified intention-to treat-approach. Results: We enrolled 243 women; 113 (89%) of the 127 women in the nitroglycerin group and 107 (92%) of 116 in the placebo group completed the 24-month assessments. Compared to placebo, those randomized to NTG had significant ($p<0.001$) increases in BMD at the lumbar spine (6.7%), femoral neck (7.0%) and total hip (6.2%) at 24 months (Figures 1-3). Furthermore, NTG significantly ($p<0.05$) increased trabecular density (11.9%), cortical density (2.2%), cortical area (10.6%), cortical thickness (13.9%), periosteal circumference (7.4%), polar moment of inertia (7.3%) and polar section modulus (10.7%; Table 1). Headache was the most common reason for discontinuing treatment; other adverse events were not significantly different between the groups. Conclusions: Once daily administration of NTG ointment has anabolic effects on cortical bone, increases bone density, and improves indices of bone strength. Nitroglycerin is very inexpensive and widely available. Its efficacy for preventing fractures should be tested in a clinical trial.

Osteogenic Differentiation and In Vivo Complementation of Osteoblast-Deficient Embryos by Induced Pluripotent Stem Cells. James Oh[1], Alyssa Riley[2], Xiaojing Huang[2], Sean Wu[2], Joy Wu*[3]. [1]Endocrine Unit, Massachusetts General Hospital, USA, [2]Cardiovascular Research Center, Massachusetts General Hospital, USA, [3]Massachusetts General Hospital, USA

Induced pluripotent stem cells (iPSCs), like embryonic stem cells (ESCs), are capable of self-renewing and differentiating into cell types of all three germ layers. Furthermore, iPSCs can be derived from individual patients, without the ethical issues associated with ESC derivation, providing a genetically identical source of cells for potential regenerative therapy. To investigate the capacity of iPSCs for differentiating toward the osteogenic lineage, we generated OsxCre-eGFP and constitutively expressing ROSA-YFP iPSC lines by introducing Oct4, Sox2, Klf4, and c-Myc into fibroblasts from transgenic mice carrying these reporter alleles. OsxCre-eGFP iPSCs were differentiated in vitro using the hanging droplet method and cultured in media containing ascorbic acid and β-glycerophosphate. Gene expression analysis demonstrated that markers of pluripotency decreased while markers of osteoblastogenesis increased with differentiation. Alizarin red stain was detected after 14 and 21 days in osteogenic culture, confirming deposition of mineralized matrix. To assess the osteogenic potential of iPSCs in vivo, we employed a model of embryonic osteoblast-deficiency by intermating Runx2 heterozygous mice to generate Runx2 null embryos. These embryos lack bone formation due to a failure of osteoblast differentiation. We introduced wild-type ROSA-YFP iPSCs into blastocysts from Runx2 heterozygous cross-matings and assessed YFP+ cell contribution by whole-mount fluorescence and histological analysis. We observed the presence of YFP+ iPSCs in Runx2 null embryos with partial skeletal contribution. Furthermore, these iPSCs were associated with areas of mineralization. In summary, iPSCs can undergo osteogenic differentiation in vitro and partially reconstitute an osteoblast-deficient skeleton in vivo. Further investigation using genetically modified iPSCs may provide new insights into the molecular pathogenesis of bone disease, and serve as in vitro models for screening of therapeutic agents.

IGFBP-2 from Mesenchymal Stromal Cells (MSCs) in the Bone Marrow Niche Regulates Hematopoietic Stem Cell Proliferation and Marrow Engraftment. Anne Breggia*[1], Masanobu Kawai[1], Eliza Grlickova-Duzevik[2], David Clemmons[3], Clifford Rosen[1]. [1]Maine Medical Center, USA, [2]Maine Medical Center Research Institute, USA, [3]University of North Carolina, USA

IGFBP2 (BP2) is one of 6 IGF binding proteins that shuttles IGFs to their respective receptors. We previously reported that PTH induces IGFBP2 synthesis in calvarial osteoblasts and that global deletion of BP2 results in small spleens, very low bone formation, impaired bone resorption and increased marrow adiposity. *In vitro*, bone marrow from *bp2*-/- mice show impaired recruitment of both osteoblasts and osteoclasts. BP2 null males also have a hematopoietic phenotype in which increased percentages of lymphoid and myeloid subpopulations are found in both the peripheral blood and spleen. Lodish identified BP2 as a critical factor for hematopoietic stem cell proliferation *ex vivo*. In this study, we hypothesized that BP2 serves a critical role as a proliferative factor in the bone marrow niche. Using RNA from purified mouse mesenchymal stem cells (Stem Cell Technologies), we first found that BP2 gene expression levels were 6-8 times higher than in purified B or T cells. We next performed non competitive bone marrow transplants (BMT) by transplanting LY 5.1+ donor cells into lethally irradiated WT and *bp2*-/- recipients. Donor engraftment was not different between strains as shown by greater than 70% donor cells present in the peripheral blood of recipient mice from both strains. However, in competitive repopulation transplantation using same strain donor-recipient pairs, *bp2*-/- donor cells engrafted *bp2*-/- recipient bone marrow 30% less efficiently (P=0.01) than WT transplants. In addition, there were significantly fewer mature lymphoid (CD3, CD19) and myeloid (CD11b, LY6G and F480) cells in the peripheral blood of bp2-/- recipients ($p \leq 0.05$). In response to administration of a single component of the IGFBP2 molecule, the heparin binding domain (HBD), to *bp2*-/- mice, trabecular bone mass was rescued and osteoblast number increased. Importantly, in vivo administration of the HBD suppressed the percentages of mature monocytes, macrophages and neutrophils in the peripheral circulation, comparable to those found in WT mice. Taken together these data demonstrate that BP2, which is synthesized by MSCs and inducible by PTH, is a potent regulator of hematopoiesis and may specifically control stem cell fate in an IGF binding independent manner within the marrow niche. Niche regulation by IGFBP2 may be therapeutically important to clinical bone marrow transplantation which is currently the only treatment option for many hematologic and solid tissue malignancies.

Differentiation of Hematopoietic Cell Lineages is Altered in the Absence of Sclerostin. Corey Cain*[1], Gabriela Loots[2], Randell Rueda[1], Jennifer Manilay[1]. [1]University of California, Merced, USA, [2]LLNLUC Merced, USA

Purpose: Hematopoietic stem cells (HSCs) are in direct contact with osteoblasts (OBs) in the endosteum and trabecular regions of the long bones. OBs are considered "niche" cells that support HSC self-renewal and maintenance and are also important for B cell production in the bone marrow. Sclerostin (SOST) is a negative regulator of bone growth that is secreted by osteocytes and functions to reduce osteoblast proliferation by inhibiting WNT signaling through binding to LRP receptors. SOST-knockout (KO) exhibit generalized hyperosteosis and smaller bone marrow cavities due to an increase in proliferating OBs, osteocytes and excessive mineralization, while LRP5 KO mice are osteopenic. SOST expression is primarily OB and osteocyte-specific, but the effect of absence of SOST on hematopoiesis is unknown. We hypothesized that the increase in OB activity in SOST KO mice would result in increased numbers of self-renewing HSCs and reduce HSC differentiation whereas the decrease in OBs in LRP5 KOs would result in a reciprocal phenotype.

Methods: Bone marrow cells were isolated from SOST KO, LRP5 KO, and wild-type (WT) control mice. Phenotypic characterization of all hematopoietic cell lineages was performed using fluorescent activated cell sorting (FACS). RT-PCR for SOST and LRP5 was assessed in FACS-purified cell populations and digested bone.

Results: Surprisingly, no difference in HSC frequency or absolute number was observed between WT and SOST KO mice. Numbers of common lymphoid progenitors (CLP) and B lymphocytes were also reduced. Furthermore, lack of SOST did not affect myeloerythroid progenitor numbers but reduced the number of mature macrophages and granulocytes in the bone marrow. SOST expression was observed in the HSC, CLP and B cell lineages. Preliminary data showed reduced HSC and CLP numbers in LRP5 KOs.

Conclusions: In SOST KO mice, HSC numbers were unaffected, despite increased OB activity. In contrast, in LRP5 KOs, HSC numbers were reduced. These unexpected results suggest that SOST and LRP5 play different roles in WNT signaling in the OB niche. Lymphoid and myeloid differentiation was blocked in the absence of SOST. Interestingly, SOST is expressed in HSCs, B cells, and granulocytes. Therefore, whether SOST acts in a cell-autonomous or a non-cell autonomous manner on hematopoietic cells is still unclear. These findings have important safety implications for the clinical use of SOST-specific antibodies for the treatment of osteoporosis.

Gsα-Dependent Signaling in the Osteoblast Lineage Regulates Bone Marrow Hematopoietic Niches. Engin Ozcivici[1], Cris Lo Celso[2], Stefania Lymperi[2], David Scadden[2], Henry Kronenberg[3], Joy Wu*[3]. [1]Mass General Hospital, USA, [2]Center for Regenerative Medicine, Massachusetts General Hospital, USA, [3]Massachusetts General Hospital, USA

Gsα is a heterotrimeric G protein subunit that mediates cyclic-AMP-dependent signaling downstream of G protein-coupled receptors, including the parathyroid hormone (PTH)/PTH-related peptide (PTHrP) receptor (PPR). Deletion of Gsα early in the osteoblast lineage in Osterix-Cre:Gsa(fl/fl) mice results in reduced bone mass with fewer osteoblasts, with impaired differentiation of bone marrow B cell precursors. Since expression of constitutively active PPR in osteoblasts increases trabecular osteoblast number as well as hematopoietic stem cells (HSCs), we hypothesized that ablation of Gsα in osteoblasts would negatively impact HSC number. Eight day-old conditional knockout (KO) mice were sacrificed and their bone marrow analyzed for primitive HSCs. Compared to control littermates, KO mice had 37% fewer long term (LT) HSCs, corresponding to the most primitive and quiescent hematopoietic population. Gsα KO mice have a dramatic reduction in osteoblast number, which may indirectly impact HSC number and function. In an effort to assess the direct effects of Gsα in osteoblasts, sorted $Lin^{-}Sca1^{+}c\text{-}Kit^{+}$ (LKS) cells, a population highly enriched for HSCs, were cultured in the presence of primary calvarial osteoblasts from control or KO mice. Six days later, the frequency of hematopoietic cells was decreased by 17% in wells containing KO osteoblasts. Furthermore, the frequency of B220 positive B cell precursors was reduced by 29%. We have previously shown that B cell precursor development is blocked at the pre-pro-B to pro-B cell transition in Gsα KO bone marrow, and can be rescued by the addition of interleukin (IL)-7. In order to investigate whether Gsα directly regulates IL-7 expression, Gsα was deleted from calvarial osteoblasts by infection with an adenovirus expressing Cre recombinase. IL-7 mRNA levels were reduced in the absence of Gsα. Consistent with this finding, expansion of pre-pro-B cell precursors was significantly inhibited when cultured with Gsα-deficient osteoblasts. Together these results demonstrate that Gsα signaling in cells of the osteoblast lineage plays a direct role in the bone marrow niches for HSCs as well as for more differentiated B cell precursors.

Ovariectomy Expand the Hemopoietic Stem Cell Pool Through the T cell Costimulators CD40L and OX40. J.-Y. Li*, H. Tawfeek, B. Bedi, J. Adams, M. N. Weitzmann, R. Pacifici. Division of Endocrinology, Metabolism & Lipids, Emory University School of Medicine, USA

Ovariectomy (OVX) leads to a marked increase in bone marrow (BM) hemopoietic cells, primarily by increasing the production of hemopoietic cytokines by BM stromal cells (SCs). Since T cells are known to regulate SC function, we investigated the role of T cells in the pro-hemopoietic effects of ovx. WT mice were immunodepleted of T cells by treatment with anti CD4/8 mAbs, ovx or sham operated, and then sacrificed 4 weeks after surgery. FACS analysis at 2 and 4 weeks showed that OVX induced a 2-3 fold increase in the number of hemopoietic stem cells (HSCs), B cells, and monocytes in T cell replete controls but not in T cell deficient mice. Moreover, T cells induced the expansion of HSCs by upregulating the expression of Jagged1 on SCs. Thus, T cells/SCs cross talk leading to induction of Notch signaling in HSCs is required for OVX to modulate hemopoiesis. Analysis by DXA and μCT confirmed earlier reports that OVX induces a significant trabecular and cortical bone loss in controls, but not in T cell depleted mice. Since the T cell costimulatory molecule CD40L has been shown to regulate SC function by binding to SC expressed CD40, we examined the effect of ovx on HSCs in CD40L-/- mice. At 2 weeks OVX failed to increase the SC expression of Jagged1 and the number of HSCs and mature hemopoietic cells in CD40L-/- mice, while it did so in WT control mice. Therefore, CD40L is a costimulatory molecule by which T cells regulate the capacity of SCs to promote and support hemopoiesis early after ovx. Surprisingly, analysis at 4 weeks revealed that at this time point OVX had equal stimulatory effects on HSCs and mature hemopoietic cells in WT and CD40L-/- mice. These findings suggest that late after ovx T cells regulate SCs through costimulatory molecules other than CD40L. One T cell costimulator, which is known to replace CD40L as driver of skin graft rejection, is OX40. This receptor binds to OX40L, which is expressed on antigen presenting cells. Strikingly, real time PCR analysis showed that OVX upregulated by 3-4 folds the expression of OX40 in T cells and of OX40L in SCs at 4 weeks but not at 2 weeks. Collectively, these data demonstrate that ovx expand the HSCs by upregulating Jagged1 expression in SCs through a T cell costimulatory molecule-dependent mechanism. CD40L is the T cell costimulator that plays a pivotal role in the expansion of HSCs in the early post-ovx period, while OX40 assumes a dominant role later after ovx.

Stem Cell Antigen 1 Positive (Sca-1+) Cell-Based Gene Therapy with a Modified Fibroblast Growth Factor 2 (FGF2) Produces Contrasting Skeletal Effects on Femur as Opposed to Tail Vertebra in Mice. Susan Hall*[1], Shin Tai Chen[1], Suburraman Mohan[1], Jon Wergedal[1], Apurva K. Srivastava[2], Daila S. Gridley[3], Kin-Hing William Lau[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]National Institure of Health, USA, [3]Department of Radiation Medicine, Loma Linda University School of Medicine, USA

Administration of FGF2 protein in rats results in large increases in osteoblast (Ob) and osteoid surface at bone sites rich in red (hematopoietic) marrow, but these effects decline rapidly after treatment withdrawal. We have shown that transplantation of Sca1+ cells expressing an FGF2 gene (modified to improve secretion and stability) provides sustained, high dose, local FGF2 expression and results in rapid, robust endosteal bone formation (BF) in red marrow-containing bones of recipient mice (femur, lumbar vertebra). Bone areas that contain yellow (fatty) marrow are known to differ from that of red marrow in their response to stimuli. The current study sought to determine if transplantation of hematopoietic progenitor (Sca-1+) cells and sustained FGF2 expression could also promote BF in yellow marrow bone (tail vertebra). Sublethally irradiated stem cell-deficient mice were injected I.V. with Sca1+ cells transduced with MLV-based vectors expressing FGF2 or GFP genes. At 14 weeks post transplantation, sera, long bones and vertebrae were harvested. Consistent with previous work, serum FGF2 (by ELISA) levels were significantly increased in the FGF2-transplanted group compared to controls. Transduced cell engraftment and transgene expression were confirmed by the finding of high expression levels of human FGF2 mRNA in tibial bone marrow cell extracts in the FGF2 group but not in controls. μCT analyses of femurs revealed significant increases in trabecular bone volume fraction (BV/TV), connectivity density (ConnDens) and trabecular thickness (TbTh) in the FGF2 group compared to controls (243% $p<0.05$, 373% $p<0.03$ and 118% $p<0.02$, respectively) but no significant differences in trabecular number (TbN) or separation (TbSp), suggesting increased BF. In contrast, μCT analyses of tail vertebrae showed that transplantation of FGF2-expressing cells reduced BV/TV, ConDens and TbN (60% $p<0.03$, 42% $p<0.03$ and 62% $p<0.003$, respectively) and significantly increased TbSp (182% $p<0.005$), suggesting increased bone resorption (BR). Based on our data and published findings that FGF2 exerts effects on both osteoblast and osteoclast lineage cells, we conclude that high, sustained expression of FGF2 after transplantation of FGF2-transduced Sca1+ cells produces skeletal site-specific effects to increase BF in the femur and BR in the caudal vertebra. Further work is required to elucidate the mechanisms mediating these contrasting site-specific FGF2 effects.

Directing Mesenchymal Stem Cells to Bone to Increase Bone Formation. Wei Yao*[1], Min Guan[2], Ruiwu Liu[2], Kit Lam[2], Mohammad Shahnazari[2], Jan Nolta[2], Nancy Lane[1]. [1]University of California, Davis Medical Center, USA, [2]UC Davis Medical Center, USA

Mesenchymal stem cells (MSCs) are the precursors of osteoblasts that form bone. Aging results in a reduction in the number of MSCs in the bone marrow which leads to a reduction in osteogenesis, reduced bone formation and increased bone fragility. Bone regeneration by the means of induction of osteogenesis from MSCs offers a rational therapeutic option. However, this approach is problematic due to the major obstacle of controlling the MSCs' commitment, growth and differentiation into functional osteoblasts on the bone surface. Our research group has developed a method to direct the MSCs to the bone surface. We attached a synthetic peptidomimetic ligand (LLP2A) that has high affinity for activated α4β1 integrin on the MSC surface, to a bisphosphonates (alendronate, Ale) that has high affinity for bone, to direct the MSCs to bone. Experiments. We tested the efficacy of our new hybrid compound (LLP2A-Ale) using two approaches: 1.We evaluated if LLP2A-Ale can guide the MSCs to bone using the Xenotransplantation model. We obtained human MSCs (huMSCs) and injected the cells together with LLP2A-Ale into the immunodeficient mice, NOD/SCID MSPVII. This mouse strain lacks β-glucuronidase (GUSB) so that donor cells could be easily tracked or identified using biochemical detection of GUSB. 2. We performed another study using 2 mos.old female 129SvJ mice that were treated with either PBS, Ale, LLP2A or LLP2A-Ale. The mice received monthly intravenous (iv) injections of the treatments and changes in bone mass were monitored by in vivo microCT scans of the distal femurs. Changes in bone formation were measured by histomorphometry and bone markers. In the NOD/SCID/MSPVII mice that received huMSCs, we found that LLP2A-Ale mobilized MSCs on the bone surface as compared to the control groups (PBS and MSCs) 24 hours after the injection of MSCs (~ 50% in LLP2A-Ale treated group vs. <1% in the control groups). After a single iv injection, mice treated with MSCs + LLP2A-Ale alone had nearly 20% higher cancellous bone than mice treated with MSCs alone or MSC + LLP2A or Ale. In the "normal", 2-mo-old female mice, monthly LLP2A-Ale injection increased cancellous bone mass by > 15% at 4 weeks and > 25% at 8 weeks. Bone formation (serum osteocalcin and BFR/BS) was increased by about 20% from the control groups. In conclusion. our data suggested LLP2A-Ale appears to increase MSC mobility and stimulate the MSCs towards osteoblastogenesis when they are "directed" to bone.

Lrp5-deficient Mice are Responsive to the Osteo-anabolic Action of Sclerostin Antibody. Alexander Robling*[1], Matthew Warman[2], Chris Paszty[3], Charles Turner[4]. [1]Indiana University, USA, [2]Howard Hughes Medical Institute, Department of Genetics, Harvard Medical School, USA, [3]Amgen, Inc., USA, [4]Indiana University, Purdue University Indianapolis, USA

Wnt signaling through LRP5 is modulated by the osteocytic protein sclerostin. Sclerostin is thought to bind directly to LRP5 and antagonize canonical Wnt signaling. We hypothesized that the osteo-anabolic effects of sclerostin deletion/inhibition would be lost in mice lacking Lrp5. We tested this hypothesis by measuring bone mass in mice lacking both Lrp5 and Sost, and in Lrp5-deficient mice treated with a sclerostin neutralizing antibody. For the genetic crossbreeding experiment, four genotypes were generated by crossing the progeny of an $Lrp5^{-/-}$ $Sost^{-/-}$ mating: $Lrp5^{+/+}$ $Sost^{+/+}$; $Lrp5^{+/+}Sost^{-/-}$; $Lrp5^{-/-}Sost^{+/+}$; and $Lrp5^{-/-}Sost^{-/-}$. In 17-wk old male mice, aBMD was 10.8% lower ($p<0.001$) in $Lrp5^{-/-}Sost^{+/+}$ mice, compared to WT controls ($Lrp5^{+/+}Sost^{+/+}$). $Lrp5^{+/+}Sost^{-/-}$ mice exhibited 38.7% greater ($p<0.001$) aBMD than WT controls. aBMD in the double mutants ($Lrp5^{-/-}Sost^{-/-}$) was significantly greater than in WT controls (17.6% greater; $p<0.001$) but significantly less ($p<0.001$) than in $Lrp5^{+/+}Sost^{-/-}$ mice. Female mice showed similar trends according to genotype. Next, we sought to overcome the developmental effects of Sost deletion (e.g., HBM phenotype effects) on our model by waiting until $Lrp5^{-/-}$ mice were fully adult, then inhibiting sclerostin using a neutralizing antibody (twice-weekly injection with Scl-AbIII, 25 mg/kg., for 3 wks). Whole-body aBMD increased 2-3% over the 3 wk treatment period in both $Lrp5^{+/+}$ and $Lrp5^{-/-}$ mice treated with vehicle. $Lrp5^{+/+}$ mice treated with Scl-AbIII exhibited a 21.1% increase ($p<0.001$) in whole body aBMD, whereas $Lrp5^{-/-}$ mice treated with Scl-AbIII exhibited an 18.7% increase in whole body aBMD. The percent increase induced by the antibody was not statistically different ($p=0.30$) between $Lrp5^{+/+}$ and $Lrp5^{-/-}$ mice. Cortical bone area (CA) at the midshaft femur followed similar trends as the DEXA results; Scl-AbIII improved CA by 22.8% ($p<0.001$) in $Lrp5^{+/+}$ mice and by 18.9% in the $Lrp5^{-/-}$ mice ($p<0.001$), compared to genotype-matched vehicle-treated mice. No difference in antibody mediated improvement was detected between genotypes. Collectively, our data indicate that inhibiting sclerostin can improve bone mass whether Lrp5 is present or not. It remains to be determined how much of sclerostin's action occurs via other receptors, like Lrp4 or Lrp6, and whether there are any compensatory expression mechanisms when one receptor (e.g. Lrp5) is deleted.

Sclerostin Inhibition by Monoclonal Antibody Reversed Trabecular and Cortical Bone Loss in Orchiectomized Rats with Established Osteopenia. X Li*[1], KS Warmington[1], Q-T Niu[1], FJ Asuncion[1], M Barrero[1], X Xia[2], M Grisanti[1], E Lee[1], Thomas Wronski[2], MS Ominsky[1], WS Simonet[1], C Paszty[1], HZ Ke[1]. [1]Amgen Inc, USA, [2]University of Florida, USA

Male osteoporosis is becoming an increasingly important public health problem and hypogonadism is a common cause of osteoporosis in men. Sclerostin inhibition has been shown to increase bone formation and BMD in rodents, primates, and humans. In this study, we examined the effects of sclerostin antibody (Scl-AbIII) treatment on bone loss due to androgen deficiency in rats. Six-month-old male SD rats were sham-operated or orchiectomized (ORX) then left untreated for 3 months, allowing for the development of osteopenia. At the age of 9 months, ORX rats were treated with vehicle or Scl-AbIII at 5 or 25 mg/kg (2x/week, s.c.) for 6 weeks (10/group). Sham rats received vehicle. In vivo DXA measurements demonstrated that 3 weeks of Scl-AbIII treatment at both doses fully reversed the significant deficit in lumbar spine BMD caused by 3 months of orchiectomy. Six weeks of Scl-AbIII treatment at 25 mg/kg increased lumbar spine BMD in ORX rats to a level significantly greater than sham controls. Terminal pQCT analysis at the distal femur revealed that the marked loss of trabecular BMD (-41% vs. Sham) in ORX rats was reversed by Scl-AbIII treatment in a dose-dependent manner (Table 1). MicroCT analysis at the mid-femoral diaphysis demonstrated that the significant decreases in cortical vBMC (-12% vs. Sham), cortical thickness (-8% vs. Sham), and cortical area (-11% vs. Sham) in ORX rats were restored by Scl-AbIII treatment in a dose-dependent manner. The three-point bending test at the mid-femoral diaphysis confirmed that Scl-AbIII-treated ORX rats had a dose-dependent greater maximum load and stiffness as compared with ORX controls. Dynamic histomorphometric analysis at the tibial shaft revealed that the marked reduction in periosteal bone formation rate (-95% vs. Sham) in ORX rats was fully restored to the level of sham controls in both Scl-AbIII treatment groups. Endocortical bone formation rate was further increased to a level significantly greater than sham controls in both Scl-AbIII treatment groups. In summary, sclerostin antibody treatment increased bone formation, reversed trabecular and cortical bone loss, and improved cortical geometry in adult rats with androgen deficiency. Furthermore, the increased bone mass was associated with increased bone strength. These results suggest that sclerostin inhibition may be a promising therapeutic approach for increasing both trabecular and cortical bone mass in men with osteoporosis due to androgen deficiency.

Table 1. Selective Endpoints at the Distal Femur, Mid-femoral Diaphysis, and Tibial Shaft After 6 Weeks of Treatment

			ORX		
Site	Endpoints	Sham-Vehicle (n=10)	Vehicle (n=10)	5 mg/kg (n=10)	25 mg/kg (n=10)

PTH Efficacy in a Bone Healing Model with T-Cell Deficient Rats. Masahiko Sato*, M.D. Adrian, Anita Harvey, Q.Q. Zeng, Yanfei Linda Ma. Lilly Research Labs, USA

Previously, T lymphocytes were shown to mediate the skeletal efficacy of PTH, because nude mice exhibited a blunted skeletal response to PTH (M. Terauchi et al. 2008). Therefore, we evaluated the systemic efficacy of PTH in bone healing and non-fractured sites, using NTac:NIH-Whn rats. Male, 14 week old, athymic rats (NIHRNU-M, NTac:NIH-Whn, Taconic) were maintained on a 12hr light/dark cycle at 220C with ad lib access to food (TD 89222 with 0.5% Ca and 0.4%P, Teklad, Madison, WI) and water for 2 weeks, before conducting bilateral cortical defect surgery through both anterior and posterior cortices (D. Komatsu et al. 2009). Animals were weighed and randomized into treatment groups, including vehicle and PTH groups treated with 0, 5 or 30 ug/kg/d sc hPTH1-38 for 7 weeks of treatment, starting 8 days post-surgery. Both PTH doses were efficacious with dose-dependent enhancement of BMD and BMC of the femoral diaphysis at the cortical defect (24%, 20%), intramedullary spaces (95%,95%) compared to controls, but site specific analyses showed no enhanced healing of the anterior cortex or posterior cortex. Load

to failure analyses showed dose dependent enhancement in femoral stiffness (22%) and strength (17%) relative to controls at the site of the cortical defect. PTH systemic efficacy at not affected sites (sites away from the cortical defect) were also observed with dose dependent increases in femoral neck work to failure (70%), strength (38%), serum osteocalcin levels (31%), vertebral BMC (20%), and vertebral BMD (14%). Longitudinal analyses showed that PTH enhances bone healing by stimulating woven bone formation in the intramedullary spaces and stimulating endocortical mineral apposition resulting in stronger femora, but some reductions in mineral apposition of the anterior and posterior cortices were observed relative to other animals. In addition, PTH significantly enhanced mineral apposition at other axial and appendicular sites. Mechanistic studies are in progress to clarify the basis to these PTH effects in athymic nude rats. These data indicate that the T-cell deficient rat skeleton remains responsive to PTH treatment.

Elevated Bone Mass in Mice Treated with Anti-Dickkopf-1 Neutralizing Antibodies. Robert Brommage*, Jeff Liu, Dawn M. Bright, Deon D. Smith, Sabrina Jeter-Jones, Christopher M. DaCosta, Sayadeth Khounlo, Melanie K. Shadoan, David R. Powell, David G. Potter. Lexicon Pharmaceuticals, USA

The mutant LRP5 protein in subjects with high bone mass phenotype is resistant to the inhibitory actions of Dickkopf-1 (DKK1). Knockout (KO) of Dkk1 in mice results in embryonic lethality, with heterozygous (HET) mice having increased bone mass. As part of Lexicon's Genome5000^{TM} program to characterize mouse KO phenotypes of pharmaceutically relevant genes, we generated HET Dkk-1 KO mice by targeting exons 2 and 3. BMD and bone architecture were determined by PIXImus DEXA and Scanco μCT40, respectively.

Female wild-type (WT) mice with access to running wheels from 6 to 18 weeks of age had increased bone mass. Dkk1 HET mice have elevated trabecular bone volume (TBV) compared to WTs, and access to running wheels resulted in a synergistic ($P = 0.08$ by two-factor ANOVA) elevation of TBV in the distal femur metaphysis (DFM). These results suggest Dkk1 may be important in mechanical sensing at this bone site.

We identified and characterized two monoclonal mouse antibodies capable of neutralizing Dkk1-mediated inhibition of Wnt signaling in a cell-based reporter assay. Ab-1 recognizes an epitope in the C-terminal half of Dkk1 with sub-nanomolar affinity and prevents Dkk1 from binding to LRP6 while Ab-2 recognizes an epitope in the N-terminal half of Dkk1 with sub-nanomolar affinity and does not affect Dkk1 binding to LRP6.

Treating male WT mice at 4 weeks of age for 4 weeks with neutralizing antibody Ab-2 (30 mg/kg given once per week) produced increases in BMD of the body (11%), spine (19%) and femur (11%). By microCT analyses TBV increased 18% in LV5 and 92% in the DFM. Mice given zoledronate had similar BMD gains, with a 19% increase in LV5 TBV. Whereas zoledronate treatment increased LV5 Tb.N (19%) but not Tb.Th (1%), Ab-2 treatment increased LV5 Tb.Th (10%) but not Tb.N (2%). Ab-1 treatment gave similar results but was less potent. These results indicate treating young mice with neutralizing anti-Dkk1 antibodies increases bone mass through a mechanism distinct from that of zoledronate. Treatment with the Ab-2 antibody also increased bone mass in WT adult mice, but to a lesser extent than in young mice.

Treating male WT mice at 10 weeks of age with dexamethasone (15 mg/kg) for 30 days resulted in an 8-fold elevation of serum Dkk1 levels. Dexamethasone treatment had minimal effects on bone mass but suppressed serum PINP levels (70% on Day 7 and 30% on Day 30) and this suppression was not affected by weekly Ab-2 treatment at 10 mg/kg.

Inhibition of ALK3 (BMPRIA) Signaling Using RAP-661, a Novel Soluble BMP Antagonist, Decreases Sclerostin Expression and Increases Bone Mass. Nicolas Solban*[1], Milton Cornwall-Brady[1], Yoshimi Kawamoto[1], June Liu[1], Benjamin Umiker[1], Shana Walrond[1], Rita Steeves[1], Kathryn Underwood[1], Ravi Kumar[1], Jasbir Seehra[1], Ernesto Canalis[2], R. Scott Pearsall[1]. [1]Acceleron Pharma, USA, [2]St. Francis Hospital & Medical Center, USA

Bone Morphogenetic Proteins (BMPs) induce endochondral bone formation and regulate osteoblastogenesis and osteoclastogenesis. However, the inactivation of the BMP-2 receptor ALK3/BMPRIA, specifically in osteoblasts, causes an increase in bone formation suggesting that the inhibition of endogenous ligands may have different biological consequences then those of the exogenously administered ligands. To investigate new therapeutic strategies for metabolic bone diseases, a soluble ALK3 receptor (RAP-661) with antagonist properties to the endogenous receptor was generated.

Twelve week old C57BL/6 female mice received RAP-661 (10 mg/kg, twice weekly ip) or vehicle (PBS) for 6 weeks and were assessed after 2, 4, and 6 weeks of treatment. RAP-661 treated animals appeared healthy for the duration of the study and their BMD was increased by 3%, 8% and 6% ($p<0.05$) after 2, 4 and 6 weeks of treatment, respectively. After 4 and 6 weeks of treatment, RAP-661 increased serum osteoprotegerin by 38 to 56% ($p < 0.05$), and decreased RANKL by 40 to 52% ($p < 0.05$); TRAP5b levels were decreased at week 2 by 67% ($p < 0.01$), but were equal to control levels by week 6. Histomorphometric analysis of the distal femur determined that RAP-661 increased trabecular bone volume by 63%, 90% and 68% after 2, 4 and 6 weeks, respectively, compared to controls. This increase was due to increased trabecular thickness and not number. While there was no change in osteoblast number, there was a marked increase in the mineralizing surface (67% and 115%, $p < 0.05$) and bone formation rate (80%, $p < 0.05$) after 2 to 4 weeks of treatment with RAP-661. In addition, the eroded surface and osteoclast surface were reduced after 4 weeks (36% and 44%, $p < 0.05$, respectively), indicative of an antiresorptive effect. RAP-661 decreased bone marrow adipocytes by 21 to 36% ($p < 0.05$) and decreased the skeletal expression of sclerostin, a Wnt antagonist, by 61%, 52%, and 43% ($p < 0.05$) after 2 days, 1 and 4 weeks, respectively.

These results indicate that RAP-661 increases trabecular bone volume by increasing bone formation and decreasing bone resorption. The reduction in skeletal sclerostin expression indicates that inhibition of ALK3 signaling may result in increased Wnt signaling leading to increased bone mass. In conclusion, inhibition of BMP signaling using a soluble BMP antagonist offers a promising new alternative for the treatment of bone-related disorders.

Reduced Trabecular Volumetric BMD at Metaphyseal Regions of Weight-bearing Bones is Associated with Prior Fracture in Young Girls. Joshua Farr*[1], Rita Tomas[1], Zhao Chen[2], Jeffrey Lisse[3], Timothy Lohman[3], Scott Going[3]. [1]The University of Arizona, USA, [2]University of Arizona College of Public Health, USA, [3]University of Arizona, USA

Understanding the etiology of skeletal fragility during growth is critical for the development of treatments and prevention strategies aimed at reducing the burden of childhood fractures. Thus, we evaluated the relationship between prior fracture and bone parameters in young girls. Data from 465 girls aged 8–13 from the "Jump-In: Building Better Bones" study were analyzed. Bone parameters were assessed at metaphyseal and diaphyseal sites of the non-dominant femur and tibia using peripheral quantitative computed tomography (pQCT). Dual-energy X-ray absorptiometry (DXA) was used to assess femur, tibia, lumbar spine, and total body areal bone mineral density (aBMD). Binary logistic regression was used to evaluate the relationship between prior fracture and bone outcomes, controlling for maturity, body mass, leg length, ethnicity, and physical activity. Associations between prior fracture and all DXA outcomes and pQCT parameters at diaphyseal sites were non-significant. In contrast, reduced trabecular volumetric BMD (vBMD) at distal metaphyseal sites of the femur and tibia was significantly associated with prior fracture. After adjustment for covariates, every SD decrease in trabecular vBMD at metaphyseal sites of the distal femur and tibia was associated with 1.4 (1.1–1.9) and 1.3 (1.0–1.7) times increased fracture prevalence, respectively. Prior fracture was not associated with metaphyseal bone size (i.e. periosteal circumference). In conclusion, childhood fractures are associated with reduced trabecular vBMD, but not bone size, at metaphyseal sites of the femur and tibia. Reduced trabecular vBMD at metaphyseal sites of long bones may be an early marker of skeletal fragility.

Girls Accrue More Bone Relative to Lean Mass in Puberty and this Sex-difference Maintains to Young Adulthood: Evidence from 15 - years of Longitudinal Data. Saija Kontulainen*, Donald Bailey, Robert Faulkner, Adam Baxter-Jones. University of Saskatchewan, Canada

Over a century ago the idea of constant interaction between muscles and bones was proposed. During the past decade evidence of sex-specificity in this relationship has been noted from cross-sectional data and theorised to demonstrate accrual of mechanically excess mineral in female skeleton for the reproductive needs. To reliably investigate the sex-specificity in bone mineral content (BMC) accrual in relation to muscle gain from adolescence to adulthood, we examined 15-years of longitudinal data from 127 (66 females) participants of the Saskatchewan Pediatric Bone Mineral Accrual Study (PBMAS). Dual energy x-ray absorptiometry derived BMC (g) and lean body mass (g) of total body (TB), trunk, arms and legs were measured annually from 1991-97 and 2002-2006. Peak height velocity (PHV) was determined for each participant and the age from PHV was calculated to determine biological age at each measurement time. Using random effects models, we analyzed the influence of sex on BMC to lean ratio at each site from adolescence to adulthood while controlling for variations in tempo and timing of body composition development and physical activity.

In the random effects model for BMC to lean ratios in TB, arms and legs, females had 15.3 (SEE 4.8), 54.8 (SEE 8.0) and 17.6 (SEE 7.8) greater values than males, respectively. Sex had no influence on trunk BMC to lean ratio (4.0, SEE 3.1).

When the confounders of maturation, fat mass and physical activity were controlled, females had on average 10% greater total body BMC to lean ratio than males. These longitudinal results support the theory of the mechanically excess bone accrual in pubertal female skeleton and resulting bone mineral reserve in adult females for reproductive needs.

FR0010

Magnitude and Timing of Peak Bone Mineral Accrual in Young Girls. Joan Lappe*[1], Robert Heaney[2], Michael Davies[2], Diane Cullen[2]. [1]Creighton University Osteoporosis Research Center, USA, [2]Creighton University, USA

Purpose: The greatest lifetime increase in bone mass occurs during adolescence, and the amount accrued affects the risk of osteoporosis later in life. In girls, the fastest accrual occurs around the time of menarche. The purpose of this prospective study is to estimate the time over which this rapid accrual occurs and the magnitude of bone mass accrual.

Methods: Healthy girls, ages 9 -11 years and in Tanner Stage 1-2 at baseline, were participants in 2 randomized trials to determine the effects of optimal dietary calcium intake on bone mineral content (BMC) accrual. This analysis includes 160 girls who were followed for 8-10 years and experienced menarche during follow up. DXA scans were done every 6 months. Each girl's spine BMC at menarche (MABMC) was computed (mean of BMC values immediately prior to and immediately after menarche). All the spine BMC's for one girl were divided by MABMC to yield a sequence of relative BMC's, aggregated at half year intervals from menarche. Then the aggregated average for all girls for each half year step was computed. The times and aggregated averages were fitted to a 4-parameter sigmoid function.

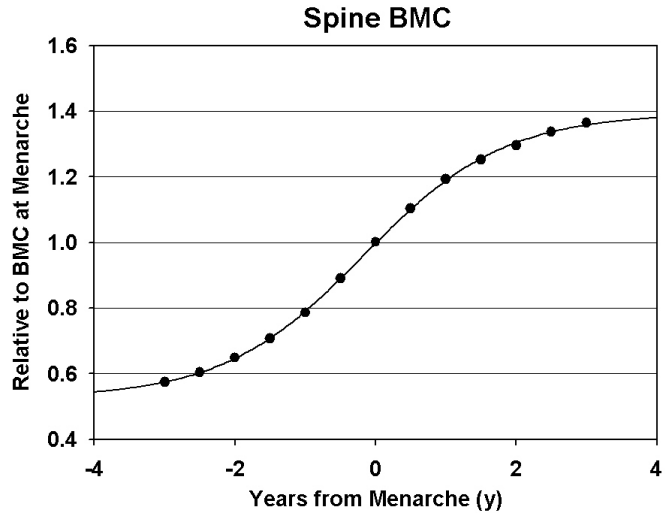
Results:

Descriptives at baseline and end of study - median (min, max)

	Baseline	End of study
Age (yrs)	9.6 (8.7, 11.5)	17.9 (11.9,20.1)
Height (m)	1.38 (1,25, 1.61)	1.65 (1.43, 1.81)
Spine BMC (gm)	22.6 (12.5, 40.8)	57.3 (33.1, 81.8)
Weight (kg)	34.5 (22.5, 56.0)	63.4 (36.4, 112.0)
Menarcheal age (yrs)	12.8 (10.1, 16.7)	N/A

The rapid BMC gain occurred over 4 years (± 2 yrs around menarche). The maximum gain in BMC occurred at menarche, with 21.7% of the rapid gain occurring ± 6 mos around menarche. In aggregate, the gain in spine BMC is about 62% of the value achieved at the end of study (late adolescence).

Discussion: This prospective study expands on and confirms the findings of others that peak BMC accrual in girls is coincident with menarche.[1] Furthermore, this study provides longer follow up than previous studies in a cohort of girls who were very similar in age and pubertal stage at baseline. These data provide a very good estimate of the amount of bone gained during the rapid accrual phase and the time course for this accrual. Our findings can help clinicians evaluate skeletal development in their young female patients.



Spine bone mineral accrual

Maternal Plasma Long Chain Polyunsaturated Fatty Acids Determine Bone Health in their Children at Age of Four: Southampton Women's Survey. Dinesh Dhanwal*[1], Philip Calder[2], Kim Miranda[3], Sian Robinson[3], Hazel Inskip[3], Elaine Dennison[4], Cyrus Cooper[2]. [1]Maulana Azad Medical College, New Delhi andMRC, Southampton UniversityUK, India, [2]University of Southampton, United Kingdom, [3]MRC, United Kingdom, [4]MRC Epidemiology Resource Centre, United Kingdom

Background: Maternal nutrition during pregnancy affects bone health in the children of those pregnancies. Previous studies have shown an association between maternal fatty acid status and offspring bone density in experimental animals and in human infants, but there are no studies in older children.

Objective: To determine the association between maternal long chain polyunsaturated fatty acid (LCPUFA) status in pregnant women and bone mineral density in their children at the age of four years.

Material and methods: The study population included 1455 mothers from the Southampton Women's Survey and their children (763 boys and 692 girls). Maternal dietary intakes of total n3 and n6 PUFA were assessed using a food frequency questionnaire. The concentrations of LCPUFA in maternal plasma phosphatidylcholine (PC) at 34 weeks of gestation were determined by gas chromatography. Bone density measures were made by DXA in the children at the age of four years.

Results: Maternal plasma PC eicosapentaenoic acid (EPA) showed a significant positive association with whole body, spine and hip bone mineral density (BMD) ($r = 0.099$, $p = 0.0009$; $r = 0.096$, $p = 0.011$ and $r = 0.086$, $p = 0.022$ respectively) and with whole body and spine volumetric (V) BMD ($r = 0.092$, $p = 0.015$; and $r = 0.092$, $p = 0.015$ respectively). Maternal plasma PC n-3 docosapentenoic acid (DPA) showed a significant positive correlation with whole body and spine BMD and with spine vBMD ($r = 0.099$, $p = 0.0009$; $r = 0.111$, $p = 0.003$ and $r = 0.104$, $p = 0.009$ respectively). After multivariate analysis, associations between maternal plasma PC EPA and BMD at spine (both total and v BMD) and between maternal plasma PC DPA and whole body BMD, spine BMD and spine vBMD remained significant. There were no significant associations of maternal plasma PC arachidonic acid or docosahexaenoic acid with BMD in the children.

Conclusion: The present study demonstrates a positive association between the status of two n-3 LCPUFA (EPA and DPA) in late pregnancy and BMD in the children of those pregnancies at the age of 4 years. These findings suggest an important effect of early exposure to n-3 LCPUFA and childhood bone development.

FR0021

Impairment of Bone Microarchitecture and Lipodystrophy in Young B6 Mice Treated with the Second Generation Anti-psychotic, Risperidone. Ingrid De Paula*[1], Sutada Lotinun[2], Gavin Welch[3], Sumithra Urs[4], Masanobu Kawai[1], Sheila Bornstein[1], Ann Maloney[4], Mark Horowitz[5], Roland Baron[6], Clifford Rosen[1]. [1]Maine Medical Center, USA, [2]Harvard School of Dental Medicine, USA, [3]Foundation for Blood Research, USA, [4]Maine Medical Center Research Institute, USA, [5]Yale University School of Medicine, USA, [6]Harvard School of Medicine & of Dental Medicine, USA

Risperidone(R) is an atypical antipsychotic widely used in adolescents and children. Adverse effects such as weight gain and hyperprolactinemia can be striking, particularly in young individuals. In this study we hypothesized that R treatment of mice would result in a fat redistribution phenotype and might impair peak bone mass. Young (4 week) male C57BL6 mice were orally (added to food) treated with R at a dose of 1.25mg/kgxdaÿ[1] for 5 weeks. Control mice(C) received a regular 10% fat per calorie diet. During this period food ingestion and body weight were measured daily. At the 5th week, body composition and bone mineral density were analyzed by DXA. In a smaller number of mice body fat content was evaluated by MRI. At sacrifice liver, epididymal and retroperitoneal adipose tissues were weighed. Bone microarchitecture was evaluated by microCT and histomorphometry. Liver oil-red-O staining was performed. T test was used in statistical analysis with a 95% confidence interval. R mice (n=12) tend to gain more weight than C mice (n=11) despite no differences in food intake. Surprisingly, total % body fat by DXA (R:14.6% C:18.6%, $p<0.01$), epididymal (R:14.5mg/gbw C:20.8mg/gbw, $p<0.01$) and retroperitoneal fat weight(R:2.9mg/gbw C:5.0mg/gbw, $p<0.01$) were significantly lower in R than in C mice. R livers were heavier in R than in C ($p<0.008$) and had massive lipid droplet formation. R mice tended to have lower total bone mineral density by DXA, reduced femoral cortical thickness by microCT ($p<0.008$) and lower tibial BV/TV by histomorphometry (R:7.3% C:8.8%,$p<0.05$). All bone resorption parameters such as osteoclast surface per bone surface(R:5.7% C:2.5%, $p=0.01$), osteoclast number per tissue area (R:11.8/mm^2 C:6.4/mm^2, $p<0.02$), osteoclast number per bone perimeter (R:2.3/mm C:1.1/mm, $p=0.009$) and eroded surface per bone surface (R:2.56% C:0.98%, $p=0.002$) were increased in R vs C mice. These results suggest that adipose distribution (visceral vs epididymal and retroperitoneal) is significantly altered by R treatment of pubertal mice, even before excessive weight gain occurs. The detrimental effects of R on bone were principally associated with increased indices of bone resorption with no changes in parameters of bone formation. In sum, R has a profound effect on fat metabolism and the skeletal phenotype. Prolonged use in younger animals and individuals may be associated with the metabolic syndrome as well as impaired peak bone acquisition and maintenance.

High Dose Recombinant Growth Hormone Therapy is More Effective in Pre-pubertal Compared to Pubertal Patients with Growth Failure in Well Controlled Hypophosphatemic Rickets. Agnes Linglart*, Isis Marchand, Pierre Bougneres, Anya Rothenbuhler. AP-HP; Université Paris 5; INSERM, France

Twenty-five to 30% of patients with well controlled X-linked hypophosphatemic rickets (XLHR) show linear growth failure despite optimal treatment with calcitriol and phosphates and have a final height under -2 SDS. Previous studies in small cohorts of patients (maximum N=6) demonstrated improvement in mean height Z-scores under recombinant growth hormone (rGH) therapy. To confirm the benefit of rGH therapy on linear growth we included 18 children and adolescents with hypophosphatemic rickets and growth failure in a controlled clinical trial. The inclusion criteria were the following: XLHR with mutation in the PHEX gene, minimum of one year of optimal oral treatment with phosphate and calcitriol prior to inclusion, insufficient "catch up growth" (height below -2 SDS) after rickets was improved and alkaline phosphates normalized. Patients were put on 80 µg/kg/day of rGH (conventional treatment with phosphate and calcitriol was continued) and monitored every three months (height, weight, growth velocity, metabolic markers of calcium and phosphate metabolism and IGF-1). RGH dose was then adjusted to growth velocity, weight and IGF-1 levels. The study population was divided into two sub-groups: 11 pre-pubertal patients (before and during the rGH trial), 6.0 ± 2.5 years of age, and 7 pubertal patients (Tanner stage 2 or 3 at inclusion) 13.0 ± 1.1 years of age. In pre-pubertal children, both mean height Z-score and mean height velocity Z-score increased significantly at +12 months (M12, N=11) and +24 months (M24, N=7) of the trial (height SDS: baseline -2.3 ± 0.8, M12 -1.5 ± 0.7, M24 -0.98 ± 1.0; height velocity SDS: baseline -1.0 ± 1.1, M12 4.4 ± 1.6, M24 2.3 ± 1.7, respectively). In pubertal patients rGH treatment was a lot less beneficial; mean height SDS went from -2.4 ± 1.1 at baseline to -1.8 ± 1 at M12 and to -1.8 ± 1 at M24. Prepubertal patients displayed low IGF-1 levels prior to rGH therapy (-1.2 ± 0.2 SDS) and increased their IGF-1 levels to 0.05 ± 0.6 SDS (M12) and 0.2 ± 0.4 SDS (M24). Differently, pubertal patients had normal IGF-1 levels (-0.4 ± 0.8 SDS) significantly increased by rGH treatment (1.3 ± 1.0 SDS at M24). Rickets was not modified by rGH treatment.

2- years recombinant GH is effective and safe for treating growth failure in well controlled XLHR when initiated before puberty. IGF-1 levels suggest that XLHR children switch from great IGF-1 sensitivity to IGF-1 resistance. However, follow-up until final height is needed to evaluate the long term benefit of rGH on height.

Age-Related Loss of Hip Bone Strength Varies by Gender and Loading Condition: The AGES-Reykjavik Study. Thomas Lang*[1], Sigurdur Sigurdsson[2], Kristin Siggeirsdottir[2], Diana Oskarsdottir[2], Gunnar Sigurdsson[3], Gyda Karlsdottir[2], Gudny Eiriksdottir[2], Tamara Harris[4], Vilmundur Gudnason[5], Joyce Keyak[6]. [1]University of California, San Francisco, USA, [2]Icelandic Heart Association, Iceland, [3]Landspitali, Iceland, [4]National Institute on Aging, USA, [5]Icelandic Heart Association Research Institute, Iceland, [6]University of California, USA

The risk of incident hip fracture rises rapidly with age, and is particularly high in women. This increase in fracture risk comprises both the age-related increase in the risk of falls and declines in the strength of the proximal femur. To better understand the extent to which proximal femoral strength declines with age as a function of gender and loading condition (fall loading vs normal physiologic loading), we have carried out the first longitudinal analysis of proximal femoral strength in men and women using subject-specific finite element modeling (FEM).

In the AGES-Reykjavik Study vQCT scans of the hip hip (Siemens Somatom 4, 120 kVp, 150 mAs, 1-mm slice thickness sampled at 3 mm) were performed at a baseline visit in 2002-2004 and at a second visit 5.05 ± 0.25 years later. From these, 140 subjects (72 men, 69 women, aged 68-87 years) were randomly selected for longitudinal evaluation using FE models of the left proximal femur, analyzed under single-limb stance loading which simulates normal physiologic loading of the hip. These models incorporated nonlinear material properties and predicted peak fracture load (STANCE); analogous non-linear modeling for fall loading is not yet available, and thus we used linear modeling for a posterolateral fall (FALL). We computed five-year percentage changes in FALL and STANCE. ANOVA was employed to compute compare bone strength loss between genders and the paired Student's T-Test was used to compare between loading conditions.

Results are displayed in Table 1. Significant loss of bone strength occurred for each loading condition within both genders ($p<0.001$). Women tended to lose proximal femoral strength at higher rates than men ($p=0.07$ for FALL, $p=0.03$ for STANCE), and in women, FALL was lost at a sharply higher rate than STANCE ($p<0.001$).

Our longitudinal results indicate that women lose hip bone strength at a rapid rate (nearly 14%/5years for FALL), which is consistent with the sharp age-related increases in hip fracture risk documented for women. The gender difference in hip bone strength loss is consistent with the higher incidence of hip fracture among women. For women, the 40% lesser loss of STANCE compared to FALL strength ($p<0.001$), supports previous findings in animal and human studies that the sub-volumes of bone stressed under normal physiologic loading are relatively protected in aging.

%changes/5 yr	FALL (SD)	STANCE (SD)	p-loading condition
Women	-13.8 (13.5)	-8.6 (8.8)	<0.001
Men	-5.2 (16.0)	-3.2 (7.5)	0.3
p-gender	0.07	0.03

Bone Density and Structure of Patients on Bisphosphonates with Atypical Femur Fractures. Angela Cheung*[1], Jonathan Adachi[2], Robert Josse[3], Robert Bleakney[4], Christian Viellette[1], Aliya Khan[5], Moira Kapral[1], Sophie Jamal[6], Heather McDonald-Blumer[7], Earl Bogoch[8]. [1]University Health Network, Canada, [2]St. Joseph's Hospital, Canada, [3]St. Michael's Hospital, University of Toronto, Canada, [4]Mt. Sinai Hospital, Canada, [5]McMaster University, Canada, [6]The University of Toronto, Canada, [7]Mount Sinai Hospital, Canada, [8]St. Michael's Hospital, Canada

Purpose: Atypical femur fractures have been reported recently with bisphosphonate use. We examined the bone density and bone structure of patients on bisphosphonates with atypical femur fractures.

Methods: This is a cross-sectional study of patients referred to the University Health Network Osteoporosis Clinic for assessment of atypical femur fractures. All patients were assessed by an osteoporosis physician. All radiographs were independently reviewed by a musculoskeletal radiologist as well as an osteoporosis expert, and areal BMD by DXA (Hologic Discovery A®, Hologic Inc., Massachusetts, USA) was performed at the lumbar spine, total hip and femoral neck, and HRpQCT (Xtreme CT®, Scanco Medical, Switzerland) at the distal radius and tibia.

Results: Sixteen patients (15 women and 1 man) were included in the study. Six were Chinese, 2 were Indian, 8 were European Canadian. Mean age was 67.2 (range

46.4-88.1) years. Mean duration of bisphosphonate use was 7.5 (range 2 to 10.6) years. Mean serum 25-hydroxyvitamin D level close to the time of fracture was 93nmol/L. Although most patients (11/16) had comorbid conditions or medications (rheumatoid arthritis, pemphigus, liver transplant, diabetes, cancer, steroid or warfarin use), 5 did not. Mean BMD T-score at the lumbar spine, total hip and femoral neck were -0.68, -0.48 and -0.90, respectively. On HRpQCT scans, there is decreased cortical thickness, marked cortical porosity and a lack of trabecular structure with empty ''holes'' on many of the scans (see Table).

Conclusions: Patients on bisphosphonates with atypical femur fractures have poor bone quality and structure as measured by HRpQCT. These results suggest that low bone turnover and increased mineralization may not be the only explanation for these atypical insufficiency fractures.

Table. HRpQCT scans of Patients on Bisphosphonates with Atypical Femur Fractures

Mean	TotalvBMD (mg/cm^3)	CortvBMD (mg/cm^3)	TrabvBMD (mg/cm^3)	CTh (mm)	Tb Th (mm)	Tb N (mm^{-1})	Tb Sp (mm)	BV/TV (%)
Radius	266.8	824.9	101.8	0.65	0.065	1.37	0.918	0.085

Collagen Cross-link Concentration Influences the Fatigue Behavior of Human Vertebral Trabecular Bone. Stephanie Viguet-Carrin*[1], David Panus[2], Helene Follet[3], Pierre Delmas[1], Elise Morgan[4], Roland Chapurlat[1], Mary Bouxsein[5]. [1]E. Herriot Hospital, France, [2]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center & Harvard Medical School, Boston, USA, USA, [3]INSERM, Université De Lyon, USA, [4]Boston University, USA, [5]Beth Israel Deaconess Medical Center, USA

Although the response of trabecular bone to cyclic loading may contribute to fragility fractures, few studies have investigated the factors that influence this behavior. Thus, the aim of this study was to determine the relative contributions of bone density, microarchitecture, and collagen crosslink content to the fatigue properties of human vertebral trabecular (Tb) bone. L2 vertebrae were obtained from 28 donors (age 54–95; 13 M, 14 F, 1 unknown). We evaluated one Tb core per vertebrae for microarchitecture by μCT and fatigue properties by cyclic testing under a constant strain (0 to 0.4%) at 2 Hz. Outcomes included the initial stiffness (E_0), loss of stiffness at failure (ΔF), number of cycles to failure (Nf), strain at failure and rate of modulus degradation. Collagen crosslink content was assessed by HPLC (pyridinoline (PYD), deoxypyridinoline (DPD) and pentosidine (PEN)). Parametric tests were used except for some non-Gaussian parameters (collagen characteristics and Nf). Results: There were no differences between men and women, and no relationship between age and microarchitecture or collagen characteristics. Among all the parameters characterizing the fatigue tests, only E_0 and ΔF decreased with age ($r = -0.40$; $p=0.04$ and $r = -0.41$; $p=0.03$, respectively). Neither bone volume or microarchitecture were associated with fatigue properties. Enzymatic cross-link content (PYD, DPD) and their combination (PYD + DPD) were associated with fatigue properties. PYD and PYD + DPD content were positively associated with Nf ($rsp = 0.52$, $p=0.004$; $rsp = 0.53$, $p=0.004$, respectively) and negatively associated with the rate of modulus degradation ($rsp = -0.52$, $p=0.005$ for both). PYD, DPD and PYD + DPD content were negatively related to strain at failure ($rsp = -0.57$, $p=0.002$; $rsp = -0.40$, $p=0.04$; $rsp = -0.58$, $p=0.001$, respectively). In contrast, PEN content was not associated with any fatigue properties. These findings indicate that collagen crosslink content, specifically the trivalent mature enzymatic crosslinks of type I collagen, may influence the fatigue behavior of human vertebral trabecular bone.

FR0034

Decreased PTH Secretion is Associated with Low Bone Formation and Vertebral Fracture Risk in Postmenopausal Women with Type 2 Diabetes. Masahiro Yamamoto*[1], Toru Yamaguchi[1], Mika Yamauchi[1], Kiyoko Nawata[2], Toshitsugu Sugimoto[3]. [1]Shimane University Faculty of Medicine, Japan, [2]Department of Health & Nutrition, The University of Shimane, Junior College, Matsue Campus, Japan, [3]Shimane University School of Medicine, Japan

We previously reported that patients with type 2 diabetes (T2DM) had an increased risk of vertebral fractures (VFs) despite higher bone mineral density (BMD) compared to non-T2DM controls (JBMR 2009), and that advanced glycation end-products (AGEs) and its endogenous secretory receptor (esRAGE) were associated with VFs independent of BMD (JCEM 2008 and Diabetes Care 2009), suggesting the existence of poor bone quality in T2DM. Bone turnover is one of the components of bone quality, and bone formation represented by serum osteocalcin (OC) level is decreased in T2DM. Although PTH plays an important role in bone formation, the association of PTH level with bone formation or VFs in T2DM is still unclear. The aim of this study is to clarify the involvement of PTH in decreased bone turnover or increased VF risk in T2DM. We compared parameters including serum levels of intact PTH and N-mid-OC as well as lumbar and femoral BMD values between Japanese T2DM patients (123 postmenopausal women and 132 men over 50 years old) and non-DM controls (189 women and 51 men), who were within normal creatinine levels. PTH and OC levels in T2DM were significantly lower than those in the controls in both genders (women: 22 ± 10 vs. 46 ± 15 pg/ml and 14 ± 6 vs. 23 ± 9 ng/ml, respectively, $P<0.01$; men: 21 ± 10 vs. 46 ± 19 pg/ml and 10 ± 4 vs. 15 ± 5 ng/ml, respectively, $P<0.01$). Multivariate analysis adjusted for age, BMI, serum creatinine, calcium and phosphorus also showed that PTH was significantly and positively correlated with OC in T2DM (women: r=0.32?P<0.01; men: r=0.34, P <0.01). However, PTH levels were not correlated with HbA1c levels in either gender. When T2DM patients were divided into four groups by PTH and OC level, multivariate logistic regression analysis adjusted for age, BMI, serum creatinine level and lumbar BMD showed that the group with both lower PTH and lower OC in T2DM women had a significantly increased risk of VFs than the group with both higher PTH and higher OC (odds ratio 4.3, 95%CI 1.2-16.1, P=0.03). These results showed that suppressed bone formation in T2DM was associated with decreased PTH level irrespective of HbA1c levels, and that the coexistence of diminished PTH and OC levels in postmenopausal T2DM women was a risk factor of VFs independent of BMD. These findings suggest that suppressed PTH secretion may induce low bone formation and reduced bone quality, which may result in VF occurrence in T2DM women.

Improved Evaluation of Hip Structure using High Resolution Cortical Thickness Measurement from Clinical CT Data. Graham M Treece, Andrew H Gee, Paul Mayhew*, Kenneth Poole. University of Cambridge, United Kingdom

The distribution of cortical bone in the proximal femur is believed to be critical in determining fracture resistance. Ageing leads to thinning of femoral neck cortical bone, which can become as thin as an egg-shell by the eighth decade in critical areas (0.3mm). In current clinical practice, hip bone mineral density estimates made with 2-dimensional dual-energy x-ray absorptiometry ('DXA') are specific for predicting hip fracture but have low sensitivity. Recent studies have instead utilised multi-detector computed tomography (MDCT) to examine femoral neck cortical thickness and 3-D structure and its potential for in vivo hip fracture prediction. However, existing CT technology is limited in its ability to measure cortical thickness, especially in the sub-millimetre range which lies within the point spread function of today's clinical scanners. We present a novel analysis technique that is capable of producing unbiased cortical thickness estimates down to 0.3mm, considerably outperforming previous methods (referred to here as simple thresholding, and 50% relative threshold). The technique relies on a mathematical model of the anatomy and the imaging system, which is fitted to the data at a large number of sites around the proximal femur, producing around 17,000 independent thickness estimates per specimen. In a series of experiments on sixteen cadaveric femurs, estimation errors were measured as -0.01 ± 0.58mm (mean $\pm$ 1 std. dev.) for cortical thicknesses in the range 0.3mm to 4mm. This compares with 0.25 ± 0.69mm for simple thresholding and 0.90 ± 0.92mm for a variant of the 50% relative threshold method. In the clinically relevant sub-millimetre range, thresholding increasingly fails to detect the cortex at all, whereas the new technique continues to perform well. The many cortical thickness estimates can be displayed as a colour map painted onto the femoral surface. Computation of the surfaces and colour maps is rapid and largely automatic. The technique is ideally suited to the evaluation of cortical bone structure in life, in clinical fracture prediction, and in assessing the structural response of the hip to interventions.

Investigation of Statistical Shape and Density Modeling as a Discriminator for Clinical Fracture Risk. Todd Bredbenner*[1], Ryan S. Potter[1], Robert L. Mason[1], Lorena Havill[2], Eric Orwoll[3], Daniel P. Nicolella[1]. [1]Southwest Research Institute, USA, [2]Southwest Foundation for Biomedical Research, USA, [3]Oregon Health & Science University, USA

In this preliminary study, the performance of statistical shape and density modeling (SSDM) methods to predict the risk of future hip fracture was investigated. Baseline QCT data of the right hip was obtained for 40 participants, including 20 who fractured a hip (mean 5.6 year observation, validated by physician review) and 20 who did not, randomly selected from the Osteoporotic Fractures in Men (MrOS) Study.

QCT data was processed to develop a volumetric mesh model of geometry and bone density for each of the 40 proximal femurs. Each model consisted of over 36,000 geometry and density variables (e.g. spatial location and density at each 3D mesh node located at corresponding anatomic positions for all femurs). The set of models was combined and the number of geometry and density variables was reduced using a principal component analysis; individual models were described using the average femur model plus a weighted linear combination of 39 independent and uncorrelated principal components (PCs) that do not have explicit meaning, but rather describe unique features of 3D bone geometry and density. By definition, PC weighting factors cumulatively described the total variance in proximal femur geometry and bone density distribution in a highly compact and efficient manner. Using Wilcoxon rank sum analyses, 3 PCs were found to be significantly different between men with and without subsequent fracture: PC4 ($p = 0.022$), PC15 ($p < 0.05$), and PC18 ($p = 0.037$). These 3 new variables describe the independent, complex, and subtle differences in 3D shape and bone density between participants with and without fracture. Stepwise logistic regression was used to develop a discriminator using PCs against fracture or no fracture group membership. The area under Receiver Operator Characteristic curve for the regression using 5 PCs was significantly greater than for proximal femur aBMD (DXA QDR 4500W; Hologic) (Figure 1) in this small sample.

Statistical shape and density modeling methods compactly and efficiently described the total geometry and bone density distribution variability within this small set of 40 proximal femur models defined from the MrOS cohort. Furthermore, the description of sample variation using SSDM allowed the application of relatively simple statistical tools to investigate important structural differences (e.g. geometry and density distribution traits) that may allow improved prediction of those at risk of subsequent hip fracture.

Local Topological Analysis at the Distal Radius by HR-pQCT: Application to *In Vivo* Bone Microarchitecture and Fracture Assessment in the OFELY Study. Jean-Baptiste Pialat*[1], Nicolas Vilayphiou[2], Stephanie Boutroy[3], Pierre-Jean Gouttenoire[4], Elisabeth Sornay-Rendu[5], Roland D. Chapurlat[6], Francoise Peyrin[4]. [1]INSERM U831, Université de Lyon & Hospices Civils de Lyon, France, [2]INSERM Unit 831 & Université de Lyon, France, [3]INSERM, Université De Lyon, France, [4]European Synchrotron Radiation Facility (ESRF), France, [5]INSERM, France, [6]INSERM U831 & Université de Lyon, France

Purpose: Local geometric analysis has been developed for high resolution imaging techniques. The aim of our study was to test the feasibility and efficiency of such technique at 82 µm resolution and its ability to detect patients with fracture in a subset of patients from the OFELY cohort.

Methods: 33 women with prevalent wrist fractures were compared with their age and BMI-matched controls. Bone microarchitecture was assessed by HR-pQCT (XtremeCT, Scanco Medical AG, Switzerland), and finite element analysis (FEA) was based on HR-pQCT images of the distal radius [1]. A new local topological analysis method was applied to label each bone voxel as rod, plate or branch [2]. Then the bone volume to total volume (BV/TV), and the rod and plate ratio over bone volume (RV/BV and PV/BV) or total volume (RV/TV, PV/TV) were calculated. These Topological parameters (TPs) were compared to each other, microarchitectural and FEA parameters with Pearson or Spearman correlation tests, depending on the distribution of variables. [2] test was used to evaluate the distribution of wrist fracture in tertiles of RV/TV, PV/TV, RV/BV, and BV/TV (1st & 2nd versus 3rd tertile). Associations between TPs and wrist fractures were computed in a paired logistic regression model, OR [95% CI] per SD change.

Results: Good correlations were found between PV/TV or RV/TV and microarchitectural parameters or bone strength evaluated with FEA (Table 1). In contrast, RV/BV and PV/BV were weakly correlated with TbN ($|r|=0.24$ and 0.31). Moreover, negative correlation between RV/BV and stiffness computed by FEA directly suggested the loss of bone strength related to conversion from plates into rods during bone loss. Individuals with rod-like structure were more likely to have wrist fracture (χ^2 test $p=0.0017$ for RV/BV). We also found an association between wrist fracture and all topological parameters (OR=2.31 [1.18-4.55] per SD increase of RV/BV, $p=0.015$ and OR=2.04 [1.09-3.82] per SD increase of PV/BV, $p=0.025$).

Conclusions: Local topological analysis at 82µm resolution is feasible and improves the microarchitectural description. Further studies might outline how changes from plates to rods impact bone strength.

Non-collageneous Proteins Influence Crystal Orientation and Shape: A SAXS Study. Atharva Poundarik*[1], Ondrej Nikel[2], Caren Gundberg[3], Deepak Vashishth[2]. [1]Rensselaer Polytechnic University, USA, [2]Rensselaer Polytechnic Institute, USA, [3]Yale University School of Medicine, USA

Bone is a complex composite material comprising of mineral (hydroxyapatite) phase, collagen and non-collageneous proteins like osteocalcin (OC) and osteopontin (OPN). Through mechanisms like ligament bridging, diffuse damage and microcracking that aid in energy dissipation, bone averts fracture. Mineral crystals span a few nanometers in either direction and occupy the lowest levels of bone's structural hierarchy [1]. Any modification at this level may alter bone metabolism and affect bone fragility.

Previous studies on OC and OPN knock-out mice (OC-/- and OPN-/-) have demonstrated that these proteins play a key role in crystal structure and organization [2,3]. Here we use small angle X-ray scattering (SAXS) to show that their absence causes a measurable change in crystal orientation and shape. X-ray scattering spectra (Nanostar, Bruker) were obtained from longitudinal femoral cortical sections of three mouse genotypes: wild type (WT), OC-/- and OPN-/-. The 2-D SAXS data [intensity I(q,), scattering vector (q) and polar angle ())]was processed after noise correction to obtain crystal orientation. The spherically averaged intensity function was analysed

based on Porod's law ($I=Pq^{-4}$, at large q) to estimate differences in crystal size and shape [4].

Crystal orientations along the long axis of bone were greater for the knock-out samples (OC-/-, 6.10 deg. and OPN-/-, 5.25 deg.) than WT (4.89 deg.). Greater degree of crystal orientation in both knock-out specimens implied that increased mineral heterogeneity results from the absence of OPN and OC in bone matrix. Furthermore, consistent with previous FTIR studies [2], the Porod analysis revealed a larger surface to volume ratio in OC-/- as compared to WT indicating smaller crystal dimensions. Such differences were not observed in the bones from OPN-/-. Thus, in contrast to the presence of more plate like mineral in WT and OPN-/-, OC-/- mice tend to have more rod-like crystals. We conclude that osteocalcin is a stronger regulator of crystal organization than osteopontin in bone and its absence may alter the organizational hierarchy of bone at higher scales.

FR0048

BMD and TBS Micro Architecture Parameters Assessment at Spine in Patients with Primary Hyperparathyroidism (PHPT) before and One Year after Parathyroidectomy. Emilie Maury[1], Renaud Winzenrieth[2], jean-claude Souberbielle[3], Emile Sarfati[4], Catherine Cormier*[5]. [1]Service De Rhumatologie A, AP-HP Groupe Hospitalier Cochin - Saint Vincent De Pa, France, [2]Med-Imaps, PTIB, France, [3]Laboratoire d'Explorations Fonctionnelles, Hopital Necker-Enfants Malades, France, [4]epartment of endocrine surgery,hopital Saint-Louis, APHP, France, [5]AP-HP Groupe Hospitalier Cochin, France

PHPT is a very common endocrinopathy which is often diagnosed during a biological exploration in osteoporotic patients and is considered as a frequent cause of secondary osteoporosis. Increase in bone mineral density (*BMD*) following parathyroidectomy (PTX) has been reported in numerous studies. However, only BMD evaluated by DXA is taken into account. Trabecular bone score (*TBS*) is a grey-level texture measurement, which correlates with 3D parameters of bone micro-architecture. The aim of our study was to examine bone microarchitecture assessed by TBS and BMD in PHPT female subjects assessed before and one year after PTX, and to evaluate theirs associations with clinical variables.

We present a longitudinal study on 29 PHPT Caucasian postmenopausal women with mean age and BMI of 62.1 ± 10.4 years and 25.5 ± 6.5 Kg/m^2 respectively who were all operated on. Before PTX, all patients had a measurement of serum total and ionized calcium, phosphate, PTH, C-telopeptide of type 1 collagen (CTX), as well of 24-hour urine calcium and phosphate reabsorption rate (TRP). BMD and TBS were evaluated at AP Spine (L1-L4) with DXA prodigy (GE-Lunar), QDR 4500 (Hologic), and TBS iNsight® (Med-Imaps) within 6 months before PTX, and one year after PTX. Both DXA were cross-calibrated. Correlations (Spearman rank test) were evaluated between pre-Surgery BMD or TBS or their difference during the study period, and biological variables independently of each other. Differences between pre and post PTX values were assessed using Wilcoxon rank test for paired data.

Pre- and post-Surgery data are presented in Table 1. Before PTX, BMD and TBS were correlated together ($p<0.0001$), with 46% of TBS explained by spine BMD. Before PTX, neither BMD nor TBS was correlated with any of biological parameters. After PTX, BMD and TBS increased significantly by $4,7 \pm 5.4\%$ and $1.6 \pm 4\%$ respectively, without correlation between BMD and TBS gains. Pre-PTX serum total calcium was correlated ($p=0.035$) with the BMD gain one year post-PTX. No other correlation was found between pre-PTX biological parameters and the post-PTX change in BMD or TBS.

The present study is the first to report data on changes in spine BMD and bone microarchitecture both assessed by DXA in PHPT women after PTX. Consistent with previously published data, spine BMD increased after PTX, while TBS increased more slightly. This last result is consistent with what was published when iliac crest biopsies were analyzed longitudinally post-PTX.

Bone Microarchitecture Assessment in Postmenopausal Women with Atypical Fractures and Long Term Bisphosphonate Use. Maria Belen Zanchetta*, Marcelo Sarli, Fabio Massari, Rodolfo Spivacow, Mirena Buttazzoni, Fernando Silveira, Cesar Bogado, Jose Ruben Zanchetta. Instituto de Investigaciones Metabolicas (IDIM), Argentina

Recent reports have suggested a link between atypical fractures and long-term bisphosphonate use. The pathophisiology of these events is unknown.

Our aim was to describe bone microarchitecture in five patients with atypical fractures and long term biphosphonate treatment using High Resolution peripheral computerized Tomography (HR-pQCT).

We identified 5 postmenopausal women who have received bisphosphonate treatment for more than 10 years (mean 14.8 ± 3, 9 years) and who presented with atypical low-energy fractures, defined as fractures occurring in a fall from a standing height or less in atypical sites. Three patients sustained subtrochanteric or proximal diaphyseal fractures and two suffered a pelvic fracture (see table 1). No patient had a history of vertebral fractures. We compared bone volumetric density and architectural parameters measured by HR-pQCT of the radius and tibia in these 5 fractured patients with 54 healthy, ambulatory, postmenopausal, non- treated and non- fractured women selected from our database with similar age and BMD values and with 8 postmenopausal women who have received long term treatment with bisphosphonate (mean 9.6 ± 4.9 years) and who have not suffered an atypical fracture. All women had no conditions or other treatments known to affect bone or mineral metabolism.

ArealBMD at the lumbar spine and femoral neck was measured using DXA (Hologic QDR4500 ;Hologic, Bedford, MA). Volumetric BMD and microarchitecture were measured at the distal radius and tibia using a three-dimensional HR-pQCT system (XtremeCT; Scanco Medical AG, Bassersdorf, Switzerland).Comparisons between groups were assessed by the two-sample T test.

There were no statistically significant differences in age, years since menopause, BMI and BMD T-scores of the lumbar spine and femoral neck between the groups.

In the atypically fractured group cortical density and thickness in radius and tibia seems to be disminished compared with the others two groups. We do not know whether this tendency is due to some atypical response to long term bisphosphonate treatment in a subgroup of women or constitutes a genetic baseline characteristic cortical structure of these five women.Although they are all atypical fractures, pelvic fractures and femoral shaft fractures may not have the same pathophisiology. Additional prospective studies are needed to establish a clear association between atypical fractures and prolonged bisphosphonate treatment.

Intermittent PTH Treatment Increases Intracortical Osteocyte Density and Decreases Fat Mass in Ovariectomized Rats. Steven Tommasini*[1], Andrea Trinward[2], Alvin Acerbo[3], Lisa Miller[4], Stefan Judex[5]. [1]SUNY Stony Brook, USA, [2]State University of New York at Stony Brook, USA, [3]Brookhaven National Laboratody, USA, [4]Brookhaven National Laboratory, USA, [5]Stony Brook University, USA

Some pharmaceutical treatments for osteoporosis have the potential to deteriorate mechanical properties of the skeleton by altering specific aspects of bone's tissue quality. Here, we hypothesized that PTH and bisphosphonate treatments differ in their effect on intracortical porosity, which has been linked to the stiffness and strength of cortical bone. Further, it is possible that any potential changes in bone porosity are not modulated directly by the specific treatment, but indirectly by altered adiposity. Here, we examined the effects of treatment on intracortical porosity and adiposity in the OVX rat. Six-month old female Sprague-Dawley rats were assigned to either: baseline control, age-matched control, untreated OVX, OVX treated with either 15μg/kg/d hPTH(1-34) (H-PTH) or 0.3μg/kg/d (L-PTH), or OVX treated with either 100mg/kg/2xwk Alendronate (H-ALN) or 1mg/kg/2xwk (L-ALN). Treatments started at 6 mo of age and rats were sacrificed at 6, 8, and 12 mo of age (n=10/group/age). There were no significant differences in femoral diaphysis geomtery or composition among groups as measured via μCT (36μm resolution). Synchrotron CT (0.75μm resolution) detected intracortical microporosities not detected by conventional μCT. Within ages, treatments did not differ in %porosity or avg pore size. However, %porosity decreased with age for all groups. Even though no differences in %porosity were detected, prolonged H-PTH treatment maintained a 54% greater number of osteocyte lacunae (avg vol=250μm^3) and 46% more vascular canals (>1000μm^3) compared to all other groups ($p<0.05$). Tissue mineral density was inversely related to avg pore size (r=-0.83). *In vivo* μCT revealed PTH-treated rats also had significantly lower abdominal fat volume/body weight compared to all other groups ($p<0.01$). The data suggest that the greater number of osteocyte lacunae may be related to changes in metabolic rate, which has been correlated with osteocyte density. The increase in microporosities also may be evidence of ostecytic osteolysis previously reported with continuous PTH treatment. The mechanical consequences of the changes in porosity are yet to be established, but do not necessarily have a negative impact on bone's ability to resist load as very small pores have the potential to delay crack propagation by absorbing shear forces. Therefore, understanding how osteoporosis treatments modulate the interactions between adiposity and bone quality may be critical for reducing fracture risk.

A Comparison of Resistance and Aerobic Exercise Training on Physical Ability, Bone Mineral Density and Osteoprotegerin in Older Women. Elisa Marques*[1], Flávia Wanderley[1], Daniel Gonçalves[1], Margarida Coelho[1], João Viana[2], Pedro Moreira[1], Jorge Mota[1], Joana Carvalho[1]. [1]University of Porto, Portugal, [2]Loughborough University, United Kingdom

Purpose: This study compared the effects of a moderate-impact resistance training protocol and a moderate-impact aerobic training protocol on bone mineral density (BMD), physical ability and serum osteoprotegerin (OPG).

Methods: Seventy-one older women were randomly assigned to resistance exercise (RE), aerobic exercise (AE) or control group (CON). RE included 3 sets of 8 repetitions at 70 to 80% of 1 repetition maximum focused on exercises with attachments to the proximal femur and additional complementary upper body exercises. AE program included dynamic activities involving stepping, skipping, walking, jogging, dancing, aerobics and step choreographies at an intensity that gradually increased from 65% to 85% of the heart rate reserve. Both interventions were conducted 3 times per week for 8 months. Outcome measures included proximal femur BMD (by dual X-ray absorptiometry), muscle strength, dynamic balance, handgrip strength, walking performance, fat mass, anthropometric data, and serum OPG. Potential confounding variables included dietary intake, accelerometer-based physical activity and molecularly defined lactase nonpersistence.

Results: After 8 months, the RE group exhibited increases in BMD at the trochanter (2.3%) and total proximal femur (1.9%), and a trend (although nonsignificant) to improve muscle strength. In addition, reduced body mass index was observed. RE and AE decreased the percentage of fat mass and increased walking performance. CON group showed increases in fat mass and maintained or slightly decreased muscle strength. No significant interactions were observed for waist circumference and handgrip strength. Moreover, no significant changes in BMD were observed for AE and CON groups, and no associations were found between lactase nonpersistence and BMD changes. No group differences were apparent in baseline values or change in dietary intakes. Although a significant increase in physical activity level was observed, the change was similar among the groups and did not correlate with any bone and functional adaptations. No significant changes were observed in OPG levels, yet RE group showed the slighter positive mean percent change (0.52%) compared to the negative percent change in AE (-2.7%) and CON (-7.8%) groups.

Conclusion: Data suggest that 8 months of RE may be more effective than AE for inducing favorable changes in BMD, while both interventions demonstrate to protect against the functional weakness that is strongly related to fall-risk.

Downregulation of Sost/sclerostin Expression is Required for the Osteogenic Response to Mechanical Loading. Xiaolin Tu*[1], Yumie Rhee[2], Racheal Lee[3], Jeffrey Benson[3], Keith Condon[3], Nicoletta Bivi[3], Lilian Plotkin[1], Charles Turner[4], Alexander Robling[3], Teresita Bellido[1]. [1]Indiana University School of Medicine, USA, [2]IUMS, Yonsei University, College of Medicine, South korea, [3]Indiana University, USA, [4]Indiana University, Purdue University Indianapolis, USA

The expression of osteocyte-derived sclerostin is reduced by mechanical loading, raising the possibility that osteocytes coordinate the osteogenic response to mechanical force by locally unleashing Wnt signaling. We investigated herein whether Sost downregulation is a pre-requisite for loading-induced anabolism by examining the response of transgenic mice (TG) overexpressing human Sost in osteocytes (driven by the 8kb-DMP1 promoter) and wild type (WT) littermates at 4-month of age. Loads required to obtain equal strains in TG and WT mice were measured ex vivo in 6 mice/genotype using gauges on ulnar midshafts. Loading induced 14% higher strains in TG (1295.5με/N) compared to WT (1114.8με/N) mice, indicating that TG bones are less resistant to mechanical force. Right ulnae were subjected to in vivo cyclic axial loading at low, medium, and high strains for 1min/d, 2Hz; left ulnae were unloaded controls. Endogenous (murine) Sost mRNA expression measured 24h after 1 loading bout at high strain was similarly decreased in WT and TG mice ($44\pm15\%$ and $47\pm8\%$ respectively, compared to unloaded ulnae; n=3/group). In contrast, human Sost, only expressed in TG mice, was not affected by loading. Six-8 mice/group were loaded on 3 consecutive days and forelimbs were collected 16d after initiation of loading. Dynamic histomorphometric analysis revealed that basal periosteal bone formation rate (pBFR) was similar in WT and TG mice. Loading caused a strain-dependent increase in pBFR in WT mice (0.08 ± 0.05; 0.24 ± 0.16; and 0.50 ± 0.18 um3/um2/d; $p<0.05$ vs unloaded ulnae for low, medium and high strain, respectively), resulting from an increase in both mineralizing surface covered by osteoblasts (MS/BS) as well as activity of individual osteoblasts (MAR). In contrast, loading-induced pBFR was dramatically reduced in TG mice by 70-82% (0.02 ± 0.02, 0.07 ± 0.08, and 0.09 ± 0.05 um3/um2/day), with significant changes only induced by high strains. Reduced pBFR resulted mainly from a marked decrease in MAR, which was not different in loaded vs unloaded ulnae in TG mice at any strain magnitude tested. Loading-induced MS/BS was also reduced in TG mice, with significant increase only induced by high strains. Dose-response curves of pBFR vs strain revealed an overall reduced mechanosensitivity and increased osteogenic threshold in TG bones. Therefore, downregulation of Sost/sclerostin is an obligatory step in the mechanotransduction cascade that directs osteogenesis to where bone is needed.

FR0055

Modulation of Gene Expression by Mechanical Loading in Mice with Conditional Ablation of the Connexin43 Gene (*Gja1*). Susan Grimston*[1], Marcus Watkins[2], Jin Norris[3], Valerie Salazar[2], Michael Brodt[3], Matthew Silva[2], Roberto Civitelli[2]. [1]Washington University School of Medicine, USA, [2]Washington University in St. Louis School of Medicine, USA, [3]Washington University in St. Louis, USA

We have previously reported attenuated response to anabolic mechanical loading at the endocortical surface in mice with conditional ablation of *Gja1* in osteoblasts. To achieve insights on the mechanisms of such attenuated response, we studied gene expression in cortical bone shortly after application of mechanical loading, using *DM1-Cre;Gja1flox/–* (cKO) mice. These mice, where *Gja1* is selectively ablated in the osteo-chondroprogenitor lineage, have a distinctive cortical bone phenotype characterized by larger cross-sectional area but reduced cortical thickness and decreased bone strength. They also have increases in both endocortical bone resorption and periosteal bone formation. We applied axial compression to the tibia of 2-month-old male mice at 7 N peak force for 120 cycles, with 10 sec rest between cycles. The contralateral tibia was used as an internal control. Tibiae were collected 2 hours post load, and after careful removal of the bone marrow, the bone was pulverized for total RNA extraction and real time qPCR analysis. *Gja1* mRNA was barely detectable in cKO bones, confirming effective *Gja1* deletion. In wild type (WT) littermates, abundance of *Cox2* mRNA, a gene known to be regulated by mechanical stimulation, increased 3-fold ($p<0.01$), as opposed to only 1-fold increase in cKO mice. Interestingly, *Sost* mRNA abundance was dramatically down-regulated (~90%; $p=0.04$) by mechanical loading in WT mice. In cKO mice *Sost* was already about 50% lower relative to WT, and mechanical load down-regulated *Sost* mRNA in cKO, though to a lesser extent (~70%, n.s.) than in WT mice. *BMP-4* mRNA was also significantly down-regulated by mechanical loading in both genotypes, whereas *β-catenin* and *NFATc1* mRNA, also reported to be involved in mechano-responsiveness, were only marginally increased after mechanical stimulation in both groups. Finally, *RANKL* mRNA decreased 50% ($p<0.05$) in loaded WT tibiae, but it did not change in cKO mice. Thus, mechanical skeletal loading rapidly regulates expression of genes involved in BMP-2/4 and Wnt signaling in cortical bone consistent with activation of bone formation, in addition to reduced RANKL expression consistent with suppression of bone resorption. Genetic ablation of *Gja1* in osteogenic cells alters these responses, perhaps reflecting an increased bone turnover state with consequent decreased ability to further activate bone formation upon stimulation.

Developing an Atlas of GFP Reporters and Cre Drivers of Interest to the Skeletal Biologist. David Rowe*[1], Dong-Guk Shin[2], Peter Maye[1], Xi Jiang[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut, USA

Promoter driven GFPs and Cre transgenic mice are widely utilized tools for the skeletal biologist. Unfortunately the characterization of different transgenic lines is highly variable and not widely appreciated, which can limit their utility and can even generate erroneous conclusions. Following the lead of the neuroscience community (http://neurosciencebluprint.nih.gov/factSheet/MouseLines.htm) in which web sites of BAC-GFP and Promoter Cre drivers are presented, we have begun to outline the elements of an atlas of reporter mice of value to the skeletal biology community. This pilot database has been developed to assess if the skeletal biologists would find an appropriately expanded and sophisticated resource to be of value to their research. The database documents a DNA construct map of the transgenic line and provides a survey of tissues where it is expressed and sites where no activity was detected. The images are taken from cryosections of non-decalcified skeletal tissues. GFP reporters were either made in house, submitted by other investigators or acquired from the MMRRC or Jackson Laboratory repositories. The activity is imaged in growing mice or at a site of bone fracture. Currently no histological sections from embryos have been obtained, but whole mounts of intact embryos have been acquired with a stereoscopic fluorescent microscope. In the case of Cre drivers, their activity was obtained by crossing with a recently released Ai9 Cre reporter mouse line (*Nat Neurosci* 13:133, 2010), which uniformly and robustly expresses tomato fluorescent protein in soft and mineralized tissue. Besides depositing the reporter activity in intact tissues, image data of primary cultures derived from various tissues (bone marrow stromal, neonatal calvaria and tendon) can provide additional understanding of the expression properties of the reporter. Strategies for annotating the various image types are being evaluated for their effectiveness for recalling images in response to anticipated queries of the dataset. The value of Cre mediated genetic studies depends on the knowledge of the temporal and cellular pattern of promoter activity, which can be assessed through a well-designed and populated promoter-GFP reporter database. Assembling this information will require a continuing community effort both in contributing existing or newly created transgenic mice and in generating the finances to support the technical efforts to build the database.

FR0068

ALK5, a TGF-beta type I Receptor, Regulates Osteoblast-Dependent Osteoclast Maturation and is Required for Cartilage Matrix Remodeling. Tomoya Matsunobu*[1], Kiyoyuki Torigoe[2], Muneaki Ishijima[3], Ashok Kulkarni[2], Yukihide Iwamoto[1], Yoshihiko Yamada[2]. [1]Graduate School of Medical Sciences, Kyushu University, Japan, [2]National Institute of Dental & Craniofacial Research, NIH, USA, [3]Juntendo University, School of Medicine, Japan

Transforming growth factor-beta (TGF-beta) exerts its diverse activities during development and pathogenesis. TGF-beta forms a specific complex with TGF-beta type I (TbrI/Alk5) and type II (TbrII) receptors, which activates downstream signaling through Smad-dependent and -independent pathways such as MAPK pathways. Previously, we showed that mice lacking ALK5 in chondrocytes and skeletal progenitor cells using Col2a1-Cre ($ALK5^{Col2CKO}$) and Dermo1-Cre ($ALK5^{Dermo1CKO}$), respectively, are perinatally lethal, and display defects in axial skeleton formation such as severe spinal scoliosis. In addition, TGF-beta is required for osteoblast proliferation and differentiation. In this study, we analyzed the limb development of these mutant mice in order to identify the role of TGF-beta signaling in cartilage formation and matrix remodeling. While femurs of $ALK5^{Col2CKO}$ mice were comparable with those of control mice, femurs of $ALK5^{Dermo1CKO}$ mice were significantly shorter than those of control mice. The length of the resting, proliferative and hypertrophic zones in $ALK5^{Dermo1CKO}$ femurs was similar to that in control and $ALK5^{Col2CKO}$ mice. In growth plates of $ALK5^{Dermo1CKO}$ growth plates, chondrocyte proliferation and differentiation were normal, and expression levels of extracellular matrix proteins and GAG (glycosaminoglycan) were similar to those in wild-type growth plates. We found that the cartilage matrix was not degraded and remained in primary spongiosa of E18.5 $ALK5^{Dermo1CKO}$ femurs. Analysis of tartrate-resistant acid phosphatase (TRAP) as a marker for osteoclasts revealed that TRAP-positive osteoclasts were decreased in E18.5 $ALK5^{Dermo1CKO}$ femurs, although osteoclast progenitors formed. We found that RANKL expression by osteoblasts in $ALK5^{Dermo1CKO}$ growth plates was substantially reduced. Since Dermo1-Cre was not expressed in hematopoietic lineage cells, the decreased number of mature osteoclasts in the primary spongiosa of $ALK5^{Dermo1CKO}$ femurs is likely due to reduced RANKL-mediated osteoclast differentiation. Our results suggest that TGF-beta signaling is required for cartilage matrix remodeling during endochondral ossification by promoting osteoclastogenesis in an osteoblast-dependent manner.

Directed Differentiation of ES cells to the Chondrocyte Lineage. April Craft*[1], Jason Rockel[2], Gordon Keller[1]. [1]McEwen Centre for Regenerative Medicine, University Health Network, Canada, [2]Stem Cell & Developmental Biology, The Hospital for Sick Children, Canada

Osteoarthritis is a progressively debilitating disease that results from the significant degeneration of cartilage in the weight-bearing joints. The joint-lining chondrocytes (articular) are unable to regenerate upon injury. Defining the signaling pathways that regulate the generation of articular chondrocytes from embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) offers the opportunity to gain new insights into the origins of the disease and will provide a novel unlimited supply of patient-specific cells for transplantation therapies. Our approach to achieve efficient development of chondrocytes from PSCs relies on the stage specific recapitulation of embryonic signaling pathways in serum-free differentiation cultures. Studies in our lab have shown that the development of mesoderm subpopulations can be monitored quantitatively by the expression of the receptor tyrosine kinases Flk1/KDR and PdgfRα, and that it is possible to selectively induce subsets of mesoderm by manipulating two key TGFβ signaling pathways: BMP and activin/Nodal pathways. We have applied these approaches and found that BMP inhibition during activin and Wnt-mediated induction of primitive streak-like populations from mESC differentiation cultures results in the generation of a PdgfRα+ population with enriched somitic and chondrogenic potential, and reduced hematopoietic and cardiac potential. When cultured in appropriate monolayer conditions (containing BMP4 and bFGF), ESC-derived somitic mesoderm cells generated a strikingly homogeneous population of chondrocytes that expressed Sox9 and collagen II, and stained positive with Alcian blue. We have begun to modify the monolayer culture conditions to promote the development of the two chondrocyte subsets, articular and growth plate chondrocytes, which will be distinguished initially based on GDF5, ERG and collagen 10 gene expression. Our preliminary data suggests that the BMP, GDF5, FGF, and Hedgehog signaling pathways may play a role in the specification of articular chondrocytes from ESC-derived somitic mesoderm. Given that these steps represent the earliest stages of commitment to the chondrocyte lineages, these findings will contribute greatly to our overall understanding of how joint-lining cartilage develops which will ultimately lead to the development of novel therapies for the treatment of diseases such as osteoarthritis.

FR0073

Lkb1 Regulates Growth Plate Dynamics in the Mammalian Skeleton. Lick Pui Lai*, Andrew McMahon. Harvard University, USA

Liver kinase b1 (Lkb1) is a serine-threonine protein kinase upstream of the AMPK family, and regulates multiple cellular activities, including cell cycle progression and cell polarity. We have removed Lkb1 specifically in chondrocytes, in order to investigate the role of Lkb1 in the chondrocyte development program. Remarkably, the growth plates of the conditional knock-out mice were elongated, and got progressively longer by postnatal day 3. Specifically, the length of the columnar chondrocyte region doubled in comparison to wild type mice. These data indicate that Lkb1 plays a critical role during normal development to control the length of the growth zone. Analysis of a number of molecular determinants of growth plate organization suggests a delay in hypertrophic chondrocyte differentiation in Lkb1 mutants. The mTOR signaling pathway is one of the key pathways regulated by AMPK. To determine the role of mTOR in mediating the effect of Lkb1 in chondrocytes, immunostaining was performed with a specific antibody for mTOR and phosphorylated eukaryotic translation initiation factor 4E-BP1. Elevated level of mTOR in the pre-hypertrophic region of the growth plate was accompanied by enhanced phosphorylation of 4E-BP1, consistent with heightened mTOR signaling when Lkb1 is removed. Taken together, these data suggest that removing Lkb1 in growth plate chondrocytes results in delayed chondrocyte hypertrophic differentiation, and this is mediated by elevated mTOR signaling in chondrocytes. With mTOR being a key convergent point of multiple growth-regulating signaling pathways including AMPK, IGF, and Wnt, Lkb1 regulation of mTOR is likely to have a critical role in mammalian skeletal development.

Postnatal Deletion of the G-protein Subunit Alpha Synergizes with Gq/11 g-Proteins when Mediating PTH Receptor-dependent Fusion of the Epiphyseal Growth Plate. Andrei Chagin*[1], Tatsuya Kobayashi[2], Jun Guo[2], Takao Hirai[3], Min Chen[4], Lee Weinstein[5], Susan Mackem[6], Stefan Offermanns[7], Henry Kronenberg[2]. [1]Karolinska Institutet, Sweden, [2]Massachusetts General Hospital, USA, [3]Kyoto Prefectural University of Medicine, Japan, [4]National Institute of Diabetes, Digestive & Kidney Diseases, National Institutes of Health, USA, [5]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [6]National Cancer Institute, USA, [7]University of Heidelberg, Germany

Recently we showed that ablation of PTH/PTHrP receptor (PPR) from epiphyseal chondrocytes of postnatal mice induced abrupt fusion of the growth plate associated with accelerated chondrocyte hypertrophy, cell death and decreased proliferation. The PPR is a G protein-coupled receptor that activates multiple heterotrimeric G proteins.

To explore the mechanism of this dramatic phenotype, we systemically explored the role of different G proteins in the postnatal growth plate including stimulating G protein subunit alpha (Gsa), extra large isoform of Gsa (XLas), as well as Gq/11 and G12/13 families of G proteins. For this purpose we used mice with collagen-2 (Col2) driven tamoxifen-inducible Cre (Col2-CreERt), mice that also harbor a floxed exon 1 of the *Gnas* gene (Gsa fl/fl), mice with disrupted exon2 of *Gnas*, DSEL mice defective in activation of Gq/11 by the PPR, Ga12-deficient mice and Ga13 fl/fl mice.

We found that ablation of Gsa in the postnatal growth plate dramatically impaired bone growth. This phenotype was associated with permanent disruption of bone epiphyses due to accelerated chondrocyte hypertrophy and growth plate disorganization. In contrast to mice lacking PPR in cartilage, mice missing Gsa in cartilage did not fuse the growth plate completely. The remnant of epiphyseal cartilage consisted of chondrocytes in post-mitotic and prehypertrophic stages that persisted between the epiphysis and metaphysis of long bones. This observation suggests that additional pathways are activated by PPR to cause fusion of the growth plate. Therefore we screened for the other G proteins involved in PPR-dependent growth plate fusion. Preliminary experiments revealed potential involvement of Gq/11 signaling. Indeed, mice without Gsa and with a PPR unable to activate Gq/11 signaling have a dramatically smaller cartilage remnant. Interestingly, neither XLas nor G12/13 G-proteins are involved substantially in postnatal bone growth regulation. The growth plates of mice lacking both Gsa and XLas looked identical to those missing only Gsa. No growth plate phenotype was observed in mice without Ga12, Ga13 or both.

In conclusion, we have shown that Gsa is essential for normal linear growth of postnatal mice and might synergize with Gq/11 to suppress postnatal growth plate fusion. Neither XLas nor G12/13 G-proteins seem to be needed for postnatal bone growth.

Zonal Disorganization and Premature Apoptosis of Chondrocytes in the Growth Plate of FGFR3 Mutant Mice. Clair Francomano[1], Zijun Zhang*[2]. [1]Great Baltimore Medical Center, USA, [2]Saint Louis University, USA

Skeletal dysplasia of achondroplasia, featured with disproportional short limbs, includes subtypes of achondroplasia, hydrochondroplasia, thanatophoric dysplasia (TD), and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN). The type II TD (TDII) patients have severely shortened limbs, macrocephaly, short ribs and hypoplastic thorax and usually die within a few days after birth. Genetically, TDII is caused by a single recurrent mutation (K650E) in the second tyrosine kinase domain of fibroblast growth factor receptor 3 (FGFR3). A mouse model has been created with K644E mutation of FGFR3, using in vivo Cre-loxP system, to simulate the phenotype of TDII. The homozygeous mutants do not survive after birth. The heterozygeous K644E mutants have shortened limbs, especially tibia and humerus. On histology, the ossified diaphysis is particularly short in the mutants, comparing with wild type mice. In this study, Fgfr3/K644E-neo mice mated with Col2a1-Cre mice for a cartilage specific phenotype. The limbs of newborns, which were significantly shorter than the wild type mice, were dissected for histology, immunohistochemistry for type X collagen and transmission electron microscopy (TEM). On histology, the growth plate of the mutants showed typical disorganized chondrocyte columns. In addition, the hypertrophic zone of growth plate defined with chondrocytes that are type X collagen positive was significantly expanded in the mutants, comparing with the wild type mice. TEM revealed apoptotic chondrocytes that are characteristic with a condensed nucleus in the upper level or proliferative zone of the growth plate in the mutants, but not in the normal chondrocyte columns found in the wild type mice. Those apoptotic chondrocytes in the mutant's growth plate were relatively small in size and surrounded by collagen fibrils in a square shape, indicating the cells have not enlarged to an expanded round shape as usually seen in hypertropic chondrocytes. In conclusion, this TDII model demonstrated that a FGFR3 mutation leads to not only disorganization of chondrocyte columns but also disorganization of zonal distribution in the growth plate. Apoptosis of chondrocytes at a premature stage may contribute to the breakdown of chondrocyte columns and expanded "hypertrophic zone" in the growth plate, and eventually causes the disorder of bone growth in TDII.

β-Catenin Controls Osteoclast Formation through Regulation of OPG and RANKL Expression in Chondrocytes. Baoli Wang*, Hong-ting Jin, Dezhi Tang, Mei Zhu, Brendan F Boyce, Di Chen. University of Rochester Medical Center, USA

The regulatory mechanism of endochondral bone remodeling remains unclear. In the present studies we generated inducible chondrocyte-specific β-catenin conditional knockout (cKO) and conditional activation (cAct) mice to investigate the role of β-catenin in postnatal skeletal development. Results from Micro-CT showed significant bone destruction in epiphyseal bone area but not the diaphyseal bone area in 3-month-old β-catenin cKO mice. We measured trabecular bone parameters in proximal tibia of 3-month-old mutant mice and found that BV, BMD, and Th.N. were significantly reduced (68, 66 and 58% reduction, respecitively) and SMI was significantly increased (increased 100%) in β-catenin cKO mice. In contrast, BV and BMD were significantly increased (increased 109 and 101%, respectively) in β-catenin cAct mice. Histologic analysis showed that TRAP-positive osteoclast numbers were significantly increased in β-catenin cKO mice, but significantly reduced in the β-catenin cAct mice; while bone formation rates (BFR) were not changed in these mutant mice. Results from chondrocyte/spleen cell co-culture experiments showed that primary chondrocytes isolated from β-catenin cKO mice significantly stimulated multi-nucleated osteoclast formation (increased 2-fold). Addition of OPG significantly inhibited osteoclast formation (72% inhibition). Rankl expression was increased by 2-fold and OPG expression was decreased by 60% in chondrocytes derived from β-catenin cKO mice. In contrast, chondrocytes derived from β-catenin cAct mice inhibited osteoclast formation. To determine if bone marrow (BM) cells are involved in bone loss phenotype observed in the β-catenin cKO mice, BM cells were cultured with M-CSF and 1,25-OH2 vitamin D3. No changes in osteoclast formation were observed. Consistent with this finding, β-catenin protein levels and expression of Rankl and OPG were not changed in BM cells derived from β-catenin cKO mice. These results suggest that BM cells from β-catenin cKO mice did not affect osteoclast formation. We then treated β-catenin cKO mice with bone resorption inhibitor Alendronate (2 mg/kg, once a week, subcutaneous injection) and found that Alendronate significantly reversed the bone destruction phenotype observed in β-catenin cKO mice. In this study, we provide the novel evidence that β-catenin signaling in chondrocytes regulates osteoclast formation through modulation of Rankl and OPG expression.

Expression Pattern of TgfβR2 and Joint Formation Related Genes in Developing Limbs. Tieshi Li*[1], Lara Longobardi[1], Timothy Myers[1], Froilan Granero-Molto[1], Yun Yan[1], Douglas Mortlock[2], Anna Spagnoli[1]. [1]University of North Carolina at Chapel Hill, USA, [2]University of Vanderbilt, USA

We have previously reported that the*Tgfβr2$^{PRX\text{-}1KO}$* mouse, in which the TGF-β type II receptor (*Tgfβr2*) is conditionally inactivated in developing limbs lacks interphalangeal joints (Spagnoli A et al, J Cell Biol, 2007). To provide a sensitive read-out of *Tgfβr2* expression pattern, a *Tgfβr2-β-Gal-Bac* mouse was generated. A GFP-IRES-β-GEO cassette was inserted into the mouse bacterial artificial chromosome (BAC) clone RP24-317C21 (containing *Tgfβr2*) at the endogenous *Tgfβr2* translational start. Construct was used to generate the *Tgfβr2-β-Gal-Bac* mouse containing β-galactosidase (β-Gal) as an imaginable reporter for *Tgfβr2* expression under the control of endogenous (within 195.8kb) *Tgfβr2* gene regulatory sequences. E12.5 to E18.5 *Tgfβr2-β-Gal-Bac* embryos were subjected to LacZ staining. Transverse, longitudinal and sagittal limb sections were obtained from wild-type and LacZ-stained *Tgfβr2-β-Gal-Bac* embryos and subjected to immunohistochemistry and/or in situ hybridization for Jagged1, Notch1, Notch2, GDF5. We found that in developing autopods, β-gal activity was first evident (E12.5) within the forelimb and then (E13.5) in the hindlimb. An intense temporally and spatially characterized *Tgfβr2-β-Gal* expression/activity was noted in the developing interphalangeal joints. Such expression, which started at E13.5, was initially limited to cells in the dorsal and ventral regions of the interzone and then extended (E15.5- E18.5) laterally and proximally in the perichondrium. β-gal activity was undetectable in the central region of the interzone. Depending on the development stage, *Tgfβr2-β-Gal* expression distinctly over-lapped with expressions of GDF5, Notch1, Notch2 and Jagged1, indicating that essential componβents of the Notch system are co-expressed by TGFβRII+ joints cells and corroborating our previous findings that the TGFβRII signaling is needed to regulate expression of these genes. We also found a peculiar *Tgfβr2-β-Gal* expression/activity that started at E13.5, in the dorsal and ventral perichondrium of middle part of phalange that gradually decreased from E13.5 to E18.5 where it was found primarily surrounding the developing tendons/ligaments. Our findings show a dynamic and spatiotemporally regulated expression pattern of *TgfβR2* during joint/digit formation. Co-expression studies indicate that *TgfβR2* expressing cells provide a signaling niche to promote joint development in synchrony with the GDF5 and Notch pathways.

MiR-204 and miR-211 Specifically Inhibit Runx2 Expression and Regulate Mesenchymal Stem Cell Differentiation and Bone Formation. Jian Huang*[1], Bing Shu[2], Lan Zhao[1], Di Chen[3]. [1]University of Rochester, USA, [2]Orthopaedics, University of Rochester, USA, [3]University of Rochester Medical Center, USA

Mesenchymal stem cell (MSC) differentiation is controlled by key transcription factors, such as Runx2 and Runx2 expression is tightly regulated at transcriptional and post-transcriptional levels. We found that miR-204 and its homolog miR-211 were expressed in MSCs. Multiple miR-204/211 binding sites were identified in the 3'-UTR of the Runx2 gene by mutation analysis. Over-expression of miR-204 decreased Runx2 protein levels (~50%) in C3H10T1/2 and ST2 progenitor cells. Significant reduction in ALP activity and the expression of osteoblast marker genes such as osteopontin and osteocalcin (40 and 70% reduction) and the mineralized bone nodule formation (75% reduction) were observed in miR-204 over-expressing ST2 cells; while enhancement of adipocyte formation demonstrated by increased Oil red O staining and the adipocyte-specific gene expression such as adipsin and ap2 (increased over 3-fold) was found in ST2 cells over-expressing miR-204. In contrast, retroviral over-expression of a miR-204/211 complementary fragment 'sponge', significantly increased Runx2 protein levels by 3-fold. Inhibition of miR-204/211 promoted osteoblast differentiation by increasing ALP activity, osteopontin and osteocalcin expression, and the mineralized bone nodule formation (increased 2-5 fold), and suppressed adipocyte differentiation (over 75% reduction in Oil red O staining and adipocyte marker gene expression) in ST2 cells. To further determine the role of miR-204/211 in vivo, we generated miR-204/211 sponge conditional transgenic (cTg) mice in which the expression of sponge transgene is activated by Prx1-Cre-mediated recombination. We have analyzed three lines of these cTg mice and found that trabecular bone mass (up 46%) and bone mineral density (up 32%) were significantly increased in these cTg mice by micro-CT and histology analyses. Runx2 protein expression, ALP activity and mineralized bone nodule formation were significantly up-regulated in bone marrow stromal (BMS) cells derived from the sponge cTg mice compared to those from Cre-negative controls. These effects were reversed by transfection of Runx2 siRNA into BMS cells derived from sponge cTg mice. In this study, we demonstrated for the first time that miR-204/211 act as important endogenous negative regulators of Runx2 and regulate mesenchymal stem cell differentiation and bone formation in vitro and in vivo.

MiR-29b Expression Is Dependent of COL1A1 in Bone Marrow Stromal Cells of Osteogenesis Imperfecta Patients During Osteoblast Differentiation. Carla Kaneto*[1], Francisco Jose De Paula[2], Patrícia Lima[3], Dalila Dalila[4], Karen Prata[4], João Pina Neto[5], Sumithra Urs[6], Dimas Covas[4], Wilson Silva[7]. [1]School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil, [2]School of Medicine of Ribeirao Preto - USP, Brazil, [3]Department of Natural Science, The State University of Bahia, Vitória da Conquista, Bahia, Brazil., Brazil, [4]Regional Blood Center of Ribeirão Preto & National Institute of Science & Technology in Cell Therapy, Brazil, [5]Department of Genetics, Medical School of Ribeirão Preto, University of São Paulo, Brazil, [6]Maine Medical Center Research Institute, USA, [7]Department of Genetics, Medical School of Ribeirão Preto, University of São Paulo., Brazil

The majority of cases of Osteogenesis Imperfecta (OI) are caused by mutations in one of the two genes, COL1A1 and COL1A2 that code for the two chains that trimerize to form the procollagen 1 molecule. However, alterations in gene expression and microRNAs (miRNAs) are responsible by the regulation of cell fate determination and may be evolved in OI phenotype. The mononuclear cell fractions were derived from bone marrow from eight different donors [five patients with Osteogenesis Imperfecta (MOOI1-MOOI5) and three normal donors (MON1-MON3)], who gave consent after full information and approval by the hospital committee. All MNC (mononuclear cells) were isolated and cultivated until the third passage, when the osteogenic differentiation was induced. Eight novel mutations coding region of COL1A1 and COL1A2 genes were identified and four may be responsible for causing OI phenotype. In COL1A1: 1 missense mutation (p. Gly290Glu), 1 nonsense mutation (Arg1026Ter), 1 out-of-frame insertion mutation (p.Leu69GlufsX74) and 2 silent mutations. In COL1A2: 1 missense mutation (p. Gly835Ser) and 2 silent mutations. The distribution of mutations in our patients is similar to that reported in the literature, with glicine substitutions in the helical domain resulting in severe phenotype. In patient MOOI5 with Bruck Syndrome (BS), a very rare disorder characterized by Osteogenesis Imperfecta and arthrogryposis multiplex congenital, 3 mutations were detected which are considered non pathogenic, as they do not alter an amino acid. The RNA was harvested at seven time points during the differentiation period (MSC, D+1, D+2, D+7, D+12, D+17 and D+21) and cDNA was synthesized. qRT-PCR amplification mixtures contained 20 ng template cDNA, 2X Power SYBR Green Master mix buffer (10 µL) (Applied Biosystems) and 400 to 600 nM forward and reverse primers for COL1A1 in a final volume of 20 µL. TaqMan® MicroRNA Assays (Applied Biosystems) were used to assess miR-29b expression levels. Interestingly, miR-29b and COL1A1 expression were severely reduced in both OI type I and type III patients, suggesting miR-29b expression is not a requirement for supporting osteoblast differentiation in OI patients. The data obtained for BS patient showed miR-29b and COL1A1 expression profiles similar to normal samples. Studies of Bruck syndrome have found normal secretion of collagen 1 in three families and mutations in the COL1A1 and COL1A2 genes have not been detected.

Repression of Mineralization by the Trps1 Transcription Factor. Dobrawa Napierala*[1], Yao Sun[2], Izabela Maciejewska[3], Elda Munivez[1], Terry Bertin[1], Rena D'Souza[2], Chunlin Qin[2], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Dentistry, Texas A&M Health Science Center, USA, [3]Baylor College of Dentistry, Texas A&M Heatlt Science Center, USA

Trps1 is a transcriptional repressor, whose mutations cause an autosomal dominant craniofacial and skeletal dysplasia tricho-rhino-phalangeal syndrome (TRPS). The *Trps1* expression pattern in mineralizing tissues suggests its involvement in differentiation and/or function of cells destined to produce mineralizing matrix. In perichondrial cells *Trps1* is highly expressed prior to mineralization, and the onset of mineralization of perichondrial cells coincides with decreased expression of *Trps1*. Similarly to perichondrial cells, *Trps1* is expressed in developing preodontoblasts, but not in mature secretory odontoblasts, which produce dentin. Our analyses of *Trps1* mutant mice (*Trps1ΔGT* mice) as well as mice over-expressing *Trps1* in osteoblasts and odontoblasts (*Col1a1-Trps1* mice) suggest that *Trps1* acts as a repressor of mineralization. Our previous studies of *Trps1ΔGT/ΔGT* mice revealed that loss of *Trps1* leads to accelerated perichondrial mineralization. This mutant phenotype was corrected by additional partial deficiency of *Runx2*, which demonstrated genetic interaction between these transcription factors. We confirmed the Trps1-Runx2 interaction at the molecular level and demonstrated that Trps1 acts as a repressor of Runx2. Interestingly, the Trps1 repressive activity is context-dependent; since *Trps1* deficiency has no apparent effect on mineralization of teeth, while over-expression of *Trps1* inhibits dentin mineralization. Only moderately decreases bone mineral density (BMD) in trabecular bone of *Col1a1-Trps1* mice. Using a combination of histological and biochemical analyses of dentin we have demonstrated dramatically reduced levels of major non-collagenous dentin matrix proteins:dentin phosphoprotein (Dpp) and dentin sialoprotein (Dsp), and dramatically decreased expression of the *Dspp* gene. Using chromatin immunoprecipitation (ChIP) assay, we have demonstrated that Trps1 binds to the *Dspp* promoter in odontoblastic cell lines. In summary, our data revealed tissue-specific repression of mineralization by Trps1. Additionally, we have identified the *Dspp* gene as a target of the Trps1 transcriptional repressor.

TIP39/PTH2R Signalling in Chondrocytes Alters Endochondral Bone Development in vivo. Dibyendu Panda*[1], David Goltzman[2], Andrew Karaplis[1]. [1]McGill University, Canada, [2]McGill University Health Centre, Canada

PTH2 receptor (PTH2R) /TIP39 (tuberoinfundibular peptide of mol wt 39 kD) signalling appears to be a potent inhibitor of chondrocyte proliferation and differentiation in vitro. We have also demonstrated that both TIP39 and PTH2R are present in situ in the newborn mouse growth plate. The receptor localized mainly in the resting zone of periarticular chondrocytes, while the ligand TIP39 was expressed exclusively in prehypertrophic chondrocytes.

To study TIPPTH2R function at the in vivo level, we generated transgenic mice overexpressing human PTH2R in chondrocytes under the control of the rat type II collagen promoter/enhancer. PTH2R transgenic mice revealed impairment of endochondral bone formation associated with reduced expression of type II and type X collagen expression. Chondrocytic cell proliferation in the transgenic mice, as measured by bromodeoxyuridine incorporation, was reduced compared to that of wild-type mice. Mineralization in trabecular bone, as determined by Von Kossa staining, was reduced in transgenic mice both in the primary and secondary spongiosa. Trabecular bone volume, as measured by micro CT analysis, was reduced in the transgenic mice compared to wild type. While examining the mechanism for the observed reduction in trabecular bone, we noted a significant increase in beta-catenin expression at the lower hypertrophic zone and upper primary spongiosa in the PTH2R transgenic mice, as compared to the wild type controls. At the cellular level, TIP39 reduced active glycogen synthetase kinase (phosphorylated GSK) level in the PTH2R expressing CFK2 Cells, thus augmenting beta-catenin signalling.

Moreover, we observed a delay in the development of the secondary ossification center in the PTH2R transgenic mice compared with wild type animals. A significant decrease in the expression of GDF5 and WDR5 proteins was evident in the chondrocytes around the secondary ossification center in the transgenic mice that may explain in part the molecular mechanisms by which TIP39/PTH2R signalling modulates the development of the secondary ossification center.

In summary, our experiments with Col2a-PTH2R transgenic mice indicate that TIP39/PTH2R signalling, through regulation of specific gene expression, contributes, at least in part, to specific events in both endochondral bone formation and in establishment of the secondary ossification site.

Novel Role of CXCR4 in Bone Development and Growth. Wei Zhu*[1], Stephen Doty[2], Adele Boskey[2]. [1]Hospital for Special SurgeryWeill Medical College of Cornell University, USA, [2]Hospital for Special Surgery, USA

Introduction: CXC chemokine receptor 4 (CXCR4) is the primary receptor for stromal derived factor-1 (SDF-1). We previously discovered that blocking of the SDF-1/CXCR4 signal axis inhibited osteogenic differentiation of mesenchymal stem/precursor cells induced by bone morphogenic protein 2 (BMP2). In this study, we aimed to further elucidate the role of CXCR4 in bone development and growth using a transgenic mouse model.

Methods: $CXCR4^{flox/flox}$ mice were interbred with osterix (Osx)-Cre mice to generate conditional knockouts that have CXCR4 deletion in Osx-expressing osteoprogenitor cells (CXCR4-KO). The overall skeletal change and bone quality were determined by high-resolution x-ray and microCT. The CXCR4 effect on osteogenic differentiation was examined by comparing the BMP2-induced alkaline phosphatase (ALP) activity, a marker for preosteoblasts, in osteoprogenitors derived from calvarias of newborn CXCR4-KO mice with that of wild type controls. Moreover, we sequentially injected mice with xylenol orange and tetracycline (4-day interval), and assessed new bone growth by measuring the distance between the two fluoro-labeled mineralization fronts. The CXCR4 effect on growth plate was detected by alcian blue and type X collagen staining for chondrocytes, and pro-collagen I immunohistochemistry for osteoblasts.

Results: The skeletal size of CXCR4-KO mice was ~32% smaller than that of littermate wild types of the same sex and age (1&4-wk-old). Decreased trabecular bone volume fraction, thickness and number were detected in tibias of CXCR4-KO mice, and decreased cortical thickness was found in both tibias and calvarias of CXCR4-KO mice. While BMP2 stimulation increased ALP activities in CXCR4-expressing osteoprogenitors derived from wild type mice, no significant increase in ALP activities was found in osteoprogenitors derived from CXCR4-KO mice. Moreover, the rate of new bone formation (BFR) in CXCR4-KO mice was 31% lower than that of wild type mice (Fig1). Growth plate abnormalities were found in tibias of CXCR4-KO mice, including disorganized proliferating chondrocytes, decreased hypertrophic differentiation, and decreased number and activity of osteoblasts lining the trabecular bone surfaces.

Conclusion: Our data shown that CXCR4 deletion in osteoprogenitor cells led to decreased osteogenic differentiation and bone growth, accompanied by growth plate disorganization. This finding suggests that CXCR4 is an endogenous mediator essential for bone formation.

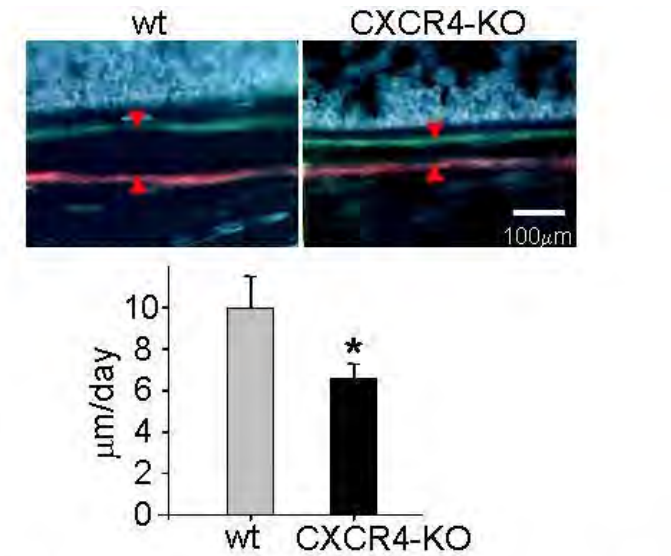

Fig 1. Decreased bone growth in CXCR4-KO mice. BFR was measured by dividing the distance between xylenol orange and tetracycline labels by 4-day time interval. N=5 tibias for CXCR4-KO or wild type control.

Procollagen Type III N-Terminal Peptide (P3NP) is Inversely Associated with Lean Mass in Women. Vasan Ramachandran[1], Sarah Berry*[2], Robert McLean[3], Peggy Cawthon[4], Douglas Kiel[5]. [1]Boston University School of Medicine, USA, [2]Hebrew SeniorLife/Beth Israel Deaconess Medical Center, USA, [3]Hebrew SeniorLife, Harvard Medical School, USA, [4]California Pacific Medical Center Research Institute, USA, [5]Hebrew SeniorLife, USA

The discovery of biomarkers associated with muscle mass could lead to improved diagnostic and treatment options for sarcopenia. Type III Procollagen is a major component of skeletal muscle, and Procollagen Type III N-terminal peptide (P3NP) is released during periods of collagen turnover. It is unknown whether elevated levels of circulating P3NP might be associated with low muscle mass. Therefore, we performed a cross-sectional analysis to determine the association between serum P3NP and lean mass (total and appendicular) in men and women of the Framingham Offspring Study. Participants included 251 men and 306 women (106 premenopausal, 330 postmenopausal) with serum P3NP measured during a routine study visit (1995-1998) and lean mass measured by whole body DXA (1996-2001). Total lean mass (kg) was defined as total body soft tissue mass minus total body fat mass, whereas appendicular lean mass included arms and legs only. We examined the association between P3NP and total and appendicular lean mass, using multivariable linear regression. Age, BMI (kg/m^2), current smoking status, alcohol intake (g/week), and for women, hormone replacement, were considered using backwards stepwise models. Because P3NP may be influenced by sex hormones, we performed analyses separately in men, premenopausal women, and postmenopausal women. Mean age of participants was 57 years (range 32-84). Mean total lean mass was 54.7kg in men, 37.0kg in premenopausal women, and 36.3kg in post-menopausal women. Median serum P3NP was 3.2mg/L in men, 3.1mg/L in premenopausal women, and 3.0mg/L in post-menopausal women (range 0.02-53.3 mg/L). In the multivariable analyses, serum P3NP was inversely associated with total and appendicular lean mass in women, although the results were not statistically significant in premenopausal women (Table). No association between serum P3NP and total or appendicular lean mass was observed in men. Results were unchanged when additionally adjusting for indicators of cardiac muscle mass (left ventricular end diastolic diameter and weight). This is the first study to suggest that serum P3NP could potentially be a useful biomarker of muscle mass in postmenopausal women if it is found to have adequate sensitivity and specificity for muscle turnover. Prospective studies of serum P3NP and changes in

Multivariable association between serum P3NP (mg/L) and lean mass (kg) [β coefficient (p-value)]			
	Men	Pre-menopausal women	Post-menopausal women
Total lean mass	-0.04 (0.68)	-0.17 (0.20)	-0.13 (0.006)
Appendicular lean mass	0.00 (0.96)	-0.08 (0.25)	-0.05 (0.03)

PTH Anabolic Action is Influenced by the Deficiency of TRPV4 in Bone. Paksinee Kamolratanakul*[1], Yoichi Ezura[2], Fumitaka Mizoguchi[1], Tadayoshi Hayata[3], Hiroaki Hemmi[1], Takuya Notomi[4], Teruo Amagasa[1], Masaki Noda[1]. [1]Tokyo medical & dental university, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [4]GCOE, Tokyo Medical & Dental University, Japan

PTH is known as crucial agent for bone remodeling and marked as standard treatment for osteoporosis. TRPV4, as a family of Transient Receptor Potential Vanilloid, plays roles on calcium permeable nonselective cation channel. In addition, TRPV4 deficiency mice showed suppression in unloading-induced bone loss. Either PTH (through PTHR1) or TRPV4 play a role on calcium cascade regulation and have a potential on bone remodeling, however relation of this two molecules remain undiscovered. Accordingly, we challenged the hypothesis whether TRPV4, as a part, effects on PTH/PTHR1-regulated bone metabolism. First, we examined the effect of the intermittent human PTH injection into mice for 4 weeks on bone mineral density (BMD). Intermittent injection of PTH increased BMD by 20% and this increase was statistical significant. Intermittent PTH injection also tended to increase the average value for BMD in TRPV4 knockout mice (8%), however, this difference was not statistical significant. In addition to BMD, we also examined by micro CT as the levels of bone volume per tissue volume (BV/TV) in the femur of the mice. PTH injection increase BV/TV by 18.75% in wild type mice. In case of TRPV4 knockout mice, there was a trend to increase BV/TV value by injection human PTH in intermittent regimen, however, the difference was not statistical significant. With the respect to the histological examination, bone marrow cells and osteoclast appearances were similar regardless of the absence or presence of TRPV4. Upon PTH injection, there was an

increase in osteoblasts and osteoclasts and stromal cells, however, this was similarly observed in TRPV4 knockout mice. Quantification of osteoclastic cells after culturing bone marrow cells taken from wild type or TRPV4 knockout mice in presence of MCSF and RANKL for 5 days exhibited more than 2 folds increase of osteoclast number in wild type mice being exposed to PTH injection. In contrast, number of osteoclasts in culture were similar regardless of the genotype in culture of bone marrow cells, PTH injection did not increase osteoclast cell development in the culture of bone marrow cells. These data suggested that at least for the precursor cells of osteoclasts, TRPV4 is required for the efficient development of osteoclasts in culture in presence of RANKL and M-CSF. Preliminary experiment using TRPV4 knockout mice and constitutively active PTH/PTHrP receptor (H223R mutation) showed some trends of the wild type and heterogeneous TRPV4 that exposed to ca-PPR transgenic mice. Although there was a trend to have some increase in the heterogeneous knockout of TRPV4, p value was 0.25. These data indicated that, at least, in PTH injection models, TRPV4 may interfere the action of PTH receptor signaling in bone.

FR0103

Contrasting Osteogenic Response to Mechanical Stimulation Between C57BL/6J and C3H/HeJ Inbred Mice Is In Part Due to Genetic Variations in the Leptin Receptor, Which is a Negative Bone Mechanosensitivity Modulating Gene. Kin-Hing William Lau*[1], Sonia Kapur[2], Chandrasekhar Kesavan[3], Mehran Amoui[2], Subburaman Mohan[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]Jerry L. Pettis Mem. VAMC, USA, [3]JLP VA Medical Center, USA

Genetic is a key factor in determining bone response to loading. Accordingly, C57BL/6J (B6) mice respond to in vivo loading with an increased bone formation, but C3H/HeJ (C3H) mice show no such response. Genetic studies of the C3H/B6 pair of mouse strains revealed that bone mechanosensitivity is regulated by genes located in multiple loci on several chromosomes (Chr). Congenic mouse studies have identified a region in Chr 4 that harbors mechanosensitivity modulating genes. Because leptin receptor (Lepr) gene is located inside this Chr 4 region, we sought to show that Lepr plays a key modulating role in bone mechanosensitivity and that genetic variation of Lepr contributes to the different osteogenic responses to loading in C3H and B6 mice. In a previous ASBMR meeting, we reported that leptin-deficient ob/ob mice exhibited enhanced osteogenic response to mechanical loading. In this study, we compared the osteogenic response to loading (2-week four-point bending) in tibia of Lepr-deficient db/db mice [in B6 background] with that in tibia of wild-type (WT) littermates. To adjust for the 6% greater bone size in db/db mice, the load was adjusted to produce the same level of mechanical strain (4603 με at 9N for db/db mice vs. 4549 με at 7N for WT mice). This strain yielded significantly greater osteogenic response in db/db mice compared to WT mice [bone area (21.2% vs.10.6%), periosteal circumference (10.0% vs. 4.9%), BMC (30.9% vs. 12.4%), and vBMD (12.3% vs. 4.9%). We next compared the effects of a 30-min fluid shear (20 dynes/cm^2) on [^{3}H]thymidine incorporation (TdR) and Erk1/2 phosphorylation in db/db osteoblasts (Obs) to WT Obs. While the shear stress increased TdR and Erk1/2 in WT Obs, the stimulations were greater in db/db Obs ($p<0.01$ for each parameter). siRNA-mediated suppression of Lepr expression in B6 Obs enhanced, and in C3H Obs restored, their anabolic responses. These results confirm that Lepr signaling has a negative modulating role in bone mechanosensitivity. In addition, the Lepr signaling (Jak2/Stat3 phosphorylation) was several-fold higher in C3H Obs than in B6 Obs. Of the 3 single nucleotide polymorphisms (SNP) in Lepr between C3H and B6, one yielded an I359V substitution in C3H near the leptin binding region, suggesting that this SNP may contribute to a "hyperactive" Lepr signaling in C3H Obs. In conclusion, genetic variations in Lepr in part contribute to the contrasting osteogenic response to loading between B6 and C3H mice.

Identification of Quantitative Trait Loci for Musculoskeletal Mechanosensitivity. Stefan Judex*[1], Engin Ozcivici[2], Weidong Zhang[3], Leah Rae Donahue[4]. [1]Stony Brook University, USA, [2]Mass General Hospital, USA, [3]The Jackson Laboratory, USA, [4]Jackson Laboratory, USA

Bone and muscle are highly sensitive to the removal and application of mechanical signals but little is known about the genetic basis defining the large differences in muscle and bone's mechanosensitivity between individuals. Here, we subjected 450 adult F2 female progeny of BALB and C3H (high- and low-mechanosensitivity) mice to 3wk of disuse (hindlimb unloading) and 3wk of subsequent reambulation to investigate changes in cortical bone and muscle and to define the underlying quantitative trait loci (QTL). *In vivo* μCT quantified longitudinal changes in middiaphyseal cortical bone and muscle surrounding the diaphyseal femur. Genome wide scans determined chromosomal regions with significant ($p<0.01$) QTL. During disuse, the marrow cavity expanded up to 22% in high-responders, concomitant with a 7% smaller cortical bone area. During reambulation, high-responders experienced an 11% contraction of the marrow area and a 9% increase in bone area. Tissue mineral density declined up to 8% during disuse and increased up to 3% during reambulation. Similarly, muscle loss amounted up to 26% during disuse and muscle gain reached 32% during reambulation. For both bone and muscle, low-responders were largely unresponsive during both experimental phases. The loss of cortical bone during disuse was not correlated with bone gain upon reambulation while in muscle, a moderate correlation (R^2=0.32) was observed between the two experimental phases. Further, those mice that experienced the greatest changes in muscle mass did not coincide with those individuals that experienced the greatest changes in cortical bone morphology during disuse or reambulation. For cortical bone area, 6 QTL were identified at baseline, 5 QTL during disuse, and 2 QTL during reambulation. For muscle area, we found 3 QTL at baseline, 1 during disuse, and 2 during reambulation. For both bone and muscle, QTL at baseline were distinct from those associated with unloading and reloading. In addition, there was little overlap between bone and muscle QTL. These data emphasize the strong influence of genetic variations on the mechanosensitivity of the musculoskeleton. They also show that the genetic regulation of the initial response to both the removal or application of mechanical signals is distinct between bone and muscle and that the development of physical interventions for musculoskeletal ailments may have to be optimized independently for bone and muscle.

ASARM-peptides are Physiological Inhibitors of Renal Calcification. Peter Rowe*[1], Anne-Marie Hedge[1], Yan Hong[2], Aline Martin[3], Lesya Zelenchuk[1], Valentin David[3]. [1]University of Kansas Medical Center, USA, [2]University of Kansas Mecical Center, USA, [3]UTHSC, USA

Acidic-Serine-Aspartate-Rich MEPE-associated (ASARM) peptides are protease resistant mineralization inhibitors released from MEPE and DMP1 (SIBLING proteins). These peptides are present in urine and circulation. MEPE-transgenic mice over expressing ASARM-peptides are resistant to diet induced renal calcification. We described previously a competitive inhibitor of PHEX (SPR4) that binds specifically to ASARM-peptides and reverses the X-linked Hypophosphatemic Rickets (HYP) mineralization defect *in vitro*. Here we describe the renal *in vivo* effects of 28 day osmotic pump infusion of SPR4 peptide in wild type and HYP mice

Wild type and HYP mice (C57BL/6; n=5, male) were infused with vehicle (0.9% NaCl) or peptide (276 nmoles/hr/kg) for 28 days (Alzet Osmotic pumps). Animals were sacrificed on day 28 after overnight metabolic cage housing. Blood was then collected by cardiac exsanguination and chemistries assayed for urine and sera. Kidneys were removed and scanned by micro computed tomography (μCT) or used to prepare mRNA for RT/PCR analysis of gene expression.

In wild type mice, SPR4 treatment induced an increased fractional excretion of phosphate (FEP) (+20%; $P<0.05$), with normophosphatemia. In contrast no significant change was observed with treated HYP mice. FGF23 expression was markedly increased in wild type mice (+50%; $P<0.05$) and was coincident with decreased expression of NPT2a (-35%; $P<0.05$), NPT2c (-47%; $P<0.05$) and renal-Klotho (-73%; $P<0.05$). Circulating PTH levels were also increased in both wild type (+91%; $P<0.05$) and HYP mice (+132%; $P<0.056$ trend). In both wild-type and HYP SPR4 infused mice, a significant and marked increase in osteopontin (OPN) was measured in urine (WT= +166%, $P<0.05$, HYP= +124%; $P<0.05$) and sera (WT=+44%; $P<0.05$, HYP=+ 58%; $P<0.05$). The changes in OPN levels were also coincident with a significant and marked renal calcification with both WT and HYP mice (Figure 1A and B).

This study shows ASARM-peptides play a major role in suppressing renal microcalcification. The secondary increase in osteopontin levels is likely an adaptive response designed to inhibit the larger crystals that occur due to the sequestration of ASARM-peptides. Also, the changes in FGF23, PTH and NPT2a/c are likely due to competitive inhibition of PHEX and a secondary neutralization of ASARM-peptide by SPR4. Finally, ASARM-peptides may play a role in chronic kidney disease and mineralization bone disorders (CKD-MBD). Further studies are necessary to confirm this.

FGFR1-Mediated Expression of Fgf23 and Dmp1 in Bone Bridges the Local and Systemic Regulation of Mineralization. Emily Farrow*[1], Yumie Rhee[2], Lelia Summers[3], Soo Park[3], Racheal Lee[3], Teresita Bellido[3], Kenneth White[3]. [1]Indiana University, USA, [2]IUMS, Yonsei University, College of Medicine, South korea, [3]Indiana University School of Medicine, USA

FGF23 circulates from bone to the kidneys to control phosphate metabolism, which is critical for normal skeletal mineralization. Local production of FGFs in bone is necessary for proper cell differentiation, as well as for skeletal formation and function. Of note, activating mutations in FGFR1 are uniquely associated with increased FGF23 in patients with the autosomal dominant disorder osteoglophonic dysplasia (OD). Whether paracrine and autocrine FGFs act through FGFR1 to regulate FGF23 and genes associated with elevated FGF23, which then function systemically, is unclear. To examine this question, we first tested for Fgfr1-4 mRNA expression in UMR-106 cells, and determined that these cells predominantly express Fgfr1 mRNA (between 100-10,000 fold over Fgfr2-4), and Fgfr1 protein. FGFs produced in bone, including FGF2 (as positive control, activates Fgfr1-4), and FGF8 (activates Fgfr1), increased phospho-Erk1/2 (p-Erk1/2) and activated Egr1 transcription (50-fold; $P<0.05$ vs. control), a marker of FGF-dependent MAPK signaling. Treatment with FGF8 resulted in a dose- and time dependent increase in Fgf23 mRNA (30-40 fold maximum at 25 nM and time of 24 h; $P<0.05$), which was significantly reduced by the p-Erk1/2 inhibitor U0126 ($P<0.05$). FGF16, which activates Fgfr2-4, showed no effect on Fgf23 mRNA or p-Erk1/2 in UMR-106 cells. Furthermore, differentiated primary cultures of mouse calvarial cells that express Fgfr1-3, treated with FGF2 or FGF8, stimulated Fgf23 mRNA over 200-fold vs. control ($P<0.01$). Loss of function mutations in Dentin matrix protein-1 (Dmp1) are responsible for autosomal recessive hypophosphatemic rickets (ARHR), a disorder associated with increased FGF23. FGF8 dose-dependently elevated Dmp1 mRNA with a 4000-fold increase at a maximum dose of 100 nM in UMR-106, indicating co-regulation with Fgf23 downstream of Fgfr1. To test this relationship in the converse disorder of phosphate wasting, tumoral calcinosis, we used the KL-null mouse, which has markedly elevated Fgf23. Interestingly, Dmp1 mRNA (4-fold; $P<0.005$), as well as protein expression in mature osteocytes were increased in KL-null bone. In sum, local FGF activity through Fgfr1 leads to marked elevation of Fgf23 and Dmp1 in bone cells, and in bone from a TC model. Thus, co-regulation of Fgf23 and Dmp1, likely through both local and systemic factors, is necessary for maintaining the balance of mineral and protein components required for proper bone mineralization.

FR0112

Placenta Expresses Klotho and FGFR1 in Syncytiotrophoblast and Might Be a Target Organ of FGF23. Yasuhisa Ohata*[1], Miwa Yamazaki[1], Tomoko Okada[1], Masahiro Nakayama[2], Keiichi Ozono[3], Toshimi Michigami[4]. [1]Department of Bone & Mineral Research, Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [2]Department of Clinical Laboratory Medicine & Anatomic Pathology, Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]Osaka Medical Center, Research Institute for Maternal & Child Health, Japan

Serum levels of phosphate (Pi) in fetus are maintained higher than the maternal levels during late gestation. Although it is suggested an active materno-fetal transport contributes to the high levels of serum Pi in fetus, the mechanism underlying the regulation of serum Pi in fetal stage is poorly understood. In adults, it has been established that fibroblast growth factor (FGF) 23 plays a central role in Pi metabolism as a phosphaturic hormone as well as in vitamin D metabolism, and that Klotho is required as a cofactor for the action of FGF23. Klotho is a single-pass transmembrane protein, and has both transmembrane and soluble forms. We previously reported that human placenta expressed Klotho, and that serum levels of soluble Klotho were about 5-fold higher in cord blood compared with adults (ENDO 2009 meeting). Based on these findings, we tested the hypothesis that placenta might be a target organ of FGF23 in the current study. To address this issue, we first examined the expression of FGF receptors, Na^+/Pi cotransporters, and the molecules involved in vitamin D metabolism in placenta. RT-PCR analyses revealed the expression of *FGF receptor (FGFR) -1*, *-2*, and *-3* as well as *Klotho* both in human and mouse placenta. As to the Na^+/Pi cotransporters, placenta expressed *NPT2b*, *Pit1*, and *Pit2* both in human and mouse. The expression of *1α-hydroxylase*, *24-hydroxylase*, and *vitamin D receptor* was also detected in human and mouse placenta. Then, to investigate whether Klotho and FGFR are co-expressed in the same cells in placenta, we performed immunohistochemical staining, and revealed their co-expression in syncytiotrophoblasts. Syncytiotrophoblast is the main site of feto-maternal interface, and plays the major role in placental functions, including the exchange of ions, gas, and nutrients. An antibody against the phosphorylated FGFR (Y653/Y654) positively immunostained the syncytiotrophoblasts, and so did an antibody against early growth response-1 (EGR-1), a target gene of FGF signaling. We then determined the serum levels of FGF23 in cord blood and found that they were significantly lower than those in adults, suggesting that FGF23 circulating in maternal blood might exert its functions in syncytiotrophoblasts in placenta. Taken together, our results have demonstrated that syncytiotrophoblast in placenta expresses both Klotho and FGFR1 and might be a target of FGF23 signaling, which may play a role in the Pi homeostasis and vitamin D metabolism in fetus.

Soluble Klotho Acts as a Coactivator of FGF23 in Bone but not in Kidney to regulate Mineralization. Tomoko Minamizaki*[1], Yuji Yoshiko[2], Yukiko Konishi[1], Hirotaka Yoshioka[1], Katsuyuki Kozai[1], Jane Aubin[3], Norihiko Maeda[4]. [1]Hiroshima University Graduate School of Biomedical Sciences, Japan, [2]Hiroshima University, Japan, [3]University of Toronto Faculty of Medicine, Canada, [4]DHiroshima University Graduate School of Biomedical Sciences, Japan

Fibroblast growth factor 23 (FGF23) is expressed primarily in osteoblasts/osteocytes (Obc cells) and acts on kidney and parathyroid to suppress the type II sodium-phosphate cotransporter and 1α(OH)ase expression and parathyroid hormone production, respectively. Klotho, a senescence-related membrane protein, forms a complex with FGF23-FGF receptor (FGFR), which is necessary for FGF23-specific signaling. In spite of the fact that Klotho is not expressed in bone, accumulating evidence suggests that bone may be an additional target of FGF23. We therefore tested the hypothesis that the extracellular domain of Klotho (KLe), which is truncated and secreted into the circulation, contributes to FGF23 action in bone. Recombinant FGF23 (rFGF23) formed a complex with FGFR only in the presence of rKLe in the rat Obc cell culture model. rFGF23-induced mineralization defects in the rat Obc model were abrogated by blocking FGF23-specific signaling, by removal of soluble Klotho from the fetal bovine serum (FBS) used for the cultures or by substituting serum from *Klotho*-mutant (*kl/kl*) mice for untreated FBS. This model also revealed that neither Wnt signaling nor the calcium channel TRPV5, a known target of KLe, was involved in the rKLe effects. To confirm that KLe and FGF23 act on bone in vivo as we observed in vitro, we intravenously injected rKLe into 4-week-old mice pretreated with $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ increased serum FGF23 and calcium levels with a slight decrease (not significant) in serum phosphorus levels. A single injection of rKLe increased ERK1/2 phosphorylation within 2h in bone but not in kidney, suggesting that KLe contributes to FGF23 signaling in bone. We next injected rKLe subcutaneously and daily for 12 days over the calvaria of 10-day-old *kl/kl* mice, a model that exhibits cryptogenic overproduction of FGF23 with high serum levels of phosphorus, calcium, $1,25(OH)_2D_3$ and FGF23. rKLe treatment did not alter these serum parameters, but did activate ERK1/2 in bone but not in kidney, and increased the number of cells in *kl/kl* bone that were double immunoreactive for FGF23 and phosphorylated ERK1/2. rKLe treatment also increased the amount of unmineralized osteoid in the parietal bone and up- or down-regulated the levels of expression of certain osteoblast marker mRNAs in *kl/kl* bones. Our data suggest that KLe forms a complex with FGF23-FGFR in bone, resulting in mineralization defects through an FGF23-dependent ERK signaling pathway.

Endogenous PTH Contributes to Bone Regeneration, Formation and Remodeling by Stimulating Osteoprogenitor Cell Recruitment following Marrow Ablation. Qi Zhu*[1], Lei Shu[1], Jun Yan[2], Andrew Karaplis[3], David Goltzman[4], Dengshun Miao[5]. [1]Nanjing Medical University, China, [2]Second Hospital of Suzhou University, Peoples republic of china, [3]McGill University, Canada, [4]McGill University Health Centre, Canada, [5]Nunjing Medical University, Peoples republic of china

To determine whether endogenous PTH plays a role in stimulating recruitment of osteoprogenotior cells for osteoblastic bone formation and remodeling *in vivo*, marrow ablation was performed in tibiae and femurs of 8-week-old wild-type (WT) and PTH null ($PTH^{-/-}$) mice. Newly formed bone tissues were analyzed from 1-3 weeks postsurgery using micro-CT and histopathology. Bone formation related gene and protein expression levels were evaluated by real-time RT-PCR and Western blots, respectively. At 1 week postsurgery, trabecular bone volume, osteoblast numbers, ALP positive areas, and type I collagen positive areas were all decreased significantly in the diaphyseal regions of bones of $PTH^{-/-}$ mice compared to WT mice, indicating delayed osteoblastic bone formation. Gene expression levels of Cbfa1, ALP, type I collagen and OCN, and protein expression levels of Cbfa1, PTHR, and IGF-1 were also down-regulated significantly in bones of $PTH^{-/-}$ mice compared to WT mice at this time. Bone marrow regeneration was also delayed in $PTH^{-/-}$ mice. In contrast, by 2 weeks postsurgery all parameters related to osteoblastic bone formation were increased significantly in $PTH^{-/-}$ mice compared to WT mice. By 3 weeks postsurgery, trabecular volume had recovered to pre-surgery levels in WT mice, however, remnants of newly formed trabecular bone remained in $PTH^{-/-}$ mice. TRAP positive osteoclast numbers and surface were reduced in $PTH^{-/-}$ mice at 1 week postsurgery. At 2 weeks postsurgery, although TRAP positive osteoclast numbers were increased, the TRAP positive osteoclast surface was still reduced significantly in $PTH^{-/-}$ mice compared to WT mice. The expression of PTHrP in newly formed bone tissues was up-regulated at both gene and protein levels at 1 and 2 weeks postsurgery in $PTH^{-/-}$ mice compared to WT mice. This up-regulation of PTHrP expression may have contributed to new bone formation in PTH deficient mice followed bone marrow ablation by recruiting

osteogenic cells. Long bones from WT mice transplanted 1week after bone marrow ablation into the back muscle of PTH intact β-galactosidase transgenic mice for 1 week, demonstrated Lac-Z positive osteoblastic and fibroblastic cells in the newly formed bone surface and bone marrow cavity, respectively, demonstrating the circulating origin of the repopulating cells. Our study indicates that endogenous PTH is required for optimal bone regeneration, formation and remodeling by stimulating osteoprogenitor cells derived from the circulation.

Mechanistic Insights into the Dysregulation of PTH Secretion in Hyperparathyroidism: In Vivo Analysis and In Vitro Studies in Parathyroid Glands. Wenhan Chang*[1], Tsui-Hua Chen[1], Nathan Liang[1], Christopher Dinh[1], Viet Pham[1], Hanson Ho[1], Zhiqiang Cheng[1], Chia-Ling Tu[1], Dolores Shoback[2]. [1]University of California, San Francisco, USA, [2]VA Medical Center, USA

Controversy exists as to the basis for PTH hypersecretion in primary and secondary hyperparathyroidism (HPTH) with roles hypothesized for the shift to the right in the set-point for Ca-mediated secretion (Ca-PTH set-point), an expansion of the Ca-nonsuppressible PTH (nonCa-PTH) pools within the gland, and progressive increases in cell number. To test the role of the CaSR in PTH secretion in HPTH, we generated mice with early-onset HPTH by knocking-out one allele of the casr gene conditionally (Het-KO) in the parathyroid glands (PTGs). Het-KO mice displayed HPTH by 2 weeks of age that progressed over time. Serum fibroblast growth factor (FGF)-23 and 1,25-OH vitamin D (1,25-D) levels were also elevated in 2-week-old HET-KO mice. We observed gender- and age-dependent differences in the severity of HPTH in these mice. In male HET-KO mice, serum PTH levels increased progressively from 114±27 pg/mL at 8 weeks of age to 167±18 and 340±39 pg/mL at 12 and 24 weeks of age, respectively. In female HET-KO mice, serum PTH had peaked at 308±47 pg/mL by 8 weeks of age and remained comparably elevated at 12 (264±49 pg/mL) and 24 weeks (250±47 pg/mL) of age. We developed a novel in vitro PTH secretion assay on intact micro-dissected mouse PTGs and compared the Ca-PTH set-points by incubating glands sequentially with media containing different [Ca^{2+}] (0.5–3 mM) and measuring their protein content by BCA assay, as an index of gland mass. At 4 weeks of age, >85% of PTH secretion was suppressed by high [Ca^{2+}] (3 mM) in both Wt and Het-KO PTGs. At 12 weeks of age, we observed an increase in the nonCa-PTH pools – which accounted for ≍40% of the total PTH secretion (Total-PTH) in both Wt male and female mice. The nonCa-PTH pools were further expanded to ≍75 and 60% of the Total-PTH in male and female HET-KO mice, respectively. As expected, Ca-PTH set-points were significantly right-shifted (≍1.2 mM Ca^{2+} in Wt to ≍1.5 mM Ca^{2+} in the HET-KO PTGs) at both time-points. There were no significant changes in gland size in female Het-KO at 4 and 12 weeks of age and in male HET-KO mice at 4 weeks of age. Male HET-KO PTGs, however, doubled in mass by 12 weeks of age. We are assessing gene expression in these PTGs and serum FGF23 and 1,25-D levels in older HET-KO and Wt mice. We conclude that haploinsufficiency of the PTG-CaSR leads to a right-shifted set-point as well as an expanded pool of Ca-nonsuppressible PTH – both hallmarks of HPTH in vivo.

FR0121

Stimulation of Bone Formation and Mineralization Post-Weaning Without Parathyroid Hormone. Beth J. Kirby[1], Andrew Karaplis[2], Christopher Kovacs*[1]. [1]Memorial University of Newfoundland, Canada, [2]McGill University, Canada

The maternal skeleton significantly resorbs and demineralizes during lactation to provide calcium to milk, followed by intense bone formation to reattain the pre-pregnancy bone mineral content (BMC). Osteoclast-mediated resorption and osteocytic osteolysis cause the lactational losses of mineral and are stimulated by low estradiol and mammary-derived PTHrP. In contrast, the mechanisms that stimulate bone formation after weaning are not established. Limited data from humans have shown that PTH increases after weaning; PTH can stimulate bone formation. We therefore hypothesized that PTH stimulates bone formation and skeletal mineralization during post-weaning.

We studied wt and *Pth* null sister mice. In a prior study with a standard 1% calcium diet many *Pth* null mothers died of hypocalcemia in the puerperium, failed to lactate, or culled their litters to an average of 2 pups. To avoid maternal hypocalcemia, in the current study wt and *Pth* null sisters were placed on a 2% calcium with lactose "rescue diet" and mated to the same males. Total body and regional (spine, hindlimb) BMC were measured by DXA (PIXImus, Lunar) during pre-pregnancy baseline, end of pregnancy, end of lactation, and weekly for 21 days post-weaning. Blood and urine were collected at each time point.

On the 2% calcium diet wt mice lost 5.3% of spine BMC during lactation as compared to the expected ~20% loss that wt mice in the same genetic background experience on a 1% calcium diet. *Pth* null mice lost 5.7% of spine BMC and completely restored this within 14 days post-weaning to a value that was 4.1% higher than pre-pregnancy baseline. The BMC excursions did not differ significantly between wt and *Pth* null mice. Two bone formation markers were assessed. Osteocalcin rose in *Pth* nulls from 47.6±6.0 to 79.6±6.0 ng/ml by day 7 post-weaning ($p<0.01$); wt mice showed a similar post-weaning osteocalcin peak of 74.6 ng/ml that did not differ from *Pth* nulls. Wt and *Pth* null mice also achieved similar values of P1NP by day 7 during post-weaning.

In summary, wt and *Pth* null mice lactated normally but the high calcium diet reduced the magnitude of BMC decline during lactation. *Pth* null and wt sisters lost a similar amount of BMC during lactation and restored it fully by day 14 post-weaning. Osteocalcin and P1NP increased in both genotypes by day 7 post-weaning. In conclusion, PTH is not required to stimulate bone formation post-weaning and enable recovery from skeletal losses incurred during lactation.

FR0122

The Anabolic Action of Parathyroid Hormone on Bone is Mediated by Monocyte Chemoattractant Protein-1. Joseph A. Tamasi*[1], Emi Shimizu[2], Noah Benton[2], Joshua Johnson[2], Nigel Morrison[3], Nicola Partridge[4]. [1]Physiology & Biophysics, University of Medicine & Dentistry of New Jersey, USA, [2]Basic Science & Craniofacial Biology, New York University College of Dentistry, USA, [3]Griffith University, Gold Coast Campus, Australia, [4]New York University College of Dentistry, USA

Parathyroid hormone (PTH) is the major hormone regulating calcium homeostasis, but it also has a significant role as an anabolic hormone in bone when administered by intermittent injection. The mechanisms for the bone anabolic effect of PTH are not understood. However, it has been established that the anabolic effects of PTH require osteoclast activity. PTH acts through a single receptor on the osteoblast to regulate many known genes. Previous microarray studies in our laboratory have shown that the most highly regulated gene, monocyte chemoattractant protein-1 (MCP-1), is rapidly and transiently induced when PTH(1-34) is injected intermittently in rats for 14 days. Through further in vivo studies, we found that rats treated with PTH(1-34) for 14 days showed a significant increase in serum MCP-1 levels 2 h after PTH injection (159 pg/ml) compared to basal levels obtained prior to the last injection (65 pg/ml). Furthermore, serum MCP-1 levels increase with the duration of treatment. Compared to vehicle treatment, PTH(1-34) treatment in rats for 1, 7 and 14 days showed a 24%, 53% and 79% increase in serum MCP-1 levels 2 h after injection, respectively. Using immunohistochemistry, increased MCP-1 expression is evident in trabecular osteoblasts by the second PTH(1-34) injection with peak staining occurring between 3 and 7 days of treatment. Male and female MCP-1 knockout mice injected daily with 80 ug/kg PTH(1-34) for 6 weeks showed significantly reduced anabolic effects of PTH compared to wild type mice as measured by pQCT and micro-CT. PTH-treated male MCP-1 null mice have significantly less trabecular bone mineral density (means, mg/cm^3, vehicle: 454; PTH: 486) than the corresponding PTH-treated wild type mice (means, mg/cm^3, vehicle: 452; PTH: 521). Trabecular bone volume (BV/TV) increased 27% in PTH-treated wild type mice with a corresponding increase in trabecular thickness (Tb.Th), however no increase in BV/TV or Tb.Th was observed in the PTH-treated MCP-1 null mice. Histomorphometric analysis revealed that the 2 fold increase in osteoclast surface and osteoclast number observed with intermittent PTH treatment in the wild type mice was completely eliminated in the MCP-1 null mice. Consequently, the lack of osteoclast activity in the MCP-1 null mice was paralleled by a significant reduction in bone formation rate. We conclude that osteoblastic MCP-1 expression is essential for the anabolic effects of PTH on bone.

Differential Role of Fibronectin Originating from Different Sources in the Bone Marrow on Metastasis Formation. Anja von Au*[1], Christine Hoffmann[1], Matthaeus Vasel[1], Marco Cecchini[2], Inaam Nakchbandi[1]. [1]Max-Planck Institute for Biochemistry & University of Heidelberg, Germany, [2]University of Bern, Switzerland

The extracellular matrix affects tumor cell behavior by binding to surface receptors or modifying growth factor availability. Fibronectin (FN) is expressed in the premetastatic niche, which suggests a critical role for it in tumor development. We sought to examine the role of FN produced by cells of the osteoblastic niche and differentiate it from the effects of other cells in the bone marrow on the formation of bone metastasis.

Mice carrying the Mx or collagen α1(I) promoter attached to cre were mated to nude mice homozygote for a floxed FN gene resulting in mice with deleted FN in the bone marrow (Mx) or in osteoblasts (Col). A bone seeking luciferase expressing MDA-MB-231 tumor cell line was used.

Cardiac injection in Mx-mice resulted in increased median survival from 6.6 in CT to 8.7 weeks ($p<0.05$). Growth assessed using tibia injections was slower at days 14 and 18 after injection (day 18: CT 30±6 $x10^5$ vs. Mx 12±7 $x10^5$ relative luminescence units (RLU), $p<0.05$). This suggested a defect in early angiogenesis that was confirmed (CT 148±10 vs. Mx 89±8 CD31-stained blood vessels/mm^2, $p<0.005$). Histomorphometry revealed an increase in osteoblasts adjusted to tumor-bone interface (CT 44±6 vs. Mx 63±2 Ob/BS, $p<0.05$).

Cardiac injection in Col-mice revealed survival prolongation from 6.6 to 7.6 weeks ($p<0.05$). Tibia injections showed decreased early growth until day 18 (day 7: CT 5±2 $x10^4$ vs. Col 2±0.3 $x10^4$ RLU, $p<0.05$). After that growth was comparable until death at day 40 (1.7±0.5 $x10^8$ vs. 1.7±0.4 $x10^8$ RLU). Despite the lack of difference

in growth histomorphometry showed increased osteoclasts (CT 0.8±0.2 vs. Col 3.6±0.4 OC/BS, $p<0.01$). This presumably resulted from decreased circulating osteoprotegerin levels (CT 4.9±0.4 vs. Col 3.7±0.3 ng/ml, $p<0.05$) that developed in the presence of tumor, because untreated mice had lower and comparable levels (CT 2,4±0.1 vs. Col 2.2±0.2 ng/ml, p=NS). To determine whether osteoblasts lacking FN produce less osteoprotegerin we examined conditioned media from primary osteoblasts and found a significant decrease in osteoprotegerin in Col (CT 3.1±0.4 vs. Col 1.7±0.02 ng/ml, $p<0.05$).

Since osteoblasts produce FN, the increase in osteoblasts could support the comparable early growth in Mx and CT. The increase in osteoclasts in Col is not associated with increased tumor growth raising the possibility that an intermediary involved in the vicious cycle is disturbed in the absence of osteoblast FN.

Enpp1: A Potential Facilitator of Breast Cancer Bone Metastasis. Wen Min Lau[1], Michele Doucet[1], Ryan Stadel[1], Kristy Weber[2], Scott Kominsky*[3]. [1]Johns Hopkins University School of Medicine, USA, [2]Johns Hopkins University, USA, [3]Johns Hopkins School of Medicine, USA

Metastasis is the ultimate cause of mortality in breast cancer patients, developing in the bone more frequently than any other site. Moreover, bone metastasis is frequently incurable and commonly causes significant morbidity in the form of bone pain, pathological fractures, nerve compression, and hypercalcemia. Critical to our ability to prevent and treat bone metastasis is the identification of the key factors mediating its establishment and understanding their biological function. To address this issue we utilized an *in vivo* selection process to generate murine mammary tumor sublines possessing an enhanced ability to colonize either the bone or liver following intracardiac injection. A comparison of gene expression between these sublines by genome-wide cDNA microarray analysis revealed several potential mediators of bone metastasis, including the pyrophosphate-generating ectoenzyme ecto-nucleotide pyrophosphatase/phosphodiesterase I (Enpp1). By qRT-PCR and Western analysis we found that expression of Enpp1 was elevated in human breast cancer cell lines known to produce osteolytic metastasis in animal models compared to non-metastatic and normal mammary epithelial cell lines. Further, mRNA expression was elevated in human breast cancer bone metastasis relative to primary breast tumors and normal mammary epithelium by qRT-PCR and immunohistochemical analysis. To examine the potential role of Enpp1 in the establishment of bone metastasis, we stably increased the expression of Enpp1 in the breast cancer cell line MDA-MB-231 and examined their ability to colonize the bone and induce osteolysis following direct injection into the tibia of athymic nude mice. Interestingly, in two separate experiments, MDA-MB-231 cells with increased expression of Enpp1 demonstrated an enhanced ability to establish osteolytic tumors relative to cells expressing vector alone, as determined by digital radiography. In addition, similar results were observed following intracardiac injection of tumor cells in athymic nude mice. Taken together, these data suggest a potential role for Enpp1 in the establishment of breast cancer bone metastasis.

Myeloid-Derived Suppressor Cells Expand During Breast Cancer Progression and Promote Tumor-induced Bone Destruction. Sabrina Danilin*[1], Julie Sterling[2], Alyssa Merkel[2], Josh Johnson[2], Rachelle Johnson[2], James Edwards[2], Gregory R Mundy[2]. [1]Vanderbuilt University, USA, [2]Vanderbilt University Medical Center, USA

Breast carcinoma is a highly metastatic cancer that preferentially metastasizes to bone, causing osteolytic lesions in 70% of patients. Myeloid-Derived Suppressor Cells (MDSC), identified as Gr-1+CD11b+ cells in mice, are a heterogeneous population of myeloid cells at different stages of differentiation that expand in blood, spleen and bone marrow during cancer growth. They are responsible for cancer immunosuppression and are recruited into the primary tumor where they directly promote cancer growth, recurrence and burden. However, little is known about their role at metastatic sites. We hypothesized that MDSCs in bone marrow create a favorable microenvironment for tumor cell and promote cancer cells induced osteolysis. Since immunodeficient mice are used to study breast cancer bone metastasis in vivo, and MDSCs play a critical role in immunosuppression, we first injected nude mice in the mammary fat pad with MDA-MB-231 human cancer cells or immunocompetent balb/c mice with 4T1 cells and assessed MDSCs. FACS analysis and histology demonstrated that MDSCs' expansion and ability to promote tumor growth was similar in both models, validating the use of nude mice for their study. To assess the role of MDSCs in tumor-induced bone disease, we inoculated MDA-MB-231 cells into the left cardiac ventricle of nude mice and monitored metastasis progression by X-ray and GFP fluorescence imaging and MDSCs by FACS weekly. MDSCs were then isolated from normal and tumor-bearing mice, and gene expression and in vitro function assessed. By FACS, we detected an increase in the Gr-1+CD11b+ population as expected, but more importantly, the GR-1lowLy6C+ subpopulation which gives rise to monocytic cells also increased from 6 to 12% in bone marrow of tumor mice. Furthermore, in vitro experiments showed that MDSCs differentiate into osteoclasts when cultured with RANKL and M-CSF and that they increase PTHrP mRNA expression in cancer cells. This enhancement in PTHrP expression is likely due to the 2 fold increase in TGF-ß expression found in MDSCs isolated from tumor mice compared to MDSCs isolated from control mice. Overall, these results demonstrate that MDSCs expand in breast cancer bone metastases in vivo, that they are potential precursors for osteoclasts in vivo and that they are able to influence breast cancer cell behavior. This suggests that MDSCs may help establish a permissive microenvironment for tumor cell metastases to bone and contribute to tumor-induced bone disease.

Treatment with Interleukin 6 Receptor Antibodies Inhibits Breast Cancer Growth in a Murine Model of Bone Metastasis. Katja Boernert[1], Yu Zheng*[1], Hong Zhou[2], Anastasia Mikuscheva[3], Frank Buttgereit[3], Colin Dunstan[4], Markus Seibel[2]. [1]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, [2]Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, [3]Humboldt University, Germany, [4]University of Sydney, Australia

In patients with metastatic breast cancer, high circulating interleukin-6 (IL-6) levels are associated with disease progression and poor prognosis. We previously demonstrated in murine models of bone metastasis that increasing or decreasing bone resorption results in corresponding changes of tumor IL-6 expression and tumor progression, indicating that IL-6 may have a role in sustaining metastatic cancer growth in bone1. In the present study, we investigated the effect of blocking IL-6 receptor (IL-6R) signalling on cancer growth in a murine xenograft model, using either the anti-human IL-6R antibody, tocilizumab (Tmab), or the anti-mouse IL-6R antibody, MR16-1.

Five week-old BALB/c nu/nu female mice were inoculated with 50,000 cells each of the human breast cancer cell line, MDA-MB-231, via intra-tibial injection. Tibiae were monitored by x-ray imaging on days 10, 17 and 21 (sacrifice), followed by histological and histomorphometric analysis, including proliferation index, TUNEL staining for apoptosis, and TRAcP staining for osteoclast activity.

In a dose finding study, mice were randomized into 7 groups (n=3 each), receiving Tmab or MR16-1 at doses of 20mg/kg, 50mg/kg and 100mg/kg i.p. every 3 days, or vehicle. The inhibitory effect on cancer growth in bone was most pronounced at a dose of 50mg/kg/3d for Tmab, and 100mg/kg/3d for MR16-1, as assessed by x-ray quantification of osteolytic areas on days 10, 17 and 21, histological measurement of total tumor area, tumor proliferation index and tumor apoptosis rate on day 21.

Further experiments with larger group numbers (n=8) established that both Tmab and MR16-1 were able to inhibit osteolysis on day 10, 17 and 21 ($p=0.066$ for MR16-1 on day 21; $p<0.05$ for all other groups and time points, compared to controls).

The anti-mouse IL-6R antibody, MR16-1, inhibits endogenous IL-6 signalling in the host cell, whereas the anti-human IL-6R antibody, Tmab, not only blocks tumor-induced IL-6 activity, but also affects tumor derived IL-6 which acts on the murine IL-6R as well. Of note, we observed similar effects on tumor progression in bone for treatment with Tmab and MR16-1, suggesting that IL-6 affects tumor progression regardless of species origin. Our data indicate that IL-6 plays an important role in bone metastatic growth and may be a potential treatment target in breast cancer.

Activation of Notch Signaling Contributes to the Pathogenesis of Osteoma and Osteosarcoma with a Mouse Model. Jianning Tao*, Shan Chen, Ming ming Jiang, Terry Bertin, Francis Gannon, Brendan Lee. Baylor College of Medicine, USA

Human osteosarcoma (OS) is the most common primary bone cancer, comprising approximately 20% of all bone tumors and about 5% of pediatric tumors overall. Most OS occurs sporadically and our understanding of its molecular basis is still limited. From a signaling perspective, dysregulation of several evolutionally conserved pathways including Wnt, TGF/ BMPs, SHH and FGFs has been found in human OS tumor samples and cell lines. Recently, our and other studies suggest that activation of Notch signaling contributes to the pathogenesis of human OS. Notch signaling plays an important role in the developmental processes and adult tissue homeostasis by regulating cell fate determination, proliferation, differentiation and apoptosis. Notch, a transmembrane receptor, releases its intracellular domain (NICD) into the nucleus to regulate transcription of target genes such as the Hey and Hes family of transcription factors. Altered Notch signaling has been associated with several cancers in which the data suggest that Notch can act both as an oncogene and tumor suppressor gene depending on its expression levels and timing. Our previously established human tumor xenografts in nude mice showed decreased tumor growth after chemical or genetic inhibition of Notch signaling, suggesting that its inhibition may be a therapeutic approach for the treatment of OS. To generate a mouse osteosarcoma model and examine the role of Notch signaling in bone tumorigenesis, we established a bitransgenic mouse line that constitutively expressed a single copy of Notch NICD in osteoblasts. The resulting bitransgenic Notch gain-of-function (GOF) mice developed osteosclerosis at age of two months. Histomorphometric and molecular analysis of cavarial and long bones indicated that Notch could stimulate proliferation of immature osteoblasts while inhibiting their differentiation into mature

osteoblasts. This gain of function phenotype was reminiscent of osteoblastic tumors. Indeed, aging studies of these GOF mice showed that they spontaneously developed osteoma at 100% penetrance. Of 24 aged mice to date, we have detected multifocal malignant tumors in six of them by gross examination. Pathological analysis confirmed that one of them was telangiectatic osteosarcoma, featured by poorly differentiated osteoblast-like cells, tumor osteoid, necrosis and hemorrhage. Together, our preliminary data support our hypothesis that Notch activation may be a dominant mechanism for OS pathogenesis.

Bone Remodeling Regulated by ARF is a Therapuetic Target for Prevention of Osteosarcoma. Michelle Hurchla*[1], Dan Rauch[2], John Harding[2], Hongju Deng[2], Lauren Shea[2], Mark Eagleton[2], Stefan Niewiesk[3], Michael Lairmore[3], David Piwnica-Worms[2], Thomas Rosol[4], Jason Weber[2], Lee Ratner[2], Katherine Weilbaecher[5]. [1]Washington University in St. Louis, USA, [2]Washington University School of Medicine, USA, [3]Ohio State University, USA, [4]The Ohio State University, USA, [5]Washington University in St. Louis School of Medicine, USA

The ARF tumor suppressor is a critical regulator of ribosomal biogenesis and p53-dependent cell cycle arrest and apoptosis. We have reported that Arf-/- mice have hyperactive osteoclasts (OC). Surprisingly, microCT analysis showed that trabecular bone volume was significantly increased in Arf-/- mice. Further examination revealed that osteoblast (OB) function was also enhanced, resulting in a high bone turnover state with a net increase in bone formation. The in vivo bone formation rate and serum osteocalcin levels of Arf-/- mice were significantly higher than those of Arf+/+. In vitro, we observed significant increases in the progenitor number, proliferation, differentiation and mineralization of OB from Arf-/- mice. We have previously shown that malignancies induced by Tax, an HTLV-1 oncogene, cause the expression of bone-tropic factors that enhance tumor growth. We hypothesized that the increased rate of bone remodeling in Arf-/- mice would facilitate malignant transformation by Tax. Crossing Tax+ and Arf-/- mice resulted in the spontaneous development of osteosarcomas in 100% of the Tax+Arf-/- animals by 7 months of age. Osteosarcoma (OS), characterized by neoplastic bone-forming OB, is the most prevalent form of primary bone cancer. Pathologically, Tax+Arf-/- tumors were well-differentiated OS characterized by abundant woven bone formation and increased OC recruitment. Cell lines established from these tumors consist of a heterogeneous mixture of alkaline phosphatase (ALP)-positive cuboidal OB and ALP-negative fibroblast-like cells. These cell lines express mature OB markers, have the ability to form mineralized nodules in vitro, and grow progressively when transplanted into immunocompromised mice. In addition to mutations or inactivation of ARF, deregulation of the tumor suppressors p53 and Rb and amplification of c-myc are common in human OS. We demonstrate that similar alterations in these pathways are present in Tax+Arf-/- OS. We hypothesized that uncoupling OB and OC would inhibit the high bone remodeling present in Tax+Arf-/- mice and lessen malignant transformation of OB. Treating Tax+Arf-/- mice with the bisphosphonate OC inhibitor zoledronic acid weekly from 1 to 9 months of age prevented or delayed the onset of OS. This discovery reveals an important role for bone remodeling in osteosarcoma and implicates OC-inhibition and bisphosphonates as novel therapeutics for targeted prevention or treatment of OS.

FR0138

Disruption of Prostaglandin E Biosynthesis and Its Receptor EP4 Attenuated Angiogenesis, Tumor Growth and Bone Metastasis of Cancer. Morichika Takita[1], Satoshi Yokoyama[1], Masaki Inada*[2], Chisato Miyaura[1]. [1]Tokyo University of Agriculture & Technology, Japan, [2]Toyko University of Agriculture & Technology, Japan

Bone metastasis of cancer is accompanied by severe bone destruction with increased bone resorption. We recently found that prostaglandin E (PGE) biosynthesis in bone is mediated by an inducible PGE synthase, membrane-bound PGE synthase-1 (mPGES-1), and PGE production is closely related to the growth and bone metastasis of cancer. In fact, tumor growth and bone metastasis are markedly attenuated in the mice lacking mPGES-1 after injection of malignant melanoma B16 cells. Metastasized tumor is frequently associated with neo-vascularization in various tissues. In this study, we investigate the roles of PGE2 and its receptor EP4 in tumor associated neo-vascularization using mPGES-1-null (mPGES-/-) mice and EP4-null (EP4-/-) mice. When B16 cells were implanted subcutaneously into C57BL/6 wild-type (WT) mice, B16 cells grew rapidly to form solid tumor with angiogenesis. In mPGES-/- mice, however, the tumor volume of B16 was markedly reduced compared with WT mice. Angiogenesis associated with B16 growth was also decreased in mPGES-/- mice. Using the quantitative models of in vivo laser imaging for neo-vascularization, a red fluorescent labeled PEG particle was injected to WT and mPGES-/- mice. In WT mice, neo-vascularization around solid B16 tumor was obviously, but the signal was decreased in mPGES-/- mice. To clear the source cells of PGE2 and angiogenic factors, dermal fibroblasts were obtained from WT and mPGES-/-, and co-cultured with fixed-B16 cells. Production of PGE2 was markedly increased in the conditioned medium from WT fibroblast culture, while dermal fibroblasts from mPGES-/- mice produced negligible amounts of PGE2. Dermal fibroblasts obtained from WT produced vascular endothelial cell growth factor (VEGF)-A and basic fibroblast growth factor (bFGF), and the levels was elevated by adding PGE2. On the other hand, the levels of VEGF-A and bFGF in the conditioned medium were quite low in the culture of dermal fibroblasts collected from mPGES-/- mice. In EP4-/- mice, solid tumor growth and angiogenesis of B16 were markedly attenuated in vivo, and dermal fibroblasts from EP4-/- mice produced only negligible levels of VEGF-A and bFGF. These results suggest that PGE2 produced by host stromal cells elicits the production of VEGF-A and bFGF by fibroblasts via EP4-mediated pathway to induce endothelial angiogenesis and progression of tumor growth.

Frequent Attenuation of Tumor Suppressor WWOX in Osteosarcomas is Associated With Increased Tumorigenicity and Elevated RUNX2 Levels. Sara Del Mare*[1], Kyle Kurek[2], Zaidoun Salah[1], Suhaib Abdeen[1], Eugenio Gaudio[3], Nicola Zanesi[3], Hussain Sadiq[4], Matthew Warman[5], Gary Stein[6], Janet Stein[4], Jane Lian[6], Rami Aqeilan[7]. [1]The Lautenberg Center for Immunology & Cancer Research, Hebrew University-Hadassah Medical School, Israel, [2]Children's Hospital Boston Department of Pathology, USA, [3]Department of Molecular Virology, Immunology & Medical Genetics, Comprehensive Cancer Center, Ohio State University, USA, [4]Department of Cell Biology, University of Massachusetts Medical School, USA, [5]Department of Orthopaedic Surgery, Howard Hughes Medical Institute, Children's Hospital Boston & Harvard Medical School, USA, [6]University of Massachusetts Medical School, USA, [7]Ohio State University, USA

The WW domain-containing oxidoreductase (*WWOX*) is a *bona fide* tumor suppressor gene that is reduced or absent in most common human malignancies. We recently demonstrated that the short-lived *Wwox*-deficient mice develop periosteal osteosarcomas (OS) and display defects in bone formation. OS are highly aggressive primary bone tumors that commonly affect young patients and frequently metastasize to the lungs, imparting a poor prognosis. Molecular mechanisms underlying OS formation are far from being fully understood. To further investigate the etiology of this aggressive disease and develop new therapeutic targets, we determined expression and tumor suppressor function of WWOX in human OS to shed light on the molecular and signaling pathways in which it is involved. Our analysis revealed that the majority (4/6) of human OS cell lines displayed reduced WWOX expression as assessed by real-time PCR and Western blot analyses. Ectopic expression of WWOX in human OS cell lines having reduced WWOX expression, inhibited proliferation and attenuated invasion *in vitro*, and suppressed tumorgenicity in nude mice. Expression of WWOX was associated with reduced RUNX2 expression in OS cells, whereas RUNX2 levels were elevated in femurs of *Wwox*-deficient mice with accompanying OS formation. Furthermore, we demonstrated that WWOX reconstitution in HOS metastatic OS cells was associated with downregulation of RUNX2 levels and RUNX2 target genes, consistent with the ability of WWOX to suppress RUNX2 transactivation activity. These data are consistent with the observation that WWOX expression is attenuated in the majority of human OS specimens and is associated with aberrant RUNX2 levels. Together, our findings strengthen the evidence of a tumor suppressor role for WWOX in OS and suggest that it is mediated, at least in part, by regulation of RUNX2 levels.

Calcitonin Lowers Serum FGF23 Levels in Patients with X-linked Hypophosphatemia. Eva Liu*, Thomas Carpenter, Caren Gundberg, Karl Insogna. Yale University School of Medicine, USA

In X-linked hypophosphatemia (XLH), elevated circulating levels of FGF23 result in renal phosphate wasting and suppression of proximal renal tubular 1-alpha hydroxylase activity. For the past 30 years the cornerstone of medical therapy for XLH has been calcitriol and supplemental phosphorus. However, calcitriol stimulates production of FGF23, which is not desirable. Calcitonin (CT) has been reported to increase circulating levels of $1,25(OH)_2$ D in XLH but whether it affects FGF23 levels is not known. We therefore administered a single, intradermal dose of salmon CT (200 MRC units) to seven subjects with XLH and six normal controls and measured serum FGF23, $1,25(OH)_2$ D and indicies of mineral homeostasis at baseline and serially over the next 24 hrs. Data were analyzed using repeated measures 1-way ANOVA and 2-way ANOVA. In subjects with XLH, CT significantly and rapidly reduced serum FGF23 to a mean value that was $77 \pm 7\%$ of baseline by 4 hours post injection (66 ± 5 pg/mL $\rightarrow$ 52 ± 8 pg/mL; p=0.0002). This decrease was sustained for the next 16 hours. In control subjects, FGF23 did not change significantly following treatment (p=0.16). By 2-way ANOVA, the effect of CT on serum FGF23 was significantly different when subjects with XLH were compared to controls (p=0.01). The decline in FGF23 in subjects with XLH was accompanied by a significant increase in serum $1,25(OH)_2$ D

(45 ± 3 pg/mL $\rightarrow$ 69 ± 5 pg/mL; p=0.0005). There was a comparable increase in $1,25(OH)_2$ D in control subjects and by 2-way ANOVA the response was not different in the two groups (p=0.15). In XLH patients, there was an increase in serum phosphate and the renal phosphate threshold (TmP/GFR) following treatment with CT that was maximal at 10 hours post injection (p=0.0003) while normal subjects had a fall in both these parameters, first noted at 10 hours (p=<0.0001). These results indicate that CT differentially regulates FGF23 in patients with XLH as compared to normal individuals. The rise in $1,25(OH)_2$ D levels in XLH could be due to the known effect of CT to augment proximal renal tubular production of the hormone as well as due to the fall in FGF23. The suppression of FGF23 levels in patients with XLH suggests that CT may be a promising new therapeutic agent for this disease.

***Runx2* haploinsufficiency rescues the craniosynostosis phenotype of *Axin2*-knockout mice.** Meghan McGee-Lawrence*[1], David Razidlo[1], Frank Secreto[1], Xiaodong Li[1], Wei Hsu[2], Jane Lian[3], Jennifer Westendorf[1]. [1]Mayo Clinic, USA, [2]University of Rochester Medical Center, USA, [3]University of Massachusetts Medical School, USA

Runx2 and Axin2 regulate craniofacial development and skeletal maintenance. Deletion of either *Axin2* or *Runx2* causes opposing craniofacial phenotypes in mice: *Runx2* haploinsufficient mice develop cleidocranial dysplasia (CCD) and $Axin2^{-/-}$ mice develop craniosynostosis (CS). We recently showed that Axin2 levels are elevated in $Runx2^{-/-}$ calvarial cells and that Runx2 represses the *Axin2* promoter, suggesting a direct relationship between these two factors *in vivo*. The goal of the current study was to elucidate the molecular interactions between Axin2 and Runx2 and to explore their cooperative effects *in vivo*.

Axin2 is a negative feedback inhibitor of canonical Wnt/beta-catenin signaling. Runx2 represses *Axin2* transcription and its DNA binding domain is necessary for this regulation. In this project, we identified four putative Runx2 binding elements in the *Axin2* promoter and determined that Runx2 specifically bound these sites in gel shift assays. In chromatin immunoprecipitation (ChIP) assays performed on lysates from MC3T3 cells, Runx2 bound *Axin2* promoter regions containing Runx2 binding sites identified in the gel shift experiments. Association of Runx2 with regions of the *Axin2* promoter containing these sites was enriched 5- to 6-fold as compared to a downstream region lacking a Runx2 binding site. Runx2-mediated repression of *Axin2* transcription was blocked by addition of a histone deacetylase (Hdac) inhibitor, trichostatin A. Hdac3 associated with *Axin2* promoter fragments containing Runx2 binding elements in ChIP assays and repressed the *Axin2* promoter. These data suggest that Runx2 and Hdac3 regulate *Axin2 in vivo*.

To determine if Axin2 and Runx2 are components of the same molecular pathway, we mated $Runx2^{+/-}$ and $Axin2^{-/-}$ mice to generate double-mutant $Axin2^{-/-}$:$Runx2^{+/-}$ mice. CS was assessed in skulls of 4 week-old male mice by measuring skull length (nose tip to coronal suture) following microCT (Fig 1). Similar to previous studies, *Axin2* deficiency reduced skull length (-17%) as compared to wildtype animals. Skull lengths were similar in $Runx2^{+/-}$ and wildtype mice. Interestingly, $Axin2^{-/-}$:$Runx2^{+/-}$ mice had skulls that were 10% longer than $Axin2^{-/-}$ mice and were comparable in length to wildtype and $Runx2^{+/-}$ mice. These data indicate that *Runx2* haploinsufficiency rescues the CS phenotype in $Axin2^{-/-}$ mice. Together our data suggest that Runx2 directly regulates *Axin2* expression and is required for enhanced calvarial bone formation in $Axin2^{-/-}$ mice.

Age-dependent Arthropathy in Circadian Mutant Mice. Elizabeth Yu*, Sadiq Hussain, Robert Dallmann, Stacey Russell, Jane Lian, David Weaver. University of Massachusetts Medical School, USA

The purpose of this study is to investigate an age-dependent arthropathy observed in circadian mutant mice. In the circadian oscillator, CLOCK and NPAS2 form heterodimers with BMAL1 to drive rhythmic expression of genes that regulate physiology and behavior. $Clock^{-/-};Npas2^{m/m}$ mutant mice lack circadian rhythms. These mice also exhibit progressive arthropathy. To study this arthropathy, $Clock^{-/-};Npas2^{m/m}$ mutant and wild-type mice were subjected to X-ray, micro-computed tomography (micro-CT), and histological analysis to characterize the age of onset, progression, and anatomical distribution of this arthropathy. $Clock^{-/-};Npas2^{m/m}$ mice exhibit site-specific, age-dependent calcification of calcaneal tendon and costosternal junction tissue. These calcifications are detectable by X-ray and micro-CT by 11-12 weeks of age and by histology as early as 6-7 weeks of age. Calcifications enlarge over time and by 40 weeks of age, $Clock^{-/-};Npas2^{m/m}$ mutant mice exhibit extensive calcification of the calcaneal tendon and costosternal junction tissue. These findings are similar to those reported in another arrhythmic circadian mutant mouse, the $Bmal1^{-/-}$ null mouse (Bunger et al., Genesis. 41:122, 2005). $Clock^{-/-};Npas2^{m/m}$ calcaneal tendon and costosternal junction tissue samples are also being analyzed at the age of onset of disease using immunohistochemistry to identify cell types present in those tissues as calcifications begin to form. RNA is additionally being extracted from affected tissues at the age of disease onset to study changes in gene expression between $Clock^{-/-};Npas2^{m/m}$ and wild-type tissues.

From these data we conclude that $Clock^{-/-};Npas2^{m/m}$ and $Bmal1^{-/-}$ mutant mice exhibit similar arthropathy phenotypes. Due to their roles as transcription factor heterodimers in the circadian oscillator, we hypothesize that CLOCK:BMAL1 and NPAS2:BMAL1 heterodimers drive the expression of one or more genes that prevent age-dependent arthropathy.

Conditional Deletion of SKI-1 Using 3.6kb COL1-Cre Leads to Vertebral Fusions, Hind Limb Paralysis, and Impaired Lower Limb Development. Jeffrey Gorski*[1], Nichole Huffman[2], Qian Chen[2], Sarah Dallas[2], Paul Trainor[3], Nabil G. Seidah[4]. [1]University of Missouri, Kansas City, School of Dentistry, USA, [2]University of Missouri - Kansas City, USA, [3]Stowers Institute of Medical Research, USA, [4]Laboratory of Biochemical Neuroendocrinology, IRCM, Canada

Proprotein convertase SKI-1 (subtilisin kexin isozyme1/site-1) activates transmembrane transcription factor precursors including SREBP-1 and -2, CREB-H, OASIS, and ATF-6, facilitating their import into the nucleus. Since the latter three factors have been shown to be required for normal bone formation and the SKI-1 knockout is embryonic lethal, we sought to investigate the skeletal function of SKI-1 by producing a bone-restricted knockout (cKO). Floxed SKI-1 mice were bred with transgenic mice expressing the rat 3.6 COL1 Cre transgene. The cKO [genotype $SKI\text{-}1^{f/f}$:$Cre^{+/-}$] newborns, representing 7% of live births, were paralyzed with severely under-developed lower limbs with reduced musculature and a short curly tail. Ten day old mice were euthanized when average weights of cKO and controls [control genotypes $SKI\text{-}1^{f/f}$:$Cre^{-/-}$; $SKI\text{-}1^{f/+}$:$Cre^{+/-}$; or $SKI\text{-}1^{f/+}$:$Cre^{-/-}$] were 3.8 +/- 0.8 gm and 6.4 +/- 1.6 gm (p=0.025), respectively. MicroCT scans showed that cKO mice exhibited fused lumbar vertebrae, but the central spinal canal remained open. ROSA26 mice were bred with 3.6 COL1 Cre mice to determine the embryonic expression pattern of the Cre transgene. Histological analyses for β-galactosidase (LacZ) revealed a gradient of expression at embryonic day E11.5 with strongest expression occurring distally in the developing spinal column. This region corresponds to where vertebral fusions were observed in cKO newborns. LacZ was expressed in the mantle layer surrounding the neural tube and in discrete cells within the ventricular zone. At this time during spinal column development, neural and cartilage cell precursors at these locations are actively proliferating and differentiating. We have shown elsewhere that SKI-1 is required for mineralization of osteoblastic cultures where it regulates transcription of *fibronectin, Phex, Dmp1, COL1A1* and *COL1A2* by activating transmembrane transcription factor precursors. Our data identify SKI-1 as a major developmental regulator of the spine and lower limbs. The presence of the phenotype at birth and the developmental expression pattern of the Cre transgene suggest that vertebral defects are patterned embryonically during somite segmentation, potentially through altered expression of matrix proteins fibronectin and collagen. SKI-1 deficient mice represent a novel model for mechanistic studies of birth defects altering the coordinated development of the spinal column with the nerves, muscle and cartilage/bone of the lower limbs.

Molecular Mechanism of the ACVR1^{R206H} Mutation of Fibrodysplasia Ossificans Progressiva. Kyung Woo[1], Hyun-Mo Ryoo[2], Ginah Song*[3], Hyun-Jung Kim[4], Jeong-Hwa Baek[5]. [1]Seoul National University, School of Dentistry, Korea, [2]Seoul National University, School of Dentistry, South korea, [3]Seoul National Univ. School of Dentistry, South korea, [4]BioRunx Co Ltd, South korea, [5]Seoul National University School of Dentistry, South korea

Fibrodysplasia ossificans progressiva (FOP), a rare genetic and catastrophic disorder characterized by progressive heterotopic ossification, is caused by a point mutation, c.617G>A; p.R206H, in the activin A receptor type 1 (ACVR1) gene, one of the bone morphogenetic protein type I receptors (BMPR-Is). Although hyperactivated BMP signaling has been suggested to explain the pathogenesis, the molecular consequences of this mutation are still unknown. Here we studied the impact of ACVR1 R206H mutation on BMP signaling, its downstream signaling cascades and protein expression level in murine myogenic C2C12 cells and human embryonic kidney (HEK) 293 cells. We found that ACVR1 was the most abundant of the BMPR-Is expressed in mesenchymal cells but its contribution to osteogenic BMP signal transduction was minor. The R206H mutant caused weak activation of the BMP signaling pathway, unlike the Q207D mutant, a strong and constitutively active form. The R206H mutant showed a decreased binding affinity for FKBP1A/FKBP12, a known safeguard molecule against the leakage of transforming growth factor (TGF)-β or BMP signaling. The decreased binding affinity of FKBP1A to the mutant R206H ACVR1 resulted in leaky activation of the BMP signal, and moreover, it decreased steady-state R206H ACVR1 protein levels. Interestingly, while WT ACVR1 and FKBP1A were broadly distributed in plasma membrane and cytoplasm without BMP-2 stimulation and then localized in plasma membrane after BMP-2 stimulation, R206H ACVR1 and FKBP1A were mainly distributed in plasma membrane regardless of BMP-2 stimulation. The impaired binding to FKBP1A and translocalization to plasma membrane related with altered receptor internalization by R206H ACVR1 mutation may result in mild hyperactivation of BMP-signaling in extraskeletal sites such as muscle, which lead to progressive ectopic bone formation in FOP patients.

Gremlin is Required for Normal Skeletal Development, but Postnatally it Suppresses Bone Formation. Anna Smerdel-Ramoya[1], Stefano Zanotti[2], Ernesto Canalis*[1]. [1]St. Francis Hospital & Medical Center, USA, [2]Saint Francis Hospital & Medical Center, USA

Bone morphogenetic proteins (BMPs) play a central role in the regulation of bone formation. BMP activity is controlled by secreted BMP antagonists, such as gremlin and noggin, which bind and prevent BMP signaling. The patterning of distal limb skeletal elements is tightly regulated by the reciprocal interactions between BMPs, fibroblast growth factors (FGF) and Sonic hedgehog (SHH). By inhibiting BMP action, gremlin allows for FGF and SHH expression and for proper limb patterning and development. Null mutations of *Gremlin1* (*Grem1*) in mice result in serious developmental abnormalities, leading to newborn lethality. We demonstrated that transgenics overexpressing gremlin under the control of the osteocalcin promoter exhibit decreased bone formation leading to osteopenia and fractures. In contrast, conditional inactivation of *Grem1* in osteoblasts leads to a transient increase in bone formation and bone mass. Recently, we observed that mice carrying the global deletion of *Grem1* in a mixed genetic background (C57BL/6/FVB) survived, allowing for the study of the consequences of the *Grem1* inactivation from development to adulthood. *Grem1* null mice were smaller than littermate controls, and contact radiography revealed a single bone in both forelimbs and hindlimbs. In accordance with the role of gremlin in skeletal development, bone mineral density and bone histomorphometry of the femur revealed osteopenia at 1 month of age in *Grem1* null mice, secondary to decreased trabecular number, without sex distinction. Osteoblast and osteoclast cell number were not altered, but in accordance with the inhibitory effect of gremlin on BMP activity, bone formation was increased leading to a recovery of bone mass in older animals. Therefore, despite their smaller size the osteopenia was reversed at 3 and 6 months of age in *Grem1* null mice. Osteoblast cell cultures from *Grem1* null mice revealed sensitization to the actions of BMP-2 so that BMP had a greater effect on alkaline phosphatase expression and activity and mineralized nodule formation in *Grem1* null cells. Interestingly, noggin expression was increased, suggesting that it may act as a compensatory mechanism in the absence of gremlin. In conclusion, gremlin plays a critical role in limb development, but by opposing BMP activity gremlin decreases bone formation and when in excess it causes osteopenia.

Loss of Bmp2 Impairs Appositional Growth in the Endochondral Skeleton. Luciane Capelo*, Karen Cox, Vicki Rosen. Harvard School of Dental Medicine, USA

Removal of Bmp2 from the early limb has catastrophic consequences on the adult skeleton where bones lacking Bmp2 undergo spontaneous fractures that are not able to heal (Bmp2fl/fl; Prx1::Cre mice). The failure of fracture healing observed in these mice is a direct result of the absence of Bmp2 expression in the periosteum. However, the cause of the spontaneous fractures is unknown. Gross examination of Bmp2fl/fl; Prx1::Cre bones determined they were similar in length to bones of wt mice but greatly reduced in width. As appositional bone growth is controlled by the periosteum, we hypothesized that loss of periosteal Bmp2 expression impairs appositional bone growth in the endochondral skeleton. We focused our attention on mice from birth (NB) to 23 weeks of age. Morphological analysis of Bmp2fl/fl; Prx1::Cre mice showed that the width/length ratio is abnormal in the fore and hind limbs in all ages studied. NB mice exhibit a 20% reduction in cross sectional area at midshaft of radius and ulna in comparison to control mice. At 2 weeks of age, a 50% reduction is observed in cross sectional area at midshaft of the same bones. This difference is maintained over time and is also observed in the hind limb so that by 9 weeks, femurs lacking Bmp2 are half of the width of control mice whereas bone length does not differ significantly between groups. These data suggest that as bones lacking periosteal Bmp2 grow in length but not in width, they become unstable and subsequently fracture. Our data identify a unique role for Bmp2 as a physiological regulator of appositional bone formation during bone growth and also point to a role for Bmp signaling in maintaining bone width proportional to bone length in order to preserve bone strength during growth and aging.

Fig. 1. Morphology of the forelimb of wild-type (control) and Bmp2 deficient mice (Bmp2fl/fl;Prx1::Cre). Dashed lines in the x-rays on the left identify the area of cross sections presented in the right panels.

A Local Application of Recombinant Human Fibroblast Growth Factor-2 for Tibial Shaft Fractures: A Randomized, Double-Blind, Placebo-Controlled Trial. Hiroshi Kawaguchi*[1], Hiroyuki Oka[2], Seiya Jingushi[3], Toshihiro Izumi[4], Masao Fukunaga[5], Katsumi Sato[6], Takashi Matsushita[7], Kozo Nakamura[8]. [1]University of Tokyo, Faculty of Medicine, Japan, [2]University of Tokyo, Japan, [3]Kyushu Rosai Hospital, Japan, [4]Saihaku Hospital, Japan, [5]Kawasaki Medical School, Japan, [6]Tohoku Rosai Hospital, Japan, [7]Teikyo University, Japan, [8]The University of Tokyo, Japan

Development of synthetic materials is desired to prevent delayed union of bone fractures. Our series of animal studies have shown that a local application of fibroblast growth factor-2 (FGF-2) accelerates fracture healing through its mitogenic activity on mesenchymal cells, and our recent dose-escalation trial has revealed a dose-dependent effect of recombinant human FGF-2 (rhFGF-2; 0.2, 0.4, and 0.8 mg) in a gelatin hydrogel on bone union of patients with surgical osteotomy. Based on these results, we performed a randomized, double-blind, placebo-controlled trial in which patients with fresh and closed tibial shaft fractures of transverse or short oblique type were randomly assigned to three groups receiving a single injection of the gelatin hydrogel containing either 0 (placebo: P), 0.8 mg (low-dosage: L), or 2.4 mg (high-dosage: H) of rhFGF-2 into the fracture gap at the end of an intramedullary nailing surgery. The primary outcome was the time to bone union determined by extracortical bridging calluses on radiographs during 24 weeks. The sample size was calculated to be 23 per group having 90% power to show at least 20% advantage of the agent. Of 194 patients who visited 48 institutions for two years, 85 met the eligibility criteria, and 70 (24 in P, 23 each in L and H groups) completed the study. None of the baseline patient variables was significantly different among the three groups ($p>0.05$). The cumulative percentages of patients with bone union were higher in the rhFGF-2 treated groups ($p=0.031$ and 0.009 in L and H groups, respectively) than in the P group, although there was no significant difference between L and H groups

(p=0.776). The Cox proportional-hazards model showed that rhFGF-2 treatment, but not any of the baseline variables, was the sole significant factor for bone union (hazard ratio=1.94 and 1.85 in L and H groups, respectively). At 24 weeks, 4, 1 and 0 patients in P, L, and H groups, respectively, remained delayed union. The percentage of patients who achieved full-weight bearing without pain showed a tendency to be higher in the rhFGF-2-treated groups, although not statistically significant. There was no significant difference in the profiles of adverse events among the three groups, all of which had recovered before 24 weeks. In conclusion, a local application of the rhFGF-2 hydrogel accelerated healing of tibial shaft fractures with a safety profile. The optimum concentration of rhFGF-2 for clinical use may be around 0.8 mg.

Activation of the Kynurenine Pathway of Tryptophan Degradation Plays a Role in Osteoblastogenesis. Wei Li[1], Christopher Vidal*[1], Ralph Nanan[1], Brigitte Nanan[1], Gustavo Duque[2]. [1]Sydney Medical School-Nepean, The University of Sydney, Australia, [2]University of Sydney, Australia

Recent reports suggest that pharmacological inhibition of gut-derived serotonin (GDS), an end product of tryptophan degradation, is a potential bone anabolic treatment for osteoporosis. Since tryptophan degradation may play an important role in bone cells differentiation, in this study, we tested whether other alternative pathways for tryptophan degradation play a role in bone formation. To test our hypothesis, we selected interferon gamma (IFNγ) due to its potent anabolic effect on bone, its well known inhibitory effect on serotonin release and its stimulatory effect on tryptophan degradation in immune and cancer cell models. Human mesenchymal stem cells (MSC) were treated for one week with osteoblastogenesis induction media containing either IFNγ(1,10 and 100 nM) or vehicle alone. Undifferentiating MSC, Jurkat cells and human T lymphocytes were treated under the same conditions. Microarray analysis (Affymetrix), real time PCR, western blots and osteoblastogenesis assays (alizarin red, alkaline phosphatase) were performed. Microarray and real time PCR analysis showed a significant upregulation of the gene of indoleamine 2,3-dioxygenase (IDO), the initial enzyme in the kynurenine pathway of tryptophan degradation, in MSC under osteogenic conditions as compared with the non-differentiating cell types ($p<0.001$). Furthermore,whereas IFNγ treatment increased IDO expression in immune cells (2 fold), IDO expression was not significantly increased by IFNγ treatment in undifferentiating MSC. In addition, the induction of IDO in osteogenic conditions was significantly higher (9 fold) in the osteogenic differentiating MSC treated with an anabolic dose of IFNγ(100 nM)as compared with the untreated osteogenic differentiating MSC (4 fold) ($p<0.001$). This higher induction of IDO was associated with earlier and higher osteoblastogenesis. Finally, no changes in the serotonin synthesis pathway genes, including tryptophan hydroxylase, were identified in any of the cell conditions. In summary, in this study we have identified that tryptophan degradation through the kynurenine pathway is exclusively activated in MSC during osteogenic conditions. The anabolic effect of IFNγ on bone could be partially explained by the very potent stimulatory effect of IFNγ on IDO activity. In conclusion, activation of the kynurenine pathway could constitute a novel anabolic therapy for osteoporosis in the future.

Deficiency of Chemokine Receptor CCR1 Causes Osteopenia Due to Impaired Functions of Osteoclasts and Osteoblasts. Tadahiro Iimura[1], Akiyoshi Hoshino*[2], Akira Yamaguchi[1]. [1]Tokyo Medical & Dental University, Japan, [2]National Center for Global Health & Medicine, Japan

Chemokines are characterized by the homing activity of leukocytes to targeted inflammation sites. Recent research indicates that chemokines play more divergent roles in various phases of pathogenesis as well as immune reactions. A chemokine receptor, CCR1, and its ligands are thought to be involved in inflammatory bone destruction, but their physiological roles in the bone metabolism in vivo have not yet been elucidated. In this study, we investigated the roles of CCR1 in bone metabolism using CCR1-deficient mice. *Ccr1*$^{-/-}$ mice have fewer and thinner trabecular bones and low mineral bone density in cancellous bones. The lack of CCR1 affects the differentiation and function of osteoblasts. *Runx2*, *osteopontin*, and *osteonectin* were significantly upregulated in *Ccr1*$^{-/-}$ mice despite sustained expression of *osterix* and reduced expression of *osteocalcin*, suggesting less potency to differentiate mature osteoblasts. In addition, mineralized nodule formation was remarkably disrupted in cultured osteoblastic cells isolated from *Ccr1*$^{-/-}$ mice. Osteoclastogenesis induced from cultured *Ccr1*$^{-/-}$ bone marrow cells also decreased in number and size due to the abrogated cell-fusion. *Ccr1*$^{-/-}$ osteoclasts exerted no osteolytic activity concomitant with reduced expressions of *rank* and its downstream targets, implying that the defective osteoclastogenesis is involved in bone phenotype in *Ccr1*$^{-/-}$ mice. The co-culture of wild-type osteoclast precursors with *Ccr1*$^{-/-}$ osteoblasts failed to facilitate osteoclastogenesis. This result is most likely due to a reduction of the *rankl* expression. These observations suggest that the axis of CCR1 and its ligands are likely to be involved in crosstalk between osteoclasts and osteoblasts through modulating RANK-RANKL-mediated interaction.

Evidence that Osteoclast-derived Osteoactivin is a Novel Bone Coupling Factor: Transgenic Animal and In Vitro Studies. Matilda Sheng*[1], Jon Wergedal[2], Mehran Amoui[3], David Baylink[1], Subburaman Mohan[2], Kin-Hing William Lau[2]. [1]Loma Linda University, USA, [2]Jerry L. Pettis Memorial VA Medical Center, USA, [3]Jerry L. Pettis Mem. VAMC, USA

Our unpublished data suggest that osteoclast(Oc)-derived osteoactivin (OA) could function to couple bone resorption (BR) to bone formation (BF). To test this hypothesis, we first sought to define the effects of Oc-derived OA on BR. Oc produce an abundance of OA, a unique transmembrane protein. Our published in vitro studies indicate that Oc-derived OA stimulates BR activity of Oc. To confirm the effects of OA on BR in vivo, we generated a colony of transgenic (Tg) mice with targeted OA overexpression in cells of Oc lineage using a TRAP promoter. Marrow-derived Oc (md-Oc) of Tg mice showed ~2-fold increases (↑) in OA mRNA and protein ($p<0.05$ for each) compared to md-Oc of wild-type (WT) littermates. At 4 weeks old, Tg mice had significant ($p<0.05$) decrease (↓) in %bone (-21%) and ↑ in Oc # (+18%), %TRAP.PM (+28%), and Oc.BS (+34%). md-Oc of Tg mice were much larger (~2-fold) and had 2-fold ↑ in TRAP activity ($p<0.05$) than WT md-Oc. Resorption pits created by Tg md-Oc were also twice as large ($p<0.03$). Conversely, siRNA-mediated suppression of OA expression (by >60%) in RAW246.7-derived Oc reduced cell size (by 75%), cathepsin K and MMP9 expression (each by ~30%). To fulfill the requirements for a coupling factor (CF), Oc-derived OA should stimulate BF. In this regard, analyses of histomorphometric BF parameters of 8-week old male Tg mice revealed that Tg mice had a significantly ($p<0.05$ for each) ↑ in %TLS (~25%), MAR (~20%), and BF/BS (~25%) in cortical bone. Consistent with the literature that soluble OA is a stimulator of Ob differentiation, attached marrow cells of Tg mice showed >2-fold increase in bone nodule formation compared to WT controls. Condition medium (CM) of Tg md-Oc also produced ~2-fold ↑ on ALP activity of stromal cells compared with CM of WT md-Oc. Together our findings indicate that OA stimulates BR in vivo and in vitro and the OA derived from Oc stimulates BF both in vitro and in vivo, thereby fulfilling the definition of a CF. That the coupling of BF to BR is inherently complex process is supported by several types of evidence, including the fact that several CFs have been validly proposed. This study adds an additional CF candidate and thus places us one step closer to defining the signaling network necessary to understand this exceedingly important regulatory process which acts to promote the adequate structure and function of the skeleton and thereby prevent bone fragility diseases.

Muscle Derived Factors Influence the MLO-Y4 Osteocyte Response to Shear Stress. Nuria Lara*[1], Todd Hall[1], Letticia Brotto[1], Joedd Biggs[1], Cheng Lin Mo[1], Sandra Romero-Suarez[1], Marco Brotto[1], Lynda Bonewald[1], Mark Johnson[2]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri, Kansas City Dental School, USA

Sarcopenia and osteoporosis normally manifest as twin diseases of the musculoskeletal system during aging and may be interdependent. We hypothesized that muscle secretory factors enhance the positive effects of physical loading of bone by muscle and that these factors decrease with aging. To begin to test this hypothesis, conditioned media from C2C12 muscle cells and from primary muscle was tested on the activation of the PI3K/Akt pathway in response to fluid flow shear stress (FFSS) in the MLO-Y4 osteocyte cell line. The PI3K/Akt pathway was chosen as it mediates the effects of both the prostaglandin and b-catenin pathways, known to be important in osteocyte signaling. Conditioned media (CM) was collected from C2C12 cells grown in growth media to induce myoblast formation and from C2C12 cells induced to differentiate into myotubes using differentiation media (2.5% horse serum) for 7 days. Intact muscles from 12 month old wildtype mice, extensor digitorum longus (EDL) and soleus (SOL), were dissected, mounted, stretched and electrically stimulated to produce maximal tetanic force and ½ maximal tetanic force using an intermittent stimulation protocol to produce CM from these muscles. All CM was added to MLO-Y4 media at 10% final concentration. MLO-Y4 cells were subjected to FFSS (2 dynes/cm^2) for 2 hours in the presence or absence of CM, the cells collected, and western blotting performed using antibodies against phospho-Akt, Akt and the endogenous control, GAPDH. Activation of the PI3K/Akt pathway in response to FFSS was significantly increased in the presence of myotube CM (2-3 fold) above myoblast CM or MLO-Y4 media. PI3K/Akt activation in the presence of EDL CM was enhanced 2-3 fold above that of SOL CM or control media. These data demonstrate that mature muscle cells release factors that affect the response of MLO-Y4 osteocytes to fluid flow shear stress and that EDL muscle produce greater amounts of these factors compared to SOL muscle. These data suggest that physical loading of bone by muscle may involve more than loading and that factors released by muscle cells may be able to condition and/or regulate the response of osteocytes to loading.

Skeletal Phenotype of the Leptin Receptor-Deficient db/db Mouse. Garry Williams*[1], Karen Callon[2], Maureen Watson[2], Dorit Naot[2], Jessica Costa[2], Michelle Dickinson[2], Yaoyao Ding[2], Yu Wang[3], Ian Reid[2], Jillian Cornish[2]. [1]University of Auckland, Auckland School of Medicine, New zealand, [2]University of Auckland, New zealand, [3]Hong Kong University, Hong kong

Leptin is a major hormonal product of the adipocyte which regulates appetite and reproductive function through its hypothalamic receptors. It has now become clear that the skeleton has emerged as an important site of action of leptin. The signalling form of the leptin receptor has been found in several cell types including human osteoblasts, rat osteoblasts and human chondrocytes. Previously we have shown leptin to be an anabolic factor in vitro, stimulating osteoblast proliferation and inhibiting osteoclastogenesis. Leptin increases bone mass and reduces bone fragility when administered peripherally but has an indirect inhibitory effect on bone mass via the hypothalamus when administered directly into the central nervous system. The net effect of leptin on bone mass in vivo remains controversial.

Data from animal models where there is an absence of either leptin production (ob/ob) or its receptor (db/db) have been contradictory. In this study we compared the bone phenotype of leptin receptor-deficient (db/db) and wild-type (WT) mice. Micro-CT analysis was done on proximal tibiae using a Skyscan 1172 scanner. Db/db mice had significantly reduced trabecular bone volume (13.0 $\pm$ 1.62% in WT vs 6.01 $\pm$ 0.601% in db/db, p=0.002) and cortical bone volume (0.411 $\pm$ 0.0215mm^3 in WT vs 0.316 $\pm$ 0.00353mm^3 in db/db, p=0.0014), trabecular thickness (0.0484 $\pm$ 0.00107mm in WT vs 0.0451 $\pm$ 0.000929mm in db/db, p=0.041) and trabecular number (2.68 $\pm$ 0.319mm^{-1} in WT vs 1.343 $\pm$ 0.1478mm^{-1} in db/db, p=0.0034). Additionally, we have determined the material properties of db/db cortical bone by three-point bending and at the nanoscale as measured by nano-indentation, showing that the bone strength (13.3 $\pm$ 0.280N in WT vs 7.99 $\pm$ 0.984N in db/db, p=0.0074), and the reduced modulus, a measure of a material's stiffness (28.5 $\pm$ 0.280GPa in WT vs 25.8 $\pm$ 0.281GPa in db/db, p<0.0001) were significantly reduced.

These results demonstrate that in the absence of leptin signalling there is reduced bone mass indicating that leptin indeed acts in vivo as a bone anabolic factor, mimicking the in vitro results. This concurs with the results from peripheral administration of leptin and together with the fact that leptin is produced peripherally by adipocytes in fat tissue and the bone marrow, suggests that the direct effects of leptin on bone cells over-ride the central effects.

The Role of Nell-1 in Cartilage Development and Differentiation. Ronald Siu*[1], Wei Wei Chen[2], Xinli Zhang[1], Benjamin Wu[1], Kang Ting[1], Cymbeline Culiat[3], Chia Soo[1]. [1]University of California, Los Angeles, USA, [2]Zhejiang University, China, [3]Oak Ridge National Laboratory, USA

Nell-1 (a protein strongly expressed in neural tissue encoding EGF-like domain; novel epidermal growth factor (EGF)-like protein) is a potent osteochondrogenic growth factor. We have shown that Nell-1 (1) induces significant bone formation *in vivo*, (2) is a direct target of the master osteogenic transcription factor Runx2, and (3) promotes proliferation and maintenance of the differentiated state of chondrocytes *in vitro* and *in vivo*. Meanwhile, a chemically induced nonsense point mutation in the mouse *Nell-1* gene severely disrupts Nell-1 expression. Homozygous *Nell-1* deficient (ND) mice die perinatally and exhibit numerous skeletal abnormalities associated with cartilage and connective tissue. The purpose of this study is to elucidate the effect of *Nell-1* in cartilage development.

Histology revealed abnormal proximal displacement of the patella from its normal position at the distal end of the femur as well as compression and structural abnormalities in the intervertebral discs (Figure 1). These phenotypes resemble the widespread laxity of connective tissue observed in Ehlers-Danlos syndrome (EDS) in humans, a cartilage disease characterized by extreme flexibility of joints. Indeed, mutations of type V collagen (*Col5a1*) and tenascin X (*Tnxb*) are associated with EDS, and expression of these genes is reduced in ND mice, possibly explaining this phenotype.

To identify molecular mediators of Nell-1 function in chondrocytes, we performed microarray analysis comparing Nell-1 and vehicle-treated ATDC5 prechondrocytic cells, which revealed nuclear factor of activated T-cells cytoplasmic 2 (*Nfatc2*) as a Nell-1 primary response gene. Adenoviral overexpression of wild type or dominant-negative Runx2 revealed that Runx2 is required for *Nfatc2* induction. Recombinant Nell-1 protein inhibits hypertrophy of ATDC5 cells, similar to the function of Runx2 in the perichondrium, but this inhibition is reversed by siRNA knockdown of *Nfatc2* expression. Finally, we found that *Nell-1*, *Runx2*, and *Nfatc2* are co-expressed in the femoral perichondrium of wild type mice, but expression of all three genes were diminished in ND mice (Figure 2), suggesting that Nell-1 is required for *Runx2* and *Nfatc2* expression *in vivo*.

Together, our results suggest important roles for Nell-1 in normal chondrogenesis and cartilage organization during development and possibly also during postnatal tissue repair.

IGF-I Signaling Regulates the Interaction of Osteoblasts and Osteoclasts via the RANKL/RANK and Ephrin B2/EphB4 Signaling Pathways. Yongmei Wang*[1], Hashem ElAlieh[2], Daniel Bikle[1]. [1]Endocrine Research Unit, Division of Endocrinology UCSF, USA, [2]University of California, San Francisco/VA Medical Center, USA

We and others have shown that insulin-like growth factor-I (IGF-I) signaling stimulates both osteoblast (OB) differentiation and osteoclastogenesis and is required for the communication between OBs and osteoclasts (OCLs). However, the mechanisms underlying these processes have not been evaluated. Recent studies found that ephrin B2-EphB4 bidirectional signaling mediates OB and OCL differentiation and communication. To address whether such signaling is involved in IGF-I action, we used knockout mouse models and in vitro culture systems to investigate the mechanism by which IGF-I signaling regulates OB differentiation and their interaction with OCLs focusing on the roles of ephrin B2/EphB4 and RANKL/RANK.

In wild-type (WT) bones, immunohistochemistry demonstrated that ephrin B2 is expressed in OBs and OCLs, while EphB4 is expressed only in OBs. The expression of ephrin B2 and EphB4 was dramatically decreased in OBs and OCLs in global IGF-I knockout (IGF-IKO) mice. In vitro, IGF-I (10 ng/ml) increased the mRNA levels of ephrin B2 and EphB4 in bone marrow stromal cell (BMSC) culture (day 14). Knockdown of EphB4 by siRNA (siEphB4) at day 12 of BMSC culture significantly decreased the mRNA levels of alkaline phosphatase (AP) and osteocalcin (OCN) by 53% and 72%, respectively. Similar results were found for ephrin B2 knockdown (siEphrinB2). IGF-I increased the mRNA levels of AP (68%) and OCN (330%) in control cultures, but induced less or no change in the siEphbrinB2 and siEphB4 cultures. Blocking the interaction of EphB4 and ephrin B2 by TNYL-RAW (a specific antagonist of EphB4) in the OB-OCL co-cultures resulted in the formation of fewer (60% decreased) TRAP positive cells, and the TRAP positive cells that did form contained only one or two nuclei. IGF-I increased OCL number by 40% in control co-cultures, but this effect was abolished in the co-cultures treated by TNYL-RAW. In the control co-cultures, IGF-I increased the mRNA levels of RANKL (49%) RANK (171%) and NFATc1 (30%), respectively, while decreased the mRNA levels of OPG (80%). These effects were likewise blunted in the cultures treated by TNYL-RAW.

Our data indicate that IGF-I promotes OB and OCL differentiation via both ephrin B2/EphB4 and RANKL/RANK signaling by stimulating ephrin B2 production in OBs and OCLs, EphB4 in OBs as RANKL in OBs and RANK in OCLs. These changes enhance OB/OCL communication leading to their mutually dependent differentiation.

FR0194

Thyroid Hormone (T3) Acting via TRα1 is a Key Regulator of IGF-I Transcription in Osteoblasts and Bone Formation in Mice. Weirong Xing*[1], Sheila Pourteymoor[2], Jon Wergedal[3], Carlin Long[4], Graham Williams[5], Subburaman Mohan[3]. [1]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, [2]JL Pettis Memorial VA Medical Center, USA, [3]Jerry L. Pettis Memorial VA Medical Center, USA, [4]University of Colorado Health Sciences Center, USA, [5]Molecular Endocrinology Group, Division of Medicine & MRC Clinical Sciences Centre, Imperial College, United Kingdom

It is becoming increasingly established that T3 is essential for normal skeletal development. Since recent Cre/loxP studies reveal a key role for bone-derived IGF-I in regulating peak bone mass, and since IGF-I expression is reduced in mouse models of T3 deficiency, we hypothesized that T3 effects on skeletal growth result from a T3-induced increase in local IGF-I action. Accordingly, T3 treatment increased IGF-I expression (5-15 fold) at both mRNA and protein levels in a dose and time-dependent manner in osteoblasts (Obs). To determine which T3 receptor (TR) isoform is involved in mediating T3 effects, we examined TR expression levels and found greater expression of TRα1 than TRα2 and TRβ1 and no detectable levels of TRΔα1, TRΔα2 or TRβ2 expression in Obs. Transfection of MC3T3-E1 cells with TRα siRNA led to a 70% reduction in TRα1 and TRα2 expression, no effect on TRβ1 expression, and inhibition (>50%, $P<0.01$) of T3-induced IGF-I expression. Adenovirus-mediated overexpression of TRα1 markedly enhanced T3-induced IGF-I expression compared to β-gal control in MC3T3-E1 cells. The rapid effect of T3 on IGF-I expression suggested a direct effect of T3 on IGF-I gene transcription. Accordingly, IGF-I mRNA half-life was not altered in T3 treated cultures in the presence of actinomycin D. Since a putative T3 response element (TRE), located in the first intron 2113-2152 nucleotides from the transcription start site, was highly conserved among rat, mouse and human IGF-I genes, we inserted a 155 bp portion of the mouse Igf-I gene containing the putative TRE upstream of a thymidine kinase promoter (pTAL-Luc reporter) and found increased luciferase activity (2.3 fold, $P<0.01$) after 48h treatment with T3. Furthermore, nuclear extracts from T3 treated MC3TE-E1 cells bound specifically to the putative TRE in gel mobility shift assays. We next evaluated the role of IGF-I in mediating T3 biological responses using metatarsal organ cultures derived from newborn conditional IGF-I knockout (KO) mice in which IGF-I is disrupted in type I collagen producing Obs and corresponding wild type (WT) mice. Lack of IGF-I expression in Obs caused a marked reduction in 10 ng/ml T3-induced increase in mineralized length (25% in WT vs 8% in KO vs vehicle, $P<0.01$) after 10 days. Conclusions: 1) T3 via TRα1 regulates IGF-I gene transcription in Obs; and 2) T3 effects on skeletal growth are mediated in part via T3-induced local IGF-I expression.

Bone-specific Calibration of Extracellular Matrix Material Properties by TGF-β and Runx2 is Required for Hearing. Jolie Chang*[1], Delia Brauer[2], Carol Chen[1], Omar Akil[1], Guive Balooch[3], Mary Beth Humphrey[4], Alexandra Porter[2], Robert Ritchie[5], Sally Marshall[1], Grayson Marshall[1], Lawrence Lustig[1], Tamara Alliston[1]. [1]University of California, San Francisco, USA, [2]Imperial College, United Kingdom, [3]LBNL, USA, [4]University of Oklahoma Health Sciences Center, USA, [5]UC Berkeley, USA

The mineralized collagen matrix of bone has unique material properties that are anatomically distinct, such that the elastic modulus of bone matrix ranges from 15 GPa in calvariae to 30 GPa in cochleae. In addition to their structural importance, the material properties of the extracellular matrix (ECM) are powerful determinants of cell function. Like biochemical signals, properties such as elastic modulus direct cell lineage selection, differentiation, and gene expression. Stiff matrices drive mesenchymal stem cells to undergo osteogenic differentiation, while compliant matrices promote neurogenic differentiation. Conversely, subtle changes in a tissue's ECM material properties disrupt cell proliferation and drive disease progression and tumorigenesis. Therefore, mechanisms that regulate ECM material properties are critically important in development and in disease. However, the molecular mechanisms that establish tissue-specific material properties and couple them to healthy tissue function are largely unknown.

Because healthy bone exhibits a range of material properties, the skeleton serves as an ideal model system to define mechanisms that establish ECM material properties, and to test the hypothesis that ECM material properties are calibrated for tissue-specific function. Using nanonindentation of bone from *Runx2*+/- mice, we identify Runx2 as a lineage-specific transcription factor that helps to establish the material properties of the ECM. We find that Runx2 regulates the material properties of bone matrix through the same TGF-β-responsive pathway that controls osteoblast differentiation. In the ear, inadequate levels of Runx2 activity compromise the unique material properties of cochlear bone and cause hearing loss, likely providing a basis for the unexplained cause of sensorineural hearing loss in human cleidocranial dysplasia. Remarkably, osteoblast-specific inhibition of TGF-β signaling rescues both the material properties and hearing loss of $Runx2^{+/-}$ mice. While this work advances our understanding of the control of bone matrix quality and the role of bone in hearing, it also suggests a paradigm by which signaling pathways and lineage-specific transcription factors cooperate to define the functionally essential material properties of a specific tissue.

Classical TGFβ Signaling in Osteoclasts is Not Required for Maintenance of Bone Volume and Architecture: Evidence from Osteoclast-Specific TGFβRII Null Mice. Daniel Perrien*[1], Jeffry Nyman[1], Ying X. Wang[2], Chad S. Boomershine[2]. [1]Vanderbilt University Medical Center, USA, [2]Vanderbilt University, USA

Transforming growth factor beta (TGFβ) is a critical regulator of osteoblast differentiation and bone turnover and has been implicated in postmenopausal osteoporosis and cancer induced osteolysis. Numerous *in vitro* studies have reported direct, but often contradictory, effects of TGFβ on osteoclast (OCL) differentiation and apoptosis. However, the physiological relevance of TGFβ signaling in OCL to bone volume and density *in vivo* has not been demonstrated. TGFβ has two known signaling pathways: the well characterized classical pathway that requires binding of both TGFβRI and TGFβRII to activate Smad signaling, and the poorly characterized nonclassical pathway utilizing TGFβRIII/betaglycan. Based on cell culture studies, it was hypothesized that loss of TGFβ signaling via the classical TGFβRI/II pathway in OCL would inhibit osteoclast differentiation, thereby increasing bone volume and reducing turnover,. To test this hypothesis, LysM-cre mice were crossed with $TGF\beta RII^{flox/flox}$ mice to delete the gene encoding TGFβRII specifically in OCL and macrophages ($TGFRII^{OCL-/-}$). Skeletal effects were determined by microCT and histomorphometric evaluation of metaphyseal trabecular and diaphyseal cortical bone in the femora of 3 month old female wildtype (WT) and $TGFRII^{OCL-/-}$ mice (n=10 and 15, respectively). Surprisingly, deletion of TGFβRII in OCL's did not significantly alter trabecular bone volume (BV/TV, 0.060 +/-0.034 vs. 0.050 +/- 0.015; p=0.306), number, thickness, separation, or connectivity density (all $p>0.10$). Similarly, cortical thickness, cross sectional area, and polar moment of inertia were not significantly altered in $TGF\beta RII^{OCL-/-}$ mice. However, the material BMD of cortical, but not trabecular, bone was significantly increased ($p<0.025$) in $TGF\beta RII^{OCL-/-}$ mice (1283.1 mgHA/ccm +/-26.6) compared to WT (1258.2 mgHA/ccm +/-21.6). The bending strength and modulus of the femoral diaphysis, as determined by three point bending, were also not significantly altered in $TGF\beta RII^{OCL-/-}$ mice. These data demonstrate that classical TGFβ signaling via the receptor I/II complex in cells of the macrophage lineage is not required for normal skeletal development and homeostasis and calls into question the physiological relevance of previous *in vitro* studies concerning the effects of exogenous TGFβ on OCL development, function, and apoptosis. However, the effect on cortical mineral density suggests that TGFβ signaling in OCL may have an indirect effect on osteoblast activity and matrix mineralization.

Tamoxifen-Induced Deletion of Smad4 in Osteoblasts Enhances Proliferation in the Periosteum, Growth Plate, and Bone Marrow. Valerie Salazar*[1], Gabriel Mbalaviele[2], Roberto Civitelli[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

Smad4, a transcription factor of the TGFβ/BMP pathway, can physically interact with components of the canonical Wnt pathway. We previously reported that siRNA-mediated knockdown of Smad4 in C3H10T1/2 cells synergistically enhances the ability of Wnt3a or activated β-catenin to stimulate *Cyclin-D1* transcription. We also find that Smad4 antagonizes pro-mitotic signals from canonical Wnts or activated β-catenin. To assess how Smad4 affects osteoblast proliferation *in vivo*, we mated $Smad4^{flox/flox}$ mice to *Osx-CreERT2* (kindly provided by T Kobayashi and H Kronenberg, Massachusetts General Hospital, Boston, MA. USA) and then evaluated BrdU incorporation in bone following Tamoxifen-induced, conditional ablation of *Smad4* in Osterix^{+} cells. Macroscopic examination of β-galactosidase activity in bones from $ROSA26^{fl(LacZ)}$; *Osx-CreERT2* mice indicates that 5 doses of Tamoxifen (2 mg/day, i.p.) are sufficient to induce substantial gene recombination in femurs and tibias of 6 week old male mice. On histology, we find strong β-galactosidase activity in a high percentage of cuboidal cells lining cortical and trabecular bone surfaces. By contrast, Tamoxifen treatment activates recombination in very few osteocytes or chondrocytes, and virtually no bone marrow cells. Thus, *Osx-CreERT2* represents a good model to achieve inducible and post-natal gene recombination in osteoblasts. We used immunofluouresence to detect BrdU incorporation in Tamoxifen-treated control (*Osx-CreERT2*) or *Smad4 cKO* (*Smad4flox/flox; Osx-CreERT2*) mice. Proliferation was altered in several compartments within the bone marrow microenvironment of *Smad4 cKOs*. Tamoxifen-induced ablation of *Smad4* in osteoblasts greatly increased the number of BrdU-positive cells in the primary and secondary spongiosa, as well as proliferating chondrocytes in the growth plate. Surprisingly, acute loss of *Smad4* affected proliferation of osteoblasts depending on resident location within the bone. While proliferation greatly decreased on the endosteum, it was markedly activated on the periosteum. In summary, the *Osx-CreERT2* mouse model efficiently induces post-natal gene recombination in osteoblasts. Tamoxifen-induced ablation of *Smad4* in osteoblasts alters proliferation in the osteogenic, chondrogenic, and bone marrow compartments. These data suggest Smad4 functions in osteoblasts to regulate the proliferative capacity of discrete populations within the bone marrow microenvironment, potentially through indirect mechanisms.

Absence of Bone Remodeling Compartment Canopies Correlates with an Arrested Reversal Phase and Deficient Bone Formation in Post-menopausal Osteoporosis. Ellen Hauge[1], Thomas Andersen*[2], Jens Bollerslev[3], Per Kjærsgaard-Andesen[4], Jean-Marie Delaisse[5]. [1]Aarhus University Hospital, Denmark, [2]Vejle Hospital, IRS-CSFU, University of Sourthern Denmark, Denmark, [3]National University Hospital, Norway, [4]Department of Orthopaedic Surgery, Vejle Hospital, University of Sourthern Denmark, IRS-CSFU, Denmark, [5]Vejle Hospital, University of Southern Denmark, Denmark

The reason why bone reconstruction is deficient during bone remodeling in post-menopausal osteoporosis (PMO) remains poorly understood, despite intensive research on osteoclasts (OC) and osteoblasts (OB), and despite detailed histomorphometry of bone surfaces (BS). Based on observations on normal, primary hyperparathyroidism (PHPT), myeloma, and Cushing patients, we showed recently that bone remodeling compartments (BRC) are critical for bone reconstruction during remodeling. BRCs are formed by a canopy of flattened OB-like cells separating the remodeling area from the marrow cavity, and associated with capillaries. Here we investigated whether the BRC concept can be extended to PMO.

Masson trichrome-stained sections of cancellous bone from 23 PMO patients and respectively 10 and 4 aged-matched controls and PHPT were assessed for ES, OS, BS, Oc.S, Ob.S, and Reversal cell surfaces (Rvc.S), identified as mononucleated cells on ES. Each parameter was related to the presence or absence of BRC canopies.

Controls and PHPTs showed more than 75% of ES/BS under BRC canopies, 8 of the 23 PMOs were similar to controls and PHPTs (PMO+ group), whereas the other 15 PMOs showed less than 75% of ES/BS under BRC canopies (PMO- group). Interestingly, the PMO- showed significantly less Ob.S/BS (8.8 vs. 14.3 %) and more Rvc.S/BS (13.6 vs. 8.3 %) than the PMO+, which were similar to controls and PHPTs. Oc.S/BS was unaffected. This thus indicates that in the absence of BRC, bone reconstructing OBs are decreased, even if RVCs were recruited to the remodelling sites. Interestingly also, when analyzing specifically the Rvc.S away from any visible resorption or reconstruction event, PMO- showed an increased extent of these specific Rvc.S compared to PMO+, controls, and PHPTs (6.6 vs. below 3.1 %). This observation can best be explained by an increased frequency of remodelling events that had stopped at the level of the reversal phase. Since RVCs are commonly considered as the OB progenitors, this would mean that RVCs are arrested and do not differentiate into bone forming OBs

In conclusion, there is a strict link between BRCs and formation of new bone during bone remodeling in PMO. The bone remodeling step that is most critically affected by the absence of BRCs is the reversal phase, which is arrested, and does not progress to OB differentiation and bone formation. Prevention of reversal phase arrest could be a future target for PMO treatment.

Bone-resorbing Osteoclasts Secrete A Factor That Stimulates Osteoblastic Differentiation. Sunao Takeshita*[1], Toshio Fumoto[1], Kyoung-ae Park[1], Hiroyuki Aburatani[2], Shigeaki Kato[2], Masako Ito[3], Kyoji Ikeda[1]. [1]National Center for Geriatrics & Gerontology, Japan, [2]University of Tokyo, Japan, [3]Nagasaki University Hospital, Japan

Bone is constantly remodeled through resorption of old bone by osteoclasts and deposition of new bone by osteoblasts. The net bone mass is regulated through a balance between preceding resorption and subsequent formation; however, the factor(s) and mechanism that couple the two processes are not fully understood. We hypothesized that such coupling factor is secreted or presented by osteoclasts and stimulates osteoblastic differentiation. Through global gene expression analysis during osteoclastogenesis, we have identified a protein, named couplin, that is secreted specifically by mature osteoclasts actively engaged in bone resorption and acts on marrow stromal cells to stimulate osteoblastic differentiation *in vitro* and bone formation *ex vivo*. The expression of couplin in bone decreases with aging and alendronate treatment, and increases in a high bone turnover state, such as PTH treatment. Loss- and gain-of function experiments by mouse genetics revealed that the deletion of the couplin gene in osteoclasts results in low bone mass due to insufficient bone formation, while mice overexpressing couplin are protected from bone loss with aging. Thus, couplin is a factor that relays from bone-resorbing osteoclasts to osteoblastic bone formation, thereby regulating the rate of bone turnover.

FR0204

Co-translocation of the Osteoclastogenic Estrogen Element Binding Protein and ß-Catenin to the Nucleus of Osteoblasts is Regulated by Wnt Signaling. Hong Chen*[1], Mark Nanes[2], Linda Gilbert[3], Martin Hewison[4], John Adams[5]. [1]VA / Emory University School of Medicine, USA, [2]VA Medical Center & Emory University, USA, [3]VA Medical Center GA, USA, [4]UCLA, USA, [5]University of California, Los Angeles, USA

The heterogeneous nuclear ribonucleoprotein (hnRNP)-like estrogen response element binding protein (ERE-BP) is a nucleic acid binding protein that functions as a competitor with estrogen receptor α (ERα) for occupancy of target gene estrogen response elements (ERE). Here we report that in bone, ERE-BP can also act independently of estradiol-ERα to stimulate osteoclastogenesis. Overexpression of ERE-BP promotes osteoclastogenesis by stimulating RANKL (7-fold) and RANK expression (3-fold) in osteoblasts(OB) and osteoclast precursor RAW cells, respectively. ERE-BP directly stimulates RANKL transcription 2 fold as shown in transient transfection assays utilizing a mouse RANKL promoter luciferase reporter. In contrast, silencing ERE-BP decreases osteoblastic RANKL promoter activity. Co-cultures of bone marrow cells with ERE-BP lentevirus-transducted ST-2 stromal cells induced formation of multinucleated, TRAP+, calcitonin receptor-expressing cells and increased calcium resorption from bone slices by 22% ($p<0.01$). Osteoprotegerin(OPG) expression and ratio of OPG/RANKL were decreased in the ERE-BP co-culture system. Wnt signaling has been suggested to influence osteoclastogenesis in genetic models that silence β-catenin and concomitant effects on the regulation of RANKL. To determine if ERE-BP interacts with Wnt/β-catenin signaling, immunofluorescent staining of β-catenin and ERE-BP was performed in preosteoblastic MC3T3 cells. ERE-BP and β-catenin were co-localized in the cytoplasm of unstimulated cells. Co-immunoprecipitation with either anti-ERE-BP or anti-β-catenin antibody resulted in reciprocal pull-down from whole OB cell extracts. Stimulation with Wnt3a-conditioned medium or the GSK3β inhibitor LiCl for 4 hours resulted in translocation and co-localization of β-catenin and ERE-BP in the nucleus. ERE-BP overexpression in OBs also stimulated the movement of β-catenin to the nucleus. ERE-BP expression did not affect β-catenin mRNA levels. Taken together, these results indicate that: 1] ERE-BP stimulates osteoclastogenesis and bone resorption, 2] ERE-BP and β-catenin co-chaperone one another to the nuclear compartment of OBs; 3] the co-translocation of ERE-BP and ß-catenin to the nucleus is regulated by Wnt signaling. We therefore hypothesize that ERE-BP can influence bone turnover not only via disruption of ERα signaling, but also via interaction with the Wnt/β-catenin pathway.

Genetic Dissection of the Molecular Events Taking Place in Osteoblasts and Triggered by Leptin Signaling in the Brain. Gerard Karsenty, Daisuke Kajimura*. Columbia University, USA

A large body of evidence has identified leptin as an important, negative regulator of bone mass accrual that acts through a neural relay to eventually affect bone

formation. A major mediator linking leptin signaling in the brain to bone cells is the sympathetic nervous system acting through the *Adrb2* expressed in osteoblasts. Although some aspects of the sympathetic signaling in osteoblasts have emerged, there are still many steps that are unknown. To address this question, we generated and analyzed an allelic series of cell-specific gene deletion in the mouse. Extending previous results, we show here that an osteoblast-specific deletion of the *Adrb2*, the only adrenergic receptor expressed in osteoblasts, results in a high bone mass phenotype caused by an increase in bone formation and a decease in bone resorption parameters. Moreover and unlike what is observed in wild type mice, intracerebroventricular (ICV) infusion of leptin could not decrease bone mass in the $Adrb2_{osb}$ -/- mice. These results demonstrate formally that the sympathetic tone, acting through *Adrb2* expressed in osteoblasts, is a mediator of leptin regulation of bone mass. Next, we generated an osteoblast-specific deletion of *Creb*, a transcription factor and a major downstream target of sympathetic signaling in many cell types. $Creb_{osb}$ -/- mice were also resistant to the deleterious effect of leptin ICV infusion on bone mass. *cMyc* is a well characterized downstream target of Creb that also regulates cell proliferation. As expected, deletion of *cMyc* in osteoblasts decreased their proliferation, but also abrogated the deleterious effect of leptin ICV infusion on bone formation. Lastly, through the generation and studies of several compound heterozygous mice, we could establish the existence of a genetic cascade taking place in osteoblasts, downstream of leptin signaling in the brain and that includes *Adrb2*, *Creb and cMyc*. Hence, this study provides a complete molecular road maps explaining how, under the control of leptin, sympathetic signaling in osteoblasts regulates osteoblast proliferation and bone formation.

Histone Deacetylase Inhibition Causes Bone Loss. Meghan McGee-Lawrence*[1], Angela L. McCleary-Wheeler[1], Minzhi Zhang[1], Bridget A. Stensgard[1], Jane Lian[2], Jennifer Westendorf[1]. [1]Mayo Clinic, USA, [2]University of Massachusetts Medical School, USA

Histone deacetylase inhibitors (HDIs) are used clinically to treat cancer, epilepsy, and other conditions. Their effects on the mineralized skeleton are not well understood. In vitro, histone deacetylase inhibition accelerates osteoblast maturation and induces osteoclast apoptosis. Paradoxically, long-term in vivo administration of the HDI valproate, such as for the treatment of epilepsy, reduces bone mineral density and increases fracture risk. The purpose of this study was to determine the effects of the clinically relevant pan HDI, suberoylanilide hydroxamic acid (SAHA; Vorinostat), on bone mass and cellular activity in vivo.

Seven week-old male C57BL/6 mice received daily SAHA (100 mg/kg) or vehicle (PEG400/DMSO) intraperitoneal injections for 4 weeks. All animals also received dual calcein injections prior to sacrifice. Western blots on spleen lysates for acetylated histone 3 confirmed HDI activity in the SAHA-treated mice. Micro-computed tomography revealed that SAHA induced significant trabecular bone loss in the distal femoral metaphysis, as evidenced by decreases in bone volume fraction (-22%), trabecular number (-9%), and apparent mineral density (-21%), and an increase in trabecular separation (+11%) (Fig 1). Cortical bone at the femoral midshaft was not affected by SAHA. Serum levels of P1NP, a global marker of bone formation, were decreased (-23%) in SAHA-treated mice. Expression levels of osteoblastic genes including osteocalcin and osteopontin were also lower following SAHA treatment. SAHA reduced histological measures of osteoblast number; however, it increased local indices of osteoblast activity including mineral apposition rate (MAR) and bone formation rate (BFR/BS). Neither serum (TRAcP 5b) nor histological (Oc.S/BS) markers of osteoclast number were affected by SAHA. Our data suggest that SAHA causes bone loss by reducing overall osteoblast number, even while increasing activity of pre-existing committed osteoblasts. These data support the hypothesis that HDIs negatively affect the proliferation, survival and/or pluripotency of mesenchymal stem cells while simultaneously promoting differentiation and increased activity of cells already committed to the osteoblastic lineage. This effect could contribute to the bone loss observed both in our study and seen clinically after long-term administration of HDIs.

Loss of *Connexin43* in Mature Osteoblasts and Osteocytes Results in Delayed Mineralization and Bone Remodeling During Fracture Healing. Alayna Loiselle*[1], Andrew Billingsley[1], Emmanuel Paul[1], Yue Zhang[2], Henry Donahue[3]. [1]Penn State Hershey, USA, [2]Penn State University, USA, [3]The Pennsylvania State University College of Medicine, USA

Connexin 43 (*Cx43*) is the most abundant gap junction protein in bone, and regulates osteoblast differentiation. Mice with osteoblast/osteocyte specific (Osteocalcin-Cre) loss of Cx43 display decreased gap junctional intercellular communication, bone density and cortical thickness. The purpose of this study was to examine the role of *Cx43* in mature osteoblasts during fracture healing, and test the hypothesis that loss of *Cx43* results in decreased osteoblast differentiation, and a delay in fracture healing. A closed fracture was produced by three-point bending in Osteocalcin-Cre+; $Cx43^{flox/flox}$ (KO) and Cre- $Cx43^{flox/flox}$ (WT) mice. Healing was assessed by μCT, histology and *in situ* hybridization.

A bridging callus was present in WT and KO mice 14 days after fracture, with Alcian blue staining of the cartilaginous callus in both groups. By 21 days, Alcian Blue and *Col2* positive cells were still present in the fracture callus of KO mice indicating a persistence of cartilage. In contrast, the callus in WT mice had been mineralized, and had abundant *Osteocalcin* expression indicating mature osteoblasts. The total volume of KO fractures was significantly greater than WT fractures at this time (KO: 9.47 ± 0.37; WT: 4.15 ± 0.17; $p=0.017$) consistent with a larger callus volume. Using a novel μCT analysis to identify remodeling bone, we found that high density BV/TV was decreased in WT mice compared to KO (0.05 ± 0.02; 0.157 ± 0.012, $p=0.014$), indicating more remodeling in WT bones.

At 28 days a large mineralized callus was still present around the fracture site of KO animals, while the callus had been remodeled in WT mice. Additionally, there was still expression of *RANKL* and *OPG* in KO callus, indicative of osteoclastogenesis and active bone remodeling, whereas *RANKL* and *OPG* expression had decreased in WT fractures. At 35 days after fracture, the callus in KO mice had been nearly completely remodeled, however areas of woven bone remained.

These data indicate that loss of *Cx43* in mature osteoblasts results in delayed completion of endochondral bone formation and bone remodeling during fracture healing. These studies identify a novel role for the gap junction protein *Connexin 43* during fracture healing, suggesting that loss of *Cx43* can result in delayed mineralization and remodeling due to decreased osteoblast differentiation. Therefore, enhancing *Cx43* expression or gap junctional intercellular communication may provide a novel means to enhance fracture healing.

Osteoclast Secretion of the Chemokine Sphingosine-1-Phosphate is Crucial for Recruitment of Osteoblast Lineage Cells. Patrick Quint*[1], Moustapha Kassem[2], Jennifer Westendorf[3], Sundeep Khosla[4], Merry Jo Oursler[3]. [1]Mayo Clinic Rochester, USA, [2]Odense University Hospital, Denmark, [3]Mayo Clinic, USA, [4]College of Medicine, Mayo Clinic, USA

Bone is a dynamic tissue that continuously remodels and, under most conditions, resorbed bone is nearly precisely replaced in location and amount by new bone. This laboratory is investigating how preosteoblastic cells are recruited to the site of bone degradation following the resorption phase of bone turnover. Using ten-fold concentrated osteoclast conditioned medium, we observed that osteoclasts release factors that stimulate preosteoblastic stromal cells' mineralization. To determine candidate osteoclast coupling factors, we compared gene expression between preosteoclasts and mature osteoclasts and determined that Sphingosine-1-phosphate 1 (SPHK1) was upregulated during differentiation, and thus may contribute to osteoclast influences on stromal cells. The enzymatic product of SPHK1 is the chemokine sphingosine-1-phosphate (S1P), which is too small to be concentrated in the conditioned media in the above experiment. To determine whether low molecular weight coupling factors contribute to mineralization stimulation, we compared effects of concentrated verses unconcentrated conditioned media on mineralization of mouse calvarial cells and human bone marrow stromal cells overexpressing telomerase (hMSC-TERT cells). Mineralization stimulation by unconcentrated conditioned medium was nearly the same as concentrated conditioned medium (Figure 1). As an early step in preosteoblast recruitment, stromal cells move to the vicinity of the bone surface. Cell movement can be either random (chemokinesis) or directed toward a stimulus (migration). We therefore compared calvarial cells for chemokinesis and migration responses to concentrated and unconcentrated osteoclast conditioned media. Both conditioned media stimulated chemokinesis and migration. Interestingly, the unconcentrated conditioned medium stimulation level was over 80% of that of the concentrated conditioned medium. These data supported that much of the stimulatory effect was due to a small molecule and we therefore examined the role of S1P in hMSC-TERT cell chemokinesis and migration. A S1P receptor agonist stimulated chemokinesis and migration in both osteoclast conditioned media and control media (osteoclast precursor conditioned media) whereas the receptor antagonist suppressed chemokinesis and migration when added to osteoclast conditioned media.

These data support that the chemokine S1P is likely to contribute coupling of bone formation to bone resorption.

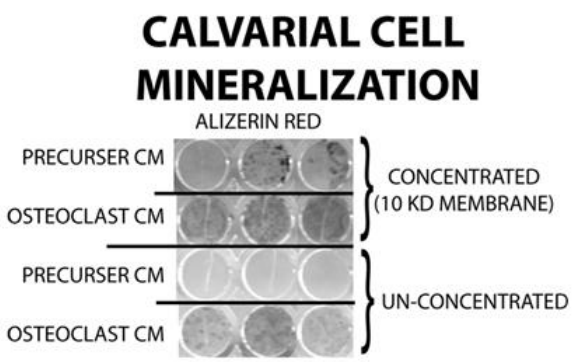

Figure 1. Un-concentrated or 10-fold concentrated conditioned media (CM) from either osteoclast precursors or mature osteoclasts were used to feed calvarial cells for 14 days. Cells were then fixed and stained with Alizerin red to visualize mineralization.

Figure 1: Mineralization of Calvarial Cells

Retinaldehyde Dehydrogenase 1 Deficiency Promotes Osteoblastogenesis and Increases Trabecular and Cortical Bone Mass. Shriram Nallamshetty*[1], Sheila Bornstein[2], Masanobu Kawai[2], Yougen Xi[3], Mark Horowitz[3], Clifford Rosen[2], Jorge Plutzky[1]. [1]Brigham & Women's Hospital, USA, [2]Maine Medical Center, USA, [3]Yale University School of Medicine, USA

The retinoid X receptor (RXR) mediates the pleotropic effects of retinoids -the biologically active structural derivatives of vitamin A (retinol). The nuclear receptor peroxisome proliferator activated receptor-gamma (PPARγ), a key regulator of bone remodeling and stromal cell fate in the marrow, requires heterodimerization with RXR for its transcriptional activity. As such, RXR and retinoids represent critical nodal points in PPARγ pathways. Despite this, the role of RXR and its ligands in determining PPARγ responses in the skeleton remains undefined. Recently we reported that retinaldehyde (Rald), a retinol metabolite with no previously documented role outside of the retina, inhibited the PPARγ-RXR complex and repressed adipogenesis *in vivo*. Mice lacking retinaldehyde dehydrogenase 1 (Raldh1), which converts Rald to retinoic acid (RA), had high Rald levels in adipose tissue and were protected against diet-induced obesity. We hypothesized that global Raldh1 deletion (*Raldh1-/-*) would impair PPARγ activation in bone marrow stromal cells (MSCs) and increase bone mass. Therefore, we performed developmental phenotyping of female *Raldh1-/-* and wild-type (WT) mice on a C57B6 background. DXA scans showed higher femoral bone mineral density as early as 8 weeks of age in *Raldh1-/-* mice (BMD 0.062 vs. 0.049; $p < 0.001$). These differences persisted at 12, 18, 26, and 36 weeks of age. On μCT, *Raldh1-/-* mice had significantly higher trabecular bone density at 8, 12, and 18 weeks of age (BV/TV of 0.11 vs. 0.05; 0.034 vs 0.093; 0.038 vs 0.101 respectively [$p<0.001$]). *Raldh1-/-* mice also had significantly higher trabecular numbers and lower SMI at these ages. To investigate the molecular basis of these skeletal changes in *Raldh1-/-* mice, we performed *in vitro* osteoblastogenesis assays using MSCs from 12-week-old WT and *Raldh1-/-* mice. *Raldh1-/-* MSCs demonstrated enhanced osteoblastogenesis and mineralization as measured by alkaline phosphatase and alizarin red staining respectively. MSC-derived osteoblasts from *Raldh1-/-* mice demonstrated increased gene expression of Runx2, Osx, osteocalcin, and collagen. In addition, Wnt 10b expression was higher in osteoblasts derived from *Raldh1-/-* MSCs, suggesting that the shift in retinoids that occurs in *Raldh1-/-* mice drives canonical wnt/β catenin signaling and a pro-osteoblastogenic differentiation program. These data provide insight into the potential role of Rald/RXR in regulating PPARγ within the marrow niche.

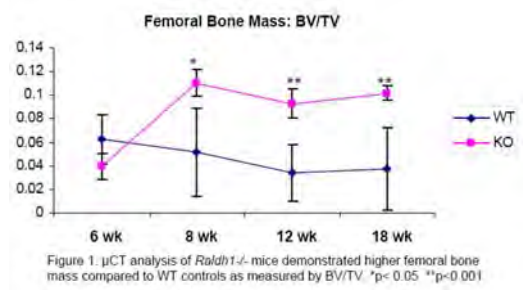

Figure 1. μCT analysis of *Raldh1-/-* mice demonstrated higher femoral bone mass compared to WT controls as measured by BV/TV. *p< 0.05 **p<0.001

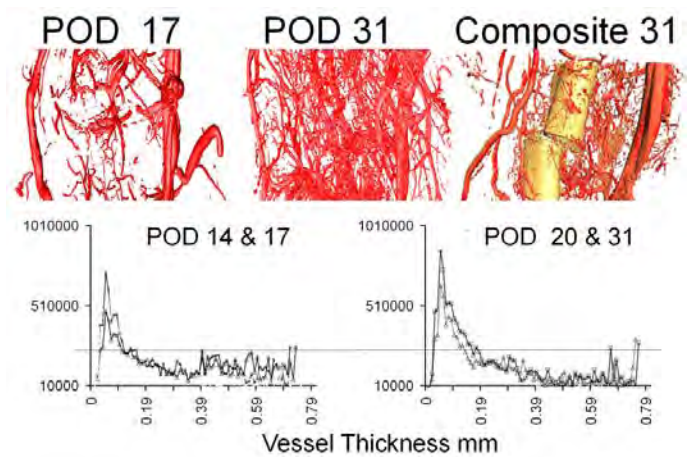
Vascular Development during Distraction Osteogenesis Proceeds by the Sequential Arteriogenesis Exterior to Bone Followed by Angiogenesis within the Bone. Elise Morgan[1], Bader Al-Awadhi[2], Daniel Hogan[3], Amira Hussein[1], Zainab Al-Aql[2], Jennifer Fitch[3], Billy Andre[1], Louis Gerstenfeld*[3]. [1]Boston University, USA, [2]Boston University School of Dental Medicine, USA, [3]Boston University School of Medicine, USA

Distraction osteogenesis (DO) is a surgical method of applying mechanical tension within an osteotomy in order to promote bone regeneration. Osteogenesis during DO has been shown to be dependent on the formation of blood vessels. The spatial interactions by which vascular and osseous tissues integrate their development were assessed by quantifying the temporal and spatial characteristics of these two tissues across the time course of DO. Following perfusion of the vasculature with a radio-opaque contrast agent, image registration and subtraction procedures were applied to sequential micro-computed tomography scans obtained before and after demineralization in order to quantitatively asses vascular and osteogenic tissues in the same sample. Immunohistological assessments were made to discriminate arteriogenesis (large vessel) from angiogenesis (small vessel) formation. Within the gap region, vessel volume was greater at the end of the consolidation period (31 days post surgery) as compared to both the baseline (end-latency; 7 days post surgery) and 7 days after distraction was initiated (14 days post surgery). Total vessel thickness was largest at the end of the active distraction period (17 days post surgery). At all timepoints, total vessel volume was greater in the extraosteal region while vessel connectivity was greater in the intraosteal region. Analysis of vessel volume in the proximal to distal orientation always showed larger values in the proximal and central regions in both intra- and extraosteal regions. Vessel formation proceeded from muscle outside into bone regenerate. Immunohistology validated the structural assessments that arteriogenesis occurred primarily during the period of active distraction while angiogenesis occurred during the consolidation phase. Regional differences in vessel formation suggest that non-uniform mechanical strains within the regenerate may play a role in providing the signals that direct the spatial orientation of new vessel formation in the DO regenerate. The intense period of angiogenesis that precedes and is concurrent with mineralized bone formation is consistent with the prevailing view that the infiltration of blood vessels promotes bone mineralization. However, the spatial association of vascular and osseous tissues within the intraosteal region also suggests a feedback loop wherein biological factors produced during the maturation of bone tissues during consolidation in turn promote angiogenesis.



Vessel Volume and Thickness

AP-1 Proteins Affect Bone Formation Negatively via both AP-1 Transcriptional Activity and Interaction with β-Catenin whereas Truncated Isoforms (FosB/2FosB) Do Not. Ilana Platt*[1], Glenn C. Rowe[2], Sutada Lotinun[1], William Horne[1], Azeddine Atfi[1], Roland Baron[3]. [1]Harvard School of Dental Medicine, USA, [2]Beth Israel Medical Center, USA, [3]Harvard School of Dental Medicine, Harvard Medical School, MGH Endocrine Unit, USA

Several genes that regulate osteoblast (OB) differentiation and function are activated by AP-1 transcription factors (TFs), composed of dimers of Fos and Jun proteins. We have demonstrated that the naturally truncated AP-1 protein, Δ2ΔFosB, which lacks FosB's Fos homology (FH) and transactivating (TA) domains, increases bone mass when overexpressed in OBs in mice. Since Δ2ΔFosB antagonizes FosB's AP-1 TA potential, we hypothesized that inhibition of FosB and AP-1 activity is critical to the anabolic actions of Δ2ΔFosB on bone. To test this hypothesis, we used

the osteocalcin (OG2) promoter to target overexpression of a dominant negative (DN) truncated form of JunD to OBs in mice. Like Δ2ΔFosB, DNJunD lacks the TA domain but can still dimerize with Fos and Jun proteins and bind to DNA, antagonizing AP-1 activity. Compared to littermate controls, calvarial OBs from 1 day old OG2-DNJunD pups have higher alkaline phosphatase activity, and tibia from 6 week old mice have significantly higher bone volume (BV/TV) and bone formation rates (BFR/BS). These results support the hypothesis that inhibition of AP-1 activity is overall anabolic to bone, possibly explaining the bone phenotype in ΔFosB/Δ2ΔFosB mice.

Since AP-1 TFs modulate Wnt target gene expression, and Wnt proteins promote OB differentiation, we then hypothesized that inhibition of AP-1 TA by Δ2ΔFosB may enhance Wnt signaling. FosB, but not Δ2ΔFosB, was immunoprecipitated with β-catenin and inhibited β-catenin-induced TOPFlash activity. Interestingly, FosB constructs in which the leucine zipper (required for dimerization) and/or the DNA binding domain are disabled prevented FosB's AP-1 TA in the AP-1 luciferase reporter assay, but did not prevent the inhibition of TOPFlash reporter activity, indicating that this effect is likely due to direct interaction of the N-terminal and/or FH domains with β-catenin, independent of the formation of the AP-1 complex and TA activity. These results suggest that AP-1 proteins negatively regulate bone formation by both AP-1 dependent and β-catenin-dependent mechanisms. ΔFosB/Δ2ΔFosB and DNJunD may therefore increase bone formation by preventing both AP1 TA and the negative effects of FosB interactions with β-catenin.

Epigenetic Control of Osteoblastogenesis by Pbx1 Repressing Hoxa10-Mediated Recruitment of Activating Chromatin Remodeling Factors. Jonathan Gordon*[1], Mohammad Hassan[1], Matthew Koss[2], Sharanjot Saini[3], Martin Montecino[4], Licia Selleri[5], Andre Van Wijnen[1], Janet Stein[1], Gary Stein[1], Jane Lian[1]. [1]University of Massachusetts Medical School, USA, [2]Cornell University Weil Medical School, USA, [3]University of California-San Francisco, USA, [4]Universidad de Concepcion, Chile, [5]Cornell University Weill Medical school, USA

Homeobox (HOX) factors have been demonstrated to be potent transcriptional and epigenetic regulators of osteogenesis. Abdominal-class homeodomain-containing (Hox) factors form multimeric complexes with TALE-class homeodomain proteins (Pbx, Meis) to regulate tissue morphogenesis and skeletal development. Here we have identified components of a Pbx1 complex that is associated with osteoblast-related gene promoters and established that Pbx1 negatively regulates Hoxa10-mediated gene transcription in mesenchymal cells. Expression of Pbx1 impaired osteogenic commitment of C3H10T1/2 pluripotent cells and differentiation of MC3T3-E1 pre-osteoblasts. Conversely, targeted depletion of Pbx1 by shRNA increased expression of osteoblast-related genes. Studies using wild type and mutated osteocalcin and bone sialoprotein promoters revealed that Pbx1 acts through a Pbx-binding site that is required for attenuation of Hoxa10 gene activation. Chromatin-associated Pbx1 and Hoxa10 were present at osteoblast-related gene promoters preceding gene expression, but Pbx1 was absent from promoters during induced transcription of osterix, osteocalcin and bone sialoprotein. Pbx1 was associated with histone deacetylases normally linked with chromatin inactivation and loss of Pbx1 from osteoblast promoters in differentiated osteoblasts was associated with increases in histone acetylation and CBP/p300 recruitment, as well as decreased H3K9 methylation. We propose Pbx1 plays a central role in attenuating the activity of Hoxa10 as an activator of osteoblast-related genes and functions to establish proper timing of gene expression during osteogenesis. These novel in vitro epigenetic mechanisms regulating the onset of bone formation are currently being addressed in an in vivo context, by osterix-Cre-mediated conditional deletion of Pbx1 during osteogenesis.

ER Stress Response Mediated by PERK-eIF2α-ATF4 Pathway is Involved in Osteoblast Differentiation Induced by BMP2. Kimiko Ochiai*[1], Atsushi Saito[2], Douglas Cavener[3], Kazunori Imaizumi[2]. [1]University of Miyazaki, Japan, [2]Division of Molecular & Cellular Bioligy, Dapartment of Anatomy, Faculty of Medicine, University of Miyazaki, Japan, [3]The Pennsylvania State University College of Medicine, USA

Various stresses conditions lead to accumulation of unfolded proteins in the endoplasmic reticulum (ER) lumen (ER stress). Eukaryotic cells have the potential to deal with unfolded proteins to avoid cellular damage. This system is termed the ER stress response. PKR-like endoplasmic reticulum kinase (PERK) is one of major transducers of ER stress response, and can phosphorylate eukaryotic initiation factor 2α (eIF2α), resulting in translational attenuation. Phosphorylated eIF2α specifically promotes the translation of transcription factor 4 (ATF4). ATF4 is well known to play important roles in osteoblast differentiation and bone formation. Recently, PERK deficient mice has been reported to exhibit severe osteopenia, and the phenotypes observed in bone tissues are very similar to those of ATF4 deficient mice. However, it is unclear that the PERK-eIF2α-ATF4 signaling pathway and/or ER stress itself are involved in osteogenesis. We examined the expression levels of many genes and proteins in bone tissues of PERK deficient mice. Phosphorylated eIF2α and ATF4 proteins were decreased in PERK deficient calvaria at postnatal day 4, and the gene expression levels of osteocalcin (OCN) and bone sialoprotein (BSP), that are targets for ATF4, were also down-regulated. Treatment of WT primary calvarial immature osteoblasts with BMP2, which is required for osteoblast differentiation, induced expression of ATF4 protein. In contrast, that in PERK deficient primary culture was severely inhibited and the levels of OCN and BSP were also decreased. There results indicate that activation of ATF4 is required for PERK signaling pathway in osteoblast differentiation. PERK deficient osteoblast culture exhibited a decrease in collagen fibers, alkaline phosphatase activities, and delayed mineralized nodule formation relative to WT culture. There abnormalities were almost completely restored by the introduction of ATF4 into PERK deficient osteoblasts. We previously reported that treatment of calvarial primary osteoblast culture with BMP2 leads to ER stress due to the production of abundant proteins during osteoblast differentiation. Taken together, physiological ER stress occurs during osteoblast differentiation and activates PERK-eIF2α-ATF4 signaling pathway followed by promotion of gene expression essential for osteogenesis such as OCN and BSP. However, further detailed investigation is required for clarifying the relationship between osteogenesis and PERK-ATF4 pathway in vivo.

FR0223

KLF10 is a Critical Mediator of Wnt Signalling in Osteoblasts. John Hawse*[1], Elizabeth Bruinsma[2], Sarah Grygo[2], Frank Secreto[3], Nalini Rajamannan[4], Thomas Spelsberg[3], Malayannan Subramaniam[3]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic College of Medicine, USA, [3]Mayo Clinic, USA, [4]Northwestern University Medical School, USA

We have previously demonstrated that KLF10 plays important roles in bone as knockout (KO) mice display a gender specific osteopenic phenotype defined by decreased bone mineral density, bone mineral content and overall loss of bone strength in female animals. Recent studies indicate that KLF10 may be involved in mediating Wnt signaling, a pathway critical for proper bone development, growth and skeletal maintenance. Therefore, we analyzed the expression levels of multiple Wnt pathway genes in calvarial osteoblasts (OBs) isolated from KLF10 KO mice relative to wildtype (WT) controls. These analyses revealed significant decreases in the basal expression levels of LRP6, cMyc, Wnts 2b, 3, 5a, 5b, 9a, 10a, 10b, and 11, as well as increased expression of the inhibitory DKK1 gene, in KO OB cells. During the course of OB differentiation, the expression levels of Wnt 10b and 11 increased significantly in WT cells but not in KLF10 KO cells. Expression of Lef, a Wnt-dependent transcription factor involved in mediating β-Catenin gene regulation, increased in WT but not KO OBs during late stages of differentiation, while expression of LRP5 was significantly decreased in KO cells. We next demonstrated that Lef was not able to activate a Lef/Tcf reporter construct (Top-Flash) when transfected into KLF10 KO OBs. However, when KLF10 was co-expressed with Lef, a significant increase in reporter activity was observed. Additionally, KLF10 alone could activate the Top-Flash reporter in both U2OS cells and calvarial OBs, and interestingly, such activation was equivalent to or exceeded that observed with Lef alone. Expression of both KLF10 and Lef led to co-activation of the Top-Flash reporter. Similarly, co-expression of KLF10 and β-catenin led to enhanced Top-Flash activity relative to either alone, and this activation was further enhanced by the addition of Lef. These data suggested that KLF10, Lef and β-catenin interact with each other to form a transcriptionally active protein complex. Indeed, co-immunoprecipitation assays demonstrated that KLF10 does interact with both Lef and β catenin in OBs. Taken together, these data implicate a previously unidentified role for KLF10 in mediating Wnt signaling and Lef transcriptional activity in OBs, and imply an important role for the Wnt pathway in the observed osteopenic bone phenotype of KLF10 KO mice.

NF-kB RelB-/- Mice Have Age-Related Trabecular Bone Gain in their Diaphyses, Indicating that RelB negatively Regulates Bone Formation. Zhenqiang Yao*[1], Chen Zhao[2], Yanyun Li[1], Lianping Xing[1], Brendan Boyce[2]. [1]University of Rochester, USA, [2]University of Rochester Medical Center, USA

NF-κBp50/p52 expression is required for osteoclast (OC) formation. RelB interacts with p52 and is required for RANKL-mediated OC formation in vitro but not for basal OC formation in vivo: no bone phenotype was reported in RelB KO mice. However, we have found that RelB-/- mice develop age-related increased diaphyseal trabecular bone volume starting at 6-8 wks-old, bone volume (BV/TV, %) being 10± 2 vs. 5±2.5, $p<0.01$ in WT mice. At 12-15 wks-old, BV/TV remained unchanged in WT mice but increased to 23.5±4.6 in the KO mice with increased Tb.N (7.6±0.5 vs 5.8±0.4/mm, $p<0.01$), no change in Tb.Th., but significantly reduced OC# in vivo (45±16 vs 70±23/mm ($p<0.01$) and RANKL and TNF mediated OC formation in vitro. c-Fos is critical for OC formation down-stream from NF-κB. We found that both RANKL and TNF-induced c-Fos mRNA expression depends on RelB and that over-expression of c-Fos rescued OC formation induced by these cytokines in KO OC precursors. Surprisingly, osteoblast (OB) surface (8±2 vs 25±9 %, $p<0.01$) and bone formation rate (BFR: 0.37±0.15 vs 1.07±0.47 um3/um2/d, $p<0.05$) were significantly reduced in the KO mice due to decreased mineral

apposition rate (MAR, 1.13±0.15 vs 1.72±0.4 um/d, $p<0.05$) and mineralizing surface (16.7±5.1 vs 35.1±9.6%, $p<0.01$) in 6-8 wk-old mice. However, KO bone marrow cells (BMC) formed more mineralized nodules earlier than WT BMCs associated with increased osteocalcin mRNA expression. In summary, 1) RelB-/- mice have age-related bone gain in their diaphyses characterized by increased trabecular number, decreased bone resorption and formation in vivo, but accelerated bone nodule formation in vitro; 2) RelB targets c-Fos to mediate OC differentiation. We conclude that RelB negatively regulates diaphyseal bone mass and helps to maintain bone homeostasis by balancing bone resorption and formation, but the precise mechanism whereby RelB regulates osteoblastic bone formation remains to be determined.

Osteoblast-targeted Overexpression of TAZ Results in Increased Bone Mass. Jee Hyun An*[1], Jae Yeon Yang[1], Sun Wook Cho[1], Ju Yeon Jung[1], Yenna Lee[1], Sang Wan Kim[1], Seong Yeon Kim[1], Jung Eun Kim[2], Jung Ho Hong[3], Chan Soo Shin[1]. [1]Department of Internal Medicine, Seoul National University College of Medicine, South korea, [2]Department of Molecular Medicine, Kyungpook National University, South korea, [3]College of Life Science, Korea University, South korea

Osteoblasts are derived from mesenchymal progenitors and differentiation to osteoblasts and adipocytes are reciprocally regulated. Transcriptional coactivator with PDZ-binding motif (TAZ) is a transcriptional coactivator that induces differentiation of mesenchymal cells into osteoblasts while blocking differentiation into adipocytes. To investigate the role of TAZ on bone metabolism in vivo, we have generated transgenic mice that overexpress TAZ under the control of procollagen type 1 promoter (Col1-TAZ). Whole body bone mineral density (BMD) measurement by DXA showed that Col-TAZ mice exhibited significant increase in BMD by 7.0% at 8 weeks of age and the difference was maintained up to 20 weeks of age. Furthermore, micro-CT analysis of distal femur at 16 weeks of age demonstrated significant increase in trabecular bone volume (14.5%), trabecular number (12%) and trabecular thickness (2%) in Col1-TAZ mice compared with WT littermate. In addition, dynamic histomorphometric analysis of lumbar spine revealed increased bone formation rate. When primary calvaria cells were cultured in osteogenic medium, the induction of alkaline phosphatase (ALP) activities were significantly increased in Col1-TAZ mice compared with WT littermate with consistent increase in mineralizing nodule formation assessed by Alizarin Red stain. Finally, quantitative real-time PCR analysis showed that the expression of Runx2, Col type 1, ALP and osteocalcin was significantly increased in calvaria cells from Col1-TAZ compared to those from WT littermate. Taken together, these results suggest that TAZ is a positive regulator of bone mass in vivo.

Sclerostin Is a Direct Target of Osteoblast-Specific Transcription Factor Osterix. Fan Yang[1], Wanjin Tang[2], Sarah So[2], Benoit de Crombbrugghe[3], Chi Zhang*[2]. [1]Bone Research Laboratory,Texas Scottish Rite Hospital, USA, [2]Bone Research Laboratory, Texas Scottish Rite Hospital, USA, [3]Dept of Genetics, University of Texas M.D. Anderson Cancer Center, USA

Bone formation is a developmental process involving the differentiation of mesenchymal stem cells to osteoblasts. Osterix (Osx) is an osteoblast-specific transcription factor required for bone formation and osteoblast differentiation. Osx knock-out mice lack bone completely and cartilage is normal. Our recent observations that Osx inhibits Wnt pathway provide a novel concept of feedback control mechanism involved in bone formation. Mechanisms of Osx inhibition on Wnt pathway are not fully understood. In this study Microarray was carried out to compare the RNA expression profiles of wild type and Osx-null calvarial cells at E18.5 in mice embryos. Our results revealed that Sclerostin (Sost) expression was abolished in Osx-null calvarial cells, and this was confirmed by quantitative real-time RT-PCR, suggesting Osx is required for Sost expression. We hypothesize that Osx may target Sost directly. Sost is a Wnt signaling antagonist and plays a role on bone remodeling. Overexpression of Osx in stable C2C12 mesenchymal cell line using Tet-off system was found to result in Sost expression upregulation. To test Osx regulation of Sost expression in vitro, we made a luciferase reporter construct driven by 1kb Sost promoter. Transient transfection assay showed that Osx activated Sost promoter activity in a dose-dependent manner. To define minimal region of Sost promoter activated by Osx, we made a series of deletion mutants of Sost promoter constructs, and narrowed down the minimal region to the proximal 250bp by transfection assay. Gel Shift Assay indicated that Osx bound to one GC-rich binding site within this minimal region of Sost promoter, and that point mutations of this binding site disrupted Osx binding. Moreover, the same point mutations in 250bp Sost promoter reporter disrupted the promoter activation by Osx, suggesting that the GC-rich binding site was responsible for Osx activation of Sost 250bp region promoter. To further examine physical association of Osx with Sost promoter in vivo, quantitative Chromatin immunoprecipitation (ChIP) assays were carried out. We observed the Osx association with endogenous Sost promoter in primary osteoblasts from mouse calvaria. Taken together, these findings support our hypothesis that Sost is a direct target of Osx. This provides a new additional mechanism through which Osx inhibits Wnt pathway during bone formation.

G Proteins Differentially Regulate Wnt/β-catenin Signaling in Skeletal Development and Disease. Jean Regard*[1], Michael Collins[1], Pamela Robey[2], Lee Weinstein[3], Yingzi Yang[4]. [1]National Institutes of Health, USA, [2]National Institute of Dental & Craniofacial Research, USA, [3]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [4]NIH/NHGRI, USA

Wnts are a family of secreted glycoproteins that control many aspects of skeletal development and homeostasis. The "canonical" Wnt signaling pathway is transduced through the stabilization of β-catenin. Despite their central importance in development and diseases, the mechanisms regulating Wnt signaling remain incompletely understood. The Frizzled family of Wnt receptors are 7 transmembrane-containing proteins with homology to G protein-coupled receptors (GPCRs), though the precise roles of G proteins in transducing Wnt signals are not known. Through a series of in vitro and in vivo experiments we have explored the interactions of the four major Gα protein families ($G\alpha_s$, $G\alpha_{i/o}$, $G\alpha_{q/11}$, $G\alpha_{12/13}$) with the Wnt/β-catenin signaling pathway. Gain-of-function experiments suggest activated $G\alpha_s$ potentiates Wnt/β-catenin signaling, though $G\alpha_s$ is not itself sufficient to activate this pathway. Similar activation of $G\alpha_q$ or $G\alpha_{13}$ inhibits Wnt/β-catenin signaling while activation of $G\alpha_{i/o}$ has no effect. Activated forms of $G\alpha_s$, $G\alpha_q$ and $G\alpha_{13}$ (but not $G\alpha_{i2}$) co-immunoprecipitate with Axin while wildtype forms either fail to bind or bind less robustly, demonstrating activity-dependent enhanced binding. Thus, Gα proteins may act through Axin, a core component in this pathway that assembles the β-catenin destruction complex. Importantly, removal of $G\alpha_s$, $G\alpha_{i/o}$, $G\alpha_{q/11}$ or $G\alpha_{12/13}$ from cells has no effect on the ability of Wnt to activate β-catenin, suggesting Gα proteins are not required for signaling. To test the functional significance of these Gα/Wnt/β-catenin interactions in vivo, we utilized a combination of mouse genetics and human disease samples. Removal of $G\alpha_s$ from the developing mouse limb leads to a profound decrease in Wnt/β-catenin signaling and decreased bone formation, demonstrating a physiologically important interaction in vivo during skeletal development. Also, activating mutations of human $G\alpha_s$ known to cause McCune-Albright Syndrome (MAS) potentiate Wnt/β-catenin signaling and β-catenin is upregulated in fibrous-dysplastic bone and thyroid tissues from MAS patients. This observation indicates that dysregulation of Wnt/β-catenin signaling may be at least partially responsible for the pathophysiology of this debilitating human syndrome. In conclusion, our data suggests that Gα proteins are playing physiologically significant regulatory roles in Wnt/β-catenin signaling during both skeletal development and disease.

Insulin Receptor Signaling in Osteoblasts Regulates Bone Acquisition and Glucose Metabolism. Ryan Riddle*[1], Keertik Fulzele[2], Douglas Digirolamo[3], Xuemei Cao[4], Chao Wan[5], Marie-Claude Faugere[6], Mehboob Hussain[3], Jens Bruning[7], Thomas Clemens[3]. [1]Johns Hopkins University School of Medicine, USA, [2]Massachusetts General Hospital; Harvard Medical School, USA, [3]Johns Hopkins University, USA, [4]University of Alabama at Birmingham, USA, [5]University of Alabama, Birmingham, USA, [6]University of Kentucky Medical Center, USA, [7]University of Cologne, Germany

Management of constant energy supply in an environment of variable food intake is critical for the survival of all terrestrial species. Mammals have evolved intricate networks of local and circulating factors that coordinate energy expenditure. Bone is increasingly recognized for its role in coordinating global energy utilization via the insulin secretagogue, osteocalcin. For this putative bone-pancreas hormonal network to function efficiently, we reasoned that insulin should regulate osteoblast activity. To test this idea, we generated mice lacking the insulin receptor (IR) specifically in the osteoblast (Ob-ΔIR). Six-week-old Ob-ΔIR mice demonstrated reduced (47%) trabecular bone volume and reduced osteoblast numbers. *In vitro*, primary ΔIR osteoblasts failed to differentiate and demonstrated reduced Runx2 and osteocalcin mRNA expression. Insulin treatment induced a 3-fold increase in osteocalcin promoter activity and a 2.5-fold increase in Runx2 occupancy of the OSE2 element (CHIP). Transcriptional profiling and immunoprecipitation experiments conducted in insulin-treated and ΔIR osteoblasts indicated that insulin regulates osteoblast differentiation by suppression of the Runx2 inhibitor, Twist2. Surprisingly, as Ob-ΔIR mice aged, they developed marked peripheral adiposity and biochemical changes indicative of insulin resistance. Insulin and glucose tolerance tests showed that the Ob-ΔIR mice exhibited profound glucose intolerance and insulin resistance accompanied by lowered energy expenditure but normal food intake. Pancreatic β-cell mass and *Ins1* and *Ins2* expression were reduced in the pancreas of Ob-ΔIR mice compared to controls, suggesting that insulin resistance is accompanied by reduced insulin secretory reserves. Importantly, both total and undercarboxylated osteocalcin serum levels were decreased significantly in Ob-ΔIR mice compared to controls. Finally, we measured the effect of a 2-week infusion of undercarboxylated osteocalcin on glucose

and insulin sensitivity. Osteocalcin infused Ob-ΔIR mice had blunted glucose excursions and more pronounced reductions in serum glucose following a bolus of insulin relative to controls. These results suggest the existence of a bone-pancreas endocrine loop, through which insulin signaling in the osteoblast ensures osteoblast differentiation and stimulates osteocalcin production, which in turn regulates insulin sensitivity and pancreatic insulin secretion to control glucose homeostasis.

FR0235

Insulin Signaling in Osteoblasts is a Positive Regulator of Bone Resorption. Jianwen Wei*, Tatsuya Yoshizawa, Mathieu Ferron, Patricia Ducy, Gerard Karsenty. Columbia University, USA

Insulin is one of the most important hormones in vertebrates. This is explained in large part because insulin acts on numerous cell types and has pleiotropic functions in these cells. The classical insulin target tissues are liver, muscle and white adipose tissue, where it regulates glucose and energy metabolism. However, the fact that the insulin receptor is expressed in many cell types suggests that the spectrum of insulin target tissues and of insulin functions is broader than that. In particular, that the insulin receptor is expressed in osteoblasts along with the fact that injection of a bolus of insulin increases phosphorylation of the insulin receptor in bone suggests that insulin may regulate aspects of bone physiology. In order to address this question, we generated mice lacking the insulin receptor in the osteoblast lineage only. Unexpectedly, *InsR osb-/-* mice develop a severe low turnover, low bone mass phenotype. Histomorphometric and biochemical analyses revealed that insulin signaling in osteoblasts normally favors bone resorption by osteoclasts. A molecular analysis of this latter phenotype revealed that insulin signaling in osteoblasts is a powerful regulator of *Osteoprotegerin* expression. Co-culture assays followed by a thorough gene expression analysis demonstrated that the main osteoclast function regulated by insulin signaling in osteoblasts is the acidification of the extracellular matrix. This occurs through its regulation of the expression of *Cathepsin K* and *Tcirg1,* two genes mutated in of human skeletal dysplasia. These results identified a signaling cascade downstream of insulin signaling in osteoblasts leading to acidification of the bone extracellular matrix by osteoclasts. As such, they revealed that insulin is a major hormonal regulator of bone remodeling.

PIN1 Mediates The Effects of Notch on The Stability of NFATc2 Transcripts. Stefano Zanotti*[1], Anna Smerdel-Ramoya[2], Ernesto Canalis[2]. [1]Saint Francis Hospital & Medical Center, USA, [2]St. Francis Hospital & Medical Center, USA

Notch are transmembrane receptors that determine cell fate decisions. Interactions of Notch with its ligands result in the release of its intracellular domain (NICD), which is the mediator of Notch signaling. Nuclear Factor of Activated T-Cells (NFAT) are a family of four transcription factors that determine cell differentiation and function. NFATc1 and NFATc2 are expressed by osteoblasts. Notch is a suppressor of osteoblastogenesis, whereas the role of NFATc1 and NFATc2 in osteoblast differentiation is controversial. We have shown that Notch regulates NFAT transactivation in osteoblasts, but the mechanisms involved are not known. To investigate the actions of Notch on NFATc1 and NFATc2 expression, osteoblasts from $Rosa^{Notch}$ mice, where NICD is induced following the deletion of a STOP cassette by CRE recombination, were used. Notch downregulated NFATc1 mRNA by suppressing its transcription. In contrast, Notch induced NFATc2 by a post-transcriptional mechanism, without affecting NFATc2 transcription. To determine the rate of decay of NFATc1 and NFATc2 mRNA, osteoblasts were treated with 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) to inhibit RNA polymerase II. Notch did not modify the half-life of NFATc1 mRNA, confirming that it downregulated NFATc1 exclusively by transcriptional mechanisms. In contrast, Notch extended the half-life of NFATc2 transcripts from 2 h to 8 h, demonstrating that Notch stabilizes NFATc2 mRNA. To study the mechanisms involved, we explored the role of Peptidyl-Prolyl Cis/Trans Isomerase Nima-Interacting Protein (PIN1), an isomerase that regulates the mRNA stability of secreted proteins. PIN1 acts on mRNA-binding proteins and catalyzes the cis/trans isomerization of the peptide bond between a phosphorylated Serine/Threonine and a Proline residue. To test whether PIN1 mediated the effects of Notch on NFATc2 mRNA stability, PIN1 was down regulated in $Rosa^{Notch}$ osteoblasts by RNA interference, in the context, or not, of NICD overexpression. Downregulation of PIN1, as well as the use of a specific inhibitor of PIN1 activity, reversed the stabilizing effect of Notch on NFATc2 mRNA. This is the first report demonstrating post-transcriptional regulation of NFATc2 mRNA and documenting that the role of PIN1 extends beyond the control of mRNA stability of secreted proteins. In conclusion, Notch stabilizes NFATc2 transcripts through a PIN1 dependent mechanism.

Age-related Declines in Expression of CYP27B1 and in Osteoblast Differentiation in Human MSCs. Shuo Geng*, Shuanhu Zhou, Julie Glowacki. Brigham & Women's hospital, USA

Human marrow contains adherent cells with potential to differentiate to osteoblasts and other cell lineages. We and others showed that there is an age-related decline in osteoblast potential and that osteoblast differentiation can be stimulated by 1,25-dihydroxyvitamin D ($1,25(OH)_2D$). We recently reported that human marrow stromal cells (hMSCs) have vitamin D hydroxylases and that expression of CYP27B1/1α-hydroxylase (1α) is related to clinical features of the subject from whom the hMSCs were obtained (Endocrinology 2010;151:14). This study tests the hypothesis that 25-hydroxyvitamin D (25OHD) stimulates osteoblast differentiation in hMSCs that express 1α and that there may be effects of age. Human MSCs were prepared from bone marrow that was discarded from subjects undergoing joint replacement. Low-density mononuclear cells were isolated by centrifugation on Ficoll/Histopaque 1077; after overnight culture in phenol red-free αMEM, 10% fetal bovine serum, and antibiotics, non-adherent cells were removed and the adherent MSCs were expanded and studied. Osteoblast differentiation was assessed by measurement of alkaline phosphatase activity. Osteoblastogenesis of hMSCs (n=33 subjects, ages from 27 to 83 years) was stimulated by 10 nM $1,25(OH)_2D_3$ with a significant age-related decrease in response with age (r=-0.381, p=0.029). In a series of 20 samples from elders (66 ± 11), $1,25(OH)_2D_3$ stimulated osteoblastogenesis in 55%. In 30% of those samples, both $1,25(OH)_2D_3$ and $25OHD_3$ stimulated osteoblastogenesis. Expression of 1α in 27 subjects (57 ± 12) was inversely correlated with age (r=-0.498; p=0.008, Figure). The constitutive expression of 1α in the younger group (<50 years, n=12) was 1.8-fold greater than in the older group (>55, n=15, p=0.007). To test for a role of 1α in the stimulation of osteoblastogenesis by $25OHD_3$, a cytochrome P450 inhibitor ketoconazole (10 μM) was added to some cultures. Osteoblastogenesis was stimulated by $25OHD_3$ ($p<0.05$), but there was no stimulation in the presence of ketoconazole. This suggests that 1α-hydroxylation of $25OHD_3$ may be needed for its stimulation of osteoblastogenesis. The age-related decline in constitutive expression of 1α may account for the age-related decline in osteoblast differentiation in hMSCs.

Dicer Excision in Mature Osteoblasts in the Postnatal Skeleton Induces High Bone Mass by Inactivating miR that Attenuate Bone Formation. Tripti Gaur*[1], Sadiq Hussain[1], Stacey Russell[1], Lammy Kim[2], Jennifer Colby[1], Dana Frederick[1], Andre Van Wijnen[1], David Eyre[3], Janet Stein[1], Gary Stein[1], Stephen Jones[1], Jane Lian[1]. [1]University of Massachusetts Medical School, USA, [2]University of Washington, USA, [3]University of Washington Orthopaedic Research Labs, USA

Studies have reported the requirement of miRNA (miR) processing by a ribonuclease enzyme, Dicer, for the control of gene expression to regulate cell growth and differentiation in mammalian tissues. We established a requirement for miRs and Dicer in bone development and homeostasis by conditional deletion of Dicer in mature osteoblasts using Osteocalcin-Cre. Analysis of the ratio of precursor miR to mature miR for selected miRs was higher in $Dicer^{\Delta oc/\Delta oc}$ bone samples as expected, confirming reduced miR biogenesis following Dicer ablation. Our microCT results show that $Dicer^{\Delta oc/\Delta oc}$ induces an increase in the mass of long bones in adult mice beginning at 1 month and progressing up to up to 8 months of age. Cortical porosity was reduced significantly in $Dicer^{\Delta oc/\Delta oc}$ mice. The membranous calvarial bone had increased BMD without excessive bone formation. Dynamic histomorphometry by calcein labeling revealed more than a 2-fold increase in bone matrix apposition in both cortical and trabecular region in $Dicer^{\Delta oc/\Delta oc}$ femurs compared to the control mice, rendering a thickened bone from the periosteal side. However, normal bone

architecture and cellular organization with similar osteocyte density was observed. With increased rate of bone formation, lamellar bone but not woven bone, was revealed by polarizing microscopy. Mature collagen crosslinks (hydroxylysyl pyridinoline and lysyl pyridinoline) were comparable between $Dicer^{c/c}$ and $Dicer^{\Delta oc/\Delta oc}$ when examined at 2 and 4 months of age, again suggesting normal collagen fibril organization. Biomechanical and mineral property studies are in progress to evaluate the bone quality. To further explore the molecular basis for the unusual bone phenotype of $Dicer^{\Delta oc/\Delta oc}$ mice, we examined collagen levels in affected bone. In agreement with a previous report indicating that miRs expressed in osteoblasts/osteocytes negatively regulate bone matrix proteins and collagens, we observed a 5-fold increase in gene expression for Type I collagen in Dicer-ablated bone, and a decrease for Types III and V, typically higher in immature bone. Furthermore, in silico analysis of miRs in osteoblasts suggests that upregulation of canonical Wnt components in $Dicer^{\Delta oc/\Delta oc}$ bone, contribute to the high bone mass phenotype. We conclude that miRs regulate osteoblastogenesis and the acquisition of bone mass, in part by targeting bone matrix genes and the canonical Wnt pathway.

Mechanical Inhibition of Adipogenesis Achieved via a Regenerated β-catenin Signal is Amplified by Incorporating a Refractory Period. Buer Sen*[1], Zhihui Xie[2], Natasha Case[3], Maya Styner[3], Clinton Rubin[4], Janet Rubin[3]. [1]University of North Carolina At Chapel Hill, USA, [2]UNC-CH, USA, [3]University of North Carolina, Chapel Hill, School of Medicine, USA, [4]State University of New York at Stony Brook, USA

Mechanical signals are recognized as anabolic to bone and inhibitory to fat. Evidence indicates that both low intensity vibration (LIV) and high magnitude strain (HMS) achieve these outcomes by directly biasing mesenchymal stem cell (MSC) lineage towards osteoblastogenesis and away from adipogenesis. To understand the molecular cues and the "idealized" mechanical requirements for direct mechanical control of MSC lineage selection, we studied the effects of daily LIV or HMS in cultures of C3H10T1/2 or bone marrow derived MSCs cultured in adipogenic conditions for 7-10 days. LIV (0.6g, 90 Hz) delivered for 20 or 40 minutes 1X day failed to repress adipogenesis, as measured by increased fat marker proteins (adiponectin, aP2). LIV significantly and robustly reduced acquisition of fat phenotype when a second 20 min LIV treatment was added each day. The second treatment achieved efficacy only if delivered after a rest period of >1 hour between mechanical treatments. The ability of the second LIV treatment to suppress adipogenesis was enhanced by increasing the rest period to more than 3 h. The addition of a third LIV treatment each day, again following a 3h rest period, further augmented repression of adipogenesis (30% decrease in adiponectin with 2x LIV/day, 75% with 3x/day - see Fig). Similarly, 400 cycles of HMS (2% strain, 0.17 Hz, 40 min), showed increased efficacy when the HMS was divided into 2 x 20 min (200 cycles) sessions separated by >1 h. These results are consistent with the presence of a biological refractory period independent of the type of mechanical input. The signal cascade triggered by LIV exposure involved inhibition of GSK3β with subsequent activation of β-catenin: siRNA silencing of β-catenin negated LIV's effect on adipogenesis. Finally, MSCs treated with 2 x LIV daily for 7 d showed increased induction of osteocalcin mRNA by BMP 100 ng/ml compared to MSC that were not exposed to LIV: osteocalcin increased by $62 \pm 12\%$ after LIV and $38 \pm 9\%$ in control. Our data suggests that mechanical input triggers a burst of signaling in MSCs, where the extent of cellular response depends more on treatment scheduling than magnitude of the mechanical signal. Once the MSC response is triggered via LIV or HMS, the biological system must "reset" before it can fully respond again. As such, incorporating a biological refractory period into a treatment regimen should enhance the response to repeated high or low magnitude mechanical signal.

Mechanical Signals Protect the Bone Marrow Stem Cell Niche from Damage due to a High Fat Diet. Benjamin Adler*[1], Danielle E. Green[1], Ete M. Chan[1], Stefan Judex[1], Clinton Rubin[2]. [1]Stony Brook University, USA, [2]State University of New York at Stony Brook, USA

Obesity is widely thought to compromise bone quality and bias the differentiation of bone marrow stromal cells (BMSCs) towards adipogenesis. Obesity also increases lifetime susceptibility to illness, implicating a compromised immune system perhaps due to impaired hematopoiesis as marrow adiposity increases. Hematopoietic stem cells (HSC) occupy a complex niche in which they are co-localized, interact with, and are regulated by osteoblasts, BMSCs, bone structure and vasculature. Low intensity vibration (LIV) has been shown to stimulate proliferation of BMSCs and bias their differentiation towards osteoblastogenesis and suppress adiposity. In this study, we hypothesize that animals fed a high fat diet will suffer impaired hematopoiesis, and considering LIV's influence on BMSCs, that these mechanical signals may also serve to protect the HSC niche and hematopoiesis from this diet-induced impairment. To test this hypothesis, 7 wk old male C57Bl/6J mice were fed either a high fat (45% Kcal from fat-FDC,FDV) or regular diet (RDC) and subject to LIV (90Hz, 0.25g)(FDV), or sham handling (FDC, RDC) for 15min/day, 5 days/wk for 6 weeks (n=7 per group). At sacrifice, marrow was extracted from the left leg and stained for flow cytometry. Side population cells which are c-kit+, Lin-, and Sca-1+ (SPKLS) are highly enriched for HSC's, whereas the c-kit+, Lin-, and Sca-1+ (KLS) compartment contains both HSC's and progenitor cells. Means were compared with one-way ANOVAs and Tukey post hoc tests. High fat feeding increased the proportion of SPKLS cells in both FDC and FDV animals by 23 and 21% compared to RDC (NS). In contrast, the proportion of KLS cells in the FDC group dropped by 28% (p=0.03 to RDC), whereas FDV KLS cells fell by only 14% (NS to RDC). Although HSC proportions were almost identical in both the FDC and FDV groups, the drop in FDC KLS cells, which represent early progenitors, implies that the high fat diet compromised HSC differentiation. LIV resulted in 19% more KLS cells than the fat diet controls, suggesting that these mechanical signals mediated a partial rescue of HSC function. That even a short term increase in dietary fat can result in significant negative effects on HSC function is alarming and intimates the effects of chronic changes to the bone marrow niche on hematopoiesis and health. The partial rescue of HSC function by LIV suggests that the systemic chronic complications of obesity may ultimately be checked by non-pharmacologic means.

Peptide-mediated Disruption of N-cadherin-LRP5/6 Interaction Stimulates Wnt Signaling, Osteoblast Replication and Differentiation. Eric Haÿ*[1], Thibault Buczkowski[1], Pierre Marie[2]. [1]Inserm U606 & University Paris Diderot, France, [2]INSERM Unit 606 & University Paris Diderot, France

Canonical Wnt signalling plays an important role in the control of osteoblastogenesis. We previously showed that N-cadherin interacts with the Wnt co-receptors LRP5/6 and downregulates osteoblast proliferation, differentiation and bone formation via attenuation of Wnt, ERK and PI3K/Akt signalling. In this study, we investigated the functional domains of N-cadherin that interact with LRP5/6. To this goal, MC3T3-E1 osteoblastic cells were transfected with full length N-cadherin or N-cadherin constructs lacking the last 153 (Delta 153), 114 (Delta 114) or 62 (Delta 62) aminoacids (AA) that interact with axin, cyclin D1, casein kinase 1 (CK1) or GSK3. The expression of truncated N-cadherin constructs was confirmed by western blot analysis and immunocytochemistry. Immunoprecipitation analysis showed that transfection with Delta 62 abolished the physiological interaction between N-cadherin and LRP5. In contrast to full length N-cadherin, transfection with Delta 62 N-cadherin did not affect beta-catenin transcriptional activity. Interestingly, transfection with Delta 62 N-cadherin increased cell replication, alkaline phosphatase (ALP) activity and osteoblast gene expression (Runx2, ALP, Col1A1) in MC3T3-E1 cells. This indicates that deletion of the Delta 62 domain abolishes N-cadherin-LRP5 interaction, and thereby promotes osteoblast proliferation and differentiation. We previously showed that N-cadherin interacts with the 28 last AA in the LRP5/6 intracellular domain in osteoblasts. We therefore hypothesized that blocking this interaction may promote Wnt signaling. Immunoprecipitation analyses showed that a synthetic cyclic peptide containing the last 28 AA of LRP5 abolished the functional interaction between N-cadherin and LRP5 in MC3T3-E1 osteoblasts. Strikingly, this peptide increased beta-catenin nuclear translocation and transcriptional activity, and enhanced ERK and PI3K/Akt signalling in MC3T3 cells, resulting in increased cell proliferation and osteoblast gene expression. The results show that 1) the 28 last AA in the LRP5/6 intracellular domain physiologically interacts with the 62 last amino acids of N-cadherin, and 2) peptide-mediated disruption of the interaction between LRP5/6 and N-cadherin intracellular domains results in increased osteoblast proliferation and differentiation, thus providing a novel potential target to promote osteoblastogenesis.

Disruption of Cathepsin K in the Osteoclast Lineage Increased Bone Formation through Coupling-dependent Mechanism. Sutada Lotinun*[1], Riku Kiviranta[2], Lynn Neff[1], Jean Vacher[3], Eero Vuorio[2], William Horne[1], Georgios Sabatakos[4], Roland Baron[5]. [1]Harvard School of Dental Medicine, USA, [2]University of Turku, Finland, [3]Institut De Recherches Cliniques De Montréal, Canada, [4]Procter & Gamble Pharmaceuticals, Inc., USA, [5]Harvard School of Medicine & of Dental Medicine, USA

Loss of function mutation of cathepsin K (CathK) in humans causes pycnodysostosis. It has been shown that CathK-null mice have high bone formation rate (BFR) and high numbers of poorly functional osteoclasts (OCs) (Kiviranta et al., 2005; Pennypacker et al., 2009). We have reported that ablation of CathK in hematopoietic cells using Mx1-cre-LoxP (Mx1-cre;CKLP$^{fl/fl}$ mice) eliminated most of CathK mRNA expression in OCs but not in osteoblasts (OBs). Mx1-Cre-induced CathK deficiency resulted, as expected, in moderate osteopetrosis with increases in cancellous bone volume (+163%) and number of poorly functional OCs (+178%). Interestingly, BFR and OB number were also markedly increased (+188% and +214%, respectively). Both ALP and mineralized bone nodules were increased in Mx1-Cre;CathK$^{fl/fl}$ OBs cultured *in vitro*. In contrast, targeted deletion of CathK in OB lineage had no effect on bone formation or bone resorption, suggesting that deletion of CathK in OC induces the increased BFR. However, the mechanism leading to increased BFR in Mx1-cre;CKLP$^{fl/fl}$ mice remains undefined. We proposed that deletion of CathK in OCs causes a release of coupling factors, recruiting osteoprogenitors to the remodeling sites and stimulating bone formation. To test this hypothesis, we specifically deleted CathK in the OC lineage by crossing with CD11b-cre mice. CD11b-Cre-induced CathK deficiency increased OC number but also resulted in increases in several indices of bone formation (MS, MAR, BFR, and OB number), demonstrating that the increased BFR is OC-mediated. Steady-state levels of OB marker genes osterix and osteocalcin also increased. We measured *in vitro* gene expression of OC-derived coupling factors, including wnt10b, ephrin b2, and sphingosine kinase (SPHK), an enzyme that catalyzes the phosphorylation of sphingosine to sphingosine 1-phosphate (S1P). Ablation of CathK in OCs increased SPHK1 but not SPHK2, wnt10b or ephrin b2. Immunostaining confirmed the increased SPHK1 in OCs. Our data provide evidence that the increased BFR in CathK-null mice is due to changes in OCs and that S1P may be one of the coupling factors that induce this increase.

CD68 Regulates Osteoclast Function via Mediation of Attachment to Bone. Jason Ashley*, Zhenqi Shi, Xu Feng. University of Alabama at Birmingham, USA

Adhesion of osteoclasts to the bone surface by way of the sealing zone has long been recognized as an important feature of their bone resorptive activity; however, how osteoclasts form this strong attachment at the sealing zone has not been fully elucidated. In an effort to identify mediators of osteoclast/osteoclast precursor attachment to bone, we developed a phage-display library from cDNA derived from bone marrow macrophages (BMMs) grown on bone slices and screened that library in a bio-panning assay with a selection bias towards phages with high affinity for bone matrix. Sequencing of cDNA from an adherent phage identified CD68 as a candidate bone adhesion molecule. CD68, a heavily-glycosylated transmembrane protein belonging to the Lysosome Associated Membrane Protein (LAMP) family, is highly expressed by macrophages and osteoclasts. Unlike most LAMPs, CD68 possesses a largely O-glycosylated mucin-like domain that faces either the lumen of the lysosome or the extracellular space depending on its localization. *In vitro* antibody blockade and RNAi experiments revealed that, in the absence of functional CD68, BMM attachment to bone slices is reduced. Furthermore, osteoclasts formed *in vitro* from shRNA-silenced BMMs do not spread properly and fail to efficiently resorb bone. These data indicate that CD68 plays an important role in osteoclast function by mediating their attachment to bone. Interestingly, during osteoclastogenesis there is an increase in CD68 expression concomitant with a decrease in apparent molecular weight (MW), which is likely due to a decrease in glycosylation. We found that M-CSF alone increases CD68 expression, while RANKL is required for the change in MW. This shift is apparent within 36 hours of initial RANKL treatment and becomes more pronounced as osteoclastogenesis progresses. RANK signals through multiple intracellular TRAF-binding and non-TRAF-binding motifs. Using human Fas/mouse RANK chimeric receptors that allow specific activation of TRAF versus non-TRAF motifs, we found that stimulation of receptors with functional TRAF motifs, but not those without, induces a reduction in CD68 MW that parallels the shift seen in BMMs treated with RANKL, indicating that the RANKL-induced change in CD68 MW is mediated through TRAF signaling. The findings described above show that CD68 plays a role in bone resorption by mediating osteoclast attachment and this function likely depends upon a RANKL-induced reduction in CD68 glycosylation.

Osteoclast Attachment and Motility are Regulated by Nitric Oxide Through the Dual Effects of IRAG on Calcium Release and Cytoskeletal Protein Interactions. Lisa Robinson*, Harry Blair, Beatrice Yaroslavskiy. University of Pittsburgh, USA

Control of osteoclast activity is critical to the maintenance of skeletal mass. Previous studies showed that nitric oxide (NO), a negative regulator of bone resorption, promotes detachment and motility of osteoclasts: we observed disassembly of the cytoskeletal complexes required for specialized osteoclast attachments at resorption sites after NO signals, and found that NO-stimulated osteoclast motility required inositol-1,4,5-trisphosphate receptor (IP3R) controlled calcium release. In the present studies, using human osteoclasts in vitro, we further explored the molecular mechanisms of osteoclast regulation by NO, focusing on the roles of the IP3R1-associated cGMP-dependent protein kinase substrate (IRAG). Two isoforms of IRAG exist, resulting from alternative splicing; both are expressed by the osteoclast. As in other cell types, the larger (endosomal) form of IRAG is found at the endoplasmic reticulum, where it is proposed to act as a scaffold facilitating phosphorylation of IP3R1 by PKG1beta. Co-immunoprecipitation and Western blot studies revealed specific binding of the endosomal IRAG to IP3R1 in osteoclasts and serine phosphorylation of both by the cGMP-dependent protein kinase (PKG). Unexpectedly, we found that IRAG-IP3R1 association was not static in osteoclasts: NO stimulated dissociation of the complex. Both NO antagonists and PKG inhibitors stabilized the IRAG-IP3R1 complex. NO-dependent Src activation, which by phosphorylating IP3R1 enhances calcium release, also promoted dissociation of IRAG from IP3R1. When IRAG was suppressed by siRNA, basal calcium levels increased, and calcium regulation by NO was lost, consistent with IRAG as a link between NO and IP3R1. Immunofluorescence studies also showed IRAG localization to podosomes but the predominant form at this site was the smaller isoform, hitherto of unknown function. Using co-immunoprecipitation and Western blotting we detected binding of IRAG to cytoskeletal regulatory proteins migfilin and VASP. Inhibition of IRAG expression by siRNA reduced cell spreading and attachment, and altered podosome distribution, the resulting pattern resembling that of osteoclasts with attachment defects associated with osteopetrosis. Together these results identify IRAG as a mediator of NO effects on osteoclast attachment involved both in the regulation of IP3R1 calcium release and in interactions with cytoskeletal proteins critical to osteoclastic bone resorption.

Bone Marrow Stromal Cells Suppress TACE-mediated M-CSFR and RANK Shedding to Facilitate Osteoclastogenesis and Suppress DC Differentiation from Monocytes. Masahiro Hiasa*[1], Masahiro Abe[2], Ayako Nakano[3], Asuka Oda[2], Hiroe Amou[2], Keiichiro Watanabe[4], Shingen Nakamura[2], Hirokazu Miki[2], Kyoko Takeuchi[2], Kumiko Kagawa[2], Shuji Ozaki[2], Eiji Tanaka[1], Kenzo Asaoka[1], Toshio Matsumoto[5]. [1]University of Tokushima Graduate School, Japan, [2]University of Tokushima, Japan, [3]University of Tokushima Graduate School of Medicine, Japan, [4]The University of Tokushima Graduate School of Oral Science, Japan, [5]University of Tokushima Graduate School of Medical Sciences, Japan

Multiple myeloma (MM), a malignancy of plasma cells, arises and expands in the bone marrow and generates devastating osteoclastic bone destruction. In contrtast to enhanced osteoclastogenesis, dendritic cells (DCs) decrease in number and function in MM, suggesting the dysregulation of OC and DC differentiation from their precursor, monocytes. We recently reported that GM-CSF and IL-4, an inducer of DC differentiation, up-regulate TNF-alpha converting enzyme (TACE) expression in monocytes to cleave their surface M-CSF receptor (M-CSFR) and RANK and disrupt osteoclastogenesis (Blood, 2009). Because bone marrow stromal cells (BMSCs) play an important role in osteoclastogensis in MM, we explored the role of BMSCs in the regulation of monocyte differentiation into OCs and DCs. BMSCs suppressed DC induction and resumed osteoclastogenesis from monocytes along with the restoration of surface M-CSFR and RANK expression on monocytes in the presence of GM-CSF and IL-4. BMSCs secreted a large amount of TIMP-3, an inhibitor for TACE. The suppression of TIMP-3 production in BMSCs by TIMP-3 siRNA significantly increased M-CSFR ectodomain shedding in monocytes and resumed GM-CSF and IL-4-mediated DC differentiation from monocytes in the presence of BMSCs, suggesting the regulation of TACE activity in monocytes and monocyte differentiation by BMSC-derived TIMP-3. The TIMP-3 production by BMSCs was further enhanced by IL-6 and TGF-beta which are known to be over-produced in MM bone lesions. Interestingly, RANK ligand induced TIMP-3 mRNA expression in RAW264.7 cells; TIMP-3 expression was robustly up-regulated in OCs compared to that in their precursor monocytes while TACE expression showed no appreciable change. These results suggest that BMSCs up-modulate M-CSFR and RANK on monocytes through TIMP-3 elaborated by BMSCs to facilitate osteoclastogenesis and suppress DC differentiation, and that TIMP-3 expression is induced in OCs by themselves during osteoclastogenesis to further block TACE activity and enhance the surface expression of these receptors. Besides the up-regulation of RANK ligand expression in BMSCs by MM cells, the suppression by BMSCs of TACE-mediated shedding of M-CSFR and RANK may dysregulate monocyte differentiation towards OCs to cause extensive bone destruction and immunodeficiency in MM.

Identification of a Novel Osteoclastogenic Co-activator for Nfatc1, OCAN. Min-Young Youn*[1], Sally Fujiyama-Nakamura[1], Shigeaki Kato[2]. [1]IMCB, University of Tokyo, Japan, [2]University of Tokyo, Japan

Osteoclastogenesis is the highly regulated process governed by diverse factors. Among them, Nfatc1 is a prime transcriptional factor throughout osteoclastogenesis. With differentiation signal, Nfatc1 is dramatically induced by auto-amplification with its unique promoter status, suggesting involvement of specialized epigenetic regulation. However, epigenetic complexes assisting Nfatc1 expression and/or function during osteoclastogenesis remain to be identified. To address this issue, we tried to biochemically purify epigenetic regulators associating with Nfatc1. Nuclear extracts prepared from RANKL-induced Raw264 cells were applied into Nfatc1-antibody column, and then candidate proteins were identified by MALDI-TOF/MS analysis. Among several identified factors, we focused on an uncharacterized protein 'osteoclastogenic co-activator for Nfatc1 (designated as OCAN)', simultaneously purified with Brg1 and Baf protiens of SWI/SNF-type chromatin remodeler complex. These interactions were also confirmed by co-immunoprecipitation experiment, suggesting that OCAN is a novel component of SWI/SNF-type chromatin remodeler complex to support Nfatc1 function. To understand the role of OCAN, transcriptional activity of Nfatc1 was detected by luciferase assay. Interestingly, its transcriptional activity was enhanced by OCAN overexpression. Consistently, OCAN knockdown resulted in decreased expression of osteoclast-specific genes such as CtsK and TRAP with inhibited osteoclast formation. These results indicate that OCAN plays a role as a co-activator of Nfatc1 during osteoclastogenesis. To define the molecular mechanism of OCAN, the recruitment of Nfatc1 on promoters of its target genes was detected with ChIP assay. Nfatc1 could not be recruited on its target genes without OCAN protein. Similarly, recruitment of Brg1 was reduced in OCAN-knockdown cells. Taken together, OCAN can be considered as a novel component of a SWI/SNF-type chromatin remodeler complex to reorganize the chromatin status for DNA-binding ability of Nfatc1.

MicroRNA-21 Has a Central Critical Role in Osteoclastogenesis. Keith Hruska, Toshifumi Sugatani*. Washington University in St. Louis School of Medicine, USA

MicroRNAs, integral elements in the post-transcriptional control of gene expression, are implicated in many physiological cellular processes and contribute to molecular alterations in pathophysiological conditions. Our previous studies have demonstrated that conditional deletion of Dicer with a cre-lox strategy employing a cre directed to the myeloid-osteoclast lineage, CD-11b-Cre mice, produced mild osteopetrosis due to decreased osteoclast numbers and bone resorption, indicating that microRNA biogenesis is obligatory for osteoclastic control of bone metabolism. Dicer is an endoribonuclease in the RNase III family that cleaves double-stranded RNA and precursor-microRNA into short double-stranded RNA fragments called small interfering RNA. However, the mechanisms of microRNA action and the biological roles of specific microRNAs in osteoclastic control of bone metabolism are not fully understood. We found that two microRNAs of 617 mouse microRNAs are robustly expressed during osteoclastogenesis using a high-throughput analysis. In the analysis of the role of one of these, microRNA-21 (miR-21), we demonstrated that its expression and function was critical in osteoclastogenesis. Gene silencing of miR-21 significantly inhibited TRAP-positive osteoclast formation. In investigating the biological function of miR-21 in osteoclastogenesis, we focused explicitly on the function of programmed cell death 4 (PDCD4), one of the targets of miR-21, in osteoclastogenesis. Forced expression of PDCD4 significantly suppressed TRAP-positive osteoclast formation numbers due to attenuated c-Fos activity and expression of NFATc1. Moreover, the expression of osteoclast-specific markers such as cathepsin K and integrin beta-3 was inhibited by PDCD4 overexpression. In addition, forced expression of PDCD4 robustly induced the expression of nuclear factor I-B (NFIB) which is a target of miR-21, and additionally, a transcriptional repressor of the miR-21 promoter. Also, c-Fos overexpression triggered miR-21 transcription through several binding sites of AP-1 in the miR-21 promoter, and the expression of miR-21 was extremely attenuated in c-Fos deficient osteoclast precursors. On the basis of these results, we conclude that mir-21 is central to a novel mechanism regulating osteoclast development beginning with pro-osteoclastogenic cytokines triggering c-Fos expression and stimulation of microRNA-21 gene expression due to suppression of PDCD4.

Regulatory Role of Osteoactivin/Gpnmb in Osteoclast Differentiation and Function In Vivo. Joyce Belcher*[1], Fabiola Del Carpio- Cano[2], M. Alexandra Monroy[3], Steven Popoff[4], Fayez Safadi[4]. [1]Temple University, School of Medicine, USA, [2]Temple University School of Medicine, Department of Anatomy & Cell Biology, USA, [3]Temple University School of Medicine, Department of Anatomy & Cell Biology & Department of Surgery, USA, [4]Temple University School of Medicine, USA

Osteoactivin/Gpnmb (OA/Gpnmb) is a glycoprotein initially identified in bone and later found to be strongly expressed in bone-forming osteoblasts. Recent literature suggests that OA/Gpnmb is also expressed in bone-resorbing osteoclasts; therefore, we sought to elucidate a role for OA/Gpnmb in osteoclast differentiation and function. We first examined osteoclast differentiation in response to M-CSF and RANKL in culture. Non-adherent mouse bone marrow hematopoietic stem cells (HSCs) were cultured in the presence of 50ng/ml of M-CSF for two days and then with M-CSF and 100 ng/ml of RANKL in the presence or absence of 50ng/ml recombinant OA/Gpnmb. We observed a dramatic increase in multinucleated TRAP-positive osteoclasts and the number of nuclei per osteoclast in OA/Gpnmb-treated compared to control cultures. Additionally, analysis of HSCs showed increased cell proliferation in response to exogenous OA/Gpnmb treatment. Next, we assessed osteoclast differentiation using a mouse model with a natural mutation in the OA/Gpnmb gene caused by a premature stop codon that results in the generation of a truncated OA/Gpnmb protein. These mice exhibit a skeletal phenotype associated with decreased bone mass. Histomorphometric analysis of femoral sections revealed increased numbers of TRAP-positive osteoclasts in OA/Gpnmb mutant compared to WT mice. Although the number of osteoclasts was higher in OA/Gpnmb mutant mice, ELISA assessment of serum levels of C-terminal collagen telopeptide (CTx), a marker for osteoclast activity, showed a significant reduction in OA/Gpnmb mutant compared to WT mice. These data suggest that although osteoclasts are increased in number they appear to be functionally defective in the OA/Gpnmb mutant mice in vivo. When osteoclasts were differentiated in ex vivo cultures of hematopoietic progenitors derived from OA/Gpnmb mutant and WT mice, we observed decreased osteoclast number and size in OA/Gpnmb mutant compared to WT cultures. This decrease was abrogated when cultures were treated exogenously with recombinant OA/Gpnmb. Western blot analysis of HSCs revealed decreased PU.1 and CSF-receptor expression in OA/Gpnmb mutant in comparison to WT, suggesting that the mutation in OA/Gpnmb affects early commitment to the osteoclast lineage. Collectively, these data implicate a regulatory role for OA/Gpnmb in osteoclast differentiation and function.

Vitamin E Induces Osteoclast Fusion and Decreases Bone Mass. Koji Fujita*[1], Makiko Iwasaki[2], Takako Koga[3], Hiroshi Takayanagi[4], Kimitaka Takitani[5], Hiroshi Tamai[5], Hiroyuki Arai[6], Hiroshi Ito[7], Kenichi Shinomiya[8], Shu Takeda[9]. [1]Dept. of Orthopedics, Tokyo Medical & Dental University,Global Center of Excellence (GCOE) Program, International Research Center for Molecular Science in Tooth & Bone Diseases, Japan, [2]Dept. of Orhopedics, Tokyo Medical & Dental University, Japan, [3]Dep of Cell Signaling, Graduate School of Medical & Dental Sciences, Tokyo Medical & Dental University, Japan, [4]Tokyo Medical & Dental University, Japan, [5]Department of Pediatrics, Osaka Medical College, Japan, [6]Department of Health Chemistry, Graduate School of Pharmaceutical Sciences, The University of Tokyo, Japan, [7]Dept. of Nephrology, Endocrinology & Metabolism Keio Univ., Japan, [8]Dept. of Orthopedics, Tokyo Medical & Dental University, Japan, [9]Keio University, Dept. of Nephrology, Endocrinology & Metabolism, Japan

Vitamin E, a fat-soluble vitamin, is well known as an antioxidant. Of eight forms of food-derived vitamin E, only α-tocopherol is secreted into the general circulation through the action of α-tocopherol transfer protein (α-TTP) expressed in the liver. Therefore, α-TTP knockout (KO) mice develop severe vitamin E deficiency. To clarify the role of vitamin E in bone metabolism, we analyzed bone phenotype of α-TTPKO mice.

At three months of age, α-TTPKO mice showed high bone mass. Histomorphometric analysis revealed that bone resorption of α-TTPKO mice was increased, which is also confirmed by an increase in serum TRAP5b. In contrast, no change in bone formation was observed in α-TTPKO mice. Interestingly, when we cultured osteoclast using serum from α-TTPKO mice, osteoclast differentiation was markedly hampered, indicating that lack of α-tocopherol in the serum is responsible for the high bone mass in α-TTPKO mice. In line with that, addition of α-tocopherol to the culture media during the maturation phase of osteoclastic differentiation significantly induced osteoclast fusion. In contrast, α-tocopherol did not affect proliferation of osteoclast precursors or osteoclast apoptosis. Molecular analysis revealed that *DC-STAMP*, essential molecule for osteoclast fusion, was specifically increased by α-tocopherol treatment, while expression of *Atp6v0d2*, *Meltrin-α*, *CD44*, *CD47* and important molecules for cell fusion was unchanged. Moreover, induction of osteoclast fusion by α-tocopherol was abolished in *DC-STAMP* knockdown osteoclasts or osteoclasts

generated from DC-STAMPKO mice, demonstrating that α-TTP regulates osteoclast fusion through DC-STAMP.

Finally, wild type mice fed a high-α-tocopherol diet developed low bone mass phenotype due to increase in bone resorption. Taken together, these results demonstrated that α-tocopherol regulates osteoclast fusion and bone resorption in a DC-STAMP-dependent manner and excessive intake of vitamin E may cause osteoporosis.

Dok-1 and Dok-2 are adaptor proteins and act as negative regulators of the Ras-Erk pathway downstream of M-CSF signaling system. These two molecules are preferentially expressed in hematopoietic cell lineage and are involved in the regulation of macrophages. Dok-1 and Dok-2 promote recruitment of p120 rasGAP and this action is critical for their negative regulation of the Ras-Erk pathway. Although osteoclasts are derived from hematopoietic stem cells and share similarities with macrophages regarding the developmental processes, the molecular mechanisms of Dok protein function in osteoclastic regulation in pathophysiological condition have not yet been fully understand. Double deficiency of Dok-1 and Dok-2 reduces the levels of bone mass (bone volume per tissue volume, BV/TV) in mice, although the levels of the number of TRAP positive cells per bone surface were similar between Dok-1 and Dok-2 double knockout mice compared to wild type, leaving a possibility that the function of osteoclastic cell may be enhanced by the deficiency of these two molecules. With regard to the development of osteoclasts in vitro in the presence of M-CSF and RANKL, the deficiency of Dok-1 and Dok-2 enhances sensitivity of the osteoclast progenitor cells in the bone marrow to M-CSF to develop into TRAP positive osteoclastic cells. Therefore, Dok-1/2 may play a role in M-CSF dependent activation during osteoclast differentiation in vitro. To further examine whether such characteristics of Dok-1/2 would be involved in the pathophysiological situation, we examined the effects of Dok-1 and Dok-2 deficiency on bone loss in postmenopausal osteoporosis model. In wild type mice, ovariectomy reduced bone mass and also the uterine weight. In Dok-1/2 double deficient mice, uterine weight loss was similarly observed compared to wild type mice. In contrast, however, ovariectomy-induced bone loss was enhanced in the region of the secondary trabecular bone. These observations suggest a role of Dok-1/2 in establishing osteopenic situation in the postmenopausal osteoporosis model of the ovariectomised mice.

LIS1, a Plekhm1 Binding Protein, Regulates Microtubule Organization/ Transportation and Cathepsin K secretion in Osteoclasts and is indispensable for Osteoclast Formation and Function. Shiqiao Ye*[1], Yunfeng Feng[2], Kanan Vyas[3], Stavros Manolagas[1], Haibo Zhao[1]. [1]University of Arkansas for Medical Sciences, USA, [2]Department of internal medicine, Washington University School of medicine, USA, [3]Center for Osteoporosis & Metabolic Bone Diseases, University of Arkansas for Medical Sciences & Central Arkansas Veterans Healthcare System, USA

Osteoclasts (OCs) secret protons and cathepsin K to resorb mineralized bone matrix through lysosome exocytosis. Mutations or deletion of PLEKHM1 is responsible for osteopetrosis in the ia/ia rat as well as a subset of patients with intermediate osteopetrosis. Moreover, we and others have demonstrated that Plekhm1 is associated with lysosomes in OCs and regulates cathepsin K secretion. However, the precise function of plekhm1 in OCs remains unknown. To better understand how Plekhm1 might regulate OC activity we searched for potential Plekhm1 binding proteins. GST-Plekhm1 was used to pull-down associated proteins from mature murine OC lysate followed by mass spectrometry analysis. By this method, we have identified LIS1 as a novel Plekhm1 binding protein in OCs. The interaction between LIS1 and Plekhm1 was further confirmed by co-immunoprecipitation of endogenous LIS1 with HA-tagged Plekhm1 from mature OCs. Mutations or deletion of the LIS1 gene has been documented in patients with lissencephaly, a severe human developmental brain disorder that is caused by incomplete neuronal migration. LIS1 is part of a highly conserved evolutionary pathway that regulates microtubule dynamics and cytoplasmic dynein motor function. When expressed as V5-tagged protein, LIS1 co-immunoprecipitates and co-localizes with cytoplasmic dynein independent of Plekhm1 in OCs. To elucidate the role of LIS1 in OC we knocked down its expression by lenti-viral vector mediated shRNA expression. LIS1 protein levels were decreased by 90% in the LIS1 shRNA transduced BMMs, pre-Ocs, and mature OCs as compared with control cells. Decreased LIS1 expression dramatically attenuated the formation of multinucleated, TRAP+ OCs. Additionally, both the size and total area of resorption pits were decreased in LIS1 shRNA expressing OCs as compared with control OCs. Furthermore, the medium level of CTx, a marker of bone resorption, was 10 times lower in LIS1 knockdown OCs. Knockdown of LIS1 also induced aggregation of microtubules and lysosomes around nuclei and caused a decrease in cathepsin K secretion and the labeling of lysosomal membrane protein LAMP-2 at the ruffled border membrane. Taken together, these findings demonstrate for the first time that LIS1 regulates OC microtubule organization, transportation and lysosome secretion by binding to and modulating dynein and Plekhm1. We, therefore, conclude that because of these functions LIS1 is essential for osteoclast formation and bone resorption.

Rac Deletion in Osteoclasts Causes Severe Osteopetrosis. Monica Croke*[1], F. Patrick Ross[2], Steven Teitelbaum[3]. [1]Washington University School of Medicine, USA, [2]Hospital for Special Surgery, USA, [3]Washington University in St. Louis School of Medicine, USA

The unique ability of the osteoclast to normally resorb bone requires the αvβ3 integrin. Liganding this heterodimer induces a canonical signaling complex which transits the small GTPase, Rac, from its inactive GDP- to its active GTP-bound form. While the molecular mechanisms by which αvβ3 activate Rac, are in hand, whether the GTPase meaningfully impacts osteoclast function is unknown. We find that deletion of Rac1 or Rac 2, alone, does not alter skeletal structure. However, variable reduction of Rac1 in osteoclastic cells of Rac2-/- mice, yields osteopetrosis more severe than occurs with deletion of other members of the integrin-activated signaling complex, save c-src. Osteoclasts lacking Rac1 and 2 (RacDKO), in combination, fail to effectively resorb bone. On the other hand, osteoclasts are abundant in RacDKO osteopetrotic mice and normally express the cells' maturation markers. These data indicate that the osteopetrotic lesion of RacDKO mice largely reflects impaired function and not arrested differentiation of the resorptive polykaryon. The dysfunction of RacDKO osteoclasts represents failed cytoskeleton organization as evidenced by reduced motility and inability to spread or generate the key resorptive organelles, actin rings and ruffled borders. The ability of Rac to organize the osteoclast cytoskeleton is regulated by binding of effector proteins to specific amino acids in its Switch 1 domain. Multiple Rac effectors likely cooperate to assemble and maintain the dynamic actin ring. Supporting this hypothesis, expression of Rac1 constructs containing point mutations that target separate Rac-effector interactions (T35S, F37A or Y40C) fail to rescue actin ring formation and bone resorption activity. Additionally, activation of p21 activated kinase (PAK), a Rac effector that activates several actin modifying proteins, is diminished in the Rac dKO OCs both in response to c-Fms and αvβ3 activation. Thus, Rac1 and Rac2 are mutually compensatory and while their combined absence does not impact differentiation, it promotes severe osteopetrosis by dysregulating the osteoclast cytoskeleton.

The Distinct Roles of Cbl and Cbl-b in Osteoclast Differentiation, Survival and Function are Due to Unique Phosphorylation-dependent Interaction of Cbl with PI3K. Naga Suresh Adapala*[1], Alexander Tsygankov[1], Mary Barbe[2], Archana Sanjay[2]. [1]Temple University, USA, [2]Temple University School of Medicine, USA

Cbl and Cbl-b proteins are E3 ubiquitin ligases and adaptor proteins that are expressed in osteoclasts (OCs). Although both proteins share domain organization and significant homology their absence in mice results in disparate skeletal phenotypes: adult Cbl-/- mice are normal whereas deficiency of Cbl-b results in osteopenia due to hyperactivity of OCs. Interaction of Cbl with PI3K depends on phosphorylation of tyrosine737 within YEAM motif of Cbl, which is not present on Cbl-b. Previously we have demonstrated that in contrast to Cbl-/-, ablation of PI3K binding site on Cbl in mice (YF mice) results in increased bone volume due to defective OC function despite two-fold increase in OC numbers. We also showed that YF OCs have increased survival in response to RANKL due to increased AKT activation. These data suggested that Cbl and Cbl-b have different roles, thus while Cbl-b negatively regulates bone resorption, Cbl positively mediates OC function. To investigate the distinct roles of Cbl and Cbl-b we generated YF mice in the Cbl-b$^{-/-}$ background (CYB mice). Micro CT analysis of the tibiae from 12 wk old male mice showed that in the absence of Cbl-b, the decrease in OC function due to YF Cbl mutation is lost and the mice showed decreased bone volume similar to Cbl-b KO (BV/TV% WT 8.1 ± 0.10, CYB: 6.4 ± 0.11, Cbl-b-/-: 4.9 ± 0.08). On the other hand, TRAP staining of long bones showed that similar to YF samples the OCs numbers were increased in CYB mice (OC/mm^2, WT: 6 ± 0.4, YF: 12.8 ± 2.04, CYB: 10.5 ± 0.2).

We also examined osteoclast differentiation, survival and pit formation in *ex vivo* culture system among the five genotypes. Our data showed that compared to the Cbl-/- and Cbl-b-/- which had normal differentiation and survival, in YF and CYB OCs both differentiation and survival in response to RANKL was increased 2 and 3 fold respectively. At the molecular level AKT phosphorylation was unchanged in the absence of Cbl or Cbl-b protein. However, in YF and CYB OCs, in response to RANKL sustained and enhanced AKT phosphorylation was seen. The enhanced AKT activation in YF and CYB OCs was further confirmed by increased phosphorylation of GSK a AKT substrate. Cumulatively, these in vivo and in vitro results confirm that Cbl and Cbl-b perform distinct non-redundant roles in osteoclast biology. Thus while bone resorption is negatively regulated by Cbl-b, Cbl by binding to PI3K positively modulates osteoclast function while negatively regulating differentiation and survival.

A Marrow 'Guardian' Cell inhibits Marrow Space Mineralization and Trabecularization through Sost/sclerostin Expression. Jian Feng[1], Xianglong Han*[2]. [1]Texas A&M Health Science Center, USA, [2]Baylor College of Dentistry, TX A&M Health Science Center, USA

It is well known that bone marrow ablation leads to rapid new bone formation within the marrow space and that this bone is gradually removed and replaced with marrow. We hypothesize that a 'guardian' cell exists in the marrow space that inhibits bone formation to maintain normal marrow function. It has been shown that Sost/Sclerostin is a major negative regulator of bone formation. This factor is highly expressed in osteocytes embedded in bone, but we sought to test if also present in marrow cells. To accomplish this goal, we compared Sclerostin expression by both Western blot and real-time RT-PCR of flushed bone marrow cells to extracted mineralized bone. In Western immunoblotting, the identical 24 kDa bands were detected in protein extracts from both the bone marrow cell and the cortical bone matrix by using a monoclonal anti-SOST antibody. A quantitative real-time PCR assay showed a ratio of Sost mRNA in long bone to bone marrow as 2:1. In situ hybridization further confirmed expression of Sost mRNA in a mesenchymal-like bone marrow cell with a slightly lower expression intensity than that in osteocytes embedded in bone matrix. Next, we generated a Sost-cre mouse line where the Cre is under control of a Sost BAC clone containing the entire cis-regulatory region of murine Sost gene. Both lacZ positive osteocytes and bone marrow cells were detected when Sost-cre mice were crossed with Rosa 26-lacZ reporter mice similar to the in situ hybridization data. We have also generated mouse models where either the BMP receptor 1a was deleted or ?-catenin was constitutively activated in progenitor cells using either 3.6 Col 1a1-cre or inducible Mx1-cre. Characterization techniques include radiographs, micro-CT, scanning electron microscope, H&E and TRAP assays. Surprisingly, in both of these models (3.6 Col-cre x Bmpr1a fl/fl or Mx1-cre x mutant ?-catenin exon 3 fl/fl) over 80% of bone marrow space was filled with trabecular bone with little changes in osteoclast numbers. In the BMP receptor 1a conditional knockout mice, there was a decrease in Sost/sclerostin expression and an increase in ?-catenin signaling. Taken together, the above data support a hypothesis that an early marrow progenitor cell expresses Sost to prevent ectopic marrow bone formation, and that trabecular versus cortical bone mass is differentially regulated. Identification and characterization of this marrow 'guardian' cell will provide further information on how bone mass is differentially controlled. (This study was supported by NIH grants to JQF for DE015209, AR051587; and LFB/JQF/SEH for AR046798)

Bone-Muscle Crosstalk is Demonstrated by Morphological and Functional Changes in Skeletal and Cardiac Muscle Cells in Response to Factors Produced by MLO-Y4 Osteocytes . Nuria Lara[1], Todd Hall*[1], Chad Touchberry[1], Jon Andresen[1], Marco Brotto[1], Mark Johnson[2], Michael Wacker[3], Christopher Elmore[1], Sandra Romero - Suarez[1], Cheng Lin Mo[4], Lynda Bonewald[1], Neerupma Silswal[1]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri, Kansas City Dental School, USA, [3]University of Missouri-Kansas City School of Medicine, USA, [4]Univsity of Missouri - Kansas City, USA

Osteocytes, which compose 90-95% of all bone cells, are mechanosensory cells that also function in an endocrine fashion to target the function of other organs such as kidney. We hypothesized that osteocytes could target muscle and that the effects of muscle induced mechanical loading of bone could regulate muscle signaling factors produced by osteocytes. To begin to examine this hypothesis, we tested the effects of conditioned media (CM) from MLO-Y4 osteocytes with and without fluid flow shear stress (FFSS) on C2C12 muscle cells, HL-1 cardiac muscle cells and A7R5 vascular smooth muscle cells.

CM was obtained from static MLO-Y4 osteocytes and cells subjected to FFSS (2 or 16 dynes/cm^2) for 2 hours. CM was applied to C2C12 myoblasts and replaced the complete growth media (CGM) that stimulates proliferation of myoblasts, to HL-1 cardiac myocytes serum starved for 48 hours in Claycomb's minimal media, and to A7R5 vascular smooth muscle cells grown in DMEM with 10% FBS. All muscle cells were monitored for morphological changes for up to 4 days. As PGE2 is a major osteocyte signaling factor induced by FFSS, PGE2 (5μM) was tested on morphology and intracellular calcium (Ca^{+2}) homeostasis in C2C12 muscle cells.

CM from static or 2 dynes/cm^2 FFSS treated MLO-Y4 cells promoted robust differentiation of C2C12 myoblasts into myotubes (~13-15 myotubes in CM vs. 3-5 myotubes in CGM per random field of view, n=3). PGE2 had no effect on myotube formation suggesting this effect was not due to PGE2, but to other osteocyte factors. In C2C12 myotubes induced by normal differentiation media with 2.5% horse serum, caffeine challenge produced a single peak calcium transient whereas PGE2 induced 4-6 oscillatory calcium waves. This suggests that PGE2 produced by osteocytes could have an effect on gene expression as this oscillatory pattern of Ca^{+2} waves has been linked with modulation of gene activity. MLO-Y4 FFSS (16 dynes/cm^2) CM increased HL-1 cardiac myocyte cell area by 28.4 $\pm$ 14.2% (n=3), indicative of cardiac hypertrophy. In contrast, MLO-Y4 CM had no effects on A7R5 vascular smooth muscle cells.

Our data suggest that factors released from osteocytes can influence muscle cell morphology and function. By promoting the differentiation of myoblasts into myotubes, osteocytes may modulate muscle repair and regeneration. Our results support the hypothesis that osteocytes might act as an endocrine organ that modulates the function of striated muscles.

Cx43 in Osteocytes, but not in Osteoblasts, Is Required to Preserve Osteocyte Viability, Bone Geometry and Material Stiffness. Nicoletta Bivi*[1], Mark Nelson[2], Racheal Lee[3], Jeffrey Benson[3], Keith Condon[3], Jiliang Li[2], Matthew Allen[3], Teresita Bellido[3], Lilian Plotkin[3]. [1]Indiana University, USA, [2]Indiana University, Purdue University Indianapolis, USA, [3]Indiana University School of Medicine, USA

Mice lacking connexin (Cx)43 in osteoblasts and osteocytes (Cx43^{fl};OCN-Cre mice, named Cx43$^{\Delta OB/OT}$) exhibit increased prevalence of cortical osteocyte apoptosis, higher endocortical resorption and periosteal apposition leading to wider femoral cross-sections, as well as decreased material stiffness (Young's modulus) likely resulting from the reduced collagen crosslinking detected by FTIR. Deletion of Cx43 in osteoblastic cells has been shown to delay differentiation, abolish pro-survival signaling induced by bisphosphonates and parathyroid hormone, and impair prostaglandin/ATP release and the osteogenic response to mechanical loading. To distinguish the individual contribution of osteocytes vs. osteoblasts to the Cx43$^{\Delta OB/OT}$ mouse phenotype, we removed Cx43 exclusively from osteocytes by mating Cx43^{fl} mice with 8kb-DMP1-Cre mice (Cx43$^{\Delta OT}$). The deleted form of Cx43 was found in genomic DNA by PCR and Cre mRNA was detected by qPCR in bone from Cx43$^{\Delta OT}$ mice, but not from control Cx43^{fl} littermates. Deleted Cx43 or Cre transcripts were not found in heart or kidney from either mouse. Moreover, Cre mRNA expression was detected in green fluorescent protein (GFP)-expressing cells (osteocytes) and not in GFP negative cells (osteoblasts) isolated from calvaria of 8kbDMP1-Cre mice crossed with 10kbDMP1-GFP mice, confirming osteocyte-specific expression of Cre recombinase. Cx43$^{\Delta OT}$ mice exhibited a marked increased in the prevalence of osteocyte apoptosis (12.6$\pm$7.4% vs. 1.1$\pm$1.4%) as well as empty lacunae, an additional sign of cell death, (13.1$\pm$6.9% vs. 0.8$\pm$0.5%) in femoral middiaphysis (n=5/group, $p<0.05$). This was associated with an increase of 26% in femoral marrow cavity area and 20% in total cross-sectional area by μCT, likely the result of increased endocortical resorption and periosteal apposition, respectively. In addition, Young's modulus was 22% lower in Cx43$^{\Delta OT}$ mice as measured by femoral 3-point bending. Therefore, Cx43 deletion only from osteocytes is sufficient to induce osteocyte apoptosis, and to alter bone geometry and material stiffness. We hypothesize that Cx43 is required to sense and transmit physiological survival signals in osteocytes and that, in its absence, apoptotic osteocytes trigger resorption resulting in larger bones. In addition, Cx43 expressed in osteocytes is required to maintain proper bone material stiffness, a function attributed to osteoblasts, but, unexpectedly, not fulfilled by Cx43-expressing osteoblasts in our Cx43$^{\Delta OT}$ mice.

Homozygous Deletion of the *SOST* Gene Results in Enhanced Union and Increased Hard Callus Formation in Healing Fractures. Michelle McDonald*[1], Alyson Morse[2], Lauren Peacock[2], Kathy Mikulec[2], Ina Kramer[3], Michaela Kneissel[4], David Little[2]. [1]The Childrens Hospital Westmead, Australia, [2]The Kids Research Institute, The Children's Hospital Westmead, Australia, [3]Novartis Institutes for BioMedical Research, Che, [4]Novartis Institutes for Biomedical Research, Switzerland

Sclerostin, transcribed by the *Sost* gene, is expressed by osteocytes and is a negative regulator of bone formation. Sclerostin antagonizes Wnt/β-catenin signaling activity via interaction with the Lrp5/6 co-receptor, negatively regulating osteoblast differentiation. Therefore the complete deletion of S*ost* in mice results in an extensively high bone mass. We sought to examine bone repair in the absence of *Sost* in these mice, hypothesizing that the complete loss of the *Sost* gene would result in enhanced bone repair with increased bone volume and content within the repairing callus.

Homozygous-null mice (*Sost* -/-) were compared to wildtype (*Sost* +/+, WT) littermates after tibial closed fracture stabilized by external fixation. Time points examined were 2 weeks (cartilage callus) and 4 weeks (hard callus). Outcome measures were plain X-ray for union, QCT, Micro CT (μCT), and histology.

At 2 weeks there was a 79% decrease in cartilage content in the *Sost* -/- calluses compared to WT ($p<0.05$), consistent with a trend to an increase in the rate of union. At 2 weeks QCT revealed increases of 88% in BMC, 25% in BMD and 50% in bone volume in the *Sost* -/- calluses compared to WT ($p<0.01$). At 4 weeks all fractures had united and BMD was increased by 31% in *Sost* -/- compared to WT ($p<0.01$). μCT of the *Sost* -/- calluses showed a 51% and 44% increase in 3 dimensional BV/TV at 2 weeks and 4 weeks respectively ($p<0.01$).

At the early stage of repair *Sost* -/- mice showed enhanced cartilage removal and earlier hard callus union, along with increased bone content, density, volume and BV/TV. During hard callus remodelling *Sost* -/- mice continued to have increased bone density and BV/TV. This suggests that the absence of sclerostin resulted in enhanced endochondral ossification to union resulting in a denser hard callus.

FR0285

Role of Histone Deacetylases (HDACs) in PTH-mediated Repression of MEF2-dependent Sost Expression in UMR-106 Cells. Stefan Baertschi*, Heidi Jeker, Simone Degen, Hansjoerg Keller. Novartis Institutes for BioMedical Research, Switzerland

Previously, we have shown that parathyroid hormone (PTH) treatment leads to suppression of sclerostin (SOST) expression by inhibiting myocyte enhancer factor 2 (MEF2), which activates the SOST gene bone enhancer. However, the molecular mechanisms of MEF2 inhibition by PTH in osteocytes are yet unknown. In muscle, MEF2 activity is repressed by direct binding of class IIa histone deacetylases (HDACs 4, 5, 7 & 9), which shuttle between cytoplasm and nucleus, regulated by phosphorylation of conserved serines. To study a role of class IIa HDACs in MEF2-mediated SOST expression we first determined their RNA expression levels in SOST-expressing UMR106 cells using quantitative RT-PCR (qPCR). HDAC5 and 7 were strongly expressed, HDAC4 much less and HDAC9 only marginally. High Content Analysis was used to analyze class IIa HDACs nucleo-cytoplasmic shuttling in response to PTH using GFP fusion-proteins. Only HDAC5 showed a rapid nuclear import upon PTH stimulation within 20 minutes. Mutating two conserved serines, which are involved in nuclear export, to alanines we generated a nuclear enriched HDAC5 mutant (S2A) that mimicked PTH-induced nuclear accumulation of wt HDAC5. S2A inhibited MEF2-dependent bone enhancer activity in transient transfections by 52% whereas wt HDAC5 was inactive. Accordingly, the nuclear export inhibitor Leptomycin B led to a strong nuclear retention of HDAC5 and inhibited endogenous Sost expression by 62%. Next, we analyzed the effect of HDAC enzyme inhibition on SOST expression. The pan-HDAC inhibitor Trichostatin A repressed SOST expression similarly as PTH indicating that SOST expression requires HDAC enzymatic activity. Furthermore, the class I HDAC2,3,8 inhibitor Apicidin also led to full inhibition of SOST expression suggesting a specific activating role for class I HDACs. Compared to class IIa HDAC5, HDAC1 and 2 were similarly expressed, HDAC3 much lower and HDAC8 only marginally. Finally, we analyzed the effect of PTH on nucleo-cytoplasmic localization of HDAC3, which is the class I HDAC known to shuttle. In contrast to PTH-induced nuclear import of HDAC5 PTH led to nuclear export of HDAC3. In summary, these data suggest that the PTH-mediated SOST repression involves nuclear import of HDAC5 inhibiting MEF2 and nuclear export of HDAC3. The catalytic activity of HDAC2,3 may be required for SOST expression. Hence, HDAC2,3 inhibitors might have a potential as bone formation stimulators.

Tracking Osteocyte Lineage Plasticity In Vitro. Slavica Pejda*[1], Tomislav Kizivat[1], Mohammad fatahi[1], John Igwe[2], Ivo Kalajzic[3]. [1]Department of Reconstructive Sciences, University of Connecticut Health Center, USA, [2]Department of Orthopedic Surgery,University of Connecticut Health Center, USA, [3]University of Connecticut Health Center, USA

Presently, there is no evidence that mature osteoblast and osteocytes are able to dedifferentiate. However, dedifferentiation of these cells could provide an additional source of cells for skeletal reconstruction/repair. The use of visual transgenes, such as GFP, has been instrumental in identifying cells at different stages of maturation. However, markers that are under the control of specific promoters that are no longer expressed after the cell reaches a point when promoter activity ceases, or when a cell transitions to an alternative differentiation state cannot be used to track cell histories. It is then necessary to to use a tool like the Cre/loxP system for lineage tracing. In this study we present evidence that preosteocytes/osteocytes can undergo dedifferentiation, accompanied by dramatic changes in gene expression. We have utilized previously developed transgenic mice in which Dmp1 promoter had been used with GFP as a visual marker of current stage of differentiation (DMP-GFP) or to drive Cre recombinase and turn on an historical marker in osteocytes and odontoblasts (DMP-Cre).

Primary bone chip outgrowth cell (BCOC) cultures were prepared after surface osteoblasts have been removed using enzymatic digestion. When we utilized a DMP-GFP transgene, outgrowth cells were GFP negative by epifluorescence and by immunofluorescent staining using GFP antibody. Using DMP-Cre mice, floxed GFPreporter+ cells emerged from bone chips after 48-72 hours, where GFP expression iindicates their previous osteocytic phenotype. In addition, a large proportion of BCOC's began to express a-SMA-GFP. Preliminary results obtained by microarray analysis of BCOC isolated 7 days after plating and compared to the RNA of marrow stromal cells showed large increases in markers characteristic of mature osteoblast/osteocytes, including Bglap, Ibsp, Phex, Osterix, BMP8a, and Pthr1. Expanded BCOC's in vitro were transplanted by intra-bone marrow cavity injection. Four weeks after transplantation, GFP-labeled donor cells were detected as numerous osteocytes deeply embedded in newly formed bone.

Our results indicate that under certain conditions cells embedded in the matrix can emerge out and begin to proliferate. This process does not preclude the ability of outgrowth cells to differentiate again into mature osteocytes. Future studies should be aimed at evaluating factors that affect the process of dedifferentiation with the goal of increasing bone formation in vivo and in vitro.

FR0287

Use of a Sost-GFP Mouse Model to Determine the Role of the AKT-GSK3β in Osteocyte Function and to Map Local Strain Fields around Osteocytes with Loading. Stephen Harris*[1], Marie Harris[1], Jelica Gluhak-Heinrich[1], Wuchen Yang[1], Yong Cui[2], Ryan S Potter[3], Lynda Bonewald[4], Daniel Nicolella[3]. [1]University of Texas Health Science Center at San Antonio, USA, [2]U. of Texas Health Science Center at San Antonio, USA, [3]Southwest Research Institute, USA, [4]University of Missouri - Kansas City, USA

Sost/sclerostin is primarily expressed in mature osteocytes and negatively responds to mechanical loading in osteocytes. The Akt-GSK3β pathway is central to the mechanical load response of MSC, osteoblasts and osteocytes. Using a recombineering approach, we placed an EGFP reporter construct into a 189kb mouse DNA fragment containing the Sost gene with all the cis-regulatory regions. Tranasgenic mice generated with Sost-GFP showed GFP selectively in most osteocytes, as well as an unknown population of cells in the bone marrow. We used an ex vivo culture of long bones, femur and tibia, from 2 month old animals, in which the growth plate region and bone marrow and osteoblasts are removed by collagenase-trypsin digestion. These ''bone tubes'', containing primarily osteocytes in their ''natural'' home of cortical bone were then used for experiments. The bones were treated ex vivo for 4hrs with the GSK3 specific inhibitor, BIOS, for microarray analysis and network reconstruction. This is the first database derived from cortical long bone osteocytes in older animals. The gene expression signature in these long bone osteocytes overlap with primary calvarial osteocytes and with a subset that is unique to the long bone osteocytes. From over 1200 genes, a gene regulatory network, centered on β-catenin and Mef2 action was constructed using Ingenuity Pathway Analysis and other bioinformatic tools. This system proved useful for determining for the first time the genes upregulated in osteocytes downstream of GSK3β node which include DMP1, Mepe, Osterix, Myogenin, Mef2c, Tcf7, BMP3, BMP2, and Wnt7b. To determine how these genes may be regulated by loading, strain-mapping around osteocyte lacunae was performed. Using Dismap, the strain field distribution was determined using the Sost-GFP osteocytes as landmarks. The intact, digested, tibial 'bone tubes' were loaded in 3-point bending at 3N and images of the GFP positive osteocytes were captured. The load was then removed and the osteocyte distribution again captured. We observed extremely variable local strain distribution with the strains around the osteocytes reaching up to 10-20,000 microstrain around some lacunae. These observations with ''live'' osteocytes confirm previous observations with polished pieces of hydrated ''dead'' bone and support the concept that regions around osteocytes are strain concentrators. This Sost-GFP model will be useful to perform correlations of strain with GFP and gene expression.

Late Osteoblastic/Osteocytic Cell Line IDG-SW3 Expresses Dmp1-GFP, SOST and FGF23 *in vitro* and Promotes New Bone Formation *in vivo*. Stacey Woo*[1], Lianxiang Bi[1], Mark Johnson[2], Lynda Bonewald[1]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri, Kansas City Dental School, USA

Limitations of existing cell lines reflect the need for additional model systems to study osteocyte biology and function. The Immortomouse/Dmp1-GFP (IDG)-SW3 osteoblastic/osteocytic cell line was previously shown to generate an extensive mineralizing matrix containing Dmp1-GFP positive cells, suggesting differentiation towards the osteocyte phenotype. To further characterize these cells and determine their capacity to mimic primary bone cells, *in vitro* 2D and 3D culture was compared, and the capacity of these cells to support new bone formation in non-healing calvarial defects was examined. The cells maintained viability for at least 35 days in culture. On 2D collagen surfaces, IDG-SW3 expresses the osteocyte-selective genes Dmp1, SOST,

and FGF23. Expression of the early osteocyte marker, Dmp1, is first detectable by qRT-PCR at day 3, rises dramatically, plateaus at day 14, and is maintained to day 21 and 35. The GFP fluorescence pattern mirrors Dmp1 mRNA expression. Expression of the late osteocyte marker, SOST, is first detectable at day 14 and increases by day 21 and 35 by qRT-PCR. FGF23 expression is maintained at low levels, first detectable at day 14 and increasing from day 21-35 by PCR.

In 3D collagen gels and sponges, the cells both penetrate the collagen and grow on the surface, forming multilayers containing cells and extracellular matrix as shown by transverse histological sections. Cells within the gels and sponges show a dendritic morphology and dramatic GFP expression. Cells cultured for 14 days on 3D collagen sponges were placed into calvarial defects, and bone healing was monitored at 2, 4, and 6 weeks by *in vivo* μCT analysis. At week 6, fractional bone volume (BV/TV) was significantly greater in IDG-SW3-filled calvarial defects compared to controls, with empty and sponge-filled defects showing negligible healing at all time points (0.100 ± 0.027 versus 0.007 ± 0.002 and 0.018 ± 0.001, respectively; $p<0.05$). Our results suggest that IDG-SW3 cells trigger events leading to bone formation *in vivo*. We conclude that IDG-SW3 is a promising new model system for osteocytes with unique advantages over existing osteocyte cell lines, namely expression of an osteocyte-selective lineage marker, an osteocyte selective gene profile, embedding in a mineralized extracellular matrix, penetration of cells in 3D matrices, and accelerated bone healing *in vivo*.

Calcimimetics Regulate FGF23, Sclerostin and Dkk1 Expression in Bone in a Rat Model of Chronic Kidney Disease-Mineral and Bone Disorder with Secondary Hyperparathyroidism. Victoria Shalhoub*[1], Eliane Valente[1], Edward Shatzen[1], Sabrina Ward[1], Charles Henley[1], Xuechun Xia[2], Xiaodong Li[1], Thomas Wronski[2], William Richards[1]. [1]Amgen Inc, USA, [2]University of Florida, USA

Renal osteodystrophy affects patients with chronic kidney disease-mineral and bone disorder (CKD-MBD) and secondary hyperparathyroidism (SHPT). Calcimimetics, documented allosteric activators of the parathyroid gland calcium sensing receptor, suppress parathyroid hormone (PTH) synthesis, thereby lowering serum calcium and phosphorus in CKD-MBD dialysis patients. However, little is known about calcimimetic regulation of osteoblast/osteocytic genes in CKD-MBD. This study examined regulation of fibroblast growth factor 23 (FGF23), sclerostin and Dkk1 in 5/6 nephrectomized (Nx) rats, a model of CKD-MBD. Male SD rats (250g, 2 months) were placed on a high phosphate diet post Nx surgery. Three weeks post-Nx, sham operated and Nx rats were given 14 days of vehicle (sham-veh, Nx-veh) or R-568 (Nx-R568) (30 mg/kg, po, daily) (n = 10/group). Blood was drawn pre- and 4 hrs post-dose on days 0, 7 and 14. On day 14 (5 weeks post-Nx), bones were harvested for in situ hybridization (ISH) and cancellous histomorphometry. Serum PTH and FGF23 levels were measured using intact ELISAs (Immutopics, San Clemente, CA and Kainos, Japan). Five weeks post-Nx, Nx-veh rats had elevated serum BUN, creatinine, iPTH, and FGF23; increased osteoid surface (32.6+11.9 vs 12.5+5.1, P<0001), higher surface based bone formation rate (0.76+0.17 vs 0.45+0.16, P<0.01), and osteoblast surface (32.9+12.1 vs 12.7+4.7, P<0001) compared with sham-veh. ISH localized FGF23 mRNA to growth plate chondrocytes and osteoblast-like cells near the growth plate in sham-veh and Nx-veh. Nx-veh rats also expressed FGF23 in osteoblast-like cells lining metaphyseal trabecular bone. In sham-veh rats low/moderate sclerostin mRNA levels were found in osteocytes of metaphyseal and diaphyseal cortical bone. Dkk1 was expressed at low levels in osteoblast-like cells near the growth plate, osteocytes of metaphyseal trabecular bone and few osteocytes of diaphyseal cortical bone. In Nx-veh rats with SHPT sclerostin and Dkk1 expression was diminished. After 14 day R568 treatment FGF23 mRNA was not detectable in Nx rat bones, whereas sclerostin (but not Dkk1) expression recovered. Failure to detect FGF23 and recovery of sclerostin transcripts paralleled R568-induced declines in serum PTH. FGF23 expression was up-regulated and sclerostin was down-regulated in bones of CKD-MBD rats with SHPT. These changes, which were prevented by 14 day calcimimetic treatment, may be related to regulation of serum PTH levels.

Construction and Validation of a Simplified Fracture Risk Assessment Tool for Canadian Women and Men: Results from the CaMos and Manitoba BMD Cohorts. William Leslie*[1], Claudie Berger[2], Lisa Langsetmo[3], Jonathan Adachi[4], David Hanley[5], George Ioannidis[6], Robert Josse[7], Christopher Kovacs[8], Tan Towheed[9], Stephanie Kaiser[10], W.P. Olszynski[11], Jerilynn Prior[12], Sophie Jamal[13], Nancy Kreiger[14], David Goltzman[15]. [1]University of Manitoba, Canada, [2]McGill University, Canada, [3]Canandian Multicenter Osteoporosis Study, Canada, [4]St. Joseph's Hospital, Canada, [5]University of Calgary, Canada, [6]Sympatico, Canada, [7]St. Michael's Hospital, University of Toronto, Canada, [8]Memorial University of Newfoundland, Canada, [9]Queen's University, Canada, [10]Dalhousie University, Canada, [11]Midtown Medical Center (#103), Canada, [12]University of British Columbia, Canada, [13]The University of Toronto, Canada, [14]University of Toronto, Canada, [15]McGill University Health Centre, Canada

Using data from a new Canadian FRAX® model, we updated risk tables for the Canadian Association of Radiologists and Osteoporosis Canada (CAROC) fracture risk assessment system. CAROC is based on sex, age, BMD and two clinical risk factors (prior fragility fracture and corticosteroid use). CAROC provides a simple semi-quantitative alternative to FRAX but does not require computer or web access, and categorizes 10 year fracture probability for major osteoporotic fractures as low (<10%), moderate (10-20%) or high (>20%). METHODS: Risk tables for women and men were constructed from Canadian FRAX estimates for major osteoporotic fractures using the Manitoba BMD cohort (36,730 women and 2,873 men age 50+ years) after removing the effect of prior fragility fracture and corticosteroid use. We then determined sex- and age-specific femoral neck T-score cutoffs corresponding to fracture probabilities of 10% and 20%. This defined the basal CAROC risk categories, which were subsequently increased (low to moderate, moderate to high) for each clinical risk factor. We independently validated the new risk tables in the CaMos cohort (4,778 women and 1,919 men age 50+ years). RESULTS: The new CAROC cutoffs are substantially lower than the old cutoffs which were based on Swedish fracture data (most notably for women 50-75 years and men 70-85 years). The new CAROC system demonstrated a high level of overall concordance (89% and 88%) with FRAX in both the CaMos and Manitoba cohorts when the FRAX risk category was defined using the same cutoffs (10% and 20%). Concordance was highest in individuals without additional risk factors (92% and 93%), followed by those with both risk factors (100% and 76%), and lowest for those with a single risk factor (61% and 74%). Ten year fracture outcomes (Kaplan-Meier estimates) in the CaMos and Manitoba cohorts showed similarly good discrimination and calibration for both CAROC (6.1-6.5% in low risk, 13.5-14.6% in moderate risk, 22.3-29.1% in high risk individuals) and FRAX systems (6.1-6.6% in low risk, 14.4-16.1% in moderate risk, 23.4-31.0% in high risk individuals). Recategorization of the CAROC risk category under FRAX was <5% for low risk, 20-24% for moderate risk and 27-30% for high risk. CONCLUSION: The new CAROC system is well calibrated to the Canadian population and shows a high overall degree of concordance with the FRAX. The CAROC system is a simple alternative when it is not feasible/possible to use the full FRAX tool.

Enhancement of Hip Fracture Prediction Using Finite Element Analysis of CT Scans. David Kopperdahl*[1], Paul Hoffmann[1], Sigurdur Sigurdsson[2], Thor Aspelund[2], Kristin Siggeirsdottir[2], Gudny Eiriksdottir[2], Tamara Harris[3], Vilmundur Gudnason[2], Tony Keaveny[4]. [1]O.N. Diagnostics, USA, [2]Icelandic Heart Association Research Institute, Iceland, [3]Intramural Research Program, National Institute on Aging, USA, [4]University of California, Berkeley, USA

Finite element modeling of the proximal femur has potential for improved fracture risk assessment over areal BMD, particularly for subjects in the osteopenic range, since there is evidence that some osteopenic individuals have femoral strength values more typical of those with severe osteoporosis. In this study, we assessed the ability of finite element analysis to enhance prediction of hip fractures in both women and men, with a focus on those in the osteopenic range.

The study used a case-cohort design of 199 incident hip-fracture cases (131 women; 68 men) and 724 no-hip-fracture controls (412 women; 312 men), taken from the 3088 subjects of the AGES-Reykjavik study aged 65-93 years who had quantitative computed tomography (CT) scans of the hip at baseline and 5-year follow-up. Average follow-up was 5.7 years. Non-linear 3D finite element analysis of the CT scans, performed blinded to fracture status, simulated a sideways fall to provide measures of strength and a strength-to-density ratio. Load-to-strength ratios were calculated based on patient weight, height, and the thickness of soft tissue over the trochanter. Since DXA was not available, femoral neck areal BMD as measured from the CT scans was used to classify subjects as osteopenic (-2.5<-1.0) or osteoporotic (T<-2.5). Cox proportional hazards analysis was performed to estimate hazards ratios per SD change. Multivariable survival analysis was used to assess if adding any biomechanical outcomes to areal BMD improved overall prediction. This was done for the entire study sample (n=923) and a subset of osteopenic subjects (n=377).

We found that all finite element outcomes, and the strength-to-density ratio, were predictive of fracture in both women and men, as was femoral neck areal BMD (Figure). In multivariable models including both age and sex, the biomechanical predictors where chosen instead of areal BMD when using stepwise selection. In multivariable models forced to include age, sex, and areal BMD, stepwise selection added body mass index and two additional biomechanical terms ($p<0.05$) to the model. For the osteopenic group, the AUC for this latter model (0.77) was significantly higher ($p=0.04$) compared to the AUC (0.75) for the same model without the additional biomechanical terms; this enhancement did not reach significance for the full cohort ($p=0.08$).

We conclude that finite element analysis can enhance prediction of hip fracture, particularly for those with low bone density.

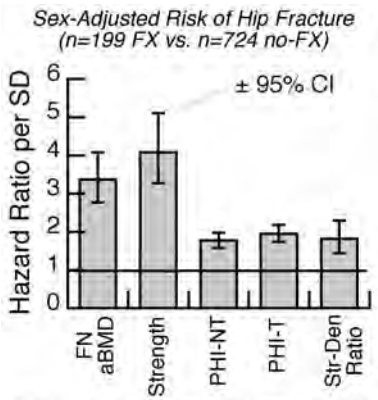

Figure: Strength: from the finite element analysis; FN aBMD: areal BMD of the femoral neck, measured from the CT scan; PHI-NT and PHI-T: load-to-strength ratios, excluding and including patient-specific trochanteric soft tissue thickness, respectively; Str-Den ratio: ratio of femoral strength to volumetric BMD (cortical plus trabecular).

Fracture Prediction and Calibration of a Canadian FRAX® Tool: A Population-Based Report From CaMos. Lisa-Ann Fraser[1], Lisa Langsetmo[2], Claudie Berger[3], George Ioannidis[4], David Goltzman[5], Jonathan Adachi[6], Alexandra Papaioannou[7], Robert Josse[8], Christopher Kovacs[9], Wojciech P. Olszyynski[10], Tanveer Towheed[11], David Hanley[12], Stephanie Kaiser[13], Jerilynn Prior[14], Sophie Jamal[15], Nancy Kreiger[16], Jacques Brown[17], Helena Johansson[18], John Kanis[19], William Leslie*[20]. [1]University of Western OntarioMcMaster University, Canada, [2]Canandian Multicenter Osteoporosis Study, Canada, [3]McGill University, Canada, [4]Sympatico, Canada, [5]McGill University Health Centre, Canada, [6]St. Joseph's Hospital, Canada, [7]Hamilton Health Sciences, Canada, [8]St. Michael's Hospital, University of Toronto, Canada, [9]Memorial University of Newfoundland, Canada, [10]University of Saskatchewan, Canada, [11]Queen's University, Canada, [12]University of Calgary, Canada, [13]Dalhousie University, Canada, [14]University of British Columbia, Canada, [15]The University of Toronto, Canada, [16]University of Toronto, Canada, [17]Laval University, Canada, [18]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [19]University of Sheffield, Belgium, [20]University of Manitoba, Canada

PURPOSE: To validate a new Canadian WHO fracture risk assessment (FRAX®) tool in a prospective, population-based Canadian cohort, the Canadian Multicentre Osteoporosis Study (CaMos).

METHODS: Ten year estimates of major osteoporotic fracture and hip fracture were derived from observed CaMos data using the Kaplan-Meier method for women (N=4,778) and men (N=1,919). These rates were compared with predicted ten year fracture rates based on the FRAX tool (both without and with BMD) developed by the WHO and calibrated for the Canadian population. Predicted and observed fracture risks were compared in men and women for each quintile of predicted fracture risk. Fracture prediction, using FRAX with BMD, FRAX without BMD, and BMD alone, was compared using ROC analysis. Cox proportional hazards models were used to investigate the contribution of individual FRAX variables within this population.

RESULTS: FRAX-estimated ten year risk for major osteoporotic fracture was not significantly different from the actual rates in men (predicted 5.4% vs. observed 6.4% [95% CI 5.2-7.5%]), and was very similar in women (predicted 10.8% vs.observed12.0% [95% CI 11.0-12.9%]). FRAX was well calibrated for hip fracture risk in women (predicted 2.7% vs. observed 2.7% [95% CI 2.2-3.2%]) but underestimated risk in men (predicted 1.3% vs. observed 2.4% [95% CI 1.7-3.1%]). There was close correlation between predicted and observed risk in women with a regression slope for major osteoporotic fractures of 1.07 (95% CI 0.97-1.17) and for hip fractures 0.93 (95% CI 0.83-1.03), where a slope of 1.00 indicates perfect calibration. The corresponding slopes in men were 1.26 (95% CI 1.04-1.48) and 1.83 (95% CI 1.39-2.27) respectively, but were based on fewer numbers of fractures with wide CIs. FRAX with BMD was more predictive of fracture risk than FRAX without BMD or BMD alone for both major osteoporotic fractures and hip fracture (Table). Age, body mass index, prior fragility fracture and femoral neck BMD were significant independent predictors for major osteoporotic fracture; sex, age, prior fragility fracture and femoral neck BMD were significant independent predictors of hip fractures.

CONCLUSION: The Canadian FRAX tool generally provides fracture risk estimates that agree closely with observed fracture rates in Canadian women (though less well in men), thereby providing a valuable tool for Canadian clinicians assessing patients at risk of fracture.

ROC analysis for FRAX measures vs BMD alone.

	Major Fractures		Hip Fractures	
	ROC Area	Std. Error	ROC Area	Std. Error
FRAX with BMD	0.687	0.011	0.799	0.016
FRAX without BMD	0.657	0.011	0.766	0.017
Femoral neck T-score	0.664	0.011	0.760	0.018
Minimum T-score	0.675	0.011	0.746	0.018

FR0302

FRAX or Fiction: Should We Treat All Long Term Care Residents for Osteoporosis? Julie Wagner*[1], Kimberly Zukowski[1], MaryAnne Ferchak[1], Carroll Lee[1], Sherry L. Knoblock[1], Donna Medich[1], Gail Fiorito[2], Megan Miller[1], Subashan Perera[1], David Nace[1], Neil Resnick[1], Susan Greenspan[1]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh, USA

Purpose: Although osteoporosis and clinical fractures are common in long term care (LTC) residents, little data are available on screening or treatment strategies for such patients. Our aims were to examine different screening strategies for LTC residents and to determine their impact on therapeutic recommendations.

Methods: We examined the prevalence of osteoporosis and vertebral fractures (VF) using bone mineral density (BMD) and DXA-derived VF assessments in 96 frail women LTC residents with no previous history or diagnosis of osteoporosis. Classification of osteoporosis included a spine, total hip, or femoral neck T-score <-2.5 SD (+BMD) or the presence of a VF (+VF). We determined if patients were eligible for treatment using 2008 NOF clinical guidelines by BMD alone (+BMD), VF alone (+VF), a combination of +BMD plus +VF, FRAX with hip BMD alone (+FRAX), a combination of +BMD plus +FRAX, or FRAX using body mass index (BMI) only (+FRAX BMI).

Results: Age and BMI were similar among the groups (Table). 44% of patients were classified with osteoporosis by BMD T-scores alone. 55% of all residents had vertebral fractures by VFA. Using combination +BMD and +VF, 71% of residents would be treated. This means that 38% of residents with osteoporosis would have been missed by BMD alone. If FRAX were utilized for patients without osteoporosis by BMD or VF criteria, 33% would be eligible for treatment. Using NOF criteria for those with +BMD plus +FRAX, 75% would be treated. However, if BMD and VF were unknown and only +FRAX BMI used, 99% of patients would be eligible for treatment.

Conclusions: We conclude the recommended treatment criteria would suggest therapy in 44 to 99% of LTC residents depending on the screening strategy employed. Using BMD plus VF knowledge or BMD plus FRAX would lead to recommended treatment of 71 to 75% of such women. BMD alone would miss 38% of residents with osteoporosis. FRAX without BMD (using BMI alone) likely overestimates the need for treatment. Further studies are needed to determine the appropriate screening strategy for these patients.

Table: Patients Eligible for Treatment Based on Screening Strategy (Mean ± SEM unless otherwise noted)

	+ BMD only	+VF only	+BMD plus +VF	+FRAX alone	+BMD plus +FRAX	+FRAX BMI alone
N (%)	42/96 (44%)	53/96 (55%)	68/96 (71%)	30/91 (33%)	72/96 (75%)	95/96 (99%)
Age (years)	87.6 ± 0.7	87.0 ± 0.6	87.3 ± 0.6	86.3 ± 0.8	87.0 ± 0.5	86.6 ± 0.5
BMI (kg/m^2)	26.5 ± 0.7	26.5 ± 0.7	26.6 ± 0.6	26.9 ± 0.9	26.7 ± 0.5	27.1 ± 0.5
Spine T-score	-1.5 ± 0.2	-0.7 ± 0.3	-0.8 ± 0.2	-0.3 ± 0.2	-1.0 ± 0.2	-0.7 ± 0.2

Underestimated Fracture Risk in Patients with Unilateral Hip Osteoarthritis as Calculated by FRAX. Nithya Setty*, Giulia Rinaldi, Julie Glowacki, Thomas Thornhill, Meryl Leboff. Brigham & Women's Hospital, USA

Osteoporosis (OP) and osteoarthritis (OA) are two age-related degenerative diseases previously believed to be mutually exclusive (Br J Rheumat. 1996, 35:813). We found however, that 25% of women with advanced OA had occult OP (J Bone Joint Surg Am. 2003,85A:2371), and that femoral neck (FN) bone mineral density T-scores were higher in hips with OA than in contralateral ones, likely attributable to reactive bone, osteophytes, subchondral osteosclerosis, and larger area (J Clin Densitom. 2010,13:24). The recently developed FRAX calculator (http://sheffield.ac.uk/FRAX) makes it possible to estimate age and gender-specific, 10-year absolute total (clinical spine, hip, forearm and humerus) and hip fracture risk on the basis of clinical risk factors and FN T-score. OP treatment is recommended for patients with a calculated fracture risk of ⩾20% for total fractures and ⩾3% for hip fractures (National Osteoporosis Foundation. 2008,Clinician's Guide). The objective of this study was to determine, for subjects with unilateral hip OA, whether the calculated FRAX fracture risk was underestimated in subjects when using the OA vs. the contralateral FN T-score, and whether the calculated risk could impact clinical decisions regarding OP therapy. We determined clinical risk factors and bilateral hip T-score for 40 subjects (26 women and 14 men, age ⩾40 years) scheduled for hip replacement due to unilateral advanced hip OA. We compared FRAX 10-year probability risks of total and hip osteoporotic fracture using the FN T-score of the OA vs. the contralateral hip. We found significant differences in FRAX total fracture ($p=0.00044$) and hip fracture ($p=0.0089$) risk using the OA vs. the contralateral FN T-score, where the mean difference ± SEM in total fracture risk was 2.53 ± 0.66, and hip fracture risk was 1.41 ± 0.51. The mean difference ± SEM in FN T-scores between the OA vs. the contralateral hip was 0.75 ± 0.18 ($p=0.00013$). The fracture risk differences resulted in OP treatment recommendations for 10% vs. 22% of subjects at risk for total fractures and for 20% vs. 33% of subjects at risk for hip fractures when using the OA vs. contralateral hip BMD, respectively. These data indicate that subjects with advanced OA are at risk for osteoporotic fractures, and that fracture risk with FRAX is underestimated when calculated with the FN T-score in an OA hip. Recommendations for OP diagnosis should avoid BMD testing of OA hips for fracture risk prediction and OP treatment decisions.

In Vivo Quantification of Intracortical Porosity and Cortical Remnants Adjacent to Marrow Identifies Individuals at Risk for Fracture Better than Prevailing Methods. Ali Ghasem-Zadeh[1], Sandra Iuliano-Burns[1], Ego Seeman[1], Roger Zebaze*[2]. [1]Austin Health, University of Melbourne, Australia, [2]Austin Health, Australia

Background

We reported that ~ 50% of bone lost during ageing occurs by remodelling in cortex adjacent to marrow enlarging and coalescing pores leaving a transitional zone (TZ) of trabecular-appearing cortical remnants. We hypothesized that quantification of this TZ of cortical remnants identifies individuals with fracture.

Methods

We studied 20 women with forearm fracture and 47 age, height and weight matched controls. Images were collected at the distal radius using HRpQCT (Scanco Medical). Total, cortical and trabecular volumetric density (T, Ct, and Tr vBMD) were analyses using a newly developed software (Strax1.0) which assesses the compact-appearing cortex (CC) and the layer of cortical remnants. Thicknesses of the compact-appearing cortex (Th. CC) and cortical remnants of the TZ were measured. We further separated the TZ into inner (ITZ) and outer (OTZ) zones, the ITZ being adjacent to marrow, a location of higher remodeling than in the OTZ and CC. The proportion of the total cortical thickness (CC + TZ) occupied by the CC and the ITZ were measured and denoted %CC and %ITZ. Porosity (Po) was measured in each zone.

Results

Total cortical thickness was similar in cases and controls (952.9 ± 39.7 vs 986.3 ± 28μm; NS)(mean ± SEE). However, the % CC was reduced in fracture cases relative to controls (70.91 ± 1.03 vs 72.85 ± 0.40; $p=0.038$), mostly due to an increase in the % ITZ (12.82 ± 0.43 vs $15.59 \pm 1.1\%$; $p=0.01$). In absolute terms, the thickness of the CC in fracture cases was reduced (664.1 ± 39 vs 710.3 ± 28μm; NS) and the thickness of the ITZ was increase (155.8 ± 74 vs 129.6 ± 36; $p=0.05$) compared to controls. Porosity in compact-appearing cortex was similar in cases and controls (2.4 ± 0.52 vs $2.89 \pm 0.43\%$, NS) but Po in the ITZ was higher in cases than controls (48.32 ± 2.93 vs 42.02 ± 1.48; $p = 0.03$). Po ITZ correlated modestly with density parameters with r2 respectively 0.03, 0.17 and 0.47 for Ct D, vBMD and Tr D suggesting density does not fully capture porosity. Differences in Ct vBMD (262.5 ± 12.79 vs 288.54 ± 9.5), vBMD (853.6 ± 4.59 vs 858.94) and Tr vBMD (111.8 ± 7.84 vs 132.2 ± 5.55; $p=0.04$) were smaller and/or non-significantly different.

Conclusion

Porosity producing trabecularization is an important indicator of structural decay and fragility. Quantification of this process in vivo identifies individuals at risk for fracture beyond currently existing measurements.

FR0316

A Four Years Exercise Intervention Program in Pre-Pubertal Children Increases Bone Mass and Bone Size But Do Not Affect the Fracture Risk. Bjarne Lofgren*[1], Jan Åke Nilsson[2], Magnus Dencker[2], Magnus Karlsson[3]. [1]Clinical & Molecular Osteoporosis Research Unit Dept. of Clinical Sciences, Lund University, Dept of Orthopaedics, Skåne University Hospital, Sweden, [2]Skane University Hospital, Sweden, [3]Skåne University Hospital Malmö, Lund University, Sweden

Abstract

Introduction: Pediatric exercise intervention studies, that evaluate if exercise could be used as a prevention of fragility fracture, span at maximum 24 months and uses bone traits as surrogate endpoints for fractures. But reports have inferred that increased training may possibly lead to more trauma and more fractures. Therefore we designed a 48 months controlled exercise intervention study with also fracture as endpoint.

Material and Methods: The intervention group achieved 40 minutes/day of school physical education and the controls 60 minutes/week. Included were 2395 children aged 7-9 years, 446 boys and 362 girls in the intervention (2675 person-years) and 807 boys and 780 girls in the control group (5661 person-years). Fractures were prospectively registered. In 73 boys and 48 girls in the intervention and 52 boys and 48 girls in the control group, skeletal development was followed by dual energy X-ray absorptiometry (DXA). Bone mineral content (BMC; g) in lumbar spine (LS), femoral neck (FN) and trochanter, bone width (cm) in third lumbar vertebra (L3) and FN and hip structural analyses (HSA) variables were included.

Results: The rate ratio (RR) for fractures in the intervention group was 1.11 (0.78, 1.57) (mean (95% CI)). In the DXA measured children, there were at baseline no group differences in age, anthropometrics or bone parameters. The mean annual gain in both BMC and bone width was higher in the interventions than in the controls groups, for LS BMC 0.6 standard deviations (SD) higher in both girls ($p<0.01$) and boys ($p<0.05$), in trochanter BMC 0.5 SD higher in girls ($p<0.01$), in femoral neck width 0.5 SD higher in girls ($p < 0.05$) and 0.3 SD higher in boys ($p <0.05$) and in L3 width 0.5 SD higher in girls ($p<0.05$).

Conclusion: Increased duration of moderate intense exercise in 7-9 year old children could be used on population based level as to improve bone mass and bone size without increasing the fracture risk.

DXA Self-Scheduling Improves Osteoporosis Screening. Amy Warriner*[1], Ryan Outman[2], Kenneth Saag[2], Elizabeth Kitchin[2], Sarah Morgan[2], Jeffrey Curtis[2]. [1]UAB, USA, [2]University of Alabama at Birmingham, USA

Purpose: U.S. guidelines recommend bone density screening with central dual energy x-ray absorptiometry (DXA) in all women 65 years or older. However, less than one-third of eligible U.S. women undergo DXA testing. The main barrier in achieving greater rates of osteoporosis screening is identifying a systematic, effective and generalizable way for healthcare providers and patients to schedule and receive DXA results.

Methods: We conducted a group randomized, controlled trial involving 39 primary care physicians at the University of Alabama at Birmingham. Women 65 years or older with no DXA scan in the past 4 years cared for by these physicians were identified using administrative billing data. Randomization was performed in two waves, each forming a cohort. In each cohort, 30 patients per physician were randomized to the intervention (sent mailed materials twice); the remaining patients comprised the control group (received no mailing). The intervention included a patient brochure regarding osteoporosis and fracture risk and a letter providing patients the opportunity to self-schedule a DXA. Results from the two cohorts were similar and pooled for analysis. Stratified results compared receipt of DXA among women receiving primary care proximate to the site where the DXA scanner was located (62% of study population) vs. more distant satellite clinics which required additional travel to the DXA scanner.

Results: Of 5122 identified women meeting inclusion criteria, 978 women were randomized to the intervention group and 4,144 to the control group. A total of 19.5% of women in the intervention group received a DXA, compared to 6.3% women receiving DXA in the control group (risk difference [RD] for DXA receipt 13.2%, 95% CI 10.8 – 16.0%), Figure 1. Comparing intervention to control group patients, receipt of DXA in main clinic patients was greater (22.7% for intervention group vs. 7.6% for control group, RD = 15.1%, 95% CI 11.9 – 18.7%) compared to satellite clinic patients (13.4% for intervention group vs. 4.3% for control group, RD = 9.1%, 95% CI 5.7 – 13.3%).

Conclusions: DXA scheduling and receipt was improved significantly through the use of a simple mailed osteoporosis brochure and the availability for patients to self-schedule their own DXA scans. This modality may be an effective component of a multi-faceted quality improvement program to increase rates of osteoporosis screening.

Evaluation of the Risk of Fracture in Early Postmenopausal Women: Predictive Value of Baseline BMD and Development of Prognosis BMD T-score Thresholds. Jean-Michel Pouilles[1], Florence Tremollieres*[2], Patricia Dargent[3], Nicolas Drewniak[4], Claude Ribot[2]. [1]Menopause Center. Hôpital Paule de Viguier, France, [2]Hopital Paule De Viguier, France, [3]INSERM Unit 953 (ex 149), France, [4]Inserm U953, France

Osteopenia (op) is common in healthy early postmenopausal (PM) women. It is still not clear how those women should be managed with regard to their long-term risk of osteoporosis (OP) and we lack suitable algorithms for identifying higher-risk subgroups for fracture. The aim of this study was (1) to determine the number of healthy early PM women who had progressed from normal/op to OP over a 12-year follow-up period of time and (2) to identify the baseline T-score thresholds associated with less than 10% risk of developing OP and/or incident OP fracture. We analyzed DXA of the lumbar spine (LS) and femoral neck (FN) from 713 women ⩾45 years of age (mean:54±4 yrs) from the MENOS cohort with at least 2 BMD measurements (using the same Lunar GE DPX-IQ) at baseline and the final follow up time point examination. None of the women were or had taken OP medication or HRT throughout the follow-up. We only considered major incident fractures that occurred with minimal trauma. The lowest LS or FN T-score was used to classify women as having OP or op. We derived T-score thresholds associated with a 90% probability of not developing OP and/or a 1st incident fracture over the follow-up period (NPV:90%).

At baseline, 28.8% of the women were classified as normal and 50.2% and 21% as having op and OP, respectively. Over an average follow-up period of time of 12.4 yrs (± 2), 5 (2%) normal women and 118 (33%) with op developed densitometric OP. 73 women sustained a 1st low-energy fracture including 41 wrist, 15 symptomatic spine, 12 humerus and 5 hip fractures. At baseline, 82% of the women with fracture had either op (n=30) or OP (n=30). Women with a baseline T-score at the lower of the 2 sites above -1.9 (75% of the population) and -1.5 (55%) exhibited a risk of less than 10% of developing pure densitometric OP and/or incident fracture, respectively. Women with OP and/or fracture had significantly lower mean baseline BMD values, a higher FRAX score, a higher rate of vertebral (but not femoral) bone loss (-0.21±0.7 vs -0.43±0.7%/yr, $p<0.001$) and higher serum osteocalcin levels. Baseline BMD was associated with a better discriminative value than the rate of vertebral bone loss to predict OP and/or incident fracture (AUC: 0.80 vs 0.66, $p<0.001$).

In conclusion, about 33% of early PM women with op will develop OP within the 1st PM decade. Women with a minimum T-score above -1.5 had a 90% probability of avoiding OP and/or a low-trauma major fracture in the next 10 years.

FR0322

FRAX and UK-Based Diagnostic and Therapeutic Decisions the Day Before a Fracture in the Netherlands. Tineke van Geel*[1], Sandrine Bours[2], Kirsten Huntjens[2], Geert-Jan Dinant[1], Joop van den Bergh[3], Piet Geusens[2]. [1]Maastricht University/Caphri, Netherlands, [2]Maastricht University Medical Centre, Netherlands, [3]VieCuri Medical Centre Noord-Limburg, Netherlands

Objective: To investigate the predictive value of FRAX to assess the short-term fracture risk using the cut-off points as prescribed by the National Osteoporosis Guideline Group (NOGG).

Methods: In total, 509 patients aged between 50 and 90 years, who attended the emergency room at a hospital in the Southern part of the Netherlands at the time of a low trauma fracture, were included in this study. All risk factors prescribed in the FRAX were assessed, including the femoral neck bone mineral density (FN-BMD) measurement by dual energy X-ray absorptiometry (DXA). Using FRAX, the 10-year fracture risk was calculated and diagnostic and therapeutic decisions according to NOGG before the current fracture, with and without BMD.

Results: The FRAX was completed for 482 patients with a fracture (75% women) of whom 8% sustained a hip fracture, 58% a major fracture (clinical spine, forearm or shoulder) and 34% a minor fracture (all other fractures).

Before the fracture and based on major fracture risk of FRAX without FN-BMD, 44% would not have required treatment, 43% would have needed a BMD measurement, and 14% would have required treatment. If FN-BMD was included, 17% would and 83% would not have required treatment. Of the patients with osteoporosis before the fracture 70% were considered at low risk and 30% of them would have been advocated treatment.

In women (n = 362) after their fracture and based on major fracture risk of FRAX without FN-BMD, 1.4% would not have required treatment, 66% would have required a BMD measurement, and 33% would have required treatment. If FN-BMD was included, 30% would and 70% would not require treatment. Similar results were found if 10-year hip fracture risk was used.

Conclusion: Most patients with a fracture would have been considered at low risk the day before a low trauma fracture occurred and would not have been advocated treatment according to UK-FRAX and NOGG. This indicates that this treatment decision algorithm is not useful for short term fracture prediction and prevention in the Netherlands. Extrapolating these results to the Netherlands, without BMD, only 11.200 of the 80.000 patients older than 50 years yearly presenting with a fracture would have required treatment before the fracture and 34.400 would have needed a DXA measurement. With BMD, 13.600, instead of 11.200, would have been advocated treatment the day before the fracture.

FR0327

Dual Effect of Adipose Tissue on Bone Health during Growth. Heli Viljakainen*[1], Minna Pekkinen[2], Elisa Saarnio[2], Christel Lamberg-Allardt[2], Outi Mäkitie[3]. [1]Helsinki University Central Hospital for Children & Adolescents, Finland, [2]University of Helsinki, Finland, [3]Helsinki University Central Hospital for for Children & Adolescents, Finland

Recent studies suggest association between body fat and childhood bone health, although conflicting findings have also been reported. The aim of the present study was to examine the association between body fat content and BMD, bone turnover markers, and calcitropic factors in apparently healthy children and adolescents in a cross-sectional setting.

The study was carried out as a school based cross-sectional cohort study with 186 subjects (61% girls) aged from 7 to 19 years. Background characteristics, including medical history and lifestyle factors, were collected by a questionnaire. Anthropometry, BMD and body composition measurements with DXA and pQCT, a fasting blood sample and a second morning void urine sample were obtained.

Body mass index exceeded 25 kg/m^2 and 30 kg/m^2 in 6 and 2 subjects, respectively. Relative weight (height-adjusted weight) was calculated for 176 subjects, of whom 31 (19%) had relative weight above 20% (=overweight) and 3 above 40% (=obesity). Girls were on average significantly older and had more advanced puberty than the boys. Girls had a higher fat percent than boys, but age and gender specific Z-scores for fat percent did not differ between the genders. The subjects were divided into three groups, representing low, intermediate and high adiposity, based on age and gender specific fat percentage Z-scores. Multivariate analysis was performed to all bone variables using lean body mass, pubertal development, dietary intake of calcium and intensity of physical activity as covariates. In pQCT, a significant difference between the groups was observed in cortical BMD (MANOVA; p=0.02) in proximal radius, the intermediate group having the highest values. Similarly, DXA-derived LS and WB BMD Z-scores differed significantly between the groups (MANOVA; p=0.026 and p=0.036, respectively), with highest values in the intermediate group. High body fat content associated also with low bone turnover markers, low PTH, high S-Ca and high urinary calcium excretion.

These findings suggest that normal body fat content is beneficial for bone health in growing children and adolescents while both low and high body fat content have adverse skeletal effects.

A Population-Based Analysis of the Post-Fracture Care Gap 1996-2008: The Situation Is Not Improving. William Leslie*[1], Marina Yogendran[1], Mahmoud Azimee[1], Suzanne Morin[2], Colleen Metge[1], Patricia Caetano[1], Lisa Lix[3]. [1]University of Manitoba, Canada, [2]McGill University Health Centre, Canada, [3]University of Saskatchewan, Canada

Previous reports have documented low rates of BMD testing and/or osteoporosis treatment in older individuals who have sustained a non-traumatic fracture. We previously reported improvement in testing and treatment rates between 1997/98 and 2001/02, but even in the final study year only 20.5% of women post-fracture underwent an intervention (*Can Fam Physician 2008;54:1270*). OBJECTIVE: To characterize temporal changes in post-fracture BMD testing and/or osteoporosis treatment initiation from 1996/97 to 2007/08. METHODS: A population-based

administrative data repository for the province of Manitoba, Canada, was accessed to identify non-traumatic fractures in men and women age 50 years and older. High-trauma fractures, residents of personal care homes, and those with recent BMD testing (preceding three years) were excluded. The outcomes of interest were BMD testing and/or dispensation of an osteoporosis medication in the twelve months post-fracture (with/without exclusion of those on treatment at the time of fracture). RESULTS: 33,578 fracture events met the inclusion criteria (30,920 after exclusion of individuals on treatment at the time of fracture). Post-fracture BMD testing in increased from 0.7% in 1996/97 to 8.9% 2007/08. Osteoporosis medication use increased from 9.9% in 1996/97 to 19.1% in 2001/02 and then declined to 11.9% in 2007/08 (6.1%, 12.3%, 5.9% respectively after exclusion of those already on treatment). Based on either BMD testing or treatment initiation, rates increased from 10.1% in 1996/97 to 21.8% in 2001/02 and have been stable thereafter (maximum 15.3% after exclusion of individuals already on treatment). Other factors associated with any intervention were sex (men 4.4% vs women 24.5%), area of residence (lower in the rural north), socioeconomic status (least in lower income quintile groups), and fracture site (hip 15.1%, spine 37.5%, humerus 15.8%, forearm 18.9%, pelvis 20.9%, other 15.4%). CONCLUSIONS: The post-fracture ''care gap'' has not narrowed in recent years. Following an initial improvement, rates of medication initiation have actually declined since 2001/02. Novel strategies are required to disseminate and implement best practices at the point of care to reduce the risk of recurrent fractures and the associated morbidity and mortality.

FR0338

In COPD Inhaled Glucocorticoids, but not β2-Agonist are Associated with Vertebral Fracture Risk. Stefano Gonnelli*[1], Carla Caffarelli[1], Stefania Maggi[2], Stefania Rossi[1], Paola Siviero[2], Gaetano Crepaldi[2], Ranuccio Nuti[1]. [1]University of Siena, Italy, [2]CNR - Center on Aging, Italy

Although inhaled glucocorticoids (GCs) are being more frequently prescribed in the managements of COPD, their role in the reduction of bone mineral density (BMD) and in fracture risk still remains controversial. Also inhaled β2-adrenergic agonists have been associated with an increased fracture risk.

The EOLO (Evaluation of Obstructive Lung disease and Osteoporosis) study enrolled a total of 3,030 ambulatory COPD patients (1,778 men and 1,262 women) aged 50 years or over. Of COPD patients, 68.3% were treated with GCs (55.0% inhaled GCs, 3.9% oral GCs and 9.5% oral + inhaled GCs) 16.8% were not treated with specific COPD medications and the remaining 14.7% were treated with short-or long-acting β2-agonists, xanthines or antimuscarinics but not with GCs. The COPD patients treated with inhaled GCs (n=1653) were divided in to 3 groups on the basis of the daily dose of inhaled GCs expressed as beclometasone equivalents: ≤ 750 μg; 750 – 1500 μg; ⩾ 1500 μg. Beta2-agonists (long-acting and short-acting) was expressed as albuterol equivalents. Spirometry and the presence of vertebral fractures on lateral chest X-ray were evaluated. Ultrasound parameters at calcaneous, namely Stiffness were also measured by Achilles apparatus (GE, Lunar).

The risk of fractures was markedly increased in patients with very severe or severe COPD, (OR=2.05; CI 1.28- 3.28 and OR=1.40; CI 1.06- 1.82, respectively). Moreover, the risk of vertebral fractures was significantly increased in patients taking the highest dose (>1500 μg) of inhaled GCs (OR=1.4; CI 1.04 - 1.89). The use of inhaled GCs at doses ranging from 750 and 1500 μg was associated to a positive, but not significant, increase in vertebral fracture risk. On the contrary, the different daily doses of β2-agonists were not associated with an increased risk of vertebral fractures. Both COPD severity and inhaled GCs at daily dose > 1500 μg were associated to Stiffness value lower than 57%. On the contrary the daily dose of inhaled β2-agonists was not associated to a reduction in Stiffness values.

In conclusion, in COPD patients the highest doses of inhaled GCs, but not inhaled β-adrenergic agonists, are associated with to an increased risk of vertebral fractures and to a reduction of QUS at calcaneous.

FR0339

Inhibition of the Serotonin Transporter and Risk of Fracture in Older Women. Susan Diem*[1], Terri Blackwell[2], Katie Stone[3], Jane Cauley[4], Elizabeth Haney[5], Kristine Ensrud[6]. [1]University of Minnesota, USA, [2]California Pacific Medical Center Research Institute, USA, [3]California Pacific Medical Center-Research Institute, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]Oregon Health & Science University, USA, [6]Minneapolis VA Medical Center / University of Minnesota, USA

Recent work has suggested a possible role for circulating serotonin in the regulation of bone mass, raising the possibility that use of medications that inhibit the serotonin transporter and raise extracellular serotonin levels may have effects on bone health. To test the hypothesis that degree of serotonin transporter inhibition is associated with risk of non-spine fracture, we assessed current use of antidepressant medications and incident fractures over a 12 year period in a cohort of 7024 older women participating in the Study of Osteoporotic Fractures. We categorized specific antidepressant medications by degree of serotonin transporter inhibition (low, intermediate, and high). Antidepressant use status was updated at each follow-up visit (an average of 4.9 and 9.8 years after initial assessment) using time-dependent methods. The hazard ratio (HR) and 95% CI for risk of fracture was calculated by category of serotonin transporter inhibition using Cox regression models. All results were adjusted for the following characteristics, which were updated at each follow-up visit: age, race, BMI, health status, history of fall in previous 12 months, cognitive function, depression, and neuromuscular function.

Average length of follow-up was 7.87± 3.45 years. Of the 7024 women (average age 80 years at initial visit), 1992 (30%) women experienced ⩾ 1 non-spine fracture during the follow-up period, including 670 (10.1%) with a hip fracture and 383 (5.5%) with a wrist fracture. Below are the age- and multivariable-adjusted HRs for risk of fracture by level of serotonin transporter inhibition use. After adjustment for multiple confounders, use of medications with the highest level of serotonin inhibition was associated with an increased risk of non-spine fracture (table), including hip and wrist fractures. However, there was no evidence of a graded association between degree of serotonin transporter inhibition and risk of these fractures as risk of fracture appeared to be greater among women using medications with a low degree of serotonin transporter inhibition than that among women using medications with an intermediate degree of inhibition. These results suggest that degree of inhibition of the serotonin transporter may not explain the observed association between use of antidepressant medications and higher risk of fractures.

Fracture Type	Hazard Ratio (95% CI) by Degree of Serotonin Transporter Inhibition			
	No Use (N=6382)*	Low† (N=152)*	Intermediate† (N=206)*	High† (N=272)*

FR0342

Reduced Rate of Bone Loss Predicts Survival Post-Fracture and May Mediate Mortality Risk Reduction Associated With Bisphosphonate Treatment: Data From An 18-Year Prospective Study From Dubbo Osteoporosis Epidemiology Study. Dana Bliuc*, Nguyen Nguyen, Tuan Nguyen, John Eisman, Jacqueline Center. Garvan Institute of Medical Research, Australia

Mortality risk is increased following all osteoporotic fractures, but factors contributing to this risk are poorly defined. Bone loss is associated with mortality risk, but its role in mortality post-fracture is unclear. Bisphosphonates (BP) also reduce mortality post-fracture but the mechanism is unknown. The aims of this study were to: 1) examine the association between bone loss and mortality risk in the presence of fracture and 2) determine whether the effect of BP on mortality risk is mediated by a reduction in bone loss.

All low trauma fractures and mortality data were collected from 777 women and 514 men aged 60+ from the Dubbo Osteoporosis Epidemiology Study who had at least 2 bone mineral density (BMD) measurements (April 1989-May 2007). Bone loss was the difference between the first and last BMDs, and for those with fractures, was measured post-fracture. Co-morbidities, muscle strength and medication obtained at baseline and updated 2-yearly. Cox proportional hazards models used to determine mortality risk.

There were 226 fractures in women and 68 in men over 15 (IQR: 9-17) and 14 years (IQR: 7-16) with 284 deaths (101 post-fracture) in women and 246 (43 post-fracture)

in men. A 3%/yr increase in bone loss increased mortality risk by 47% in women and 29% in men, after adjusting for fracture (time dependent) and other frailty markers. In those with fractures, post-fracture bone loss ⩾1%/year increased mortality risk by ⩾50% in both genders after confounder adjustment compared with <1% bone loss.

The relationship between bone loss and BP was explored in 65 subjects on BP, and 1285 on no treatment. BP was independently associated with a 71% mortality risk reduction after adjustment for frailty markers. Bone loss was non-significantly less in the BP group compared to non-treated group (-0.44g/cm^2 vs -0.63g/cm^2; p= 0.37). However, when bone loss was added to the model, BP and bone loss were independent mortality risk predictors, and the effect size of BP on mortality reduction increased by 20%, suggesting a greater effect of BP on mortality in the presence of bone loss. This effect was driven by those on BP and calcium ± vitamin D, where bone loss was significantly less ($p<0.05$) and fewer deaths occurred.

Thus, reduced bone loss is associated with better survival in the presence of fracture and may play a role in the mortality risk reduction observed with bisphosphonates.

FR0343

The Impact of Two Educational Interventions on Osteoporosis Diagnosis and Treatment After a Fragility Fracture: a Randomized-controlled Trial. Louis Bessette*[1], Sonia Jean[2], Sophie Roy[3], K. Shawn Davison[4], Louis-Georges Ste-Marie[5], Jacques Brown[1]. [1]Laval University, Canada, [2]Institut National De Sante Publique, Canada, [3]Institut national de santé publique du Québec, Canada, [4]Centre de recherche du CHUQ, Canada, [5]Hospital Saint-LucCHUM, Canada

Purpose: To investigate the utility of two education-based interventions for increasing the diagnosis and treatment of osteoporosis in women (>50y old) after fragility fracture (FF).

Methods: This study was part of the Recognizing Osteoporosis and its Consequences in Quebec (ROCQ) programme. Women who recently suffered a FF were recruited from hospitals and from an administrative database-generated list of women who had recently suffered a FF (Quebec Ministry of Health). Six to eight months after FF, women were randomized into one of three groups: 1.) usual care, 2.) documentation group, or 3.) documentation and video group. Documentation consisted of information for both the patient and their respective primary care physician regarding osteoporosis, FF and the need for treatment following FF. The 15-minute video consisted of similar information as the documentation, but went into greater depth. Rates of osteoporosis diagnosis and treatment at randomization and after 12 months were compared.

Results: At randomization, a total of 1,174 women had neither a diagnosis nor treatment for osteoporosis and 1,314 women were without osteoporosis treatment. No significant baseline differences existed among groups for any investigated variable. In the group of women without diagnosis and treatment for osteoporosis at randomization, diagnosis of osteoporosis 12 months after randomization occurred in 12% of the control group, 15% of the documentation group (p=0.07) and 16% ($p<0.05$) of the video group (all vs. control group). Treatment rates for this group were 8% for the control group, 12% for the documentation group (p=0.052) and 11% for the video group (p=0.06). In the group of women with no treatment at randomization, osteoporosis therapy was initiated in 10% of the control group, 13% of the documentation group (p=0.11), and 13% of the video cohort (p=0.12). The greatest impact on diagnosis and treatment was whether a woman passed on the documentation to her primary care physician (18% for receiving diagnosis and 14-15% for receiving appropriate treatment).

Conclusions: Educational interventions alone are not satisfactory to significantly increase diagnosis or treatment for osteoporosis in women over the age of 50y who have recently suffered a FF. Having the patient provide their primary care physician with documentation had the largest impact on both receiving a diagnosis of osteoporosis and in obtaining appropriate treatment.

FR0344

Validation of Diagnostic Codes for Subtrochanteric, Diaphyseal, and Typical Hip Fractures Using Administrative Claims Data. Pongthorn Narongroeknawin[1], Nivedita Patkar[1], Bita Shakoory[1], Archana Jain[2], Jeffrey Curtis[1], Elizabeth Delzell[1], Philip Lander[1], Robert Lopez-Ben[1], Michael Pitt[3], Monika Safford[1], David Volgas[1], Kenneth Saag*[1]. [1]University of Alabama at Birmingham, USA, [2]University of Alabama, USA, [3]Radiology, University of Alabama at Birmingham, USA

Purpose:

Recent studies have raised concern about a possible association of subtrochanteric and diaphyseal fractures of femur (SFF and DFF) with long-term bisphosphonate use. Administrative claims databases provide large sample sizes and high generalizability to test these associations if these fractures can be accurately identified. To develop and validate claims-based algorithms for identification of SFF and DFF, we assessed the accuracy of hospital and physician diagnosis codes to identify these fractures.

Method:

We identified adults with an ICD-9 code for femoral fracture (820.xx, 821.xx, 733.14, 733.15) at University of Alabama at Birmingham Hospital from 01/04 to 12/08. All patients with SFF and random sample of other femoral fracture types were selected, medical records and radiology reports were reviewed independently by two physician reviewers, providing a gold standard for SFF and DFF. Discordance among record reviewers was adjudicated by consensus of an expert panel of radiologists and an orthopedic trauma surgeon. We assessed diagnostic properties of algorithms based on ICD-9 diagnosis codes appearing on hospital discharge and surgeons' fracture repair records to identify a SFF or DFF.

Results:

We identified 137 persons with suspected SFF and randomly selected 55 persons with suspected DFF. The positive predictive value (PPV) to identify SFF ranged from 69% to 89% based on the level and source of diagnosis codes (Table). PPVs for DFF were slightly greater, ranging from 81 to 97%. Case algorithms that accepted SFF or DFF primary or secondary diagnosis code on hospital discharge record had PPVs of 69% and 89% for SFF and DFF respectively. Algorithms that required both primary hospital discharge diagnosis code and the same diagnosis code from the surgeon who performed the fracture repair had highest PPVs.

Conclusion:

Administrative claims data-based algorithms that combined hospital discharge with surgeon's diagnosis codes to identify cases of SFF and DFF yielded relatively high PPVs, particularly for DFF. A more specific case algorithm that required SFF diagnosis code both as the primary discharge diagnosis and as the surgeon's diagnosis resulted in the highest PPV. Work is underway to identify atypical fractures with ''beaking'' and transverse morphology. These claims algorithms will be useful in future population-based observational studies to evaluate the association between osteoporosis medications and subtrochanteric and diaphyseal fractures.

Positive Predictive Value (PPV) of Various Case Identification Algorithms for Subtrochanteric and Diaphyseal Femoral Fractures

Case Identification Algorithm	Number of identified cases by different algorithms (%)*	PPV (95% CI)
Subtrochanteric Femoral Fractures (n=137)		
• Any position on hospital discharge diagnosis list (primary or other)	137 (100)	69 (61-76)
• Primary hospital discharge diagnosis	107 (78)	74 (66-82)
• Surgeon's diagnosis on administrative claim	87 (64)	80 (71-88)
• Both primary discharge diagnosis AND surgeon's diagnosis	81 (59)	89 (81-97)
Diaphyseal Femoral Fractures (n=55)		
• Any position on hospital discharge diagnosis list (primary or other)	55 (100)	89 (81-97)
• Primary hospital discharge diagnosis	35 (64)	94 (87-100)
• Surgeon's diagnosis on administrative claim	46 (84)	81 (72-90)
• Both primary discharge diagnosis AND surgeon's diagnosis	44 (80)	97 (90-100)

*Compared to a case finding algorithm that accepted any SFF or DFF diagnosis on any position of hospital discharge diagnosis list

Association of Stressful Life Events with Incident Falls and Fractures in Older Men: the Osteoporotic Fractures in Men (MrOS) Study. Howard Fink*[1], Michael Kuskowski[1], Lynn Marshall[2]. [1]GRECC, Minneapolis VA Medical Center, USA, [2]Oregon Health & Science University, USA

In case-control analyses, major life events have been associated with hip fracture, but such studies are prone to bias. Therefore, using a prospective cohort design, we examined the association of stressful life events with risk of incident falls and fractures. We hypothesized that any observed risk would be moderated by evidence of social support.

We used data from MrOS, a longitudinal cohort study of men aged >=65 yrs. Approximately 2 yrs after MrOS baseline (V1), subjects reported by interim questionnaire (IQ) whether they'd experienced stressful life events in the past 12 months (e.g. wife/partner serious illness, loss of/separation from other close relative or friend, serious financial trouble) and regarding their level of social support (e.g. live with spouse/partner, number of living children, presence of confidant). Self-reported incident falls and fractures occurring after IQ were collected every 4 months, with fractures confirmed by radiology reports. Total hip BMD was measured at V1 and history of falls in the past year was measured by IQ. Log binomial regression and Cox proportional hazards regression were used to model risk (and 95% confidence intervals (CI)) of falls and fracture outcomes, respectively.

Of 5705 men completing the IQ, 55% reported >=1 stressful event in the past year. In the year after the IQ, 13% (n=779) of men reported 2+ falls and 2% (n=107) had a confirmed clinical fracture. After adjustment for age and past falls, compared to men with no stressful events, those with stressful events had a small increased risk of multiple falls in the following year (any stressful event: RR=1.09 [95%CI: 1.01-1.18]; 1 event: RR=1.05 [0.97-1.14]; 2 events: RR=1.16 [1.05-1.29]; 3+ events: RR=1.19 [1.03-1.38]). After adjustment for age and BMD, compared to men with no stressful events, those with stressful events had a modestly increased risk of clinical fracture in the following year (any stressful event: HR=1.44 [95%CI: 0.97-2.16]; 1 event: HR=1.35 [0.88-2.09]; 2 events: HR=1.36 [0.75-2.48]; 3+ events: HR=2.61 [1.25-5.42]). Results were unchanged after adjustment for social support variables.

In this older male cohort, stressful life events were independently associated with a small risk of subsequent falls and a modest increase in fracture risk. This risk was not moderated by social support. Further studies should examine mechanisms through which stressful events increase risk of these adverse outcomes.

Baseline Serum Interleukin-6 (IL-6), Tumor Necrosis Factor-α (TNF-α) and C-reactive Protein (CRP) Do Not Predict Subsequent Hip Bone Loss in Men or Women: The Framingham Osteoporosis Study. Robert McLean*[1], Xiaochun Zhang[2], James Meigs[3], Joao Fontes[4], L. Adrienne Cupples[5], Douglas Kiel[2], Marian Hannan[6]. [1]Hebrew SeniorLife, Harvard Medical School, USA, [2]Hebrew SeniorLife, USA, [3]Massachusetts General Hospital, USA, [4]Framingham Heart Study & Boston University, USA, [5]Boston University School of Public Health, USA, [6]HSL Institute for Aging Researchand Harvard Medical School, USA

In vitro studies suggest that several pro-inflammatory cytokines increase bone resorption and that their activity is amplified following estrogen withdrawal. Yet there is little epidemiologic evidence that circulating concentrations of inflammatory markers predict bone loss in men and women, or that estrogen status may influence this relation. We therefore examined the associations of serum concentrations of the cytokines IL-6 and TNF-α, and CRP, a marker of systemic inflammation, with bone loss among men and women in the Framingham Offspring Study. We hypothesized that increased baseline concentrations of inflammatory markers would be associated with greater bone loss, and that this association would be strongest among postmenopausal women not using hormone replacement therapy (HRT). Baseline fasting blood samples were obtained (1998-2001) from 501 men, 106 premenopausal women, 206 postmenopausal using HRT at baseline, and 334 postmenopausal not using HRT. Serum IL-6 (pg/mL) and TNF-α (pg/mL) were measured using ELISAs and CRP (mg/L) using a high-sensitivity assay. Total femur bone mineral density (BMD; g/cm^2) was measured at baseline with a Lunar DPX-L (1996-2001) and at follow-up using a Lunar Prodigy (2002-05), accounting for equipment change. Bone loss was calculated as percent BMD change per year. Within each of the 4 groups defined by sex, menopause status and HRT use, participants were categorized into tertiles of inflammatory markers. We used analysis of covariance to compare mean bone loss in each of the upper 2 tertiles to the lowest tertile and test for a linear trend across tertiles, adjusting for baseline age (y), BMI (kg/m^2), height (in), physical activity, and current smoking (y/n). Mean age at baseline was 61 y (range 29-85 y), and mean follow-up time was 4.6 y (range 1.5-7.9 y). There were no statistically significant associations between inflammatory markers and total hip bone loss in any of the sex/menopause/HRT groups (Table). Our findings suggest that circulating biomarkers of inflammation are not associated with hip bone loss in men or groups of women categorized by menopause status and HRT use. Future investigations of inflammation and BMD should address limitations of our study by including longitudinal measures of inflammatory markers, more precise measures of estrogen status (e.g. sex hormones), and larger samples that could detect the small bone loss effects suggested by our results.

Least squares-adjusted mean annual % change (SE) in total femur BMD for tertiles of inflammatory biomarkers in Framingham Offspring men and women.

Incidence of Subtrochanteric and Diaphyseal Fractures in Older White Women: Data from the Study of Osteoporotic Fractures. Michael Kelly[1], Rosanna Wustrack*[1], Douglas Bauer[1], Lisa Palermo[1], Shane Burch[1], Katherine Wilt[2], Jane Cauley[3], Kristine Ensrud[4], Dennis Black[1]. [1]University of California, San Francisco, USA, [2]California Pacific Medical Center, USA, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]Minneapolis VA Medical Center / University of Minnesota, USA

Purpose: Recent case reports have raised concerns for an increasing incidence of low energy subtrochanteric and diaphyseal femur fractures, which may be associated with long-term bisphosphonate therapy. The incidence of these fractures has not been well defined. The goal was to determine the incidence of low energy, subtrochanteric and diaphyseal femur fractures in the Study of Osteoporotic Fractures (SOF). Methods: 9704 women over age 65 were recruited in 1986 and have been followed for up to 23 years. Radiographic reports for all femur fractures occurring in the intertrochanteric region and below were independently reviewed by two orthopaedic surgeons to determine location of the fracture. These fractures were originally classified as hip (HP) or upper leg. Fractures were reclassified as intertrochanteric (IT), intertrochanteric with subtrochanteric extension (ITST), subtrochanteric or diaphyseal (SH), and distal metaphyseal(DM). Fractures previously classified as femoral neck (FN) were included for analysis without review. Any SH fractures of a high energy mechanism, that were periprosthetic or were pathologic were excluded. The risks per person-year for HP and SH fractures were calculated. Results: 1,396 women with HP fractures were identified in 9704 women. 78 SH fractures were identified in 74 women. After exclusions, there were 48 SH fractures in 45 women. The overall incidence of HP fractures was 103/10,000, and SH fractures was 3/10,000 person-years. The SH fractures represented less than 2% of all hip fractures. For all 3 fractures, incidence increased with age. Conclusions: Subtrochanteric and diaphyseal femur fractures were rare occurrences, far outnumbered by femoral neck and intertrochanteric hip fractures, in this prospective cohort. Those patients greater than 85 years old sustained more fractures of all subtypes.

Increasing Kyphosis Predicts Worsening Mobility Among Older Community-Dwelling Women: A Prospective Cohort Study. Wendy Katzman, DSc*[1], Eric Vittinghoff[2], Kristine Ensrud[3], Dennis Black[4], Deborah Kado[5]. [1]University of California San Francisco, USA, [2]University of California, USA, [3]Minneapolis VA Medical Center / University of Minnesota, USA, [4]University of California, San Francisco, USA, [5]University of California, Los Angeles, USA

Purpose: Although hyperkyphosis has been associated with impaired mobility in cross-sectional studies, no one has determined whether increasing kyphosis has a detrimental effect on mobility over time. We performed a prospective cohort study to determine whether increasing kyphosis angle is independently associated with worsening mobility, as measured by the Timed Up and Go test. Methods: We used data from 11 clinical centers in the United States including 3,223 women age 55-80 years who were randomized to the placebo arms of the Fracture Intervention Trial, a randomized controlled trial of the effect of alendronate on risk for osteoporotic fractures in osteoporotic and osteopenic women. The primary predictor, change in kyphosis angle, was measured using the Debrunner Kyphometer at baseline and an average of 4.4 years later; the outcome was change in mobility measured as performance time on the Timed Up and Go test that was assessed over the same time interval. Covariates included baseline age, kyphosis angle, body mass index, self-reported health status, grip strength, the number of baseline vertebral fractures, incident vertebral fractures, and change in total hip bone mineral density (BMD). Results: The mean kyphosis angle at baseline was 48.0, SD = 11.9 degrees. Over an average of 4.4 years of follow-up, the kyphosis angle increased a mean of 4.0, SD = 9.4 degrees. Increasing kyphosis angle was associated with increase in mobility performance time $p<0.0005$, independent of other significant predictors of worsening mobility including age, baseline kyphosis, health status, grip strength, body mass index, change in hip BMD, and new vertebral fractures. For every standard deviation increase in kyphosis angle, Timed Up and Go performance times increased by 0.16 seconds (95% C.I.:0.08,0.25), that is more than the expected increase in mobility time over one year. Conclusion: In older women, increasing kyphosis angle was independently associated with worsening mobility over time. If this association is confirmed in other cohorts, randomized controlled trials should be conducted to determine whether reducing hyperkyphosis preserves mobility in older community-dwelling women.

Previous Fractures Increase Risk for Subsequent Fractures at Multiple Sites: Global Longitudinal Study of Osteoporosis in Women. Stephen Gehlbach*[1], Kenneth Saag[2], Jonathan Adachi[3], Silvano Adami[4], Steven Boonen[5], Susan Greenspan[6], Coen Netelenbos[7], Philip Sambrook[8], Stuart Silverman[9], Julie Flahive[10], Ethel Siris[11]. [1]University of Massachusetts, USA, [2]University of Alabama at Birmingham, USA, [3]St. Joseph's Hospital, Canada, [4]University of Verona, Italy, [5]Center for Metabolic Bone Disease, Belgium, [6]University of Pittsburgh, USA, [7]VU Medical Center, The netherlands, [8]Royal North Shore Hospital, Australia, [9]Cedars-Sinai/ UCLA, USA, [10]COR, UMass Medical School, USA, [11]Columbia University College of Physicians & Surgeons, USA

Background: History of fracture is a potent predictor of future fracture in postmenopausal women. We assessed the relationship between 10 prior fracture locations and incident fractures. Methods: The Global Longitudinal study of Osteoporosis in Women (GLOW) is an observational cohort study of women ⩾55 years recruited by 723 primary physician practices (17 sites, 10 countries). All non-institutionalized patients visiting the practices within the previous 2 years were eligible. Self-administered questionnaires were mailed (2:1 over-sampling of women ⩾65). At baseline, patients reported any prior fractures since age 45 at 10 specified locations (clavicle, upper arm, wrist, spine, rib, hip, pelvis, upper leg, lower leg, ankle). At 1-year follow-up, patients reported the frequency and location of incident fractures sustained in the past year. Results: Complete baseline and 1-year fracture data were available for 50,332/60,393 women (83%); 23% reported a prior fracture since age 45 (1 bone, n=8883, 17.6%; 2 bones, n=2065, 4.1%; ⩾3 bones, n=808, 1.6%). Overall, 1958 patients reported incident fractures at 1-year follow-up; rates of incident fractures are shown in the Table, by location of prior fracture. In logistic regression analyses, adjusting for age and multiple prior fractures, 7/10 prior fracture locations were associated with any incident fracture; the greatest odds ratios (ORs) were for rib (2.3), spine (2.0) and wrist (1.7). Prior fracture locations varied in their predictive implications for incident fracture. The strongest predictors of hip and spine incident fracture were prior fracture of spine (OR 4.17), hip (OR 2.96) or rib (OR 2.06). Major incident fracture was significantly associated with prior fracture of the upper leg (OR 3.45) and upper arm (OR 3.04). Minor incident fracture was significantly associated with prior fracture of the rib (OR 2.42), wrist (OR 1.72) and ankle (OR 1.42). Having ⩾1 prior fracture added substantially to the likelihood of incident fracture: the OR for incident fracture increased from 2.0 for 1 prior fracture to 3.6 for 2 prior fractures and 5.5 for ⩾3 prior fractures. Conclusion: A broader range of prior fracture sites should be considered in both clinical assessments and risk model development.

Abnormal Microarchitecture and Decreased Stiffness Suggest That Postmenopausal Ankle Fractures Reflect Bone Fragility. Emily Stein*[1], Xiaowei Liu[2], Thomas Nickolas[3], Adi Cohen[3], Dionisio Ortiz[4], Valerie Thomas[3], Perry Yin[2], Felicia Cosman[5], Jeri Nieves[5], Donald McMahon[1], X Guo[2], Elizabeth Shane[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA, [3]Columbia University Medical Center, USA, [4]SUNY Downstate College of Medicine, USA, [5]Helen Hayes Hospital, USA

Ankle fractures are not typically considered osteoporotic fractures. However, bone quality in patients with low trauma ankle fractures has not been explored.

Women with a history of low trauma ankle fracture after menopause (FX; n=19) and women with no history of fragility fracture (C; n=110) had aBMD of lumbar spine (LS), total hip (TH), femoral neck (FN) and 1/3 radius (1/3R) measured by DXA. Trabecular (Tb) and cortical (Ct) volumetric BMD (vBMD) and Tb microarchitecture were measured by HRpQCT (Xtreme CT, voxel size ~82 μm) of the radius (DR) and tibia (DT). Finite element analysis (FEA) of HRpQCT scans was performed to estimate bone mechanical properties. Individual trabeculae segmentation (ITS) based morphological analysis was performed to assess plate (P) and rod (R) structure of the bone.

Women with fractures tended to be older (71±2 vs 68±1 years; $p<0.07$) but were similar with respect to time since menopause, race, and BMI. Mean T-scores of FX were above the osteoporotic range (LS:-1.4±0.2; TH:-1.2±0.2; FN:-1.8±0.2; 1/3R:-1.4±0.3) and did not differ from C; only 26% of FX had osteoporosis at any site. In contrast, HRpQCT, FEA, and ITS measurements at both DR and DT differed between FX and C (Table). At DR, FX had lower Tb number, increased Tb separation and network heterogeneity, and a striking loss of central (inner) trabeculae relative to outer subcortical trabeculae compared to C. At DT, FX had lower total and Tb density and tended to have lower Ct density; FX had lower Tb number, increased Tb separation and network heterogeneity and tended to have lower Ct thickness. Tb dropout was more uniformly distributed across the Tb compartment than at the radius. Whole bone stiffness was ~15% lower at DR and DT in FX ($p<0.05$). ITS revealed that FX had lower R bone volume fraction(rBV/TV:-10%,$p<0.05$) R number(-4%,$p<0.05$), and R-R junction density(-13%,$p<0.05$) at DR and tended to have lower rBV/TV(-9%,$p<0.09$), P number(-4%,$p<0.08$), R number(-4%,$p<0.08$), R-P junction density(-11%,$p<0.06$) and P-P junction density(-11%,$p<0.07$) at DT.

Postmenopausal women with ankle fractures have microarchitectural deterioration and decreased stiffness compared to women with no fracture history. The occurrence of these changes at both the radius and tibia provides evidence for a generalized decrease in bone quality. These findings suggest that low trauma ankle fractures should be considered similarly to other more classical osteoporotic fractures.

Bone Microstructure During and After Lactation. Åshild Bjørnerem*[1], Ali Ghasem-Zadeh[2], Thuy Vu[3], Ego Seeman[2]. [1]Department of Community Medicine, University of Tromsø, Norway, [2]Austin Health, University of Melbourne, Australia, [3]Endocrine Centre, Austin Health, University of Melbourne, Australia

Estrogen deficiency increases bone turnover and bone loss. Lactation is an estrogen deficient state believed to be associated with reversible bone loss. As bone loss assessed using DXA may partly be the result of changes in marrow composition, we assessed the effects of lactation on volumetric bone mineral density (vBMD) and microarchitecture from baseline 14.6 days (2-25) after delivery, with follow-up during 5.2 months (2-7) of breastfeeding, and with the third measurement more than 6 months after weaning in 82 women aged 20-42 years. Total, cortical and trabecular vBMD, cortical and trabecular cross-sectional area (CSA), cortical and trabecular thickness, and trabecular number were measured at the distal tibia and radius using high-resolution 3-D peripheral quantitative computed tomography (HR-3D-pQCT XtremeCT; Scanco Medical, Switzerland).

During lactation, tibia total and cortical vBMD diminished by 0.6 and 0.3% at distal tibia ($p<0.05$), whereas tibia trabecular vBMD was unchanged. Cortical CSA was reduced by 1.8 and 1.4%, cortical thickness was reduced by 1.8 and 1.3%, while trabecular CSA increased by 0.2 and 0.3%, trabecular thickness increased by 5.9 and 4.5% and trabecular number diminished by 4.4 and 2.1% at tibia and radius, respectively (all $p<0.05$). After weaning, cortical vBMD was 0.7 and 0.8% lower than baseline at tibia and radius, whereas trabecular vBMD was 3.1 and 4.0% higher than at baseline at tibia and radius.

We infer that intracortical and endocortical bone loss occurred during lactation as reflected in lower cortical vBMD and thinner cortices perhaps due to trabecularization of cortex. The lack of decline in trabecular vBMD during lactation may be an underestimation of trabecular bone loss because of cortical trabecularization erroneously inflating trabecular vBMD. Lactation may cause a deleterious effect on cortical structure as cortical bone loss was not completely restored after weaning in humans.

Estradiol Replacement Therapy Lowers Serum Sclerostin Levels in Postmenopausal Women. Faryal Mirza*[1], Pamela Taxel[1], Yun Ey Chung[2], Sandra Jastrzebski[3], Lawrence Raisz[1], Joseph Lorenzo[1]. [1]University of Connecticut Health Center, USA, [2]Univ. of Connecticut Health Center, USA, [3]Univ of Connecticut Health Center, USA

Purpose: Sclerostin is a negative regulator of Wnt signaling and bone formation. We previously reported that serum estrogen levels inversely correlate with serum sclerostin levels in postmenopausal women. In this study, we examined the effect of short-term estradiol replacement therapy on serum sclerostin levels in postmenopausal women.

Methods: We evaluated 18 postmenopausal women at baseline, ten of whom received 1 mg of micronized 17-β estradiol (E2) daily and were re-evaluated at 3 weeks. Serum sclerostin levels were measured along with levels of E2, estrone (E1), sex hormone binding globulin (SHBG) and serum and urine bone formation and resorption markers. Free estrogen index was calculated as (E2+E1 (pmol/l)/SHBG, FEI) The Wilcoxon Ranks test was used to compare differences with treatment. Spearman product moment correlations were used to evaluate the relationships between changes in sclerostin, sex hormones and bone markers.

Results: Mean age of the subjects was 56 ± 3 years. E2 treatment significantly changed the serum levels of the following: E2 (10 ± 1 to 89 ± 19 pg/ml, $p<0.005$), E1 (26 ± 2 to 344 ± 54 pg/ml, $p= 0.005$), SHBG (62 ± 8 to 106 ± 14 nmol/l, $p <0.005$) and FEI (3 ± 1 to 16 ± 2 pmol/nmol, $p <0.005$). Serum sclerostin level decreased significantly with E2 treatment (24 ± 3 to 19 ± 2 ng/ml, $p = 0.005$). When the ratio of bone specific alkaline phosphatase (BSAP) to urine deoxypyridinoline (DPD) and BSAP to urine N-telopeptide (NTX) were used as measures of relative bone formation to resorption at baseline, we found significant inverse correlations with serum sclerostin ($r = -0.854$, $p = 0.007$and $r = -0.737$, $p = 0.015$, respectively), consistent with an association between decreasing serum sclerostin and an increasing bone formation to resorption ratio. In addition, with E2 treatment, the decline in sclerostin correlated positively with increases in the BSAP to NTX ratio ($r = 0.812$, $p = 0.01$), further supporting this relationship.

Conclusions: E2 replacement in postmenopausal women significantly lowered serum sclerostin levels. Moreover, baseline serum sclerostin levels show a strong inverse correlation with the ratio of basal bone formation to resorption. The change in serum sclerostin levels with E2 treatment is also inversely associated with changes in the ratio of bone formation to resorption. We conclude that estrogen decreases serum sclerostin levels by mechanisms that are linked to the ratio between bone formation and resorption.

Oxytocin Mediates the Anabolic Action of Estrogen on the Skeleton. Graziana Colaianni[1], Adriana DiBenedetto[2], Roberto Tamma[2], Giovanni Greco[2], Stefania Dell'Endice[2], Concetta Cuscito[2], Lucia Mancini[2], Ling-Ling Zhu[3], Xuan Liu[3], Yuanzheng Peng[3], Jianhua Li[3], Jammel Iqbal[3], Li Sun[4], Alberta Zallone[1], Mone Zaidi*[5]. [1]University of Bari Medical School, Italy, [2]Department of Human Anatomy & Histology, University of Bari, Italy, [3]The Mount Sinai Bone Program, Mount Sinai School of Medicine, USA, [4]Mount Sinai School of Medicine, USA, [5]Mount Sinai Medical Center, USA

We have shown that the posterior pituitary hormone oxytocin directly regulates bone mass by acting on its receptor, Oxtr, on osteoblasts and osteoclasts (Tamma et al., PNAS, 2009). Here we demonstrate that oxytocin is produced peripherally by osteoblasts, and is required for the anabolic action of estrogen on the skeleton. Thus, mice lacking the Oxtr failed to respond to 17ß-estradiol (50 µg/mice/day, s.c.) in terms of the increases in bone mineral density (Piximus) and mineral apposition rate (histomorphometry) noted in wild type littermates. Impressively, the decline in bone mineral density at the spine post-ovariectomy was not reversed by 17ß-estradiol, whereas a robust reversal of this drop was noted in wild type, sham-operated littermates. This in vivo insensitivity to estrogen was accompanied ex vivo by an attenuated ability of Oxtr-/- bone marrow stromal cells to form mineralizing CFU-ob colonies in response to 17ß-estradiol (10-8 M). To study this lack of responsiveness further, we knocked down the Oxtr using siRNA, which resulted in a marked reduction in Oxtr expression on Western immunoblotting. In Oxtr-sufficient cells, 17ß-estradiol (10-8 M) stimulated the expression of osteoblast genes, namely osteocalcin, Runx2, osterix, BMP-2, bone sialoprotein, and schnurri2; these responses were either strongly attenuated or abrogated in Oxtr siRNA-treated osteoblasts. We next explored the peripheral source of oxytocin. Quantitative PCR and Western immunoblotting showed that both Oxtr and oxytocin were expressed in osteoblasts, and that 17ß-estradiol (10-8 M) stimulated the expression of both molecules in a time-dependent manner. This is consistent with an autocrine function of locally produced oxytocin in mediating the osteoblastic action of estrogen. Interestingly, however, the effect of estrogen on oxytocin synthesis was exerted via a non-genomic route. We found that, for estrogen-induced oxytocin synthesis, estrogen must act extracellularly at a membrane site to activate the MAP kinase Erk. Thus, cell impermeant BSA-conjugated 17ß-estradiol produced as robust an increase in oxytocin and oxtr mRNA as did free 17ß-estradiol. However, the estrogen-mediated increase in oxytocin mRNA, but not Oxtr mRNA was sensitive to PD98059, an inhibitor of Erk phosphorylation. Overall, the study not only expands our premise for a novel pituitary bone axis, but also, in revealing a new bone marrow location for oxytocin production, strengthens the notion of the skeleton serving as a hormone-producing endocrine organ.

FR0370

High Seretonin Levels and High Platelet Count are Associated with Low Bone Mineral Density in Elderly Men, MrOs Sweden. Dan Mellstrom*[1], Malin Aronsson[2], Mattias Lorentzon[3], Osten Ljunggren[4], Magnus Karlsson[5], Ulf Lerner[6], Claes Ohlsson[7]. [1]Sahlgrenska University Hospital, Sweden, [2]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Institute of Medicine & Geriatrics, University of Gothenburg, Sweden, Sweden, [3]Center for Bone Research at the Sahlgrenska Academy, Sweden, [4]Uppsala University Hospital, Sweden, [5]Skåne University Hospital Malmö, Lund University, Sweden, [6]Center for Bone Research at the Sahlgrenska Academy, Dept. of Internal Medicine, University of Gothenburg, Sweden, Sweden, [7]Centre for Bone & Arthritis Research, Sweden

Recent experimental studies demonstrate a role of circulating serotonin in the regulation of bone mass (Yada et al. Cell 2008). One previous cross-sectional study evaluating 275 women showed an indirect association between serum serotonin and BMD in total body and spine (Mödder et al JBMR 2009). Circulating serotonin is to a large extent bound to platelets. The relative role of platelet count and serum serotonin for BMD is unknown. We measured serum serotonin (155±77 ng/ml) in 1010 elderly men (70-80 year) in the Gothenburg part of MrOS Sweden, using a competitive enzyme-linked immunosorbent assay (ELISA) (Immuno-Biological lab, Inc, Minneapolis, MN). BMD was measured with a Hologic 4500.

Serum serotonin associated inversely with BMD in the hip (total hip $r = -0.08$, $p<0.01$; neck -0.08, $p<0.02$; trochanter $r = -0.08$, $p<0.02$). However, serum serotonin also associated with body weight $r = -0.09$ ($p<0.01$) and body fat mass $r = -0.13$ ($p<0.01$) and after adjustment for BMI and age, no significant association between serotonin and BMD was found. Serum serotonin associated strongly directly with platelet count $r = 0.28$ ($p<0.001$). Interestingly, platelet count was independently (adjusting for serum serotonin, BMI and age) associated with BMD at all investigated bone sites (Standardized β = -0.08 for total BMD, -0.14 for spine BMD, -0.16 for total hip total, -0.14 for femoral neck and -0.14 for trochanter BMD; $p< 0.01$).

In conclusion, although serum serotonin in univariate analyses associated with BMD at hip bone sites, no significant association was seen after adjustment for BMI. Serum serotonin associated strongly with platelet count and we made the novel observation that platelet count was an independent predictor of BMD at all investigated bone sites.

Neural and Endocrine Signalling Interact to Control Bone and Adipose Homeostasis. Ayse Zengin*, Ronaldo F Enriquez, Amy D Nguyen, Amanda Sainsbury, Herbert Herzog, John Eisman, Paul Baldock. Garvan Institute of Medical Research, Australia

The coordinated control of bone and fat mass is now well appreciated. Endocrine and neural pathways that regulate bone and fat mass have a similar origin within the hypothalamus, suggesting the potential for interaction between them. Here we show interaction between androgens and neuropeptide Y (NPY) in control of osteoblast and adipocyte activity. NPY, a critical component of efferent neural signalling, acts through central Y2 and peripheral Y1 receptors to regulate bone and fat mass. In bone, the anabolic phenotype of NPY Y1 receptor deficient mice ($Y1^{-/-}$) was completely attenuated by orchidectomy (ORX), however, this attenuation was not evident following ORX in wild type or $Y2^{-/-}$ mice. In adipose tissue, ORX increased white adipose tissue mass of $Y1^{-/-}$, but not in wild type or $Y2^{-/-}$ mice. These differential responses between $Y1^{-/-}$ and $Y2^{-/-}$ mice suggest a receptor-specific interaction between androgens and NPY.

In order to further investigate this interaction, the skeletal response to ORX was examined in NPY deficient mice ($NPY^{-/-}$) in comparison with $Y1^{-/-}$ and $Y2^{-/-}$ mice. Mice underwent ORX or sham-operation at 8 weeks of age; skeletal and adipose responses were examined at 16 weeks of age.

White adipose tissue (WAT, g) was decreased post-ORX in wild type (0.98 ±0.08 vs 0.47 ±0.05, $p<0.0001$). This loss was absent in $NPY^{-/-}$ (0.73 ±0.06 vs 0.72 ±0.09), this is in contrast to $Y1^{-/-}$ which gained WAT post ORX (0.81 ±0.02 vs 1.28 ±0.14, $p<0.01$). Cancellous bone volume (BV/TV) was reduced by ORX in wild type (7.7 ±0.9 vs 3.5 ±0.2, $p<0.0001$) and $NPY^{-/-}$ (11.6 ±1.6 vs 6.7 ±0.4, $p=0.003$) however, BV/TV in ORX-$NPY^{-/-}$ mice remained greater than ORX-wt ($p<0.0001$), in contrast to *ORX-*$Y1^{-/-}$. The NPY-mediated anabolic phenotype involves greater mineral apposition rate (MAR µm/d). MAR in wild type mice was not affected by ORX (1.1±0.05 vs. 1.2±0.07, $p=0.28$) but was increased in $NPY^{-/-}$ (1.8 ±0.1 vs 2.2 ±0.1, $p=0.006$). This is in contrast to the loss of MAR post-ORX in $Y1^{-/-}$ compared to ORX-wild type mice.

Bone and fat mass are regulated by interactions between NPY and androgens. The similarity between $NPY^{-/-}$ and $Y2^{-/-}$ responses, indicates that Y2 signalling regulates the loss of bone and fat post-ORX. However, the unique post-ORX responses involving Y1 receptors indicate a complex relationship between central and peripheral signalling between androgens and the NPY system.

Comparison of Transdermal and Subcutaneous Teriparatide Pharmacokinetics and Pharmacodynamics of Bone Markers in Postmenopausal Women.

Yael Kenan[1], Efrat Kochba[1], Michal Shahar[1], Hana Gadasi[1], Galit Levin[1], Ajit Suri[2], Kyoungah See[2], A. Joseph Foldes[3], Sophia Ish-Shalom*[4], Toshio Matsumoto[5], Robert Lindsay[6], Claus Christiansen[7], Robert Neer[8]. [1]TransPharma-Medical, Israel, [2]Eli Lilly & Company, USA, [3]Hadassah-Hebrew University Medical Center, Israel, [4]Rambam Health Care Campus, Technion Faculty of Medicine, Israel, [5]University of Tokushima Graduate School of Medical Sciences, Japan, [6]Helen Hayes Hospital, USA, [7]Nordic Bioscience, Denmark, [8]Massachusetts General Hospital, USA

TransPharma-Medical has developed a system for transdermal (TD) delivery of teriparatide to alleviate the discomfort of subcutaneous (SC) injections and to improve acceptance and compliance. The TD delivery of teriparatide utilized radiofrequency ablation to create microchannels in the skin, allowing rapid diffusion into systemic circulation from a subsequently applied drug patch. In a phase 1 study, TD 50, 70, and 90 µg teriparatide demonstrated significant increases in bone turnover, similar to SC 20 µg teriparatide[1]. The aim of this phase 2 study was to compare efficacy (bone turnover markers), safety, and teriparatide pharmacokinetics (PK) in a 3-month, randomized, multicenter study in postmenopausal women with osteoporosis (mean ± SD, age 65.1 ± 6.8 yr). Patients were randomly assigned to either open-label SC 20 (n=36) or double-blind TD 50 (n=34) or 80 µg (n=34) once-daily teriparatide. Blood samples for PK analysis were taken at 0 (pre-dose), 0.25, 0.5, 1, 1.5, 2, 2.5, 3, 4, 6, and 8 hours post-dose. PK parameters ($AUC_{0\text{-}t}$, Cmax, Tmax, and T1/2) were evaluated at days 1 and 96. PINP and CTX increased from baseline to day 96 with TD 50, 80, and SC 20 µg teriparatide ($p<0.05$); TD increases were dose-dependent (PINP, p=0.02; CTX, p=0.007)[2]. There was a dose-proportional increase in Cmax and AUC for TD 50 and 80 µg (Table). Cmax and AUC values at days 1 and 96 were similar for TD, indicating no accumulation of drug or temporal change in PK (Table). The Tmax for PK profile following TD treatment, similar to that reported in phase 1[1], was shifted to the right ($p<0.0001$) for TD 50 and 80, compared with the SC injection group, indicating a delayed time to peak concentration and a slower absorption of TD than SC teriparatide. Compared with SC 20 µg on day 1, the TD 50 and 80 µg geometric mean (95% CI) AUC-ratios were 1.65 (1.03-2.64, p=0.037) and 2.48 (1.51-4.08, p=0.0005, respectively. The Cmax-ratios were 0.64 (0.47-0.88, p=0.0068) and 0.98 (0.65-1.47, p=0.92) for TD 50 and 80 µg, respectively. No clinically significant differences across study groups or time were observed for hypercalcemic, dermatologic, or other adverse events. In conclusion, the TD system of microchannels and subsequently applied drug patch to facilitate diffusion of teriparatide into systemic circulation, may be an effective alternative to SC injection delivery of teriparatide.

Does Anabolic Therapy Correct the Homogeneity In Bone Composition Associated With Osteoporosis?

Adele Boskey*[1], Lyudmila Spevak[1], David Dempster[2], Anthony Hodsman[3]. [1]Hospital for Special Surgery, USA, [2]Columbia University, USA, [3]St. Joseph's Health Care, Canada

Treatment with intermittent PTH(1-34) (Teriparatide) is reported to stimulate new bone formation in osteopenic/osteoporotic patients and animal models of osteoporosis. Previously we reported that Fourier Transform Infrared Imaging (FTIRI) of iliac crest biopsies at 6.25 um spatial resolution (54 untreated patients with and without fractures) revealed significant differences in material properties (mineral crystal size and composition and collagen maturity) in both cortical and cancellous regions that, based on multiple logistic regressions were predictive of fracture risk. We also have limited data (17 patients) that the pixel distribution of values (heterogeneity) of these parameters was significantly reduced in fracture cases. The present pilot study compared FTIRI compositional analyses of iliac crest biopsies obtained after treatment from 10 PTH treated osteoporotic women who had fractures at base-line (and were treated for 1 month with 50 ug daily subcutaneousl compared to age, and sex-matched non-treated fracture controls. Results showed that in two age groups (53-70 and 71-80) the mean mineral:matrix, collagen maturity, crystallinity, and carbonate content did not differ among treated and non-treated controls in cortical or cancellous bone, although the cancellous bone parameters were always less than the age-matched parameters for the same age group. Global averages over all age ranges for cancellous bone (figure 1) showed slight but significant decreases in mineral/matrix (Min/Mat) ratio and increases in collagen maturity (XLR) with no change in crystallinity (Cryst) or carbonate/phosphate (CO3/PO4) content with PTH(1-34) treatment. Additionally, the pixel heterogeneity based on the line-width at half maximum for each of these parameters in each bone area was significantly greater for the PTH(1-34)-treated subjects than for controls, although the mean BMDs for each age group were not different. Since increased tissue heterogeneity has recently been correlated with reduced micro-crack propagation in Finite Element Models, these data suggest that an anabolic therapy can correct the loss of heterogeneity in bone composition that is associated with osteoporosis, thereby improving the structural integrity of the bone.

Effects of Teriparatide and Strontium Ranelate on Periosteal Bone Formation in the Ilium of Postmenopausal Women with Osteoporosis.

Robert Recker*[1], Fernando Marin[2], Jan Stepan[3], Qing Q. Zeng[2], Xiahoai Wan[2], Sophia Ish-Shalom[4], Federico G. Hawkins[5], Georgios Kapetanos[6], M Pilar de la Peña[7], Jordi Farrerons[8], Yanfei Ma[9]. [1]Creighton University Osteoporosis Research Center, USA, [2]Lilly Research Labs, USA, [3]Charles Univ., Czech republic, [4]Bone Metabolism Unit, Technion Univ., Israel, [5]Endocrinology, Hospital 12 de Octubre, Spain, [6]Orthopedic Surgery, Aristotelion Univ., Greece, [7]Clínica Médica Monraz, Mexico, [8]Internal Medicine, Hospital Sant Pau, Spain, [9]Eli Lilly & Company, USA

The periosteum contains osteogenic cells that regulate bone size, the outer shape of the bone and its cortical thickness. Periosteal expansion serves to improve the biomechanical properties of bone. Our purpose is to describe the bone envelope-specific effects of daily subcutaneous injection of teriparatide (TPTD, 20 µg/d) or oral strontium ranelate (SrR, 2 g/d) in postmenopausal women with osteoporosis using biopsy specimens from a completed study[1]. Transiliac crest biopsies were obtained

after tetracycline double labeling from 49 subjects (TPTD: 27; SrR: 22) at the end of 6 months of treatment. The specimens were examined for single and double-labeled surfaces, mineralized surfaces as a percent of bone surfaces (MS/BS %), bone formation rate per bone surface (BFR/BS), and mineral apposition rate (MAR). Histomorphometric results were analyzed using an exact permutation test as a safeguard against potential non-normality of the data (Table).

The percent of specimens that exhibited double labels was higher in the TPTD (70%) than the SrR group (27%) ($p<0.005$, Fisher's exact test). Specimens that showed single label were also more frequent in the TPTD (93%) than in the SrR (64%) group ($p<0.05$). The endocortical results were similar to those for the periosteal envelope (data not shown).

Conclusion: Bone formation and mineralization variables, including MS/BS% and MAR, were statistically significantly higher for TPTD than SrR treated women at periosteal and endosteal combined cortices after 6 months of treatment. These findings provide new insights into the structural basis by which TPTD improves cortical bone geometry in patients with osteoporosis.

FR0387

Bisphosphonates and Glucocorticoid Osteoporosis in Men: Results of a Randomized Controlled Trial Comparing Zoledronic Acid With Risedronate. Philip Sambrook*[1], Christian Roux[2], Jean-Pierre Devogelaer[3], Kenneth Saag[4], C Lau[5], Jean-Yves Reginster[6], C Bucci-Rechtweg[7], G Su[7], David Reid[8]. [1]Royal North Shore Hospital, Australia, [2]Hospital Cochin, France, [3]St. Luc University Hospital, Belgium, [4]University of Alabama at Birmingham, USA, [5]University of Hong Kong, Hong kong, [6]CHU Centre Ville, Belgium, [7]Novartis Pharmaceuticals Corporation, USA, [8]University of Aberdeen, United Kingdom

Purpose: There are limited data available on the effect of bisphosphonates in men receiving glucocorticoid therapy. We studied 265 men, mean age 56.4 yrs (range 18 – 83), among the patients enrolled in two arms of a double-blind, double dummy, 1-year study comparing the effects of Zoledronic acid (ZOL) *vs.* Risedronate (RIS) in patients either commencing glucocorticoid treatment at a dose of at least 7.5 mg per day of prednisone or equivalent (prevention arm, n=88) or continuing long-term treatment of glucocorticoid at that dose (treatment arm, n=177).

Methods: Patients received either ZOL 5 mg infusion at study entry or RIS 5 mg daily, along with calcium (1000 mg) and vitamin D (400-1200 IU) supplementation daily. The primary endpoint was difference in bone mineral density (BMD) at the lumbar spine (LS) at 12 months. Secondary endpoints were changes in BMD at other sites such as total hip (TH) and femoral neck (FN), changes in biochemical markers of bone turnover (β-C-terminal telopeptides of type 1 collagen [β-CTx] and procollagen type 1 aminoterminal propeptide [PINP]), and overall safety.

Results: In the treatment arm, ZOL increased LS BMD by 4.7% compared with 3.3% for RIS and at TH the changes were 1.8% *vs.* 0.2%, respectively. In the prevention arm, bone loss was prevented by both treatments. At the LS the changes were 2.5% *vs.* -0.2% for ZOL *vs.* RIS and at TH the changes were 1.1% *vs.* -0.4%, respectively. The differences between ZOL and RIS were significant at the LS in the treatment ($p<0.025$) and prevention ($p<0.0025$) arms as well as at TH (p=0.0004 and $p<0.025$ for treatment and prevention, respectively). In the treatment sub-group, ZOL demonstrated a significantly greater reduction in serum β-CTx and PINP relative to RIS at all time-points. In the prevention sub-group, ZOL demonstrated a significantly greater reduction in β-CTx at all time-points, and in PINP at Month 3 (p=0.0297) only. Both treatments were well tolerated in men, albeit with a higher incidence of influenza-like illness and pyrexia events post-infusion with ZOL.

Conclusion: Once yearly IV infusion of ZOL preserves or increases bone density within 1 year to a greater extent than daily oral RIS in men receiving glucocorticoid therapy.

FR0388

BMD Response to a Novel Delayed-release Risedronate 35 mg Once-a-Week Formulation Taken With or Without Breakfast: One Year Results. Michael McClung*[1], Michael Bolognese[2], Paul Miller[3], Joseph Sarley[4], Leigh McCullough[5], Jacques Brown[6], Robert Recker[7]. [1]Oregon Osteoporosis Center, USA, [2]Bethesda Health Research, USA, [3]Colorado Center for Bone Research, USA, [4]Procter & Gamble Pharmaceuticals Health Care Research Center, USA, [5]Warner Chilcott Phamaceuticals, USA, [6]Laval University, Canada, [7]Creighton University Osteoporosis Research Center, USA

Bisphosphonates (BPs) are the standard of care for postmenopausal osteoporosis. The dosing instructions of oral BPs per their approved labels require that they be taken on an empty stomach at least 30 to 60 minutes before the first food or drink or other medications. One year efficacy and safety results of a novel delayed release (DR) formulation of risedronate 35 mg once-a-week (OaW) that can be taken with or without breakfast will be presented.

This phase III study was a randomized, double blind, active controlled study conducted at 43 study centers across North America, Europe and South America. The primary efficacy analysis was to test the non-inferiority, based on the percent change in lumbar spine BMD from baseline at Endpoint (last observation carried forward at Week 52), of the risedronate 35 mg OaW DR formulation taken before or after breakfast compared to the 5 mg daily immediate release (IR) dose taken per label. Participants were postmenopausal women at least 50 years of age, ⩾ 5 years since last menses, with a lumbar spine or total hip BMD corresponding to a T-score < -2.5 or a T-score < -2.0 with at least one prevalent vertebral fracture (T4 to L4). Patients were randomly assigned to risedronate 35 mg OaW DR following breakfast (FB) (n=307), or risedronate 5 mg IR daily (n=307) or risedronate 35 mg OaW DR at least 30 minutes before breakfast (BB) (n=308).

At one year, the risedronate 35 mg OaW DR formulation, whether taken before or after breakfast, was shown to be non-inferior to the 5 mg IR daily. The mean percent changes in BMD at the hip (total proximal femur, femoral neck, and femoral trochanter) were similar across groups. Both the 5 mg IR daily and the 35 mg OaW DR regimens were well tolerated, and the overall frequency of adverse events was similar.

At one year, Risedronate 35 mg OaW DR, whether taken before or after breakfast, provided similar efficacy and tolerability to risedronate 5 mg/day IR taken per the label.

FR0389

Comparison of Risedronate and Alendronate on Bone Remodeling, Architecture and Material Properties; a Cross-sectional Study in Women with Postmenopausal Osteoporosis. Eleftherios Paschalis[1], Roger Phipps*[2], Frank Ebetino[3], Babul Borah[4]. [1]Ludwig Boltzmann Institute for Osteology, Austria, [2]Husson University School of Pharmacy, USA, [3]Procter & Gamble Pharmaceuticals, Inc., USA, [4]Procter & Gamble Pharmaceuticals, USA

The effects of risedronate and alendronate on bone architecture, remodeling, and material properties were analyzed in transiliac crest biopsies collected from a non-randomized cross-sectional sample of 100 women with postmenopausal osteoporosis. Subjects recruited at 8 sites were at least 5 yr postmenopause and had been treated for >3 years with daily or weekly alendronate (n=68, mean age 70 yr) or risedronate (n=32, mean age 70 yr). Subjects received standard tetracycline labeling, and biopsies were placed in 70% ethanol and were embedded in methylmethacrylate. Complete biopsies were scanned at 8 µM resolution using a Scanco MicroCT40 scanner. After thresholding and masking, architecture measurements were derived from 3-D data sets, and grey level images were calibrated against HA standards to allow for measurement of mineralization. Five-µm thick sections were prepared for static and dynamic histomorphometry. Five-µm thick sections were also prepared for FTIR analysis of mineral crystallinity and collagen cross-links ratio for assessment of bone material properties and maturity of the bone matrix. All analyses were performed blinded. Values are medians, and groups were compared with the Wilcoxon Rank Sum test.

There were no significant differences in patient demographics including lumbar spine and total hip T-scores, and previous fractures. Mineralizing surface, bone formation rate and activation frequency (histomorphometry), and the low:high mineralization ratio in trabecular and cortical bone (micro-CT) were all significantly higher in risedronate-treated subjects than in alendronate-treated subjects. While trabecular architecture parameters (bone volume, trabecular thickness, trabecular number) were all higher in risedronate treated subjects, most differences were not statistically significant. There was no significant difference in cortical porosity between the 2 treatment groups. By FTIR, there were no statistically significant differences between the two drugs, although a trend towards younger (tissue-age wise) bone matrix at forming surfaces in risedronate treated subjects was consistent with published data from non head to head studies. These results support that long-term treatment with risedronate suppresses bone remodeling less than treatment with alendronate, but provides corresponding preservation of trabecular and cortical bone architecture and material properties.

Parameter	Alendronate	Risedronate	P-value
Trabecular bone volume (%)	15.4	17.5	0.12
Trabecular thickness (µm)	123	138	0.04
Mineralizing surface (%)	1.32	2.55	0.01
Activation frequency (#/yr)	0.12	0.20	0.01
Low high mineralization ratio - trabecular	0.26	0.41	0.01
Low high mineralization ratio - cortical	0.22	0.30	0.02
Collagen cross link ratio – trabecular forming surfaces AUC 0-49 µm depth	182	132	0.70

FR0390

Disintegration Times of Brand and Generic Bisphosphonates Available in Canada. W.P. Olszynski*[1], Jonathan Adachi[2], Jana Davison[3], K. Shawn Davison[4]. [1]Midtown Medical Center (#103), Canada, [2]St. Joseph's Hospital, Canada, [3]a priori medical sciences inc., Canada, [4]Laval University, Canada

Purpose: The purpose of this investigation was to compare the disintegration times among Canadian-marketed brand (Fosamax 70mg, Fosavance 70mg, Actonel 35mg) and generic (Novo-Alendronate 70mg and Apo-Alendronate 70mg) bisphosphonates. Differences in disintegration times among brand and generic versions of bisphosphonates may translate into differences in tolerability, safety and effectiveness between brand and generic formulations.

Methods: All tests were performed with the use of a Vanderkamp Disintegration Tester as per the United States Pharmacopeia guidelines. The time to tablet disintegration was recorded for each tested tablet. All tests were performed over a three day period, with an approximate third of each group tested daily. Between 18 and 20 samples were tested for each bisphosphonate group (n=18 for Novo-alendronate, n=20 for all others). Basic descriptive statistics were completed for all tablet groups. Analysis of variance was used to assess whether there were significant differences in disintegration time among the tablets tested and the Tukey post-hoc procedure was used to establish whether significant differences existed between specific tablet groups. Alpha was set at $p<0.05$ for all tests.

Results: The mean $\pm$ SD disintegration times were significant faster for the Apo-Alendronate (26 ± 5.6 seconds) and the Novo-Alendronate (13 ± 1.1 seconds) as compared to the brand alendronate (150 ± 50.5 seconds), the brand alendronate plus vitamin D (378 ± 60.5 seconds) and the brand risedronate (101 ± 20.6 seconds). There was no significant difference in disintegration time between the two generic forms of alendronate. Brand alendronate with vitamin D had a significantly slower disintegration time than all other tablets tested.

Conclusions: Generic formulations of alendronate were found to disintegrate significantly faster than brand versions of alendronate or risedronate. The rapid disintegration of the generic compounds were found to be similar to those reported for tablets specifically-engineered for disintegration in the mouth (<30 seconds). The rapid disintegration of generic alendronate as compared to brand versions of the alendronate or risedronate may have important safety implications, particularly for adverse events in the oesophagus. Further, the potential for quick-disintegrating alendronate to come into contact with food or drink while adhered to the oesophagus may be higher, thereby decreasing its effectiveness.

FR0393

The Effect of Long Term Bisphosphonate Therapy on Cortical Thickness Ratio of the Proximal Femur. Quang Ton*[1], Kashif Ashfaq[2], John Kleimeyer[3], Aasis Unnanuntana[2], Joseph Lane[2]. [1]Englewood Hospital & Medical Center, USA, [2]Hospital for Special Surgery, USA, [3]Weill Cornell Medical College, USA

There is little in the literature which attempts to prove a causal relationship between long-term bisphosphonate (BP) use and alteration of bone strength. Previous studies identified typical radiographic characteristics of patients with a so-called "BP fracture'' that include cortical thickening at the subtrochanteric (ST) area [Neviaser+2008]. A small subset of these patients develop low energy proximal femoral fractures. These patients have cortical thickness of >30%, while osteoporotic patients with similar fractures not on BP have cortical thickness of < 25%. Our hypothesis was that long term BP therapy results in progressive thickening of the proximal femoral cortex.

This study was a retrospective review of 49 patients from 1996-2010. Patients included were post-menopausal women on BP for at least 5 years and had serial dual energy X-ray absorptiometry (DXA) before and after treatment. Baseline and most recent hip DXA were uploaded into an imaging system and standard technique was used to measure the proximal femur. Measurement was intially standardized by first doing calibration and then measuring the medullary and femoral diameter at a level 3.5 cm and 4.0 cm from the tip of greater trochanter (GT) downwards which represented the ST area. These measurements allowed us to derive the cortical thickness ratio (CTR), periostal, and endosteal growth. The data was compared by using a paired t-test of the initial and last DXA.

The baseline average CTR 3.5 cm below the tip of GT was 0.40 + 0.06 mm. This ratio was decreased to 0.38 + 0.06 mm after 5 years of BP therapy. The difference was not statistically significant before and after treatment ($p = 0.108$). The baseline average CTR 4.0 cm below the tip of GT was decreased from 0.44 + 0.06 mm to 0.42 + 0.07 mm, when compared before and after 5 years of BP treatment ($p = 0.0005$). The difference was statistically significant. The average periosteal thickening ratio was -0.03 + 0.10; while the endosteal thickening ratio was -0.03 +0.10.

This study suggests that the cortical thickness of the proximal femur does not change over long-term BP of at least 5 years. There is neither periosteal nor endosteal growth after the treatment. Our hypothesis that patients on prolonged BP treatment get increased cortical thickness was thus disproved, therefore patients with ST fractures may have had thickened cortices at the onset of their BP treatment and these BP may not have resulted in further thickening of the cortices.

Zoledronic Acid Improves Health-related Quality of Life in Patients with Hip Fracture: Results of HORIZON-RFT. Jonathan Adachi*[1], Kenneth Lyles[2], Cathleen Colon-Emeric[2], Steven Boonen[3], C Pieper[2], Carlos Mautalen[4], Lars Hyldstrup[5], Christopher Recknor[6], L Nordsletten[7], C Bucci-Rechtweg[8], G Su[8], Erik Fink Eriksen[9], Jay Magaziner[10]. [1]St. Joseph's Hospital, Canada, [2]Duke University Medical Center, USA, [3]Center for Metabolic Bone Disease, Belgium, [4]Centro de Osteopatías Médicas, Argentina, [5]Hvidovre Hospital, Denmark, [6]United Osteoporosis Center, USA, [7]Ullevål University Hospital, Norway, [8]Novartis Pharmaceuticals Corporation, USA, [9]Oslo University Hospital, Norway, [10]University of Maryland, Baltimore, USA

Purpose: In HORIZON-RFT, annual i.v. zoledronic acid (ZOL) 5 mg infusion significantly reduced the rate of new clinical fractures and all-cause mortality compared with placebo.[1] A pre-defined exploratory objective of the same study was to analyze the benefits of ZOL *vs.* placebo on Health-related quality of life (HRQoL) using the EQ-5D health questionnaire in selected countries.

Methods: In this randomized, double-blind, placebo-controlled trial 2127 patients were randomized to single infusion of ZOL 5 mg (n=1065) or placebo (n=1062) within 90 days after surgical repair of low-trauma hip fracture, followed by annual infusions up to 3 years, with a median follow-up time of 1.9 years. HRQoL was measured using EQ-5D-Visual Analogue Scale (VAS) and -utility scores (EuroQol instrument) at end of the study. Analysis of covariance model included baseline EQ-5D status, region and treatment as explanatory variables.

Results: At baseline, patients (mean age: 75 years; 24% men and 76% women) were well-matched between treatment groups with mean EQ-5D VAS of 65.82 in ZOL group and 65.70 in placebo group. At the end of the study, mean change from baseline in EQ-5D VAS was greater for ZOL *vs.* placebo in all patients (7.67 ± 0.56 *vs.* 5.42 ± 0.56), and in subgroups of patients experiencing clinical vertebral fractures (8.86 ± 4.91 *vs.* -1.69 ± 3.42), non-vertebral fractures (5.03 ± 2.48 *vs.* -1.07 ± 2.16), and clinical fractures (5.19 ± 2.25 *vs.* -0.72 ± 1.82) with treatment difference significantly in favor of ZOL (Figure). EQ-5D utility scores were comparable for ZOL and placebo groups but more patients on placebo consistently had extreme difficulty in mobility (1.74% for ZOL *vs.* 2.13% for placebo; p=0.6238), self-care (4.92% *vs.* 6.69%; p=0.1013) and usual activities (10.28% *vs.* 12.91%; p=0.0775).

Conclusion: In addition to reducing the risk of vertebral, hip, and non-vertebral fractures, treatment with ZOL significantly improved overall quality of life in patients with low-trauma hip fracture.

Efficacy and Safety of Bazedoxifene in Postmenopausal African American Women. Amy B. Levine*[1], Monika Ciesielska[1], Arkadi Chines[2]. [1]Pfizer Inc, USA, [2]Wyeth Research, USA

The results of 2 global, double-blind, placebo- and active-controlled, phase 3 studies (2-year prevention study [mean age, 58 y]; 3-year treatment study [mean age, 66 y]) have demonstrated the efficacy and safety of bazedoxifene (BZA) in the prevention and treatment of postmenopausal osteoporosis. The purpose of this analysis was to evaluate the effects of BZA on bone mineral density (BMD), bone turnover, and safety parameters in African American women enrolled in these studies. The data from these 2 studies were pooled and an integrated analysis was performed. Five hundred and five African American women were randomly assigned to receive daily treatment with BZA 20 mg (n=119), BZA 40 mg (n=141), raloxifene (RLX) 60 mg (n=120), or placebo (PBO; n=125); they also received supplementation with calcium and vitamin D. Mean lumbar spine BMD T-scores at baseline were –2.3, –2.6, –2.3, and –2.7 in the BZA 20- and 40-mg, RLX 60-mg, and PBO groups, respectively. At 24 months, the mean (±standard error) percent changes from baseline in BMD at the lumbar spine were significantly greater with BZA 20 or 40 mg and RLX 60 mg (0.88±0.64%, 1.14±0.60%, and 1.42±0.63%, respectively) versus PBO (–0.25±0.62%; P <0.05). Similar results were seen at the total hip, femoral neck, and femoral trochanter (BZA 20 mg: 1.24±0.53%, 2.14±0.61%, 1.01±0.73%, respectively; BZA 40 mg: 1.18±0.49%, 2.39±0.58%, 1.23±0.68%, respectively; RLX 60 mg: 1.06±0.51%, 2.46±0.60%, 0.99±0.71%, respectively; PBO: –0.06±0.51%, 0.61±0.59%, –0.36±0.71%, respectively; P <0.05 vs PBO for all). BZA 20 or 40 mg and RLX 60 mg significantly reduced serum C-telopeptide (–47%, –57%, and –57%, respectively) and osteocalcin (–42%, –44%, and –45%, respectively) levels versus PBO (–35% [P <0.05] and –24% [P <0.001], respectively) at 12 months. There was a small number of vertebral fractures among African American women in the treatment study (BZA 20 mg [n=2]; BZA 40 mg [n=3]; RLX 60 mg [n=1]; PBO [n=2]). The overall incidence of treatment-emergent adverse events (95%) and serious adverse events (16%) in African American women was not different among the BZA, RLX, and PBO groups. The incidence of cerebrovascular and venous thromboembolic events was low and similar among groups. In conclusion, BZA preserved BMD, reduced bone turnover, and showed a favorable safety profile in postmenopausal African American women, which was consistent with findings observed in the entire integrated phase 3 populations.

FR0403

The effect of Raloxifene on Vertebral and Non-vertebral Fracture Risk Is Independent of Baseline FRAX® Probability. John Kanis[1], Helena Johansson[2], Anders Oden[2], Eugene McCloskey*[3]. [1]University of Sheffield, Belgium, [2]WHO Collaborating Centre for Metabolic Bone Diseases, United Kingdom, [3]University of Sheffield, United Kingdom

A major application of FRAX® has been in the clinical assessment of patients, but there is also interest emerging in its application to clinical trials. The Multiple Outcomes of Raloxifene Evaluation (MORE) study, a placebo controlled phase III trial of raloxifene in postmenopausal osteoporosis, showed that both doses tested (60mg and 120mg daily) reduced the risk of vertebral fracture with no significant effect on non-vertebral fractures. The aim of the present study was to evaluate the distribution of fracture risk assessed at baseline using the FRAX® tool in MORE and to determine the efficacy of raloxifene as a function of baseline fracture risk.

The effects of raloxifene (60 and 120 mg daily combined) compared to placebo on the risk of all clinical fractures (including clinical vertebral fractures) as well as the risk of morphometric vertebral fracture were examined as a function of baseline fracture risk. Baseline clinical risk factors and BMD were entered in country specific FRAX® models to compute the 10-year probability of major osteoporotic fractures. No information was available on parental history of hip fracture and this variable was simulated. The interaction between fracture probability and treatment efficacy was examined by Poisson regression.

The mean ± SD 10-year probability of major osteoporotic fractures (with BMD) was 21±11% (range 0.9-77.2%). Treatment with raloxifene was associated with an 18% decrease in all clinical fractures compared to placebo treatment (hazard ratio HR = 0.82; 95% CI = 0.71-0.95; p = 0.0063) and a 42% decrease in incident morphometric vertebral fractures (HR = 0.58; 95% CI = 0.48-0.69; p < 0.001). Efficacy was shown over the whole range of fracture probability and the interaction between fracture probability and treatment was not significant. The efficacy or raloxifene on vertebral fracture risk was significantly greater at lower ages. At the 90th percentile of age (75 years) vertebral fracture risk was reduced by 31% irrespective of FRAX® probabilities. In contrast at younger ages, efficacy was higher and increased further still with decreasing fracture probability.

Raloxifene (60 and 120 mg doses combined) significantly decreased the risk of all clinical fractures and morphometric fractures in women. Overall, there was no significant interaction between efficacy and fracture probability. In the case of morphometric vertebral fractures efficacy decreased significantly with increasing age.

Impact of Comorbidities on Hospitalization Costs Following Hip Fracture. Lucas Nikkel*[1], Christopher Hollenbeak[2], Kevin Black[2], Edward Fox[2]. [1]Pennsylvania State University College of Medicine, USA, [2]Pennsylvania State Hershey Medical Center, USA

INTRODUCTION: Hip fractures are common in elderly populations and have important implications for healthcare costs and health-related quality of life. Patients with hip fractures frequently present with comorbid illnesses. However, little is known about the relationship between comorbid illness and hospital costs or length of stay (LOS) following hip fracture in the United States. We hypothesized that specific individual comorbid illnesses and the presence of multiple comorbid illnesses would be directly related to the cost of hospitalization and the length of stay for older patients following hip fracture.

METHODS: Using ICD-9-CM diagnosis codes, 35,221 patients age 55 or older were identified from the 2007 Nationwide Inpatient Sample (NIS) database with an isolated femoral neck or intertrochanteric fracture. Using generalized linear models, we estimated the impact of comorbidities on hospitalization costs and LOS, controlling for patient, hospital, and procedure characteristics.

RESULTS: Hypertension, deficiency anemias, and fluid and electrolyte disorders were the most common comorbidities. The mean number of comorbidities was 2.9. Only 5.1% of patients presented without comorbidities. The average cost for a hospitalization following hip fracture in our reference patient (no comorbidities, age 55-64, white, female from the Northeast, undergoing open reduction with internal fixation (ORIF) at a medium-sized, non-teaching, urban hospital) was $13,739 (p<0.001). Patients presenting with weight loss or malnutrition had the largest increased hospitalization costs (+$5,928; p<0.001), followed by pulmonary circulation disorders (+$3,444; p<0.001). Most other comorbidities significantly increased the cost of hospitalization. In comparison, partial hip arthroplasty added $2,190 (p<0.001) to the cost relative to ORIF, and total hip arthroplasty added $4,966 (p<0.001). Male and non-white patients also had elevated hospitalization costs. There was a general trend of increasing number of comorbidities associated with increased hospitalization costs and LOS. Comorbidities and patient characteristics that elevated costs also increased the LOS.

CONCLUSIONS: Comorbidities significantly affect the cost of hospitalization and length of stay following hip fracture in older Americans, even while controlling for other variables. These findings have important implications for hospital cost savings through better management of comorbidities in this population.

Physician Notification From Administrative Health Data Is A Cost-Effective Post-Fracture Intervention: Interim Report From A Randomized Controlled Trial. William Leslie*, Patricia Caetano. University of Manitoba, Canada

Post-fracture care is suboptimal and strategies to address this major ''care gap'' are urgently required. Case management is effective but is resource-intensive and difficult to deliver to a widely scattered population. HYPOTHESIS: Post-fracture notification of physicians and/or patients will lead to improved osteoporosis care. METHODS: An RCT (NCT00594789) was conducted across the Province of Manitoba, Canada, in which men and women age 50 or older with recently reported fracture (hip, spine, humerus, and forearm) from medical claims data, and without recent BMD testing

(three years) or osteoporosis therapy (last year), were randomized to three groups: Group 1 received usual care; Group 2 (MDs only) had mailed notification to the reporting and primary care physicians (alert letter, BMD requisition, management flow chart); Group 3 (MDs and patient) had physician notifications and patient notification (alert letter). BMD testing and/or osteoporosis treatment initiation in the next six months was documented from a population-based data repository. RESULTS: During the initial ten months (June 2008 to March 2009), 2,901 fracture patients meeting the inclusion criteria were randomized. Groups were well balanced. Group 1 (usual care) intervention rates were all less than 10%. There was a significant improvement in all outcome measures for groups 2 (MDs only) and 3 (MDs and patient). There was no additional benefit in patient notification in addition to physician notification. The adjusted odds ratio (OR) for treatment initiation in group 2 was 7.2 (95% CI 4.9-10.5) and in group 3 was 8.0 (95% CI 5.4-11.7). In addition to randomized group, factors associated with treatment initiation included age and sex, but not fracture site (Table). Direct costs related to the initiative (programming, case identification, mailings) were $12,379 CDN. The incremental cost per individual started on osteoporosis therapy (net above usual care treatment rates) was $31 CDN. CONCLUSIONS: This post-fracture intervention, based upon medical claims data, provides an easy way to enhance post-fracture care. The approach is scalable, can be delivered to a widely scattered population, and requires minimal infrastructure. This low cost intervention may complement more resource-intensive programs based on case managers.

Effects of the Cathepsin K Inhibitor, ONO-5334, on BMD as Measured by 3D QCT in the Hip and the Spine After 12 Months Treatment. Klaus Engelke*[1], Shinichi Nagase[2], Thomas Fuerst[3], Richard Eastell[4], Harry Genant[5], Maria Small[2], Tomohiro Kuwayama[2], Steve Deacon[2]. [1]University of Erlangen, Germany, [2]ONO PHARMA UK LTD, United Kingdom, [3]Synarc, Inc., USA, [4]University of Sheffield, United Kingdom, [5]UCSF/Synarc, USA

Purpose: To evaluate the efficacy of the Cathepsin K inhibitor, ONO-5334 in a randomized, double-blind, parallel-group study using quantitative computed tomography (QCT).

Methods: 285 post-menopausal female subjects (age: 55-75) with osteoporosis (with no fragility fractures) or osteopenia (with a fragility vertebral fracture) were equally randomized to five study arms: three doses of ONO-5334 (50mg bd, 100 or 300mg qd), placebo (PBO) or Alendronate (ALN, 70mg qw). Calcium and vitamin D were given to all subjects. 3D QCT scans of the spine (L1 and L2) and of the proximal femur were taken at baseline and after 1 year. QCT (exploratory endpoint) analysis was performed for those patients who provided informed consent for this assessment, with MIAF (Medical Image Analysis Framework) in various integral, cortical and trabecular volumes of interest. 188 subjects had baseline and follow-up femur scans, 193 subjects had baseline and follow-up spine scans.

Results: Percentage BMD changes in total vertebral body of L1 plus 2 and total femur after 12 months relative to baseline are shown in the table. In the spine, analysis of mid, superior and inferior sub volumes showed very similar results compared to those for the total vertebral body. Vertebral volume did not change in any treatment. In the femur, results for the neck were very similar to those of the total femur but in the trochanter integral %BMD changes were slightly higher for the ONO-5334 and ALN groups. In all hip regions, trabecular %BMD changes were higher for ONO-5334 50mg, 300mg and ALN groups. Total volume and cortical thickness of the hip did not change significantly in any group.

Conclusions: In the spine ONO-5334 50 mg bd and 300 mg qd demonstrated similar increases from baseline that were consistently superior to 100 mg qd and roughly equivalent to alendronate (ALN). As expected, percentage increases were larger in the integral and trabecular VOIs compared to the cortical VOIs. In the hip the three doses of ONO-5334 showed a similar pattern as in the spine with 50 mg bd and 300 mg qd showing similar increases from baseline that were consistently superior to 100 mg qd. Compared to ALN, ONO-5334 showed nearly equivalent increases in integral BMD and numerically superior increases in trabecular BMD in the femur. Cortical increases were similar between ONO-5334 and ALN.

Hip QCT Results From the FREEDOM Trial: Evidence for Positive BMD/ BMC Changes in Integral, Trabecular, and Cortical Bone With Denosumab. Harry Genant*[1], Klaus Engelke[2], Jose Ruben Zanchetta[3], Arne Hoiseth[4], Chui Kin Yuen[5], Sigitas Stonkus[6], Michael Bolognese[7], Edward Franek[8], Thomas Fuerst[9], Hoi-Shen Radcliffe[10], Cesar Libanati[11], Michael McClung[12]. [1]UCSF/Synarc, USA, [2]Synarc, Germany, [3]Instituto de Investigaciones Metabolicas (IDIM), Argentina, [4]Curato Røntgen, Norway, [5]Manitoba Clinic, Canada, [6]Kaunas University of Medicine, Lithuania, [7]Bethesda Health Research, USA, [8]Central Clinical Hospital MSWiA, Poland, [9]Synarc, Inc., USA, [10]Amgen Inc, United Kingdom, [11]Amgen Inc, USA, [12]Oregon Osteoporosis Center, USA

Denosumab, a fully human monoclonal antibody to RANKL, decreased bone resorption, increased bone mineral density (BMD), and reduced vertebral, nonvertebral, and hip fractures in postmenopausal women with osteoporosis in the FREEDOM trial (Cummings SR et al., NEJM, 2009:361:756). In FREEDOM, subjects received 60 mg denosumab or placebo every 6 months for 3 years; all subjects received daily supplements of calcium and vitamin D. Hip QCT scans were obtained at baseline and at months 12, 24, and 36, in a subset of women and were analyzed using Medical Image Analysis Framework (MIAF) software (University of Erlangen, Germany), in a blinded-to-treatment manner. MIAF allows the determination of integral, trabecular, subcortical, and cortical BMD for the hip (proximal femur) as well as various sub-regions with precision errors of 1.5% to 2.5%. These analyses enable thorough evaluations of compartmental changes which may have different relevance to bone strength. This exploratory analysis evaluated the magnitude of changes from baseline and from placebo in denosumab-treated subjects with hip QCT at baseline and month 36 who completed 36 months of treatment (denosumab n=45; placebo n=36). Data from month 36 were excluded for 19 subjects due to CT scanner malfunction at 1 site. Baseline mean age was 74 years, mean years since menopause was 25, and mean aBMD T-score of the total hip was –1.85 for all subjects. Denosumab resulted in significant improvements in vBMD and bone mineral content (BMC) from baseline by 12 months. Over 36 months, the improvements from baseline in integral hip BMD reached 6.3% and 4.8% for BMC (both $p<0.0001$). These gains were accounted for by significant and consistent increases in cortical, subcortical, and trabecular BMD and BMC (Table). In the placebo group, integral hip BMD and BMC decreased at 36 months from baseline by –1.4% and –2.8%, respectively (both $p\leq0.0231$), mainly attributable to losses in both the subcortical and trabecular compartments. The differences between denosumab and placebo were highly significant ($p\leq0.0008$) at 12, 24, and 36 months for integral, cortical, and trabecular BMD and BMC, except for cortical BMD at 12 months ($p=0.0661$). In summary, denosumab results in significant improvements in both vBMD and BMC from baseline and placebo across integral, cortical, subcortical, and trabecular hip compartments. These changes support the clinical effect of denosumab to reduce hip fractures as observed in the FREEDOM trial.

Table. Mean Percent Change and 95% CI from Baseline

		Bone Mineral Content			Bone Mineral Density		
		Month 12	Month 24	Month 36	Month 12	Month 24	Month 36

[1]Hospital Clinic Barcelona, Spain, [2]Hospital Clinic of Barcelona, Spain, [3]Department of Radiology. Hospital Clinic, Spain, [4]Hospital Clinic, Spain, [5]Department of Rheumatology. Hospital Clinic Barcelona, Spain, [6]Department of Radiology. Hospital Clínic Barcelona, Spain, [7]Universitat De Barcelona, Spain

The aim of the study was to compare the effects of vertebroplasty vs conservative approach in the quality of life and pain of patients with painful osteoporotic vertebral fractures, as well as to analyze the secondary adverse effects and the development of new fractures in both treatment groups during a 12-months follow-up period.

Methods: Randomized, controlled trial of subjects with acute painful osteoporotic vertebral fractures (less than 12 months duration and unhealed, as confirmed by magnetic resonance imaging [MR]). At baseline, complete anamnesis and evaluation of quality of life (by Qualeffo-41questionnaire) and pain (by VAS measurement) were performed as well as MR of whole column and dorsolumbar X-rays. Outcomes, secondary effects and complications were assessed at 2 weeks and at 2, 6 and 12 months. X-rays were performed at baseline and at 12 months and also when symptoms suggested a new vertebral fracture or when a significat height loss was observed (>2 cm).

Results: A total of 121 patients were enrolled, and 77 (37 of 59 in the vertebroplasty group and 40 of 62 in the placebo group) completed the 12-month follow-up. The baseline clinical characteristics of the participants were similar in both groups. There was a significant improvement in overall pain and quality of life in both study groups at each follow-up assessment. When compared with conventional therapy the improvement in VAS was greater in patients treated with vertebroplasty at 2 (p=0.026) and at 12 months (p=0.045). Similar improvements were seen in both groups of patients with respect to quality of life measurements. Patients treated with vertebroplasty presented a higher incidence of vertebral fractures than those with conservative approach (20.3% vs 4.8%, p=0.0087).

Conclusions: Vertebroplasty and conservative treatment are both associated with a significant improvement in pain and quality of life in patients with painful osteoporotic vertebral fractures throughout a one-year follow-up period. Patients treated with vertebroplasty showed greater pain relief at 2 and 12 months after treatment, although this procedure was associated with a significant increase in the incidence of vertebral fractures.

Alfacalcidol Improves Muscle Power, Muscle Function and Balance in Elderly Patients with Reduced Bone Mass. Erich Schacht[1], Johann Diederich Ringe*[2]. [1]ZORG (Zurich Osteoporosis Research Group), Switzerland, [2]Medical Clinic 4, Klinikum Leverkusen (University of Cologne), Germany

Objective: In an open, multi-center, uncontrolled, prospective study on a cohort of patients with reduced bone mass, we investigated the effect of daily therapy with 1 mcg alfacalcidol* on muscle power, muscle function and balance performance.

Subjects and methods: Out of the 2097 participants, who were recruited for this study in Germany, 87.1% were postmenopausal women and 12.9% were men. The patients had a mean age of 74.8 years and a mean BMI of 26.3 kg/m^2. Out of the total number of patients, 75.3% had osteoporosis (87.1% in women), 81% had a diagnosis of ''increased risk of falls'' and 70.1% had a creatinine clearance (CrCl) of < 65ml/min. At onset and after 3 and 6 months participants underwent muscle function and muscle power tests: the Timed-Up and Go Test (TUG) and the Chair Rising Test (CRT), as well as a balance test: the Tandem Gait Test (TGT), the latter performed only at baseline and at 6 months.

Successful performance in these tests is associated with a significantly lower risk for falls and non-vertebral fractures in elderly patients (successful test performance: TUG ≤ 10 sec., CRT ≤ 10 sec., TGT ≥ 8 steps)♂.

Results: After 3 months of treatment with alfacalcidol, participants already showed a statistically significant improvement in the performance of the two muscle tests. This effect (n =1970 for TUG; n = 1857 for CRT) had further increased by the end of the therapy period. We observed a significant increase in the number of participants able to successfully perform the different tests: 24.6% at baseline and 46.3 % at the end for the TUG (p< 0.0001) and 21.7% at baseline and 44.2% at the end for the CRT (p=0.0001). After treatment, the mean time used for the TUG was decreased by 3.0 sec (17.0 sec at the onset) and by 3.1 sec (16.5 sec at the onset) for the CRT.

At the end of the observation time the percentage of participants (n=1933) able to perform the balance test (8 steps in the TGT) increased from 36.0% to 58.6% (p<0.0001).

No cases of hypercalcemia were registered.

Conclusion: We conclude that treatment with alfacalcidol increases muscle power, muscle function and balance. The significant improvement in the risk tests for falls TUG, CRT and TGT may have a preventative effect on falls and fractures. We suggest that the quantitative risk tests used in this study are reliable surrogate parameters for the risk of falls and fractures in elderly patients.

Efficacy of Rapid Oral Replacement of Vitamin D: 300,000 IU and 150,000 for Severe and Moderate Deficiency. Muhammad Javaid*[1], Kerri Rance[2], Vicki Toghill[2], William Fraser[3], John Wass[4]. [1]University of Oxford, United Kingdom, [2]Nuffield Orthopaedic Centre, United Kingdom, [3]Royal Liverpool University Hospital, United Kingdom, [4]Holmby House, United Kingdom

Purpose: Vitamin D deficiency is a risk factor for falls and fracture. While in clinical trials, daily calcium and vitamin D replacement is effective in normalizing the vitamin D levels, adherence to daily preparations is very poor and unlikely to be effective. Whilst higher dose replacement regimens have been tested, the sample sizes are typically small. We therefore audited the effectiveness of rapid oral replacement of vitamin D in a pragmatic clinical setting.

Methods: Patients referred to secondary care metabolic bone unit for assessment and treatment of osteoporosis have a baseline serum level of 25(OH)D measured using HPLC with MS. Patients were loaded with either 300,000 IU (50,000 IU D3 daily for 6 days) if severe deficiency (25(OH)D less than 25 nM) and 150,000 IU (50,000 IU D3 daily for 3 days) if moderate deficiency 25(OH) D between 25 and 50 nM). We used 50,000 IU cholecalciferol capsules (Biotech). Patients were contacted by letter if they required treatment and invited to collect their prescription from the hospital pharmacy or have the supplement posted to their house. We also asked patients to have a serum calcium and in a subset a serum 25(OH)D measured between 2 and 4 weeks after the loading dose. We defined biochemical repletion as more than 50 nM 25(OH)D and hypercalcaemia as a albumin adjusted serum calcium of greater than 2.65 mM.

Results: Between August and December 2009, 201 patients identified as requiring vitamin D supplementation, collected the supplement and had a recorded measured at 2- 4 weeks. Of those with severe deficiency, 92% had biochemical repletion afterwards and of those with moderate deficiency 97% were replete (Figure). No patient had post loading concentrations of more than 250 nM. Using a higher threshold of repletion (> 75nM), only 14% of severe deficient (after 300,000 iu loading) and 32% of moderate deficient (after 150,000 IU) achieved this level. We could not exclude an effect of season or adherence to therapy. Of those with hypercalcaemia, one had pre-existing primary hyperparathyroidism and the other was established on daily teriparatide. In both the hypercalcaemia was asymptomatic. No patient contacted the helpline with side-effects, however these were not systematically assessed.

Conclusion: In patients with osteoporosis and vitamin D deficiency, oral loading of cholecalciferol was effective at achieving repletion using a threshold of 50 nM but not 75 nM. Further studies demonstrating the target level in patients with osteoporosis and the clinical rather than biochemical effectiveness of high dose replacement are urgently required.

A Catechol-derivative Inhibits Tph1 Synthesis and Cures Osteoporosis in Ovariectomized Mice. Vijay Yadav*, Yuli Xie, Gerard Karsenty, Patricia Ducy. Columbia University, USA

Tryptophan hydroxylase 1 (Tph1) catalyzes the rate-limiting step in the biosynthesis of gut-derived serotonin, a molecule that affects a variety of physiological processes. Recently it was demonstrated that gut-derived serotonin negatively regulates osteoblasts proliferation and bone formation. Here we report the identification of a novel catechol-derivative, Catechol-3,6-bismethyleneiminodiacetic acid (CBMIDA) as a Tph1 inhibitor that can selectively reduce serotonin levels in the serum after oral administration without any significant effect on brain serotonin content. Furthermore, oral administration of this small molecule once daily for up to 6 weeks prevents the development of and fully rescues, in a dose-dependent manner, osteoporosis in ovariectomized mice because of an isolated increase in bone formation. These molecules add to the emerging class of Tph1 inhibitors that have the potential to become novel anabolic treatments for low bone mass diseases such as osteoporosis.

Decreased Oxidative Stress and Greater Bone Anabolism in the Aged, as Compared to the Young, Murine Skeleton by Parathyroid Hormone. Robert Jilka*, Maria Jose Almeida, Elena Ambrogini, Li Han, Paula Roberson, Robert Weinstein, Stavros Manolagas. University of Arkansas for Medical Sciences, USA

Intermittent administration of PTH is an effective anabolic therapy in the elderly but the underlying mechanisms are poorly understood. Studies in mice have revealed that age-related bone loss is associated with increased levels of reactive oxygen species (ROS) and phosphorylated $p66^{Shc}$ (an amplifier of oxidative stress), decreased glutathione, and decreased Wnt signaling, osteoblast survival and bone formation rate (BFR). The reduction in Wnt signaling is due to activation of FoxO transcription factors by ROS, resulting in diversion of β-catenin from Tcf- to FoxO-mediated transcription; and to activation of PPARγ by oxidized lipids produced by Alox15, leading to proteasomal degradation of β-catenin. Increased expression of Alox15 also contributes to oxidative stress by producing the pro-oxidant 4-hydroxynonenal. Based on these advances, we investigated whether PTH antagonizes the cellular and molecular mechanisms leading to age-related bone loss. Daily injections of 100 ng/g of PTH(1-34) produced a greater increase in vertebral trabecular bone mineral density and cancellous bone volume, and a greater expansion of the endocortical bone surface in the femur, in 26 as compared to 6 month old female C57BL/6 mice. PTH increased trabecular connectivity in vertebrae and the toughness of both vertebrae and femora in old, but not young, mice; and increased BFR and reduced osteoblast apoptosis to a greater extent in old mice. Most strikingly, PTH reduced ROS, phosphorylated $p66^{Shc}$ and Alox15, and increased glutathione, in bone of old mice. PTH also increased Wnt signaling in old mice as indicated by the expression of 8 Wnt target genes. Moreover, PTH attenuated the H_2O_2-induced increase in ROS, phosphorylated $p66^{Shc}$, as well as H2O2-induced suppression of Wnt signaling in cultured osteoblastic cells; and increased expression of the anti-oxidant enzyme aldehyde dehydrogenase 3a1 by 10-fold in vitro and in vivo. These findings suggest that PTH-stimulated Wnt signaling is augmented in aged mice by the ability of the hormone to attenuate pathways that would otherwise reduce β-catenin, i.e. activation of FoxOs by ROS, and activation of PPARγ by oxidized lipids. We propose that the increased efficacy of intermittent PTH in the aged skeleton is due to a novel anti-oxidant effect that increases osteoblast survival and enhances the ability of the hormone to stimulate Wnt signaling. Thus, PTH represents a mechanistically rational therapy for osteoporosis in the elderly.

FR0425

Sclerostin Antibody Treatment Enhances Fracture Healing and Increases Bone Mass and Strength in Non-fractured Bones in an Adult Rat Closed Femoral Fracture Model. CY Li*, HL Tan, M Barrero, E Lee, FJ Asuncion, MS Ominsky, HZ Ke. Amgen Inc, USA

Inhibition of sclerostin with a sclerostin antibody (Scl-Ab) significantly increased bone formation, resulting in increased bone mass and bone strength in animal models of osteoporosis. Bone formation also plays an important role in fracture healing, and Scl-Ab was shown to increase bone mass and bone strength in the fractured bones of adolescent mice, rats, and monkeys. In this study, we further examined the effect of Scl-Ab on fracture healing in skeletally mature rats.

Seven to 7.5-month-old male SD rats underwent a standard closed femoral mid-diaphyseal fracture stabilized with an intramedullary pin. Animals were subcutaneously injected with saline (Veh, n=18) or Scl-Ab at 25 mg/kg (n=14), twice per week for 7 weeks. Both fractured and intact contralateral femurs were collected for densitometry (DXA and micro-CT) and bone strength testing (3-point bending) at the end of the study.

In the central 30% of the fractured femurs, Scl-Ab significantly increased DXA BMD and BMC by 11% and 19%, respectively, compared with Veh (both $p<0.05$). The fracture callus was isolated from the original cortex by micro-CT, and a 1mm region at the fracture line was analyzed. Scl-Ab significantly increased callus region area (+16%), callus vBMC (+26%), and callus bone volume/total volume (+41%) compared with Veh (all $p<0.05$). The Scl-Ab-mediated increase in bone mass at the fracture site was associated with increased bone strength, as demonstrated by a 76% increase in peak load and a 125% increase in stiffness compared with Veh (both $p<0.05$).

Scl-Ab also increased bone mass in the intact contralateral femur, as demonstrated by significant increases in micro-CT vBMC at the cortical diaphysis (+10%) and the trabecular region of the distal metaphysis (+39%) compared with Veh (both $p<0.05$). The increase in diaphyseal vBMC with Scl-Ab was associated with a significant increase (+17%) in peak load in the contralateral femurs compared with Veh ($p<0.05$).

In summary, systemic administration of a sclerostin antibody improved bone mass and bone strength in the fractured and intact long bones of skeletally mature rats. These results support the potential use of sclerostin antibody as a therapeutic to enhance fracture healing in adults.

FR0427

The Osteoanabolic Effect of Systemic Dkk1 Inhibition is Associated with Canonical Lrp5/6 and Erk Signaling in Bone and is Modulated by N-cadherin in Osteoblasts. Valerie Salazar*[1], Jin Norris[2], Lisa Huang[2], Gabriel Mbalaviele[2], Roberto Civitelli[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

Neutralizing antibody to Dkk1, a natural antagonist to Lrp5/6, increases bone mass. We previously reported that mice lacking the *N-cadherin* gene specifically in osteoblasts (*$Cdh2^{flox/flox}$; Col1α1Cre*) require 4-fold less Dkk1 neutralizing antibody (αDkk1) to generate a bone anabolic response (5mg/kg compared to 20mg/kg for *wild type* controls). To understand the mechanism of enhanced sensitivity in *$Cdh2^{flox/flox}$; Col1α1Cre* (*Ncad cKO*) mice, we investigated the molecular mechanism of action of αDkk1. Western blot analysis on protein from tibias of *wild type* (*WT*) mice indicates that a bone anabolic dose of αDkk1 (20mg/kg) stimulates phospho-inhibition of GSK3β, accumulation of β-catenin, and phospho-activation of Jnk. Thus, systemic inhibition of Dkk1 leads to rapid activation of canonical Lrp5/6 signaling in bone. In *WT* mice, this signal cascade peaks 30 minutes post-injection, returns to baseline at 60 min, and is reactivated at 2 hrs. By contrast, accumulation of β-catenin is sustained in tibias from *Ncad cKOs*, and only 5mg/kg αDkk1 is required for Lrp5/6 pathway activation. Thus, osteoblast N-cadherin antagonizes activation of, and prevents prolonged signaling through, the Lrp5/6 pathway in bone. This may be partially explained by increased mRNA expression of *Lrp5* in *Ncad cKO* mice. *Dkk1*, *SOST*, and *β-catenin* mRNA are unchanged. Systemic inhibition of Dkk1 also regulates Erk1/2 in bone. In *WT* tibias, a sub-anabolic dose of αDkk1 (5mg/kg) is sufficient to stimulate Erk1/2, which peaks at 45 min and returns to baseline by 2 hrs. By contrast, Erk1/2 phosphorylation cycles are weaker and more rapid in *Ncad cKOs*, yielding 2 distinct peaks in 2 hrs. Thus, N-cadherin promotes high and sustained levels of Erk1/2 activity in bone. Moreover, the strength and kinetics of Erk1/2 activity in *WT* mice following an anabolic dose of αDkk1 (20mg/kg) more closely

resemble that of *Ncad cKOs*. Hence, Dkk1 inhibition generates dose-dependent Erk1/2 activity profiles in bone that are sensitive to expression of N-cadherin in osteoblasts. In summary, accrual of bone mass in response to systemic inhibition of Dkk1 is accompanied by bone-specific signaling through canonical components of the Lrp5/6 pathway and Erk1/2. Removing *Cdh2* selectively in osteoblasts modulates local signaling through Lrp5/6 and Erk1/2, resulting in enhanced sensitivity to the osteoanabolic effect of Dkk1 inhibition.

FR0430

Prolonged Bisphosphonate Release after Treatment in Women with Osteoporosis. Relationship with Bone Turnover. Pilar Peris*[1], Merce Torra[2], Ana Monegal[2], Varinia Olivares[3], Raquel Reyes[3], Angels Martinez-Ferrer[2], Nuria Guanabens[4]. [1]Hospital Clinic of Barcelona, Spain, [2]Hospital Clinic Barcelona, Spain, [3]Hospital Clinic, Spain, [4]Universitat De Barcelona, Spain

Bisphosphonates (BP), especially alendronate and risedronate, are the most commonly used drugs for osteoporosis treatment. These compounds are incorporated into the skeleton, where they inhibit bone resorption. Thereafter BP are slowly released during bone turnover. However, at present, there are few data on the release of BP in patients who have received treatment with these drugs for osteoporosis. This information is essential for evaluating the possibility of BP cyclic therapy in these patients and for controlling their long-term presence in bone tissue. Therefore, the aim of the study was to evaluate the urinary excretion of alendronate and risedronate in patients who have been treated with these drugs for osteoporosis and to analyze its relationship with bone turnover, time of previous drug exposure and time of treatment discontinuation.

Methods: we included 43 women (aged 65±9 years) who had been previously treated with alendronate (n=36) or risedronate (n=7) for osteoporosis and had not been treated with other antiosteoporotic treatment prior to the analysis. Both BP were detected in 24-hour urine by HPLC. Weight, height, length of treatment, time of treatment cessation and renal function were recorded in all patients. In addition, coincident with BP determination, bone formation (PINP) and bone resorption (NTX) markers were analyzed. Both BP were also determined in urine in a control group of 7 women during alendronate or risedronate treatment.

Results: Alendronate was detected in 41 % of women who had been previously treated with this drug whereas no patient previously treated with risedronate showed urinary detectable values of this BP. All control group patients showed detectable values of both types of BP. In patients with detectable alendronate levels the time of drug cessation was shorter than in patients with undetectable values of this BP (11.8±3.8 vs 30.7±19.9 months, $p<0.001$). No patient with more than 19 months from cessation of alendronate treatment showed detectable values of the drug. Alendronate levels were inversely related to time of treatment discontinuation ($r=-0.403$, $p=0.01$) and the latter was directly related to the bone resorption marker NTX ($r=0.394$, $p=0.02$). No relationship was observed with age, length of drug exposure, renal function or weight.

Conclusions: Contrary to risedronate, which was not detected in patients after cessation of treatment, alendronate was frequently detected in women previously treated with this agent up to 19 months after discontinuation of therapy. The relationship between alendronate levels and both bone resorption and time of treatment cessation further indicates a residual effect of this drug in bone despite treatment discontinuation.

Skeletal Uptake and Desorption of Fluorescently Labeled Bisphosphonate is Anatomic Site-Dependent. Demin Wen[1], Liu Qing[2], Gerald Harrison[1], Ellis Golub[3], Sunday Akintoye*[1]. [1]University of Pennsylvania, USA, [2]The Fourth Military Medical University, China, [3]University of Pennsylvania School of Dental Medicine, USA

Objectives. Bisphosphonates commonly used to treat osteoporosis, Paget's disease, multiple myeloma and hypercalcemia of malignancy have been associated with bisphosphonate-associated jaw osteonecrosis (BJON). A potential etiological factor is disproportionate concentration of bisphosphonate in the jaws; but it is unclear if regional biodistribution and bioavailability of bisphosphonates is site-dependent. Using a rat model, we tested the hypothesis that skeletal uptake and release of pamidronate (a nitrogen-containing bisphosphonate) is anatomic site-dependent.

Methods. Four female nude rats received tail vein injection of 80 nmol/kg body weight of fluorescently-tagged pamidronate (OsteoSense^{TM}680) followed by optical imaging after 24 hours. On sacrifice, individual bone parts were recovered and re-scanned using similar *in vivo* imaging parameters. Bound bisphosphonate in bone parts was desorbed using sequential EDTA decalcification. Bisphosphonate signal intensity per unit area normalized to adjacent background intensity was expressed as relative fluorescence units (RFU) after defining specific regions of interest (ROI) correlating with bone sections subjected to bisphosphonate desorption. Recovered labeled bisphosphonate was measured with a fluorometer while calcium released in solution was measured with a flame atomic absorption spectrophotometer. Mean site-specific RFU was correlated with bisphosphonate and calcium amounts from corresponding bone sections. Skeletal site differences of ROIs were analyzed and compared based on oral, axial and appendicular regions. Data expressed as mean ± standard deviation was analyzed by one-way ANOVA followed by Dunn-Sidak post hoc multiple comparisons with statistical significance set at $p < 0.05$.

Results. Bisphosphonate signal intensity was similar in oral and appendicular bones but lower in axial bones. However, liberation of hydroxyapatite-bound bisphosphonate following sequential EDTA decalcification resulted in significantly higher bisphosphonate release from oral bones relative to axial and appendicular sites ($p < 0.05$).

Conclusions. This study demonstrated regional site-disparity in rat skeletal uptake and release of bisphosphonate in oral, axial and appendicular bones that suggest possible preferential bisphosphonate uptake in the jaw bone. (Work supported by NIH/NIAMS research grant AR050950, University of Pennsylvania Research Foundation and USPHS/NIH/NCI grant 5K08CA120875-03).

FR0432

Insulin like Growth Factor and Bone Mass is Influenced by Higher Protein Intake During One Year of Caloric Restriction. Deeptha Sukumar*[1], Hasina Ambia- Sobhan[1], Robert Zurfluh[1], Theodore Stahl[2], Sue Shapses[1]. [1]Nutritional Sciences, Rutgers University, USA, [2]Department of Radiology, University of Medicine & Dentistry/Robert Wood Johnson Medical School, USA

Weight (wt) reduction induces bone loss by several factors including reduced Ca absorption and serum insulin-like growth factor-1 (IGF-1). The role of high protein (HP) diets on bone is controversial; the negative effects mediated by higher urinary Ca excretion and acid load, and positive effects by increasing serum IGF-1 and Ca absorption. Previous studies examining the effect of protein intake on bone during wt loss have not controlled for Ca intake (diets either being deficient or excessive in Ca intake). Our goal was to examine how bone responds to caloric restriction during a 1 year randomized trial using 2 levels of protein intake with controlled Ca intake of 1.2 g/day. We screened 182 women (2006-2009) and after drop-outs/exclusion, 47 (58.0 ± 4.4 years; body mass index of 31.4 ± 4.6 kg/m^2) were allocated to either a normal (NP, 18%, n = 21) or higher (HP, 30%, n = 26) protein and a lower fat intake (28%). We measured bone mineral density and content (BMD, BMC), fat and lean mass using dual energy x-ray absorptiometry and serum and urine were analyzed for bone regulating hormones and turnover markers. After 1 year, subjects lost 6.4 ± 4.7 % of body wt, 11.8% of fat mass and 2.8 % of lean mass with no differences between the groups. Protein intake was 18% (60 g/d) and 24% (86 g/d) of total calories in the NP and HP groups, respectively. Intake of Ca, vitamin D and other nutrients were not significantly different between the groups. Repeated measures ANOVA using diet (HP and NP) and time (0, 6 and 12 months) showed a significant interaction resulting in greater loss of BMD at ultra distal radius, lumbar spine and hip in the NP compared to HP diet. There was also a greater increase in bone resorption (deoxypyridinoline) in the NP than HP group ($p < 0.05$; trend for PYD). The HP diet resulted in greater increases in IGF-1 and its binding protein (IGFBP-3) ($p < 0.05$), and tended to increase estradiol ($p=0.06$) more than the NP group. Interestingly, caloric restriction (in both groups) reduced serum parathyroid hormone ($p < 0.05$), increased 25-hydroxy-vitamin D by 2.6 ± 5.2 ng/mL ($p<0.001$) and pyridinoline crosslinks (PYD) ($p<0.02$). These data show that the positive effect of dietary protein on bone is not due to higher Ca intake. In summary, a higher dietary protein- calorie restricted diet that increases serum IGF-1 and IGFBP-3 may be responsible for attenuating bone loss at certain sites in postmenopausal women.

FR0435

A Multi-Modality Imaging Comparison of Odanacatib to Alendronate in the Ovariectomized Rhesus Monkey. Paul McCracken*[1], Richa Jayakar[2], Mona Purcell[1], Parker Mathers[1], Alan Savitz[1], John Szumiloski[1], Jacquelynn Cook[1], Bernie Dardzinski[2], Thomas Hangartner[3], Sherri Motzel[1], Richard Hargreaves[1], Jeffrey Evelhoch[1], Le Thi Duong[1], Donald Williams[1]. [1]Merck Research Laboratories, USA, [2]Merck & Co., Inc., USA, [3]Wright State University, USA

The aim of this study was to evaluate efficacy of the Cathepsin K inhibitor, odanacatib (ODN), and compare to alendronate (ALN) in the estrogen-deficient model of the ovariectomized (OVX) rhesus monkey by multiple imaging modalities. Macro- and micro-architectural imaging markers relevant to bone strength were measured at multiple anatomic locations at baseline, 3, 6, 9, 12, and 18 months of treatment in OVX-monkeys (16/group, age 10-22 yrs) treated with either vehicle (VEH), ODN (2 mg/kg/d) or ALN (30 ug/kg/week) for 20-months. BMD, cortical and cancellous parameters were interrogated in the ultradistal radius, ultradistal tibia, distal radius and distal tibia by hr-pQCT (XtremeCT, Scanco Medical), similar regions by MRI (Siemens TIM Trio), lumbar vertebrae and proximal femur by quantitative CT (GE-DST), and in standard locations by DXA (GE Lunar iDXA). QCT analysis was done using QCTPro (Mindways Software, Inc.), modified for non-human primate analysis. QCT trabecular vBMD of the spine increased by 11% and 9.9% for ODN and ALN, respectively, by 18 months of therapy and were significantly ($p<0.001$) higher than VEH. QCT integral vBMD taken from a 1.5mm region in the

femoral neck increased by 11% for ODN and 6.8% for ALN, where ODN was significantly higher than ALN (p=0.028) and VEH (p<0.001). VBMD by hr-pQCT (D100) in the ultradistal radius and ultradistal tibia increased by 13.9% and 12.7% respectively for ODN and 2% and 8.2% for ALN, where ODN was significantly higher than ALN (R p<0.001, T p<0.001) and VEH (R p<0.001, T p=0.031). Cortical thickness by hr-pQCT in the ultradistal radius and ultradistal tibia increased by 25.1% and 17%, respectively, for ODN and 1% and 8.2% for ALN, where ODN was significantly higher than ALN (p<0.001, p=0.003) and VEH (p<0.001, p=0.012). Cortical thickness by hr-pQCT in the distal radius and distal tibia increased by 6.7% and 5.6%, respectively, for ODN and 2.9% and 2.4% for ALN, where ODN was significantly higher than ALN (p=0.039, p=0.014) and VEH (p=0.001, p=0.030). In summary, in-vivo imaging markers have demonstrated the positive therapeutic effects of ODN and differentiated ODN from ALN on vBMD in the hip, radius and tibia, and cortical thickness in the radius and tibia of OVX rhesus monkeys. The translational application of imaging parameters relevant to fracture risk at multiple skeletal sites will be evaluated in odanacatib clinical trials.

FR0438

Efficacy of ONO-5334, a Cathepsin K Inhibitor, on Bone Mass and Strength in Ovariectomized Cynomolgus Monkeys. Hiroyuki Yamada*, Hiroshi Mori, Akiko Kunishige, Satoshi Nishikawa, Yasuaki Hashimoto, Makoto Tanaka, Tsutomu Shiroya. ONO Pharmaceutical Co., Ltd., Japan

ONO-5334 is a small molecule and an orally-active inhibitor of cathepsin K, which plays an important role in osteoclast-mediated bone resorption. We have previously reported that ONO-5334 increased lumbar areal BMD (L3-5) compared with ovariectomized (OVX) control in cynomolgus monkey 1). Therefore, we evaluated the efficacy of ONO-5334 on integral, trabecular and cortical BMC, separately, and bone strength in the lumbar vertebra in this study.

Female cynomolgus monkeys were assigned to one of the following 6 groups (20 per group): sham operated, OVX control treated with vehicle, ONO-5334 1.2, 6 or 30 mg/kg, or alendronate (ALN) 0.05 mg/kg. ONO-5334 was administered orally once daily from the day following OVX surgery for 16 months. ALN was administered intravenously once every 2 weeks. After necropsy, bone mass (volumetric BMC) and strength (maximum load) at the 4th lumbar were measured by pQCT and compression test, respectively.

OVX caused a significant decrease in cortical vBMC (p<0.05 vs sham). ONO-5334 at 6 and 30 mg/kg significantly increased integral and cortical vBMC (both p<0.05 vs OVX) and increased trabecular vBMC to sham level. ALN tended to increase cortical vBMC. Maximum load and ultimate strength (maximum load divided by cross sectional area) tended to decrease due to OVX and significantly increased by ONO-5334 at 6 and 30 mg/kg (both parameters p<0.01 vs OVX). ALN tended to increase ultimate strength. Maximum load was significantly correlated with integral vBMC in OVX + ONO-5334 groups (r=0.80, p<0.0001).

These results suggest that ONO-5334 increases bone mass by affecting cortical bone as well as trabecular bone in the lumbar vertebra. In addition, ONO-5334 has a positive effect on bone strength. A good linear relationship between bone mass and strength was confirmed, and suggests that the increase in bone mass with ONO-5334 treatment corresponds to a parallel increase in bone strength.

N-Butyryl Glucosamine (GlcNBu) Preserves Bone in the Ovariectomised Rat Model: Possible Mechanism through Serotonin Reuptake Inhibition. Karen Rees_Milton*[1], Marc Grynpas[2], Tassos Anastassiades[3]. [1]Dept of Medicine, Queen's University, Canada, [2]Samuel Lunenfeld Research Institute, Canada, [3]Queen's University, Canada

Purpose: Studies in bone homeostasis in post-menopausal OP have emphasized primarily osteoclastic rather than osteoblastic (OB) regulation. We have been using a model of post-menopausal OP, the ovariectomised (Ovx) rat, for pre-clinical studies of N-butyryl glucosamine (GlcNBu), as an agent for preventing OP in this model. We had reported that secreted phosphoprotein 24 (spp24) was significantly up-regulated in the livers of the Ovx rats, suggesting an indirect protective effect of GlcNBu on the bone through the liver. Here we report on a possible direct mechanism of action of GlcNBu at the OB level, through serotonin (SR or 5-hydroxytryptamine, 5HT) reuptake inhibition (SSRI). The skeletal effects of SSRIs are uncertain but functional 5HT and 5HTT (5HT transporter) receptors in bone cells have been identified.

Methods: The groups of mature female rats were: Glucose (Glc)-fed, non-OVX (control); GlcNBu-fed, non-OVX; Glc-fed, OVX; GlcNBu-fed, OVX. At 6 months, animals were euthanized and the bones evaluated for bio-mechanical properties and bone mineral densities (BMD). We quantified spp24 in the sera by immunoassay, utilizing chitosan coated plates, permitting preliminary isolation of the spp24 (Anal. Biochem. (2010) 396(2):310-2). The proliferation of the OB cell line, UMR-106, in the presence and absence of SR and the SSRI fluoxetine hydrochloride was studied, using the quantitative Perkin Elmer ATPlite chemiluminescence assay.

Results: Ovariectomy resulted in lower femoral and spinal BMDs. GlcNBu-fed OVX rats demonstrated maintenance of femoral head, total femur and spine BMDs. Orally administered GlcNBu, preserved bone biomechanical properties in the OVX rat. There was a strong positive correlation between serum spp24 and IGF-1 concentrations. Experiments with UMR-106 indicate that OB proliferation and alkaline phosphatase activity is suppressed by SR, and more so by the SSRI, fluoxetine hydrochloride, in a dose-dependent fashion. Pre-incubating the UMR-106 cells with GlcNBu significantly reverses the SSRI-dependent inhibition, but less so SR-dependent inhibition.

Conclusions: 1. Orally administered GlcNBu, preserves BMD and bone biomechanical properties in the OVX rat. 2. At the OB level, GlcNBu may be acting through the re-uptake mechanism of SR. 3. At the level of the liver, GlcNBu's protective effect on bone may be indirectly mediated by spp24, possibly through IGF-1.

Quantitative Computed Tomography Based Finite Element Analysis to Estimate *In-Vivo* Bone Strength of Proximal Femur in Odanacatib Treated Rhesus Monkeys. Antonio Cabal*[1], Seetha Ramudu Kummari[2], Stephen Krause[1], Mona Purcell[1], Paul McCracken[3], Le Thi Duong[3], Bernard Dardzinski[1], Sherri Motzel[1], Donald Williams[1]. [1]Merck & Co., Inc., USA, [2]Case Western Reserve University, USA, [3]Merck Research Laboratories, USA

Preclinical evaluation of disease burden and treatment efficacy is critical to the development of new therapies for osteoporosis. Clinically translatable imaging modalities beyond DXA, such as quantitative computed tomography (QCT) has the potential to estimate bone strength *in-vivo* using image-based finite element analysis (FEA). The effects of Cathepsin K inhibitor, odanacatib (ODN), on *in-vivo* estimates of bone strength in the proximal femur was quantified using QCT (GE Healthcare) of the hip based fall loading configuration FEA in the estrogen-deficiency induced osteopenia of the ovariectomized (OVX) rhesus monkey. QCT data were obtained for three OVX groups of monkeys treated with vehicle (VEH), 2 mg/kg ODN (daily oral), and alendronate (ALN, subcutaneous 15 ug/kg twice weekly; n=16/group, age 11-18 years at study start). ODN was dosed with a novel VEH (different from our previous monkey study) which significantly improved bioavailability of ODN to approximately 13 uM per 24 hours. Longitudinal QCT measurements were made at 0, 12, and 18 months post-treatment, with the treatment starting within 10 days of OVX. Strength of the proximal femur was defined as 4% deformation of the (non-linear force-deformation curve) femoral head with respect to the greater trochanter. Percent change of strength from baseline (pre-treatment) for the ODN, ALN, and VEH groups at 18 months were 17.1%, 6.4%, and 3.2%, respectively, with ODN group showing statistically significant differences (p<0.05) from the VEH and ALN groups. Measurable differences were observed in the geometry, average volumetric BMD, and FEA estimated hip bone strength between the ODN-treated group as compared to ALN- and VEH-treated estrogen deficient non-human primates.

Increased Bone Cell Vitamin D Activity: The Basis for Synergy between Dietary Calcium and Vitamin D for Bone Health? Howard Morris*[1], Alice Lee[2], Rebecca Sawyer[3], Shunji Iida[4], Peter O'Loughlin[5], Paul Anderson[3]. [1]SA Pathology, Australia, [2]Discipline of Physiology, University of Adelaide, Australia, [3]Endocrine Bone Laboratory, Hanson Institute, Australia, [4]Oral Functional Science, Hokkaido University, Japan, [5]Chemical Pathology, SA Pathology, Australia

Clinical studies indicate that the combination of vitamin D and dietary calcium supplementation reduces the risk of fracture to a greater extent than either supplement alone. Preclinical dietary studies indicate that an adequate vitamin D status reduces osteoclastogenesis and increases trabecular bone volume.[1] We now report data from further preclinical dietary studies of high dietary calcium increasing 25-hydroxyvitamin D (25D) metabolism by bone cells associated with increased cortical and trabecular bone volumes and increased bone strength. Female Sprague-Dawley rats aged 6 or 9 months of age were fed either 0.1% or 1% calcium supplemented AIN-93-VX diets containing 0, 100, 600, or 1000 IU vitamin D3/kg for 3 or 6 months following which they were killed and blood, kidney, femora and tibia collected for analyses. 25D-1α-hydroxylase (CYP27B1) mRNA was analysed in bone and kidney by quantitative RT-PCR. Cortical and trabecular bone regions were analysed by micro-CT and Ultimate Load measurement was obtained from 3-point bending at the tibia. Bone CYP27B1 mRNA levels were 3 to 4 fold higher in animals fed 1% compared to 0.1% calcium diets (P<0.05) independent of vitamin D status which was opposite to these mRNA levels in kidney. Mean serum 25D levels ranged from 14.0($\pm$1.5) to 161($\pm$38.8) nmol/L. Regression analyses demonstrated significant positive relationships between serum 25D and proximal femoral trabecular bone volume (R^2 =0.23, P<0.01) and femoral cortical bone volume (R^2 =0.22, P<0.01). The increase in femoral cortical bone volume with increasing serum 25D level was significant with animals fed 1% calcium (P<0.05) with no change in animals fed the 0.1% calcium diet. Mechanical testing demonstrated that Ultimate Load measurement was highest on tibiae from animals fed 1% calcium and the highest vitamin D diets (P<0.05). An adequate vitamin D status (serum 25D levels >80 nmol/L) is required to maintain cortical and trabecular bone volumes in mature rats fed a 1% calcium diet but these levels of vitamin D cannot maintain these bone volumes in animals fed 0.1% calcium

diet. The maintenance of bone volume is independent of serum 1,25D and PTH levels. The increased bone volume with 1% diet calcium is associated with increased mRNA levels for bone CYP27B1 responsible for bone cell conversion of 25D to 1,25D.

PTH and ALN reduce fractures and alter bone mechanical properties in the *oimloim* mouse model of OI. Cesare Ciani*[1], Kirsten Stoner[2], Michael Cross[1], Liza Osagie[1], Bettina Willie[1], Marjolein Van Der Meulen[2], Mathias Bostrom[1]. [1]Hospital for Special Surgery, USA, [2]Cornell University, USA

Osteogenesis Imperfecta (OI), a genetic disorder typically caused by a mutation in Type I collagen, manifests with defective connective tissue resulting in multiple skeletal fractures. Intermittent bisphosphonate therapy is the standard treatment, while parathyroid hormone (PTH) is currently under evaluation as an alternative. This study investigated the effects of PTH, both individually and in combination with alendronate (ALN) in the oim/oim mouse model of OI.

68 oim/oim mice and 68 wild type (WT) mice were randomized into 4groups: saline, ALN, PTH and PTH+ALN, each for 12weeks. A baseline untreated OI group was euthanized at 4weeks (Table 1). Outcome measurements included fracture incidence, cancellous histomorphometry and three-point bend testing.

Fracture number was reduced in all OI treated groups compared to the OI saline group ($p<0.05$), with ALN causing the greatest reduction (2.5 compared to 5.4 of the saline group), and PTH+ALN the least (Figure 1). ALN increased trabecular number in both OI and WT mice (9.1 and 9.4 respectively compared to 2.9 and 4.8 in OI and WT saline groups). ALN and ALN+PTH significantly increased bone volume fraction (BV/TV) in OI mice compared to OI PTH group, resulting in BV/TV values equal to untreated WT levels (Figure 2). PTH did not alter any cancellous histomorphometry. ALN decreased energy to failure and increased bending stiffness in all groups. In OI mice PTH+ALN restored strength and energy to failure to WT saline levels. ALN and PTH+ALN treatments increased bending strength in OI mice.

While PTH alone did not alter cancellous histomorphometry, fracture incidence was reduced comparable to ALN treatment. PTH+ALN improved cancellous architecture and reduced fracture number. Reduction in fracture number can be attributed to increased bone volume fraction when OI bone was treated with ALN. Individual ALN treatment produced brittle behavior in both OI and WT femora, but used in combination with PTH strength and ductility were rescued to WT levels. Ultimately, PTH and ALN's effect on fracture number, and their synergistic effect on mechanical properties cannot solely be ascribed to morphological changes, but reflects changes in intrinsic bone tissue material properties to be assessed in future studies.

Table 1: PTH and saline were injected daily at a dose of 30 µg/kg. Alendronate was injected weekly at a dosage of 0.03 mg/kg.

Genotype – age	Baseline	12 weeks Saline	12 weeks PTH	12 weeks ALN	6 weeks PTH +6 weeks ALN
oim/oim – 4 weeks	n = 13	n = 17	n = 17	n = 17	n = 17
+/+- 4 weeks	n = 0	n = 17	n = 17	n = 17	n = 17

Figure 1: Fracture number in OI mice; * p < .05 vs baseline; ** p < .05 vs saline.

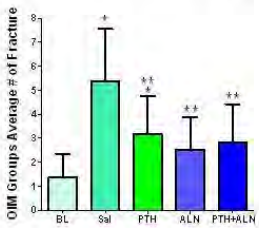

Figure 2: Trabecular bone volume fraction (BV/TV); * p < .05 vs OI baseline, saline and PTH; # p < .05 vs wt saline and PTH; ## p < .05 vs WT ALN.

FR0446

Bone turnover and 1,25-dihydroxyvitamin D are independent determinants of circulating FGF23: a sub-analysis of CHIBA (Coronary Heart Disease of Ischemia and Bone Association) study. Daisuke Inoue*[1], Toshihiro Amaki[1], Yuichiro Shimizu[2], Seiji Fukumoto[2], Yusuke Nakatsu[1], Kengo Ayabe[1], Jun-ichi Ohashi[1], Tadanao Higaki[1], Nobuyuki Tai[1], Fumitaka Nakamura[1], Ryo Okazaki[1]. [1]Teikyo University Chiba Medical Center, Japan, [2]University of Tokyo Hospital, Japan

FGF23 is a phosphaturic hormone physiologically secreted by cells of the osteoblast lineage. Despite accumulating knowledge on its function and mode of action, little is known about in vivo regulators of FGF23 production. We previously reported that in 301 male subjects who visited the cardiovascular unit of our department for coronary angiography, bone turnover markers, particularly MMP-dependent ICTP, was a good predictor of both cardiac damage (proBNP) and dysfunction (LVEF). In the present study, we aimed to identify determinants of circulating levels of FGF23 in a part of this cohort. Subjects included in this sub-analysis were 168 males (64±11y.o.) with normal renal function (eGFR>60 ml/min).

We found that intact FGF23 levels were significantly correlated most strongly with ICTP (r=.254, p=0.001), and also with TRACP-5b and N-mid osteocalcin, but not with βCTX, BAP, PICP, Ca, P, hsCRP or proMMP-9. 1,25D was also negatively correlated with FGF23 as expected. There was a positive correlation between 25D and 1,25D, and a negative association between PTH and 25D, but neither 25D nor PTH showed a correlation with FGF23. And the correlation between ICTP and FGF23 remained significant even after adjusted for PTH, 25D, 1,25D, Ca, P, parameters of glucose and lipid metabolism, hsCRP, proMMP-9, proBNP and LVEF. Interestingly, stepwise multiple regression analysis revealed ICTP, 1,25D and blood sugar (BS) as independent determinants of FGF23. HbA1c and C-peptide correlated with BS, but not with FGF23. These results were intriguing in light of the fact that osteocalcin secreted by osteoblasts regulates glucose metabolism. However, we were unable to find any association of undercarboxylated osteocalcin (ucOC) with BS or FGF23 in this population. And although the association between BS and FGF23 seemed stronger in those with high BS, exclusion of the highest extremes resulted in loss of statistical significance. Thus, a possible association between FGF23 and high BS in a diabetic range remains an open question.

Collectively, these results demonstrate a novel link of FGF23 secretion to bone turnover, and possibly blood glucose as well. Our observations further suggest that FGF23 production by osteoblasts and osteocytes may be under the influence of the same regulatory mechanism that controls their endocrine and paracrine function governing bone and glucose metabolism.

Effect of Vitamin D Nutrition on Indices of Disease in Patients With Primary Hyperparathyroidism. Sudhaker Rao, Joanna Miragaya*, Sara Ahmadi, Liliana Garcia, Nayana Parikh, Mahalakshmi Honasoge, Arthur Carlin, Gary Talpos, Meredith Mahan, Sudhaker Rao. Henry Ford Hospital, USA

Vitamin D nutrition has been implicated in the clinical expression of primary hyperparathyroidism (PHPT) in most, but not all studies. However, very little is known about the effect of vitamin D nutrition on biochemical indices of disease severity. Accordingly, we determined the effect of vitamin D nutrition, as assessed by serum 25-OHD (the best available index of vitamin D nutrition) on adenoma weight, and on biochemical indices of disease severity, as assessed by serum calcium (Ca), PTH, alkaline phosphatase (AP) and phosphate (P) in a large cohort of 933 patients with surgically verified PHPT and normal renal function.

Materials & Methods: All patients with normal renal function, defined as serum creatinine <1.5 mg/dl, operated between January 1, 1992 and December 31, 2007 were included. Patients with familial PHPT, renal failure, failed surgery, and persistent PHPT were excluded. Parathyroid pathology was based on the report. Vitamin D status was defined by serum 25-OHD level. A level <20ng/ml was considered deficiency in the initial analyses, and the analyses were repeated with cut-off levels of <15 ng/ml and <30 ng/ml.

Results: Among the 933 patients there were: 461 blacks and 845 women with a mean age of 61 ± 12y. Other relevant data are in the Table. Adenoma weights are shown both in arithmetic mean ± SD and geometric mean ± multiplicative SD. As a group, patients with 25-OHD <20 ng/ml had larger tumors, and greater effect on disease indices (higher PTH, AP (total and bone specific), and lower P). Serum Ca, creatinine and 1,25DHCC were similar in the 2 groups. There was a highly significant inverse correlation between gland weight and serum 25-OHD level (r= -0.26; p<0.0001). In a multiple regression model only the 25-OHD level was a significant predictor of gland weight with the expected significance for the relationship between gland weight and Ca & PTH. In the ROC analysis to predict tumor weight of either >500 mg or >1000 mg, the AUC for 25-OHD was 0.72 (for both with p<0.001). Results were almost identical for the 25-OHD cut-off level of <15 or <30 ng/ml.

Conclusions: Vitamin D nutrition adversely affects parathyroid adenoma size (growth?) and disease expression as assessed by biochemical markers. Restriction of vitamin D intake for fear of aggravating hypercalcemia in PHPT is not warranted.

Osteocyte Proteins Regulating Mineralization and Systemic Phosphate Homeostasis are Altered Early in CKD-MBD in Humans and *Jck* Mice. Fabiana Graciolli*[1], Luciene dos Reis[1], Yves Sabbagh[2], Wen Tang[3], Stephen O'Brien[3], Shiguang Liu[3], Aluizio Carvalho[4], Rosa Moysés[1], Susan Schiavi[2], Vanda Jorgetti[5]. [1]Universidade de São Paulo - Nephrology Division, Brazil, [2]Genzyme Corp, USA, [3]Genzyme Corporation, USA, [4]Federal University of São Paulo, Brazil, [5]University of São Paulo, Brazil

Disturbances in mineral and bone metabolism occur early in CKD, as illustrated by the early increase in the phosphaturic hormone FGF23 with subsequent elevation of PTH. The relationship of these hormonal changes with the progression of bone disease in CKD is not understood. Additionally, the recent finding that FGF23 expression is regulated by proteins associated with mineralization suggest that osteocyte specific pathways may play a role in coordinating bone mineralization with systemic mineral metabolism in normal physiology that may become deranged during the disease state. As a first step in addressing the natural history of CKD-MBD and the potential role of the osteocyte in the mineral dysregulation associated with CKD progression, we examined the expression of key osteocyte proteins using immunostaining in bone biopsies from patients with early CKD pre-dialysis patients (CKD; n=9; creatinine clearance = 49 ± 17 ml/min), CKD patients on hemodialysis (HD; n=8), and age, sex matched normal individuals (n=4). As shown in Table 1, the total number of osteocytes (Ost) was higher in HD than in CKD patients. We also observed significant increases in percentage of osteocytes expressing SOST, PTHR1 and both total and phosphorylated β-catenin in trabecular bone. As CKD progressed, the number of SOST and PTHR1 expressing cells decreased, whereas the number of of osteocytes expressing phosphorylated β-catenin continued to increase. Interestingly, an increase in the number of FGF23 expressing cells was observed only in stage 5 CKD bones. In order to confirm these findings, we evaluated bones from Jck mice, which is a progressive preclinical CKD model, and we found similar results. Taken together, our data suggest that in CKD, bone changes occur very early, before the detection of biochemical disturbances. The molecular mechanisms involved in CKD bone disease and a causal effect of these proteins expression should be elucidated in further studies.

Circulating Osteogenic Cells are Decreased in Type 2 Diabetes Mellitus. John Manavalan[1], Aruna Kode[1], Jayesh Shah[1], Daniel Donovan[1], Carlos Lopez-Jimenez[1], James Sliney[1], Rebecca Ives[2], Pat Kringas[1], Lauren Golden[1], Matthew Freeby[1], Stavroula Kousteni[2], Mishaela Rubin*[1]. [1]Columbia University, USA, [2]Columbia University Medical Center, USA

Type 2 Diabetes Mellitus (T2D) is associated with an increased fracture incidence despite normal bone mineral density (BMD). Previous data show suppressed bone formation in T2D, but the mechanisms for this are poorly understood. We hypothesized that the supply of osteogenic cells is decreased in T2D, possibly via effects of insulin resistance on oxidative stress and osteocalcin. Osteogenic cells can be detected in the peripheral blood (PB) by flow cytometry using antibodies for osteoblast-specific ligands, such as osteocalcin (OCN), and the early stem cell markers CD34 and CD146. To evaluate the effects of T2D on these cells, we studied 28 T2D subjects (19 female; 52 ± 14 yrs; fasting plasma glucose: 179 ± 66 mg/dl; HgbA1c 8.9 ± 3%) and 28 matched non-diabetic controls (Cntls). Expression profiling of the cell populations using real time PCR was performed in a small sub-group of T2D (n=3) and matched Cntls (n=3) for OCN, insulin receptor and superoxide dismutase 2 (SOD2), a transcriptional target of the oxidative stress marker forkhead box O1 (FOXO1). The percentage of PB cells that expressed osteocalcin (OCN+) on the cell surface was significantly lower in T2D vs. Cntls (0.7 ± 0.4 vs. 1.3 ± 0.6%; p<0.0001). Although overall OCN+ cells were lower, T2D subjects had more cells that co-expressed the early markers CD34 and CD146. The sub-population of OCN+ cells that co-expressed CD146 was increased in T2D (53.7 ± 40 vs, 6.5 ± 6%; p<0.0001) and there were more OCN+ cells that co-expressed CD34 and CD146 (5.8 ± 7 vs. 2.9 ± 3%; p=0.06) in T2D. In T2D, higher levels of OCN+/CD146+ were significantly correlated with higher HgbA1c levels (r=+0.62, p=0.008) in males. Expression profiling of the OCN+/CD34+ cell populations showed decreased expression in T2D of OCN by more than 2-fold (p<0.05) and of insulin receptor by more than 2-fold (p<0.05), while SOD2 expression was increased more than 2-fold (p<0.05).

These data suggest that T2D subjects have a significant decrease in circulating osteogenic cells, along with a disproportionate increase in the expression of early cell markers. Worsening glycemic control was associated with an increase in early osteogenic cells in diabetic men. Decreased insulin receptor expression may lead to an increase in the FOXO1 target SOD2, which in turn suppresses osteocalcin expression. Alterations in insulin sensitivity and oxidative parameters may be associated with an arrested development of osteogenic cells in T2D.

Deletion of the MDS1 Gene in Mice Results in Disk Degeneration and Kyphosis Through Mis-regulation of Matrix Protein Synthesis by Tendon/ligament Cells. Lianping Xing*[1], Subhash Juneja[2], Caroline Zeiss[3], K Lezon-Geyda[1], D Reynolds[1], Zhenqiang Yao[1], S Lin[1], G Perkins[1], T Ardito[1], W Philbrick[1], H Awad[1], Brendan Boyce[2], Archibald Perkins[1]. [1]University of Rochester, USA, [2]University of Rochester Medical Center, USA, [3]Yale University, USA

Intervertebral disk degeneration (IVDD) and kyphosis frequently accompany osteoporosis in the elderly. However, the causes of IVDD and kyphosis remain poorly understood, and there are few animal models to study these conditions. Here, we generated myelodysplasia syndrome 1 null mice (Mds1-/-) using a lacZ knock-in approach. Mds1-/- mice are viable and at 2 weeks-old exhibit slight lumbar lordosis, reduced vertebral bones and narrowed intervertebral space. The spine abnormalities progress with aging and by 8 weeks-old, their thoracic column becomes extremely kyphotic, which is associated with IVD collapse, vertebral fusion, bone loss (BV/TV (%) in L2: 8+2 vs 40+8 in WT), and reduced vertebral biomechanical strength (Max load (N): 1+0.2 vs 6+1 in WT). Interestingly, long bones of Mds1-/- mice are normal. To investigate the cellular and molecular mechanisms leading to the spine defects, we examined the distribution of Mds1-expressing cells by LacZ staining. We found LacZ+ cells in the sclerotome and developing limbs at E9.5 and within the cartilaginous anlagen of developing vertebral bodies and their processes at E14.5. In newborns, LacZ+ cells were only seen in the tendinous layer surrounding vertebral bodies and anchoring the intercostal muscles to the ribs and in ligaments between vertebral processes. Ultrastructural analyses of sacral and tail tendons and the IVDs of Mds1-/- mice revealed marked disarray of the collagen fibrils with small diameters (Fibril diameter: 74+19 vs 224+61 nM in WT). Because tendon and ligament are closely related and derived from the same lineage in sclerotomes and express scleraxis (scx), a distinct marker for tendon and ligament cells, we cultured tendon cells from Mds1-/- and WT mice and compared the expression levels of tendon and extracellular matrix genes. Mds1-/- tenocytes expressed 10-20-fold less scx, tenomodulin and decorin; 5-10-fold less cartilage oligomeric matrix protein; 2-fold less biglycan and fibromodulin than WT cells, but similar levels of collagens 1, 2, 3, and 8, tissue inhibitor of metalloproteinase 3 and lysyl oxidase. In summary, Mds1-/- mice develop progressive IVDD, kyphosis and osteoporosis associated with dysfunctional tendon and ligament cells. Our findings indicate that the transcription factor, Mds1, not only regulates hematopoiesis, but also plays an important role in maintaining spine integrity by regulating the functions of tendon/ligament cells and affecting extracellular matrix production.

Type 1 Diabetes Mellitus Effects Bone: Results of Histomorphometric Analysis. Robert Recker[1], Laura Armas*[2]. [1]Creighton University Osteoporosis Research Center, USA, [2]Creighton University, USA

Diabetes Mellitus has a detrimental effect on the body's microvascular system effecting the kidneys, eyes and nerves. The effect on bone is less well known. Patients with Type 1 diabetes have lower bone mass and higher fracture risk than age and sex matched controls. The effect of diabetes on bone micro-architecture and turnover is not well elucidated. We report here preliminary results of eighteen subjects (10 females, 8 males, age 21-47) with Type 1 diabetes for a median of 16 years. The subjects were otherwise healthy without diabetic complications and the females were premenopausal. Two subjects had experienced low trauma fractures. A transilial bone biopsy was obtained after tetracycline labeling. The biopsy specimens were fixed, embedded, sectioned, and evaluated as previously described by Baron et al. Two sections, >250 μm apart, were read from the central part of each biopsy. Mann-Whitney U test was used to compare the results with an existing set of premenopausal controls. Structural measures such as bone volume (BV/TV) and trabecular thickness (TbTh) were lower in the diabetic subjects compared to premenopausal controls (Table 1). The dynamic data showed increased remodeling rates with greater mineralizing surface, mineral apposition rate and activation frequency. The two subjects that had experienced low trauma fractures had lower activation frequencies of 10 and 19 /yr respectively. Histomorphometry in diabetics demonstrates a decrease in bone volume and an increase in remodeling to levels similar to postmenopausal women. This is consistent with the results obtained from microCT and DXA measurements. The increased remodeling may not be related to increased fracture risk though, as the 2 subjects that fractured had lower activation frequency.

Prevention of Fractures After Solid Organ Transplant: A Meta-analysis. Emily Stein*[1], Dionisio Ortiz[2], Zhezhen Jin[3], Donald McMahon[1], Elizabeth Shane[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]SUNY Downstate College of Medicine, USA, [3]Columbia University, USA

Bone loss and fracture are serious sequelae of organ transplantation, particularly in the first year post-transplant. The majority of interventional studies designed to prevent transplant bone loss have been inadequately powered to detect effects on fracture.

We performed a meta-analysis to determine whether treatment with bisphosphonates (BPs) or active vitamin D analogues (vitD) during the first year after transplant reduced fracture risk, and to provide an accurate estimate of the effect of these interventions on rates of bone loss. A systematic review of the literature was conducted using MEDLINE/Pubmed, Cochrane database, and abstracts from scientific meetings. Randomized clinical trials of BPs or vitD compared to placebo that assessed incidence of fracture during the first year following solid organ transplantation were included. For each study, log odds ratio (OR) of fractures was estimated along with its standard error (SE). The relative percentage change in 12 month in lumbar spine (LS) and femoral neck (FN) bone density from baseline between groups was calculated along with its SE. Heterogeneity was examined by Cochran Chi-square tests. Fixed-effects (FEM) and random-effects models (REM) were used.

Ten studies of 817 transplant recipients (135 fractures) were included. Treatment with BPs or vitD reduced the number of subjects with fracture compared to placebo using FEM (OR 0.56, 95% CI of 0.32-0.96, see figure below); the results by REM did not reach significance (OR 0.56, 95% CI 0.28-1.11). No reduction was seen in total number of fractures (OR 0.33, 95% CI 0.10-1.02; REM) or number of vertebral fractures (OR 0.28, 95% CI 0.07-1.03; REM). A significant increase in LS BMD was found by both FEM (2.87, 95% CI 2.05-3.68) and REM (3.15, 95% CI 1.39-4.92). Similarly, a significant increase in FN BMD was observed by FEM (3.07, 95% CI 2.16-3.98) and REM (3.24, 95% CI 1.82-4.66). When BP trials were examined separately, there was no significant reduction in any fracture outcome with treatment, but significant increases in LS BMD and FN BMD were still observed.

Treatment with BPs or vitD during the first year following solid organ transplant was associated with a reduction in the number of subjects with fractures, though this reduction was only significant using FEM. In contrast, significant improvements in LS and FN BMD were observed with treatment. Additional studies are required to demonstrate a consistent effect of treatment on fracture reduction.

Mechanical Loading Increases Estrogen Receptor Alpha Expression in Osteocytes and Osteoblasts Despite Chronic Energy Restriction. Sibyl Swift*[1], Joshua Swift[2], Elizabeth Greene[1], Susan Bloomfield[1]. [1]Texas A&M University, USA, [2]United States Navy, USA

Moderate energy restriction (40% EnR) in young, exercising women can attenuate the positive effects of exercise on bone. We sought to determine whether 40% EnR limits the bone response to mechanical loading (LOAD) through a down-regulation of estrogen receptor alpha (ERα) in osteocytes and/or osteoblasts, resulting in an attenuation of the cancellous bone response to loading. After an 8 wk acclimation, 12 female Sprague-Dawley rats (7-mo-old) were sacrificed as baseline controls (BC). The remaining 48 rats were randomized to control groups (ADLIB-SHAM and ADLIB-LOAD) and fed AIN-93M rat diet ad lib for 12 wks. EnR groups (EnR40-SHAM and EnR40-LOAD) were fed modified AIN-93M with 40% less energy but 100% of all other nutrients provided. At wk 12, rats in both LOAD groups were anesthetized and subjected to muscle contractions once every 3 days (75% peak isometric strength; 4 sets of 5 reps; 1000ms isometric + 1000ms eccentric contraction). SHAM groups were anesthetized and fine wire electrodes implanted without any muscle contraction. Histomorphometric analyses revealed that 40% EnR resulted in significantly lower proximal tibia Tb.Th (-6-fold), higher Tb.Sp (+127.4%), and lower BV/TV (-2-fold) in SHAM but not LOAD rats (vs ADLIB-SHAM). ObS/BS (+23-fold) and OS/BS (+13-fold) were greater in both LOAD groups vs. ADLIB-SHAM. Mechanical loading prevented reductions in mineralizing surface (MS/BS) and bone formation rate (BFR/BS) resulting from EnR; EnR40-LOAD was 5-fold higher vs. SHAM groups. EnR significantly blunted cancellous bone's response to mechanical loading. BFR/BS and MS/BS were -33 and -52% lower, respectively, in the EnR40-LOAD vs. ADLIB-LOAD group. Immunostaining revealed that osteoblast and osteocyte expression levels of ERα protein were +6 and +26-fold greater, respectively, in EnR40-LOAD vs. EnR40-SHAM. However, EnR did not diminish these LOAD-induced increases in ERα expression. These data suggest that a brief period of mechanical loading is able to mitigate losses in cancellous bone microarchitecture related to 40% energy restriction. Chronic energy restriction does limit the bone formation response to mechanical loading, but this may not be the result of a dowregulation in ERα protein on osteoblasts and osteocytes (mechanosensors in bone).

A Key Role for CARM 1 Arginine Specific Methylation in Vitamin D Receptor Mediated Transcription. Leila Mady*, Yan Zhong, Puneet Dhawan, Sylvia Christakos. University of Medicine & Dentistry of New Jersey, USA

Hormone dependent transcriptional regulation involves chromatin remodeling by coactivator proteins. Although roles of acetylation and phosphorylation in chromatin remodeling have been widely studied, recent findings have also indicated an important role for methylation. Little is known however about the exact role of methyltransferases and their regulation by different physiological signaling pathways. Using

MDCT renal distal tubule cells or VDR transfected COS-7 and the rat 24(OH)ase promoter (-298/+74) we found that CARM1 (co-activator associated arginine methyltransferase 1) cooperates with the p160 coactivator GRIP1 to enhance $1,25(OH)_2D_3$ induced transcription. Transfection of GRIP1 (0.05 ug) enhanced $1,25(OH)_2D_3$ induced transcription 2 fold and co-expression of GRIP (0.05 ug) + CARM1 (0.2 ug) resulted in a 4 fold enhancement. All activity was dependent on $1,25(OH)_2D_3$. When a CARM1 mutant lacking methyltransferase activity or when the GRIP1 mutant ΔAD2, which lacks the binding site for CARM1, was used, cooperative activation was not observed. Thus, the coactivator function of CARM1 requires methyltransferase activity and coexpression of GRIP1. When PRMT2A, another arginine methyltransferase, was substituted for CARM1, cooperative transactivation with GRIP1 was not observed, suggesting a preferential role for CARM1. ChIP analysis using methyl (R17)H3 antiserum indicated that dimethylation of histone H3 at arginine 17, which is mediated by CARM1, occurs in a $1,25(OH)_2D_3$ dependent manner, further supporting the participation of CARM1 in VDR mediated gene activation. Western blot analysis of MDCT cells indicated a 9.6 ± 1 fold induction of methyl(R17)H3 (the CARM1 methylated form of H3) 30 minutes after $1,25(OH)_2D_3$ treatment. This induction was completely inhibited when the cells were co-treated with 1mM 8 bromo cAMP and $1,25(OH)_2D_3$ for 30 minutes. These findings suggest that the PKA signaling pathway may serve as a molecular switch for controlling CARM1 enzymatic activity, at least in distal tubule cells. Our findings are the first to describe $1,25(OH)_2D_3$ regulation of the CARM1 methylated form of histone 3 and inhibition of the $1,25(OH)_2D_3$ induction by the cyclic adenosine monophosphate signaling pathway. Our findings suggest an interplay between acetylase and methylase in VDR mediated regulation of gene transcription and that CARM1 methylation may play a key role in activation and modulation of $1,25(OH)_2D_3$ induced transcription.

Identification of Novel Vitamin D Receptor Target Genes in Osteoblasts Based on Promoter Interaction with the Vitamin D Response Element Binding Protein. Thomas Lisse*[1], Ting Liu[1], John Adams[2], Martin Hewison[3]. [1]UCLA/Orthopaedic Hospital Research Center, USA, [2]University of California, Los Angeles, USA, [3]UCLA, USA

Heterogeneous nuclear ribonucleoprotein (hnRNP) C1/C2 plays a pivotal role in vitamin D receptor (VDR) signaling by acting as a vitamin D response element-binding protein (VDRE-BP). Transcriptional regulation by the active form of vitamin D_3, 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) involves occupancy of VDRE by VDRE-BP or $1,25(OH)_2D_3$-bound VDR; this relationship is disrupted by over-expression of VDRE-BP and can result in a form of human hereditary vitamin D-resistant rickets (HVDRR). To characterize the impact of VDRE-BP on bone function we carried out DNA array analyses using B-lymphoblastic cells from an HVDRR patient and an age and sex-matched normal (wild type; WT) human subject. Data defined a sub-cluster of 114 genes induced or suppressed (>1.5-fold) in WT cells after exposure to 10 nM $1,25(OH)_2D_3$. Of these, 113 were rendered insensitive to $1,25(OH)_2D_3$ by over-expression of VDRE-BP in the HVDRR cells. Using a selection of these genes, further studies were carried out to determine whether over-expression of VDRE-BP also suppressed $1,25(OH)_2D_3$-mediated transcription in human osteoblastic cells. Prominent amongst the VDRE-BP-regulated, $1,25(OH)_2D_3$-responsive genes identified in osteoblast-like cells was the DNA-damage-inducible transcript 4 (DDIT4), an inhibitor of the mammalian target of rapamycin (mTOR) signaling pathway. Chromatin immunoprecipitation (ChIP) assays using $1,25(OH)_2D_3$-treated osteoblasts confirmed that liganded VDR and VDRE-BP compete for binding to the proximal promoter region of the DDIT4 gene in a similar fashion to that observed for other $1,25(OH)_2D_3$ target genes such as CYP24A1. A role for $1,25(OH)_2D_3$-induced DDIT4 expression in regulating mTOR signaling was confirmed by $1,25(OH)_2D_3$-induced suppression of phosphorylated $S6K1^{T389}$ protein (a downstream target of mTOR). The functional importance of this $1,25(OH)_2D_3$-action in osteoblasts was underlined by the fact that rapamycin inhibition of mTOR suppressed antiproliferative responses to $1,25(OH)_2D_3$. These data confirm that VDRE-BP is an important component of the transcriptional apparatus required for normal $1,25(OH)_2D_3$-VDR-mediated transcription and cell function. Conversely, over-expression of VDRE-BP exerts a dominant-negative effect on transcription of many $1,25(OH)_2D_3$-target genes. Characterization of VDRE-BP action in $1,25(OH)_2D_3$-treated osteoblasts highlights an entirely novel role for vitamin D as a regulator of mTOR – a known 'master regulator' of cell function.

MBD4 Is an Epigenetic Regulator In the Vitamin D Metabolism. Takeshi Kondo*[1], Mi-sun Kim[1], Yuuki Imai[2], Shino Kondoh[2], Yoko Yamamoto[1], Takahiro Matsumoto[1], Ken-ichi Takeyama[1], Shigeaki Kato[3]. [1]IMCB, University of Tokyo, Japan, [2]The University of Tokyo, Japan, [3]University of Tokyo, Japan

We have previously reported that 1α,25(OH)2D3 (VD) is potent to induce HDAC/VDR co-repressor complex and negatively regulates transcription in the CYP27B1 gene promoter by direct DNA binding of VDIR (bHLH transcription factor) to a specific negative vitamin D response element, while parathyroid hormone (PTH) induces gene expression of CYP27B1 at the transcription level (Murayama A *et al*., EMBO J, 2004). More, recently, we have also reported that VD -dependent transrepression of this gene was regulated by DNA methytransferases associating with liganded-VDR/VDIR co-repressor complex through repressive histone modification and epigenetic DNA methylation. Conversely, MBD4 (methyl-CpG binding domain-4) in the co-respressor complex was phosphorylated by PTH-activated protein kinase C and phosphorylated MBD4 facilitated demethylation of the methylated CpG sites in the CYP27B1 promoter (Kim MS *et al*., Nature, 2009). Although these findings have clarified a part of functions of VDR and MBD4 in the transcriptional mechanisms, the roles of MBD4 in vitamin D metabolism remain unknown. In this study, we tried to characterize the physiological role of MBD4 in bone and mineral metabolisms using $MBD4^{-/-}$(KO) mice. Endogenous Cyp27b1 gene expressions in kidneys of both wild-type (WT) and MBD4KO mice were significantly suppressed by vitamin D treatment. However, subcutaneous injection of PTH significantly recovered Cyp27b1 gene expression only in VD-pretreated WT mice, not in VD-pretreated MBD4KO mice. In addition, the Cyp27b1 gene expression of MBD4KO mice was also significantly reduced by changing calcium content in the diet, compared with WT mice. These findings indicate that the responsiveness against PTH stimulation in kidneys is impaired in MBD4KO mice, at least on the transcriptional level of Cyp27b1 gene. Moreover, from the results of radiological analysis such as soft X-ray and μCT, twenty four week-old MBD4KO mice exhibited bone loss in the diaphyseal area of long bones and calvaria compared to WT mice. Interestingly, this bone loss of MBD4KO mice was rescued by feeding with high calcemic diet. Taken together, these results suggested that MBD4 plays a physiological role in bone metabolism. However, it is still unclear whether the bone mass alteration in MBD4KO mice is due to loss of direct MBD4 functions in bone cells or the results from loss of responsiveness to PTH in the kidney. Further characterization of MBD4 functions in bone metabolism will be presented.

The VDR/RXR Cistrome in Intestinal/Colonic Cells Regulates Genes Involved in Proliferation and Differentiation, Calcium and Phosphate Transport and Xenobiotic Metabolism. Mark Meyer*, J. Pike. University of Wisconsin-Madison, USA

1,25-Dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) plays a central role in calcium and phosphorus homeostasis. In the intestine, these actions regulate calcium and phosphate transporter genes, xenobiotic-metabolizing genes and genes involved in development, growth and differentiation. To explore potential targets of vitamin D action in intestinal/colonic cells, we conducted a ChIP analysis linked to deep sequencing (ChIP-seq) of VDR/RXR in LS180 cells and correlated genome-wide binding to changes in histone modification and gene expression. While VDR binding was detected at 728 sites under basal conditions, VDR bound to over 8150 sites following activation by $1,25(OH)_2D_3$. A similar analysis revealed that RXR binding at 8902 sites was comparable. While some sites were located near gene promoters, most were located within introns and/or at distal intergenic regions. Many sites contained one or more VDRE-like sequences. Genome-wide ChIP-seq analysis also revealed that many of these sites were marked by histone H4 acetylation (H4ac) and that occupancy by VDR/RXR increased this histone mark. RNA polymerase II density was also increased. Importantly, $1,25(OH)_2D_3$ induced VDR/RXR binding at target genes identified previously including *CYP24A1*, *TRPV6* and *SLC34A3*, and at *CYP3A4* and *CYP3A7* in the xenobiotic-metabolizing multigene locus. Perhaps most interesting was the observation that VDR/RXR binding was also observed at genes involved in intestinal epithelial cell proliferation and differentiation, including genes involved in Wnt/b-catenin activation and at β-catenin targets such as *c-MYC*. At this gene, VDR bound to not only the proximal enhancers located at both ends of the gene, but also to upstream regions known to mediate β-catenin activation, including a distal site at -335 kb. Analysis of the CDX2 homeobox, C/EBPβ and β-catenin ChIP-seq cistromes revealed that these transcription factors also play roles in $1,25(OH)_2D_3$-regulated gene expression. In fact, while generally pre-bound, CDX2 binding overlapped 1255 sites to which activated VDR was associated. Direct gene expression studies confirmed that many but not all of these genes were regulated in LS180 cells by $1,25(OH)_2D_3$. These studies indicate that $1,25(OH)_2D_3$ exerts complex actions in intestinal/colon cells that impact not only calcium/phosphorus homeostasis and xenobiotic metabolism, but intestinal cell proliferation as well. This latter activity may be useful therapeutically in colon cancer.

Axial and Appendicular Bone Properties in Ambulatory Children with Cerebral Palsy. Tishya Wren*[1], David Lee[1], Robert M. Kay[1], Frederick J. Dorey[1], Vicente Gilsanz[2]. [1]Childrens Hospital Los Angeles, USA, [2]Children's Hospital of Los Angeles, USA

Children with cerebral palsy (CP) have deficient bone growth and an increased propensity for non-traumatic fractures. However, most studies of bone in children with CP have been limited to individuals with moderate to severe involvement (GMFCS levels 3-5). Higher functioning children with CP (GMFCS 1-2) may also be at risk for deficient bone acquisition due to muscle weakness and mobility limitations. The purpose of this study was to examine the relationship of axial and appendicular bone properties in ambulatory children with CP to functional (GMFCS) level.

Quantitative computed tomography (QCT) measurements were compared among 37 children with CP (N = 12, 5, 18, 2 for GMFCS levels 1, 2, 3, 4; age 9.3 $\pm$ 1.5 years; 18 male) and 37 controls with the same age and sex distribution. Vertebral (L3) properties were compared between CP and control and across GMFCS levels. Tibia properties were compared only across GMFCS levels because tibia data were not available for the controls. The primary method of analysis was linear regression. Simple and multivariable regression produced similar results, and only the multivariable results are presented here. The final multivariable model included height, weight, sex as covariates since height, weight, and their respective percentiles decreased with increasing disease severity ($P<0.03$).

There was no difference in vertebral cancellous bone density based on diagnosis (95% CI for coefficient: -15 to 7; P=0.49) or GMFCS level (CI: -12 to 8; P=0.68). The control group had larger vertebrae (CI: -81 to 9; P=0.02) than the children with CP, primarily due to smaller vertebral size in GMFCS levels 3 and 4 (CI: -98 to -7; P=0.02). In the tibia, geometric properties of the diaphysis decreased with increasing GMFCS level (CI: 35 to -1 for CSA, -25 to -6 for CBA; $P<0.05$). Cancellous density of the metaphysis also decreased with increasing GMFCS level (CI: -16 to -2 for entire metaphysis, -35 to -6 for slice; $P<0.02$) although values were similar between GMFCS levels 1 and 2.

This study is among the first to examine bone in higher functioning children with CP. The results suggest that children with CP of all levels may have reduced bone mass in their tibias, while spine deficits differentially affect more involved children. Since the lifespan of persons with CP is increasing and even small bone deficits may manifest as osteoporosis later in life, it is important to study bone acquisition in all children with CP.

Effect of Vitamin D2 and D3 Supplementation in Healthy Adolescents from a Risk Region of Vitamin D Deficiency in Argentina. Cristina Tau*[1], Edit Scaiola[2], Juliana Castagneto[1], Marina Rodriguez[3], Carina De Roccis[4], Zulma Pellisa[1]. [1]Metabolismo Cálcico y Óseo, Endocrinología, Hospital de Pediatría J.P.Garrahan, Buenos Aires, Argentina, [2]Servicio de Pediatria,Hospital Regional de Ushuaia, Tierra del Fuego, Argentina, [3]Servicio de Clínica Médica, Hospital Regional de Ushuaia,Tierra del Fuego, Argentina, [4]Laboratorio, Hospital Regional de Ushuaia,Tierra del Fuego, Argentina

In order to improve vitamin D status of healthy adolescents from Ushuaia (55˚S), in the south of Argentina, three periodic vitamin D2 or vitamin D3 supplementations of 100,000 IU were administered every three months: at the beginning of Winter (March), during winter (June), and in spring (September). Serum 25-hydroxyvitamin D (25OHD) was measured before the study, a month after the first supplementation, and two months after receiving the third supplementation (September 2008, April, and November 2009). After informed consent was signed by the parents, we studied 34 healthy adolescents, age (mean $\pm$ SD) 18.5$\pm$2 years old (range 14.7 to 21.6), 21 girls and 13 boys. An inquiry was made in reference to sun exposure, calcium intake by dairy products. Weight, height, and type of skin of each individual were considered. None had received previous vitamin D. Serum calcium(SCa), phosphate(SP), and alkaline phosphatase(AP) were measured at the beginning of the study. Weight was 0.16$\pm$0.74 (Z-Score), height was 0.2$\pm$0.81. Seventeen adolescents received vitamin D2 or ergocalciferol and 17 received vitamin D3 or cholecalciferol. SCa was 9.35$\pm$0.37 mg/dl, SP was 4.3$\pm$0.73 mg/dl, AP: 91$\pm$63 mg/dl. Basal levels of serum 25OHD were 13$\pm$6.3 ng/ml (range 2-26) in september/spring 2008 (D2 group: 14.4$\pm$6.4, D3 group: 11.8$\pm$6.1). One month after the first supplementation, 25OHD increased significantly in both groups: 29$\pm$7 range 16-44 ng/ml ($p< 0.01$), but was higher in the D3 than in the D2 group (31.6$\pm$5.4 vs 25.7$\pm$7.3 ng/ml, $p<0.012$). At the end of the study, 14 months after the beginning of the study, 25OHD decreased significantly: 22$\pm$5.3 range 12-32 ng/ml ($p<0.018$). However, although 25OHD decreased in both groups when compared with the one-month peak, they did not differ between them (D3: 23.9$\pm$5.1 and D2: 20.2$\pm$5ng/ml). None of the adolescents had vitamin D intoxication (>50 ng/ml). Values less than 15 ng/ml were seen at the end of the study in 2 individuals who received D2. Calcium intake was below FDA recommendations: 570$\pm$320 mg/day. These results indicate that to prevent vitamin D deficiency in risk zones, three supplementations of 100,000 IU of vitamin D during fall, winter and spring, would be adequate and safe to increase 25OHD levels. Morever, vitamin D2 or D3 are efficient to prevent vitamin D deficiency.

SA0003

Increased Bone Turnover in Preterm Infants Assessed by Serial Measurements of Urinary Osteocalcin and C-terminal Telopeptides of Type I Collagen (α-CTX-I and β-CTX-I). Kaisa Ivaska*[1], Leena Kilpelainen[2], Mikko Hakulinen[3], Tiina Lyyra-Laitinen[3], Esko Vanninen[3], Natalia Habilainen-Kirillov[1], Tanja Kuiri-Hanninen[2], Ulla Sankilampi[2], Kalervo Vaananen[1], Leo Dunkel[2]. [1]University of Turku, Department of Cell Biology & Anatomy, Finland, [2]Kuopio University Hospital, University of Eastern Finland, Department of Pediatrics, Finland, [3]Kuopio University Hospital, Department of Clinical Physiology & Nuclear Medicine, Finland

Moderate prematurity and rapid postnatal growth in preterm infants may have an impact on bone metabolism and development. The purpose of the present study was to evaluate bone metabolism in preterm infants during the first six months of life and compare them with full term infants.

Bone turnover was analyzed in 67 preterm infants (gestational age 24.7-36.7 weeks, median 32.9) and in 58 full term infants (gestational age 37.0-42.1 weeks, median 39.7) at postnatal day 7 (D7) and thereafter monthly until the age of six months (M1-M6). Bone turnover was assessed by measuring urinary osteocalcin midfragments (U-OC) and urinary concentrations of C-terminal telopeptides of type I collagen (α-CTX-I and β-CTX-I, indicative for resorption of native and aged type I collagen, respectively). All results were corrected for urinary creatinine. Bone mineral content was assessed by dual energy x-ray absorptiometry at the corrected age of 14 months.

U-OC was significantly higher ($p<0.001$) in preterm group compared with the full term group at all time points analyzed (D7-M6). Similarly, α-CTX-I concentration was significantly higher in preterm group from time point M2 to M6 (all $p<0.001$). β-CTX-I concentrations were similar in preterm and full term infants. In preterm infants, median U-OC concentration increased by two fold by M2 ($p<0.001$) and then started to decline, reaching the initial level by M6. Similar postnatal increase in median α-CTX-I concentration was seen in both preterm and full term groups by the age of one month. Bone mineral content at the age of 14 months did not differ between the two groups and there were no gender differences.

In conclusion, urinary OC and α-CTX-I concentrations reflect bone metabolism in infants and are suitable markers for serial monitoring of bone turnover in early postnatal life. Bone turnover, as assessed by urinary OC or α-CTX-I, was faster in preterm infants than in full term infants. Increased bone turnover in preterm infants resulted in normal bone mineral content by the age of 14 months.

Measuring Trabecular Density in the Peripheral Pediatric Skeleton: How Well Does pQCT Compare to QCT? Babette Zemel*[1], Keenan Brown[2], Soroosh Mahboubi[3], Rohama Khadija[4], Krista Whitehead[3], Mary Leonard[1]. [1]Children's Hospital of Philadelphia, USA, [2]Mindways Software, USA, [3]The Children's Hospital of Philadelphia, USA, [4]University of Texas, USA

Appendicular sites are preferred for QCT measures of trabecular density (TrabDen) in children due to lower radiation exposure compared with spine scans. However, open growth plates complicate reference line placement, and differences in TrabDen distribution along the metaphysis and changes in bone dimensions during growth present additional challenges. This study compared distal tibia TrabDen measured at a single 2.3 mm slice by peripheral QCT (pQCT, Stratec XCT 2000) vs. QCT TrabDen averaged across the entire distal metaphysis (Siemens Somatom Sensation, Mindways QCT Pro Software) taken at two study visits, 12$\pm$1 months apart.

Subjects (n=40, ages 9 to 21y) were participants in an ongoing blinded randomized control trial to treat low TrabDen in youth with Crohn disease. Tibia length was measured anthropometrically and from the QCT scan. Metaphyseal length (MetLength) was defined using density values along a central ellipse as the distance from the distal peak (just proximal to the growth plate) to the zero density point where trabecular bone was no longer detectable (see Figure). QCT TrabDen was calculated using a threshold of 450mg/cm^3 and averaged across the MetLength. pQCT TrabDen was measured at 3% from the proximal edge of the distal physis (threshold 600 mg/cm^3). Correlation analysis and paired t-tests were used for cross-sectional and longitudinal comparisons.

TrabDen by pQCT vs. QCT at baseline (r=0.76) and 12 months (r= 0.78) showed excellent agreement. Baseline vs. 12 month correlations for TrabDen were high and not significantly different for pQCT (r=0.68) and QCT (r=0.79), respectively. MetLength was consistent over time (r=0.77) and varied modestly as a function of tibia length and sex (p for interaction=0.03, overall R2=0.20). pQCT TrabDen (but not QCT TrabDen) was significantly associated with MetLength (r=0.33 & 0.42, for baseline and follow-up, respectively). pQCT Trabden increased significantly over 12 months ($p<0.01$) but not QCT TrabDen.

These findings demonstrate good agreement between a single slice 3% distal tibia pQCT TrabDen measurement and QCT TrabDen averaged across the entire metaphysis at multiple time points, and stability in both measures over time. However, longitudinal changes in pQCT TrabDen may be related to bone growth and re-distribution of trabecular bone along the MetLength. Further research is needed to optimize the use of pQCT in the assessment of TrabDen for bone health in children.

Systemic Biomarker Profiling of Metabolic and Dysplastic Skeletal Diseases Using Multiplex Serum Protein Analyses. Michael Whyte*[1], Deborah Wenkert[1], Denise C. Dwyer[2], David L. Lacey[2], Marina Stolina[2]. [1]Shriners Hospital for Children, USA, [2]Amgen Inc, USA

Understanding the etiology and pathogenesis of dysplastic and metabolic bone diseases has come from both genetic and biochemical investigation. Here, we describe our approach to systemic biomarker profiling using multiplex serum protein analyses to study age- and disease–mediated changes in healthy controls and patients as well as family members with these disorders.

The Research Center at Shriners Hospital for Children, St. Louis, Missouri, serves as a national referral center for inpatient diagnosis, treatment, and investigation of pediatric dysplastic, nutritional, and metabolic bone disorders where collection of fasting blood is routine. At Amgen (Thousand Oaks, California), Luminex-based, micro-bead, multiplex kits are used for osteopontin, osteocalcin, ligand of receptor activator NF-κB (RANKL), osteoprotegerin (OPG), fibroblast growth factor 23 (FGF23), matrix metalloproteinases (MMP 1, 3, 7, 8, and 13), and cytokine quantitation. ELISA kits are used for prostaglandin E_2 (PGE_2), bone-specific alkaline phosphatase (BAP), tartrate-resistant acid phosphatase (TRACP 5B), and collagen formation/degradation markers. Serum levels of sclerostin (SOST) and dickkopf (DKK1) were evaluated by custom ELISAs (developed at Amgen, Inc).

All sera were obtained after donors fasted at least 4 hours. To establish reference ranges, we studied 9 healthy children and 18 healthy adults (ages 6-60 yrs). MMPs (1, 3, 7, 8, and 13) correlated positively with age (R^2 0.26 - 0.64, $p<0.05$), whereas osteocalcin, BAP, c-terminal propeptide of collagen type I (CICP), and TRACP 5B correlated negatively (R^2 0.23 - 0.71, $p<0.05$). The patients represented 30 established and 14 unique diagnoses. Affected family members (dominant disorders) and obligate carriers (recessive disorders) were also studied, reflecting a total of 110 individuals. Our analyses revealed that serum concentrations of FGF23 were significantly increased in x-linked hypophosphatemia (XLH), TRACP 5B in osteopetrosis, and RANKL in juvenile Paget's disease, whereas decreases in BAP were documented for hypophosphatasia, validating our array strategy.

Hence, our multiplex serum protein analyses could reveal unique markers for specific bone disorders, and enhance understanding for a wide range of skeletal diseases.

To Asses the Incidence of Low Vitamin D Levels in Children with Osteogenesis Imperfecta and to Determine its Effect on Bone Healing and Number of Fractures. Antony Kallur*, Richard Kruse, Lauren Davey, Michael Bober. A.I. DuPont Hospital for Children, USA

Purpose: The prevalence of Vitamin D insufficency inchildren with OI is unknown.The aims of this study are to determine the correlation between low vitamin D level on bone quality and number of fractures. Low vitamin D levels in children with Osteogenesis Imperfecta negatively affects bone quality and increases fracture risk, requiring routine monitoring of vitamin D levels and supplementation.

Methods: We retrospectively reveiwed the medical records of patients on our database with diagnosis of Osteogenesis Imperfecta. All the patients with Vitamin D levels done were included in the study. We reveiwed the database and extracted the first ever value of Vit D assayed.

The treatment, number of fractures, surgeries and whether Bisphonates were used and complications were analysed.

Results: We had 61 patients who met our inclusion criteria. The average levels were 32.4ng/ml with 30 patients (50%) with levels less then 30ng/ml. 9 of the 61 patients had levels less then 20ng/ml (15%). The values ranged from 61ng/ml to 14ng/ml with a standard deviation of 11.66.

Conclusions: Children with O.I. have significant incidence of Vitamin D insufficency and defficency futher putting them at riskl for fractures. This has to be addressed when assessing and treating patients with OI.

Effects of Repetitive Loading on the Growth-Induced Changes in Bone Mass and Cortical Bone Geometry: A 12-Month Longitudinal Study in Pre- and Post-Menarcheal Tennis Players. Gaele Ducher*[1], Shona Bass[2], Leanne Saxon[3], Robin Daly[4]. [1]Penn State University, USA, [2]Deakin University, Australia, [3]Royal Veterinary College, United Kingdom, [4]The University of Melbourne, Western Hospital, Australia

Pre- and early-puberty may be the most opportune time to strengthen the skeleton, but there is little longitudinal data to support this claim. The aim was to study longitudinal growth and exercise-induced skeletal benefits relative to menarche in young female tennis players. Competitive players (n=45) aged 10-17 yrs were followed over 12 months. At baseline, 13 players were pre-menarcheal, of which 10 had menarche during follow-up (PRE/PERI). The remaining 32 players were post-menarcheal at baseline (POST). All players started playing tennis before menarche (mean 6.9 ± 1.9 yrs); PRE/PERI had similar training volume than POST (11 ± 5 vs. 12 ± 6 hrs/wk) but shorter playing history (5.7 ± 2.0 vs 7.5 ± 2.0 yrs, $p<0.05$). The osteogenic response to loading was studied by comparing the playing and nonplaying humeri for DXA BMC and MRI total bone area (ToA), medullary area (MedA), cortical area (CoA) and muscle area (MCSA) at the mid and distal humerus. Growth effects: Over 12 months, growth-induced gains (nonplaying arm) in BMC, ToA and CoA at the mid and distal humerus were greater in PRE/PERI (9-19%, $p<0.001$) than in POST (2-7%, $p<0.05$-0.001). There were no within group changes in MedA, with the exception that mid humerus MedA decreased in POST. Exercise effects: At baseline, BMC, ToA, CoA and MCSA were 7-19% greater in the playing vs. nonplaying arm in both PRE/PERI and POST ($p<0.001$); MedA was smaller in the playing vs. nonplaying arm in POST only ($p<0.05$). Over 12 months, these side-to-side differences increased further for mid ToA and CoA and distal ToA in PRE/PERI, and BMC, distal ToA and CoA in POST ($p<0.05$). When comparing the annual gains in the playing arm after accounting for the corresponding changes in the nonplaying arm, the increases in mid ToA, CoA, and MCSA were greater in PRE/PERI than POST ($p<0.05$). At both skeletal sites, the smaller the side-to-side differences in BMC and CoA at baseline, the larger the exercise benefits at 12 months ($r=-0.36$ to -0.48, $p<0.01$). Training parameters and exercise-induced changes in MCSA were not predictive of the exercise benefits in BMC, ToA or CoA. In conclusion, both pre- and post-menarcheal tennis players showed significant exercise-induced skeletal benefits within a year, but these benefits tended to be greater in pre-menarcheal girls. Accelerated rates of growth and smaller pre-existing bone asymmetries due to past training were associated with greater skeletal responsiveness to loading.

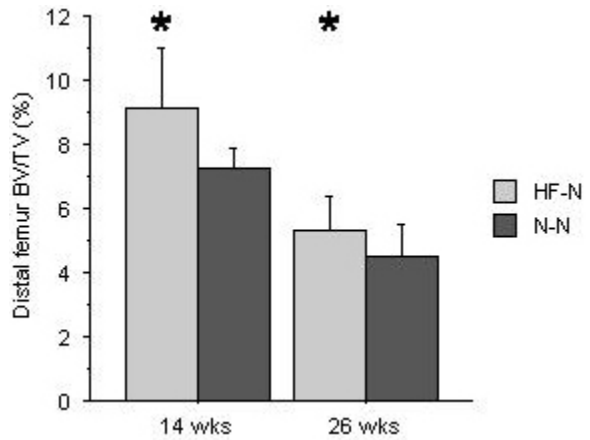
Maternal Perinatal Diet Induces Developmental Programming of Bone Architecture. Maureen Devlin*[1], Corinna Grasemann[2], Alison M. Cloutier[1], Mark R. Palmert[2], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]The Hospital for Sick Children, Canada

The discovery of complex interactions of bone, fat, and brain suggests that osteoporosis and obesity may share common origins. Prior work has shown maternal diet in gestation and lactation triggers developmental programming that raises metabolic disease risk, but potential skeletal effects are unknown. We hypothesize that maternal diet induces perinatal programming that alters postnatal skeletal acquisition, bone mass and strength. Given recent evidence for central hypothalamic mediation of skeletal homeostasis, we predict that such programming alters central regulation of bone mass. Methods: To test this hypothesis and establish a contribution of developmental programming to skeletal acquisition, we compared postnatal skeletal acquisition in pups from mothers fed high fat (HF, 45% kCal/fat) or normal (N, 18% kCal/fat) diet. Female (F) C57Bl/6J mice were fed N or HF diet ad lib. from 6 wks prior to breeding through gestation and lactation. At 3 wks of age we weaned F pups from HF mothers (HF-N) and N mothers (N-N) onto N diet ad lib. Outcomes at 14 and 26 wks of age included body mass, body length, %body fat, total body bone mineral density (BMD, g/cm^2) via pDXA, cortical (Ct) and trabecular (Tb) architecture at the midshaft and distal femur via μCT, and glucose tolerance. Results: At 14 and 26 wks of age, body mass, body length, %body fat and glucose tolerance did not differ in F HF-N vs. N-N. Total body BMD increased by 50% more in N-N vs. HF-N from 14-26 wks of age (+12% vs. +8%), suggesting impaired skeletal acquisition. Thus HF-N had 3% lower BMD at 26 wks and 5-9% lower BMC at 14 and 26 wks vs. N-N ($p<0.05$ for all). In the midshaft femur, Ct.Th was 6% lower in HF-N vs. N-N at 14 wks of age ($p<0.03$), but Ct.BA/TA (%) did not differ between HF-N and N-N at either timepoint. Most provocatively, in the distal femur, Tb.BV/TV (%) was 19-26% higher in HF-N vs. N-N F at 14 and 26 wks ($p<0.05$ for both). Conclusion: These data reveal complex effects of perinatal diet on postnatal skeletal acquisition. Female HF-N pups show lower bone acquisition from 14-26 wks of age, with lower Ct.Th at 14 wks of age, but higher distal femur Tb. bone volume vs. N-N at both timepoints. We propose that maternal HF diet may impair postnatal BMC acquisition in pups, but also slow age-related Tb. bone loss. Our data support the hypothesis that maternal diet alters postnatal skeletal homeostasis, and highlight the need for further work to identify the mechanisms involved.



Distal femur BV/TV (%)

Physical Activity is Associated with Increased Volumetric Bone Density and Bone Strength in Early Childhood. Zoe Cole*[1], Nick Harvey[2], Miranda Kim[2], Keith Godfrey[2], Hazel Inskip[2], Nick Wareham[3], Ulf Ekelund[3], Elaine Dennison[2], Cyrus Cooper[4]. [1]MRC Epidemiology Resource Centre, Southampton General Hospital, United Kingdom, [2]MRC Epidemiology Resource Centre, United Kingdom, [3]MRC Epidemiology Unit, United Kingdom, [4]University of Southampton, United Kingdom

Introduction: Both femoral geometry and bone mass have been shown to independently to predict both hip strength and fracture risk in adults. Whereas intrauterine and early postnatal life has been shown to influence bone mass, the relationship between hip geometry and strength is poorly understood. We therefore used a large prospective cohort study to explore the relationships between growth and lifestyle in early life and hip geometry, strength and volumetric density at 6 years old.

Methods: Children were recruited at 6 years old from the Southampton Women's Survey. Their mothers diet lifestyle and anthropometry had previously been characterised before and during pregnancy. The children underwent measurement of bone mass by DXA (Hologic), including hip structure analysis (HSA), and by pQCT at the tibia (Stratec). Physical activity (PA) was assessed by accelerometry (Actiheart, Cambridge Neurotechnology Ltd, Cambridge, UK) for 7 continuous days. Diet was assessed using a validated food frequency questionnaire and detailed anthropometric data was also collected.

Results: There were 215 children with PA data who underwent a DXA scan, of these 49 children also underwent pQCT assessment. Mean daily time spent in vigorous activity (VPA) was positively associated increased measures of volumetric BMD for whole body ($r=0.32$, $p<0.001$), lumbar spine ($r=0.16$, $p=0.02$) and hip ($r=0.15$, $p=0.03$). In the subset that underwent pQCT, VPA was positively related to cortical volumetric bone mineral density ($r=0.29$, $p=0.05$). Increased daily time in VPA was also positively associated with femoral neck and intertrochanteric section modulus ($r=0.23$, $p=0.001$; $r=0.23$, $p=0.001$ respectively), cross sectional area (CSA) ($r=0.26$, $p=0.0002$; $r=0.24$, $p=0.0009$) and cortical thickness ($r=0.17$, $p=0.02$; $r=0.19$, $p=0.009$). These relationships were independent of maternal and childhood dietary, lifestyle and anthropometric factors. Similar associations for VPA with section modulus ($r=0.17$, $p=0.02$) and CSA ($r=0.16$, $p=0.02$) were observed at the femoral shaft.

Conclusions: Higher levels of vigorous physical activity in childhood are associated with increased femoral neck strength, both in terms of geometric shape and volumetric mineral density. This work supports the notion that increasing physical activity in childhood is likely to be a potential public health strategy to improve childhood skeletal development and reduce the burden of osteoporotic fracture in later life.

Skeletal Deficits and Recovery in Methylphenidate Treated Rats. Michelle Mary*[1], Haden Janda[1], Christine Snearly[1], Winfred Abrams[2], Nora Volkow[3], Gene-Jack Wang[4], Lisa Robinson[4], Mala Ananth[4], Tim Wigal[5], James Swanson[5], Panayotis Thanos[4], Michael Hadjiargyrou[6], David Komatsu[1]. [1]InMotion Orthopaedic Research Center, USA, [2]University of Tennessee, USA, [3]Laboratory of Neuroimaging, NIAAA, NIH, USA, [4]Behavior Neuropharmacology & Neuroimaging Lab, Medical Dept. Brookhaven National Laboratory, USA, [5]Child Development Center, University California Irvine, USA, [6]State University of New York at Stony Brook, USA

Up to 9% of American youths are diagnosed with Attention Deficit Hyperactivity Disorder (ADHD), 90% of which are treated with methylphenidate (MP). This study examined the effects of MP in adolescent rats to test the hypotheses that long-term treatment is detrimental to skeletal development and cessation of treatment leads to recovery of normal skeletal characteristics.

Four-week old male Sprague-Dawley rats were randomized to 3 groups (n=24/grp): low-dose (MP low), high-dose (MP high), and vehicle (Veh). MP was administered daily via drinking water with MP high and MP low rats receiving 30 or 4 mg/kg, respectively, for 1 hour followed by 60 or 10 mg/kg, respectively, for 1 hour. Veh rats received water with no MP. After 3 months, half of the rats (n=12/grp) were sacrificed. The remaining rats (Recovery) were taken off treatment and sacrificed 5 weeks later. Femora and tibiae were harvested for: DXA determination of BMD, BMC, and area; caliper measurements of length, anterior-posterior (AP) and medial-lateral (ML) diameter; and 3-point bending tests for energy to failure (EF), stiffness (SF), and ultimate force (UF), as well as histologic and gene expression analyses. Serum was also collected for biomarker analyses. One-way ANOVA and Dunnett's tests were used to identify significant differences ($p<0.05$).

Weight gain during treatment in MP high rats was 15% less than Veh rats. Femoral and tibial BMD and BMC were lower in MP high compared to Veh (femur: 6% & 9%; tibia: 5% & 9%, respectively). In addition, femoral AP diameter was smaller in MP low (5%) and MP high (9%) as compared to Veh. Biomechanically, EF was lower in MP low (25%) and MP high (31%) compared to Veh, and UF was 14% lower in MP high. In the Recovery rats, none of these parameters were significantly different. Serum ALP was 31% higher in MP high rats compared to Veh, and similarly elevated in Recovery rats.

In summary, MP treatment resulted in less weight gain and weaker, less mineralized, smaller bones, particularly at high doses. However, these effects were ameliorated within 5 weeks. Higher serum ALP in MP high rats suggests increased osteoblast activity, but bone specific ALP remains to be quantified. Also, ongoing experiments to assess osteoclast activity, histology, and gene expression need to be completed to determine how MP impairs skeletal development. Clinically, these data suggest that adolescents treated with high dose MP may have weaker bones and an increased fracture risk.

The Lifetime OsteoGenic Exercise Score: A Method to Estimate Bone Status in Young Adult Women. Tara Dahn, Jo Welch*. Dalhousie University, Canada

A simple tool to predict bone status would have both clinical and public health applications. Furthermore, if bone status was known to women when they were young adults, early adoption of lifestyle choices that favor better bone health could minimize future age-related bone deterioration. The purpose of the study was to develop a tool based on exercise history to predict the category of bone status in young adult women. For this study, 80 non-smoking women, aged 18-25, mean height, 67 cm, mean weight 63 kg, were recruited. They completed a simple questionnaire that included their exercise history and age at menarche. A Lunar Achilles InSight bone ultrasonometer was used to measure Stiffness Index (SI) at the calcaneus. An equation that could quantify impact loading from exercise was then developed. The Lifetime OsteoGenic Exercise Score (LOGES) uses the following formula to score each exercise reported in an exercise history questionnaire: LOGES = $(AR^2*D*F*M)/ [(YS/2)+1]$, where AR = activity rating; activities were divided into 5 categories based on published effects on bone, D = duration of participation (y), F = frequency of participation (hr/wk), M = developmental period multiplier, based on whether activity occurred before, during or after puberty, and YS = years since cessation of activity (y). The score for each exercise activity was then summed to provide a total score for each subject. Subjects were ranked by their total scores. The list of ranked subjects was then partitioned into five equal groups, based on activity levels, which resulted in mean SI per group of 99.8, 105.9, 108.2, 110.5, and 114.3. The relationship between group mean activity level and SI was strong ($R^2 = 0.96$). To test the reliability of the scoring system, 8 people unfamiliar with exercise and bone health were provided with 5 minutes of verbal explanation and a short written description of the scoring system. Each novice rater then scored the same 5 randomly selected subjects from their initial questionnaires. The Pearson's correlation coefficient for inter-rater reliability was R = 0.996. In conclusion, the LOGES system enabled the classification of young women into categories of bone status based on exercise and pubertal history. This system of estimating bone status is reliable and offers a method to screen young women, who rarely receive bone tests, for bone status.

IBD Causes Greater Bone Loss in Male Compared to Female Mice. Regina Irwin, Laura McCabe*. Michigan State University, USA

Inflammatory bowel disease (IBD) is the most common chronic gastrointestinal disease in the United States. Nearly 1.4 million males and females are affected with one of the two major forms of IBD which are Crohn's disease and ulcerative colitis. One complication of IBD is bone loss. Purpose: To examine the influence of gender on IBD induced bone loss. Method: *Helicobacter hepaticus* was used to induced IBD in male compared to female IL-10 knockout mice. This model effectively simulates Crohn's disease. Mice, at 14 weeks of age, were gavaged with bacteria and after 6 weeks bone parameters were examined. Results: Both sexes experienced significant decreases in bone parameters, however, the losses were less in females. Specifically, IBD decreased bone mineral content and denisty by 26% in males, but only by 15% in females. Similarly, IBD caused a decrease in bone volume fraction and trabecular thickness, by 37% and 19%, in males and only by 16% and 10% in females. In contrast, osteocalcin expression in bone was reduced to a similar extent (50%) in both males and females. Histomorphometry demonstrated similar changes in osteoblast and osteoclast numbers in male and female mouse bones. Conclusion: Our findings suggest that the female skeleton is partially protected from IBD induced bone loss. A potential beneficial role for estrogen is currently being investigated.

PTH Increases and Serum NTX is Associated with Maternal Bone Loss in Pregnant Adolescents. Bridget Essley*[1], Allison McIntyre[2], Beth Cooper[2], Thomas McNanley[2], Tera Kent[1], Frank Witter[3], Z. Leah Harris[3], Kimberly O'Brien[1]. [1]Cornell University, USA, [2]University of Rochester Medical Center, USA, [3]Johns Hopkins University, USA

Bone turnover increases during pregnancy and a net loss of bone can occur over the course of pregnancy. Pregnant adolescents may be at increased risk for bone loss as the calcium (Ca) demands of the developing fetus are added to the demands of adolescent growth. Pregnant teens are also at increased risk for insufficient Ca intakes and vitamin D insufficiency. To assess the relationships between vitamin D status, parathyroid hormone (PTH), and Ca intake on maternal bone health across gestation, pregnant adolescents ($\leq$ 18 y) were recruited at $\geqslant$ 12 weeks of gestation and followed at 3 points across pregnancy (at approximately 16, 25 and 34 wks gestation). At each visit an ultrasound of the calcaneus was performed and a 24-hr dietary recall and FFQ were obtained. Blood samples were collected at mid-gestation (25.3 $\pm$ 3.4 weeks) and maternal and cord blood were obtained at delivery (39.2 $\pm$ 2.8 weeks). 25(OH)D, intact PTH, osteocalcin (OC: a marker of bone formation) and N-telopeptide (NTX: a marker of bone resorption) were measured in all blood samples. Teens were 17.1 years of age at entry into the study (n=141). Vitamin D insufficiency (25(OH)D $\leq$ 20 ng/mL) was found in 49% of teens at mid-gestation, 48% at delivery, and 46% of neonates were D insufficient at birth. In adolescents, 25(OH)D was inversely related to PTH at mid-gestation (p=0.034, n=93) and delivery (p=0.066, n=76). PTH increased across gestation ($p<0.05$, n=76) and was elevated (PTH $\geqslant$ 46 pg/mL) in 13% of teens at mid-gestation (n=93) and 32% of teens at delivery (n=81). Ca intake averaged 874 $\pm$ 379 mg/day (recall) and 975 $\pm$ 484 mg/day (FFQ) and was not related to PTH or changes in maternal calcaneus measures. Markers of bone turnover increased across gestation and the increases in OC and NTX per week were positively correlated (p=0.002, n=57). The average change in ultrasound bone measures were negative (n=120) indicative of maternal bone loss across gestation. The increase in NTX per week was positively associated with changes in bone ultrasound measures (SOS, QUI, BMD; $p<0.05$, n=94). This population exhibited a high prevalence of vitamin D insufficiency, net loss of maternal bone across gestation and unexpected increases in PTH across gestation. Calcitriol analyses are underway and a model will be constructed to elucidate the main determinants of maternal bone loss and fetal bone growth in this population of pregnant adolescents.

Acute Mandibular Lesion in a 12 year old Girl with McCune Albright Syndrome and Fibrous Dysplasia. Nancy Dunbar*[1], David Ebb[2], Ksenia Tonyushkina[3], Thomas Carpenter[4], Leonard Kaban[2]. [1]Baystate Medical Center, USA, [2]MassGeneral Hospital for Children, USA, [3]Baystate Children's Hospital, USA, [4]Yale University School of Medicine, USA

McCune Albright Syndrome (MAS) is caused by activating, somatic mutations of GNAS, resulting in fibrous dysplasia (FD) of bone, café-au-lait skin markings and precocious puberty. Only two mutations have been reported in MAS (commonly, at R201 and also at Q227). No genotype/phenotype correlations are known. Fibrous dysplasia in MAS can be severe, causing significant disfigurement, pain and restriction of function. Uncommonly, aggressive cystic lesions arise, usually in the craniofacial area, and are associated with disfigurement and pain. These lesions have been shown to produce excessive amounts of FGF23.

We report a 12 year old girl with MAS, severe polyostotic fibrous dysplasia, and a 5x5cm mandibular lesion, which had acutely expanded in one week. The superior aspect of the lesion was bony to palpation but ballotable inferiorly; the overlying skin was yellowed. The lesion stabilized after 10 further days and the pain remitted. Radiographic studies revealed an expansile lesion with fluid-fluid levels eroding through the inferior cortex of the mandible (see images below). Widespread fibrous dysplasia occurred throughout the mandible and skull base. Bone pain had been treated during the previous year with intravenous pamidronate at 3-month intervals, last administered 10 weeks prior to the observation of the lesion. Of interest, an acutely expanding lesion involving her right orbit led to surgical excision in Kyrgystan at age 7.

During the preceding several months, serum alkaline phosphatase activity increased from 513 to 686 IU/L, circulating PTH increased from 31 to 60 pg/ml, and circulating 1,25(OH) decreased from 64 to 24 pg/ml. Serum 25-OHD, calcium and phosphorus levels were stable within the normal range. Surgical enucleation of the mandibular lesion was performed. Gross inspection was consistent with an aneurysmal bone cyst. Histopathology and pre/post-operative serum FGF23 levels are pending. Treatment with interferon to stabilize the vasculature is under consideration pending the histopathology.

This case presents the clinical course and therapeutic response to an aggressive cystic lesion in the mandible of a 12-year-old girl with severe MAS/FD presumed to be an aneurysmal bone cyst. The role of FGF23 in the pathogenesis of acute cystic lesions in FD, and the role of interferon in their treatment are currently unknown.

SA0019

Bone Health in Children with Neurofibromatosis Type 1 - a High Incidence of Abnormal Vertebral Morphology and Altered Skeletal Geometry. Peter Simm*[1], Julie Briody[2], Aaron Schindeler[2], Christopher Cowell[2], David Little[2], Kathryn North[2], Craig Munns[2]. [1]Royal Children's Hospital, Melbourne, Australia, [2]The Children's Hospital At Westmead, Australia

There is increasing evidence that some young people with Neurofibromatosis Type 1 (NF1) have an abnormal bony phenotype, however this is yet to be fully characterized. We performed a bone health assessment on 23 patients with NF1 (11 female) aged between 5 and 16 years (mean age 9.5 yrs).

Results showed that this is a highly heterogenous group, however there is a subgroup who have an abnormal bone phenotype. Dual energy absorptiometry (DXA) scanning showed a mean lumbar spine bone mineral density (BMD) Z score of 0.1 SD (corrected for height), with a wide spread (+/-1.43).

Peripheral quantitative computerised tomography (pQCT) showed a distinct phenotype, with the mean results showing a low trabecular BMD (-0.89 SD, +/-0.61, p <0.001) at the 4% site and reduced bone area (-0.73 SD, +/-1.31, p = 0.02), cortical thickness (-0.51 SD, +/- 0.81, p = 0.009) and a trend towards reduced stress strain index (-0.38 SD, +/- 1.15, p = 0.14), but normal cortical BMD (0.65 SD, +/-1.23, p = 0.03), at the 66% site of the tibia. Muscle cross sectional area was also reduced (-0.63 SD, +/- 1.06, p = 0.01) which may be contributing to the observed skeletal geometry.

Of the 21 patients who had spinal Xrays, 7 (33%) had significant anterior wedge deformity by Genant criteria with greater than 15% loss of anterior height compared with posterior height, predominantly in the mid thoracic region. A further 4 patients had abnormal shaped vertebrae without meeting the Genant criteria. Therefore over 50% of our patients showed vertebral body changes. The significance of these findings is unclear as there was no correlation between low BMD on DXA scan and vertebral changes. Whether the vertebral changes reflect bone weakness and fragility, or rather dysplasia, remains to be determined.

Metacarpal index was reduced (1.91, N >2.0), with 8 pts (35%) having a score less than 1.75. 4 patients had a vitamin D level of <50 nmol/L, despite no patients having established risk factors for Vitamin D deficiency. Only 3 patients reported a previous fracture. The subjects had mean height Z score of -0.4 SD but had increased body mass index Z score (0.4 SD).

Our results confirm that there is a subset of patients with NF1 who have an abnormal bone phenotype. We plan to follow our cohort longitudinally to obtain data on prospective incidence of fracture and to follow the vertebral body changes in the more severely affected individuals.

Impact of Weight Gain on Bone Mineral Content in Adolescents with Type 1 Diabetes. Sowmya Krishnan*[1], Brianna Bright[2], Mary Murray[3], Kenneth Copeland[2], David Fields[2]. [1]The University of Oklahoma Health Sciences Center, USA, [2]University of Oklahoma health science center, USA, [3]University of Utah, USA

Background: Lower spine and whole body bone mineral content (BMC) has been reported in adolescents with type 1 diabetes, while overweight status in adolescents without diabetes has been shown to be associated with higher BMC. It is not known if being overweight is protective for the bones of adolescents with type 1 diabetes. The following is a cross sectional study examining the influence of weight status on BMC in overweight and normal weight adolescents with type 1 diabetes.

Methods: A total of 31 adolescents with type 1 diabetes (HbA1c range 6.5% to 10.7% with a mean of 8.5%) participated in the study. All were Tanner stage 3 or above. 16 were overweight (mean BMI = 28.3 $\pm$ 3.6) and 15 were normal weight (mean BMI = 20.6 $\pm$ 2.0). All adolescents underwent a whole body DXA scan (Hologic QDR 4500, Waltham, MA). Additionally 21 wore a step activity monitor and 18 completed a detailed 4-day food recall.

Results: Adolescents with type 1 diabetes who were overweight had higher total BMC and subtotal BMC than adolescents with type 1 diabetes who were normal weight, though this difference did not reach statistical significance (p=0.0692 and 0.0594 respectively). As expected, both total BMC and subtotal BMC correlated significantly with age (r=0.55, p=0.0014 and r=0.50, p=0.0038 respectively). BMC measures (both total and subtotal) did not significantly correlate with any other variables, including physical activity measures (total steps/day, sedentary time/day) or vitamin D and calcium intake.

Conclusion: Overweight adolescents with type 1 diabetes had higher total and subtotal BMC values compared to normal weight adolescents with type 1 diabetes, indicating a similar relationship of BMC to overweight and normal weight status as that reported in non-diabetic adolescents. These observations pertain to adolescents with relatively well-controlled type 1 diabetes; whether they can be generalized more broadly to all diabetic patients regardless of glycemic control remains to be demonstrated.

Paternal Deletion of the GNAS Imprinted Locus in a Girl Presenting with AHO, Severe Obesity and ACTH-independent Adrenal Hyperplasia. Caroline Kannengiesser[1], Stéphanie Maupetit-Méhouas[2], Sabine Rouleau[3], Régis Coutant[3], Agnes Linglart[4], Caroline Silve*[5]. [1]Assistance Publique-Hôpitaux de Paris; Université Paris 7. Hôpital Bichat Claude Bernard, Service de Biochimie hormonale et génétique, France, [2]INSERM U986, France, [3]Department of Pediatric Endocrinology, University Hospital, France, [4]INSERM U986; Assistance Publique-Hôpitaux de Paris. Endocrinologie-diabétologie pédiatrique et Centre de référence des maladies rares du métabolisme du calcium et du phosphore, Hôpital St-Vincent de Paul, France, [5]INSERM Unit 986, France

Diseases due to GNAS genomic or epigenomic alterations include : 1. pseudohypoparathyroidism (PHP) 1a characterized by Albright Hereditary Osteodystrophy (AHO) with multi-hormonal resistance due to maternally inherited Gsa loss of function (LOF) mutations; 2. pseudoPHP, characterized by AHO without hormonal resistance due to paternally inherited Gsa LOF mutations; 3. PHP1b usually presenting with selective PTH resistance without AHO due to maternal epimutations of the GNAS differentially methylated regions (DMRs); and 4. McCune-Albright syndrome characterized by hyperplasia and increased function of endocrine glands, including the adrenal, due to somatic Gsa gain of function mutations. Patients with Gsa LOF mutations usually present with ectopic mineralization, which are more severe when the mutation are paternally inherited. We investigated a girl who presented with AHO, no ectopic ossification, severe obesity (as in PHP1a), no hormonal resistance (as in PPHP), bilateral adrenal hyperplasia and increased function (as in McCune Albright) as indicated by hirsutism, amenorrhea, acne, elevated circulating androgens (testosterone, SDHA) and elevated cortisol cycle albeit normal urinary cortisol and no Cushing syndrome. She was the only child born to healthy parents. Systematic sequencing of the GNAS coding exons 1 to 13 did not show any mutation nor heterozygous polymorphism. Methylation analysis of the GNAS DMRs using enzymatic digestion after bisulfite treatment or methylquantification showed a maternal pattern of methylation of the entire GNAS locus. Genome wide CGH-array analysis (Nimblegen 12*385K) demonstrated the presence of a ~1.575 Mb genetic deletion encompassing the entire GNAS locus. The deletion was confirmed by allelic quantification of genomic DNA; microsatellites analysis of the parents and proband DNAs demonstrated the paternal origin of the deletion. In summary we describe a new case of constitutional paternal deletion of chromosome 20 encompassing the entire GNAS locus and associated with a paradoxical phenotype. While the short stature and the bone features defining AHO are likely due to Gsa haploinsufficiency, the mechanisms leading to the severe obesity and adrenal gland bilateral hyperplasia need to be elucidated. Because a defect in none of the genes included in the deleted genetic interval are likely to be associated with the phenotype, it is tempting to speculate that the absence of XLS and/or AB and AS transcript expression due to the paternal deletion contributes to the phenotype.

Evidence of Metabolic Bone Disease in Young Infants with Multiple Fractures Misdiagnosed as Child Abuse. Chuck Hyman[1], Marvin Miller[2], David Ayoub*[3]. [1]Pediatrician, USA, [2]Wright State University Boonshoft School of Medicine, USA, [3]Clinical Radiologists, SC, USA

Purpose: Assess the presence of clinical and evidence of metabolic bone disease in young infants presenting with multiple unexplained fractures (MUFs) undergoing an investigation for child abuse.

Methods: We have evaluated the radiographs and pertinent medical records of 40 infants with MUFs and their mothers for signs and risk factors of impaired bone metabolism.

Results: The average age of presentation was 12.6 $\pm$ 9.0 weeks (range 2-52). Twelve of thirteen (92.3%) mothers tested had subnormal 25OH vitamin D. Ten were deficient (<20 ng/ml) and two within the insufficient (<30 ng/ml) range. Ten of seventeen (58.8%) infants had subnormal 25OH vitamin D. Most infants with normal vitamin D levels were tested many weeks after presentation and had been supplemented. Twenty-seven mothers (68%) had 2 or more risk factors for VDD. There was evidence of decreased fetal bone loading in 17/40 (43%) pregnancies. Twenty percent of women had gestational diabetes. Acid lowering drugs which can decrease calcium absorption were used in at least 16 (40%) mothers while pregnant and in 11 (27.5%) of infants.

There were 14.1 $\pm$ 9.0 fractures, including classic metaphyseal lesions (CMLs), per infant (range 3-47). One hundred eighty-nine CMLs were encountered in 37 infants (5.1 per infant; range 0-15). Epiphyseal separations were suspected in 5.8% of CMLs. All other CMLs were clinically silent and healed without callus or periosteal reaction. Multiple rib fractures were seen in 33 infants (7.8 per infant; range 2-20). Infants had at least one non-CML fracture at these sites: skull (20.0%), which was always linear and usually diastatic, clavicle(32.5%), thoracolumbar spine(17.5%), appendicular diaphysis (40.0%) or metaphysis (15.0%), scapula (5.0%), and small bones of hands/feet (20.0%). All infants displayed multiple radiographic signs of metabolic bone disease (Table 1).

Conclusions: This study reports a large series of infants with MUFs who had clinical and radiographic evidence of metabolic bone disease likely of multifactorial etiology overlooked during an investigation for child abuse. While metabolic bone disease is a

known cause of increased bone fragility and MUFs, its differentiation from inflicted or accidental injury remains challenging. Careful review of the radiographs with attention to the unappreciated signs or risk factors that impair fetal and infant bone mineralization is critical to avoid an erroneous diagnosis of child abuse and its consequences.

Table 1. Radiographic signs* in 40 infants with MUFs

radiographic sign	n	%
metaphyseal hypermineralization	38	95.0%
metaphyseal clubbing	37	92.5%
calvarial mineralization defects	31	77.5%
trabecular thickening	30	75.0%
bowing deformity of lower leg	30	75.0%
ulnar cupping	24	60.0%
rachitic rosary	23	57.5%
periosteal neostosis	19	47.5%
subperiosteal resorption	18	45.0%

New Case of Infantile Generalized Arterial Calcification: Evolution from Prenatal Diagnosis to 12 Months of Age under Bisphosphonates' Therapy. Thomas Edouard*[1], Nathalie Alos[2], Joaquim Miro[1], Chantal Lapierre[1], Jacques Michaud[1], Gilles Chabot[3]. [1]CHU Sainte-Justine - Université Montréal, Canada, [2]CHU Sainte Justine, Canada, [3]Hopital Saint Justine, Canada

Background: Generalized arterial calcification of infancy (GACI, OMIM 208000) is a rare autosomal recessive disease characterized by extensive calcification of large- and medium-sized muscular arteries. The diagnosis is prenatal or in early infancy, with variable clinical presentations including heart failure, hypertension or failure to thrive. This disease is linked to mutations in the ENPP1 gene which encodes an enzyme that generates inorganic pyrophosphate (PPi), a potent inhibitor of hydroxyapatite crystal formation. Treatment with bisphosphonates, which are synthetic PPi analogues, has been proposed as a means to reduce arterial calcifications in GACI patients. GACI has been reported to be frequently lethal, and the efficiency of any therapy, including bisphosphonates, remains unknown.

Case report: We report on a girl who was diagnosed prenatally at 32 weeks gestation with GACI when a routine fetal ultrasonographic examination revealed arterial calcification and pericardial effusion. The parents were healthy and non consanguineous without relevant family history. The newborn baby was born by vaginal delivery at 364/7 weeks gestation with normal birth weight and length but no pulses were palpable. Secondary to pericardial effusion, he developed mild respiratory distress in the first hour of her life and required pericardial fluid drainage and respiratory support for 6 days. Ultrasonographic and tomodensitometric evaluations confirmed diffuse arterial calcification that involved the coronary, main and branch pulmonary and aorta arteries. Mutational screening demonstrated mutations in ENNPP1 gene, which correspond to c.583T/C.

Evolution: Intravenous disodium pamidronate (3 infusions at days 8, 15, 18 of 0.25mg/kg, 0.50 mg/kg and 0.50mg/kg respectively) was changed to oral disodium etidronate (starting dose of 20 mg/kg daily: 50 mg die) at 3 weeks of age. Follow-up included 3-monthly clinical reviews and assessments of mineral homeostasis, 6-monthly DEXA, ultrasonography and tomodensitometric studies, and annual x-rays of the wrists and knees. Progressive resolution of arterial calcifications was seen by 3 months of age and etidronate dosage was kept at 50 mg daily. At 12 months, under 6mg/kg of etidronate, growth and development, serum mineral homeostasis and areal bone mineral densitometry of the lumbar spine remained normal. X-rays of the wrist and knees didn't show any sign of rickets.

The Use of Intravenous Bisphosphonate Therapy to Treat Vertebral Fractures due to Osteoporosis among Boys with Duchenne Muscular Dystrophy. Anne Marie Sbrocchi*[1], Frank Rauch[2], Pierre Jacob[1], MaryAnn Matzinger[1], Leanne M. Ward[1]. [1]University of Ottawa, Canada, [2]McGill University, Canada

Purpose: Boys with Duchenne Muscular Dystrophy (DMD) are at risk for vertebral fractures. Bisphosphonates have been used to treat the spine fragility; however, detailed analyses of the response to therapy are lacking. The objective of this study was to assess the efficacy and safety of IV bisphosphonate treatment for painful vertebral fractures among boys with DMD.

Methods: This was a one-year, retrospective observational study of 7 boys (age 7.9-14.0 years) with DMD who had received either IV pamidronate (9 mg/kg/year) or zoledronic acid (0.1 mg/kg/year) to treat painful vertebral fractures. The co-primary outcomes were back pain status and change in vertebral morphometry (with categorization as per the Genant score) at 12 months post-bisphosphonate initiation. Changes in vertebral heights were deemed to be statistically significant if they exceeded the Least Significant Change at the 99% confidence level. Secondary outcomes included development of new vertebral fractures, changes in lumbar spine areal bone mineral density (BMD), and adverse events.

Results: A description of the cohort at baseline and 12 months is presented in the Table. Pubertal development was Tanner stage 1 (n=6), and Tanner stage 2 (n=1). All but one boy had received glucocorticoids prior to treatment initiation (average cumulative steroid exposure per patient 16,058 mg/m^2 in prednisone equivalents), and only one was fully ambulatory. There were 27 fracture events noted in the 7 patients at baseline; 3 fractures in 1 patient, 2-4 in 2 patients and >5 in 2 patients. Of the 27 fracture events, 14 improved, 11 stabilized and 2 deteriorated (30% to 37% and 15% to 32% loss in vertebral height). All but one Grade 2 (moderate) and Grade 3 (severe) vertebral fractures improved (n=11) or stabilized (n=6) at 12 months. There were 3 new Grade 0.5 fractures in 2 boys apparent after 1 year of therapy. Back pain either resolved completely (n=4) or improved (n=3). The mean ± SD spine BMD also increased (see Table). First-dose side effects were present in 4 patients and included fever and malaise (N=4), and hypocalcemia (N=2).

Conclusion: In boys with spinal osteoporosis and DMD, IV bisphosphonate therapy administered over 12 months was associated with improvements not only in spine BMD, but also in the more clinically relevant back pain and vertebral morphometry. The therapy was generally well-tolerated.

Clinical Characteristics	Results 12 Months Post Bisphosphonate Initiation (N=7)

***In vivo* Microstructural Quantification of Finger Joints using High-Resolution pQCT.** Christoph Kolling[1], Kathryn S Stok*[2], Thomas L Mueller[2], Ralph Müller[2], Jörg Goldhahn[2]. [1]Schulthess Clinic, Switzerland, [2]ETH Zurich, Switzerland

Fingers are a primary target of destructive processes like rheumatoid arthritis (RA) leading to bony erosions, destruction of the subchondral bone and local osteopenia, and results in loss of hand function. Evaluation of treatment success is limited to measures such as counting of swollen joints or scoring of X-rays. In contrast, high-resolution peripheral quantitative computed tomography (HR-pQCT) can detect small changes in bone microarchitecture and is established for analysis of peripheral joints in vivo (distal tibia and radius). High-resolution structural measurements of finger joints, however, have not been performed to-date. The goal of this study was to quantify structural parameters in finger bones from a group of healthy volunteers, and to correlate this with established parameters at the ipsilateral radius.

A group of 19 healthy volunteers (aged 39 to 69) underwent clinical assessment to ensure the absence of any systematic disease. HR-pQCT measurements (Scanco Medical AG) in conjunction with a fixation device (Pearltec AG) were performed at the metacarpal-phalangeal (MCP) and proximal interphalangeal (PIP) joints of the right hand (Fig 1a) with an isotropic nominal resolution of 82 μm. Two volumes of interest were defined; the trabecular bone of the epiphyseal region, and the cortical shell surrounding it (Fig 1b). Morphometric parameters were computed, and Wilcoxon Rank-Sum and Spearman correlation coefficient were used to test statistical relationships.

Significant differences were seen for all parameters between fingers and between joint parts for average bone density, D100, and cortical thickness, Ct.Th. In the MCP, D100 and Ct.Th increased in the distal region. From finger 2 to 3 to 4, D100 decreased in the MCP and increased in the PIP. Strong correlations were observed in finger joints between the proximal and distal aspects, and strong correlations were also found between the fingers themselves. Finally, the ipsilateral radius correlated weakest to finger 2, and strongest to fingers 3 and 4, especially in the PIP distal region.

In conclusion, the data show distinct structural relations between joint parts, between joints of the same finger, and within the same region of different fingers. These findings indicate that HR-pQCT has the potential for analysing structural changes in small finger bones with the onset of RA. The healthy cohort will now be used as a normative database for examining subchondral bone changes with the onset of RA.

Agreement between pQCT and DXA-derived indices of bone geometry, density and theoretical strength in females of varying age, maturity and physical activity. Portia Flowers*[1], Jodi Dowthwaite[2], Rebecca Hickman[1], Tamara Scerpella[3]. [1]SUNY Upstate Medical University, USA, [2]State University of New York, Upstate Medical University, USA, [3]State University of New York Upstate Medical University, USA

Purpose

DXA is commonly used to assess bone but does not specifically measure cross-sectional geometry, compartmental density or skeletal strength. Indices of bone geometry and strength can be derived from DXA output (Sievanen 1996). Previously, we used pQCT as a standard to validate these DXA-derived indices in post-menarcheal females (Dowthwaite 2009). In the current study, we validate these indices across a broader maturational range.

Methods

Contemporaneous pQCT and DXA scans of the distal radius were performed in 97 females, aged 8.0 to 22.8 yrs, mean=15.1 yrs (premenarche n=42; postmenarche n=55). Ultradistal (UD) and 1/3 DXA indices were compared to 4% and 33% pQCT results, using Pearson correlations and mean differences (Bland-Altman plots). The original Sievanen formulae were modified to improve inter-method agreement for UD output.

Results

DXA and pQCT indices were significantly positively correlated with stronger correlations at 1/3 (R=0.85–0.93, $p<0.001$) than at UD (R=0.64–0.97, $p<0.001$). At UD, all DXA indices exceeded pQCT measures except periosteal cross-sectional area (CSA). At 1/3, DXA indices exceeded pQCT measures for all CSA indices. DXA indices were lower than pQCT results for bone mineral apparent density (BMAD), cortical thickness, section modulus, and fall strength ratio. Inter-method agreement was only affected by maturity level for UD BMAD and fall strength; DXA vs. pQCT differences were positive premenarche and negative postmenarche.

Conclusion

Across a broad age and maturity range, DXA-derivations for the distal radius yield useful indices of bone geometry, density and strength, providing a valuable supplement to traditional DXA assessments of the distal radius during growth.

Comparison between Clinical Diagnostic Tools and QCT-based Finite Element Models for Predicting Human Vertebral Apparent Strength In Vitro. Enrico Dall'Ara*[1], Dieter Pahr[1], Peter Varga[1], Franz Kainberger[2], Philippe Zysset[1]. [1]Vienna University of Technology, Austria, [2]Medical University of Vienna, Austria

Vertebral fracture is a common medical problem in osteoporotic individuals. Bone Mineral Density (BMD) is nowadays the gold standard to evaluate fracture risk *in vivo*. Quantitative computer tomography (QCT)-based finite element analysis (FE) may be an attractive method to predict vertebral strength. The aim of this study was to compare the ability of FE and clinical diagnostic tools to predict vertebral strength *in vitro* using an improved testing protocol.

Soft tissues and endplates were removed from 37 vertebral bodies (level T12-L5, gender 7M-3F, age 44-82). The obtained sections were scanned with QCT (0.39x0.39x0.45 mm^3) and the images calibrated with a phantom. Bone mineral content (BMC), total BMD (vBMD), areal BMD from lateral (aBMD-lat) and anterior-posterior (aBMD-ap) projections were evaluated. Wedge shape fractures were then induced in each section with a novel testing setup [1]. FE models were generated from QCT images coarsened to 1.3^3 mm^3 by converting voxels directly to hexahedral elements. The boundary conditions were well controlled during the test and accurately reproduced in the models. For both experiments and nonlinear FE, both strength (defined as maximal load: Exp_FM and FE_FM) and apparent strength (defined as maximal load divided by mean cross section area: Exp_App_FM and FE_App_FM) were computed. Density-based (vBMD) and mass-based (BMC) measurements were used to predict Exp_App_FM and Exp_FM, respectively. FE and mixed variables (aBMD-ap and aBMD-lat) were used to predict both.

FE was found to better predict Exp_App_FM and Exp_FM (R^2=0.80 and R^2=0.79) than diagnostic tools (Exp_App_FM: R^2=0.74 for vBMD, R^2=0.41 for aBMD-lat and R^2=0.48 for aBMD-ap; Exp_FM: R^2=0.70 for BMC, R^2=0.67 for aBMD-lat and R^2=0.63 aBMD-ap). In particular, prediction of Exp_App_FM with FE was quantitatively correct without fitting and significantly better than the ones found for aBMD-ap and aBMD-lat (Fischer's z-test: $p<0.01$ for both).

Due to the normalization with area that accounts for bone dimension, Exp_App_FM may be the most relevant parameter for vertebral fracture risk. It should also be emphasized that our aBMD measurements were free of the artifacts that are usually generated by the posterior elements and iliac crest during standard DEXA. Nevertheless, it remains to be tested if significantly improved FE prediction of vertebral strength enhances significantly the determination of vertebral fracture risk.

CT-based Structural Rigidity Analysis Can Alter the Course of Treatment in Patients with Skeletal Metastasis. Brian Snyder*[1], Ara Nazarian[2], Vahid Entezari[3], John Hipp[4], Nathan Calderon[5], Richard Terek[6], Edward Cheng[7], Albert Aboulafia[8], Megan Anderosn[3], Mark Gebhardt[3], Timothy Damron[9]. [1]Children's Hospital BostonHarvard Medical School, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]BIDMC, USA, [4]Baylor College of Medicine, USA, [5]UT Austin, USA, [6]Brown University, USA, [7]University of Minnesota, USA, [8]Sinai Hospital, USA, [9]State University of New York Upstate Medical University, USA

The skeleton is the 3rd most common site of metastatic cancer, and a third to half of all cancers metastasize to bone. Clinicians make subjective assessments regarding fracture risk using clinical guidelines now recognized to be inaccurate. We have developed and validated a CT-based structural rigidity analysis (CTRA) method to monitor the fracture risk associated with metastatic lesions. We hypothesize that introduction of CTRA to the physicians' decision making process will alter the management of patients with skeletal metastasis. The aim of this study was to evaluate whether patient's treatment based on clinical guidelines was changed by CTRA.

X-rays and CT scans of the involved bones were obtained on all patients with a hydroxyapatite phantom included in the image to convert the X-ray attenuation for each pixel to bone mineral density. The elastic and shear moduli of elasticity were calculated from bone mineral density using empirically derived constitutive relationships. The cross-section through the affected bone that has the largest reduction in rigidity is the weakest and assumed to govern failure of the entire bone. The orthopaedic oncologist was asked to select between: Observation, chemo/radiation, non-invasive surgical stabilization and tntercalary allograft/prosthetic replacement based on the fracture risk assessment using Mirels' score and then again after reviewing the CTRA report. Treatment plans based initially on clinical guidelines and then again after CTRA were compared to identify cases where the treatment plan was changed as a result of CTRA.

Forty seven patients with 56 metastatic lesions to the appendicular skeleton were enrolled into the study. Based on Mirels' criteria (score ⩾9), 43 (78.2%) lesions needed prophylactic fixation, while CTRA-based fracture threshold identified 28 (50.9%) lesions at risk for fracture and suggested prophylactic surgery. Treatment based on CTRA would have changed the initial treatment plan for 19 (34.5%) lesions. In 43 lesions, the clinician did not deviate from the original treatment plan, although in 11 of them CTRA indicated a different course of treatment, which of those 3 out of 11 (27.3%) were at high risk for fracture.

The results of the study suggest that CTRA has the potential to alter treatment plan based on clinical guidelines in 35% of the time. CTRA was most valuable in cases where bone destruction was moderate or osteoporosis was coexistent.

Effects of Rosiglitazone on Bone: Assessing QCT Parameters in a Mechanistic Study in Postmenopausal Women with type 2 Diabetes Mellitus. John Bilezikian*[1], Barbara Kravitz[2], E. Michael Lewiecki[3], Colin Miller[4], Allison R. Northcutt[5], Gitanjali Paul[5], Alexander R. Cobitz[5], Antonio Nino[6], Lorraine Fitzpatrick[7]. [1]Columbia University College of Physicians & Surgeons, USA, [2]GlaxosmithKline Pharmaceuticals, USA, [3]University of New Mexico School of Medicine, USA, [4]BioClinica, Inc. (formerly Bio-Imaging Technologies, Inc.), USA, [5]CVM/MDC, GlaxoSmithKline, USA, [6]GSK, USA, [7]GlaxoSmithKline, USA

Abstract

This mechanism-of-action study assessed the effect of rosiglitazone (RSG) on bone mass and structure through imaging modalities including areal bone mineral density (BMD) and hip structural analysis (HSA) with dual-energy X-ray absorptiometry (DXA) of the lumbar spine and hip, high resolution magnetic resonance imaging (hr MRI) of the wrist, digitized hip radiography and volumetric BMD of the lumbar spine and hip with quantitive computerized tomography (QCT) . Serum biomarkers of bone formation and resorption, calcium homeostasis and selected sex hormone changes over time were assessed. Parameters of glucose control included measurement of hemoglobin A1C (HbA1C), fasting plasma glucose (FPG) and serum insulin. Here we present the effect of RSG on volumetric BMD at the hip and lumbar spine as measured by QCT (CT.gov.NCT00679939).

Methods

This was a Phase IV, 52 week, double-blind, multicenter study. A total of 226 postmenopausal women were randomized in a 1:1 ratio of RSG or metformin (MET). At baseline mean age was 63.8 $\pm$ 6.5 years while mean years post-menopause was 16.9 $\pm$ 8.4. Median duration of diabetes was 3.5 (1.8 -7.8) years. Other baseline characteristics were: mean body mass index (BMI) 31.4 $\pm$ 5.9 kg/m^2; mean FPG and HbA1c were 111.7$\pm$ 23.4 mg/dl and 6.4 $\pm$ 0.65% respectively. Femoral neck BMD was 0.83 g/cm$^2\pm$ 0.141, at total hip 0.98 g/cm$^2\pm$ 0.123, and at total spine 1.05 g/cm^2 $\pm$ 0.161. Femoral neck T-score was -0.95$\pm$ 0.908, total hip -0.02$\pm$ 0.970, and total spine was -0.55 $\pm$ 1.247.

Using spiral multi-detector scanners, a subset of 79 subjects underwent QCT scans of the lumbar spine and hip at baseline and after 52 weeks of treatment. All scans were centrally evaluated and read. The change in integral, cortical and trabecular BMD at the lumbar spine and hip from baseline to week 52 was estimated within and between the two treatment groups.

Conclusion:

Volumetric trabecular, cortical and integral BMD at the hip and the lumbar spine may provide insight on the effect of RSG on bone and may help explain the increased risk of fracture reported in long-term controlled clinical trials.

Effects of Rosiglitazone on Bone: Understanding its Effects through Assessment of Bone Structure using Digitized x-rays in a Mechanistic Study of Postmenopausal Women with type 2 Diabetes Mellitus. Antonio J. Nino*[1], Claude Arnaud[2], Rene Vargas-Voracek[3], Cesar Bogado[4], Barbara Kravitz[5], Allison R. Northcutt[1], Gitanjali Paul[1], Alexander R. Cobitz[1], Lorraine Fitzpatrick[6]. [1]CVM/MDC, GlaxoSmithKline, USA, [2]University of California at San Francisco, USA, [3]Imaging Therapeutics, USA, [4]Instituto De Investigaciones Metabolicas (IDIM), Argentina, [5]GlaxosmithKline Pharmaceuticals, USA, [6]GlaxoSmithKline, USA

Abstract:

The study objective was to characterize the effects of rosiglitazone (RSG) on bone mass and structure in postmenopausal women with type 2 diabetes mellitus through different imaging modalities including dual-energy X-Ray absorptiometry (DXA) of the lumbar spine and hip region, hip structural analysis (HSA), high resolution magnetic resonance imaging (hr MRI) of the wrist, quantitative computerized tomography (QCT) of the lumbar spine and structural assessment using hip

radiographs (ImaTx). Serum biomarkers of bone formation and resorption, calcium homeostasis and selected sex hormone changes over time were assessed. Parameters of glucose control included measurement of:hemoglobin A1C (HbA1C), fasting plasma glucose (FPG),and serum insulin. Here we present findings from assessment of hip radiographs.

Methods:

This was a phase IV, double-blind, multi-center study (CT.gov. NCT00679939) of 52 weeks duration. A total of 226 postmenopausal women were randomized to RSG or metformin (MET) in a 1:1 ratio. At baseline mean age was 63.8 ± 6.5 years while mean years post-menopause was 16.9 ± 8.4. Median duration of diabetes was 3.5 (1.8 -7.8) years. Other baseline characteristics were: mean body mass index (BMI) 31.4 ± 5.9 kg/m^2; mean FPG and HbA1c were 111.7 ± 23.4mg/dl and 6.4 ± 0.65% respectively. Femoral neck BMD was 0.83 g/cm^2 ± 0.141, at total hip 0.98 g/cm^2 ± 0.123, and at lumbar spine 1.05 g/cm^2 ± 0.161. Femoral neck T-score was -0.95 ± 0.908, total hip -0.02 ± 0.970, and lumbar spine is -0.55 ± 1.247.

All subjects underwent hip radiographs at Baseline and Week 52. All radiographs were read centrally. A total of 30 femoral geometry and cortical macro-anatomical-parameters were measured including hip axis length, neck-shaft angle, neck cortical thickness and shaft cortical thickness.

Conclusion:

Trends and differences, observed between relevant group comparisons of bone structure measurements from hip radiographs of postmenopausal women followed during the study,may provide insight on the effect of RSG on bone and its relation to the risk of bone fractures.

In Vivo Evaluation of an Anatomical Subject-specific FE-model to Predict Hip Fracture Load. Erwan Jolivet*[1], Marie-Astrid DUCOBU[2], Valérie Bousson[3], Klaus Engelke[4], Jean-Denis Laredo[5], David Mitton[2], Wafa Skalli[6]. [1]Arts et métiers ParisTech, France, [2]Arts et Metiers ParisTech, CNRS, LBM, France, [3]Hôpital Lariboisière, France, [4]University of Erlangen, Germany, [5]Service de Radiologie ostéo-articulaire, Hôpital Lariboisière, Assistance Publique des Hôpitaux de Paris et Faculté de Médecine Diderot, Université Paris 7, France, [6]Arts et Metiers ParisTech, CNRS, France

Finite element models have proved their ability to predict bone strength better than DXA and several author have developed and validated in vitro subject specific finite element models. However there is still no validation on in vivo data. Using a previously validated finite-element model of the proximal femur, this study investigated first whether contra lateral femur strength could be an appropriate indicator for in-vivo model evaluation and secondly if such finite element model is able to discriminate fractured patients from controls.

The model was applied to 22 patients, 11 controls and 11 with a hip fracture. All subjects were women with age ranged from 71 to 96 years and data were collected during the 3D-QCT European project.

The CTscan acquisition and reconstruction parameters were 1 mm contiguous slices, B40s convolution kernel and 0.293 mm in-plane pixel size. First, periosteal and endosteal surfaces were semi-automatically segmented using MIAF software (Kang et al. 2004) and hexahedral patient-specific mesh was automatically generated. Bone was considered as a heterogeneous isotropic material with a Poisson's ratio of 0.4. A Young's modulus and an ultimate stress were attributed to each element based on Hounsfield Units (Duchemin et al. 2008) and a stress based criterion was defined to assess fracture load . For simulation, the boundary conditions reproduced a stance configuration.

To validate the hypothesis of using the contra lateral femur for patient analysis, both right and left femurs in the control groups were modelled. No significant difference of the fracture load was observed using a paired t-test ($p<0.05$).

Considering three range of the fracture load (low < 5000 N, middle 5000-7000 N and high fracture load > 7000 N), 55%of the patients were classified in the low level group and only 18% in the high level group. On the contrary, 14% of the control subjects were in the low level group and 55% were classified in the high level group.

These results are promising as for the identification of subjects with high risk of hip fracture. Taking into account clinical parameters, such as defined by Frax index, should still improve the accuracy to go towards fracture risk estimation.

Lean mass predicts bone mineral density and estimates of hip strength in middle-aged individuals with non-insulin-requiring type 2 diabetes mellitus. Kendall Moseley*[1], Devon Dobrosielski[2], Kerry Stewart[2], Deborah Sellmeyer[2], Suzanne Jan De Beur[3]. [1]The Johns Hopkins Hospital, USA, [2]The Johns Hopkins Bayview Medical Center, USA, [3]Johns Hopkins University, USA

Purpose: Individuals with type 2 diabetes mellitus (T2DM) typically have higher bone mineral density (BMD), but higher fracture risk, than non-diabetics. Our aim was to examine the independent contributions of fat and lean mass to BMD and estimates of hip strength in those with T2DM.

Methods: Subjects for this cross-sectional analysis were men (n=78) and women (n=56) aged 56 ± 6 years with uncomplicated, non-insulin-requiring T2DM. Total body fat and lean mass as well as total body, hip, and lumbar spine BMD were measured with dual energy x-ray absorptiometry (DXA). Abdominal visceral, subcutaneous (SQ) and total abdominal fat were measured with magnetic resonance imaging. Averaged bilateral femoral neck strength measures including section modulus (SM), cross sectional area (CSA) and buckling ratio (BR) were estimated from DXA using validated hip structure analysis (HSA) formulae.

Results: Participants had normal BMD at all sites and were overweight to morbidly obese (BMI 29 to 41 kg/m^2) with well controlled T2DM (HbA1C in women 6.6 ± 1.2%, men 6.7 ± 1.6 %). In bivariate analysis, higher lean mass was associated with higher total body, femoral neck and hip BMD and higher SM and CSA across both sexes (r=0.36-0.55). In men only, lean mass was inversely correlated with BR (r=-0.27, $p<0.05$). Increased total body fat mass and abdominal SQ fat correlated with increased total body and hip BMD as well as increased SM and CSA in women (r=0.34-0.57). In men, these fat measures correlated with only total body BMD and no estimates of hip strength. In multiple regression analyses, lean mass remained a significant predictor of total body, hip and femur BMD in men and women, while fat mass predicted only total body BMD ($p<0.05$). In a separate model including both sexes, lean mass significantly contributed to all three measures of hip strength.

Conclusions: In middle-aged men and women with non-insulin-requiring T2DM, lean mass was a significant predictor of BMD at the total body, hip and femoral neck. Lean mass predicted measures of hip strength including SM, CSA and BR. Fat mass may additionally contribute to BMD and HSA in women. These data suggest that maintenance of lean mass may preserve BMD and maintain hip integrity in those with T2DM who lose weight to improve insulin sensitivity. Strengthening exercises may be an intervention for hip fracture prevention in T2DM.

Predicting Subchondral Bone Structural Properties Using a Depth-Specific CT Topographic Mapping Technique in Normal and Osteoarthritic Proximal Tibiae. James Johnston*[1], Saija Kontulainen[1], Bassam Masri[2], David Wilson[3]. [1]University of Saskatchewan, Canada, [2]University of British Columbai, Canada, [3]University of British Columbia, Canada

Altered subchondral bone mechanical properties are undoubtedly involved in the initiation and/or progression of osteoarthritis (OA). To better understand the role of bone in OA we developed a 3D *in vivo* imaging tool: computed tomography topographic mapping of subchondral density (CT-TOMASD). CT-TOMASD employs quantitative CT (QCT) and surface projection image processing to characterize and map subchondral bone mineral density in relation to depth from the subchondral surface. The main objective of this study was to determine if CT-TOMASD could predict the structural stiffness of proximal tibial subchondral bone. A secondary objective involved assessing whether factors such as compartment (medial/lateral), age or cartilage degeneration (an indicator of OA disease) affected these predictions.

Fourteen proximal tibial compartments (4 medial, 10 lateral) from 10 donors (10M; age: 73+/-11 years) were CT scanned (0.5mm isotropic voxel) with a QCT bone density phantom. CT-TOMASD averaged subchondral bone density to depths of 1.5, 2.5, 5 and 10mm from the subchondral surface (Fig. 1). We performed indentation testing (3.5mm diameter flat indentor, 2mm/minute rate, 0.5mm displacement, 250N max load) directly at the subchondral surface (4-6 sites per compartment, 68 sites in total). Prior to indentation, cartilage degeneration was graded using ICRS scoring. Test sites were classified as normal (ICRS<2; n=39) or OA (ICRS>=2; n=29). We

related structural stiffness to CT-TOMASD measures using power-law regression models (SPSS). We adjusted the models for compartment, age and cartilage status to test effect on model prediction. If no effect was observed, we tested the coincidence of separate regression models using F tests.

CT-TOMASD measures across the 0-1.5mm layer explained 54% of the variance in stiffness (p=0.000) (Fig. 2). After adjustments, the model explained 61% of the variance in stiffness (p=0.004). Density was the primary predictor (beta=0.77; p<0.001) while side (beta=0.24; p=0.005) improved model prediction. Age (beta=0.01; p=0.859) did not improve model prediction nor did cartilage status (beta=0.13; p=0.087). F tests revealed that separate normal and OA regression models exhibited similar stiffness-density relationships. CT-TOMASD measures to depths of 2.5, 5 and 10mm from the subchondral surface explained less variation in stiffness than across the 0-1.5mm layer. CT-TOMASD has potential to predict subchondral bone stiffness *in vivo*.

Predicting Trabecular Bone Elastic Properties from MRI-derived Measures of Bone Volume Fraction and Fabric. Michael Wald*[1], Jeremy Magland[1], Chamith Rajapakse[2], Ed Guo[3], Felix Werner Wehrli[1]. [1]University of Pennsylvania Medical Center, USA, [2]University of Pennsylvania School of Medicine, USA, [3]Department of Biomedical Engineering, Columbia University, USA

Significant effort has been expended on predicting bone strength through in vivo assessment of its structure. Even though bone volume fraction (BVF) is predictive of bone strength, the variation in mechanical properties with test direction requires inclusion of measures of structural orientation. Here, we examine whether the inclusion of trabecular bone (TB) fabric can improve the BVF-based prediction of the elastic constants derived from linear μFE analysis of μMR images acquired with resolution and signal-to-noise (SNR) characteristics achievable in vivo.

Thirty demarrowed, cadaveric human distal tibia specimens were fixed in 1 mM aqueous Gd-DTPA/10% formalin solution. Images with a 160 μm isotropic voxel size were acquired using a two-channel phased-array ankle coil and a custom-designed 3D spin-echo sequence at 1.5T field strength. Micro-MR datasets were processed to yield BVF images with pure bone and pure marrow corresponding to intensities of 100 and 0, respectively. Two 7.5x7.5x7.5mm^3 sub-regions of TB were extracted from the posterior (P) and lateral (L) portions of the tibia where the TB orientation is known to be different (Figure a). Each sub-region was subjected to orientation analysis via the mean-intercept-length (MIL) algorithm where angularly-sampled MIL measurements were fit to an ellipsoid with axes λ_1, λ_2, λ_3. Six stress/strain simulations were performed via μFE analysis where each element was assigned a modulus proportional to its BVF with pure bone having 15GPa. The nine orthotropic elastic constants (three Young's moduli - E_{ii} (i=1, 2, 3), three shear moduli - G_{ij} (j=1, 2, 3), and three Poisson's ratios - v_{ij}) were fit to a model [Cowin, 1985] of the normalized fabric eigenvalues λ_1, λ_2, λ_3 and power-law functions of BVF where the exponent α was allowed to vary from 1 to 3.

Each sub-region's E_{ii} were best predicted by separate power-law functions of BVF (R^2s=0.92-0.98, Figures b and c - P and L sub-regions, respectively). Adding fabric into the model predicted the pooled data for both analysis regions and all testing directions with high accuracy (R^2=0.986, Figure d). Model agreement for pooled G_{ij} and v_{ij} were also good when fabric information was considered (R^2s=0.99 and 0.68). Non-pooled models of BVF explained variations in G_{ij}, but not in v_{ij} (P: R^2s=0.92-0.97 and 0.08-0.51, L: R^2s=0.92-0.96 and 0.04-0.42). Inclusion of fabric information established a general model between BVF and elastic constants independent of sub-region and test direction. The data emphasize (1) the importance of fabric as a predictor of bone mechanical properties, and (2) that these relationships can be assessed in the limited resolution and SNR regime of μMRI.

Quantitative Characterization of Motion Artifact in HR-pQCT Images of the Distal Radius and Tibia. Miki Sode*[1], Andrew Burghardt[2], Jean-Baptiste Pialat[3], Thomas Link[2], Sharmila Majumdar[2]. [1]University of California San Francisco & Berkeley, USA, [2]University of California, San Francisco, USA, [3]INSERM U831,Université de Lyon & Hospices Civils de Lyon, France

Motion artifacts are commonly seen in in vivo high-resolution peripheral quantitative computer tomography (HR-pQCT) images, especially at the radius. Compromised image quality confounds the accuracy of cortical and trabecular

densitometric and structure indices. It often leads to repeating the acquisition, thereby exposing the subject to more radiation. Criteria for accepting/rejecting an image are highly subjective. Therefore, the objective of this study was to develop a technique to measure motion and estimate error.

A total of 54 sets of HR-pQCT images of the distal radius (N=33) and tibia (N=21) acquired for various studies conducted in our laboratory were reviewed. Each set consisted of 2 acquisitions of the same site before and after repositioning. At least one image was graded 1 (no visible motion) according to the manufacturer-suggested quality grading system. The cortical and trabecular densitometric and structure indices were calculated for each image, and the % difference between paired was calculated. The amount of motion during a single acquisition was quantitatively measured in the following manner. First, the raw cone beam projection images were parallelized and corrected for dark and flat field intensity. Next the projected bone region at 0˚ and at 180˚ flipped with respect to the detector center were compared using i) normalized mutual information (MI), ii) sum of squared intensity difference (SSD), iii) entropy (E), iv) ratio image uniformity (RIU), and v) maximum normalized cross correlation (NXC). The mean % difference between paired acquisitions was calculated for each measure. A linear regression analysis was performed for the correlation (Spearman's ρ) between the % differences in each index and the similarity measure. Radius and tibia data were pooled.

The % differences in E, RIU, and NXC positively and significantly correlated with the % differences in cortical and trabecular densitometric and structure indices (ρ=0.27-0.58; all $p \leq 0.04$). Cortical area and thickness as well as trabecular bone volume fraction, -number and -spacing had strong correlations with these similarity measures (all $\rho \geq 0.36$ and $p \leq 0.007$) (Figure 1).

The result of this study provides a basis for quantitative characterization of motion artifact.

Radiation Therapy Causes a Rapid Loss of Bone Mineral Density of Thoracic Vertebra in Women and Men Lung Cancer Patients. Michael Lawrence*[1], Jeffrey Willey[2], Mert Saynak[1], Ted Bateman[3], Lawrence Marks[1]. [1]University Of North Carolina, USA, [2]Clemson University, USA, [3]Univesity of North Carolina, USA

Cancer patients receiving radiation therapy (RT) for pelvic tumors are at greater risk of hip fractures. The mechanisms are unknown, but recent preclinical studies have identified a rapid activation of osteoclasts. We hypothesize that RT also causes atrophy of thoracic vertebra (ThV) during lung cancer treatment. A retrospective analysis of 25 lung cancer patients was performed. Change in volumetric bone mineral density (vBMD) was examined using pre- and 6 months post-RT thoracic CT scans. Ten women (mean age of 61 years) and 15 men (72 years) were studied; no patients received chemotherapy or antiresorptive treatment.

Patients typically received a total RT dose of ~66 Gy in 2.0Gy/day fractions to the tumor. The trabecular bone of 6 vertebral bodies were contoured using UNC's RT treatment planning system (PlanUNC); the average CT density was calculated for pre- and post-RT contours. The mean dose for each ThV was determined by PlanUNC, permitting assessment of the dose-dependent nature of vBMD changes. All density changes were normalized to tissue changes well outside the treatment beam. Significance was determined by paired t-test.

The average loss of ThV vBMD for each patient was -21% ($p<0.001$), with no difference in the degree of loss for women (-21%,$p<0.001$) and men (-21%,$p<0.001$). Linear regression analysis showed no correlation with patient age and vBMD decline. By calculating RT dose to each vertebra within a patient, we were able to examine the relative radiation sensitivity of ThV trabecular bone. Significant loss of vBMD occurred across dose ranges: 45+ Gy (-24%,$p<0.001$); 35-45 Gy (-23%,$p<0.001$); 25-35 Gy (-15%,NS); 15-20 Gy (-16%,$p=0.047$); and 5-10 Gy (-20%,$p=0.003$). No differences were observed between doses using a 1-way-ANOVA.

Lung cancer patients receiving RT lost ThV vBMD in incidentally irradiated bone at a rapid rate of ~3% per month. Trabecular bone within the ThV appears to be a radiation-sensitive tissue, occurring with only a total dose of5-15 Gy. This rate of TrV bone loss confirms other clinical data from pelvic tumor RT. This rate of loss also conforms to preclinical reports showing early osteoclast activation from RT. Past studies showing bone loss or fractures from RT have only examined women. In this study, men and women were equally susceptible to bone loss. Future studies need to examine subsequent recovery of vBMD and strength. Antiresorptive therapies may be appropriate to prevent this RT-induced bone loss.

Relationship Between Age, Mineral Characteristics, Mineralization, Microhardness, And Microcracks In Human Vertebral Trabecular Bone. Delphine Farlay*[1], Yohann Bala[2], Brigitte Burt-Pichat[3], Roland Chapurlat[3], Georges Boivin[4], Helene Follet[5]. [1]University of Lyon, France, [2]Université De Lyon, France, [3]INSERM U831, Université de Lyon, France, [4]INSERM, France, [5]INSERM, Université De Lyon, USA

Relationship between mineralization and microcracks has been mainly studied on the same Bone Structural Units in cortical bone (1). Our purposes were to analyze at tissue level the contribution of bone mineralization and mineral characteristics in the development of microcracks in trabecular bone. Human vertebrae trabecular cores (L2, Ø 8.2mm, height 10mm) from 53 cadavers (54-95 yrs) were embedded in PMMA for analysis of pre-existing microcracks by bulk staining in xylenol (2), Crack length (Cr.Le) and crack density (Cr.Dn) were measured. Fourier Transform Infrared Microspectroscopy was performed on 2µm-thick sections (mean of 20 areas by sample, 30*100µm each). Mineral maturity (MM) was the ratio between apatitic/non apatitic phosphates, and mineralization index (MI) the ratio between mineral/organic matrix. Crystallinity index (CI) reflected size/perfection of bone crystals (3-4). Quantitative microradiography performed on 100µm-thick sections allowed the measurement of the degree of mineralization (DMB), and microhardness (Hv) was calculated on the surfaced block (5). Normality of the distributions was tested, and logarithmic transformation was performed for Cr.Le and Cr.Dn. Relationships between variables were tested using Pearsons' correlations. A positive correlation between age of donor and CI was found. DMB, Hv and MM were positively associated with MI. Interestingly, a positive correlation was found between Cr.Le and DMB, MI, MM, but not with CI (Table). The more mature the mineral was, the higher were the degree of mineralization and the crystallinity, and the harder was bone tissue. Moreover, the length of microcracks increased with the mineralization (degree and maturity), whereas crystals size/perfection had no influence. Thus, propagation of microcracks was more influenced by the age of mineral than by crystals dimension and composition. Finally, the density of microcracks was not influenced by mineralization, suggesting that their propagation and density are not linked. In conclusion, in vertebral bone, crystallinity (crystal size/perfection) increased with age of donor, and could explain partly bone fragility.

The Effects of Simulated Microgravity and Return to Weightbearing on Densitometric and Mechanical Properties of the Femoral Neck in the Adult Rat HU Animal Model. Joshua Kupke, Scott Morgan*, Yasaman Shirazi-Fard, Joshua Davis, Joseph Marchetti, Alyssa McCue, Susan Bloomfield, Harry Hogan. Texas A&M University, USA

Microgravity-induced bone loss is one of the primary concerns for astronaut health on long duration spaceflights. However, bone mineral density (BMD) does not always provide accurate predictions of changes in bone quality and strength. Thus, bone strength indices based on CT scans have been devised using various combinations of both geometric and densitometric properties The objective of the current study was to characterize the effects of microgravity, and recovery, on the femoral neck (FN) using the adult hindlimb unloaded (HU) rat model. An additional important goal was to compare calculated strength indices to mechanical testing results at the FN.

Adult male Sprague-Dawley rats (6-mo) were grouped into baseline (BL), weightbearing cage control (CC), and hindlimb unloaded (HU). HU animals were further divided into sub-groups (n=15 each): HU euthanized after 28d of suspension, and HU euthanized after 28, 56, and 84 days of recovery. CC groups were euthanized at the same four end points. The excised right femur was scanned ex vivo at the FN using peripheral quantitative computed tomography (pQCT). Mechanical testing was performed with the femur oriented vertically and quasi-static loading applied to the femoral head in a proximal-to-distal direction. This conventional approach creates a combination of compression, bending, and shear in the FN.

HU exposure gave rise to 6.3% lower bone mineral content (BMC) compared to BL and 7.8% lower total volumetric (integral) bone mineral density (vBMD) at the FN. The most dramatic effect was for the neck compression strength index (NCSI), defined as $vBMD^2$ times the minimum cross-sectional area. The mean NCSI was 13.4% lower for HU compared to BL. By contrast, the neck bending strength index (NBSI) was only 3.9% lower. As an estimator of bone strength, NCSI corresponds more closely to the actual maximum breaking force for the femoral neck, which was 17.1% lower after 28d HU. Considering recovery after return to weightbearing, BMC was only 2.5% lower than BL after 28d of recovery and returned to the same level as BL after 56d. After 28d of recovery, vBMD was 5.1% lower than BL but was higher after 56d. The NCSI remained 10.5% and 5.8 % lower after 28d and 56d recovery, respectively. However, the measured breaking force returned to BL levels after only 28d of recovery. Thus, the NCSI is a reasonable predictor of strength for the initial exposure to HU, but underestimates actual strength values during recovery.

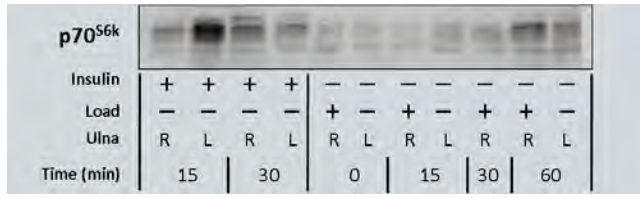
Mechanically-induced Signaling Events in Loaded Bones In-vivo Include Activation of ERK1/2 During Functional Adaptation. Jason Bleedorn*[1], Susannah Sample[2], Troy Hornberger[3], Peter Muir[4]. [1]University of Wisconsin-Madison, USA, [2]UW-Madison School of Veterinary Medicine, USA, [3]School of Veterinary Medicine - UW Madison, USA, [4]University of Wisconsin, Madison, USA

Purpose: Mechanical stimuli play an important role in the regulation of bone mass. Failure of the skeleton to maintain bone mass contributes significantly to patient morbidity and mortality in conditions such as osteoporosis. The mechanisms involved in converting biophysical signals into the molecular events that regulate functional adaptation have not been defined. The present study was designed to determine activation of mechanically-induced signaling events in bone in an in-vivo bone loading model.

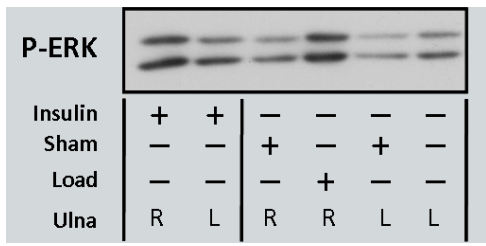
Methods: 22 male rats aged 10-12 weeks were used. 8 rats were used to determine the timeline of signaling events after mechanical loading. 4 rats were used as controls, 2 of which received insulin treatment (5 IU/kg Humulin R) as positive control, and 2 which were sham loaded. The remaining 4 rats had their right ulna loaded at 4Hz for 1,500 cycles at -3,750με (-18N). Individual rats were euthanatized and both right and left ulnas were collected at 0, 15, 30 and 60 minutes after in vivo loading. The remaining 14 rats were used for further investigation of specific time points after bone loading using the same loading protocol. Right and left ulnae were collected at 15 minutes (n=4 loaded, n=3 sham) and at 60 minutes (n=4 loaded, n=3 sham) after right ulna loading. Bones were immediately frozen in liquid nitrogen, ground to a powder with a pestle and mortar, and the proteins extracted. Phosphorylation of p70S6k, PKB, p38, JNK and ERK was examined using Western blot analysis.

Results: Mechanical loading resulted in a cascade of protein phosphorylation evident at various time points in the first phase of the study. Activation of p70S6k(389) PKB(308) PKB(473), JNK1/2 and ERL1/2 were detected in the loaded right ulna after mechanical loading. Activation of p38 was not detected at the time points examined. In the second phase of the study, activation of the ERK signaling pathway (p-ERK1/2) was consistently (n=4) seen in loaded bone at 15 minutes after mechanical loading.

Conclusion: These results confirm that it is possible to detect mechanically-induced signaling events in loaded bone during functional adaptation in-vivo. Load-induced bone formation is associated with activation of p70S6k, PKB, ERK1/2 and JNK1/2 at distinct time points in loaded bones. Further work is needed to determine whether additional mechanically-induced signaling events are evident to further characterize the molecular mechanisms that regulate functional adaptation of the skeleton.



Signaling time line for p70S6k(389) after mechanical loading of the right ulna



ERK signaling at 15 minutes following mechanical and sham loading of the right ulna

Are Exercise-induced Gains in Lumbar Spine vBMD Driven by Changes in Back Extensor and Psoas Muscle Size in Older Men? An 18-month Randomised Controlled Trial. Christine Bailey*[1], Sonja Kukuljan[2], Riku Nikander[3], Caryl Nowson[2], Robin Daly[3]. [1]The University of Melbourne, Australia, [2]School of Exercise & Nutrition Sciences, Deakin University, Melbourne, Australia., Australia, [3]The University of Melbourne, Western Hospital, Australia

Since muscle and bone are inextricably linked, it is often assumed that changes in muscle size and strength should affect bone strength predictably and correspondingly. For older adults, progressive resistance training (PRT) can markedly improve muscle mass and strength, but its effects on LS BMD are mixed. In addition, from the limited Ex trials that have reported a positive effect on LS BMD, few have examined whether the changes in bone are predominantly mediated by gains in back muscle CSA. The aims of this study were to examine: 1) the effects of a multi-component Ex program incorporating PRT and weight-bearing impact Ex on erector spinae (ErSp) and psoas muscle CSA, and CT-measured lumbar spine vBMD in older men; 2) whether any exercise-induced changes in bone were mediated by changes in muscle CSA; and 3) the effects of training load on muscle and bone. Men (n=180) aged 61 ± 7 years ($\pm$SD) were randomised to an Ex or non-Ex group with or without additional Ca-Vit D3. The Ex consisted of high intensity (60-85% 1RM) PRT and weight-bearing impact Ex performed 3 d/wk for 18 mo. QCT was used to assess L1-L3 total and trabecular vBMD (TrvBMD), and muscle CSA. Ex led to a significant 2.3% net gain in TrvBMD and 1.6-4.9% net increase in ErSp and psoas muscle CSA relative to no-Ex (all $p<0.05$). The Ex-induced gains in ErSp, psoas and total back muscle CSA were correlated with the changes in TrvBMD (r=0.26-0.33, $p<0.05$-<0.001). Similar significant correlations were observed in the no-Ex group (r=0.33-0.41, $p<0.01$-<0.001). However, further analysis revealed that there were no differences in the slopes nor intercepts for the changes in muscle and bone between the Ex and no-Ex group. This suggests that the Ex-induced gains in vBMD were not mediated by the changes in muscle size. When we examined the influence of training load on the skeletal changes, we found that the average RT load and number of impacts per session were related to the changes in TrvBMD (r=0.38 and 0.43, respectively, $p<0.001$). When both parameters were entered into the regression model, only the number of impacts per session remained significantly related to the changes in TrvBMD ($p<0.05$). In conclusion, an 18-month Ex program consisting of PRT and impact training was effective for improving both back muscle size and lumbar spine

BMD, but these skeletal changes appeared to be related to the number of impacts per session and not the gains in muscle size.

Effects of Pulsed Electromagnetic Field Stimulation on Gene Expression Related to Bone Formation in Spontaneously Hypertensive Rats. Hiroaki Takekura[1], Hiroyuki Tamaki*[2], Hideaki Onishi[2], Tomie Nishizawa[3], Kengo Yotani[1], Atsumu Yuki[1], Futoshi Ogita[1], Hikari Kirimoto[2], Kounosuke Tomori[1]. [1]National Institute of Fitness & Sports, Japan, [2]Niigata University of Health & Welfare, Japan, [3]Chukyo Women's University Junior College, Japan

Pulsed magnetic stimulation (PMS) has been used to treat bone disorders and reportedly modifies differentiation, proliferation and mineralization of osteoblasts in vitro. The spontaneously hypertensive rat (SHR) displays a disorder characterized by cancellous bone deficit in the skeleton. We examined the temporal effects of repetitive PMSs (rPMS) on bone formation in vivo for SHR tibiae and femora and investigated magnetic field mapping in bone during PMS. The magnetic sensor was placed in the distal metaphysis of the femur to determine maximum magnetic field strengths during PMS. Measurements were made at 9 positions (X-Y axis) and 9 distances (Z axis) from the sensor during PMS supplied at 10 stimulation intensities in increments of 10% of the maximal output of the stimulator. One hindlimb of male SHR and normal rats at 6 and 33 weeks old was held on the table in the prone position and the PMS probe was placed 10-20 mm from the thigh and leg. A stimulation intensity of 60-80% was used for rPMS at a frequency of 0.5-1 Hz, for 3-5 min. After sacrifice, tibiae were analyzed by quantitative histomorphometry and femora were used for analysis of bone morphogenetic protein (BMP)-2, transforming growth factor (TGF)-β2, osteocalcin (OC), and collagen (Col)-I mRNA expressions by real-time reverse transcriptase-polymerase chain reaction (RT-PCR). Magnetic field strength in the bone during PMS showed a nonlinear hyperbolic decrease and a linear increase depending on probe distance and stimulation intensity, respectively, within the range of 250-450 mT at a distance of 10-20 mm and 60-80% stimulation intensity. Lower trabecular bone volume (BV/TV) was observed in old SHR compared to normal old rats. RT-PCR showed that rPMS stimulated mRNA levels of BMP2 and TGF-β2 after 24-h of treatment compared to the contralateral hindlimb. These findings suggest that temporary local rPMS on the bone provides potent stimulation of bone formation in vivo for SHR by promoting BMP-2, and TGF-β2 production.

Loaded Physical Activity Predicts Bone Strength, but not bone microstructure, at the Distal Radius in Adolescents. Heather McKay*, Danmei Liu, Deetria Egeli, Melonie Burrows. University of British Columbia, Canada

Physical activity (PA) has a positive effect on bone mineral content and bone geometry in male and female adolescents across a range of skeletal sites. There is also evidence for the beneficial effects of PA on bone strength and bone microstructure at the distal tibia, an inherently loaded site, in adolescents during growth. However, no studies have examined the relationship between PA, bone strength and bone microstructure in adolescents at inherently unloaded sites. Our aims in this cross-sectional study were to evaluate the independent contribution of PA to bone strength and bone microstructure in adolescent males and females at the radius. We assessed the distal radius using XtremeCT (Scanco Medical) at the 7% site in 113 males (Age 17.4 ±1.6yrs; Height 175.6 ± 7.3cm; Weight 69.0 ± 15.4kg), and 97 females (Age 17.9 ±1.8yrs; Height 162.8 ± 6.9cm; Weight 59.5 ± 11.3kg). We assessed PA (loaded and unloaded) using the modified PA Questionnaire for Adolescents [1]. Our primary outcome was bone strength index (BSI, mg^2/mm^4; ToA (mm^2) x $ToD^2(mg/cm^3)$ [2]. We also assessed cortical bone density (CoD, mg/cm^3), cortical thickness (Cort.Th, mm), trabecular bone density (TrD, mg/cm^3) and trabecular number (Tb.N, 1/mm). We used multiple regression (STATA, Version 10.1) to evaluate the independent contribution of PA (PA, hours per week) to bone outcomes after adjusting for maturation (Tanner), height (cm), weight (kg), radius length and calcium intake (mg/day). Loaded PA was a significant predictor of BSI, ToA and TrD in males ($P<0.001$; Table 1). Loaded PA was a significant predictor of BSI only in females ($P<0.05$; Table 1). There was no influence of loaded PA on bone microstructure in either sex ($P<0.05$). There was no influence of unloaded PA on BSI or bone microstructure in either sex ($P<0.05$). Our results suggest that whilst loaded PA has a positive effect on bone strength at the radius in both sexes, it has no significant effect on bone microstructure. These findings are at odds with the reported beneficial effects of PA on bone microstructure at the distal tibia. Data are required to further assess the influence of PA on inherently loaded and unloaded skeletal sites across growth.

Maturity-specific Differences Attributed to Gymnastic Loading at the Distal Radius. Jodi Dowthwaite*[1], Portia Flowers[2], Rebecca Hickman[2], Paula Rosenbaum[2], Tamara Scerpella[3]. [1]State University of New York, Upstate Medical University, USA, [2]SUNY Upstate Medical University, USA, [3]State University of New York Upstate Medical University, USA

Purpose: Loading exposure during growth is linked to high bone mineral indices, but few studies address maturity and tissue-specific adaptations in bone geometry and density. The current study tests for an interaction between gymnastic loading and menarche status.

Methods: Contemporaneous pQCT (pQ) and DXA (DX) scans were performed at the radial metaphysis (4%, Ultradistal (UD)) and diaphysis (33%, 1/3) in 113 females aged 8-25 yrs (mean 14.9 yrs). Premenarcheal (PRE) subjects included 24 nongymnasts (NON), 30 gymnasts (GYM, exposure >4 h/wk). Post-menarcheal subjects (POST) included 5 gymnasts and 26 exgymnasts (EX/GYM exposure >2yrs at >6h/wk); all others were defined as NON (n=28). Two factor analysis of covariance evaluated gymnastic exposure and menarche status, adjusting for age and height.

Results: EX/GYM and NON differed in height and % body fat (NON>EX/GYM)($p<0.02$); POST exceeded PRE means for all but % body fat ($p<0.05$). At both sites, DX area, aBMD, all BMC, all periosteal and cortical areas were greater in EX/GYM than NON ($p<0.05$), as was 4% trabecular vBMD. However, diaphyseal cortical vBMD was higher in NON than EX/GYM ($p<0.05$). Interactions were influential at both sites. EX/GYM emphasized greater periosteal and trabecular/intramedullary dimensions in late puberty, whereas POST NON emphasized only thickened cortices, yielding higher total vBMD/BMAD than EX/GYM ($p<0.05$). Fewer interactions were detected by DXA.

Conclusion: Distal radius differences attributed to gymnastic loading during growth are maturity-specific. POST EX/GYM advantages emphasize bone geometry rather than density; this may reflect pubertal loading and/or training cessation (84% ex). High adjusted bone outcomes in POST NON suggest pubertal acceleration of cortical growth. Generally, DXA and pQCT results agreed. However, pQCT detected more significant interactions, potentially reflecting greater sensitivity, accuracy or positional influence.

Adjusted means for bone parameters by gymnastic exposure (two-factor ANCOVA).
For significant interactions, results are presented by menarche status.

Normal Masticatory Function Protects the Rat Mandibular Bone from Estrogen Deficiency-related Bone Loss. Anestis Mavropoulos[1], René Rizzoli[2], Stavros Kiliaridis[1], Patrick Ammann*[2]. [1]University of Geneva, Switzerland, [2]University Hospital, Geneva, Switzerland

Purpose. In a previous investigation we showed that mandibular alveolar (trabecular) bone appears to be less sensitive to estrogen-related osteoporosis than the proximal tibia spongiosa. We hypothesized that the heavy mechanical loading during mastication may protect the alveolar bone from the detrimental effects of estrogen deficiency observed in other skeletal sites. In this study we tested this hypothesis by comparing the effect of ovariectomy on the mandibular alveolar bone of Sprague-Dawley rats fed either a normal (hard) or a soft diet. Methods. Forty six-month-old female Sprague-Dawley rats underwent transabdominal ovariectomy (OVX) or sham operation (SHAM). Half of the animals received their food in the usual form of pellets (hard food), while the other half received a soft, porridge-like, isocaloric food. The experiment lasted 16 weeks. Micro-computed tomographic histomorphometry was used in order to evaluate the effect of estrogen deficiency on the mandibular alveolar bone. Results. Both experimental manipulations (OVX, soft diet) had a significantly negative impact on the micro-architecture of the mandibular alveolar bone. Soft diet led to a reduction of BV/TV (p=0.02), and trabecular thickness (p=0.03) and number (p<0.03). The conjunction of soft diet and OVX led to a significant reduction of BV/TV (p<0.001), and trabecular thickness (p<0.001), number (p<0.001), and separation (p<0.001). Ovariectomy led to 21.2% reduction of BV/TV in rats fed the soft diet (p<0.001), whereas a non significant change (-8.2%) was observed in those receiving the hard diet. Conclusions. Estrogen-deficiency seems to only minimally influence rat mandibular alveolar bone under normal masticatory mechanical loading, at least for the duration of this experiment. Soft diet and the ensuing hypofunction of the masticatory system significantly accentuated the negative effects of estrogen deficiency on the mandibular alveolar bone.

Site and Frequency Specific Effects of Whole Body Vibration on Axial and Appendicular Structural Bone Parameters in Aged Rats. Marion Pasqualini*[1], Norbert Laroche[1], Arnaud Vanden Bossche[1], Laurence Vico[2]. [1]Inserm U890 - Lyon University, France, [2]University of St-Etienne, France

Mechanical stimulation of bone by Whole Body Vibration (WBV) was shown to have osteogenic effects. Most studies of WBV in rodents were done in growing, or gonadectomized animals. There is a lack of reports of WBV in aged adult animals and thus no preclinical evidence to support WBV in the prevention of bone loss. The goal of this study was to test the skeletal effects of different WBV frequencies, applied with the same acceleration, in aged rats. Our hypothesis was that high frequencies (90Hz) are more anabolic than low frequencies (8Hz). We exposed 48 male Wistar, 10-month rats to 4 weeks of vertical vibrations for 10 min/day, 5 days/week at 0.5g at frequencies of 8Hz, 52Hz or 90Hz. Trained rats stood free on the vibrating platform, control rats stood on the unmoving platform. Proximal tibia metaphyses were scanned in vivo by micro-CT (VIVA CT40, Scanco Medical) at the initiation and the end of the training period. At sacrifice, we measured trabecular and cortical bone parameters in the distal femur and L2 vertebral body. Post-hoc multiple comparisons were done when ANOVA results were significant. Rats vibrated at 8 and 52Hz lost body weight, while weight increased under a 90Hz training. Longitudinal follow up of the trabecular proximal tibia showed no significant effect of WBV. At sacrifice however, the trabecular compartment of the distal femur showed larger trabeculae (+11%, n=12, p<.0001) and an increased degree of anisotropy (+29%, n=12, p<.0001) at 90Hz vs controls. In contrast, these parameters were decreased at 52 Hz and even more at 8Hz vs 90Hz. Bone volume, trabecular number and connection density were all increased at 90Hz as compared to 52 and 8Hz. At 90Hz vs control, the cortical thickness is increased (+11%, p<0.01) and the porosity is reduced (-50%, p<0.05). In the L2 vertebra, all trabecular parameters were improved at 90Hz vs controls, bone volume and density connection were also increased at 52Hz, while no effect was observed at 8Hz. We showed that 0.5g WBV at 8Hz and 52Hz is either deleterious or inefficient in long bones. The anabolic effects of the 90Hz regimen observed in the vertebrae suggest that bone volume would also increase in the femur and tibia after a longer training period. The cortical effects also suggest improved biomechanical properties. This study showed that in WBV, in addition to the acceleration level, frequency is an important parameter with site-specific effects.

A New Urinary Bio Marker of MMP-derived Cartilage Degradation. Anne-Christine Bay-Jensen[1], Jianxia Wang[2], Inger Byrjalsen[3], Yi Li[4], Qinlong Zheng[4], Kim Henriksen[5], Per Qvist[5], Morten Karsdal*[5]. [1]Nordic Bioscience, Denmark, [2]Nordic Bioscience China, Denmark, [3]CCBR-Synarc, Denmark, [4]Nordic Bioscience Beijing, China, [5]Nordic Bioscience A/S, Denmark

Joint degenerative disease is characterized as progressive damage of the joint tissue, which includes cartilage erosion, osteophyte formation, subchondral sclerosis, and synovial alterations. The turnover of cartilage is normally maintained by a balance between catabolic and anabolic processes. However, in the case of pathological matrix destruction, the rate of cartilage degradation exceeds the rate of formation, resulting in a net loss of cartilage matrix. The specific products of tissue formation and degradation can be measured in serum and urine, as markers of pathology. A monoclonal antibody was raised against a MMP9-derived neoepitope in type II collagen, which was identified mass spectrometry (N-terminal-GRDGAAG1053). An ELISA assay, called CIIM, was developed and optimized. The level of CIIM fragments was measured in urine samples from a normal population of men and women (N=145, age range 22 – 84 years). Immunohistochemistry was done to validate the presence of the neoepitope OA cartilage samples from patients undergoing knee replacement. The technical performance of the assay was accepted, giving inter- and intra-assay CV below 6%. We verified that the neoepitope was actually MMP-dependent by adding MMP-inhibitor (GM6001) to cartilage cultures and measuring the release of the fragment to the medium. GM6001 could inhibit the release of CIIM from catabolic active cartilage when compared to catabolic active control. Next, we measured the level of CIIM in urine of a normal population and found that there was a significant difference between men (84.8 pg/mmol creatinine, n=82) and women (126.4 pg/mmol creatinine n= 74, $p<0.01$). We also found that post-menopausal women (153.2 pg/mmol creatinine, n=47) had a higher level than pre-menopausal women (83.0 pg/mmol creatinine, n=27, $p<0.01$). We found the neoepitope to be immunolocalized to OA pathological features of the cartilage: 1) to eroded surface of the cartilage; 2) to the calcified cartilage; 3) to lesions. We developed a new biomarker assay that measures type II collagen degradation by MMP. We believed that this new markers could be a new and valuable tool for measuring cartilage breakdown observed in joint degenerative disease such as OA.

Exercise May Prevent Regional Bone Loss Induced By Monosodium Iodoacetate Osteoarthritis Model. Arnaud Boudenot*[1], stephane pallu[2], Eric Dolleans[2], Eric Lespessailles[3], Christelle Jaffre[2], Claude Laurent Benhamou[4]. [1]Inserm Unit U658Hopital Porte MadeleineOrléansFrance, France, [2]INSERM UNIT U 658, France, [3]Centre Hospitalier Regional, France, [4]INSERM Orléans-France, France

Knee injuries (i.e. anterior cruciate ligament tear or menisectomy surgery) are frequent in contact sports and may lead to early knee osteoarthritis. Monosodium iodoacetate (MIA) injection into joints is a validated animal model of induced osteoarthritis. This study aims to demonstrate the possible protective effect of exercise (treadmill running) on the subchondral bone changes at the proximal tibia (PT) and distal femur (DF) in the MIA-induced osteoarthritis model.

Male Wistar rats aged of 13 weeks (n=47) were divided into two groups: exercise (Ex) (n=24) or non exercise (NEx) (n=23). Ex rats were subjected to intermittent progressive training one hour per day, 5 days per week for 10 weeks. At the end of the training period, each group was divided into two subgroups and underwent either MIA injection (1mg/100µL NaCl) or NaCl (100µL) into the right knee joint leading to 4 groups: 1) Ex-NaCl, 2) Ex-MIA, 3) NEx-NaCl and 4) NEx-MIA. Bone Mineral Density (BMD) was evaluated on specific regions of interest (PT and DF) at baseline, after training (10 weeks) and at sacrifice (14 weeks). All data are expressed as mean ± SD. Mann-Whitney U test was used to determine the statistical significance of the differences between groups, p values lesser than 0.05 were considered significant *.

Before the MIA or NaCl injection we did not observed any significant differences between groups in BMD at the PT or DF subregions. Mean PT-BMD in the Ex-MIA group before injection was 0.429 ± 0.030 and 0.435 ± 0.021 g/cm^2 at sacrifice (p = NS). In contrast, in the NEx-MIA group we observed significantly lower values of mean TP-BMD at sacrifice than before injection (0.409 ± 0.022 vs 0.429 ± 0.025 g/cm^2; p=0.03). At sacrifice, we did not observed significant differences in BMD at DF between groups. In contrast PT-BMD of the injected knees was significantly lower in the NEx-MIA group compared to the other groups (Fig.).

These results suggest that physical activity could prevent the MIA deleterious effects on the BMD at proximal tibia in this rat model of osteoarthritis.

Preservation Effects on Bone Tissue Mechanical Properties. Sasha Rosen*[1], Bryan Kaye[2], Omar Ahmady[2], Connor Randall[3], Paul Hansma[1]. [1]University of California, Santa Barbara, USA, [2]UCSB Hansma Lab, USA, [3]UCSB, USA

Recently, The Reference Point Indentation (RPI) instrument has been shown to distinguish patients with and without fractures[(1)]. Patients with fractures tended to have larger values of Total Indentation Distance (TID) and Indentation Distance Increase (IDI)[(1-3)]. For laboratory work on cadaver bone, the bone must typically be preserved. Freezing is a commonly preferred method of bone preservation, as it prevents lysis and, thus, helps maintain the *in vivo* spatial arrangement of the bone proteins[(4)]. Another accepted approach is via chemical (namely ethanol) fixation. The advantages of chemical storage are primarily twofold; tissue decay is reduced and cell structure is preserved. In this study, the effects of these preservation techniques were evaluated using the Reference Point Indentation (RPI) instrument which performs Bone Microindentation Testing (BMT)[(1)]. Specifically, we studied the dependence of Indentation Distance Increase (IDI) and Total Indentation Distance (TID) on preservation technique.

The effects of preservation techniques were investigated on bovine femur. Baked and control samples of bovine femur were used to contrast weakened (baked) versus strong (control) organic extracellular matrix. Samples were frozen at -20℃. IDI and TID did not change after freezing baked bone. However, a 15% increase ($P<0.001$) in IDI was noted after the initial freeze cycle of control bone, but there was no difference in TID. Subsequent freeze-thaw cycles did not affect IDI or TID in both, baked and control bone. This leads us to postulate that a bone with less organic matrix will have a smaller degradation due to the first freeze-thaw cycle. Furthermore, subsequent freeze-thaw cycles no longer diminish the bone. Samples were stored in 70% ethanol at 5℃ and 25℃ for 40 days. The IDI of the samples that were stored at 5℃ increased by 18% ($P<0.001$), compared to a 35% increase ($P<0.001$) in IDI of the samples stored in 25℃. Ethanol fixation in bone and its corresponding degradation of the extracellular matrix is likely responsible for the deterioration in the mechanical properties. After exploring these common preservation techniques, we were able to determine statistically significant changes in the mechanical properties that were determined with the RPI instrument, revealing that these preservation techniques cannot maintain the mechanical properties investigated in this study.

Assessment of Bone Mineralization in Rats Treated with Sclerostin Antibody. Lindsey Edwards*[1], Amarjit Virdi[2], Kotaro Sena[2], D. Rick Sumner[2]. [1]Rush University, USA, [2]Rush University Medical Center, USA

Sclerostin antibody is being developed for the treatment of postmenopausal osteoporosis because of its robust efficacy in increasing bone volume. Generally, sclerostin, the protein product of the SOST gene, maintains bone surfaces quiescent. Neutralizing sclerostin with an antibody up-regulates Wnt signaling and activates quiescent surfaces into bone forming surfaces. While studies show that antibody treatment in animals and humans increases bone volume, little data has been published describing the quality of the newly formed bone. We hypothesize that treatment with sclerostin antibody will lead to a short-term depression in overall bone mineralization because of the anticipated increase in bone volume and the lag time associated with full mineralization. In the present experiment, the femurs of 10 Sprague Dawley rats that had received titanium implants in their contralateral limbs

were used. The rats were treated with saline or sclerostin antibody (Scl-Ab III: 25mg/kg, twice weekly) for 8 weeks. Positive effects of sclerostin antibody treatment on implant fixation were reported previously. In the present investigation, the intact femurs were harvested, formalin-fixed and scanned using micro-computed tomography (microCT) to assess bone volume and mineral density. The bones were then embedded in polymethyl methacrylate, sectioned, polished, carbon-coated and imaged using quantitative backscatter electron imaging (qBEI) as a second assessment of mineral density. Cortical bone area increased by 29% ($p < 0.001$) and trabecular BV/TV increased by 3-fold ($p<0.001$) in the sclerostin antibody-treated group. The mineral density of the cortical and trabecular bone, whether assayed by microCT or qBEI showed no statistical difference between groups (Table 1). The skewness, kurtosis and variance of the mineral frequency distributions were similar in each group. Thus, in addition to increasing bone volume, sclerostin antibody may also increase the rate of mineralization.

Table 1: Assessment of mean bone tissue mineralization at 8 weeks (n = 5). None of the differences between groups were significant, in contrast to the expectation that sclerostin antibody treatment would lead to an overall pattern of depressed mineralization.

	qBEI (calibrated grayscale units)		microCT (mg HA/cc)	
	Control	Scl-Ab Treated	Control	Scl-Ab Treated

***Runx2* Overexpression in Hypertrophic Chondrocytes Delayed Chondrocyte Maturation and Endochondral Ossification.** Ming Ding*[1], Qiping Zheng[2]. [1]Rush University, USA, [2]Rush University Medical Center, USA

Runx2 Overexpression in Hypertrophic Chondrocytes Delayed Chondrocyte Maturation and Endochondral Ossification

Ming Ding1, Sam Abbassi1, Jun Li2, Yaojuan Lu1, Rick D. Sumner1, Vale'rie Geoffroy3, Feifei Li1, Anna. Plaas2, and Qiping. Zheng1, *

Runx2, a member of the Runt domain protein family, has been demonstrated to be an essential transcription factor for osteoblast differentiation as well as a critical regulator for chondrocyte maturation. The type X collagen gene (Col10a1) is a specific molecular marker of hypertrophic chondrocytes during endochondral bone formation. It has been shown that type X collagen plays a critical role during skeletal development and maintenance by impacting the supporting properties of the growth plate and the mineralization process. Recently, a growing body of evidence suggests that Runx2 regulates type X collagen gene expression during chondrocyte maturation in different species. To investigate how Runx2 regulates murine Col10a1 gene expression and impacts chondrocyte maturation during skeletal development, we have generated transgenic mice in which Flag-tagged Runx2 cDNA was under the control of the 300-bp cell-specific Col10a1 regulatory element. Real-time PCR using total RNAs prepared from mouse limbs at the E17.5 and P1 stages showed that both Runx2 and Col10a1 mRNA were significantly increased in transgenic mice compared to their wild-type littermate controls. Histological analysis of long bone sections showed elongated hypertrophic zone with disorganized chondrocytes in transgenic mice. Skeletal staining suggests delayed ossification in craniofacial, long bone digits and the tails from embryonic day 14.5 (E14.5) till postnatal day 3 (P3). microCT analysis of the mice at 1 month stage suggests that the transgenic mice have shorter femur length. We have also performed expression analysis of marker genes for chondrocyte differentiation, maturation or apoptosis. The results showed that Sox9, Ihh (Indian Hedgehog), Mmp13 (Collagenase-3), Bcl-2 (the anti-apoptotic marker gene), and Osx (Osterix) were all significantly increased in transgenic mice. No expression level change was observed for Vegf (Vascular endothelial growth factor). Our data suggest that Runx2 regulates cell-specific Col10a1 expression and chondrocyte maturation in vivo. The Runx2 transgenic mice that have enhanced Runx2 and Col10a1 expression may trigger Ihh and Sox9 expression which dominantly arrest chondrocyte maturation. This may lead to matrix environment change and impact chondrocyte apoptosis during skeletal development and maintenance.

Dual Action of Von Hippel Lindau (VHL) in Limb Bud Mesenchyme. Elisa Araldi*[1], Richa Khatri[1], Amato Giaccia[2], Ernestina Schipani[3]. [1]MGH, USA, [2]Stanford University, USA, [3]Massachusetts General Hospital & Harvard Medical School, USA

Numerous lines of evidence suggest that the genetic program activated by hypoxia has a critical role in endochondral bone developmentt in vivo. Consistent with its avascularity, the murine fetal growth plate displays a gradient of oxygenation with a central, hypoxic region. Genetic experiments in vivo have shown that the transcription factor Hypoxia-inducible factor-1α (Hif-1α), which is a major mediator of the cellular adaptation to hypoxia, is necessary for chondrocyte survival and for differentiation of mesenchymal precursors into chondrocytes, by triggering a complex homeostatic response that involves, at least in part, the accumulation of a proper extracellular matrix.To expand our understanding of the role of the Hif family of transcription factors (Hifs) in chondrogenesis, in this study we genetically deleted Von Hippel Lindau protein (pVHL), the E3 ubiquitin ligase responsible for degradation of Hifs under normoxia, in whole limb bud mesenchyme, i.e. both in mesenchymal cells that differentiate into chondrocytes and in mesenchymal cells that give origin to the vascularized soft tissue surrounding the avascular cartilaginous primordia. Lack of pVHL in chondrocytes caused a severe shortening and thinning of the mutant cartilaginous elements, which were markedly deformed and hypocellular, and eventually collapsed, possibly as a result of cellular growth arrest and death. Conversely, lack of pVHL in the soft tissue surrounding the chondrocytic growth plates led to formation of foci of ectopic cartilage, to massive fibrosis, and to appearance of fibromyxoid tumor-like structures, which expanded into and replaced the collapsed cartilaginous structures. We are currently investigating the molecular mechanisms of this apparent dual action of pVHL in cartilage and in the surrounding mesenchyme, with particular emphasis on the role of the Hif family of transcription factors. Taken together, our findings indicate that lack of pVHL may have differential biological effects in cells of mesenchymal origin, depending on their phenotypical identity.

Histological, Functional and Contrast-based çCT Evaluation a Novel Osteoarthritis Model in Mice. Zhechao Merry Ruan*[1], Frank Gannon[1], Michael Heggeness[1], Brian Dawson[1], Ming-ming Jiang[1], Jennifer Black[2], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Vanderbilt Univeristy, USA

Osteoarthritis (OA) is common clinical condition characterized by degeneration of articular cartilage, limited intraatricular inflammation with synovitis, and changes in peri-articular and subchondral bone. Current well-characterized animal models of OA include spontaneous models in larger animals, genetics models in mice, and surgery models in rats and rabbits. However, none of these models are optimal for genetics and therapeutic studies that are clinically relevant. Patients with anterior cruciate ligament (ACL) tearing usually develop OA within 1 to 2 years after injury. And, the progression of the disease is similar to spontaneous development of OA in elder patients. Therefore, we hypothesize that ACL transected mice will provide an OA model of great genetic and therapeutic relevance. To test this, we developed a microsurgical procedure to transect the ACL in hind limbs of mouse with minimal damage to the surrounding tissues. We developed a scoring system for mouse OA based on the human OA grading system published by Priztker et. al. in 2006. Samples collected 24 hours after surgery confirmed that little damage were caused directly by the surgery to surrounding tissues. 4 weeks after surgery, histological scoring of ACL transected mouse joint samples by blinded observers showed significantly different scores in transected vs. mock surgery groups (N=10). We also observed synovitis, mast cells recruitment, and neovascularization in cartilage in the ACL transected group. To evaluate the motor skills of mice in this model, ACL transected and mock mice were subjected to various behavior tests before surgery and 4 weeks after surgery. While the walking speed and active/rest time remains similar in ACL transected group and mock, the former showed decreased rotarod running time and increased hotplate response time compared to the latter (N=15). We also observed gait changes in the ACL transected group. Finally, we established a method to evaluate mouse cartilage quantitatively and qualitatively by contrast-based micro-computed tomography (μCT). We are testing whether this method could differentiate ACL transected group from mock surgery. This model will facilitate the study of genetic manipulations in cartilage in the pathogenesis and treatment of OA.

Hypophosphatemia-independent Changes in Extracellular Matrix Proteins in Hyp Mice may Underlie the Articular Cartilage Degeneration of X-linked Hypophosphatemia. Carolyn Macica*[1], Ali Nasiri[2], Guoying Liang[3]. [1]Yale University School of Medicine, USA, [2]Yale Univeristy, USA, [3]Yale University, USA

The two major sites of paradoxical hypermineralization in patients with X-linked hypophosphatemia (XLH) occur in cartilaginous tissues; the fibrocartilaginous tendon/ligament insertion sites and at the margins of synovial joints resulting in formation of enthesophytes and osteophytes, respectively. Despite effective treatment of rickets/osteomalacia, this complication dominates the adult clinical picture. We have previously demonstrated that the Hyp mouse, a murine XLH model, develops an enthesopathy at sites most commonly affected in patients, characterized by a significant expansion of mineralizing fibrocartilage (Liang et al., 2009). Osteophyte formation is an adaptive response that occurs secondary to articular cartilage (AC) degeneration. We now identify alterations in the articular surface of Hyp mice (12 wks) that may predispose patients with XLH to AC degeneration.

We identified a significant reduction in the expression of two matrix proteins normally confined to the mineralized zone of AC; the matrix-degrading enzyme, matrix metalloproteinase-13 (MMP13) and osteopontin (OPN), a mineral-binding secreted glycoprotein. This is accompanied by a significant loss of the mineralized hypertrophic zone of AC (von Kossa), despite elevated alkaline phosphatase activity. EPIC-microCT analysis of hexabrix-labeled-AC (6 micron isometric voxel size, threshold applied to include unmineralized AC but exclude mineralized AC/bone) confirmed an increase in unmineralized AC (wt 0.096 ± 0.01 mm vs. Hyp 0.158 ± 0.01 mm, $p<0.05$). SafO staining revealed a redistribution of proteoglycans from above the tidemark into the entire articular surface. In contrast, secreted osteoblast MMP13 and OPN were unaffected in subchondral and trabecular bone, underscoring potential regulatory differences between mineralizing osteoblasts and chondrocytes in Hyp mice despite an identical metabolic backdrop.

The cellular cues for these changes likely include both mechanical and biochemical factors and may be unique to cartilaginous tissues. We thus measured markers of mineralizing hypertrophic AC of Hyp mice treated with or without oral P/vitamin D to determine the impact of correcting the abnormal phosphorous and mechanical forces of rickets/osteomalacia. We found that while the rickets was effectively treated, the AC abnormalities persisted. These data suggest a local role of biochemical factors unique to XLH in mediating changes to the architecture of the zonal arrangement that defines AC.

Muscular Function and Bone Strength Related Variables after Knee Replacement. Ari Heinonen*[1], Timo Rantalainen[2], Anu Valtonen[3], Tapani Pöyhönen[4], Sarianna Sipilä[5]. [1]Department of Health Sciences, University of Jyväskylä, Finland, [2]Neuromuscular Research Centre, Department of Biology of Physical Activity, University of Jyväskylä, Finland, [3]Rehabilitation & Pain Unit, Kymenlaakso Central Hospital & Department of Health Sciences, University of Jyväskylä, Finland, [4]Rehabilitation & Pain Unit, Kymenlaakso Central Hospital, Finland, [5]Gerontology Research Centre, Department of Health Siences, University of Jyväskylä, Jyväskylä, Finland

The bone loss after total knee replacement is apparently stress shielding related and may lead to loosening of the prosthesis. In order to provide more information for rehabilitation after knee replacement to prevent this bone loss, a sample of 29 women and 19 men who were 55 to 75 years old and had undergone unilateral knee replacement surgery an average of 10 months (range 4-17) earlier were recruited. Muscular function was assessed with maximal torgue in knee extension and flexion with an isokinetic dynamometer at an angular velocity of 60°/s. A single computed tomography (QCT) slice was obtained from femoral mid-shaft comprising both legs. The Hounsfield units provided by the QCT device were converted to volumetric bone mineral density (vBMD) values by scanning (K2HPO4) phantom liquids and calculating the linear conversion equations. Cortical cross-sectional area (CoA), cortical volumetric BMD (CoD) and density weighted section modulus (SSI) were calculated from the QCT slices for the operated and the non-operated femurs. The bones were compared to each other with ANOVA having the leg as a within subject factor. The operated thigh CoA was 3% smaller ($393 + 82$ mm^2 vs. $405 + 75$ mm^2; $p = 0.003$) and CoD 1% lower ($991+ 39$ mg/ cm^3 vs. $999 + 37$ mg/ cm^3; $p < 0.001$) than that in the operated thigh, whereas no side-to-side difference was observed in SSI ($2560 + 690$ mm^3 vs. $2600 + 630$ mm^3; $p = 0.120$). In the stepwise regression analyses knee extension and flexion torque, age, height, body mass, pain score (VAS, mm) and time since operation explained 44% of the variance in the CoA, 33% in CoD and 52 % of the variance in SSI on the operated side. Body mass explained independently 7% ($p = 0.020$) of the CoA variation, 14 ($p < 0.001$) of the CoD and 7% ($p = 0.015$) of the SSI variation. In addition, maximal knee flexion torque turned out to be the strongest independent predictor, explaining 37% ($p < 0.001$) of CoA variation, 7% ($p = 0.043$) in CoD and 45% ($p<0.001$) of the SSI variation. Further, time since operation explained independently 12% ($p=0.020$) of the CoD variation. In conclusion, the operated thigh had less cortical bone, and muscle force of the operated leg is a strong independent predictor of the femoral mid-shaft bone strength in subjects undergone unilateral knee replacement surgery. This indicates indirectly that after total knee replacement, early and efficient rehabilitation should be emphasized.

The Potential Role of Gas6 in Growth Plate Chondrocytes. Phillip Newton*[1], Ann Canfield[1], Colin Farquharson[2]. [1]University of Manchester, United Kingdom, [2]Roslin Institute & R(D)SVS, University of Edinburgh, United Kingdom

During endochondral ossification mesenchymal cells differentiate into chondrocytes and further differentiate to a state of hypertrophy. In the developing bone, the chondrocytes align to form the highly organized mature growth plate. At each stage the chondrocytes secrete specific extracellular matrix (ECM) components and ultimately this ECM becomes mineralized allowing vascular invasion and the formation of the primary spongiosa. Gas6 has previously been detected in growth plate chondrocytes by microarray analysis and recombinant Gas6 has been shown to influence chondrocyte differentiation in vitro, although a precise function and mechanism is yet to be elucidated. Signaling within the growth plate has been suggested via interactions between Gas6 and its receptors Axl and most recently, Mer. Axl and Gas6 have also been reported in chondrocytes of articular cartilage and their signalling has been shown to prevent ectopic mineralization within the vasculature via anti-apoptotic mechanisms.

To determine the spatial expression of Gas6 in the growth plate, 28-day old murine tibial growth plates were analysed by immunohistochemistry. Also, an in vitro model using chondrocyte-like ATDC5 cells was used to determine the temporal expression patterns of Gas6, Axl, Mer and chondrocyte markers by Western blot and qPCR during chondrocyte differentiation and ECM mineralization.

Gas6 was detected by immunohistochemistry in the resting, proliferating and hypertrophic zones of the growth plate but expression was concentrated in the proliferating zone. Analysis of ATDC5 cells confirmed that they underwent the expected stages of differentiation as demonstrated by the expression of collagen types II and X; ECM mineralization began at day 14 of culture. Gas6 mRNA expression was minimal at day 6 of culture and was maximally expressed at day 13 before decreasing. Total Axl protein and mRNA expression both peaked at day 8 and decreased thereafter, whereas phosphorylation of Axl was prolonged throughout culture. Mer mRNA expression was determined from day 6 and peaked at day 8 before decreasing. This data shows the spatial and temporal distribution of Gas6 within the growth plate and in addition, the detection of phosphorylated Axl within differentiating ATDC5 cells. This strongly suggests a role for Gas6 signaling in the growth plate.

The consequences of Gas6 signaling within the growth plate are unknown and further studies are required to determine Gas6 mediated events.

The Role for CTGF and Src in Mesenchymal Stem Cell Condensation Induced by TGF-β1. Fabiola Del Carpio-Cano*[1], Steven Popoff[2], Raul DeLa Cadena[3], Fayez Safadi[2]. [1]Temple University, USA, [2]Temple University School of Medicine, USA, [3]Temple University School of Medicine, Department of Physiology, USA

The aggregation/condensation of mesenchymal cells (MSC) is a critical step for chondrocyte differentiation. TGF-β1 has been shown to promote MSC migration, proliferation, and condensation. Connective tissue growth factor (CTGF) is a matricellular protein expressed during MSC condensation where regulates matrix production. Previous studies have shown that CTGF acts as a downstream mediator of TGF-β1-induced MSC condensation. Silencing of CTGF expression inhibits MSC condensation induced by TGF-β1. In the present study, we further examined the role of CTGF in TGF-β1-induced MSC condensation. We assessed MSC migration, proliferation, condensation, and other markers of chondrogenesis induced by TGF-β1 in C3H10T1/2 cells infected with adenovirus expressing either CTGF-GFP (Ad-CTGF-GFP) or GFP alone (Ad-GFP; control), both in the presence or absence of exogenous TGF-β1 (5ng/ml) treatment. CTGF overexpression inhibited TGF-β1-induced MSC condensation compared to control cultures. Overexpression of CTGF inhibited the migration and proliferation that is normally observed in cells treated with TGF-β1. We also evaluated gene expression for extracellular matrix and chondrogenesis markers (aggrecan, Col 1α2, Col 2α1, fibronectin and Sox-9) by qPCR analysis. The overexpression of CTGF inhibited the expression of all markers compared to the control infected cultures and also prevented up-regulation of markers induced by TGF-β1. Next, we examined whether Src activation plays a role in MSC condensation induced by TGF-β1. Src was activated upon TGF-β1 treatment of MSC cells. In the presence of PP2, a Src family kinase inhibitor, TGF-β1 failed to induce MSC condensation. In the Ad-CTGF-GFP overexpressing cells, Src was constitutively activated at very high levels despite the fact that these cells did not condense or

respond to TGF-β1 treatment. These results suggest that although CTGF and Src play essential roles in the induction of MSC condensation when induced by TGF-β1 in a temporal fashion, the continuos overexpression of CTGF has the opposite effect and prevents TGF-β1 induction of MSC condensation.

***RANKL* Expression in Mouse and Human T-Lymphocytes is Regulated by a Set of Cell-Type Specific Enhancers Designated the T-Cell Control Region.** Kathleen Bishop*, Xiaohua Wang, Heidi Coy, Robert Nerenz, Mark Meyer, Jenny Gumperz, J. Pike. University of Wisconsin-Madison, USA

Chronic activation of the immune system is directly linked to systemic bone loss. Excess bone resorption is likely due to elevated expression of receptor activator of NF-κB ligand (RANKL), a key osteoclastogenic factor synthesized by both osteoblasts and T-lymphocytes. In osteoblasts, RANKL expression is controlled through multiple distal elements marked by increased transcription factor occupancy, histone acetylation and RNA polymerase II recruitment. In T-cells, however, the mechanisms that underlie the expression of *RANKL* remain undefined. To explore this process, we confirmed that *RANKL* was induced in both mouse and human primary T-cells and then scanned over 400 kb surrounding the *RANKL* locus for regulatory enhancers using ChIP-chip analysis for histone H3/H4 acetylation. We identified potential *Rankl* enhancers at several regions previously characterized in osteoblasts, including the D5 enhancer, and identified a unique set of regulatory regions located over 120 kb upstream of the mouse *Rankl* TSS which we designated the T-cell control region (TCCR). Further studies showed that both DNA sequences and epigenetic modifications within the TCCR were highly conserved in both mouse and human and that histone H3/H4 acetylation levels were increased at the TCCR following activation. Inhibition of both MEK1/2 and calcineurin by U0126 and cyclosporine-A, respectively, resulted in decreased *RANKL* expression, suggesting that multiple T-cell signaling pathways are involved. Accordingly, we found that c-FOS, an effector of MEK1/2, was recruited to both the D5 enhancer and the TCCR, suggesting that c-FOS may mediate *RANKL* upregulation. The human and mouse D5 enhancers and segments of the TCCR mediated robust inducible luciferase activity following activation in Jurkat T-cells that was abrogated following mutation of the putative c-FOS response elements. Importantly, both D5 and segments of the TCCR were shown using 3C analysis to be in direct contact with the *Rankl* TSS and thus able to influence the gene's promoter directly. Finally, we note that SNPs linked to bone mineral density in both hip and spine are located within the TCCR, providing additional evidence that RANKL expression by T-cells may contribute to both normal bone remodeling as well as disease-related bone loss. We conclude that both the D5 and TCCR regions represent control segments within the *RANKL* locus that play an integral role in the transcriptional regulation of this gene in T-cells.

Effects of Inorganic Phosphate on the Dento-alveolar Complex, In Situ and I*n Vitro*. Yuri Yamamoto*[1], Sunao Sato[2], Brian Foster[3], Kenji Takada[2], Takashi Takata[4], Martha Somerman[3], Satoru Toyosawa[2]. [1]Osaka University, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]University of Washington School of Dentistry, USA, [4]Hiroshima University Graduate School of Biomedical Sciences, Japan

Objectives: The genes and associated proteins that regulate phosphate/pyrophosphate homeostasis, e.g., Ank or ENPP-1, are associated with protection from ectopic calcification. Hypercementosis has been reported in mice with mutations/knock-out of Ank and ENPP-1, where tissue pyrophosphate (PPi) levels are decreased and phosphate (Pi) to PPi ratio is increased. The aim of this study was to examine the effect of Pi/PPi imbalance on gene expression in cells associated with periodontal tissues, i.e., osteoblasts, cementoblasts and the precursor cell, follicle cells, *in vitro*.

Material and Methods: Incisors and molars obtained from mice with Ank and ENPP-1 mutations were examined at the light microscopic level. Osteoblasts, cementoblasts and follicle cells, previously isolated from mouse tissues, were cultured under different concentrations of Pi/PPi as a model to mimic the animal conditions for Ank/ ENPP-1 mutations. Changes in expression of specific genes, osteopontin (OPN), type ?collagen (Col?), dentin matrix protein 1 (DMP1), osteocalcin (OCN) and bone morphogenetic protein 2 (BMP-2), were examined by real-time reverse-transcriptase polymerase chain reaction (RT-PCR) at designated times from 12 hours to 72 hours and dose of 0, 1, 3, 5, 7mM Pi.

Results: Histological observations indicated that not only the molars but also the incisors from Ank and ENPP-1 mutant mice showed a marked increase in the amount of cementum when compared to wild-type. In ENPP-1 mutant mice, the thickened cementum was positively stained with OPN and DMP1.

BMP-2 was up-regulated 3-fold in dose and time dependent manner in the follicle cells, but wasn't changed in the osteoblasts and the cementoblasts. In contrast, DMP1 was up-regulated by 7mM Pi more than 200-fold in cementoblasts by 48 hrs and osteoblasts by 72 hrs, but was not changed in follicle cells. OCN was downregulated about 0.1 fold in dose and time dependent manner in the cementoblasts and about 0.2 fold in dose and time dependent manner in the follicle cells, but not in osteoblasts. OPN was up-regulated in all three cells.

Conclusion: These results suggest that functional changes in proteins such as ANK and ENPP-1, by affecting Pi/PPi ratio, may in turn affect mineralized tissue formation by altering expression of key genes and associated proteins in osteoblasts and cementoblasts, and further, may impact differentiation potential in follicle cells.

Amino Acids Differentially Regulate Bone Formation and Resorption. Carlos Isales*[1], Kehong Ding[1], Qing Zhong[1], Michael Cain[1], Xing-Ming Shi[1], Byung Rho Lee[1], Richard Robbins[1], Mark Hamrick[1], Wendy Bollag[1], Clare Bergson[1], Crystal Perkins[1], Justin Cowart[1], Monte Hunter[1], Brandon Scott[1], Norman Chutkan[1], Karl Insogna[2]. [1]Medical College of Georgia, USA, [2]Yale University School of Medicine, USA

The impact of dietary protein on bone mass has been controversial. Posited mechanisms for dietary protein's influence on the skeleton have focused on nutrient effects (e.g. the need for protein to model and remodel bone) or metabolic effects (e.g. the metabolic acid load imposed by sulfur-containing amino acids). However, recent data from a number of laboratories suggests that an underappreciated mechanism of nutrient action is directly on bone cells, a paradigm in which nutrients act as signaling molecules. In pursuing the possibility of direct nutrient effects on bone cells we examined individual amino-acid effects on osteoprogenitor/bone marrow stromal cells (BMSCs), a key target for bone anabolism and on osteoclasts, a key target for bone catabolism. Using BMSCs isolated from C57Bl6 mice and exposed individually to twenty of the common amino-acids we found that: (1) tyrosine, tryptophan and phenylalanine induced the largest increases in intracellular calcium as measured by single cell calcium measurements with Fura-2; (2) the same AA's that increased intracellular calcium, also led to a time-dependent increase in ERK phosphorylation, peaking at 10 minutes and returning to baseline by 30 minutes. ERK phosphorylation was not inhibited by Rapamycin (mTOR inhibitor) suggesting that the observed effects were not due to AA uptake and metabolism; and (3) tyrosine and tryptophan resulted in the greatest increases in BMSC proliferation (as measured by thymidine uptake). When the effects of all twenty common AAs were examined on primary osteoclasts isolated from C57Bl6 mice we found that: (1) cysteine, serine, methionine and arginine had the largest effect on early markers of osteoclastic differentiation while cysteine, proline, serine and arginine had the largest effects on late markers of differentiation as quantified by real time RT-PCR (vitronectin, MMP9, cathepsin K and calcitonin receptor); and (5) when osteoclastic activity was examined measuring pit resorption with Osteologic discs, the AAs: arginine, serine and proline were found to be most pro-resorptive. In summary our data

demonstrate that individual AAs can selectively activate either bone formation or breakdown. Our data also suggests that the observed differences may account for some of the discrepancies in the literature on dietary protein effects on bone since the AA composition may vary from one dietary source to another.

Arthroplasty Patients with Diabetes Mellitus Have Higher Bone Pentosidine Levels and Greater Immunohistochemical RAGE and MMP-1 than Patients without Diabetes. Karen King*[1], Allison Williams[2], Trevor Oren[1], Allan Bucknell[2]. [1]University of Colorado School of Medicine, USA, [2]VA Eastern Colorado Health Care System, USA

We previously identified a higher rate of total joint replacement surgeries (arthroplasty) in patients diagnosed with diabetes mellitus compared to patients without diabetes mellitus in a Veterans Affairs database.[1] The purpose of the present study was to identify an effect, if any, of diabetes on joint tissue metabolism.

With IRB-approval, cartilage and bone tissues were obtained as surgical wastes from total knee arthroplasty surgeries of osteoarthritis patients diagnosed with diabetes (N=10) or not diagnosed with diabetes (N=10). Osteochondral cores (5 mm dia.) were taken from the tibia plateau and either separated to cartilage and bone samples for collagen analysis or fixed whole for histology. Levels of collagen cross-links (HP, LP, and pentosidine) and total collagen were measured using HPLC. Osteochondral thin-sections were probed with monoclonal antibodies for RAGE or MMP-1.

Overall, cartilage had higher pentosidine levels than bone in both groups ($P < 0.001$). Bone pentosidine levels were higher in the group with diabetes compared to the group without diabetes (9.153×10^{-3} mol pentosidine/mol collagen vs. 6.945×10^{-3}, $P < 0.05$). Cartilage pentosidine levels were higher, but not statistically significant, in the diabetes group (2.624×10^{-2} mol pentosidine/mol collagen vs. 2.167×10^{-2}, $P = 0.075$). There were no differences between groups in the levels of HP or LP in bone or cartilage ($P > 0.05$). Immunostaining for RAGE was greater in the thin-sections obtained from the diabetes group. Immunostaining for MMP-1 was also greater in the diabetes group. Furthermore, the cells positive for RAGE and MMP-1 were located in the same regions, the cartilage superficial and mid zones and at the bone-cartilage interface.

These results support the hypothesis that hyperglycemia leads to increased pentosidine and other advanced glycation end-products in diabetes mellitus patients and that AGE-RAGE signaling causes inflammatory events such as increased MMP activity.[2] We propose that this hypothesis is applicable to the joint tissues and may be a factor (along with others such as BMI) in the increased rates of arthroplasty surgeries.

Delayed Healing and Efficient *In Vivo* Retroviral Transgene Transduction in a Mouse Segmental Defect Model of Bone Healing. Charles H. Rundle*, Nicoleta L. Popa, Jon Wergedal, Subburaman Mohan, Kin-Hing William Lau. Jerry L. Pettis Memorial VA Medical Center, USA

Approximately 10% of bone fractures display severely impaired healing that is resistant to current therapeutic approaches. Because the closed three-point bending rodent fracture model traditionally used in fracture studies heals well without intervention, its utility for investigations of impaired bone healing is limited. It is imperative to develop a rodent model that can be used to identify therapeutic approaches for severely impaired bone healing. Ideally, this model should: 1) exhibit non-union healing, and 2) permit efficient delivery of molecular therapy to the injury. To determine whether such a model of impaired bone healing is feasible in the mouse, we compared healing and transgene expression in the three-point bending fracture model with a segmental defect model. In each model, the femur was stabilized with an intramedullary pin; a drill was used to produce a 1-2 mm defect around the entire cortical circumference of the segmental defect model. Healing was monitored by radiology and by histology at 7 and 28 days healing. The segmental defect developed a callus of fibrous tissue during healing, but X-ray examination revealed that the hard callus failed progress to bony union (i.e., healing). Histomorphometry of the callus tissues at 7 days healing (N=4 to N=7 mice per group) established that the callus area of the segmental defect was reduced (38.7 ± 10.5 mm^2 vs 34.1 ± 4.8 mm^2, $p<0.05$), as was the proportion of cartilage area per callus area ($9.2 \pm 5.0\%$ vs $3.2 \pm 2.4\%$, $p<0.03$). There were no significant differences in these two parameters between models at 28 days healing, but the three-point bending fracture model had progressed to bony union, while the segmental defect model retained fibrous tissue within the defect. This model therefore exhibits bone repair with severely delayed union. To determine whether transgenes of potential benefit can be expressed from these tissues *in vivo*, we compared the closed fracture and segmental defect models (N=3 each) for expression of a ß-galactosidase gene delivered in retroviral-based vector. ß-galactosidase staining at 7 days healing demonstrated comparable transgene expression between models. Despite the loss of bony tissue in the segmental defect model, direct injection of viral vector to the injury was effective in transducing resident cells. It is therefore a valuable model to assess the therapeutic efficacy of gene therapy strategies to promote the healing of more clinically challenging bone defects.

Folate Supplementation During Pregnancy and Lactation Improves Bone Health of Female Mouse Offspring at Adulthood. Jovana Kaludjerovic*, Wendy Ward. University of Toronto, Canada

Supplementation with folic acid during the perinatal period is advocated for women of childbearing age as a prevention strategy against neural tube defects. However, the effects of folate supplementation on bone development have not been well characterized. The objective of this study was to determine if exposure to low (0 mg of folate/kg diet), adequate (2 mg of folate/kg diet) and supplemental (8 mg of folate/kg diet) amounts of dietary folate during perinatal life (defined as the period 1 week before conception to 3 weeks post conception) programs bone health at young adulthood in female mice. CD-1 mice (n = 12-16 pups/group) were randomly assigned to receive an amino acid based diet fortified with 0, 2 or 8 mg of folate/kg diet during pregnancy and lactation. At weaning, all pups were switched to an amino acid diet containing 2 mg of folate/kg diet, as this is the basal dietary requirement for rodents, and were studied to young adulthood (4 months of age). Body weight was measured weekly. Bone mineral density (BMD) and biomechanical strength at femur and lumbar vertebrae were measured at 4 months of age. There were no differences in body weight from postnatal day 1 to 10 among groups, but from postnatal day 10 to 120, mice fed a diet fortified with 2 or 8 mg of folate had significantly higher ($p<0.05$) body weights compared to folate deficient mice who grew at a significantly lower rate. Females fed a diet containing 8 mg of folate/kg diet had significantly higher ($p<0.05$) BMC and BMD at the femur and lumbar vertebrae (LV1-3) compared to those fed a folate deficient diet. Moreover, peak load of the femur midpoint, femur neck and LV2 was significantly higher ($p<0.05$) in mice fed 8 mg of folate compared to those fed a diet devoid of folate. In conclusion, exposure to dietary folate (2 or 8 mg/kg diet) during perinatal life results in normal growth and bone development in CD-1 mice. Future research should determine if the higher BMC, BMD and greater bone strength with supplemental levels of folate in utero and during suckling protect against deterioration of bone tissue during aging.

Large Scale Destabilization of Type I Collagen Triple Helix may Explain Increased Severity of Osteogenesis Imperfecta Caused by Mutations Near the Collagenase Cleavage Site. Elena Makareeva[1], Sejin Han[1], Juan Carlos Vera[1], Nydea Aviles[1], Wayne A. Cabral[1], Joan Marini[2], Robert Visse[3], Hideaki Nagase[3], Sergey Leikin*[1]. [1]National Institutes of Health, USA, [2]National Institute of Child Health & Human Development, USA, [3]Imperial College London, United Kingdom

Most cases of severe and lethal osteogenesis imperfecta (OI) are caused by substitutions of obligatory Gly residues in the triple helical region of type I collagen. Years of studies and hundreds of reported substitutions revealed no simple relationship between OI genotypes and phenotypes, probably because many different factors contribute to the disease severity. One such factor appears to be regional variations in structural and functional properties of the collagen triple helix. In the present study we focused on characterizing the region surrounding the collagenase cleavage site, in which virtually all α1(I) and many α2(I) Gly substitutions were found to be lethal. Analysis of structural changes in this region caused by various mutations revealed reversible unfolding of a significant fraction of the triple helix, clearly detectable by circular dichroism and susceptibility to different enzymes. For instance, we observed not only faster cleavage of mutant molecules by collagenases but also their efficient cleavage by a gelatinase (MMP-2) and the catalytic domain of MMP-1, which have only residual collagenase activity. Our earlier findings suggested that procollagen triple helix folding within this region may be challenging for cells even in the absence of mutations. The large scale triple helix destabilization observed in the present study suggests that mutations within this region may be particularly detrimental for procollagen folding, resulting in severe ER stress and malfunction of osteoblasts, potentially explaining the lethal OI phenotype. Further testing of this hypothesis is currently under way.

Micro-Computerized Tomographic Assessment of Zebrafish Skeleton. THEODORE CRAIG*[1], Glenda Evans[2], Theresa Hefferan[1], Michael Yaszemski[3], Stephen Ekker[4], Rajiv Kumar[3]. [1]Mayo Clinic, USA, [2]Orthopedics Research, Department of Orthopedics, Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA, [4]Department of Biochemistry & Molecular Biology, Mayo Clinic, USA

Skeletal development in the zebrafish (*Danio rerio*) is similar to that observed in mammals. The expression of genes that might play a role in skeletal development can be readily manipulated in zebrafish, and genetic screens can be used to identify novel genes important in skeletal morphogenesis in this organism. Methods to assess bone architecture and bone mineral content in zebrafish are needed. Bone specific dyes such as alizarin red and calcein can be used to assess skeletal morphology but do not yield quantitative data regarding mineralization. Assessment of skeletal structure, development and mineralization using micro-computerized tomography (μCT), a non-invasive method with high spatial resolution, has not been standardized in this organism. Thirty day-old, juvenile, zebrafish were euthanized and fixed in formalin/phosphate buffered saline. Fish were scanned with a Scanco 35 μCT instrument (integration time 300; isotropic resolution of 3.5 μm; Vasquez et al, Anat. Rec. 291:475-487, 2008) to assess skeletal morphology and bone characteristics. The data were analyzed using the Scanco software. The architecture of mandibular and pharyngeal bones and the components of the dorsal skull was clearly visualized. In the vertebrae of the spine, structure and bone density were readily determined. Data from male and female zebrafish at each of the following ages will be presented: 10 day post fertilization (dpf), 20 dpf, 30 dpf, 60 dpf and 90 dpf. For purposes of comparison skeletal architecture in fish stained with 0.1% alizarin red in 3% potassium hydroxide (Quatro and Longaker, Cells Tissues Organs 181:109-118, 2005) and 0.2% calcein in de-ionized water (Du *et al*, Dev. Biol., 238:239-246, 2001) will be presented.

Results: Micro-computerized tomography assessed the structure and bone mineral density of the zebrafish skeleton with exceptional clarity and accuracy at ~30 dpf. In the skull, cranial sutures were readily visualized and bone density determinations were readily performed on bones of the skull and vertebrae. Bone structure was visualized as early as 10 dpf. Micro-computerized tomography is more easily performed and more sensitive than the dye based methods.

Conclusions: Micro-computerized tomography can be used to assess zebrafish skeletal development and bone mineral density and should serve as a powerful tool to assess skeletal defects and changes in mineralization.

Morphological Comparison of the Skulls of Mice Mimicking Human Apert Syndrome Resulting From Gain-of-function Mutation of FGFR2 Ser252Trp and Pro253Arg. Xiaolan Du, Tujun Weng, Qifen He, FengTao Luo, Lin Chen*. State Key Laboratory of Trauma, Burns & Combined Injury, Center of Bone Metabolism & Repair, Trauma Center, Institute of Surgery Research, Daping Hospital, Third Military Medical University, China

Apert syndrome is caused mainly by two gain-of-function mutations in FGFR2, Ser252Trp and Pro253Arg. Slaney,et al found that patients with Apert syndrome resulting from FGFR2 Pro253Arg mutation have more severe syndactyly and less common cleft palate. Von Gernet found that patients with Apert syndrome resulting FGFR2 Ser252Trp, in general, have more severe craniofacial phenotypes than those of patients with FGFR2 Pro253Arg. There is, however, no well-controlled comparison of the difference in the skull morphology between Apert syndrome resulting from these two FGFR2 mutations. Taking the advantage of the mouse models mimicking these two syndromes, we did this comparison. The three-dimensional coordinate locations of 27 biologically relevant landmarks located on the skulls of mice mimicking human Apert syndrome resulting from FGFR2 Ser252Trp (Fgfr2+/S252W) and Pro253Arg (Fgfr2+/P253R) and their wild-type (WT) littermates (8w) were collected by using three-dimensional coordinate measuring machine. The euclidean distance matrix analysis (EDMA) was used to statistically characterize the three dimensional form of 10 biologically relevant landmark subsets that were designed to represent the skull shapes of the Fgfr2+/S252W and Fgfr2+/P253R mutants. In general, compared with that in WT littermates, Fgfr2+/S252W mutant mice have more shallow and wider orbit, wider anterior neurocrania, more shortened premaxilla and face height than that in Fgfr2+/P253R mice. We further found that there were significant differences in the biologically relevant landmark subsets for maxilla, orbit and anterior neurocrania ($P<0.01$). Differences were also found in face height and neurocranium($P<0.05$). There were, however, no differences in the landmark subsets for the nasal, frontal, midface, smaller midface and vault ($P>0.05$). Our results indicate that there are subtle differences in the skull morphology between Apert syndrome caused by FGFR2 Ser252Trp and FGFR2 Pro253Arg mutation. Further studies are needed to confirm these findings in detail and in patients with Apert syndrome. This work was supported by the Major State Basic Research Development Program of China (2005CB522604) and National Natural Science Foundation of China (30971607, 30530410)

Tgf-beta in the Development of the Intervertebral Disc. Rosa Serra[1], Philip Sohn[2], Megan Cox*[2]. [1]University of Alabama at Birmingham, USA, [2]UAB, USA

Transforming growth factor β (Tgf-β) signaling plays an integral part in skeletal development. Conditional deletion of Tgf-β type II receptor (Tgfbr2) from type II Collagen expressing cells has been shown to cause defects in vertebrae and intervertebral disk (IVD) development. To determine how Tgf-β affects differentiation of mesenchymal progenitor cells in the axial skeleton, we performed an RNA microarray analysis on sclerotome cells that had been cultured with or without Tgf-β1. A separate microarray screen was done using RNA collected from vertebrae and IVD tissue isolated by laser dissection from e13.5 mice. From the microarray data, we determined through hierarchical clustering analysis that Tgfbr2 deleted IVD more closely resembled developing vertebrae than developing IVD. Furthermore, scatter-plot analysis was used to show that the genes that are up-regulated by TGF-ß are primarily expressed in the IVD, supporting the hypothesis that TGF-ß can promote the IVD phenotype at the molecular level. We selected several transcription factors that were regulated by Tgf-β treatment, differentially expressed in the IVD versus the vertebrae, and/or decreased in IVD with Tgfbr2 deletion, for further study: Erg, Nfatc1, Ebf1, and cMaf. Regulation by Tgf-β was confirmed by semi-quantitative RT-PCR on RNA from primary sclerotome cells treated with Tgf-β1. In situ hybridization analysis and database searches were done to determine the expression pattern of genes in vivo. This analysis showed that Erg1 and Nfatc1 are specifically localized to the IVD and Ebf1 and c-maf are preferentially localized to the vertebrae. To study the effects of Tgf-β overexpression in axial skeleton development, we used the chick model system. Tgf-β soaked Affi-gel beads were placed into the lumbar region of the axial skeleton at stage HH 22- HH 25. Within 48h post-implantation, we are able to see an inhibition of cartilage formation as determined by Alcian blue staining in the area surrounding the bead. This suggested that Tgf-β acts to suppress cartilage formation in the sclerotome. Overall, the data support a model in which Tgf-β acts to maintain the IVD and prevent differentiation into cartilage. These experiments help to address fundamental questions about development of the axial skeleton and provide a basis for future studies aimed at disc repair or replacement.

The Role of Tgfbr2 in Sclerotome Migration During Vertebrae Development. Ying Wang*, Rosa Serra. University of Alabama at Birmingham, USA

The vertebral column develops from somites. During vertebrae development, sclerotome, a population of undifferentiated mesenchymal cells, differentiates and migrates to give rise to distinct parts of the vertebrae and ribs. Spina bifida occulta is one of the most common congenital malformations in humans leading to disability. Our laboratory has shown that deletion of TGFβ type II receptor (Tgfbr2) in Col2a expressing tissue in mice results in alterations in the formation of the vertebrae. The dorsal vertebrae of these mice failed to fuse, which mimics the symptom seen in patients with spina bifida occulta. Since sclerotome cell (SC) migration plays a key role during dorsal structure formation, we hypothesized that signaling through Tgfbr2 mediates the development of the dorsal vertebrae by regulating migration of SC. We first crossed the Col2aCre mice to the Rosa26 reporter strain to track SC migration *in vivo*. There was no observable difference between control and experimental group at E15.5. However, migration defects were seen in the mutant mice by E17.5, suggesting that TGFβ signaling is required for sclerotome migration during later stages of dorsal vertebrae development. To determine the underlying mechanism of TGFβ regulation of SC migration, we isolated SC from E11.5 embryos and performed migration assay using a chemotaxis chamber. TGFβ greatly induced wild-type cell migration, while migration of cells lacking Tgfbr2 was disrupted. Since platelet-derived growth factor (PDGF) has been shown to play a central role in regulating sclerotome migration, and it is one of the downstream effectors of the TGFβ signaling pathway, we then determined the direct effect of PDGF on SC migration. Both ligands AA and BB induced migration at distinct concentrations. The expression of PDGF-BB was greatly increased in cells treated with TGFβ, while that was decreased in cells lacking Tgfbr2. These data suggest that the action of TGFβ on SC migration may be mediated by the downstream effector PDGF-BB. The changes of PDGF-BB expression in the mutant mice will be examined by in situ hybridization analysis. To identify additional target genes involved in SC migration, we performed a microarray assay comparing

untreated and TGFβ treated SC and found that chemokine CCL21 was upregulated by TGFβ. Preliminary studies showed that CCL21 promoted SC migration. Taken together, our data suggest that PDGF-BB may mediate TGFβ induced SC migration along with other chemokines.

Hypoxia Promotes Myotube Formation and Fusion via AKT-FoxO3a Pathway. Yoshitaka Kawato*[1], Makoto Hirao[1], Yui Honjo[1], Hiroki Oze[1], Kenrin Shi[1], Akira Myoui[2], Hideki Yoshikawa[1], Jun Hashimoto[1]. [1]Osaka University Graduate School of Medicine, Japan, [2]Osaka University Hospital, Japan

Muscle is a very important organ in musculoskeletal system. There are two major pathways to create adenosine triphosphate(ATP) in skeletal muscle tissue. Change of oxygen levels is one of major determinant for skeletal muscle bioenergetics; oxidative phosphorylation and glycolysis, however it remains unknown that oxygen level also influence on myogenesis. It has been reported that normal O_2 levels in skeletal muscle tissue is relatively low (2-5%) (Kunze 1976; Heinrich 1987; Evers 1997). So, we hypothesized that myogenesis might be promoted when low oxygen tension condition. The murine myoblast C2C12 was induced to differentiate using DMEM supplemented with 2% horse serum and cultured under normoxia (20%O_2) for 4days. After that, we separated to normoxia and hypoxia (5%O_2) and cultured another 6days. We performed immunocytochemistry using mouse monoclonal anti-myosin MF20 primary antibody. Fusion index (the number of nuclei within myotubes/ total number of nuclei) was increased by hypoxia (85.7 ± 3.7%) (mean ± S.D.) compared to normoxia (34.8 ± 2.7%). Hypoxia also increased the percentage of myotubes with over six nuclei (82.4 ± 6.2%) compared to normoxia (37.8 ± 11.2%). Western blot analysis revealed the increase of myosin heavy chain protein expression under hypoxia in day7 and 10. Next, we checked the influence of p38MAPK and PI3K-AKT pathway on the hypoxia-induced promotion of myogenesis, because these pathways have been reported to play important role in the myogenesis, furthermore to be activated by hypoxia stimulation. SB203580 (p38MAPK inhibitor) blocked myotube formation dose dependently, however, hypoxia-induced influence was clearly still remained. On the other hand, LY294002 (PI3K-AKT inhibitor) abolished the myotube formation induced by hypoxia. Then, we focused on FoxO3a, which is downstream of AKT pathway and an important transcriptional factor for muscle atrophy-related genes. In fact, *atrogin-1* expression was down-regulated by hypoxia. Luciferase reporter assay revealed that FoxO3a transcription activity was down-regulated by hypoxia, and phosphorylation of AKT and FoxO3a was clearly up-regulated. Furthermore, overexpression of FoxO3a using constitutively active form FoxO3a (TM-FoxO3a) almost completely blocked hypoxia-induced myotube formation and fusion. Taken together, although further confirmation is required, down-regulation of FoxO3a activity due to phosphorylation of AKT-FoxO3a pathway is an important mechanism in hypoxia-induced myotube formation and fusion.

Impairment of Long Bone Growth and Progressive Establishment of High Trabecular Bone Mass in Mice Lacking Bone Sialoprotein (BSP). Maya Boudiffa[1], Ndéyé-Marième Wade-Gueye[2], Marco Cardelli[3], Norbert Laroche[2], Arnaud Vanden-Bossche[2], Jane Aubin[4], Laurence Vico[5], Marie-Helene Lafage-Proust[6], Luc Malaval*[7]. [1]IRCM, Canada, [2]Université de Lyon, INSERM U890, Université Jean Monnet, 42023, France, [3]Dept. of Molecular Genetics, University of Toronto, Canada, [4]University of Toronto Faculty of Medicine, Canada, [5]University of St-Etienne, France, [6]INSERM Unit 890, France, [7]INSERM U890-Université de Lyon-Université Jean Monnet, Saint-Etienne, France

Bone sialoprotein (BSP) is strongly expressed by osteoblasts, osteoclasts and hypertrophic chondrocytes, and is particularly abundant in sites of primary bone formation. We previously showed that adult mice with a knockout of the bsp gene (BSP-/-) present with low bone formation and resorption parameters but a higher trabecular bone mass than their wild type counterparts. This raises the question of the mechanisms of trabecular bone accumulation in the mutants. In this study we analysed bone development in BSP-/- mice.

Newborn BSP-/- mice do not show any general skeletal abnormality. However, microtomographic (μCT) analysis reveal a delay in membranous primary ossification, with wider sutures in BSP-/- than in BSP+/+ fetuses, as well as thinner femoral cortical bone (-/- vs +/+, M±SEM, 31.4±3.3 vs 56.4±5.3μm, N=4, $p<0.01$) and lower tissue mineral density (367±5.5 vs 400±11.0, N=5, $p<0.05$). Histomorphometric measurements on newborns show that trabecular bone volume and osteoclast parameters do not differ between genotypes (BV/TV=8.6±0.7 vs 9.9±2.8%, N=10). However, as early as 3 weeks after birth, osteoclast number (not shown) and surface drop in mutant mice of both sexes (males: 8.6±0.9 vs 6.4±0.7%, females: 7.2±1.4 vs 3.6±0.4%, N=5, $p<0.001$, 2way ANOVA), concomitant with trabecular bone accumulation (m: 15.9±1.0 vs 11.6±1.6%, f: 18.6±1.6 vs 6.8±1.3%, N=6, $p<0.001$).

Mutant mice are smaller than wild type since birth and throughout life. The growth plates are thinner in newborn BSP-/- (564±18 vs 655±36μm, N=5, $p<0.05$), with a thinner hypertrophic zone (204±10 vs 218±8μm, N=5, $p<0.05$), suggestive of lower activity. At 3 weeks of age, there is no difference in total growth plate thickness, but the proliferating zone of either sex is thinner and the hypertrophic zone thicker in BSP-/- than in BSP+/+ mice (m: 131±14 vs 94±10μm, f: 98±4 vs 84±8μm, N=5, $p<0.05$), maybe reflecting a combination of lower proliferation and impaired resorption. No differences in growth plate parameters were observed in older (10, 16, 40, 48 week) mice.

In conclusion, lack of BSP alters long bone growth through early growth plate kinetics, as well as membranous/cortical primary bone formation and mineralization. Endochondral development is however normal in mutant mice and the accumulation of trabecular bone observed in adults develops progressively in the weeks following birth, concomitant to a drop in osteoclast numbers/surfaces. Further studies are needed to clarify the impact of BSP deficiency on growth plate chondrocytes and the compensatory mechanisms that allow normal endochondral development in BSP-/- mice.

A Novel Mechanism for Dose-to-Duration Encoding: ATP Concentration Determines the Persistence of Ca^{2+}/NFATc1 Signaling through Distinct P2 Receptor Subtypes in Osteoblasts. Matthew Grol*, Alexey Pereverzev, Stephen Sims, S. Jeffrey Dixon. The University of Western Ontario, Canada

Cellular responses typically vary with the strength of the stimulus. Thus, underlying transduction mechanisms must relay quantitative information about the intensity of the signal. We and others have shown that ATP, released in response to mechanical stimuli, signals through cell-surface P2 receptors expressed in many cell types including osteoblasts. P2Y are G protein-coupled receptors that classically signal through release of calcium from intracellular stores; whereas, P2X are ATP-gated channels that permit influx of calcium from the extracellular milieu. The calcium-regulated transcription factor NFATc1 (which upon activation translocates from the cytoplasm to the nucleus) plays an essential role in the differentiation of osteoblasts; however, mechanisms leading to activation of NFATc1 during osteoblastogenesis are unknown. Our preliminary studies revealed dramatic differences in the duration of NFATc1 signaling encoded by the concentration of extracellular ATP. Thus, our purpose was to investigate the mechanisms underlying this "dose-to-duration" encoding. Live- and fixed-cell confocal microscopy were used to localize enhanced green fluorescent protein-tagged NFATc1 in osteoblasts. Both low (10-100 μM) and high (1-3 mM) concentrations of ATP induced nuclear translocation of NFATc1 that peaked at 15 min. Notably, NFATc1 returned to the cytoplasm 1 h following stimulation with low [ATP], whereas nuclear translocation induced by high [ATP] persisted for 2-3 h in duration. Since ATP activates P2Y at low concentrations and P2X7 receptors at concentrations equal to and exceeding 1 mM, we tested the contribution of these receptor subtypes. UTP (exclusively activates P2Y) mimicked responses observed with low [ATP], whereas BzATP (P2X7 agonist) induced prolonged NFATc1 translocation. Consistent with these findings, fluorescence measurements revealed that ATP or UTP (10-100 μM) cause only transient increases in cytosolic calcium concentration, whereas BzATP and ATP (1-3 mM) elicit more sustained elevations. Taken together, these findings demonstrate for the first time that the presence of multiple receptor subtypes with different affinities increases the range of ATP concentrations for which dose-dependent responses are possible. This phenomenon provides a novel mechanism by which osteoblasts may transduce differences in the intensity of mechanical stimuli over a wide dynamic range, otherwise unattainable through a single subtype of cell-surface receptor.

Hyper-occlusal Force Induced the Expression of Type XII Collagen in Periodontal Tissue. Tetsuomi Nemoto[1], Kazuko Goto[1], Hiroshi Kajiya[1], Yutaka Takahashi[1], Tsuzuki Takashi*[2], Koji Okabe[1]. [1]Fukuoka Dental College, Japan, [2]fukuoka dental college, Jpn

It is well known that excessive mechanical force by hyper-occlusion is induced to occlusal trauma. In clinical, traumatic force produce disorganization of cells and fibers, resorption of bone and cementum, resulting in tooth mobile. However, the mechanism in the process remains to be understood. In the present study, to examine morphological and biological mechanisms in occlusal trauma on periodontal ligament tissue we employed in vivo hyper occlusion model rodents.

Five weeks-old wester rats or ddy mice were kept in hyperocclusion for 0, 2, 4, and 7 days with bonding steel wire on the occlusal surface of the upper light molars. To investigate alveolar bone resorption induced by the hyper-occlusion the sections of the lower right first molar were stained with tartrate-resistant acid phosphatase (TRAP) as a maker for osteoclasts. In parallel experiments, the three parts of tooth, buccal cervix, furcation, and lingual cervix were stained with TRAP. To investigate the relationship between hyper-occlusion and regeneration of cell matrix, we examined

the effect of hyper-occlusal force on the expression of type I and type XII of collagens using immunohistochemistry and real time PCR methods.

On control animals (day 0), the furcation of teeth and arrangement of collagens fibers were in order. Type I collagen was localized in the extracellular area at furcation in teeth root. The expression and localization of type I collagens were no effects on the hyper-occlusion treatment. On contrast, the expression and localization of type XII collagen was unclear in periodontal ligament tissues.

On day 4 after the hyper-occlusion treatment, a number of TRAP-positive cells significantly increased in the furcation and lingual cervical parts of teeth compared to control animals. The type XII collagens were gradually up-regulated by hyper-occlusion treatment in time-dependent manner and localized in around periodontal ligament cells. Using real time PCR method, type I collagen mRNA expression was not up-regulated in periodontal tissues during hyper-occlusion treatment, while type XII collagen mRNAs significantly up-regulated on day 2 and 4 after hyper-occlusion treatment.

The results indicated the hyper-occlusal force significantly up-regulated the expression of type XII collagen in periodontal tissue, but not type I collagen, suggesting in the regeneration of periodontal tissues for prevention of occlusal trauma.

Toughness of Human Cortical Bone under Realistic Loading Conditions. Elizabeth Zimmermann*[1], Maximilien E. Launey[2], Robert O. Ritchie[1]. [1]University of California, Berkeley, USA, [2]Lawrence Berkeley National Lab, USA

Cortical bone invariably contains cracks and fracture mechanics provides the best methodology to characterize their resistance to fracture, or toughness. Fracture studies on the behavior of human cortical bone have provided much information on how the hierarchical microstructure of bone is able to resist the initiation and growth of incipient cracks at numerous length scales. In particular, the toughness of bone originates from a combination of plasticity mechanisms below the micron length scale (i.e., collagen uncoiling, fibrillar sliding, etc.) and crack tip shielding mechanisms at the micron scale (i.e., crack deflection, crack bridging, crack twisting, etc.).

In vivo, these cracks are subject to combinations of tension, in-plane shear and out-of-plane shear at the crack tip, which is called mixed-mode loading. To date, measurements of cortical bone toughness have only been performed under tensile loading conditions because they were assumed to be the limiting value.

In this study, human cortical bone samples were taken from three male donors. The hydrated, notched samples were tested under symmetric and asymmetric four-point bend, which allows the relative amount of tension and shear at the crack tip to be tuned. The tests were performed in an environmental scanning electron microscope to simultaneously image crack growth. Further investigations into the mixed-mode crack growth behavior and the effects of out-of-plane shear were performed.

Our results reveal that in the longitudinal orientation (crack is parallel to the osteons), bone is tougher under in-plane shear. However, in the transverse orientation (crack is perpendicular to the osteons), bone is 25% tougher in tension. This result is a consequence of both the bone matrix's ability to control the crack path through the highly mineralized cement lines, which are oriented along the longitudinal orientation, and the applied mechanical loads that drive the crack forward in tension and cause deflections under in-plane shear.

Thus, when assessing the toughness of bone, the mode I value is not always the limiting value; in addition, one orientation does not sample the same intrinsic and extrinsic mechanisms that control crack propagation in bone. Testing methods to assess the resistance to fracture in bone will be discussed in this context, especially with applications to small animal studies, which are mostly done under tensile loading conditions in the transverse orientation.

Synthesis, Characterization, and Evaluation of Bone Targeting Salmon Calcitonin Analogues in Normal and Osteoporotic Rats. Michael Doschak, Madhuri Newa, Krishna Bhandari*. University of Alberta, Canada

Purpose: To synthesize, characterize & evaluate the efficacy of bone-targeting salmon calcitonin (sCT) analogues.

Introduction: sCT elicits an antiresorptive effect by acting upon its receptors (CTRs) on bone-resorbing osteoclasts (OC). However, antiresorptive therapy utilizing conventional sCT is severely hampered by its short t1/2 (17–57 min) due to rapid systemic clearance & degradation in kidneys, liver & blood resulting in poor & variable bioavailability. Pegylation, the attachment of polyethylene glycol, improves the pharmacokinetic parameters of sCT by increasing its circulation time, & by reducing proteolysis & immunogenicity. However, as CTRs are also widely distributed in kidneys, lung, and other tissues, the competitive uptake of sCT (or pegylated sCT) by non-bone tissue resident CTRs may not always lead to optimal sCT bioavailability at bone resident OC– the desired site of action for osteopenic bone diseases. Thus, we sought to target sCT & pegylated sCT to bone by conjugation to a bisphosphonate (BP) carrier.

Methods: BP conjugates of pegylated & non-pegylated sCT analogues were synthesized, characterized by MALDI-TOF, Tris-Tricine SDS-PAGE & number of BP/sCT, & evaluated for sCT secondary structure by circular dichroism, in vitro bone mineral affinity & specificity by different calcium salt binding affinity assays, cytotoxicity in OC precursor RAW 264.7 cells by MTT assay, continued sCT bioactivity & CTR binding potential by intracellular cAMP stimulation assay in T47D breast cancer cells, sCT antibody binding ability by ELISA on calcium phosphate coated osteologic cell culture plates, & for their duration of action & effect on plasma calcium & phosphate levels in normal (n=20) & osteoporotic (OP) (n=18) rats.

Results: BP & PEG-BP conjugated sCT resulted in a stable & desirable α-helical form without altered receptor & antibody binding specificity. They exhibited significantly greater bone mineral affinity & specificity over unmodified sCT, retained strong sCT bioactivity, were non-toxic & exhibited an improved duration of action & a comparable reduction in serum calcium to that of parent sCT.

Conclusion: We report the synthesis of a new class of antiresorptive bone drug that has not previously been attempted & neither has a bone targeting formulation of the antiresorptive peptide hormone Calcitonin. These compounds hold great promise for clinical utility in the treatment of osteopenic bone disease & other related indications.

Differential Gene Expression in Osteoblast/Osteocyte Lineage Cells between *Hyp* Mouse and Wild-type Mouse. Kazuaki Miyagawa*[1], Keiichi Ozono[2], Kanako Tachikawa[1], Yuko Mikuni-Takagaki[3], Mikihiko Kogo[4], Toshimi Michigami[5]. [1]Department of Bone & Mineral Research, Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [2]Osaka University Graduate School of Medicine, Japan, [3]Kanagawa Dental College & Graduate School of Dentistry, Japan, [4]Department of 1st Oral Surgery, Osaka University Graduate School of Dentistry, Japan, [5]Osaka Medical Center, Research Institute for Maternal & Child Health, Japan

Among the molecules responsible for hereditary hypophosphatemic rickets, FGF23, PHEX and DMP1 are expressed in osteoblast/osteocyte lineage cells. In X-linked hypophosphatemic rickets (XLH) and its murine homolog *Hyp* caused by mutations in *PHEX*/*Phex* gene, serum levels of FGF23 are elevated, although the underlying mechanism is not fully understood. Therefore, in the current study, we isolated primary osteoblasts and osteocytes from *Hyp* and wild-type mice to analyze the gene expression by real-time PCR. Long bones obtained from female *Hyp* mice or wild-type mice were minced and subjected to sequential digestion with collagenase and decalcification with EGTA for fractionation of osteoblasts and osteocytes. We confirmed the high levels of serum FGF23 in female *Hyp* mice. Among the 9 fractions isolated from wild-type bones, *alkaline phosphatase* was expressed in fractions 3-5 and attenuated in the later fractions, while strong expression of *Dmp1* and *Sost* was detected in fractions 6-9, suggesting that fractions 3-5 and fractions 6-9 from wild-type mice were considered as osteoblast-rich and osteocyte-rich fractions, respectively. *Phex* and *Fgf23* were expressed in both osteoblast-rich and osteocyte-rich fractions, and the expression of *Fgf23* was more intense in osteocyte-rich fractions. Then, we analyzed gene expression in osteoblast/osteocyte lineage cells isolated from *Hyp* bones, which was compared with that in wild-type cells. The expression of *Fgf23* was stronger in *Hyp* cells, and interestingly, it was relatively high even in the early fractions (fractions 3 and 4) in *Hyp*. As to the expression of *Dmp1*, it was also higher in *Hyp* cells, and its level in fraction 5 was almost comparable to that in fractions 6-9. We also found the slight increase in *Hyp* cells in the levels of mRNA corresponding to 5'portion of *Phex* gene retained in *Hyp* allele. Next, since we have previously demonstrated that extracellular Pi triggers signal transduction via type III Na^+/Pi cotransporter *Pit1*, we determined its expression. In all the fractions, it was almost 2-fold stronger in *Hyp* cells compared to wild-type cells, suggesting the altered response to extracellular Pi. These results indicate that molecules responsible for hereditary hypophosphatemic rickets are differentially expressed in osteoblast/osteocyte lineage cells between *Hyp* and wild-type mice, which might involve the difference in responsiveness to extracellular Pi as well as that in the composition of extracellular matrix.

Increased MEPE Protein Expression in Rat Bone Tissue after a Single Bout of Mechanical Loading. Nathalie Bravenboer*[1], Maartje Broeders[2], Huib Van Essen[3], Christianne Reijnders[4], Paul Lips[1]. [1]VU University Medical Center, The netherlands, [2]dept Endocrinology, VU University Medical Center, Netherlands, [3]VU Medical Center, The netherlands, [4]Dept Dermatology, VU University Medical center, Netherlands

Skeletal integrity in humans and animals is maintained by daily mechanical loading. It has been widely accepted that osteocytes function as mechanosensors. Many biochemical signaling molecules are involved in the response of osteocytes to mechanical stimulation. One of these molecules is matrix extra cellular phosphoglycoprotein (MEPE). It has been shown that MEPE gene expression was up regulated in response to 4 point bending load. MEPE plays a role in the regulation of bone mineralization, dentin mineralization, renal phosphate handling and vitamin D metabolism. The aim of this study was to detect MEPE protein expression after mechanical loading in order to elucidate the role in the translation of mechanical stimuli into bone formation. The 4-point-bending model of Forwood and Turner (1) was used to induce a single or a repeated period of mechanical loading on the right tibia shaft, whereas the contra-lateral left tibia served as control. Repeated loading consisted of 10 loading periods in 12 days. Rats were sacrificed 6 hours after the last loading period. MEPE was detected by immunohistochemistry. MEPE positive area relative to total cortical area (PosCo %) was measured in longitudinal bone sections from loaded and unloaded tibiae. A single bout of loading resulted in doubling of PosCo in the loaded right tibia (1.17 $\pm$ 0.79%) compared to the contra-lateral control (0.60 $\pm$0.50 %, p= 0.0137). After repeated loading PosCo was unchanged in the loaded right tibia (0.61 $\pm$ 0.38 %) compared to the contra-lateral control tibia (0.61 $\pm$ 0.35 %). In rats that received no mechanical loading no difference between the right and the left tibia was observed. In conclusion MEPE protein expression is stimulated by mechanical loading, which confirms the data on MEPE gene expression. This indicates MEPE could play an important role in the translation of mechanical stimuli into bone formation.

Activation of Vascular Smooth Muscle Parathyroid Hormone Receptor Inhibits Wnt/β-Catenin Signaling and Aortic Fibrosis and Calcification in Diabetic Arteriosclerosis. Su-Li Cheng*[1], Jian-Su Shao[1], Linda Halstead[2], Oscar Sierra[1], Kathryn Distelhorst[3], Dwight Towler[2]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University in St. Louis, USA, [3]Wahsington University in St. Louis School of Medicine, USA

Vascular fibrosis and calcification contribute to diabetic arteriosclerosis, impairing Windkessel physiology necessary for distal tissue perfusion. Wnt family members – up-regulated in arteries by the low-grade inflammation of ''diabesity'' – stimulate type I collagen expression and osteogenic mineralization of mesenchymal cells via β-catenin. Conversely, intermittent administration of parathyroid hormone (PTH) inhibits Wnt/ β-catenin signaling and calcification in aorta of LDLR (low density lipoprotein receptor) -deficient mice fed with high fat diabetogenic diets (HFD). To better understand PTH type 1 receptor (PTH1R) - Wnt/β-catenin interactions in diabetic arteriosclerosis, we generated SM-caPTH1R transgenic mice, a model in which the constitutively active PTH1R variant H223R (caPTH1R) is expressed only in vasculature by employing minimal SM22 promoter. When fed with HFD, SM-caPTH1R+;LDLR+/- mice become obese and diabetic, with no improvements in fasting serum glucose, cholesterol, body weight, body composition, or bone mass vs. LDLR+/- siblings. Moreover, serum PTH and calcium levels were unaltered and urinary calcium clearance was unaffected by the transgene. However, the expression of SM-caPTH1R transgene decreased aortic β-catenin protein accumulation and aortic β-galactosidase activity in TOPGAL+ (TCF/LEF optimal promoter – β-galactosidase reporter); LDLR+/- mice on HFD. Although TNF, Msx2, Wnt7a, and Wnt7b mRNA levels were not altered, Col1A1, alkaline phosphatase, osteopontin, MMP9, Runx2, Osx, and Nox1 were down-regulated in SM-caPTH1R aorta. In contrast, p21 level was increased. Aortic calcification and collagen and Nox1 protein accumulation were also reduced in SM-caPTH1R mice. Moreover, levels of aortic superoxide – a reactive oxygen species upregulated with calcific arteriosclerosis – were concomitantly reduced by caPTH1R. Ex vivo aortic plethysmography revealed that expression of caPTH1R increased aortic compliance. In vitro, the caPTH1R suppressed myofibroblast proliferation, inhibited Wnt3a, Wnt7a, and Wnt7b -induced TopFlash and Col1A1 promoter activity, and decreased MMP9. Matrix mineralization was also reduced in caPTH1R myofibroblasts. In conclusion, cell-autonomous VSMC PTH1R inhibits arteriosclerotic Wnt/β-catenin signaling and reduces vascular oxidative stress, thus limiting type I collagen and calcium accrual in aortas of diabetic LDLR-deficient mice.

Circulating Sclerostin Levels in Disorders of Parathyroid Function: Primary Hyperparathyroidism (PHPT) and Hypoparathyroidism (HypoPT). Aline Costa*[1], Serge Cremers[1], Mishaela Rubin[1], Elzbieta Dworakowski[1], Donald McMahon[2], Shonni Silverberg[1], John Bilezikian[2]. [1]Columbia University, USA, [2]Columbia University College of Physicians & Surgeons, USA

Sclerostin is a protein product of osteocytes that is encoded by the SOST gene. It plays an important regulatory role in anabolic signaling pathways and, unimpeded, sclerostin inhibits the osteoanabolic Wnt signaling pathway. An attractive hypothesis to account for the anabolic actions of PTH is an osteocyte interaction that leads to the inhibition of sclerostin. However, the data supporting this idea comes from animal studies in which SOST gene expression is measured by mRNA, sclerostin-positive osteocytes (by immunocytochemistry), and sclerostin protein (by Western-blot analyses of bone lysates). To test the hypothesis that sclerostin is regulated by PTH in human subjects, we used a new highly specific and sensitive ELISA for sclerostin (TECOmedical, Sissach, Switzerland) to measure circulating sclerostin levels in serum of 25 subjects with PHPT and HypoPT and compared them with historical controls as reported by the manufacturer. The standard detection range is 0.25 to 4.0 ng/mL and sensitivity is 0.15ng/mL; intra-assay CV 1.3-1.6%, inter-assay CV 1.8-2.7%. Thirteen subjects had PHPT (11F/2M, median age 64 yrs) and twelve subjects had HypoPT (7F/5M, median age 49 yrs). All patients had their disease for at least 3 years. Sclerostin levels were markedly higher in hypoparathyroid subjects as compared to those with PHPT (mean$\pm$SD: 1.13$\pm$0.37 vs 0.46$\pm$0.10ng/mL, p=<0.0001) and to historical controls (mean$\pm$SD: 0.45$\pm$0.23ng/mL, p=<0.0001). Sclerostin levels in PHPT patients did not differ from historical controls p=0.68). These data suggest that sclerostin levels can be accurately measured in the circulation of human subjects. The results are consistent with the hypothesis that low PTH levels appear to favor SOST gene expression, and provide support for the hypothesis that PTH inhibits sclerostin production. The finding of normal levels of sclerostin in PHPT suggests that in a chronic state of PTH excess, sclerostin function is not perturbed, or any perturbation is not reflected in the circulation. Studies to track these levels after intervention with PTH (hypoparathyroidism) or removal of PTH (parathyroidectomy in PHPT) are currently ongoing.

Heterozygosity in the VDR Gene Influences Body Composition more than Bone Mass. Francisco Jose De Paula*[1], Sheila Bornstein[2], Ingrid Dick-de-Paula[3], Phuong Le[4], Bahman Rostama[4], Clifford Rosen[2]. [1]School of Medicine of Ribeirao Preto - USP, Brazil, [2]Maine Medical Center, USA, [3]School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil, [4]Maine Medical Center Research Institute, USA

The influence of modest vitamin D deficiency on bone and body composition in animal models is not clear. Vitamin D receptor null mice (VDR) not only have very low bone mass but also have a lean phenotype and increased insulin sensitivity. We hypothesized that mice with loss of one allele of the VDR gene (VDR+/-) might have moderate skeletal and body composition phenotypes. Female VDR+/- mice on a B6 background and B6 controls (+/+) were raised on a regular chow diet until 12 weeks (wk) of age. VDR+/- and VDR+/+ mice were treated either with PTH (sc, bovine PTH 50 μg/kg daily x 4 wk) or vehicle (VH) x 4 wk. The study comprised 4 female groups of mice: VDR+/+ VH (+/+VH, n=5), VDR+/+ PTH (+/+PTH, n=7), VDR+/- VH (+/-VH, n=10) and VDR+/- PTH (+/-PTH, n=11). Basal PTH serum levels were determined by enzyme immunoassay (Immunotopics), bone mass (aBMD) and body composition were determined by PIXIMUS before and after treatment. Bone microstructure (BV/TV) was determined by μCT in the lumbar spine (L5) and femur; MRI assessed percent body fat and femoral fat after treatment. Baseline PTH serum levels were modestly higher in VDR+/- mice (+/+= 67.7$\pm$10 vs +/- = 74.8$\pm$7 pg/ml). At 12 wk of age femoral aBMD in VDR+/+ did not differ from VDR +/- mice. Four weeks of PTH treatment for both genotypes showed a 12.2% increase in femoral aBMD from baseline (p<0.01 vs baseline, NS by genotype). With PTH treatment, total body aBMD increased slightly more in VDR+/- than VDR+/+ mice (+7 vs +6%, p=NS), whereas strikingly the VDR+/+ gained more fat mass (+0.32 $\pm$ 0.20 g) than

the VDR+/- group (-0.022 ± 0.18g). A similar trend in fat mass was noted for the PTH treated groups of VDR+/- and VDR+/+ mice (VDR +/+= +0.44 ± 0.17g vs VDR +/-= +0.28 ± 0.16 g). By μCT, L5 Trabecular thickness was higher in +/-PTH than +/-VH (+/-= 0.05676 μm ± 0.0006656 vs +/+= 0.06092 ± 0.001614 μm). Our results suggest that VDR heterozygote mice respond normally to an anabolic stimulus (PTH) and have a very mild skeletal phenotype associated with slight increases in PTH and reduced trabecular bone volume. Remarkably during continued growth at 16 weeks female VDR+/- mice with or without PTH remained leaner than VDR +/+ mice suggesting that the body composition phenotype is more pronounced than the skeletal one. Further studies to delineate the role of vitamin D in energy metabolism and its relationship to skeletal acquisition are needed.

Irradiation Primes the Skeleton for PTH Anabolic Actions. Teresa Wang[1], Amy Koh*[2], Chad Novince[3], Russell Taichman[3], Hector Rios[2], Laurie McCauley[3], Xin Li[2]. [1]U of M, USA, [2]University of Michigan, USA, [3]University of Michigan, School of Dentistry, USA

PTH is an anabolic agent used clinically to treat osteoporosis and is in investigational use for increasing hematopoietic stem cells (HSCs). Irradiated (IRR) mice have increased PTH anabolic actions compared to non-IRR mice (30% bone area increase). The purpose of this study was to identify mechanisms responsible for enhanced PTH actions in IRR mice. C57B6 mice were IRR (310-325cGy; 2 fractions 3h apart) then administered PTH (0.05μg/g/d) for 21d. Flow cytometric analysis, microarray, real-time PCR gene expression, serum assays, immunohistochemistry and bone histomorphometry were performed along with primary cell isolation and analyses. IRR reduced bone marrow (BM) cellularity with retention of osteoblastic cells lining trabeculae. IRR decreased cell numbers in calvarial cell cultures in vitro suggesting against a cell autonomous benefit of irradiation. BM added to bone marrow stromal cell (BMSC) monolayers restricted mineralization which was less restrictive with IRR vs. non-IRR BM. IRR co-culture increased BMSC numbers, and IRR BM contained more adipocytes than non-IRR BM. FGF2 and IL-6 mRNA was increased in IRR BM in vivo. IRR decreased, and PTH increased periostin mRNA in the bone marrow with greater and more widespread periostin positivity throughout the marrow. PTH significantly increased serum OCN and P1NP in IRR mice despite lower baseline levels versus non-IRR. IRR decreased B220 cells, while the % of LSK cells (lin-,sca-1+,c-kit+) was increased. IRR mice had increased % BrdU positive cells and PTH increased total numbers of BrdU positive cells in IRR mice. Osteoclast number was not altered with IRR but was increased with PTH in both groups. Megakaryocytes (vWF stain) were reduced yet were located more closely to trabecular surfaces with IRR, and PTH treatment resulted in increased megakaryocyte ploidy status. PTH anabolic activity was augmented evidenced by increased bone area, serum OCN and P1NP in IRR mice. These results suggest IRR increased osteoblastic proliferation in an indirect manner and that PTH acted in the IRR mice by increasing bone active cell populations. IRR via increased IL-6 and FGF2 may prime the skeleton for anabolic actions of PTH. Furthermore, reduced cellularity and the retention of MKs, LSKs and/or adipocytes with IRR may increase osteoblast exposure to these cells to support anabolic actions. Alternatively, irradiation may decrease inhibitory cell types that negatively affect anabolic actions of PTH.

PTH but not 25(OH)D is Directly Associated with Blood Pressure and Inversely Associated with Carotid-femoral Artery Pulse Wave Velocity. Ashley Davidson*[1], Kathy Ryan[2], Alan Shuldiner[3], Elizabeth Streeten[1]. [1]University of Maryland School of Medicine, USA, [2]Department of Endocrinology, Diabetes & Nutrition, USA, [3]Department of Endocrinology, Diabetes & Metabolism, USA

Background: Both 25-hydroxyvitamin D (25-D) and PTH have been reported to be associated with cardiovascular (CV) phenotypes in some, but not all, studies. Pulse wave velocity (PWV) is a measurement of arterial stiffness and has been shown to be associated with PTH in populations receiving hemodialysis but has not been reported in healthy individuals with normal renal function. The purpose of this study was to investigate the associations of PTH and 25(OH)D with blood pressure and other subclinical vascular disease markers in the Amish, a population with a relatively homogeneous diet, levels of physical activity and low levels of smoking which can be confounders in other populations.

Methods: This observational study included participants in the Amish Family Osteoporosis and Amish Family Calcification Studies. Generally healthy participants with normal serum calcium and creatinine had the following measured: PTH, 25(OH)D, blood pressure, coronary artery calcification (CAC by electron beam computed tomography), carotid intimal medial thickness (cIMT) and PWV [carotid-femoral (C-F) and carotid-radial (C-R)]. Association analyses were performed between both 25(OH)D and PTH and: BP (n=1108), CAC (n = 650), cIMT (n = 220), C-R PWV (n = 257) and C-F PWV (n = 249). The relations of 25(OH)D and PTH levels, adjusted for season, age and sex, with subclinical vascular disease measures were assessed by comparing mean levels by Pearson's correlation.

Results: The mean age was 51.18 ± 13.02 years (range 18-91). 59.1% of the subjects were female (n = 655). The mean 25(OH)D was 22.32 ± 5.87 ng/ml, mean PTH 55.38 ± 14.27 pg/ml, mean systolic BP 119 ± 12.9 and mean diastolic BP 74.18 ± 7.37. A positive association was found between PTH and systolic (p = 0.04) and diastolic (p = 0.0004) BP. No association was shown between 25(OH)D and BP (systolic p=0.11, diastolic p=0.11). PTH and C-F PWV were inversely associated (p = 0.03). There was no association of PTH with CAC, cIMT or C-R PWV (p = 0.85, 0.4, 0.54), nor of 25(OH)D with CAC, cIMT, C-F or C-R PWV (p= 0.8. 0.52, 0.05, 0.6). The correlation between PTH and 25(OH)D was -0.30 (p<0.0001).

Conclusions: PTH level was directly associated with systolic and diastolic BP, and inversely associated with C-F PWV. 25(OH)D was not associated with these phenotypes. These results suggest that PTH may play a direct role in cardiovascular health. Alternatively, PTH may be a surrogate marker for 1,25-dihydroxyvitamin D in these associations.

Combined *In Vivo* MicroCT and Near-Infrared Imaging Allows for Quantitative Analyses of the Tumor Microenvironment. Rachelle Johnson*[1], Lindsay Johnson[2], Don Nolting[3], Steve Munoz[1], Gregory Mundy[1], H. Charles Manning[1], Todd Peterson[1], Julie Sterling[1]. [1]Vanderbilt University Medical Center, USA, [2]Department of Biomedical Engineering, Vanderbilt University, USA, [3]Institute of Imaging Science, Vanderbilt University, USA

The majority of breast cancer and prostate cancer patients with metastatic disease will go on to develop bone metastases, which contribute largely to patient morbidity and mortality. Numerous small animal models of cancer metastasis to bone have been developed in order to study tumor-induced bone destruction, but the advancement of imaging modalities utilized for these models has lagged significantly behind clinical imaging, particularly in the bone microenvironment in response to tumor cell establishment and treatment. We hypothesized that a combination of *in vivo* micro-Computed Tomography (μCT) and Near-Infrared (NIR) imaging can be utilized to perform quantitative longitudinal and end-point analyses of bone volume and monitor protein-level changes in the tumor-bone microenvironment. We utilized the MDA-MB-231 intratibial breast cancer model and imaged mice weekly by Faxitron, *in vivo* μCT, and Maestro (fluorescence, NIR). We found that *in vivo* μCT can significantly detect individual and group level changes in bone destruction over time in a bisphosphonate drug treatment model without altering tumor cell growth (tumor-bearing v. control limb, p<0.0001; tumor limb treated v. un-treated p<0.0001). This imaging method was validated by ex-vivo μCT and histological analyses at end-point with comparable findings. In addition, we found a significant accumulation of NIR-labeled TGF-β neutralizing antibody in the hind limbs when compared to a NIR-labeled control IgG (p<0.05), and we found significantly more NIR-labeled TGF-β antibody in the tumor-bearing limb when compared to the contra-lateral PBS-injected limb (p<0.05), indicative of increased bone remodeling at sites of tumor metastasis. More importantly, this technique offers the potential for real-time, non-invasive imaging of protein changes at the tumor-bone interface, such as increased secretion of osteolytic factors. Taken together, these data

present a comprehensive analysis of the tumor-bone microenvironment, in which imaging techniques provide an accurate method of monitoring changes in bone destruction and protein expression in the vicious cycle of tumor-induced bone disease.

Influence of Connexin43 Expression on the Metastatic Phenotype and the Bone Impact of Prostate Cancer Cells. Coralie Lamiche*[1], Jonathan Clarhaut[1], Pierre-olivier Strale[1], Sophie Crespin[1], Norah Defamie[1], Marc Mesnil[1], Francoise Debiais[2], Laurent Cronier[3]. [1]CNRS - UMR 6187, Institut de Physiologie et Biologie Cellulaires, France, [2]Hopital Jean Bernard, France, [3]University of Poitiers, France

Prostate cancer (PCa) has the highest incidence in men with bone metastasis occurring in 80% of cases and mainly characterized by osteoblastic lesions. The mechanisms by which prostate cancer cells are induced to metastasize to bone are variable and complex, implicating oncogenes, pro-angiogenic factors and adhesion molecules. Among them, transmembrane proteins named connexins (Cxs) involved in gap junctional intercellular communication (GJIC) are known to permit coordinated cellular activities during development and differentiation processes. PCa cells are deficient in Cx isoforms however recent studies suggest that Cx43 could be implicated in the last stages of the tumorigenic process. Moreover, cumulated data support the involvement of Cx43 in the differentiation process of bone-forming osteoblastic cells and bone turnover. Therefore, we have investigated the role of Cx43 on the metastatic potential of PCa cells and on their impact on the osteoblastic phenotype.

To examine the effects of increased expression of Cx43 gene in PCa cells, we have performed retroviral infection in two well characterized cells lines representing different stages of cancer progression: PC3 (aggressive) and LNCaP (less metastatic). The impact on proliferation and differentiation of osteoblastic (OB) cells was evaluated in vitro by means of cocultures with OB cells from murine calvarias. In LNCaP-Cx43 cells, the Cx43 was mainly observed in plasma membrane and a functional GJIC was demonstrated by gap-FRAP and preloading assays between PCa cells as well as in the heterocellular configuration (between LNCaP and OB cells). In PC3-Cx43 cells, Cx43 was restricted to the cytoplasmic part and no cell-to-cell communication was measured. In addition, phenotypic characterization of both cell types demonstrated significant differences in adhesion, invasion and proliferation. Finally, proliferation and differentiation abilities were significantly modified by cocultures with PCa cells. The increased proliferation rate due to contact with PCa cells was not linked to the Cx43 expression level. In contrast, the impact on OB differentiation potential, revealed by alkaline phosphastase activity and qPCR analyses of differentiation markers (Cbfa-1, OCN, OPN), seems to depend on the Cx43 level.

Our *in vitro* study demonstrates that Cx43 could influence the metastatic status of prostate cancer cells. *In vivo*, preliminary data confirm the potential implication of this connexin in the bone impact.

Inhibition of ATP6V1C1 (a Subunit of the V-ATPase) Expression Decreases 4T1 Mouse Breast Cancer Cell Invasion and Bone Destruction. Shengmei Feng*[1], Lianfu Deng[2], Guochun Zhu[1], Wei Chen[3], Yi-Ping Li[3]. [1]The Forsyth Institute, Shanghai Institute of Trauma & Orthopaedics, USA, [2]Shanghai Institute of Trauma & Orthopaedics, Ruijin Hospital, China, [3]The Forsyth Institute, Harvard School of Dental Medicine, USA

Vacuolar H+-ATPases (V-ATPases) located at the plasma membrane of highly metastatic human breast cancer cells are involved in the acquisition of a more metastatic phenotype, and V-ATPase inhibitors decrease the invasion and migration of highly metastatic cells. Importantly, the ATP6V1C subunit (C) of the V-ATPase complex is primarily responsible for its enzymatic function through the control of a reversible dissociation of the V0 and V1 domains. ATP6V1C1 (C1), an isoform of the C subunit, is highly expressed in oral squamous cell carcinoma. Furthermore, we recently reported that C1 is an essential component of the osteoclast proton pump and that it is important for F-actin ring formation in osteoclasts. Nonetheless, the role and mechanisms of the C subunit in breast cancer growth and metastasis remain unknown. To reveal the role of V-ATPase subunit C1 in breast cancer, we selected single subclones of 4T1 mouse breast cancer cells after transfection with lentivirus (Lenti)-GFP and Lenti-LacZ (control; siRNA targets LacZ) or Lenti-c1s3 (siRNA targets C1). Immunohistochemistry and Western blot showed that C1 expression was significantly reduced in C1-knockdown 4T1 cells, while ATP6V1C2 (C2) was not expressed in 4T1 cells with or without C1-knockdown. Furthermore, acridine orange staining showed that C1-knockdown 4T1 cells have reduced acidification, which is similar to C1-knockdown osteoclasts. Remarkably, C1-knockdown 4T1 breast cancer cells also exhibited decreased proliferation, migration, and invasion through matrigel. PBS or one of the different 4T1 clones (i.e. 4T1, 4T1-Lacz, 4T1-c1s3-1, or 4T1-c1s3-11) was implanted into the left femur of female BALB/C mice. After 16 days, X-rays and micro-CT scanning revealed that there was reduced bone destruction compared with the control mice in the femurs and tibiae of mice in which C1-knockdown 4T1 cells were implanted. All assays were done in triplicate, and all animals were maintained according to the Guide for the Care and Use of Laboratory Animals. We report here for the first time, that C1 not C2 is an essential subunit of the V-ATPase complex in 4T1 mouse breast cancer cells and that inhibition of C1 expression in 4T1 breast cancer cells decreased their growth and invasion in vitro and in vivo. Though these data suggest that the inhibition of C1 expression can decrease the invasive properties of 4T1 cells, additional studies are needed to define the molecular mechanisms of how C1 influences 4T1 migration.

Sympathetic Nervous System Activation Increases Breast Cancer Metastasis to Bone. J. Campbell*[1], Julie Sterling[2], Yun Ma[2], GR Mundy[2], Florent Elefteriou[2]. [1]Vanderbilt Center for Bone Biology, USA, [2]Vanderbilt University, USA

Depression, while not associated with breast cancer incidence, is linked to increased recurrence and decreased survival. Increased Sympathetic nervous (SNS) outflow, a hallmark of mental stress, controls multiple processes in the bone, such as hematopoietic stem cell trafficking, osteoblast proliferation and osteoclastogenesis via β-adrenergic receptors (βAR) and cytokines also involved in cancer metastasis, such as SDF-1 and RANKL. These observations suggested a possible involvement of SNS activation in cancer cell osteotropism, tumor burden and the formation of osteolytic lesions. To address this question, we used an established model of lytic bone metastasis in which MDA-MB-231 human breast cancer cells are injected via left cardiac ventricle in athymic nude mice. Isoproterenol (Iso), a (βAR) agonist, was used as a surrogate for SNS activation. Faxitron, 3D-microtomography and histomorphometric measurements were used to quantify number and size of lytic lesions, tumor burden and BV/TV. We observed that Iso treatment before MDA-MB-231 inoculation increased the number of bone lytic lesions and lesion area ($p<0.05$). Treating with Iso after bone metastasis increased the size of the lytic lesions ($p<0.05$) but not lesion number. These results suggested that sympathetic activation alters the bone microenvironment to make it favorable for cancer cell homing and growth. Although it did not affect lytic lesion number in a model without chronic depression, βAR blockade by propranolol decreased lesion area ($p<0.05$). *In vitro*, direct stimulation of the β2AR in MDA-MB-231 cells produced no effect on migration, cell growth or *PTHrP, Rank* and *CXCR4* expression. In contrast, stimulation of the β2AR in bone marrow stromal cells, calvaria and MC3T3 osteoblasts increased *Rankl* but not *Sdf1* expression ($p>.005$). The conditioned media of Iso-treated osteoblasts increased MDA-MB-231 cell transwell migration ($p<0.005$), which could be blocked by OPG but not by the CXCR4 antagonist AMD300. These results suggest that the increase in osteolysis and metastasis observed following Iso treatment *in vivo* are due to a predominant effect on the bone marrow stroma rather than a direct effect on cancer cells. These findings support the hypothesis that depression, via sympathetic activation, make the bone marrow environment permissive to cancer metastasis, growth, or recurrence, and imply that β-blockers may reduce both bone tumor burden and relapse in breast cancer patients.

The Effect of Various Vitamin D Supplementation Regimens on 25-OH Vitamin D Levels in Breast Cancer Patients Undergoing Treatment. Alissa Huston*, Luke Peppone, Kristin Skinner, Michelle Janelsins, Gary Morrow. University of Rochester Medical Center, USA

Vitamin D (VID) deficiency is linked to decreased bone mineral density (BMD), increased breast cancer incidence, recurrence, and mortality. Breast cancer treatment, specifically hormonal therapy (HT), reduces BMD and increases fracture risk. Our study aims include: 1) determining the prevalence of VID deficiency among women receiving treatment, 2) evaluating the effect various VID supplementation regimens on deficiency, and 3) determining the association between VID levels and BMD. Serum 25-OH VID levels were obtained from approximately 224 women and BMD from 75 women undergoing treatment (HT, radiation, chemo, or any combination) for non-metastatic breast cancer (ages 24-88). The proportion of patients with VID deficiency was determined for the total sample, and compared across race and stage of disease at baseline. VID and BMD were compared using ANCOVA models. Severely VID deficient patients (<25 ng/mL) were prescribed high-dose VID (≥50,000 IU/week),

mildly deficient patients (26-31 ng/mL) were prescribed low-dose VID (≥2,000 IU/day), and patients with normal VID levels (≥32 ng/mL) were not given any prescription. The change in 25-OH VID levels was compared across the 3 supplementation levels. At baseline, 23% of all women were considered VID deficient (<20 ng/mL), while 43% were considered VID insufficient (20-31 ng/mL). Lower baseline 25-OH VID was observed in Non-Caucasian patients (Caucasian: 28.2 ng/mL vs. Non-Caucasian: 19.3 ng/mL; $p<0.01$) and patients with later-stage disease (Stage I: 29.7 ng/mL vs. Stage III: 22.9 ng/mL; $p<0.01$). Weekly high-dose VID resulted in a significant increase (+27 ng/mL; $p<0.01$) in 25-OH VID, while there was no difference between low-dose VID supplementation (+14 ng/mL; p=0.28) and no supplementation (+9 ng/mL). Among women not on bisphosphonates, spinal BMD was lower for those with deficient (<20 ng/mL: 0.99 g/cm^2; p=0.01) and insufficient follow-up VID levels (20-31 ng/mL: 1.18 g/cm^2; p=0.07) compared to those with normal VID levels (≥32 ng/mL:1.26 g/cm^2). VID deficiency was extremely prevalent in women being treated for breast cancer, and more common in breast cancer patients who presented with later-stage disease and were Non-Caucasian. Weekly high-dose VID is required to significantly increase 25-OH VID levels, as opposed to conventional low-dose VID. Lower VID levels were also significantly associated with reduced spinal BMD among women not using bisphosphonates.

The Histone Deacetylase Inhibitor, Vorinostat, Reduces Metastatic Cancer Cell Growth and Associated Osteolytic Disease, but Promotes Normal Bone Loss. Jitesh Pratap*[1], Jacqueline Akech[1], John J. Wixted[1], Gabriela Szabo[1], Robinder J. Dhillon[2], Xiaodong Li[2], Krystin Bedard[1], Sadiq Hussain[1], Andre Van Wijnen[1], Janet L. Stein[1], Gary Stein[1], Jennifer Westendorf[2], Jane Lian[1]. [1]University of Massachusetts Medical School, USA, [2]Mayo Clinic, USA

Vorinostat, an oral histone deacetylase inhibitor with anti-tumor activity, is in clinical trials for hematological and solid tumors that metastasize and compromise bone structure. Consequently, there is a requirement to establish the effects of vorinostat on tumor growth in the bone microenvironment. Metastatic cancer cells were injected into tibias of SCID mice and the effects of vorinostat on tumor growth and osteolytic disease were assessed by radiography, μCT, histological and molecular analyses. Vorinostat-treated and control mice without tumors were also examined. Vorinostat significantly decreased tumor cell proliferation and promoted apoptosis of prostate and breast cancer cells. Tumor growth in bone was reduced ~33%. Bone osteolysis was significantly reduced in the first weeks of tumor growth, but then increased with continued vorinostat treatment. The non-tumor bearing contra-lateral femurs showed significant bone loss (50% volume density of controls) after four weeks of vorinostat therapy. This same extent of bone loss occurred in vorinostat-treated normal mice (without tumors). We show that vorinostat mediated bone loss is caused by a 2 to 3 fold upregulation of factors promoting bone resorption (PTHrP, IL-8 and osteopontin); factors secreted by tumor cells to induce osteoclast activity. Thus, our studies indicate that vorinostat effectively inhibits tumor growth in bone, but has a negative systemic effect on the integrity of normal trabecular bone and thereby contributes to osteolysis independent of tumor cell activity. Vorinostat treatment reduces tumor growth but can promote osteopenia throughout the skeleton. Our studies indicate therapeutic regimens should be considered that combine vorinostat with anti-resorptive agents to prevent treatment-induced bone loss.

The Role of Tumor Derived Interleukin 6 in a Murine Model of Breast Cancer Bone Metastasis. Yu Zheng*[1], Anastasia Mikuscheva[2], Hong Zhou[3], Katja Boernert[1], Frank Buttgereit[2], Colin Dunstan[4], Markus Seibel[3]. [1]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, [2]Humboldt University, Germany, [3]Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, [4]University of Sydney, Australia

Breast cancer has a high propensity to metastasise to the skeleton. The bone microenvironment plays a central role in metastatic cancer growth as reduced bone resorption inhibits and increased bone turnover accelerates cancer growth in bone[1,2]. In patients with metastatic breast cancer, high circulating interleukin-6 (IL-6) levels have been associated with disease progression/ poor clinical outcomes. We found in animal studies that increasing or decreasing bone resorption results in corresponding changes in tumor IL-6 expression and tumor proliferation, indicating that IL-6 expression by cancer cells may play a role in sustaining breast cancer growth in bone[3]. However, it is unclear whether tumor-derived IL-6 affects cancer cell behavior *in vitro* and *in vivo*.

To investigate this question, IL-6 expression was silenced in MDA-MB-231 cells via a lentiviral-based expression system driving the production of short hairpin RNA species (shRNAs). Knock-down efficacy was 80% as assessed by real-time RT-PCR (mRNA) and ELISA (secreted protein).

In vitro characterization of control vs. knock-down MDA-MB-231 cells demonstrated that silencing of IL-6 expression significantly reduces invasiveness without affecting proliferation.

In vivo studies: Control and IL-6 knock-down MDA-MB-231 cells (50000 cells per injection) were implanted via intra-tibial inoculation into 4-week-old BALB/c nu/nu female mice (n=7/group) kept on a low (0.1%) calcium diet to induce high bone turnover[1, 2]. Tumor growth was monitored using X-ray imaging on days 10, 17 and 21, and bones were analysed by histology and histomorphometry following sacrifice on day 21 post inoculation. Compared to controls, IL-6 knock-down resulted in significantly smaller osteolytic lesions on day 10, 17 and 21 ($p< 0.05$, by X-ray analysis), and significantly reduced total tumor area on day 21 ($3.20 \pm 0.76mm^2$ *vs.* $5.57 \pm 0.98mm^2$, $p<0.05$, by histology). Growth of subcutaneously implanted tumors was similar in animals injected with IL-6 silenced or normal MDA-MB-231 cells.

We conclude that IL-6 knock-down in MDA-MB 231 cells reduces cancer cell invasiveness *in vitro* and intraskeletal tumor growth *in vivo*, supporting the conecpt that tumor-derived IL-6 has an important role in the biology of metastatic breast cancer and may be a potential therapeutic target.

A Role for the ARF Tumor Suppressor in Osteoclasts. Crystal Winkeler*[1], Monica Croke[2], Emanuella Heller[1], Michelle Hurchla[1], Chan Lee[1], Katherine Weilbaecher[3], Jason Weber[1]. [1]Washington University in St. Louis, USA, [2]Washington University School of Medicine, USA, [3]Washington University in St. Louis School of Medicine, USA

In response to oncogenic stress, the ARF tumor suppressor is able to halt both cell proliferation and growth. ARF stabilizes and activates p53 through the inhibition of Mdm2, the E3 ubiquitin ligase for p53. More recently, ARF has been ascribed p53-independent functions through its ability to inhibit ribosome biogenesis. However, there is an inherent difficulty in separating these two functions of ARF by the fact that cell growth is intimately tied to cell proliferation. To resolve this, we have chosen to study the function of ARF in osteoclasts. Osteoclasts provide a unique model in that they are post-mitotic and function independent of p53. Furthermore, understanding the growth control of osteoclasts is important in understanding diseases such as osteoporosis and osteolytic bone metastasis.

To assess osteoclastogenesis and osteoclast function *in vitro*, BMMs were harvested from wildtype or *Arf-/-* mice. Osteoclastogenesis was assessed by TRAP-staining under various concentrations of RANKL. Mature wildtype and *Arf-/-* osteoclasts were used to assess the role of ARF in ribosome biogenesis, actively-translating ribosomes, protein synthesis, and cell growth. Additionally, we crossed $Arf^{fl/fl}$ mice with mice containing *Cre* under the control of the *Cathepsin K* promoter. Resultant mice were used to assess osteoclast-specific *Arf* loss *in vivo* by vivaCT, serum CTX, and histological analysis. *Arf* loss caused enhanced osteoclastogenesis and increased osteoclast size, resulting in greater osteoclast activity. This hyperactivity was most evident in our novel osteoclast-specific *Arf*-null mice, which exhibited a decrease in bone volume and density compared to control mice. Thus, we propose a teleological function for ARF, distinct from its classical role as a tumor suppressor, in the regulation of osteoclast activity.

Controlled Bone Tissue Ablation using Novel Navigational RF Device. Andreas Kurth*[1], Dirk Proschek[2], Aaron Germain[3], Robert Poser[3]. [1]Goethe-Universität Frankfurt, Germany, [2]Dep. Orthopaedic Surgery, University Medical Center, Germany, [3]Dfine Inc., USA

Purpose: Bone metastasis is a debilitating complication that result in severe pain, pathologic fractures, dysfunction, cord compression and decreased quality of life. Radiation and surgery are the common local treatment options, along with systemic treatment for the underlying primary cancer. Radiofrequency (RF) ablation

has been successfully used in radiation resistant tumors or small localized disease. Clinical advantages of RF ablation in spinal metastasis are more immediate pain relief and less systemic toxicity. However, clinical limitations of RF ablation in treatment of vertebral lesions include lack of minimally invasive (MI) navigation in hard tissue and accurate ablation zones. The present study evaluates a novel RF ablation device for local treatment of bone metastates.

Methods: A 10 gage, bipolar, RF ablation instrument with a navigational articulating tip containing thermocouples and a proprietary RF generator were used. Based on strategically located thermocouples, the software automatically controls ablation zones using tissue (adjacent to ablation zone) temperature control. Sixty ex-vivo ablations were performed in bovine liver at each power settings for a total of 180 ex-vivo ablations. Infrared thermography recorded tissue temperature gradients during ablation at three power settings (5W, 15W, 25W). Using a porcine in-vivo model, similar ablations were performed in both liver (n=20) and cancellous bone (n=8) sites followed by gross examination, histologic processing and histomorphometric analysis.

Results: Discrete thermal profiles measured by IR and reproducible ablation zones (20x8 mm) were identified in all ex-vivo specimens. While the rate of ablation was dependent on the power setting, the size of ablation was extremely consistent across power settings. In-vivo ablation zone dimensions were within those recorded in extensive ex-vivo tests. Histomorphometric confirmation of effective, reproducible, site specific in-vivo ablation of both liver and cancellous bone were confirmed in a porcine model.

Conclusion: Site and size specific ablation zones are extremely important in treating bone metastasis that can be close to neural elements. These data demonstrate the unique ability to create reproducible ablation zones in hard tissue at variable rates, based on real time temperature mapping controlled software.

Epigenetic Silencing of the Homeobox-containing Transcription Factor Dlx2 Promotes Chemoresistance in Human Osteosarcoma Cells. Erik Sampson*[1], Vinit Amin[2], Laurence Donahue[2], Edward Schwarz[1], Regis O'Keefe[1], Randy Rosier[2]. [1]University of Rochester, USA, [2]University of Rochester Medical Center, USA

Osteosarcoma (OS) is the most common primary paediatric bone tumor. Greater than ninety percent of patients who present with metastatic OS and thirty to forty percent of patients with nonmetastatic disease will experience relapse. Drug resistance is one underlying mechanism contributing to the failure of chemotherapy to elicit a lasting response in these patients. Expression of the homeobox-containing transcription factor Dlx2 is associated with chemotherapy sensitivity in various cancer cell lines. In addition, several Dlx family members are expressed early during osteogenesis, raising the possibility that loss of Dlx2 expression during osteosarcomagenesis concomitantly renders OS cells insensitive to chemotherapy. Indeed, the expression of Dlx2 protein is decreased in OS cell lines compared to immortalized human osteoblasts. Retrovirus-mediated expression of Dlx2 in OS cell lines did not affect cell proliferation, basal apoptosis levels or *in vitro* clonogenicity a surrogate assay for *in vivo* tumorigenicity. However, OS cell lines stably expressing Dlx2 were up to ten-fold more sensitive to doxorubicin, a chemotherapeutic commonly used to treat OS, as determined by flow cytometric analysis of caspase 3 activation. Numerous homeobox genes, including several Dlx family members are potentially silenced in cancer cells via aberrant promoter DNA methylation. Epigenetic mechanisms of gene silencing including DNA methylation, histone deacetylation and histone methylation are emerging targets for novel cancer therapeutic development. The histone deacetylase inhibitor (HDACi) suberoylanilide hydroxamic acid (SAHA; vorinostat (Zolinza)) is approved by the Food & Drug Administration for the treatment of cutaneous T-cell lymphoma. The expression of Dlx2 message and protein was increased in OS cell lines treated either with SAHA or another HDACi, valproic acid (VA). Pre-treatment with SAHA or VA followed by doxorubicin had a striking, synergistic effect on apoptosis in OS cells. This synergistic increase in cell death was in part rescued by RNA interference with HDACi-mediated Dlx2 induction. Dlx2 induction therefore partially mediates rather than simply correlates with OS chemosensitization by HDACi. While future studies will be required to determine whether Dlx2 is a bona fide OS-related tumor suppressor gene, strategies to increase Dlx2 expression including HDACi or DNA methyltransferase inhibitors may overcome chemotherapy resistance in relapsed OS patients.

Identification of Novel Molecule for Melanoma Malignancy -Role of CIZ -. Kentaro Miyai[1], Masaki Noda[1], Tadayoshi Hayata[2], Tomomi Sakuma*[3], Yoichi Ezura[4]. [1]Tokyo Medical & Dental University, Japan, [2]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [3]Tokyou Medical & Dental University, Japan, [4]Tokyo Medical & Dental University, Medical Research Insititute, Japan

Metastasis of tumor to bone is one of the serious complications during tumor treatment. One of the possible key molecules for the establishment of bone metastasis would be those for cell attachment and transcription of the genes. Cas-Interacting-Zinc finger protein, CIZ, posses these two properties as it is localized at the site of focal adhesion plaque and it could trans locate into nuclei. B16, a malignant melanoma cell, are highly metastatic tumor. Therefore, we examined the possible roles of CIZ for the establishment of tumor metastasis of bone. In B16 cells, CIZ protein was expressed and localized in nuclei and cytosol. Cell migration to wild-type (WT) serum was inhibited by knockdown of CIZ, suggesting that CIZ would be one of factor for cell movement in B16. Treatment of BMP, which is involved in both cancer promotion and inhibition, suppressed migration of B16 to WT serum. Treatment with BMP suppressed CIZ expression in B16, suggesting that down regulation of CIZ by BMP may be involved in this cell migration process CIZ knock down revealed that CIZ interferes with the increase of the transcription through BMP response element by BMP treatment in Luciferase assay. Taken together, these results suggest that CIZ and BMP antagonize each other. In the host side, to examine the difference of local proliferation in bone microenvironment between WT and CIZ KO mice, we inoculated B16 into bone. After 5 weeks, CIZ KO mice suppressed cancer cell proliferation. To investigate whether CIZ-deficient microenvironment also affects cancer cell migration, migration assay was performed. B16 migrated to the side of medium containing the serum derived from WT mice, whereas migration of B16 was suppressed when serum from CIZ KO mice was used. And the size of cells that barely migrated to CIZ KO serum was significantly small compared to WT serum. These results suggest that certain factors under the control of CIZ are required for regulation of migration and morphology of B16. To investigate the molecular mechanism underlying this migration defects in CIZ KO serum, we focused on Cxcl12 involved in tumor growth and metastasis. We analyzed expression level of Cxcl12 in bone marrow, but there is no change between WT and CIZ KO mice. These results suggest that CIZ regulates tumor growth and progression in both sides of the cancer cell and host microenvironment. Breakdown of the balance between BMP and CIZ may be involved in tumor progression.

Leukemia Blasts Compromise Osteoblast Function in a Mouse Model of Acute Myelogenous Leukemia. Barbara Silva*[1], Yoshihiro Yoshikawa[2], Charles Duncan[2], Linda Johnson[3], John Manavalan[2], Ellin Berman[4], Stavroula Kousteni[1]. [1]Columbia University Medical Center, USA, [2]College of Physicians & Surgeons, Columbia University, USA, [3]Cornell University & Memorial Sloan-Kettering Cancer Center, USA, [4]Memorial Sloan-Kettering Cancer Center, USA

The bone marrow niche has been implicated in the pathogenesis of leukemia, as a permissive microenvironment required for its emergence or progression. Yet, few studies have shown how the malignant cells influence specific cell populations within the bone niche or characterized signals that orchestrate their crosstalk. In this context, we aimed to define specific bone cell populations and signals that are involved in the changes occurring in the niche after the disease is established. We injected WEHI-3b murine myelomonocytic leukemia cells into immunocompetent Balb/C mice, and compared them to a control group that had not been injected with leukemia cells. Fourteen days later, tumor engraftment was present in both femur and spine of the leukemic mice as observed by histopathological analysis. Leukemic mice showed a marked, 68%, and significant decrease in osteoblast numbers, 50% decrease in bone formation rate, and a less pronounced, 14%, but also significant, trabecular bone loss. Osteoclast numbers were not affected. The decrease in osteoblast numbers appeared to be caused by a decrease in differentiation as evidenced by reduced expression of osteoclacin, Runx2, osterix and alkaline phosphatase. A specific subset of non-hematopoietic (CD45- and CD34- negative) bone marrow cells expressing the endothelial cell marker CD105 were affected, as determined by flow cytometry. This was evidenced by a negative correlation between the tumor burden and the CD45-/CD34-/CD105+ subset of bone marrow cells. wInterestingly, gene expression studies and mineralization assays showed that this particular population of CD45-/CD34- cells has the highest osteogenic potential. Additionally, osteoblastic expression of OPG was decreased, whereas RANKL was increased, leading to a marked increase in the RANKL:OPG ratio, probably explaining the maintenance of osteoclast numbers in the presence of reduced osteoblast numbers. Expression of SDF-1, a gene implicated in normal hematopoietic cell homing in the bone marrow niche, was reduced in osteoblasts, which could contribute to derangements in normal hematopoiesis during the course of the disease. In summary, 1) osteoblastogenesis was decreased, 2) osteoblast- osteoclast uncoupling was noted, and 3) a CD45-/CD34-/CD105+ subset of bone marrow cells was identified as the osteogenic population affected by leukemic engraftment. These data demonstrate that leukemia blasts influence osteoblast growth and functional characteristics.

Targeting Wnt or BMP Pathways Differentially Modulates Osteoclast-inducing Activity of Giant Cell Tumor Stromal Cells: Biologic and Therapeutic Implications. Matthew Steensma*[1], Wakenda Tyler[2], John Healey[3], F. Patrick Ross[4], Steven Goldring[4], Ed Purdue[4]. [1]Memorial Sloan-Kettering Cancer Center/Hospital For Special Surgery, USA, [2]Rochester University, USA, [3]Memorial Sloan-Kettering Cancer Center, USA, [4]Hospital for Special Surgery, USA

Giant Cell Tumor of Bone(GCT) is an osteolytic tumor comprised of three cell populations: fibroblast-like stromal cells(SC); myeloid mononuclear cells; and multi-nucleated osteoclast(OC)-like giant cells. The SC is thought to represent the neoplastic element based on a sustained, high proliferation rate in culture and the presence of cytogenetic abnormalities. SC's express genetic markers consistent with an arrest in an early stage of osteoblast(OB) differentiation that is associated with high expression levels of the OC-inducing factor, RANKL. We aimed to test the hypothesis that SC's could be reprogrammed to undergo OB differentiation by targeting the Wnt or BMP pathways resulting in modulation of key regulators of OCgenesis, including osteoprotegerin(OPG). 6 GCT specimens were obtained in accordance with an approved IRB protocol. SC's were isolated from collagenase-dispersed tumor cells using negative selection with a CD14 magnetic bead column. Purity was assessed based on morphology, the absence of CD14 expression (FACS and IF microscopy), and the absence of OC-specific genes, including cathepsin K. SC's were cultured for 10-12 d in the presence or absence of BMP-2, SB415286(a specific GSK-3beta inhibitor and Wnt mimetic), or osteogenic medium (OGM). Differential expression of OB differentiation markers was assessed by qPCR. OPG production was determined by ELISA. The OCgenic activity of SC's was assessed using a human monocyte co-culture system. OC formation was quantified by TRAP stain cell counts done in triplicate. SC's exposed to BMP-2, SB415286, or OGM demonstrated >2-fold induction of OB-associated genes, including Runx2 and osterix. Wnt pathway activation or growth in OGM was accompanied by a marked increase in the OPG/RANKL ratio and loss of SC OC-inducing activity. Conversely, treatment with rhBMP-2 resulted in a *decreased* OPG/RANKL ratio, and *enhanced* OC formation. The capacity of Wnt and BMP pathway activation and OGM to induce SC's to undergo OB differentiation provides further evidence of their OB lineage. Surprisingly, the induction of OB differentiation by BMP or Wnt pathway activation produced differential effects on OC-inducing activity. This effect may be attributed to the differential effects of the Wnt and BMP pathways on OPG/RANKL production. The ability to manipulate the OCgenic phenotype of SC's provides a potential novel approach for treatment and insight into the mechanisms by which OB lineage cells regulate OCgenesis.

Unraveling the Molecular Connections between Anti-Cancer and Anti-Osteoporosis Drugs Using the Connectivity Map. Jameel Iqbal*[1], Xuan Liu[1], Ling-Ling Zhu[1], Jianhua Li[2], Yuanzhen Peng[3], Zuhong Lu[4], Guangyu Zhu[1], Alberta Zallone[5], Li Sun[6], Mone Zaidi[7]. [1]The Mount Sinai Bone Program & Department of Medicine, Mount Sinai School of Medicine, USA, [2]Tount Sinai School of Medicine, USA, [3]The Mount Sinai School of Medicine, USA, [4]State Key Laboratory of Bioelectronics, Southeast University, Nanjing China, China, [5]University of Bari Medical School, Italy, [6]Mount Sinai School of Medicine, USA, [7]Mount Sinai Medical Center, USA

Cancer is the second leading cause of death, and osteoporosis the leading cause of morbidity in the aging population. There is mounting evidence that bisphosphonates, the mainstay of osteoporosis therapy, have anti-carcinogenic properties. While it is known that bisphosphonates prevent bone metastases for breast, prostate and lung cancers, recent evidence suggests that these drugs can prevent the growth of breast cancer lesions. We therefore investigated the molecular mechanisms underlying the anti-resorptive and putative anti-carcinogenic actions of bisphosphonates. Human osteoclasts were treated with alendronate or risedronate to generate a unique bisphosphonate gene signature by combining affymetrix datasets from the respective drugs. We then interrogated the Connectivity Map (CMAP, Broad Institute), a powerful genetic database comprising gene expression profiles that define functional connections between drug actions, genetic perturbations, and disease states. Non-parametric, rank-based pattern-matching using the Kolmogorov-Smirnov statistic examined shared mechanisms of action to reveal both mimics and anti-mimics of the bisphosphonates. The bisphosphonate gene signature identified two anti-cancer drugs, the EGF signaling inhibitor tyrphostin AG1478 and the PARP inhibitor 1,5-isoquinolinediol. Both these anti-cancer drugs displayed potent anti-resorptive properties in vitro identical to bisphosphonates, thus attesting to their use as potential candidates for osteoporosis therapy. Given the molecular connectivity of bisphosphonates to EGFR inhibitors, we tested the effects of alendronate and risedronate on the proliferation of lung cancer cells harboring EGF receptor mutations. Both bisphosphonates potently inhibited cell proliferation. Because breast, lung, and prostate cancers are all known to have aberrant EGFR signaling, often with a dependence on Akt, we tested whether the bisphosphonates could inhibit EGF-induced Akt activation. We found that both alendronate and risedronate suppressed Akt phosphorylation: this represents a novel mechanism for bisphosphonate action that may be utilized for inhibiting cancer growth, especially for cancers with known EGFR/Akt mutations. In conclusion, CMAP could be a powerful new alternative to drug discovery, particularly as it unravels new actions of 'old' drugs. Its use could conceivably reduce the often prohibitive costs and lengthy time intervals that underpin modern drug development.

Zoledronic Acid Prolongs Time to First Skeletal-Related Event (SRE), Progression-Free Survival (PFS), and Overall Survival (OS) Versus Clodronate in Patients With Newly Diagnosed Multiple Myeloma (MM): Results of the Medical Research Council (MRC) Myeloma IX Trial. W. Gregory[1], A. Szubert[1], R. Owen[2], J. Child[1], A. Ashcroft[3], M. Drayson[4], N. Navarro Coy[1], Faith Davies[5], Graham Jackson[6], K Cocks[1], Gareth Morgan*[7], S. Bell[1]. [1]University of Leeds, United Kingdom, [2]St. James's University Hospital, United Kingdom, [3]Mid-Yorkshire Hospitals NHS Trust, United Kingdom, [4]University of Birmingham, United Kingdom, [5]Institute of Cancer Research, United Kingdom, [6]University of Newcastle, United Kingdom, [7]Royal Marsden Hospital, United Kingdom

Purpose: Myeloma cells grow within the bone marrow, and patients (pts) with MM are at high risk for SREs such as pathologic fracture or spinal cord compression. In addition to prolonging OS, an important goal is preventing these potentially debilitating SREs. Bisphosphonates (BPs) are standards of care for reducing the risk of SREs in pts with bone metastases from solid tumors or bone lesions from MM. In addition, several BPs have demonstrated anticancer activity in preclinical models. In particular, zoledronic acid (ZOL) has shown anticancer activity in preclinical models and clinical studies in various cancer types, including MM. In pts with early breast cancer, adding ZOL improved disease-free survival by 36% (P = .01) vs endocrine therapy alone (Gnant et al. *N Engl J Med.* 2009).

Methods: In the MRC Myeloma IX trial (ISRCTN68454111), pts with newly diagnosed MM were randomized to IV ZOL (4 mg q 21-28 days) or oral clodronate (CLO; 1,600 mg/d) plus antimyeloma therapy. Treatment continued at least until disease progression. All pts provided written informed consent, were evaluated for disease outcomes and safety, and the study was approved by institutional review boards. OS, PFS, and SREs were evaluated in adjusted Cox models. OS was also evaluated in an exploratory Cox model adjusted for time-dependent SRE effects.

Results: A total of 1,960 pts were evaluable, with median follow-up of 3.7 yr. In the ZOL and CLO groups, mean age was 65 yr, IgG was the predominant subtype, and ~70% of pts had bone lesions. Overall, ZOL significantly reduced the risk of first SRE by 26% vs CLO (hazard ratio = 0.74; 95% CI: 0.62, 0.87; P = .0004). Pts treated with ZOL had a significant 2-mo increase in PFS (19.5 vs 17.5 mo, respectively; P = .0179) and a 5.5-mo increase in OS (50 vs 44.5 mo, respectively; P = .0118) vs CLO. Moreover, ZOL's survival benefit remained statistically significant after adjusting for potential effects of SREs on OS (P = .0178). Both BPs were generally well tolerated. There was no significant between-group difference in the rate of acute renal failure (ZOL, 6.1%; CLO, 5.8%), and the incidence of confirmed osteonecrosis of the jaw was low (ZOL, 3.5%; CLO, 0.3%).

Conclusions: The results of the MM IX Trial demonstrate a beneficial effect of ZOL on OS and PFS, and superior SRE prevention vs CLO, in pts with MM. Moreover, ZOL OS benefits remained significant after readjustment for SREs, supporting potential anticancer activity.

Coexpressions of FGF-23 and MEPE in Causative Tumors of Oncogenic Osteomalacia. Yuki Nagata*[1], Yasuo Imanishi[1], Jun Hashimoto[2], Wataru Ando[2], Keisuke Kobayashi[1], Takafumi Ueda[3], Akimitsu Miyauchi[4], Hajime Koyano[5], Hiroshi Kaji[6], Takatoshi Saito[7], Koichi Oba[8], Yasato Komatsu[9], Hitoshi Goto[1], Takami Miki[10], Masaaki Inaba[1], Yoshiki Nishizawa[10]. [1]Osaka City University Graduate School of Medicine, Japan, [2]Osaka University Graduate School of Medicine, Japan, [3]Osaka National Hospital, Japan, [4]Omura municipal Hospital, Japan, [5]Juntendo University, School of Medicine, Japan, [6]Kobe University, Japan, [7]Jikei University School of Medicine, Japan, [8]Graduate School of Medical Sciences, Kyushu University, Japan, [9]Kyoto City Hospital, Japan, [10]Osaka City University Medical School, Japan

Purpose Oncogenic osteomalacia (OOM) is a rare disease characterized by renal phosphate wasting and osteomalacia, and is caused by the secretion of fibroblast

growth factor 23 (FGF-23) from causative tumors. Matrix extracellular phosphoglycoprotein (MEPE) as well as its proteolytic ASARM peptide elevate FGF-23 expression in bone. Although the expression of MEPE was reported in some OOM tumors, little is known whether MEPE contributes to the FGF-23 expression in OOM tumors. In this study, we attempt to determine the expressions of FGF-23 and MEPE in OOM tumors.

Subjects and Methods Eleven causative OOM tumors were examined for expressions of FGF-23 and MEPE by quantitative real-time RT-PCR and immunohistochemistry. Two hemangiopericytomas and 4 giant cell tumors, obtained from non-osteomalacic patients, were used as controls, which pathological diagnoses are common among OOM.

Results The expression levels of FGF-23 in OOM tumors were 10^5 times higher than those in non-OOM tumors. The expression levels of MEPE in OOM tumors were also 10^5 times higher than those in non-OOM tumors. Immunohistochemical examinations revealed the presence of FGF-23 in all OOM tumors, and that of MEPE in 10 of 11 OOM tumors.

Conclusions The coexpressions of FGF-23 and MEPE in OOM tumors suggest that MEPE or its proteolytic ASARM peptide may contribute to the FGF-23 overexpression in OOM tumors.

Combined Effects Of Exercise And Alcohol On Bone Status In Rats. Delphine Maurel*[1], Christelle Jaffre[2], Eric Dolleans[2], Nathalie Boisseau[3], Claude-Laurent Benhamou[2]. [1]Inserm Unit 658, Hopital Porte Madeleine, Orléans, France, [2]Inserm Unit U658, France, [3]LAPHAP Laboratory, France

Chronic alcoholism is known to alter bone balance by a decrease of bone remodeling, bone mineral density (BMD), bone mineral content (BMC) and bone resistance in rats and in men. Nowadays most of the treatments to manage bone loss are drug treatments. However, positive effects of exercise on bone are well known. To date and to our knowledge, no study has been driven to determine the possible beneficial effects of regular exercise on bone loss induced by chronic alcohol consumption. To address this question, we designed a study in rats to determine the effects of combined alcohol and exercise on bone.

Thirty-six 2-month old male Wistar rats were divided in 3 groups: Control (C), Alcohol (10 g/kg) (A) and Alcohol+Exercise (AE). The rats were alcoholised for 17 weeks, trained for 14 weeks and then sacrificed. BMC and BMD were assessed by DXA (Hologic, Discovery) and the micro architecture of cortical and trabecular bone has been measured by microCT (Skyscan 1072).

Ethanol consumption decreased significantly the BMC (19.68 ± 0.98; 15.61 ± 1.06 and 16.67 ± 1.73 g respectively for C, A and AE; $p<0.0001$) and BMD (0.205 ± 0.006; 0.189 ± 0.006 and 0.196 ± 0.008 g/cm^2; p=0.0005) of the total body and right femur (BMC: 0.88 ± 0.07; 0.70 ± 0.05 and 0.73 ± 0.08 g for C, A, and AE; $p<0.0001$; BMD: 0.389 ± 0.020; 0.337 ± 0.019 and 0.359 ± 0.019 g/ cm^2 for C, A and AE; $p<0.0001$) compared to Controls. The BV/TV parameter (15.61 ± 5.49; 11.28 ± 3.05 and 16.43 ± 3.86 % for C, A, and AE; p=0.02), the trabecular thickness (0.096 ± 0.012; 0.084 ± 0.007 and 0.101 ± 0.009 mm for C, A, and AE; p=0.0002) and the trabecular number (1.61 ± 0.44; 1.34 ± 0.29 and 1.62 ± 0.31 1/mm for C, A and AE; p=0.01) were also decreased by alcohol compared to Controls while the cortical porosity (1.01 ± 0.27; 1.39 ± 0.33 and 1.06 ± 0.31% for C, A and AE; p= 0.015) and pore number (0.24 ± 0.05; 0.34 ± 0.08 and 0.25 ± 0.06 1/µm for C, A and AE; p=0.001) increased.

The Alcohol+Exercise group had significantly higher femoral BMD, BV/TV, and trabecular thickness compared to A group as well as better cortical porosity and pore number. The maximal strain supported by the bone was also significantly higher in the AE group compared to the A group (182.73 ± 35.10 vs 144.65 ± 18.02 N/mm^2 for AE and A; p=0.017).

In conclusion, regular exercise partly prevents the bone loss and deterioration of the trabecular, cortical microarchitecture and BMD induced by chronic alcoholism.

Gene by Diet Interactions in the *Alox5* Knockout Mice (*Alox5-/-*) Is Associated with Significant Bone Loss. Phuong Le*[1], Masanobu Kawai[2], Sheila Bornstein[2], Mark Horowitz[3], Clifford Rosen[2]. [1]Maine Medical Center Research Institute, USA, [2]Maine Medical Center, USA, [3]Yale University School of Medicine, USA

Lipoxygenase 5 encoded by *Alox5* gene catalyzes the generation of leukotriene B4 from arachidonic acid, and the loss of *Alox5* has been postulated to result in the increased enzymatic conversion of prostaglandin (PG) D2 into PGJ2, an endogenous ligand for PPARγ. Polymorphisms in the *Alox5* gene and its associated protein have been linked to cardiovascular disease; intriguingly, *Alox5* is also a candidate gene regulating peak bone mass in mice. These findings led us to hypothesize that a high fat diet (HFD) in association with deletion of the *Alox5* gene could result in a major bone loss in part through activating PPARγ expression. To test our hypothesis, we fed 3 week old male C57BL/6J (B6, control) and *Alox5-/-* mice either a regular chow diet (10% fat/kcal) or a HFD (45% fat/kcal) for 13 weeks post weaning. We then examined skeletal phenotype by DXA, µCT, serum bone turnover markers, histomorphometry, and cell culture. We also examined PPARγ gene expression in 8-12 week old mice by qPCR. After 13 weeks of treatment, whole body and femoral areal bone mineral density (BMD) were significantly higher in *Alox5-/-* than in B6 ($p<0.01$). Similar phenotypic differences were noted by µCT in the femur. *Alox5-/-* mice had higher serum osteocalcin and PINP levels ($p<0.001$) than B6. *In vitro* bone marrow stromal cell cultures from *Alox5-/-* mice demonstrated greater ALP and von Kossa staining positive colonies compared to cells from B6. Osteoclast number was decreased by histomorphometry in *Alox5-/-* vs. B6 (p=0.06). On the HFD, there were marked strain differences such that B6 showed increased bone mass in the spine and femur. In contrast, *Alox5-/-* mice on a HFD had lower whole body BMD, femoral and vertebral trabecular BV/TV than *Alox5-/-* mice on a regular diet, which was accompanied by reduced trabecular number and increased osteoclast number. Serum Trap5b in the *Alox5-/-* mice was greater on the HFD while P1NP decreased significantly (p=0.04) compared to mice on a regular diet. qPCR results showed marked increase of PPARγ levels in femur from *Alox5-/-* vs. B6 on HFD. In summary, PPARγ gene associated with diet interactions in *Alox5-/-* mice causes significant bone loss by suppressed bone formation and increased bone resorption. This line of evidence may provide an insight into the important interaction between dietary fat intake and genetic predisposition to osteoporosis.

Potent Inhibition of Heterotopic Ossification by a Selective RARγ Agonist. Kengo Shimono*, Wei-en Tung, Hsu-Tsai Chi, Chrissy Mundy, Johanna Jasinski, Daine Pilchak, Julie Williams, Motomi Enomoto-Iwamoto, Maurizio Pacifici, Masahiro Iwamoto. Thomas Jefferson University, USA

Heterotopic ossification (HO) consists of formation of ectopic bone masses following trauma and involves recruitment of progenitor cells, differentiation into chondrocytes and replacement by endochondral bone. Available HO treatments such as irradiation are not fully effective and do not target any of the above HO-formation steps. Differentiation of mesenchymal cells into chondrocytes requires decreases in both retinoic acid (RA) signaling and nuclear retinoic acid receptor α (RARα) action. Indeed, we previously showed that treatment with a synthetic RARα agonist inhibits HO formation in a mouse model. Here, we asked whether another family member – RARγ- represents a previously unsuspected and possibly more powerful regulator of chondrogenesis and HO. Micromass cultures of wild type E11.5 mouse embryo limb mesenchymal cells were treated with RA (that activates every RAR isoform) or a selective RARγ agonist (γ-agonist). Numerous cartilage nodules formed in untreated cultures, but few formed in RA-treated cultures and nearly none in γ-agonist-treated cultures. When the micromass cultures were prepared with double RARα/RARβ-null limb bud cells, the same results were obtained. However, when RARγ-null cells were used, inhibition of cartilage nodule formation by RA was only about 25-30%, strongly indicating that RARγ is the major anti-chondrogenic regulator. Next, we tested whether the γ-agonist acts via a blockage of the key pro-chondrogenic BMP/Smad signaling pathway. It did but, surprisingly, it not only inhibited Smad1 nuclear translocation, but also caused rapid Smad1 degradation via proteasome action. To determine γ-agonist effectiveness in vivo, we induced HO formation by implantation of BMP-2-loaded collagen sponges in mouse calf muscles. Large ectopic HO-like cartilaginous masses formed in control mice and were replaced by bone by day 14. However, cartilage and bone formation was nearly prevented in mice receiving γ-agonist (0.4 to 4.0 mg/kg/day) by gavage; inhibition was about 95% measured by BV/TV ($p<0.01$). There were no appreciable γ-agonist side effects in terms of body weight, liver and kidney function and articular cartilage phenotype. As expected, we observed partial HO inhibition in mice receiving RA (12 mg/kg/day), but this treatment had side effects including severe skin and articular cartilage damage. In sum, our study shows that selective pharmacologic activation of RARγ represents a novel, powerful and seemingly safe treatment against HO.

Studies of Type I Collagen Mutations in Type I and IV Osteogenesis Imperfecta (OI) Patients Induced Pluripotent Stem (iPS) Cells. Xiaonan Xin*, Mary Louise Stover, Dr. Yongxing Liu, Dr. Liisa Kuhn, David Rowe, Dr. Alexander Lichtler. University of Connecticut Health Center, USA

Osteogenesis imperfecta (OI) is a heritable bone disease caused by mutations in the type I collagen genes. Severe have defective collagen fibers with inherently unstable structures causing bone fragility. Previously we reported initial derivation of iPS cells from patients with severe and mild IO, with the long term goals of investigating OI pathogenic mechanisms, and testing therapeutic strategies. In the current studies we have further characterized the cells we produced, and we are in the process of investigating the mutant collagen that they produce. The mutations in the two cell lines have been identified; as expected, the Type I OI cells contain a premature termination codon that leads to mRNA instability, and the Type III/IV cells have an alanine substituted for the glycine at amino acid position 491. RNA analysis using an ABI pluripotency low density array PCR plate showed a similar gene expression profile of the iPS cells to H9 hES cells. With the goal of identifying defined, non-human factor-free culture conditions for the iPS cells, we have showed that our cells have similar gene expression profiles when cultured in Stemgent NutriStem media compared to standard mouse embryo fibroblast conditioned media. We have developed a method for differentiating our iPS cells into a mesenchymal stem cell-like population that is over 95% CD73+ and CD44+, and negative for hematopoietic cell markers. Low density array PCR analysis demonstrated expression of mesodermal markers in the differentiated cells, and Type I collagen mRNA is also expressed. We are currently assessing the ability of the iPS cells to produce teratomas that contain bone, and we will analyze the mutant collagen produced by the differentiated cells. We are also working to develop methods to induce differentiation of these cells into osteoblasts, and also to test the zinc-finger methodology for mutation correction.

Suppression of Bone Quality by Diet-induced Obesity Correlates with Increase in Insulin Resistance and Suppression of Immune Cells. Ete M. Chan*[1], Elizabeth M. Fievisohn[1], Ada H. Tsoi[1], Mario E. Botros[1], Benjamin Adler[2], Danielle E. Green[1], Clinton Rubin[3]. [1]Department of Biomedical Engineering, Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA

Obesity is a serious condition leading to diseases such as Type II diabetes (T2D) which is known to affect bone quality, but the underlying mechanisms of this relationship are still unclear. To investigate the effect of obesity on bone quality, twenty 7w male C57BL/6J mice were randomly assigned to either a high fat (HF) diet (45% kcal) or a regular chow diet group (RD) (n=10) for ~6 months following which the trabecular bone compartment in the proximal tibia was evaluated using micro-computed tomography (microCT). Furthermore, to assess characteristics of T2D and any downstream effects resulting from obesity, 1) abdominal adipose tissue load was evaluated with microCT, 2) glucose tolerance test (GTT) was performed, 3) levels of fasting insulin and fasting glucose in blood were measured and 4) proportional changes in cells from myeloid and lymphoid lineages within bone marrow and blood (subgroup, n=4) were evaluated using flow cytometry. The HF diet treatment induced significant changes in the trabecular bone compartment in the HF group (Fig 1): As compared to the RD group, the HF group has 11% higher trabecular thickness Tb.Th ($p=.026$), but 24% lower trabecular number Tb.N ($p=.023$) and 39% larger trabecular separation Tb.Sp ($p=.05$). Accompanying changes in trabecular bone are increases in body mass (42%, $p<.001$), adipose tissue volume (56%, $p<.001$) and fasting insulin (354%, $p=.03$), indicating the prominent role of obesity in inducing insulin resistance. While body mass is positively correlated to the Tb.Th ($r=.63$, $p=.009$) and negatively correlated to the Tb.N ($r=-.54$, $p=.032$), glucose intolerance as measured by GTT is also negatively correlated to Tb.N ($r=-.61$, $p=.012$) and positively correlated to Tb.Sp ($r=.60$, $p=.014$). This indicates that glucose intolerance could contribute to the compromised bone quality. Interestingly, the HF group showed a significant reduction in the B cell proportion both in bone marrow (66.9%, $p=.011$) and blood (36.5%, $p=.045$) indicating an impairment of hematopoiesis in the bone marrow. We conclude that obesity upregulated T2D and compromised the bone marrow cells, disrupting the ability of the bone to adapt to the increased load bearing challenges.

Genetic Variation in the *LRP4* Gene Influences Bone Mineral Density and Hip Geometry while Missense Mutations Cause Sclerosteosis. Elke Piters*[1], Eveline Boudin[2], Olivier Leupin[3], Fenna de Freitas[2], Karen Jennes[2], Manuel Bueno-Lozano[4], Feliciano J Ramos-Fuentes[4], Peter H Itin[5], Torben Leo Nielsen[6], Marianne Andersen[6], Kristian Wraae[6], Kim Brixen[7], Michaela Kneissel[3], Wim Van Hul[1]. [1]University of Antwerp, Belgium, [2]Department of Medical Genetics, University of Antwerp, Belgium, [3]Novartis Institutes for Biomedical Research, Switzerland, [4]Departmento de Pediatría, Universitad de Zaragoza, Spain, [5]Department of Dermatology, University Hospital Basel, Switzerland, [6]Department of Endocrinology, Odense University Hospital, Denmark, [7]Institute for Clinical Research, Denmark

Some of us have recently reported a role for low density lipoprotein-related protein (LRP)-4 in binding to and facilitating sclerostin in its inhibition of both Wnt signaling and bone mineralization (1). In the scope of these findings, we performed mutation analysis of an extensive set of patients with different high bone mass disorders and additionally carried out an association study with a selection of *LRP4* polymorphisms in a population-based cohort from the Odense Androgen Study. Mutation analysis revealed the existence of two missense mutations in the *LRP4* gene in two unrelated patients of Mediterranean origin that both showed several typical sclerosteosis features such as an increased bone mineral density (BMD), facial asymmetry and syndactyly. The first patient was homozygous for a p.Arg1170Trp mutation while the other showed a heterozygous p.Trp1186Ser substitution. Both the mutations were absent in a large control set of mixed European origin and completely blocked the interaction with sclerostin and the concomitant sclerostin-enhancer action. The mutations occur adjacent to each other at the surface of the third extracellular β-propeller, which corresponds with the assumption that this domain is involved in sclerostin interaction and function. In another effort to implicate *LRP4* in human bone disease, we studied 2 non-synonymous coding polymorphisms in the region encoding the third extracellular β-propeller. BMD measurements of the hip and the spine as well as different hip geometry parameters were available for a total of 1404 Danish men from two age groups ([20-29 y]: n= 804; [60-74 y]: n= 600). Using linear regression analysis adjusted for age, height and weight, we were able to replicate previous associations (2, 3) between rs6485702 and BMD at all sites. The most significant association was found with whole body BMD ($p= 4.7*10^{-5}$). In addition, we found this SNP to be associated with different hip geometry parameters suggesting that LRP4 is able to regulate bone structure in addition to BMD. However, another SNP in the same region (rs2306033) did not show association with any of the studied phenotypes. Ongoing genetic and functional studies with additional SNPs will aid in delineating the region of *LRP4* that partly explains the natural variance in BMD. In conclusion, genetic variation in the *LRP4* gene determines BMD both in human bone disease and in the general population. This again illustrates the importance of LRP4 in bone homeostasis.

Low Bone Mass and Turnover Phenotype in a Mouse Model of Down Syndrome. Tristan Fowler*, John W. Bracey, Nisreen Akel, Robert A. Skinner, William R. Hogue, Frances L. Swain, Dana Gaddy, Kent D. McKelvey, Galen R. Wenger, Larry Suva. University of Arkansas for Medical Sciences, USA

Down syndrome (DS) is a human aneuploidy resulting from the presence of a third chromosome 21. It occurs in the human population at a rate of approximately 1 per 1,000 live births in all ethnic groups. This condition is associated with a number of physical characteristics and clinical conditions including a degree of mental retardation, thrombocytosis, and a 500-fold increased risk of developing megakaryocytic leukemia. Recently, DS has also been associated clinically with a dramatically increased rate of fracture in adolescent and adult patients. Since individuals with DS are reported to have a survival rate of >50% to age 50, skeletal complications should be considered in these patients. However, the specific effects of trisomy 21 on the skeleton remain poorly defined. To study this question, we determined the skeletal phenotype of the Ts65Dn mouse model of DS. Ts65Dn mice are trisomic for 104 orthologs of human Chr 21 (HSA21) genes and this model is the most widely used and accepted mouse model for DS. The mice are characterized by segmental trisomy for the region of mouse Chr 16 (MMU16) that extends from just proximal to the amyloid precursor protein (App) gene to the distal telomere and contains about 75% of the HSA21-homologous genes present in the mouse. We have discovered that adult Ts65Dn mice display a profound low bone mass phenotype, with significant decreases in bone volume fraction of the tibia and femur. Interestingly, Tb.N. was dramatically decreased whereas Tb.Sp. and Tb.Th are increased compared with euploid control littermates. The low bone mass in Ts65Dn mice is associated with a dramatic reduction in bone biochemical markers, with an approximately 50% decrease in serum P1NP and TRAP5b levels, indicative of a mechanism for low bone mass involving decreased bone turnover. In addition, the effects of trisomy 21 are not limited to trabecular bone, as the cortical geometric parameters of cortical cross sectional area, cortical thickness, total cross sectional area and periosteal perimeter are all significantly decreased in Ts65Dn mice. These dramatic changes in cortical bone were translated into significant decreases in mechanical strength and stiffness of the Ts65Dn femur. Our studies demonstrate the potential of DS mouse models to improve our understanding of chromosome 21 gene dosage effects in the skeleton and provide novel insight into the causes of the clinical observations of the extraordinary bone fragility in Down's patients.

Low Bone Mass in Genetic Hypercalciuric Stone-Forming (GHS) Rats is Associated with Higher RANKL Expression in Bone Marrow Stromal Cells. Hongwei Wang*[1], Randal Zhou[1], David Bushinsky[2], Murray Favus[1]. [1]University of Chicago, USA, [2]University of Rochester, USA

GHS rats are a useful model to study human idiopathic hypercalciuria (IH) as both share increased intestinal Ca absorption and bone resorption, decreased renal Ca reabsorption, low bone mass, and Ca nephrolithiasis. We investigated low bone mass in male and female GHS rats and normocalciuric (NC) controls. Rats were fed a diet adequate in Ca (0.8%) diet. MicroCT scanning showed reduced tibial bone density (BD) in GHS vs NC rats. Microarray analysis of GHS rat bone marrow stromal cells (BMSCs) showed reduced expression of genes that enhance bone formation (BMP2, SPP1 and SOST) while gene expressions that stimulate bone resorption (RANKL, RANK, GM-CSF, TNFα and IL1) were increased. Real time PCR confirmed the microarray results. The numbers of osteoclasts (OCs) in primary cultures of GHS rat bone marrow were increased 2-3 fold. GHS rat OCs were larger by volume, and the BMSCs contained greater RANKL expression by immunostaining. In conclusion, the data strongly suggest that GHS rats have low bone mass due to greater expression of genes of the resorptive stimulatory pathway and suppression of genes that modulate the bone formation pathway. The molecular basis for the dysregulated resorption and formation genes remains to be determined.

Mandible Length Quantitative Trait Loci (QTLs) in HcB-8 x HcB-23 Intercross. In Kyu Han[1], Gurpreet Sandhu[1], Suzanne J. Litscher[1], Neema Saless[2], Peter Demant[3], Robert Blank*[1]. [1]University of Wisconsin, USA, [2]University of California, San Francisco, USA, [3]Roswell Park Cancer Institute, USA

We previously mapped quantitative trait loci (QTLs) for femoral biomechanical performance and anatomy in a reciprocal intercross of HcB-8 and HcB-23. In that work, we determined that a robust QTL on chromosome 4 acts by altering the proliferative response to mechanical loading and that the additional affected phenotypes are secondary consequences of the modeling difference. Further, we inferred that the gene underlying the chromosome 4 QTL is *Ece1*, encoding endothelin converting enzyme 1. To further test our model, we hypothesized that there would be a mandibular size phenotype linked to the chromosome 4 QTL, related to the insertion of the masseter muscle. Here we report mapping of QTLs for mandibular length in our cross.

We subdivided the mandible into 3 segments with boundaries defined by the mentum, the posterior margin of the 3rd molar, the coronoid process, and the angle. We measured the projected distance between the landmarks from digital photographs of the hemimandibles, averaging the left and right sides. We performed linkage analysis using R/qtl and QTL Cartographer. Experiment-wide $\alpha = 0.05$ significance thresholds varied between 2.8 and 3.0.

The entire F2 progeny included 603 animals. QTLs for the mentum-molar segment are located at 67 cM on chromosome 1 with LOD = 3.8 and at 28 cM on chromosome 6 with LOD 7.5. The molar-coronoid segment has QTLs at 41 cM on chromosome 1 with LOD = 3.8 and at 67 cM on chromosome 4 with LOD = 5.7. No QTLs for coronoid-angle length were detected. There were no significant sex x QTL or cross x QTL interactions. Larger subsets of the mandible did not detect additional QTLs. The chromosome 6 QTL accounts for 8% of the mentum-molar length variance. The chromosome 4 QTL accounts for 7% of the F2 molar-coronoid length variance.

The data support our hypothesis that the chromosome 4 QTL mediates response to mechanical loading. There are no muscle of mastication insertions anterior to the molars, while the masseter inserts primarily in the region between the coronoid process and the 3rd molar. The proximal chromosome 1 QTL may also act via modeling. The chromosome 6 QTL for the anterior jaw is distinct from the male-specific QTL we identified for femoral size and mechanical performance. To the best of our knowledge, this is the first instance in which a skeletal QTL's existence has been predicted on the basis of the affected phenotypes at a remote anatomical site.

Modelling Bone Healing Deficiencies in Type 1 Neurofibromatosis. David Little[1], Aaron Schindeler[1], Ian Alexander[2], Jad El-Hoss*[1]. [1]The Children's Hospital at Westmead, Australia, [2]The Children's Medical Research Institute, Australia

Congenital tibial dysplasia (CTD) involves bowing and weakness of the tibia that leads to fracture and poor subsequent bone healing. CTD and scoliosis are key diagnostic features of the autosomal dominant genetic condition Neurofibromatosis Type 1 (NF1). Based on some compelling new evidence that CTD is associated with local double inactivation of *NF1*, we are developing advanced murine systems to model the genetics of *Nf1* inactivation in mice. We have previously shown deficient bone healing in the $Nf1^{+/-}$ mouse. We are now using a Cre-expressing adenovirus (Ad-Cre) to generate local double inactivation of *Nf1* in $Nf1^{flox/-}$ and $Nf1^{flox/flox}$ mice. Briefly, Cre-expressing adenovirus will infect local cells and excise crucial exons of the *Nf1* gene in $Nf1^{flox/flox}$ and $Nf1^{flox/-}$ mice. These mice were generated by crossing *Nf1* null ($Nf1^{+/-}$) and *Nf1* conditional ($Nf1^{flox/flox}$) strains. In the context of fracture healing we anticipate this will further impair union compared to the traditional $Nf1^{+/-}$ mouse. Cultured bone marrow cells from $Nf1^{flox/+}$ mice were exposed to Ad-Cre and this led to efficient *Nf1* excision as measured by PCR on genomic DNA. *Nf1* gene excision was also detected by PCR in a tibial fracture model where the Ad-Cre was locally injected at the time of surgery. The Z/AP reporter mice were examined to histologically track the efficiency and distribution of Cre-mediated recombination. Alkaline phosphatase positive stain confirmed virus mediated recombination of cells lining the fracture site. In $Nf1^{flox/flox}$ mice, fractures treated with Ad-Cre displayed poor fracture healing compared to Ad-GFP treated controls. Ad-Cre treated fractured where characterised by a fibrocartilaginous plug that impaired further fracture healing. These results show that local knockout of *Nf1* impairs fracture healing. Furthermore, we have generated a novel model for the local double inactivation of *Nf1* in a fracture setting using the Ad-Cre virus system. This new model will prove beneficial to test novel therapeutics and better mirror the clinical condition.

New Mouse Model for Type IV Osteogenesis Imperfecta – Cellular and Molecular Changes in Long Bone Precede Post-Pubertal Adaptation. Frieda Chen*[1], Ruolin Guo[2], Shousaku Ito[3], Luisa Moreno[4], Esther Rosenthal[1], Tanya Zappitelli[1], Ralph Zirngibl[1], Ann Flenniken[5], William Cole[6], Marc Grynpas[4], Lucy Osborne[7], Wolfgang Vogel[1], Lee Adamson[4], Janet Rossant[8], Jane Aubin[9]. [1]University of Toronto, Canada, [2]University of Rochester, USA, [3]Osaka University Graduate School of Dentistry, Japan, [4]Samuel Lunenfeld Research Institute, Canada, [5]Toronto Centre for Phenogenomics, Canada, [6]University of Alberta Hospital, Canada, [7]Toronto General Research Institute, Canada, [8]Hospital for Sick Children, Canada, [9]University of Toronto Faculty of Medicine, Canada

Mutations in type I collagen or in proteins involved in its processing have been shown to cause the genetic bone disease Osteogenesis Imperfecta (OI). By a genome-wide N-ethyl-N-nitrosourea (ENU)-induced mutagenesis screen in mice, we identified a founder mouse with the classic clinical manifestations of OI. Mapping and sequencing identified a T to C transition in a splice donor of the collagen alpha1 type I (Col1a1) gene resulting in the skipping of exon 9 and an 18 amino acid deletion in the main triple helical domain of Col1a1. $Col1a1^{Jrt/+}$ mice are smaller in size and have lower bone mineral density (BMD), decreased bone volume/tissue volume, reduced trabecular number and weaker, more brittle bones than their +/+ (wild type (WT)) littermates. Bone fractures occur at multiple sites at all ages, but with a high incidence of fractures of the pelvis and olecranon process of the ulna, in young $Col1a1^{Jrt/+}$ mice. Biochemical analyses of matrices in dermal fibroblast cultures indicated that total collagen content of the $Col1a1^{Jrt/+}$ matrices was ~40% that of WT, with the content of type I collagen only ~30% of that in WT cultures, suggesting that mutant collagen chains exert a dominant negative effect on type I collagen biosynthesis. Electron microscopic analysis of tendon and bone samples, as well as extracellular matrices deposited by dermal fibroblasts *in vitro*, indicated that collagen fibrils are markedly smaller in diameter in $Col1a1^{Jrt/+}$ versus WT mice and cell cultures. *In vitro* analysis of stromal cells indicated that the size of the osteoprogenitor population is unaffected, but osteoblast differentiation as assessed by marker expression and mineralization are reduced in stromal cell cultures from age-matched young (5-week-old) versus older (20-week-old) $Col1a1^{Jrt/+}$ versus WT mice. Expression of Col1a1 and Ocn mRNAs was increased in bones of 5 week-old $Col1a1^{Jrt/+}$ versus WT mice, while that of Opn was decreased and Alp increased in 20 week animals. Thus, $Col1a1^{Jrt/+}$ mice are a new model of dominantly-inherited type IV OI. Differences observed in the bone phenotype and osteoblasts at different ages suggest that the $Col1a1^{Jrt/+}$ model will be useful to explore further the mechanisms by which OI bone adapts during growth and adulthood and other aspects of OI pathophysiology and treatment.

Superoxide Dismutase Deficiency in Cytoplasm Exacerbated Bone Loss Under Reduced Mechanical Loading. Daichi Morikawa*[1], Yoshitomo Saita[2], Hidetoshi Nojiri[2], Chizuru Tsuda[1], Yoshinori Asou[3], Kazuo Kaneko[2], Takahiko Shimizu[1]. [1]Molecular Gerontology, Tokyo Metropolitan Institute of Gerontology, Japan, [2]Department of Orthopaedics, Juntendo Univ., Japan, [3]Section of Regenerative Therapeutics for Spine & Spinal Cord, Tokyo Medical & Dental Univ., Japan

Cu/Zn-superoxide dismutase (*Sod1*) is one of the major antioxidant enzymes in mammals. *Sod1*-deficient ($Sod1^{-/-}$) mice has been reported to present a variety of aging-like pathological changes (muscle atrophy, skin thinning, age-related macular degeneration). Last year, we have reported that $Sod1^{-/-}$ mice exhibit low turnover osteopenia via suppressed osteoblastic bone formation.

In order to clarify the cause of osteoblastic dysfunction, we compared gene expression profile between $Sod1^{-/-}$ and $Sod1^{+/+}$ osteoblasts isolated from neonates using DNA microarray. This analysis identified the down-regulated genes involved in cell adhesion in $Sod1^{-/-}$ osteoblasts. Among them, we confirmed that osteomodulin (Omd), Comp, chadherin 11, and osteopontin were significantly decreased by real-time PCR analyses in $Sod1^{-/-}$ both *in vitro* (osteoblast) and *in vivo* (whole bone). These results suggest that *Sod1* might be involved in cell adhesion and sensing of mechanical stress in osteoblast, and that oxidative stress could relate to mechanical loading in bone. Therefore, we performed hindlimb unloading (HU) in $Sod1^{-/-}$ mice.

Ten-weeks-old $Sod1^{-/-}$ and $Sod1^{+/+}$ mice were conducted in HU for 14 days. Bone mineral density by DEXA was decreased by unloading in both $Sod1^{-/-}$ and $Sod1^{+/+}$ mice compared to loading group. Interestingly, three dimensional micro CT showed that trabecular bone volume (BV/TV) was decreased more than twice in $Sod1^{-/-}$ (55% loss vs. loading) compared to $Sod1^{+/+}$ (24% loss vs. loading), however, the decrease of cortical bone volume was not significantly different between $Sod1^{-/-}$ (16.3% loss vs. loading) and $Sod1^{+/+}$ (15.8% loss vs. loading). In bone marrow cell culture after unloading, the development of TRAP positive osteoclast-like cells were increased in unloading group both in $Sod1^{-/-}$ and $Sod1^{+/+}$ mice and it tended to be accelerated in $Sod1^{-/-}$ mice.Finally, we examined whether hindlimb unloading increased reactive oxygen species (ROS) in bone marrow cells. Interestingly, ROS production was significantly increased after unloading and it peaked one week after unloading, suggesting that reduced mechanical loading increases oxidative stress in bone marrow.

Our data revealed that cytoplasmic oxidative stress could exacerbate trabecular bone loss under reduced mechanical loading.

Genome Wide Linkage of Osteocalcin to Chromosome 18 in Multi-generational Families of African Ancestry. Allison Kuipers*[1], Caren Gundberg[2], Amy Dressen[3], Candace Kammerer[1], Clareann H. Bunker[3], Ashely Edwards[3], Alan L. Patrick[4], Victor W. Wheeler[4], Anne Newman[3], Joseph Zmuda[1]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]Yale University School of Medicine, USA, [3]University of Pittsburgh, USA, [4]Tobago Health Studies Office, Trinidad & tobago

Osteocalcin (OC), synthesized by osteoblasts, is an important protein constituent of bone matrix, and is a marker of bone turnover. Emerging evidence suggests that OC may also be a novel hormonal regulator of energy metabolism. We sought to identify genomic regions involved in regulating total and uncarboxylated OC using genome-wide linkage analysis in 458 individuals from seven large multi-generational families of African ancestry residing on the island of Tobago (mean family size, 56; 4,206 relative pairs; mean age, 42.7 years). We genotyped 5361 single nucleotide polymorphisms with minor allele frequency >0.05 and spaced ~1 centimorgans apart using the Illumina Infinium II Human Linkage 12 panel. We estimated residual heritability (after adjusting for age, sex, height, and weight) and conducted multipoint quantitative trait linkage analyses using pedigree-based maximum likelihood methods. Means (and residual heritabilities) of total OC, uncarboxylated OC and percent uncarboxylated OC were 4.47μg/L (0.63 ± 0.09), 1.53μg/L (0.83 ± 0.09) and 35.53%(0.41 ± 0.09), respectively. We detected significant evidence of linkage on chromosome 18 (maximum LOD=4.17, 92cM) and suggestive evidence of linkage on chromosomes 9 (maximum LOD=2.16) and 20 (maximum LOD=2.15) for total OC. Suggestive evidence of linkage for percent uncarboxylated OC was observed on chromosome 12 (maximum LOD=2.23). Interestingly, the structural locus for OC resides on chromosome 1, outside of the linked regions. The linked region on chromosome 18 contains 15 known and predicted genes. A potential candidate gene of interest in this region is the melanocortin 4 receptor (MC4R), which regulates appetite and energy expenditure and is expressed in osteoblasts. Further studies of the linked chromosomal regions may reveal novel insight into the regulation of osteocalcin and bone metabolism.

Heritability of Densitometric, Structural and Strength Properties of Bones: Results from the GAO (Genetic Analysis of Osteoporosis) Project. Jorge Malouf*[1], Ana Laiz-Alonso[1], Ana Marin[1], Angel Martinez-Perez[2], Leonor Rib[2], Raquel Perez[2], Alfonso Buil[2], Jordi Casademont[1], Jordi Farrerons[1], Jose Manuel Soria[2]. [1]Hospital de la Santa Creu i Sant Pau, Spain, [2]Institut de Recerca (IR-HSCSP), Spain

Osteoporosis is a skeletal disorder characterized by compromised bone mass and strength that increases the risk of fracture. The genetic basis of primary osteoporosis is complex with multiple genes and environmental factors acting jointly to determine risk. However, recent advances in genetic analyses permit the identification of the genetic determinants of complex diseases. Towards this end, we designed a family-based study of the genetics of osteoporosis in a Spanish population, called GAO (Genetic Analysis of Osteoporosis).

A total of 110 individuals in 5 Spanish extended families (at least three-generation families) were included. All of the families were recruited through a proband with osteoporosis and all of them signed an informed consent. After filling a questionnaire, a spine, femur and whole body densitometry was performed using a Discovery densitometer with the APEX 2.3 software, from HOLOGIC® Bedford, Massachusetts, USA. The strength and geometrical properties of the hip were analyzed using the HSA® software included in the Apex 2.3 software.

Maximum likelihood-based covariance decomposition analysis was used to assess heritabilities (h2) and the genetic and environmental correlations (ρG and ρE) between phenotypes. Table 1 shows the h2 found among the phenotypes.

This is the first study that quantifies the genetic component of several important parameters involved in osteoporosis and fracture risk in extended pedigrees. The high heritability of the majority of them indicate that genetic effects account for a significant proportion of the observed phenotypic variation of these parameters. Thus, a strategy based on a family-based study through a genome scanning can be used to identify the specific genes involved in osteoporosis and fracture risk. Additionally, this knowledge will greatly facilitate the search for genes involved in osteoporosis, and ultimately find its way into the clinic.

A Significant Interaction between Simple Nucleotide Polymorphism (SNP) in *NFKB* and *RANK* is Associated with Women BMD in the Framingham Osteoporosis Study. Bi Hua Cheng*[1], Xing Chen[2], YanHua Zhou[3], Serkalem Demissie[3], Adrienne Cupples[3], David Karasik[4], Douglas Kiel[4], Yi-Hsiang Hsu[5]. [1]Chang Gung Memorial Hospital - Kaohsiung Medical Center, Chang Gung University, USA, [2]HSL, USA, [3]BUSPH, USA, [4]Hebrew SeniorLife, USA, [5]Hebrew SeniorLife & Harvard Medical School, USA

The RANK/RANKL/OPG signaling pathway plays a crucial role in signal transduction in osteoblasts and osteoclasts. Previous GWAS have shown that SNPs in TNFRSF11A (*RANK*), TNFSF11(*RANKL*), and TNFRSF11B(*OPG*) genes are associated with BMD. Although NFKB gene is known to mediate osteoclastogenesis via the RANK/RANKL/OPG signaling pathway, its interactions with RANK, RANKL, or OPG genes in relation to BMD have not been examined in human populations. Therefore, we performed a gene-gene interaction study to investigate this relationship. Femoral neck (FN) and L2-L4 lumbar spine (LS) BMD were measured by a Lunar DPX-L. Genotyping was performed using the Affymetrix 550K SNP chips. A total of 1,813 women and 1,375 men (mean age 62.5 yrs) with both phenotypes and genotypes in the Framingham Osteoporosis Study were in the final analysis. Genotyped SNPs were selected with (1)minor allele frequency $\geq$ 1% and (2) HWE test p-value $\geq$ 0.0001 and (3) located in the gene and within 20 kb 5' upstream flanking region (38 SNPs in *NFKB*, 37 in *RANK*, 61 in *RANKL*, and 58 in OPG). Sex-specific linear mixed-effect models were performed to determine the single SNP-phenotype associations with LSBMD and FNBMD. Covariates adjusted in the models included age, height, BMI, alcohol consumption, smoking status and principal component for their ancestral genetic background. The most significant association (the lowest p-value) with LS BMD were found for *NFKB* rs7685474,*RANK* rs2980973,*RANKL* rs7334307,and OPG rs7014574 in women and NFKB rs17032779, *RANK* rs17069956, *RANKL* rs7989838, and *OPG* rs11992072 in men. No SNP with association p-value less than 0.01 was found for FN BMD in women or men; therefore we did not perform gene-gene interaction for FN BMD. Six pair-wise interactions between the most associated SNPs in these four genes were performed in each gender. Bonferroni correction was used to adjust for multiple testing (α level=0.00416). A significant interaction between NFKB rs7685474 and RANK rs2298073 (p=0.0039) was found in women only at LSBMD. Individuals with polymorphic alleles in the RANK rs2298073(C)and the NFKB rs7685474(G)had a higher BMD compared to individuals without polymorphic alleles in both of the genes or in one of the genes (Fig 1). No significant gene-gene interactions were found in relation to LS BMD in men. This is the first genetic epidemiological study to reveal an interaction between NFKB and the RANK pathway at genetic level with LSBMD in a Caucasian population.

SA0167

Association of LRP4 Polymorphisms to Bone Properties and Fracture in Women. Maria Swanberg*[1], Jitender Kumar[2], Fiona McGuigan[3], Kristina Akesson[4]. [1]Lund University, Sweden, [2]Lund University, Sweden, Sweden, [3]University of Lund, Malmö Skane University Hospital, Malmö, Sweden, [4]Malmo University Hospital, Sweden

LRP4 and LRP5 are structurally similar members of the low density lipoprotein-receptor gene family that may regulate osteogenesis as co-receptors in the Wnt signaling pathway. Experimental data supports a role for LRP4 and -5 in regulating bone mass, growth and turnover. Genetic association to BMD and fracture has been reported for LRP4 and has been confirmed for LRP5 in several cohorts.

In this study, we examined the association of single nucleotide polymorphisms (SNPs) in LRP4 (rs3816614, rs6485702, rs2306033, rs7926667) and LRP5 (rs68242, rs498832, rs373622) to bone properties and fracture risk. Two cohorts living in Malmö, Sweden, were studied with regard to bone mineral density (BMD) and bone architecture; the PEAK-25 cohort representing 1002 young (25 years old) women, and the OPRA cohort representing 1002 elderly (75 years old) women. The OPRA cohort was followed for 5 years and additional phenotypes studied in this cohort were BMD at age 80, bone loss between age 75 and 80, femoral neck (FN) bone geometry and acquired fractures until age 80.

In the OPRA cohort, LRP4 was associated to BMD corrected for smoking and weight for total body and FN at age 75 (rs2306033 $p<0.05$) and at age 80 (rs2306033 $p<0.01$; rs3816614 $p<0.01$) and for lumbar spine at age 80 (rs6485702, $p<0.05$). Similarly, in the PEAK-25 cohort, LRP4 (rs6485702) was associated to BMD corrected for smoking and weight at the FN ($p<0.05$), lumbar spine ($p<0.05$) and total body ($p<0.01$).

In the OPRA cohort, LRP4 was also associated with the rate of total body bone loss between age 75 and 80 (rs3816614 $p<0.05$), bone quality measurements taken through ultrasound (rs3816614 $p<0.05$) and bone geometry for FN width (rs648570 $p<0.01$) and moment of inertia (rs648570 $p<0.05$).

Until age 80 in the OPRA cohort, 609 individuals had suffered at least one fracture, including 139 women with hip fractures, while 329 women had not suffered any fracture. LRP4 was associated to any fracture (rs3816614 $p<0.05$, rs2306033 $p<0.01$, rs6485702 $p<0.05$) and to hip fracture specifically (rs2306033 $p<0.01$), with more carriers of the variant alleles in the no-fracture group.

In conclusion, non-synonymous polymorphisms in the LRP4 gene were consistently associated with various bone properties i.e. BMD, bone geometry, quality, rate of bone loss and, importantly, to fracture in elderly women. In addition, LRP4 was also associated to BMD in young women, thereby having probable effects on bone throughout life.

Association of Non-coding Variants in the 3′-UTR of the Frizzled-1 Gene with Skeletal Geometry Among Afro-Caribbean Men. Yingze Zhang*[1], Allison Kuipers[2], Cara Nestlerode[1], Clareann Bunker[1], Victor Wheeler[3], Alan Patrick[3], Joseph Zmuda[2]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh Graduate School of Public Health, USA, [3]Tobago Health Studies Office, Trinidad & tobago

The Wnt/β-catenin pathway is important in osteoblast differentiation, proliferation and apoptosis. Frizzled 1 (FZD1) is a member of the Wnt/β-catenin pathway and is a trans-membrane co-receptor with LRP5 for Wnt molecules. We previously demonstrated a novel association between two common single nucleotide polymorphisms (SNP) in the promoter region of frizzled-1 (FZD1) and bone geometric properties.

In the current analysis, we tested whether SNPs in the 3′ untranslated region (UTR) of FZD1 are independently associated with measures of bone geometry. Three SNPs (rs2232163, rs3750145 and rs1052015) in the 3′-UTR of the FZD1 were analyzed in 1844 Afro-Caribbean men aged 40 years and older. The minor allele frequencies of these 3 SNPs were: 8.6%, 6.6%, and 5.2%, respectively. Haplotype analysis identified 4 haplotypes GTA, ATA, GCC, and GCA with frequencies of 84.5%, 8.6%, 5.3% and 1.5%, respectively. Association analyses of the SNPs and haplotypes with peripheral quantitative computed tomography measures were performed under an additive model adjusting for age, height and body weight and the two promoter SNPs (rs2232157, rs2232158) to test the independent association of the 3′-UTR variants. The minor allele of rs2232163 was associated with decreased ($P=0.005$) whereas the minor allele of rs3750145 was associated with increased ($P=0.04$) cortical thickness at the radius. The ATA haplotype was associated with decreased ($P=0.008$) whereas the GCA haplotype was associated with increased ($P=0.002$) cortical thickness. Interestingly, these 3′-UTR variants encompass several predicted microRNA binding sites. Functional analysis of these SNPs and haplotypes will be important to elucidate the significance of these regulatory region variants.

BMD-associated Variation at the *Osterix* Locus is Correlated with Pediatric BMI in Females. Jianhua Zhao[1], Jonathan Bradfield[1], Mingyao Li[2], Haitao Zhang[1], Frank Mentch[1], Kai Wang[1], Patrick Sleiman[1], Cecilia Kim[1], Joseph Glessner[1], Edward Frackelton[1], Rosetta Chiavacci[1], Robert Berkowitz[1], Babette Zemel[3], Hakon Hakonarson[1], Struan Grant*[3]. [1]Children's Hospital of Philadelphia, USA, [2]University of Pennsylvania, USA, [3]Children's Hospital of Philadelphia, USA

Recent genome wide association studies (GWAS) have revealed a number of genetic variants robustly associated with bone mineral density (BMD) and/or osteoporosis. Evidence from epidemiological and clinical studies has shown an association between BMD and body mass index (BMI), presumably as a consequence of bone loading. We investigated the 34 previously published BMD GWAS-derived loci in the context of pediatric BMI by leveraging our existing genome-wide genotyped European American cohort of 1,106 obese children (BMI$\geq 95^{th}$ percentile) and 5,997 controls (BMI$<95^{th}$ percentile). Evidence of association was only observed at one locus, namely *Osterix* (*SP7*), with the G allele of rs2016266 being significantly over-represented among childhood obesity cases ($P=2.85\text{x}10^{-3}$). When restricting these analyses to each gender, we observed strong association between rs2016266 and childhood obesity in females (477 cases and 2,867 controls; $P=3.56\text{x}10^{-4}$). However, no evidence of association was observed among males. Similar observations were made when treating BMI as a quantitative trait in the same cohort. Interestingly, Osterix is the only GWAS locus uncovered to date that has also been previously implicated in the determination of BMD in childhood. In conclusion, these findings indicate that a well established variant at the *Osterix* locus associated with increased BMD is also associated with childhood obesity primarily in females. These results are in keeping with the bone loading impact on BMD through increased BMI.

Bone Mineral Density Locus Associated with Coronary Artery Calcification. Laura Yerges-Armstrong*[1], Xinggang Liu[1], Elizabeth Streeten[2], Alan Shuldiner[1], Braxton Mitchell[3]. [1]University of Maryland, USA, [2]University of Maryland School of Medicine, USA, [3]University of Maryland, Baltimore, USA

Epidemiologic and in vitro studies support a relationship between calcification of bone and vascular tissue, although the nature of the relationship is unclear. To identify genes having pleiotropic effects on these two traits, we tested whether SNPs found by previous genome wide association (GWA) studies (Rivadeneira et al.: Nat Gen 2009) to be robustly associated with BMD were also associated with coronary artery calcification (CAC). Our study was carried out in a population of Old Order Amish individuals in whom we had measured BMD at the hip and spine by DXA (N=889) and calcification of the coronary arteries (N=506) by electron beam CT. On average participants were 56 years of age and 47% of the population was male. The BMD loci were extracted from a recent meta-analysis of Caucasian reference data that identified loci for BMD at the lumbar spine (LS) or femoral neck (FN). We created a genotype score for LS (15 loci) and FN (10 loci) by summing the number of copies of the high BMD allele across all loci. As expected, genotype scores were associated with BMD in the Amish (p=7.7x10-7 for FN and p=0.013 for LS) although the scores explained very little of the total variation in BMD ($r^2=0.03$ and 0.01 respectively for LS and FN). We then evaluated associations of the genotype scores with CAC quantity adjusting for the effects of age and gender. FN genotype score was not significantly associated with CAC. In contrast, analysis of the LS genotype score revealed that an increasing number of high BMD alleles was associated with lower CAC quantity ($p = 0.046$). Further analyses of the individual SNPs identified an association ($p=0.02$) between a SNP on 13q14 and CAC in our sample. These results extend previous studies suggesting a relationship between cardiovascular disease and lower bone mineral density by showing a common genetic link between the two disorders. These analyses also reveal a specific BMD variant (rs9533090 downstream of AKAP11) that is also associated with cardiovascular health.

Cooperative Effect of Serum 25-Hydroxyvitamin D Concentration and a Polymorphism of Transforming Growth Factor β-1 Gene on the Prevalence of Vertebral Fractures in Postmenopausal Osteoporosis. Kazuki Kobayashi*[1], Seijiro Mori[2], Noriyuki Fuku[3], Yuko Chiba[2], Fumiaki Tokimura[2], Takayuki Hosoi[4], Yoshiyuki Kimbara[2], Yoshiaki Tamura[2], Atsushi Araki[2], Masashi Tanaka[3], Hideki Ito[2]. [1]Tokyo Metropolitan Geriactic Hospital, Japan, [2]Tokyo Metropolitan Geriatric Hospital, Japan, [3]Tokyo Metropolitan Institute of Gerontology, Japan, [4]National Center for Geriatrics & Gerontology, Japan

Purpose: A T869→C polymorphism of the transforming growth factor β1 (TGF-β1) gene is reported to be associated with genetic susceptibility to both osteoporosis and vertebral fracture. Low serum 25-hydroxyvitamin D [25(OH)D] level is known to be associated with a higher risk for hip fracture. This study aimed to assess a possible cooperative effect of the gene polymorphism and vitamin D status on vertebral fracture risk.

Methods: Prevalence of vertebral fracture in 168 postmenopausal female patients with osteoporosis was analyzed, and its association with the TGF-β1 gene polymorphism and serum 25(OH)D concentration was assessed cross-sectionally.

Results: The fracture prevalence increased according to the rank order of the TGF-β1 genotypes CC < CT < TT, as expected. A significant difference was found not only between the CC and TT genotypes ($p = 0.005$) but also between the CC and CT genotypes ($p < 0.05$) when the patients with serum 25(OH)D of more than the median value [22 ng/mL (55 nmol/L)] were analyzed. On the other hand, when those with serum 25(OH)D of less than the median value were analyzed, a protective effect of the C allele against the fracture was blunted; statistical significance in the difference of the fracture prevalence was lost between the CC genotype and the other genotypes.

Conclusion: These data suggest that vitamin D fulfillment is prerequisite for the TGF-β1 genotype in exerting its full effect on the fracture prevalence.

Effect of Serum 25(OH)D Level on the Relationship between TGF-β1 Genotype and Prevalence of Vertebral Fracture

		Vertebral Fracture	n
25(OH)D ≥ 22 ng/mL

Genetic Association Study of Common Mitochondrial DNA Variants in Osteoporosis. Shufeng Lei*[1], Yan Guo[1], Tielin Yang[2], Hui Shen[1], Xianghong Xu[3], Shanshan Dong[1], Yao-zhong Liu[1], Yong-Jun Liu[1], Hong-Wen Deng[4]. [1]University of Missouri - Kansas City, USA, [2]The University of Missouri-Kansas City, USA, [3]University of Missouri-Kansas City, School of Medicine, USA, [4]University of Missouri, Kansas City Medical School, USA

Many lines of evidence suggest that mitochondrial DNA (mtDNA) variants are involved in the pathogenesis of human complex diseases, especially for age-related disorders. Osteoporosis is a typical age-related complex disease, however, the role of mtDNA variants in the susceptibility of osteoporosis is largely unknown. In this study, we reported a mitochondrial genome-wide association study for bone mineral density (BMD) in Caucasians.

A total of 445 mitochondrial single nucleotide polymorphisms (mtSNPs) were genotyped in a sample of 2,286 unrelated Caucasian subjects (558 males and 1728 females) by using the Affymetrix Genome-Wide Human SNP Array 6.0. SNPs were tested for association with hip BMD by the quantitative association tests implemented in PLINK, while controlling for potential confounding factors, such as age, gender, height and weight.

A SNP within the NADH dehydrogenase 2 gene (ND2), rs28571027 (C/A), was strongly associated with hip BMD ($p = 3.63 \times 10\text{-}4$). The C allele was associated with reduced hip BMD values and the effect size (ß) was estimated to be ~0.022. Our results highlighted the importance of mtDNA variants in influencing BMD variation and risk to osteoporosis. Further genetic and molecular functional investigations for the relationship between mtDNA variants and osteoporosis are warranted.

BMP2 Binds Preferentially to BMP Receptors Localized in Caveolae and Initiates Smad Signaling. Oleksandra Moseychuk*[1], Beth Bragdon[2], Jeremy Bonor[1], Anja Nohe[1]. [1]University of Delaware, USA, [2]University of MaineUniversity of Delaware, USA

Bone Morphologic Proteins (BMPs) are growth factors that regulate skeletal development and repair. They are used as therapeutics in spinal fusion and fracture repair but little is known about the initiation of signaling on the receptor level. BMP receptors (BMPRs) are found on the plasma membrane, in caveolae and clathrin coated pits (CCPs). Current literature suggests that BMP2 mediated signaling by Smad 1,5 and 8 is initiated on the plasma membrane followed by endocytosis of receptors through CCPs, however our studies demonstrate that ligand binding, BMP receptor type-Ia (BMPRIa) phosphorylation and Smad 1,5 and 8 activation occurs in caveolae within 10 min.

Combination of Atom Force Microscopy (AFM) and advance confocal imaging were used to determine the binding affinity of ligand with receptors on the surface of live cells. Biologically active AFM tip was designed by covalently linking BMP2, to an AFM tip and live C2C12 cells were transfected with Caveolin-1 GFP conjugated plasmid (protein that is responsible for the flask shape structure of caveolae) as a marker to visualize caveolae. Our AFM data together with high resolution confocal images and retraction curve data demonstrated that BMP2 binds predominantly to BMPRs localized in caveolae. Since BMPR phosphorylation is the first step of the signaling cascade, we performed fractionation of the plasma membrane based on the lipid composition to determine the location of phosphorylated form of BMPRIa in C2C12 cells. We observed phosphorylation in the lipid raft fractions, namely caveolae. Additionally, Smad 1, 5, and 8 phosphorylation was probed at different time points during BMP2 stimulation. It showed the initial phosphorylation takes place in caveolae as early as 10 min post stimulation, followed by endocytosis. After 45 min stimulation with BMP2, the phosphorylated form of Smad 1, 5, and 8 is degraded in the lysosome. Taken together, these data show that BMP2 dependent phosphorylation of BMPRIa and activation of regulatory Smads takes place predominantly in caveolae, not CCPs.

BMP2 Gene as an Organizer Coordinating Osteogenesis and Angiogenesis Postnatally and Roles in Mechanical Properties of Bone. Wuchen Yang*[1], Jeffry Nyman[2], Yong Cui[1], Jelica Gluhak-Heinrich[1], Marie Harris[1], Ivo Kalajzic[3], David Rowe[3], Gregory Mundy[4], James Edwards[2], Barbara Kream[3], Alexander Lichtler[3], Xiao-Dong Chen[1], Yuji Mishina[5], Stephen Harris[1]. [1]University of Texas Health Science Center At San Antonio, USA, [2]Vanderbilt University Medical Center, USA, [3]University of Connecticut Health Center, USA, [4]Vanderbilt University, USA, [5]University of Michigan, USA

Coordination between osteogenesis and angiogenesis is important for proper bone remodeling and repair postnatally. Our previous study using the 3.6Col1a1-Cre;BMP2 cKO mice showed that the postnatal deletion of the BMP2 gene from collagen producing osteoblasts inhibits latter stages of osteoblast differentiation and causes an intrinsic 80% reduction in the Mesenchymal Stem Cells (MSCs) population, as determined by CFU-F assays. The long bones of the 3.6Col1a1-Cre;BMP2cKO mice appeared to be less red, suggesting a decrease in vascularization. Since perivascular cells are potentially one of the MSCs niches that associated with blood vessels, we further evaluated the bones by CD146 immunohistochemistry (IHC) and confirmed that the perivascular cells are indeed reduced in vivo in the BMP2 cKO relative to control littermates. Using α-SMA-Cherry transgene, in which the perivascular candidate MSCs are labeled red on microvasculature, we confirmed a reduction of this MSCs population in vivo in the BMP2cKO mice. To address whether this reduction of the MSCs population is caused by a reduction of angiogenesis leading to the reduction of MSCs niches, collagen IV IHC was then performed for both femur and tibia. This revealed that blood vessel density is reduced 20 to 50% in the 3.6Col1a1-Cre;BMP2cKO mice at different ages up to 6 month. These results suggest that the angiogenesis is reduced after BMP2 deletion from osteoblasts. To explore the mechanism by which BMP2 in osteoblasts regulates angiogenesis, the expression level of VEGFA, an angiogenesis stimulator that is secreted by mature osteoblasts, was assayed by IHC and VEGFA association with osteoblasts was reduced 50% in the BMP2 cKO animals. Thus, ablation of BMP2 gene from osteoblasts interferes drastically with the late stage of osteoblast maturation that in turn leads to reduction

of VEGF production and results in defective angiogenesis and reduced MSCs niche availability. These phenotypes in the BMP2 cKO lead to altered geometric and mechanical properties of the long bones. There was an over 50% reduction in Work-to-fracture in the femur. A greater than 80% reduction in Post Yield toughness in the BMP2 cKO also suggests these bones are much more brittle than control bones, possibly due to the decreased vascularization and reduced MSCs population.

Dullard, a Novel BMP Inhibitor, Targets Smad1 to Suppress BMP-dependent Transcription in Mammalian Osteoblastic Cells. Tadayoshi Hayata*[1], Yoichi Ezura[2], Makoto Asashima[3], Ryuichi Nishinakamura[4], Masaki Noda[5]. [1]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]University of Tokyo, Japan, [4]Kumamoto University, Japan, [5]Tokyo Medical & Dental University, Japan

BMP plays crucial roles during osteoblast differentiation and its signaling effect is negatively regulated to maintain the appropriate signaling levels. However, mechanism of signal regulation by BMP inhibitors during osteoblast differentiation has not been fully understood. Dullard encodes a phosphatase preferentially localized in caveosome and has been reported to suppress BMP signaling pathway primarily by promoting degradation of BMP receptor complex via the lipid raft-caveolar pathway and secondarily by dephosphorylation of activated BMPR1. In osteoblasts, Dullard limits BMP responsiveness. With regard to BMP antagonistic activity in ''Xenopus animal cap assay'', Dullard does not suppress constitutively active BMPR1a (caALK3) signaling. However, in the current study, we unexpectedly found that Dullard suppresses constitutively active BMPR1 in ''mammalian osteoblastic cells''. To refine at what level Dullard can suppress BMP signaling pathway in ''mammalian cells'', BMP responsive element (BRE)-luciferase assay was performed using MC3T3-E1 cell line. Overexpression of Dullard inhibits caALK3-induced activation of BRE-reporter independently of its phosphatase activity. Furthermore, overexpression of Dullard inhibits the activity of both constitutively active phospho-mimetic Smad1 (SMAD1-EVE), in which two serine residues at C-terminal phosphorylated by receptor kinase are mutated into glutamic acid, and more potent SMAD1-EVE-MM, in which MAPK phosphorylation sites in the linker region are mutated. These epistatic experiments indicate that Dullard can suppress BMP signaling pathway at or downstream of the Smad1 level. We also tested whether Dullard affects TGF-ß signaling pathway. Dullard suppresses TGFß-induced reporter activity and constitutively active TGFBR1 (caALK5)-induced TGFß signaling independently of its phosphatase activity. In BMP-induced osteoblast differentiation, siRNA-mediated knockdown of Dullard decreases alkaline phosphatase production as well as expression of marker genes including Id3, Osterix, osteocalcin, and alkaline phosphatase. Although Dullard was previously identified as a modulator of BMP receptor degradation, it plays more extensive role as a general suppressor of BMP/TGF-ß signal transduction downstream of type I receptor/SMAD and promotes BMP-induced osteoblast differentiation. In conclusion, we identified Smad1 and TGF-ß signaling pathway as novel targets of Dullard.

Delayed Fracture Healing in Protease Activated Receptor-2 Deficient Mice. Kevin O'Neill*[1], Christopher Stutz[1], Mignemi Nicholas[1], Jeffry Nyman[2], Gregory Mencio[1], William Obremskey[1], Conor Lynch[1], Jonathan Schoenecker[1]. [1]Vanderbilt University, USA, [2]Vanderbilt University Medical Center, USA

Objectives: Extracellular proteases and inflammation are essential elements of fracture repair. Protease activated receptors (PARs) allow proteases to behave like traditional hormones. It is known that PAR-2 provides an important link between extracellular protease activation and regulation of cellular inflammation. Although PAR-2 is expressed by developing osteoblasts, its function in fracture healing is unknown. The purpose of this study was to compare fracture healing between wild-type (WT) and PAR-2 deficient (PAR-$2^{-/-}$) mice. We hypothesized that PAR-$2^{-/-}$ mice will demonstrate delayed fracture healing relative to WT mice.

Methods: With IUCUC approval, unilateral transverse mid-shaft femur fractures were created in 10 PAR-$2^{-/-}$ and 11 WT mice after intramedullary fixation. Mice were sacrificed at 7 weeks, fractured and contralateral intact femurs were harvested, and axial micro-computed tomography (µCT) images were obtained. Torsional rigidity and ultimate strength were calculated from torque versus angular displacement curves obtained by torsion testing. Bone volume fraction (BV/TV), bone mineral density (BMD), and polar moment of inertia (pMOI) were determined from µCT images.

Results: For WT mice, the torsional rigidity and ultimate strength of fractured femurs were not significantly different from intact femurs. In contrast, for the PAR-$2^{-/-}$ mice, significant differences were noted between the fractured and intact femurs for both torsional rigidity ($p=0.04$) and ultimate strength ($p=0.04$). Significant differences were also noted in PAR-$2^{-/-}$ mice between pMOI, BV/TV, and mBMD (all $p<0.001$) values of fractured compared to intact femurs (Figure 1).

Conclusions: The PAR-$2^{-/-}$ mice demonstrated delayed fracture healing measured by both biomechanical torsion testing and radiographic µCT imaging. Future studies are needed to determine if the delayed healing observed is secondary to a diminished inflammatory response in the fracture environment. Unveiling this mechanism has potential impact on the basic science of fracture healing and the development of novel pharmaceuticals that, through PAR-2, may enhance fracture healing.

Figure 1 - Ultimate torque (A) and bone volume fraction (B, BV/TV) of intact and healing femurs 7 weeks after fracture for PAR-2 knockout and wild type (WT) mice.

Effect of Infection on Bone Marrow Stromal Cells (MSCs): a Role for IL-6 in Erythropoiesis. Brian Sworder*[1], David Chou[2], Michael Grigg[2], Yasmine Belkaid[2], Pamela Robey[3]. [1]National Institutes of Health, USA, [2]NIAID/NIH, USA, [3]National Institute of Dental & Craniofacial Research, USA

Inflammation induces and necessitates changes in hematopoiesis (HP). Previous studies have examined the HP alterations that occur in the bone marrow (BM) during an immune response. However, despite the critical role that BM stroma plays in supporting HP, its function during inflammation remains largely unexplored. This study seeks to determine how BM stromal cells (BMSCs) and their influence on HP are altered during an immune response.

Mice were orally infected with the intracellular parasite, Toxoplasma gondii. This infection model causes severe systemic T helper type 1 inflammation and results in anemia and potential death. Eight days after infection, total cell number in the BM fell to half that of naïve mice. Flow cytometry analysis showed significant changes in the percentages of lymphoid, myeloid, and erythroid constituents. Notably, the fraction of nucleated cells contributing to erythropoiesis was reduced 5-fold. Conversely, there was no apparent change in the number of CFU-Fs (a subset of BMSCs) after infection.

A variety of knockout mice (IFNg receptor, iNOS, TCRa, IL-1, TNFa receptor, IFN-a/B receptor, IL-15, and IL-6) were screened to determine which molecules were important in mediating the pathogenic anemia induced by T. gondii infection. Only IL-6 KO mice were found to have better maintenance of erythropoiesis and a significantly larger erythroblast population than WT mice. IL-6 is known to play an important role in anemia associated with inflammation. However, the relative importance of IL-6 production by various cellular sources in mediating anemia is not known. To determine whether IL-6 from BM stroma might contribute, BMSCs were isolated from naïve and infected mice by FACS (VCAM+/CD45-/Ter119-). Strikingly, analysis by ELISA showed a 2-fold increase in IL-6 secretion by BMSCs after T. gondii infection. Using bone marrow transplants and ectopic ossicle models with WT and IL-6 KO cells, experiments are currently underway to more directly determine the contribution of IL-6 from BM stroma to infection-induced anemia.

Our results demonstrate that IL-6 is a key mediator of erythropoietic collapse during T. gondii infection and that BMSCs may be the relevant source of IL-6. This study also suggests that the bone marrow stroma is functionally different during an immune response, and that BMSCs are potential mediators of changes in HP composition as a consequence of inflammation.

Human Blood Eosinophils: An Extrarenal Source of Converting Inactive Vitamin D to Its Active Form and Potential Role in Inflammation. Devendra Agrawal*[1], Divya Pankajakshan[1], J. Christopher Gallagher[2]. [1]Creighton University School of Medicine, USA, [2]Creighton University Medical Center, USA

Rationale: Vitamin D, especially its most active metabolite 1,25-dihydroxyvitamin D3 or calcitriol, is essential in regulating calcium homeostasis, immune modulation, cell proliferation and differentiation. Although extra-renal synthesis of calcitriol associated with inflammatory diseases is known to occur in macrophages and epithelial cells, little is known on the existence of enzymes involved in vitamin D synthesis and metabolism in circulating immune cells. In this study, we examined such enzymes in human blood eosinophils and also investigated the effect of calcitriol, administered in vivo or added exogenously, on the expression of intracellular molecules involved in inflammation in purified white blood cells (WBCs).

Methods: Peripheral blood was drawn from healthy volunteers and WBCs were purified (purity >97%; viability >98%) and stimulated in vitro with calcitriol (100 nM) for 24 hrs. We also purified WBCs from the blood of vitamin D-deficient (25-OHD levels <20ng/ml) subjects (n= 78) before and after treatment with 800-4,200 IU/d vitamin D for 1 year. The mRNA expression of importin-alpha3 (KPNA4), CYP27B1 and CYP24A1 was examined by real-time PCR.

Results: The mRNA transcripts for CYP27B1, CYP24A1, cathelicidin, and KPNA4 were found in human blood eosinophils. In vivo administration of vitamin D for 1 yr in vitamin D-deficient subjects significant increased the mRNA transcripts of CYP27B1, CYP24A1 and cathelicidin, but significantly decreased the mRNA transcripts of KPNA4. Under in vitro conditions, stimulation of human WBCs of healthy volunteers with calcitriol decreased mRNA transcripts of KPNA4 with more pronounced reduction (60-70%) in neutrophils and eosinophils. Calcitriol increased the mRNA transcripts of CYP24A1 in human blood eosinophils.

Conclusions: Presence of both CYP27B1 and CYP24A1 in human blood eosinophils suggest their role in converting inactive vitamin D to its active form and decreased expression of KPNA4 in response to vitamin D could be one of the underlying mechanisms for the anti-inflammatory and immunoregulatory effects of vitamin D in inflammatory diseases involving eosinophils.

Meox2Cre-CSF-1 Knockout Mice: A Novel Osteopetrosis Model. Sherry Abboud Werner*, Kathleen Woodruff, Diane Horn, Marie Harris, Stephen Harris. University of Texas Health Science Center at San Antonio, USA

CSF-1, a key regulator of mononuclear phagocytes, is expressed in most tissues and exerts pleiotropic effects. This is supported by studies in spontaneous mutant op/op B6C3 mice where absence of CSF-1 leads to osteopetrosis as well as defects in fertility, mammary development and neural function. However, the biologic effect of CSF-1 knockout(KO) in specific tissues has not been explored. To determine whether Cre-lox technology provides a useful strategy for producing CSF-1KO mice, a targeting vector for generating a conditional KO allele for CSF-1(deleting exons4,5,6)was electroporated into ES cells. Heterozygous C57BL/6 mice harboring the floxed construct containing a 5' loxP site in intron 3 of the CSF-1 gene and a 3' loxP site with a FRT-polII-neo-FRT-loxP cassette in intron 6 were established. The neo cassette was removed by crossing CSF-$1^{flox+neo}$mice with heterozygous beta-actin-Flip recombinase mice and the CSF-$1^{flox-neo}$(fx) allelle was confirmed by Southern blot. CSF-1fx/CSF-1fx mice were then bred with Meox2Cre mice to produce heterozygous CSF-1KO mice that were subsequently interbred to generate mice homozygous for the KO allele(hCSF-1KO). At 3 weeks, CSF-1 was analyzed; bones were x-rayed and histological sections were examined using histomorphometry. Offspring showed the expected ratio of genotypes. Mice heterozygous for the KO allele resembled wt controls, whereas hCSF-1KO showed an osteopetrotic phenotype similar to op/op mice. hCSF-1KO showed CSF-1 deficiency, failure of tooth eruption, domed skull, stunted growth and reduced weight compared to wt. hCSF-1KO radiographs showed marked skeletal sclerosis with dense radioopaque bone in tibia and femoral metaphysis, vertebrae and pelvis. Compared to wt, hCSF-1KO hindlimbs showed an expanded growth plate with thick irregular calcified cartilage extending into the metaphysis obliterating the marrow cavity. Numerous TRAP-positive osteoclasts were identified in wt, whereas rare small weak TRAP-positive osteoclast-like cells were detected in hCSF-1KO. These findings provide the first evidence that global CSF-1KO can be achieved using a Cre-based system and that the osteopetrotic phenotype is reproducible in C57BL/6. Development of conditional CSF-1KO mice will be crucial for elucidating the mechanisms by which CSF-1 mediates its effect in targeted tissues. Results may lead to novel approaches for improving reproductive defects and regulating osteoclastogenesis in fracture repair and bone metastasis.

Serum Osteocalcin is Negatively Correlated to Insulin and Adiponectin in Hibernating Bears. Rachel Bradford[1], Patricia Buckendahl[2], Caren Gundberg[3], Kim Henriksen[4], Michael Vaughan[5], Seth Donahue*[6]. [1]Michigan Technological University, USA, [2]Rutgers University, USA, [3]Yale University School of Medicine, USA, [4]Nordic Bioscience A/S, Denmark, [5]Virginia Tech, USA, [6]Michigan Tecnological University, USA

Hibernating bears do not lose cortical or trabecular bone despite being physically inactive for up to 6 months per year. Histomorphometry shows decreased bone turnover with balanced bone formation and resorption during hibernation. The purpose of hibernation is to conserve metabolic energy when food is unavailable. Fat is the primary energy source during hibernation; bears lose 30-40% of their body mass (almost exclusively fat mass) during hibernation. Bears also experience markedly decreased kidney function and do not urinate or defecate during hibernation, but maintain eucalcemia. The purpose of this study was to quantify seasonal bear serum markers of bone formation (BSAP) and osteoclast number (TRAP), which do not accumulate with decreased kidney function. To assess bone/fat/energy relationships, we also quantified serum osteocalcin (OC), adiponectin, NPY, insulin, and glucose. Serum was collected every 10 days from black bears before, during, and after hibernation. Serum BSAP and TRAP decreased ($p<0.0001$) during hibernation by 57% and 29% respectively, supporting the histomorphometric findings of decreased bone turnover. Serum total OC, which is also a bone formation marker, increased 59% during hibernation ($p<0.0001$). This increase could possibly be explained by the accumulation of OC due to reduced renal function. Serum NPY was not significantly different in hibernating and active bears. Adiponectin decreased 30%, insulin decreased 20%, and glucose decreased 31% ($p<0.0009$) during hibernation relative to non-hibernation periods. Total OC was negatively correlated ($p<0.0001$) with adiponectin, unlike the positive association in humans. Insulin was negatively correlated ($p=0.008$) to total OC only during the pre-hibernation period. We are currently investigating seasonal changes in uncarboxylated OC. Reduced bone turnover contributes to energy conservation in hibernating bears, but the relationships between osteocalcin, adiponectin, insulin, and glucose may be different in bears than other species since bears rely on lipids for metabolic fuel nearly exclusively during hibernation (fasting). Hibernating bears are a unique model for understanding bone/fat/energy relationships and the prevention of disuse osteoporosis (i.e., bone loss due to prolonged physical inactivity); the biological mechanisms may have implications for human medicine.

The Effect of Vitamin K Supplementation on Glucose Metabolism. Hyung Jin Choi*[1], Juyoun Yu[1], Hosanna Choi[1], Jee Hyun An[1], Yenna Lee[1], Hwa Young Cho[1], Sun Wook Cho[2], Sang Wan Kim[3], Chan Soo Shin[1]. [1]Department of Internal Medicine, Seoul National University College of Medicine, South korea, [2]University of Michigan School of Dentistry, USA, [3]Seoul National University Boramae Hospital, South korea

Vitamin K has been known to regulate glucose metabolism via modulating osteocalcin and/or inflammation pathway. However, the exact mechanisms for this regulation in vivo have not been fully investigated. We have investigated the effects of vitamin K on beta-cell function and insulin sensitivity in healthy young male volunteers using frequently sampled intravenous glucose tolerance test (FSIGT) before and after 4 weeks of vitamin K treatment. Twenty-two healthy young male subjects (age 28.2±4.5; BMI 24.4±2.5) were given menatetrenone (Vitamin K2) 30mg tid for 4 weeks and FSIGT were performed before and after the vitamin K treatment and carboxylated/undercarboxylated osteocalcin, interleukin-6, CRP, and adiponectin concentrations were measured. Vitamin K treatment significantly decreased and increased undercarboxylated and carboxylated osteocalcin, respectively (both, $P < 0.05$). However, there were no significant changes in the levels of inflammation markers, ie., interleukin-6 and CRP. Vitamin K treatment significantly increased disposition index (DI), which indicates beta-cell function in relation to insulin action, compared with baseline (baseline: 2507±1448, 4 week treatment: 3468±1584; $P = 0.003$). There were no significant changes in acute insulin response to glucose (AIRg) and insulin sensitivity (SI). Change in undercarboxylated osteocalcin was significantly associated with change in AIRg after adjusting for confounding factors, including baseline AIRg, age, BMI and weight change ($P < 0.05$). There was no significant change in body weight and adiponectin concentration. Taken together, these results suggest that vitamin K treatment for 4 weeks increased beta-cell function in healthy young men, which appears to be related to the modulation of osteocalcin metabolism rather than systemic inflammation.

***Igfb2-/-* Mice Exhibit Age-related Changes in Skeletal Mass, Body Composition and Metabolic Status.** Victoria Demambro*[1], Kathryn Shultz[2], Harold Coombs[2], Jane Maynard[2], David Clemmons[3], Wesley Beamer[2], Clifford Rosen[4]. [1]Maine Medical Research Institute, USA, [2]The Jackson Laboratory, USA, [3]University of North Carolina, USA, [4]Maine Medical Center, USA

We have previously reported on a global *Igfbp2* null mouse on a C57BL/6J background in which the male mice at 16 weeks of age had significantly decreased bone volume and turnover and increased adiposity (Endocrinology 149:2051, 2008). To test the effect of IGFBP-2 absence over time, we aged Igfbp2 null (-/-) and control (+/+) males to 24 months of age. Body composition was examined by PIXImus DEXA at 2, 4, 6, 12, 18 and 24 months. Femurs were analyzed by pQCT at 4, 12 and 24 months for vBMD and MicroCT for structural changes at 4 and 12 months. Mice were evaluated for metabolic changes by ITT and GTT and serum insulin at 12 months. The -/- males were found to be heavier with increased fat mass at all time points. Whole body BMC was significantly reduced in -/- mice compared to +/+ control mice through 18 months. Remarkably, between 12 to 24 months, +/+ males had a dramatic loss in weight (-19%), whole body BMC (-13%), and fat mass (-27%), while -/- male mice appeared protected from these age related decreases by showing a significant increase in BMC (+7%) and a trend towards increased fat mass (+5%). Reductions in femoral vBMD (+/+ = -30%, -/- = -18%) and cortical thickness (+/+ = -22%, -/- = -6%) were observed, however to a lesser extent in the -/- femurs. Due to this differential rate of loss by 24 months -/- femurs were significantly increased for both measures compared to +/+ femurs. MicroCT analysis of distal femurs revealed similar decreases in trabecular BV/TV and number from 4 to 12 months of age. Interestingly there was no change in trabecular thickness in the +/+ mice with the mutants exhibiting a 16% increase during this same period. At 12 months of age, -/- mice were found to be hyperinsulinemic in both the fasted and fed states compared to +/+ mice. When glucose challenged, -/- mice exhibited higher glucose values and ITT results showed a decrease in the hypoglycemic response to exogenous insulin. Taken together, these results are indicative of a mild but significant insulin resistance. In summary, *Igfbp-2* null males appear to be protected from age related loss of bone with minor reductions in cortical mass and increased trabecular thickness. On the other hand, they seem to be more susceptible to age related increases in obesity and insulin resistance.

The Skeletal Effect of Parathyroid Hormone Treatment after Ovariectomy is Diminshed when Circulating Growth Hormone is Elevated. J. Fritton*[1], Devendra Bajaj[1], Hui Sun[2], Yinjgie Wu[2], Mary Bouxsein[3], Shoshana Yakar[2]. [1]New Jersey Medical School, USA, [2]Mount Sinai School of Medicine, USA, [3]Beth Israel Deaconess Medical Center, USA

Parathyroid hormone (PTH) is routinely prescribed to postmenopausal women to restore bone and prevent osteoporotic fracture. However, the effects of the PTH therapy are quite variable in both these women and after ovariectomy (OVX) of animals. Both growth hormone (GH) and insulin-like growth factor (IGF-1) are potent regulators of bone remodeling processes. Previous investigations utilizing OVX have revealed that a serum balance in mice that favors GH over IGF-1 diminishes the effects of ablated ovarian function and leads to reduced endosteal resorption and greater bone formation. We utilized the liver IGF-1 deficient (LID) mouse to study the possible additional effects of PTH treatment. OVX surgery was performed on 12-week-old mice followed by 4 weeks of daily (7d/wk) PTH (50 ng/g body weight) intraperitoneal (i.p.) injection. 12-μm μCT (Scanco) scans were completed for femurs and vertebrae. Whole-bone mechanical properties were quantified for mid-diaphyseal femurs by loading to failure in 4-point bending. Bone formation histomorphometry measurements were made on sections from double-labeled, calcein-injected (i.p.) mice. Contrary to the expected gains with PTH observed in controls, very small effects were found in LID mice with PTH treatment after OVX (Δ cross-sectional moment of inertia of mid-shaft femur: WT – 25%; LID – < 1%, Δ trabecular thickness: WT – 3%; LID - < 1%). One explanation for this lack of effect is that cancellous and cortical bone structures may reach homeostasis due to the previously reported enhanced expansion of cross-sectional structures in LID mice that exhibit 3-fold greater circulating GH. Our data suggest little synergism of PTH during estrogen deficiency when GH is elevated and offer a possible insight into the variability of response to PTH treatment for bone loss in postmenopausal women.

Runx2 Stimulation of HSP70/HSPA1B Gene Transcription Decreases Runx2 Protein Stability in Osteoprogenitors. Nadiya M. Teplyuk[1], Jennifer Cotton[1], Jonathan Gordon[1], Viktor I. Teplyuk[1], Mario Galindo[2], Di Chen[3], Suk-Chul Bae[4], Jane Lian[1], Janet L. Stein[1], Gary Stein[1], Andre Van Wijnen*[1]. [1]University of Massachusetts Medical School, USA, [2]University of Chili, Chile, [3]University of Rochester Medical Center, USA, [4]Chungbuk National University, South korea

Inactivation, haplo-insufficiency and dosage insufficiency of Runx2 have been linked to skeletal defects during mammalian development and in human skeletal diseases. Reduced levels of Runx2 in osteoblasts are linked to different skeletal phenotypes, including symptoms of Cleidocranial Dysplasia (i.e., craniofacial abnormalities, supernumerary teeth), as well as absence of clavicles and delayed ossification of cranial sutures in mouse models. Elevation of Runx2 levels in transgenic mouse models is associated with an osteoporotic phenotype. Consequently, it is necessary to establish how osteoblasts succeed in continuously calibrating Runx2 levels to maintain a non-pathological state. Here we show that Runx2 transcriptionally stimulates expression of HSP70, which is a key specificity factor of the C-terminal HSP70 Interacting Protein (CHIP), as well as HSP40 and other HSP proteins, in the absence of external stress signals (e.g., heat shock) in osteoprogenitor cells. Expression of a functionally defective Runx2 protein does not alter HSP70 gene expression. Importantly, we find that HSP70 interacts with Runx2 protein by co-immunoprecipitation and that down-regulation of HSP70 by siRNA depletion increases steady-state levels of Runx2, while forced expression of HSP70 decreases Runx2 levels. We propose that Runx2 controls the levels of HSP70 as a component of an auto-inhibitory rheostat that maintains Runx2 proteins levels within a physiological range that is required for normal skeletal development and bone homeostasis. Interestingly, mutations in the chaperonin function of HSPs have been linked to skeletal dysplasias.

A Tentative Role of S100A6 in Regulation of Osteoblastogenesis. Weida Lu*[1], Yingchun Zhao[2], Jing Xiao[2], Robert Recker[3], Gary Guishan Xiao[1]. [1]Creighton University, USA, [2]Creighton University Medical Center Osteoporosis Research Center, USA, [3]Creighton University Osteoporosis Research Center, USA

A progressive adipogenesis with age in bone marrow is associated with reduced bone formation and loss of bone mass. In elderly adults and osteoporotic patients at all ages, increase of bone marrow adipose tissue and decrease of matrix structure are often observed. However, the role of bone marrow adipocytes in the aging bone tissues remains unknown. In our previous study, we used two different modes of co-cultures of adipocytes and osteoblasts, which were derived from human mesenchymal stem cells (hMSC), to study the effects of hMSC-derived adipocytes on osteoblastogenesis. We identified S100A6 in osteoblastogenesis, which is regulated by hMSC-derived adipocytes, suggesting the possible role of S100A6 in the regulatory effects of adipocytes on osteoblastogenesis. In this research, we aimed to study the mechanism of the inhibitory effects of adipoctyes on osteoblastogenesis. S100A6 is one of the members in S100 calcium-binding protein family, and is reported to be an oncogenic transcriptional factor playing a major role in cancer metastasis. However, the role of S100A6 in bone formation is unknown. We hypothesized that S100A6 may play a crucial role in regulation of osteoblastogensis by hMSC-derived adipocytes. To confirm the involvement of S100A6 in osteoblastogenesis, we transfected hMSC with siRNA of S100A6 during osteoblastogenesis, and found that the number of pre-osteoblasts decreased in cells transfected with siRNA of S100A6 compared to cells subjected to negative control. The alkaline phosphatase (ALP) positive area and ALP activity also decreased significantly after transfection of siRNA of S100A6. These suggest that S100A6 may be involved in osteoblastogenesis. To further study the mechanism of S100A6 regulating bone formation, we examined expression of bone formation marker such as Runx2, and found that Runx2 expression was significantly reduced in the transfected cells compared to the non-transfected cells. We also found that the reduced osteogenesis activity, measured by ALP positive area, its activity, and Runx2 expression level, was associated with the decreased expression level of β-catenin after transfection with siRNA of S100A6. Data from this study suggest that S100A6 may play an important role in adipocytes regulatory process of osteoblastogenesis through Wnt signaling pathway. This is the first study that tackles the mechanism of S100A6 regulating osteoblastogenesis.

Bone Anabolic Factors are Specific to Osteoclasts and the Release of These Factors is Altered by Osteoclast Substrate. Catherine Cruger Hansen*[1], Anita Neutzsky-Wulff[2], Kim Andreassen[3], Morten Karsdal[1], Kim Henriksen[1]. [1]Nordic Bioscience A/S, Denmark, [2]Nordic Bioscience & University of Copenhagen, Denmark, [3]Nordic Bioscience, Denmark

Normal bone remodeling is a coupled process in which bone formation by osteoblasts succeeds bone resorption by osteoclasts, ensuring the amount of resorbed bone is replaced by an equal amount of new bone. However, in osteopetrotic patients suffering from Autosomal Dominant Osteopetrosis II (ADOII) and Autosomal Recessive Osteopetrosis (ARO), an uncoupling phenomenon occurs in which bone resorption is decreased while bone formation remains normal or increased. Additionally, the number of non-resorbing osteoclasts is increased; suggesting bone anabolic factors derive from osteoclasts independent of bone resorption. The aim of this study was to investigate the specificity of the osteoclasts ability to induce bone formation.

Human monocytes were isolated from blood and differentiated into mature osteoclasts using M-CSF and RANKL. For some experiments, RANKL was substituted with OPG to prevent osteoclast differentiation. The cells were then cultured on different substrates including decalcified and non-remodeled substrates. Conditioned medium (CM) and corresponding non-conditioned medium (non-CM) were collected during culture. TRAP activity and bone resorption were used as measurements of osteoclast quality. The pre-osteoblastic cell line 2T3 was subsequently treated with 50% of CM or non-CM in addition to relevant controls. Induction of bone nodule formation was assessed by Alizarin Red-S staining / dye extraction.

CM collected from differentiating osteoclasts was shown to induce bone nodule formation 7+ days after initiation of differentiation while CM collected from macrophages did not. This indicates that secretion of bone anabolic factors is specific to osteoclasts. On non-remodeled dentin and decalcified bone, the osteoclasts were comparable to osteoclasts on calcified bone with respect to number and activity, yet the CMs collected from mature osteoclasts cultured on decalcified bone and dentin showed a 90% reduction in anabolic activity compared to calcified bone.

In conclusion, the secretion of bone anabolic factors is specific to osteoclasts. Furthermore, the secretion of bone anabolic factors by mature osteoclasts is attenuated by altered and non-remodeled substrates. Hopefully these findings, along with further investigations, can lead to a better understanding of the uncoupling between bone resorption and bone formation.

Bone Formation Is Predicted by Triiodothyronine and Lean Body Mass in Exercising Women with Hypothalamic Amenorrhea. Jennifer Scheid*[1], Nancy Williams[2], Gaele Ducher[1], Mary Jane De Souza[3]. [1]Penn State University, USA, [2]The Pennsylvania State University College of Medicine, USA, [3]Pennsylvania State University, USA

Decreased bone formation is related to an energy deficiency in exercising women with functional hypothalamic amenorrhea (FHA), but the underlying mechanism is unclear. This impact of energy deficiency on bone formation occurs despite an apparent osteogenic impact of exercise. The purpose of this study was to examine the relative contributions of energy related factors and factors reflective of the exercise stimulus to bone formation in exercising women with FHA. In this cross-sectional study, regularly exercising women were divided according to menstrual status: 1) Ovulatory (ExOV, n= 31), 2) Amenorrheic (ExAMEN, n=21). Menstrual status was assessed by daily urinary reproductive hormones for a menstrual cycle, or 28-day monitoring period if AMEN. Type I procollagen amino-terminal propeptide (PINP), bone-specific alkaline phosphatase (BSAP), ghrelin, triiodothyronine (TT3), peptide YY (PYY), and leptin were measured in the serum. Exercise minutes per week were assessed by exercise logs. Resting metabolic rate (RMR) was assessed by indirect calorimetry and adjusted for lean body mass. Lean body mass and BMD were assessed by DXA. The ExAMEN group had similar age (23.2 ± 0.8yr), weight (57.9 ± 1.1kg), lean body mass (41.7 ± 0.9kg), and exercise minutes (336.4 ± 44.3min) compared to ExOV, but lower BMI (20.3 ± 0.4 vs. 21.5 ± 0.3 kg/m^2, $p=0.020$). ExAMEN also had lower BMD at the lumbar spine and hip ($p<0.01$). No differences were found in bone formation markers between the two groups. TT3 was lower ($p=0.060$) and PYY was higher ($p<0.001$) in the ExAMEN compared to the ExOV group. All other parameters of energy status were not different between the two groups. Independent variables in a regression model predicting PINP included TT3 and lean body mass which accounted for 34.3% of the variance in PINP ($R^2=0.371$, $p<0.001$). In the ExAMEN group alone the proportion of variance in PINP explained by TT3 and lean body mass went up to 67.6% ($R^2=0.710$, $p<0.001$). Adjusted RMR ($r=0.303$, $p=0.038$) was the only energy related variable related to BSAP in the whole sample. Energy status, measured by TT3 and adjusted RMR, and lean body mass are independent predictors of bone formation in exercising women with FHA. Combining an exercise program that improves muscle mass and an adequate energy environment could potentially optimize the skeletal benefits in exercising women with FHA.

Enhancing Effects of HDAC Inhibitors on Osteoblastic Differentiation. Rabia Islam*[1], Hyun-Jung Kim[2], Won-Joon Yoon[3], Hyun-Mo Ryoo[3]. [1]School of Dentistry, Seoul National University, South korea, [2]BioRunx Co. Ltd., South korea, [3]Seoul National University, South korea

Recently HDACs have been proven to be associated with endochondral bone formation, osteoblast maturation as well as osteoclast survival. In addition to histone proteins, many non-histone proteins including Runx2 are also reported as substrates for HDACs resulting in regulation of cell growth and differentiation. Although HDAC inhibitors (HDI) including SAHA and depsipeptide are recently approved by FDA as anti-cancer therapy and have been extensively studied for cancer treatment, the studies of HDI for bone diseases are rare. The purpose of this study is to observe the effect of HDIs including SAHA and MS-275 on osteoblast differentiation using C2C12 and MC3T3E1 cells in order to give some clues to the therapeutic usage of HDIs in bone diseases. Firstly, treatment with SAHA or MS-275 induced ALP activity and showed synergistic effect with BMP2 in C2C12 cells. To investigate their effects on bone marker gene expressions during osteoblast differentiation, C2C12 and MC3T3E1 cells were treated with SAHA or MS-275 in doses optimized after cytotoxicity and efficacy observation with cytotoxicity assay and ALP staining, respectively, and then qRT-PCR was performed for cells in different stages of

differentiation. Both SAHA and MS-275 significantly increased Runx2, Alp, and collagen type(I) gene expression. We also examined Runx2 protein level in MC3T3-E1 cells treated with or without SAHA or MS-275. Both HDIs also increased Runx2 protein expression. Further studies showed that SAHA and MS-275 increased Runx2 stability and acetylation, leading to transcriptional activation of Runx2. Taken together, SAHA and MS-275 has enhancing effect on osteoblast differentiation, indicating that they might be applicable for therapeutic usage in bone diseases.

Human Bone Resorption Lacunas Contain Specific Glycan Epitopes. Meeri Keinänen*[1], Jarkko Räbinä[2], Leena Valmu[2], Petri Lehenkari[1], Juha Tuukkanen[1]. [1]University of Oulu, Finland, [2]Finnish Red Cross Blood Service, Finland

The aim of this study was to characterize the glycan epitopes in human bone located at the resorption lacunas. We hypothesize that the glycans have a particular function in the regulation of bone remodeling.

Human bone slices resorbed with human bone marrow –derived osteoclasts were stained with various lectins. The affinity of various fluorescently labeled lectins towards resorption pits was studied before and after cleaving the glycan epitopes by enzymatic treatments. Results were visualized using confocal microscopy.

Resorption lacunas were positively labeled when treated with sialic acid binding lectins. Also, treatment with N-acetylglucosamine-, mannose- and galactose-specific lectins gave positive result in stainings. Treatment of the resorbed human bone slices with two different sialidases and N-glycosidase changed the binding of lectins, which was observed as weaker signals in confocal microscopy.

These observations show that resorption lacunas contain various glycan epitopes that might have an effect on the subsequent cellular attachment and regulation of the bone formation process.

Osteoblast Targeted Disruption of Kremen Increases Bone Accrual in Mouse. Zhendong Zhong*[1], Cassandra R. Zylstra[2], Bart Williams[2]. [1]Van Andel Institute, USA, [2]Van Andel Research Institute, USA

Kremen proteins are single-pass transmembrane proteins encoded by two genes in mammals. The molecular functions of Kremens are still being elucidated, although some studies have linked its function to regulation of the Wnt/B-catenin signaling pathway. Recently, Ellwanger et al. (Mol. Cell. Biol., 28:4874, 2008) created mice homozygous germline deletions in Kremen1 and Kremen2 and found that mice lacking both genes, both not either one singly, developed increases in bone volume and bone formation. To gain insight what cell type was responsible for this increase in bone mass, we created mice homozygous for a germline inactivation of Kremen1 that also carry an osteoblast-specific deletion in Kremen2. Analysis of these mice reveals depletion of Kremens in osteoblast can significantly increase the whole body bone density, tibia cortical bone thickness and BV/TV ratio. Thus, our data supports the idea that functions of Kremen within the osteoblast are associated with regulation of normal bone mass.

Recapturing Fracture Repair and Bone Formation using a Periosteal Derived Cell Population. Scott Roberts*[1], Eline Desmet[1], Jan Schrooten[1], Frank Luyten[2]. [1]K.U.Leuven, Belgium, [2]University Hospitals KU Leuven, Belgium

Fracture repair involves several key processes including inflammation, callus formation and bone remodeling. It has previously been shown that the integrity of the periosteum, a fibrous tissue which covers all bones, is required for successful bone repair. This is mainly due to populations of osteo/chondro progenitors being resident within the periosteum which mediate bone healing. In this study a population of human periosteal derived cells (hPDCs) was isolated and pooled from six healthy donors by collagenase digestion. These cells were shown, by FACS, to be positive for the mesenchymal stem cell markers CD73, CD90 and CD105 (100%) as well as the endothelial progenitor cell marker CD146 (4.9%) and the hematopoietic progenitor marker CD34 (45%) indicating the heterogeneous nature of this population. To mimic the environment which these cells would be exposed to during fracture healing, five different commercially available orthopedic 3D matrices composed of calcium phosphate particles in an open collagen network (NuOss^{TM}, CopiOs^{TM}, Bio-Oss$^{®}$, Collagraft^{TM} and Vitoss$^{®}$) were selected. Cells were successfully seeded onto the matrices with efficiencies of greater than 90%. Gene expression analysis for the osteo/chondro transcription factors Runx2 and Sox9, following cell seeding and 24 hours and 7 days of passive culture *in vitro*, showed similar levels of expression, indicating the persistence of bone forming progenitors. Bone formation was observed after eight weeks following implantation, subcutaneously in NMRI nu/nu mice, with hPDCs loaded on NuOss^{TM}, Bio-Oss$^{®}$, Collagraft^{TM} and Vitoss$^{®}$ matrices. NuOss^{TM} provided the most optimal environment for bone formation with 13% bone observed within the total volume of implant, when compared to Bio-Oss$^{®}$ (5.3%), Vitoss$^{®}$ (3.2%) and Collagraft^{TM} (1.9%). Interestingly CopiOs^{TM} combined with hPDC cells did not exhibit any bone formation. The formation of bone marrow sinusoids were observed throughout the NuOss^{TM}/hPDC implant, in contrast to other tested cell/matrix combinations, suggesting bone formation through a chondrogenic route as seen during fracture repair. No bone formation was observed when these matrices were implanted in the absence of cells. This study highlights the importance of optimizing the cell-matrix combination, whilst also considering the host interaction when investigating bone forming potential of progenitor cell populations.

Sodium/Proton Exchange is a Major Regulated Mechanism Supporting Bone Mineral Deposition. Li Liu*[1], Peter A. Friedman[1], Paul H. Schlesinger[2], Harry Blair[1]. [1]University of Pittsburgh, USA, [2]Washington University, USA

The osteoblast regulates bone deposition in part by secretion of nucleating proteins for hydroxyapatite, but mineralization proceeds when these proteins are absent. Because bone mineral evolves ~ 1.5 moles of protons per mole of Ca^{2+} precipitated, we hypothesized that facilitated acid transport supports mineralization. Using genome-wide expression in mineralizing human osteoblasts, we identified candidate H^+ transporters; databases on protein interactions were used to identify potential transport systems. Acid transport and expression of proteins was measured in mineralizing osteoblasts. We find that osteoblast H^+ transport involves at least two types of membrane transport. To facilitate mineral deposition at the zone of mineral deposition, there is vectorial H^+ uptake by vesicles, possibly a subset of matrix vesicles, which also express alkaline phosphatase to elevate phosphate. This transport was demonstrated by weak base accumulation by intact membrane vesicles isolated from mineralizing bone. Transport requires a K^+ gradient but it is independent of ATP; H^+ uptake is sensitive to Zn^{2+} but not to H^+ pump inhibitors; the identity of this H^+ transporter is uncertain. Bulk acid flux at the osteoblast basolateral surface proceeds by a second mechanism, vectorial facilitated H^+ transport mediated by Na^+/H^+ exchanger-6 (NHE6). NHE6 mediates cation exchange at high capacity across the gap-junction connected osteoblasts during bone synthesis. Osteoblasts express both NHE6, a specialized NHE, and NHE1, widely expressed. A chaperon protein, RACK-1, trafficks NHE6 to the cell membrane in osteoblasts. Nonmineralizing MG63 osteoblasts express low levels of NHE6 and have low Na^+-dependent H^+ transport, shown by whole cell pH in response to 40 mM proprionate, while mineralizing osteoblasts exhibit rapid Na^+/H^+-exchange and high levels of NHE6. When MG63 is transfected with NHE6, Na^+/H^+-exchange is similar to mineralizing osteoblasts. Knockdown of NHE1 has minimal effects on pH change with acid loading. Osteoblasts also express the PDZ domain-containing Na^+/H^+ exchange regulatory factor-1 (NHERF-1), a PTH-receptor binding organizing protein that complexes with SLC9-family NHEs including NHE6, and RACK-1, regulating them. In NHERF-1$^{-/-}$ mice an unusual osteomalacia with broadened mineral deposition zones and ~30% defect in matrix and mineral synthesis occur. We conclude that NHE-dependent H^+ transport, mediated mainly by NHE6, supports hydroxyapatite deposition in bone.

Stimulation of Bone Formation in Cortical Bone of the Mice Treated with a Novel Bone Anabolic Peptide with Osteoclastogenesis Inhibitory Activity. Hisataka Yasuda[1], Atsushi Inagaki[2], Kaoru Mori[2], Yuriko Furuya*[2]. [1]Oriental Yeast Company, Limited, Japan, [2]Oriental Yeast Co., Ltd., Japan

In spite of making every effort in developing bone anabolic drugs the only clinically available one is PTH. The major difficulty is lack of clarification of mechanisms regulating osteoblast (Ob) differentiation and bone formation. Here we report that a peptide known to abrogate osteoclast (Oc) differentiation *in vivo* via blocking RANKL-RANK signaling surprisingly exhibited bone anabolic effect *in vivo*. In the previous study administration of the peptide significantly inhibited bone loss by reducing NOc/BS and OcS/BS in trabecular bone in OVX mice. To investigate the effects of the peptide it was administered subcutaneously to mice three times per day for 5 days at a dose of 10mg/kg. DXA and pQCT analysis showed that the peptide augmented BMD significantly in cortical bone not in trabecular bone. Histomorphometrical analysis showed that the peptide had little effect on NOc/BS and OcS/BS in distal femoral metaphysis but markedly increased MAR and BFR in femoral diaphysis. Our findings were inconsistent with the previous report that the peptide acted as an inhibitor of bone resorption and suggested that the peptide exerted its activity through unknown mechanisms. To clarify them, we investigated the effects of the peptide on Ob differentiation/mineralization with MC3T3-E1 (E1) cells and those on Oc differentiation with RAW264 cells and sRANKL. The peptide markedly increased ALP activity and decreased TRAP activity in each cell culture in a dose-dependent manner, respectively. In addition, the peptide stimulated mineralization evaluated by alizarin red staining. Increases in ALP activity and mineralization were similarly observed in human mesenchymal cell culture under osteoblastic conditions. Increases in mRNA expression of BMP4, CTGF, IGF1, IGF2, ALP, and osteoclacin were observed in E1 cells treated with the peptide for 96 h in GeneChip analysis. Addition of p38 MAP kinase inhibitor reduced ALP activity in E1 cells treated with the peptide, suggesting a signal through p38 was involved in the mechanisms. Taken together, the peptide abrogated osteoclastogenesis by blocking RANKL-RANK signaling and stimulated Ob differentiation/mineralization at the same concentration with unknown mechanism *in vitro*. However, in our experimental conditions the peptide exhibited bone anabolic effect dominantly in vivo. Since the peptide was known to bind RANKL, we hypothesized that the peptide shows the bone anabolic activity with reverse signaling through RANKL in Obs.

Suppression of NADPH Oxidases Prevents Chronic Ethanol-Induced Bone Loss. Jin-Ran Chen*[1], Oxana P. Lazarenko[2], Kelly Mercer[3], Kartik Shankar[2], Michael L. Blackburn[2], Thomas M. Badger[2], Martin J. Ronis[2]. [1]University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, [2]University of Arkansas for Medical Sciences/ Arkansas Children's Nutrition Center, USA, [3]Arkansas Children's Nutrition Center, USA

Since the molecular mechanisms through which chronic excessive alcohol consumption induces osteopenia and osteoporosis are largely unknown, potential treatments for prevention of alcohol-induced bone loss remain unclear. We have previously demonstrated that, chronic ethanol (EtOH) treatment leads to accumulation of reactive oxygen species (ROS) in osteoblasts dependent on NADPH (nicotinamide adenine dinucleotide phosphate) oxidase (Nox). EtOH-induced ROS production might mediate both inhibition bone formation and increases in bone resorption. Using total enteral nutrition in a cycling female Sprague-Dawley rat model, we found that EtOH infusion for 4 weeks reduced bone mass ($P<0.05$) assessed by peripheral quantitative computerized tomography (pQCT) analysis. Co-administration of diphenylene iodonium chloride (DPI) a pan Nox inhibitor by daily s.c. injection of 1 mg/kg/d, abolished EtOH-induced bone loss. Static histomorphometric analysis revealed that EtOH effected both osteoblast and osteoclast indices ($P< 0.05$). EtOH decreased bone volume and the number of osteoblasts, whereas it increased osteoclast number, bone surface covered by osteoclasts and the eroded bone surface characteristic of increased osteoclastic activity. DPI was able to normalize both osteoblast and osteoclast indices affected by EtOH. EtOH-induced bone loss was associated with up-regulation of mRNA levels of all three Nox subtypes 1, 2, 4 and RANKL (receptor activator of NF-kB ligand) in bone, and EtOH-induced RANKL promoter activity in vitro ST2 cell culture ($P<0.05$). To confirm Nox activation is truly associated with EtOH-induced bone loss, we fed a 36 % alcohol containing liquid diet to nicotinamide dinucleotide phosphate oxidase-deficient p47phox-/- female mice for 6 weeks. In vivo systemic CT scan analysis revealed that, in wild type animals, EtOH reduced bone mineral density (BMD) compared to a pair fed group ($P<0.05$). In contrast, EtOH failed to down-regulate BMD in p47phox-/- female mice compared to their pair fed controls. Bone marrow cells taken from p47phox-/- female mice cultured with 50 mM EtOH for 24 h failed to induce RANKL gene expression but EtOH was able to induce RANKL gene expression in cells from wild type animals ($P< 0.05$). These data suggest that inhibition of Nox expression or activity may be new target for prevention or treatment of chronic EtOH-induced bone loss, and perhaps other conditions resulting in oxidative stress associated bone resorption such as aging. This study was supported by NIH grant RO1 AA18282 to MJR.

Duality of TRIP-1 Function in Regulating Osteoblast Activity In Vitro. Diana Metz-Estrella*[1], Tzong-jen Sheu[2], J. Edward Puzas[3]. [1]University of Rochester School of Medicine & Dentistry, USA, [2]Univesity of Rochester School of Medicine & Dentistry, USA, [3]University of Rochester School of Medicine, USA

The importance of the "TGFβ receptor interacting protein" (TRIP-1) in bone remodeling was first recognized when it was found to interact with tartrate resistant acid phosphatase (TRAP). It has been suggested that the interaction of these two proteins activate the TGFβ pathway and increase markers of osteoblast differentiation. Interestingly, TRIP-1 may also have another role inside the cell since it shares a perfect homology to a subunit of the eukaryotic initiation factor 3 complex (i.e. eIF3i). Therefore, we believe that during bone remodeling TRIP-1 integrates extracellular signals in osteoblasts and mediates regulation of protein translation. Consequently, this would lead to a control over osteoblast proliferation and differentiation. To evaluate the role of TRIP-1 in osteoblasts we transiently transfected siRNA against TRIP-1 into primary rat calvarial osteoblasts in vitro. These cells were then cultured in osteoblast differentiation media for 5 days. Cells transfected with TRIP-1 siRNA show an 84% decrease in TRIP-1 protein levels at day 3 after transfection compared to cells transfected with a control siRNA. In addition, cells transfected with TRIP-1 siRNA presented reduced alkaline phosphatase staining and exhibited a 60% decrease in alkaline phosphatase activity when compared to control cells. Using qRT-PCR we found that cells transfected with a TRIP-1 siRNA have decreased expression of osteoblast differentiation markers (i.e., collagen I, alkaline phosphatase, osteopontin and osteocalcin). Interestingly, TRIP-1 siRNA visibly reduced cell number in this assay. In relation to this, cyclin D1 protein levels were dramatically decreased in cells transfected with the TRIP-1 siRNA. These data suggested a role for TRIP-1 in cell cycle regulation. To address this possibility, cells transfected with control or TRIP-1 siRNA were labeled with BrdU and sorted by flow cytometry to assay for possible cell cycle arrest. The results suggested that cells transfected with a TRIP-1 siRNA are arrested in the S and G2M phases of the cell cycle. Moreover, luciferase reporter assays showed that knocking down TRIP-1 interferes with the normal signaling of TGFβ and BMP pathways. In conclusion, our data show that TRIP-1 is an essential protein for normal osteoblast differentiation and proliferation and through its interaction with TRAP may be one mechanism by which site-directed bone formation can occur.

Fibroblast Growth Factor Receptor 2 Expression in Pre-osteoblasts Requires the PBAF Chromatin-remodeling Complex. Fuhua Xu*, Stephen Flowers, Elizabeth Moran. Department of Orthopaedics, NJMS-UH Cancer Center, UMDNJ, USA

Unfolding of the gene expression program that converts precursor cells to osteoblasts is critically dependent on the nucleosome remodeling activity of the mammalian SWI/SNF complex. This ATPase-powered complex regulates stage-specific gene expression in all tissues. Understanding how it acts to maintain or advance specific stages of differentiation is basic to understanding molecular mechanisms of tissue development. The complex can be powered by either of two ATPases: BRM or the BRM-related gene product BRG1. We have recently shown that BRM-specific complexes restrain osteoblast differentiation, helping to maintain the committed precursor state until the pre-osteoblasts receive appropriate signals for differentiation (Flowers et al. 2009. J. Biol. Chem. 284:10067-75). In contrast, BRG1-containing SWI/SNF (also called BAF) generally acts to induce osteogenic genes.

BRG1 also participates in a related complex, designated PBAF. BAF and PBAF share most subunits, but can be distinguished by the choice of another component that also occurs as related alternatives: the ARID family subunits. These are large proteins containing interactive domains for associated proteins, as well as the ARID-motif, which specifies a DNA binding domain of loose specificity. SWI/SNF complexes contain ARID1A or ARID1B. PBAF contains ARID2. To determine whether the PBAF complex is required in osteoblast differentiation, we used an shRNA approach to target ARID2 in MC3T3-E1 pre-osteoblasts.

Cells stably depleted of ARID2 are sharply impaired for induction of the osteoblast specific marker alkaline phosphatase, and show delayed progression to a mineralization phenotype. BRG1-depleted cells are more severely impaired, showing essentially complete failure to differentiate. The results indicate that both BAF and PBAF complexes contribute to induction of the osteoblast phenotype.

Gene array analysis suggests that the BRG1-containing nucleosome remodeling complexes also play an important role in precursor cell commitment to the osteoblast lineage. Analysis of osteogenic gene expression in BRG1-depleted MC3T3-E1 cells reveals several genes expressed in pre-osteoblasts whose expression declines without BRG1. These include BMP4 and fibroblast growth factor receptor type-2 (FGFR2). Preliminary analysis of FGFR2 suggests that maintenance of its expression in pre-osteoblasts requires the PBAF complex.

Phosphorylation-Dependent SUMOylation Regulates the Activity of the αNAC Transcriptional Coactivator. Omar Akhouayri[1], Rene St-Arnaud*[2]. [1]Shriners Hospital for Childrent, Canada, [2]Shriners Hospital for Children & McGill University, Canada

To act as a transcriptional coactivator of c-Jun-dependent osteocalcin gene transcription in osteoblasts, αNAC shuttles between the cytoplasm and the nucleus. It has been shown that the subcellular localization of the protein is regulated through differential phosphorylation. We have identified an additional mode of post-translational modification of αNAC through covalent attachment of the Small Ubiquitin-like MOdifyer, SUMO. Since sumoylation has been shown to differentially impact on the stability, localization, and activity of transcriptional regulators, we have characterized the SUMO acceptor site on the protein and examined which parameters are affected by sumoylation of αNAC. We first used a commercial assay providing the components of the sumoylation cascade to show that recombinant αNAC could be sumoylated in vitro. Immunoprecipitation followed by immunoblotting with anti-SUMO antibodies then confirmed that αNAC is conjugated to SUMO1 in cultured osteoblasts and in calvarial tissue. The amino acid sequence of αNAC contains one copy of the composite 'phospho-sumoyl switch' motif, ΨKxExxS (where Ψ is a hydrophobic amino acid and K is the site of SUMO conjugation), that couples sequential phosphorylation and sumoylation. We have engineered site-specific mutants in which the putative lysine sumoylation site (K127) and the potential serine phosphoregulation site (S132) were mutated alone or in combination. Mutation K127R inhibited sumoylation, demonstrating that it is the primary SUMO conjugation site. Interestingly, mutation S132A reduced the sumoylation of αNAC, while the phosphomimetic S132D mutation increased it, confirming that the sumoylation of αNAC is regulated through differential phosphorylation of serine 132. The subcellular localization, half-life, or DNA-binding activity of αNAC were not affected by mutation at residues K127 or S132. Non-sumoylatable forms of αNAC (K127R, S132A, and K127R/S132D) were unable to coactivate c-Jun-mediated transcription, while the hyper-sumoylated S132D mutant had increased coactivating potential. Our studies characterized a novel post-translational modification of the αNAC coactivator and identified one of the rare transcriptional regulators whose activity is potentiated, not inhibited, by sumoylation. The characterization of the upstream kinase involved in the regulation of αNAC sumoylation will identify an additional pathway involved in the regulation of osteoblastic gene transcription.

Runx2 Is Necessary for Smurf1 Expression in Osteoblastic Cells. Jeong-Hwa Baek[1], Gwan-Shik Kim[2], Hyun-Mo Ryoo[3], Kyung Mi Woo[2], Kyunghwa Baek[2], Hye Lim lee*[2]. [1]Seoul National University School of Dentistry, South korea, [2]Seoul Nat'l University, South korea, [3]Seoul National University, School of Dentistry, South korea

Smurf1 is an E3 ubiquitin ligase and involved in degradation of BMP signaling molecules such as Smad1, Smad5 and Runx2. Previously we have reported that TNF-α stimulates Smurf1 expression via JNK activation and subsequent AP-1 binding to Smurf1 promoter in C2C12 cells. However, TNF-α–induced Smurf1 expression was not observed in Runx2-nulled mouse calvarial cells. Therefore, we investigated the role of Runx2 in Smurf1 expression. Runx2 overexpression induced basal Smurf1 expression and rescued TNF-α-mediated induction of Smurf1 in Runx2-nulled cells. In addition, neither Smurf1 nor Runx2 was expressed in C3H10T1/2 cells. However, Smurf1 expression was induced by exogenous Runx2 expression, not by c-Jun overexpression nor by TNF-α in these cells. Runx2 increased Smurf1 reporter activity in a dose-dependent manner. Studies using Smurf1 promoter mutants have shown that among 4 putative Runx2 binding sites (~2.7 kb) the most proximal one is important to Runx2-mediated Smurf1 expression. Runx2 directly bound to Smurf1 promoter region, and TNF-α enhanced Runx2 binding to Smurf1 promoter region, which was confirmed by ChIP assay. These results suggest that Runx2 is necessary for Smurf1 expression in osteoblastic cells.

The Osteocyte marker, Podoplanin, is Expressed in Transformed Osteoblasts and is Regulated by AP-1. Takeshi Kashima*[1], Akiko Kunita[2], Masashi Fukayama[2], Agamemnon Grigoriadis[3]. [1]Nuffield Orthopaedic Centre, United Kingdom, [2]University of Tokyo, Japan, [3]King's College London, United Kingdom

Podoplanin (E11 antigen) is a type-I transmembrane sialomucin-like glycoprotein that has been shown to be highly expressed in osteocytes both in vivo and in vitro, but not in active bone forming-osteoblasts or chondrocytes. The regulation of podoplanin expression is not well understood, although it has been reported recently that the c-Fos proto-oncogene directly regulates podoplanin expression in a skin cancer model. In this study, we aim to examine whether or not the AP-1 protein, c-Fos, upregulates podoplanin expression in transformed bone and cartilage cells, using previously isolated c-Fos-inducible MC3T3-E1 osteoblastic cells (AT9.2) and ATDC5 chondrogenic cells (DT12.4) as well as osteosarcoma cells derived from c-Fos transgenic tumors.

Induction of exogenous c-Fos in AT9.2 cells resulted in a stimulation of podoplanin expression as well as TGF-b1, a known c-Fos/AP-1 target gene. Western blot analysis of c-Fos transgenic osteosarcoma cell lines confirmed high podoplanin levels in cells overexpressing c-Fos. Further, immunohistochemical analysis showed that podoplanin was intensely positive in c-Fos osteosarcoma xenograft tumor cells. To clarify the cell type specificity of podoplanin expression, immunohistochemistry was performed in normal bone and primary c-Fos transgenic osteosarcomas. Podoplanin was expressed in osteogenic tumor cells and in cells within the tumor bone matrix resembling osteocytes. All tumor cells strongly expressed c-Fos protein as well as TGF-b1. Interestingly, no podoplanin expression was observed in chondrogenic areas within the tumors, and this was confirmed by the lack of correlation between c-Fos and podoplanin expression in c-Fos-inducible DT12.4 chondrocytes.

These data imply that c-Fos and TGF-b1 play a role in the regulation of podoplanin expression in c-Fos overexpressing / transformed osteoblasts, and suggest that the specificity of podoplanin expression is expanded along the osteogenic lineage in pathologic osteoblasts.

The RUNX2 Cistrome Defines a Regulatory Target Genome Responsible for the Osteoblast Phenotype. Mark Meyer*, J. Pike. University of Wisconsin-Madison, USA

RUNX2 is a master regulator of osteoblast differentiation and function whose primary role is to integrate the complex activities of a collection of transcription factors through target genes and multiple signaling pathways. While many osteoblast genes are targets of RUNX2, the RUNX2 regulome in osteoblast precursors has not been assessed. To define this set of RUNX2-responsive genes, we conducted a ChIP coupled to microarray (ChIP-chip) and sequencing (ChIP-seq) analysis of RUNX2

binding activity on a genome-wide level in mouse MC3T3-E1 cells and correlated these sites of RUNX2 action with enhancer-specific histone marks. RUNX2 was found to be pre-bound to approximately 4822 sites on the mouse genome. While 15% of these sites were within 5 kb of promoters, most were located within introns (36%) or at striking distances (41%) from transcriptional start sites of regulated genes. Two or more binding sites were frequently observed at target genes and over 70% contained a RUNX2 response element. The majority of these sites correlated with elevated levels of histone H4 acetylation, a covalent mark of regulatory activity. Interestingly, RUNX2 binding was specifically observed at both RUNX2 promoters, suggesting that RUNX2 auto-regulates its own expression in osteoblasts. RUNX2 binding was also evident at known sites on genes that were previously characterized as RUNX2 targets, including *Bglap2*, *Spp1*, *Alkp*, *Col1a1* and *Fgf18*, thereby validating the many additional sites found to be direct targets of RUNX2 action. RUNX2 was also found at genes involved in cell cycle control, including *Ccnd1*, *Ccnd2* and *Cdk1a*. Perhaps most interesting was the finding that RUNX2 localized directly to a surprisingly large repertoire of downstream transcription factor genes involved in osteoblast function. These include genes for *Sox9* (but not *Sox5* or *6*), *Sp7* and *Atf4* (but not *Atf1* or *2*) but also genes for *Clebpα,* β and δ, *Runx2* isotype genes *1* and *3*, *Vdr*, *c-Fos*, *c-Jun* and *Nfatc1*. We also conducted genome-wide ChIP-seq analysis for C/EBPβ and the $1,25(OH)_2D_3$-activated VDR/RXR heterodimer, two transcription factors known to interact directly with RUNX2. Interestingly, while C/EBPβ bound to over 6440 sites in the genome, 1704 of those sites were associated with pre-bound RUNX2. A similar relationship was found with VDR/RXR. We conclude that RUNX2, through its actions on multiple target genes, is indeed a master regulator of the osteoblast phenotype.

Cell Surface ATP Synthase: A Novel Mechanism for Extracellular ATP synthesis in Osteoblasts. Shyama Majumdar*[1], Vimal Gangadharan[1], Kirk Czymmek[2], Randall Duncan[1]. [1]University of Delaware, USA, [2]University of Delaware & Delaware Biotechnology Institute, USA

ATP, the energy currency of a cell, has many functions other than providing cellular energy; including extracellular signaling in a variety of tissues. We, and others, have previously demonstrated that osteoblasts, osteocytes and osteoclasts use vesicular ATP release to respond to numerous stimuli, including mechanical loading. In addition, these cells have significant basal release of ATP. However, the mechanism for basal release, as well as packaging of ATP into vesicles, remains unknown. We hypothesize that F_1F_oATP synthase is present on the cell membrane of osteoblasts and is functionally active for basal signaling in unstimulated osteoblasts. Furthermore, we hypothesize that ATP synthase is present in cytosolic vesicular membranes to package ATP in preparation for stimulated release. Immunofluorescence, cell surface protein isolation and membrane fractionation techniques were employed to demonstrate the presence of cell surface ATP synthase in MC3T3-E1 pre-osteoblasts as well in primary mouse calvarial osteoblasts. Using a luminescence based ATP assay to measure extracellular ATP synthesized in the presence of varying doses of extracellular ADP, we found that ATP synthase produces ATP in a dose dependent manner and that this synthesis is attenuated when the functional α and β subunits are blocked using blocking antibodies or angiostatin. We have demonstrated that membrane ATP synthase uses a similar hydrogen ion gradient to the mitochondrial ATP synthase by creating a hydrogen ion gradient across the cell membrane. Reducing extracellular pH significantly increased ATP synthesis. To determine the role of membrane ATP synthase during mechanical stimulation, we subjected MC3T3-E1 cells to fluid shear stress (FSS). ATP synthase protein levels increased within 1 to 5 minutes of application of fluid shear stress indicating a mechanism whereby additional ATP synthase is incorporated into the membrane in response to FSS. These data suggest that ATP synthase is present on the cell membrane of osteoblasts and is functionally active. We also predict ATP synthase is present on the vesicular membrane and may be responsible for ATP packaging into vesicles. These data suggest a novel mechanism for the basal release of ATP and the regulation of purinergic signaling in bone cells.

Heterodimerization of Purinergic ATP Receptors in Osteoblasts. Roy Choi*, Gallant Chan, Karl Tsim. The Hong Kong University of Science & Technology, Hong kong

Purinergic ATP receptor superfamily contains P2Y (G-protien-coupled receptor) and P2X (ligand-gated ion channel) subfamilies. The metabotropic P2Y receptors have been shown to involve numerous physiological processes, such as neurotransmission, neuromodulation, immunomodulation, and bone formation. Among them, activation of P2Y1 receptor (one subtype of P2Y subfamily) indirectly increases osteoclast formation and bone resorption via the stimulation of RANKL in osteoblasts, while application of P2Y2 receptor agonist blocks bone formation process, suggesting that the extracellular nucleotides can function locally as a crucial negative modulator in bone metabolism. In the present study, we focused on the interaction of P2Y1 and P2Y2 receptors in osteoblasts. Specifically, the possibility of forming P2Y1-P2Y2 receptor heterodimer in osteoblasts would be discussed, which could be used to support the significance and physiological function of receptor dimerization within P2Y receptor subfamily.

Adipogenic Cells as Primary Target of Strontium? Carole FOURNIER*[1], Anthony Perrier[2], Laurence Vico[3], Alain Guignandon[1]. [1]INSERM U890, France, [2]Laboratoire de Biologie du Tissu Osseux, France, [3]University of St-Etienne, France

Strontium Ranelate is used to treat osteoporosis and its ability to reduce fracture risks is clearly established. If Strontium (Sr) effects are late and positive on osteoblastogenesis and/or early and negative on adipogenesis is still an open question. Our work hypothesis is that SR inhibits commitment of stromal cells towards adipogenesis by regulating the balance between Runx2 and PPARy2 master genes. We treated multipotent mesenchymal cell (C3H10T1/2) with various doses of Sr (0 to 3mM) for limited durations (max 5 days) in various differentiation media (neutral, osteoblastic, adipogenic, or both). Whatever the conditions, we found that Sr inhibits PPARy2 expression without major Runx2 alteration. After a one-day-culture PPARy2 inhibition was dose-dependent and reached 80% of inhibition at 3mM of Sr in an adipogenic context. This observation may explain why Sr could be particularly efficient in physiological challenges enhancing bone marrow adiposity and/or oxidative stress such as aging, ovariectomy, and immobilisation. In an attempt to mimic such challenges we treated our cells with rosiglitazone (Rosi) a potent PPARy2 co-activator. We confirmed that Sr (3mM) was able to reduce Rosi-induced adipogenic differentiation by downregulating PPARγ2 expression by 50%. We also showed by immunodetection that PPARγ2 located in the nucleus of preadipocytes, remains in the cytoplasm under 3mM of Sr. At day 5, C3H10T1/2 treated with both Rosi and 3 mM Sr showed expression levels of adipogenic genes (PPARγ2 and C/EBP) and osteoblastic genes (Runx2 and PAL) similar to those of uncommitted cells as seen in C3H10T1/2 cultivated in αMEM alone. We also showed that Rosi alone stimulates catalase (a PPARγ-dependent gene reducing oxidative stress) expression by 300%. Further treatment with 3 mM strontium reduces catalase expression to the level of uncommitted cells. In the same culture conditions, we observed that Rosi induces an upregulation of SOD1 and 2 (cytosolic and mitochondrial antioxidant enzymes, respectively) and that further strontium treatment normalizes these alterations. The upregulation of antioxidant enzymes under Rosi likely reflects the important production of reactive oxygen species, which is counteracted by Sr treatment. These complex changes suggest that strontium acts in part through PPARγ2, key controller of the osteoblastic/adipogenic balance in which actors of oxidative stress is involved.

Differences in Oxygen Consumption Rate of Osteoblast Lineage Cells in Rats Bred for High and Low Aerobic Capacity. Riyad J. Tayim*[1], Jacqueline Cole[2], Neil R. Halonen[1], Grant C. Goulet[1], Lauren G. Koch[3], Steven L. Britton[3], Ronald Zernicke[2], Andrea Alford[2], Kenneth Kozloff[1]. [1]University of Michigan Department of Orthopaedic Surgery, USA, [2]University of Michigan, USA, [3]University of Michigan Department of Anesthesiology, USA

Cells of the osteoblast lineage are particularly responsive and sensitive to their local oxygen environment, and their ability to improve their intracellular aerobic metabolism in response to exercise may have important downstream effects on bone cell function and skeletal phenotype. In this study, we tested the influence of inherent aerobic capacity on bone metabolism independent of applied mechanical loading. Using the Koch-Britton selective breeding rat model of high capacity (HCR) and low capacity (LCR) runners, an intrinsic 5-to-7 fold functional genomic difference in aerobic exercise capacity exists between non-trained animals after 20 generations of selection. HCR have consistently demonstrated heightened skeletal mineralization and osteoblast activity correlated with their inherent aerobic capacity. In the present study, we compared cellular oxygen metabolism between HCR and LCR osteoblast lineage cells during osteoblast differentiation in vitro. Bone marrow stromal cells (BMSCs) were harvested from the femora and tibiae of 8.5 month, female, generation 25 rats (N=3), and were cultured under standard conditions for 12 days followed by osteoblast differentiation. The Seahorse Bioscience XF24 Analyzer was used to assess cellular aerobic capacity on Day 0, 3, 7, 10, 14, 21, and 28 of the differentiation time course. Basal respiration and glycolysis were assessed and normalized to cell number through time-resolved measures of oxygen consumption rate (OCR) and extracellular acidification rate (ECAR). OCR and OCR/ECAR ratios in both HCR and LCR cells suggested less glycolytic and more aerobic cell metabolism with differentiation and matrix production followed by a return to glycolysis as cells became engulfed in their ECM. HCR cells consumed less oxygen per cell than LCR through Day 14, suggesting a more efficient phenotype. With the addition of oligomycin, HCR cells showed an increase in percent oxygen consumed for ATP production at Day 14 vs. LCR, but this pattern was reversed by Day 28. The HCR/LCR selective breeding rat model allows us to investigate how intrinsic differences in aerobic metabolism result in differences in cellular aerobic metabolism within osteoblast lineage cells. Thus we are able to define cellular parameters that may be responsible for the heightened mineralization and osteoblast activity found in these animals.

Generation and Characterization of iPS Cells from CMD Patients and Healthy Controls. I-Ping Chen*[1], Xiaonan Xin[1], Mary-Louise Stover[2], Shuning Zhan[2], Jonathan Kantor[3], Ernst Reichenberger[1], Alexander Lichtler[1]. [1]University of Connecticut Health Center, USA, [2]UCHC, USA, [3]North Florida Dermatology, USA

Studying rare genetic bone disorders is clinically significant due to the lifetime debilitating impact they have on patients and limited treatment options for these disorders because little of their pathogeneses is known. Research on rare disorders is not only beneficial for future treatment of patients, but contributes to the understanding of important biological mechanisms in bone development and remodeling. Obstacles for research in this field include unavailability of tissue specimens and lack of animal models. Rapid advances in induced pluripotent stem (iPS) cell biology opened new avenues to study bone cells from such patients.

We propose to use patient-specific iPS cells to investigate craniometaphyseal dysplasia (CMD), a rare genetic bone disorder characterized by progressive thickening of craniofacial bones and widening of metaphyses in long bones. Here, we report our first success of generating and characterizing iPS cells from human skin fibroblasts and from SHEDs (stem cells from human exfoliated deciduous teeth) of CMD patients and healthy controls. Methods for generating human iPS cells from fibroblasts and SHEDs are well established. Reprogramming of somatic cells into iPS cells was performed by retroviral transduction of Oct3/4, Sox2, Klf4 and c-Myc with the addition of a vector expressing Lin28, which contains a GFP cassette to monitor transduction efficiency. Both fibroblasts and SHEDs were reprogrammed into iPS cells. Reprogrammed cells had an indistinguishable morphology from H1 and H9 human embryonic stem (hES) cells. These iPS cells expressed hES cell markers SSEA-4, TRA-1-60, TRA-1-81, Oct4 and Nanog, as shown by RT-PCR and immunocytochemistry. The pluripotency of these iPS cells is further supported by in vitro embryoid body (EB) formation. Assays for testing in vivo differentiation capability of these iPS cells by teratoma formation are in progress.

Previously, we have presented the first CMD knock-in mouse model replicating many characteristics of human CMD. We use this mouse model to generate hypotheses for subsequent iPS-based human studies. Ultimately, we plan to investigate the cellular and molecular basis of CMD in the human system, which is only possible with a sufficient supply of human cells. We expect that combining mouse data with findings generated from the use of human iPS cell technology will significantly add to our understanding of CMD pathology and will establish a system to study other craniotubular disorders.

Integrin-linked Kinase Contributes to Mechanical Regulation of GSK3β in Mesenchymal Stem Cells. Jacob Thomas[1], Natasha Case*[1], Maya Styner[1], Buer Sen[2], Zhihui Xie[1], Janet Rubin[1]. [1]University of North Carolina, Chapel Hill, School of Medicine, USA, [2]University of North Carolina At Chapel Hill, USA

GSK3β is emerging as a critical mediator of mechanical responses in mesenchymal stem cells (MSC). Mechanical strain causes inactivation of GSK3β, resulting in stabilization of β-catenin levels and indirectly increasing COX2 expression via NFATc1. Importantly, both β-catenin and COX2 influence MSC differentiation. The signaling molecules required for mechanical inhibition of GSK3β activity via phosphorylation are unknown. AKT, known to decrease GSK3β activity in response to insulin, may also participate in mechanical effects as strain rapidly activates this molecule. Integrin-linked kinase (ILK) can also directly inhibit GSK3β activity, in addition to indirect effects via activation of AKT. Here we wished to define proximal events whereby mechanical stimulation regulates both AKT and GSK3β activity in marrow-derived MSC. We compared strain to insulin, which is known to activate PI3K. Mechanical strain (2%, 0.17Hz, 30 min) caused phosphorylation of AKT at both Thr 308 and Ser 473. In the presence of the PI3K inhibitor LY294002 (20 μM), strain induction of T308~P was inhibited, but S473~P was unimpaired. Importantly, mechanical inactivation of GSK3β, measured by Ser9~P, was not blocked by PI3K inhibition, nor was the effect of strain to induce a 3X increase in COX2 mRNA. This suggested that strain regulation of GSK3β was largely PI3K independent. This contrasts with effects of insulin, which also phosphorylates AKT at both T308 and S473: inhibition of T308~P with LY294002 almost completely ablated insulin-induced GSK3β phosphorylation. To assess whether ILK was involved in PI3K independent effects of strain, siRNA (100 nM) to ILK was used. When ILK was decreased by ~70%, strain still induced AKT T308~P, but phosphorylation of S473 was absent. This may indicate that ILK is largely responsible for strain induced GSK3β inhibition, and may explain the persistence of strain effects in the presence of PI3K inhibition. In further work we hope to confirm that ILK activation is a primary response to strain, and plays a critical role in regulating MSC lineage selection.

Lamin A/C is Required during Osteoblast Differentiation to Facilitate Nuclear Mobility and Function of Runx2. Gustavo Duque*[1], Christopher Vidal[1], Lee Wei Li[2], Li Sze Yeo[3], Diane Fatkin[3]. [1]University of Sydney, Australia, [2]University of Sydney, Nepean Clinical School, Australia, [3]Molecular Cardiology & Biophysics Division, Victor Chang Cardiac Research Institute, Australia

We have recently demonstrated that inhibition of the lamin A/C (lmna) gene inhibits osteoblastogenesis *in vitro* and results in severe osteoporosis *in vivo*. However, the mechanism by which lamin A/C regulates osteoblastogenesis remains unknown. Lamin A/C is a protein of the nuclear envelope, which interacts with multiple nuclear proteins including Runx2, an important transcription factor in osteoblastogenesis. Low levels of lamin A/C are associated with impaired Runx2 transcriptional activation *in vitro*. Using lmna knockout (*lmna-/-*) mice, we undertook studies to characterize the changes in protein interactions in the nucleus in the absence of lamin A/C activity and their potential effect on Runx2 activation *in vivo*. We focused on MAN1, an inner nuclear membrane protein that not only physically interacts with lamin A/C but also has been associated with osteopoikilosis, a rare type of hyperostosis found after loss of function of the MAN1 gene. Antibodies against MAN1 were able to co-immunoprecipiate Runx2 from marrow cells extracts obtained from *lmna-/-* mice demonstrating that, in the absence of lamin A/C, they reside in the same complex. In contrast, co-immunoprecipitation between MAN1 and Runx2 was not found in bone marrow cells obtained from WT controls. Furthermore, absence of Lamin A/C determined a reduction in Runx2 nuclear complex activity identified by ELISA and co-immunoprecipitation analyses. We further examined the consequences of lamin A/C knockout on in situ nuclear organization of MAN1 and Runx2 in bone marrow cells using three dye staining confocal microscopy. We established that in WT mice lamin A/C and MAN1 expression closely overlap and the subnuclear distribution of Runx2 shows a clearly punctuated pattern. In contrast, in bone marrow cells of *lmna-/-* mice, Runx2 lacks a punctuated pattern and closely overlaps the distribution of MAN1. In summary, in absence of lamin A/C, MAN1 and Runx 2 are structurally inseparable thus affecting Runx2 function in osteoblastogenesis. We conclude that the role of lamin A/C in osteoblastogenesis is mediated by a novel molecular mechanism in which the presence of lamin A/C is required to prevent the sequestration of Runx2 by MAN1 in the subnuclear region, thus facilitating Runx2 mobility and function.

Revitalization of Bone Allografts by Murine Periosteal Cells Expressing BMP2 and VEGF. Nick van Gastel*[1], Maarten Depypere[2], Scott Roberts[3], Ingrid Stockmans[1], Sophie Torrekens[1], Jan Schrooten[4], Frederik Maes[2], Frank Luyten[5], Geert Carmeliet[6]. [1]Laboratory of Experimental Medicine & Endocrinology, Katholieke Universiteit Leuven, Belgium, [2]Department of Electrical Engineering (ESAT/PSI), Katholieke Universiteit Leuven, Belgium, [3]K.U.Leuven, Belgium, [4]Department of Metallurgy & Materials Engineering, Katholieke Universiteit Leuven, Belgium, [5]University Hospitals KU Leuven, Belgium, [6]Katholieke Universiteit Leuven, Belgium

To date, autologous bone transplantation remains the therapy of choice to treat large bone defects. Despite numerous advantages, its use is restricted by major drawbacks, including limited availability and donor site morbidity. Bone allografts lack these shortcomings and provide the strength and flexibility needed in load-bearing applications. However, allografts are not osteogenic, due to their acellular nature, which prevents integration into the host bone. Here, we show that murine periosteal cells, transiently expressing bone morphogenetic protein 2 (BMP2) and vascular endothelial growth factor (VEGF) and seeded on a segmental allograft, can substitute for the absent periosteum and improve callus formation and allograft incorporation.

First, a protocol was established to isolate periosteal cells from long bones of adult mice. Flow cytometric analysis revealed a substantial higher number of mesenchymal stem cells (MSCs) in the periosteal population as compared to bone marrow stromal cells. In addition, periosteal cells showed trilineage differentiation potential (osteogenic, chondrogenic and adipogenic) and when implanted ectopically in mice they formed a substantial amount of bone.

To enhance their therapeutic potential, periosteal cells were transduced with adenoviral vectors encoding BMP2, VEGF or GFP. Increased secretion of growth factors in the culture medium persisted for at least 14 days, as demonstrated by ELISA. Cells expressing BMP2 and VEGF were seeded onto 4mm cortical allografts and implanted into femoral defects in mice. Autografts, empty allografts and allografts with GFP-transduced cells served as controls. After 4 weeks, bone healing was analyzed using μCT and histology. Defects treated with empty allografts or grafts with GFP-transduced cells showed little callus formation and little to no remodeling of the graft. Grafts seeded with BMP2- and VEGF-transduced periosteal cells however induced the formation of a large callus, comparable to autografts, accompanied by manifest graft remodeling.

In conclusion, the successful isolation of adult mouse periosteal cells could help to further explore the role of this cell population using the available genetic mouse models. Moreover, establishing an artificial periosteum consisting of periosteal cells expressing BMP2 and VEGF considerably improves allograft incorporation into large bone defects in mice.

Role of GILZ in TNF-α-Mediated Inhibition of Marrow Mesenchymal Stem Cell Osteogenic Differentiation. Xing-Ming Shi, Nianlan Yang, Linlin He*. Medical College of Georgia, USA

Tumor necrosis factor-alpha (TNF-α) is a potent proinflammatory cytokine and it inhibits osteoblast differentiation while stimulating osteoclast differentiation and bone resorption. TNF-α activates MAP kinase pathway leading to inhibition of osterix (Osx) expression. TNF-α also induces the expression of E3 ubiquitin ligase protein Smurf1 and Smurf2 and promotes degradation of Runx2, another key transcription factor regulating osteoblast differentiation and bone formation. We showed previously that overexpression of glucocorticoid (GC)-induced leucine zipper (GILZ) enhances osteogenic differentiation of bone marrow mesenchymal stem cells (MSCs). We and others also demonstrated that GILZ is a GC effect mediator and it mimics GCs' antiinflammatory actions. In this study, we asked whether GILZ retains its osteogenic activity while mediating GC antiinflammatory action. We infected MSCs with GILZ-expressing retroviruses and exposed the cells to TNF-α in an osteogenic environment. Our results show that overexpression of GILZ can override the inhibitory effect of TNF-α on MSC osteogenic differentiation as determined by Alizarin red staining of mineralized bone nodules. Real-time qRT-PCR and Western blot analyses show that overexpression of GILZ antagonized the inhibitory effect of TNF-α on Osx and Runx2 mRNA and protein expression. Finally, we demonstrate that GILZ antagonizes TNF-α effect on Osx expression by inhibiting TNF-α-induced MAP kinase activation. Together, these results indicate that GILZ is capable of dissociating the desired anti-inflammatory GC effects from its adverse bone effects and suggest that GILZ may have therapeutic potential for preventing bone loss caused by chronic inflammation such as rheumatoid arthritis.

Zolendronate Induce Expression of Runx2 to Promote Osteogenic Commitment of Human Periodontal and Pulp Cells. Harunur Rashid*[1], Nachiket Saoji[1], Somsak Sittitavornwong[1], Haiyan Chen[1], Farah Ghori[1], Huw Thomas[1], Soraya Gutierrez[2], Amjad Javed[1]. [1]University of Alabama at Birmingham, USA, [2]Universidad de Concepcion, Chile

Bisphosphonates (BP) are widely used to treat osteoporosis and malignant bone metastasis but osteonecrosis of the jaws and musculoskeletal pain has recently emerged as a significant complication in a subset of patients receiving these drugs. BP inhibits osteoclast mediated bone resorption however its action on other skeletal cells remains largely unknown. We established primary PDL and Pulp cells from non-infected, impacted third molars of healthy individuals to explore the impact of PB treatment on cell growth and differentiation. We determined that a 14-fold dilution of clinically used dose of zolendronate is non cytoxic in exvivo cultures. Exposure of PDL and pulp cells to BP caused a significant inhibition of cell proliferation consistent with its action on osteoclast. However, BP strongly enhanced osteogenic differentiation of both PDL and Pulp cells as evidenced by progressive increase in ALP activity, matrix synthesis and mineral deposition. For a molecular understanding of how BP stimulated osteoblast differentiation, we analyzed gene expression profile by microarray analysis. Interestingly, 70% (78 of 112) of the osteogenic genes were significantly induced and 14% were down regulated upon BP treatment. These changes were noted for all the key ECM genes, considered markers of specific stages of osteoblast differentiation (ALP; 19-fold, Col1a; 19-fold, BSP; 11-fold, DSPP 42-fold, OC; 48-fold, SOST; 103-fold). BP also enhanced the expression of osteogenic regulatory molecules (FGF2; 20-fold, BMP7; 43-fold, TGFβ; 8-fold), their receptors and transducers (TGFβR; 102-fold, BMPR; 12-fold, SMAD9; 18-fold). Moreover, expression of essential transcription factors and regulators of osteoblast differentiation were robustly increased (Runx2; 21-fold, Sox9; 41-fold, Msx2; 3-fold). Similar pattern of gene profile was noted in Pulp cells, indicating BP target a common regulatory pathway in tooth derived mesenchymal progenitors. The upregulation of selected osteoblast marker genes was further confirmed by RT-PCR from primary PDL and Pulp cells of three independent individuals. EMSA and Immunofluorescence studies demonstrated that BP enhanced both DNA binding and nuclear accumulation of Runx2 protein. Finally, BP stimulated Runx2 mediated activation of the OC promoter. Taken together, our studies demonstrate that, bisphosphonate activate program of osteoblast differentiation by enhancing functional competency of Runx2 in tooth derived mesenchymal cells.

Glucocorticoids Attenuate Bone Turnover, but do not Appear to Affect Chondrocytes In Vitro. Kim Henriksen*[1], Kim Vietz Andreassen[1], Morten Karsdal[1], Anne-Christine Bay-Jensen[2]. [1]Nordic Bioscience A/S, Denmark, [2]Nordic Bioscience, Denmark

Glucocorticoids are known to attenuate bone formation in vivo leading to decreased bone volume and increased risk of fractures, whereas effects on the joint tissue are not known. This study aimed at characterizing the effect of glucocorticoids on osteoclasts and osteoblasts, as well as the closely related chondrocytes. We used CD14+ monocytes cultured in the presence of M-CSF and RANKL to investigate the effect of glucocorticoids on different osteoclastic parameters. We measured TRACP activity and Calcium release as indices of osteoclast number and activity. 2T3 preosteoblastic cells we used to characterize the effects of glucocorticoids on bone formation, either in the presence or absence of BMP-2. Alizarin Red was used to measure nodule formation, ALP activity as an indicator of osteoblastogenesis. Bovine full depth cartilage explants were cultured with or without TNF-a, OSM and IGF-1 to characterize the effects of glucocorticoids on cartilage turnover. Collagen type II degradation was measured by CIIMB, and aggrecan degradation by 373-G1. Safranin O staining was used to investigate proteoglycan content in sections of the cultured explants. In all assays Alamar Blue was used as an indicator of viability. DEX and PRED dose-dependently inhibited osteoclastogenesis by promoting cell death. For mature osteoclasts, low doses of GLUC induced bone resorption short term, whereas high doses and continued exposure led to osteoclast death. In osteoblasts glucocorticoids induced cell death in the non-stimulated cells. For BMP-2 stimulated cells; we found that GLUCs augmented nodule formation, while still reducing cell viability. In cartilage we found that GLUCs were unable to alter cartilage turnover, although at high concentrations a minor reduction in safranin O staining intensity was observed. In summary, using highly robust models of bone and cartilage turnover, we have shown that the effects of glucocorticoids on bone depend very much in the cell targeted, i.e. activated osteoblasts are further activated by GLUC, whereas non-activated cells undergo cell death. In cartilage no apparent effects were observed, indicating that cartilage may not possess glucocorticoid receptors, or that these are

not active. We believe that these model systems are highly relevant for the continued development of glucocorticoid analogues without the detrimental effect on bone.

Bone-wasting Cytokines are Up-regulated in Fragility Fractures: Role of Bone and Bone Marrow Cells. Patrizia D'Amelio*[1], Ilaria Roato[2], Lucia D'Amico[2], Luciana Veneziano[3], Elena Suman[3], Francesca Sassi[3], Giuseppina Bisignano[3], Giancarlo Isaia[1]. [1]University of Torino, Italy, [2]CeRMS (Centre for Research & Medical Studies), San Giovanni Battista Hospital, Italy, [3]Gerontology Section, Department of Surgical & Medical Disciplines, University of Torino, Italy

The roles of bone and bone marrow cells in bone turnover control and the amounts of cytokines they produce are not clear. This study compares cytokines production in patients with a fragility fracture and those with osteoarthritis (OA).

We evaluated 52 femoral heads from women subjected to hip-joint replacement surgery for femoral neck fractures due to low-energy trauma (37), or for OA (15). Total RNA was extracted from both bone and bone marrow, and quantitative PCR was used to identify RANKL, OPG, M-CSF, TGFβ, DKK-1 and SOST expression.

We found an increase of RANKL/OPG in bone marrow from fractured patients (Fig 1 A), as previously reported for the early post-menopause (1), whereas this parameter was similar in the bone (Fig.1B). It may thus be supposed that bone marrow cells are the main drivers of osteoclast formation and activity. Both RANKL and OPG were up-regulated in bone marrow from the fractured patients. The increase in OPG may be interpreted as an attempt to inhibit RANKL, and as a sign of increased bone turnover.

This pro-osteoclastogenic cytokine profile was accompanied by an increase in the Wnt pathway inhibitor DKK-1 in bone (Fig.2A) and bone marrow (Fig.2B), which reduces osteoblast activity in fractured patients. Osteoporosis may perhaps be regarded as both an osteoblast and an osteoclast disease.

TGFβ was slightly (about 1.5%) increased in OA bone (Fig.3 A). The role of TGFβ in controlling bone turnover is not completely clear. As expected, more was produced by bone marrow (Fig.3 B) with no significant difference between the two sets of patients (data not shown). Since OA chondrocytes produce more TGFβ, the small increase observed in OA bone may be due to their contribution.

We observe no difference in fractured as respect to OA patients in M-CSF and SOST expression.

In conclusion, we have demonstrated the important contribution of bone marrow cells in the regulation of bone turnover. Bone marrow from fractured patients produces more RANKL than that from patients with OA, whereas bone from fractured patients expresses more DKK-1. The cytokine pattern is thus shifted towards osteoclast activation and osteoblast inhibition in patients with a fragility fracture.

Role of T Cells in the Activation of Osteoclastogenesis in Phenylketonuria Patients. Ilaria Roato*[1], Lucia D'Amico[2], Francesco Porta[3], Alessandro Mussa[3], Marco Spada[4], Riccardo Ferracini[5]. [1]CeRMS, Center for Experimental Research & Medical Studies, A.O.U. San Giovanni Battista, Italy, [2]CeRMS, Italy, [3]Department of Pediatrics, University of Turin, Italy, [4]Department of Pediatrics, University of Torino, Italy, [5]Department of Orthopaedics, A.O.U. San Giovanni Battista, Italy

Phenylketonuria (PKU) is a rare inborn error of metabolism commonly complicated by a progressive bone impairment of uncertain etiology, as documented by both ionizing and non- ionizing techniques. We studied osteoclastogenesis and T cell activation state in 40 PKU patients, considering their bone condition and metabolism in an attempt to elucidate the pathogenesis of bone damage. Peripheral blood mononuclear cell (PBMC) cultures were performed to study osteoclastogenesis, adding or not recombinant human monocyte-colony stimulating factor (M-CSF) and receptor activator of NFκB ligand (RANKL). TNF-a, RANKL and OPG were dosed in cell culture supernatants by ELISA. RANKFc and anti-TNF-a were added in some experiments to investigate their ability to inhibit osteoclastogenesis. T cell activation state was analyzed evaluating CD69 and CD25 expression by flow citometry. Bone conditions and the phenylalanine levels in PKU patients were clinically evaluated.

PKU patients disclosed an increased osteoclastogenesis compared to healthy controls, both in unstimulated and M-CSF/RANKL stimulated PBMC cultures. These OCs formed resorbing lacunae on the mineralized supports used to test OC activity. We dosed higher TNF-a levels in PKU patients than in healthy controls. RANKL levels were detected both in PKU patients and in healthy controls cultures, but they were higher in patients than in controls. OPG levels were not statistically different between patients and controls, but the RANKL/OPG ratio was higher in PKU patients, explaining the spontaneous osteoclastogenesis in the unstimulated cultures of patients. The addition of the specific antagonist RANK-Fc inhibited osteoclastogenesis, whereas anti-TNF-a failed to inhibit it. RANKL was produced by T and B cells both in patients and in controls, but T cells from patients resulted more active than ones from controls. Osteoclastogenesis in PKU patients was inversely related to bone condition assessed by Quantitative Ultrasound and directly related to non-compliance to therapeutic diet reflected by hyperphenylalaninemia.

Spontaneous osteoclastogenesis is present in PKU patients and correlates with hyperphenylalaninemia, suggesting its role in the pathogenesis of bone impairment in PKU. Osteoclastogenesis is dependent on RANKL, which is produced by T and B cells, suggesting a direct involvement of immune system in the bone damage of PKU patients.

Comprehensive Analysis of Epigenetic Role of TGF-beta in RANKL-induced Osteoclastogenesis by ChIP-seq Approach. Tetsuro Yasui*[1], Takumi Matsumoto[2], Hironari Masuda[2], Jun Hirose[2], Yasunori Omata[2], Yuho Kadono[2], Hisataka Yasuda[3], Daizo Koinuma[2], Shuichi Tsutsumi[2], Kozo Nakamura[2], Hiroyuki Aburatani[2], Sakae Tanaka[2]. [1]University of Tokyo, Japan, [2]The University of Tokyo, Japan, [3]Oriental Yeast Company, Limited, Japan

Osteoclast differentiation from monocyte-macrophage lineage precursor cells is regulated by two essential cytokines, receptor activator of NF-κ B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF). TGF-β is a cytokine with ubiquitous proliferation and differentiation activity in many types of cells, and we recently demonstrated that TGF-β is essential for RANKL-induced osteoclastogenesis. In this study, we analyzed the role of TGF-β in osteoclastogenesis through comprehensive epigenetic approach.

To identify TGF-β-regulated genes in osteoclast precursors (OCPs), chromatin immunoprecipitation using anti-Smad2/3 antibody and massively parallel DNA sequencing was performed (ChIP-seq). 2,786 Smad2/3 binding sites were identified, and 903 genes were extracted as Smad2/3 target genes. Microarray analysis demonstrated that expression of these genes was in fact upregulated by TGF-β treatment.

To further specify the key regulatory genes of osteoclast differentiation, we analyzed histone modification profiles of OCPs. It has been recently recognized that trimethylation of histone H3 lysine 4 (H3K4me3) is associated with active transcription of a gene and trimethylation of histone H3 lysine 27 (H3K27me3) is associated with gene silencing. Dynamic changes in the histone modification pattern of cell lineage-specific genes from H3K4me3/H3K27me3 bivalent to H3K4me3 monovalent are known to be involved in the differentiation of stem cells to terminally differentiated cells. We therefore analyzed histone methylation patterns by ChIP-seq approach using anti-H3K4me3 antibody or anti-H3K27me3 antibody. We found that histone modification pattern was converted from K4/K27 bivalent to K4 monovalent by TGF-β treatment in 85 genes, with 18 of them being Smad2/3 target genes. Expression of these 18 genes was significantly upregulated by TGF-β treatment, while none of them was upregulated more than 2-fold by RANKL treatment. Interestingly, in as many as 6 out of the 18 genes, treatment of OCPs with RANKL for 72 hrs converted histone modification pattern to be H3K27me3 monovalent and gene expression was downregulated less than 1/4 fold. These findings indicate that RANKL epigenetically silences transcription of TGF-β-regulated key osteoclastogenic genes.

Combined with our finding that TGF-β most strongly promoted RANKL-induced osteoclastogenesis when TGF-β was applied to OCPs prior to RANKL stimulation, it is suggested that the role of TGF-β in osteoclastogenesis is to maintain OCPs in undifferentiated state and thus support RANKL-induced osteoclastogenesis.

Elucidating the Mechanism of Impaired Osteoclastogenesis in Cultures of Cells from +/R740S Osteopetrotic Mice. Irina Voronov*[1], Noelle Ochotny[1], Morris Manolson[1], Jane Aubin[2]. [1]University of Toronto, Canada, [2]University of Toronto Faculty of Medicine, Canada

Osteoclasts are multinucleated cells responsible for bone resorption. Vacuolar H^+-ATPases (V-ATPases), the multimeric enzymes present at the ruffled border of osteoclasts, are necessary for acidification of the resorption lacunae. V-ATPases consist of fourteen subunits, one of which, the "a3" subunit, is highly enriched in osteoclasts. Heterozygous mice with an R740S mutation in "a3" (+/R740S) have defective V-ATPase activity resulting in a higher bone density. Osteoclast number is increased in +/R740S bones, but in cultures of either bone marrow- or spleen-derived +/R740S cells, osteoclastogenesis is decreased compared to wild type (+/+) cells. We hypothesize that "a3" not only is important for acidification, but also plays a role in osteoclast differentiation.

To characterize osteoclastogenesis *in vitro*, +/R740S and +/+ bone marrow cells were cultured in the presence of RANKL and M-CSF for 6 days; the expression of osteoclast markers was analyzed by RT-PCR and apoptosis was assessed by TUNEL labeling. Gene expression levels of all osteoclast-specific markers, including tartrate resistant acid phosphatase (TRAP), osteoclast associated receptor (OSCAR), dendritic cell specific transmembrane protein (DC-STAMP), and the "d2" subunit of V-ATPase, were decreased in +/R740S cells *in vitro*, while "a3" expression was not changed compared to +/+ cells. "a3" and "d2" protein expression levels showed a similar pattern as determined by Western blotting. TUNEL assay results demonstrated that there was no difference in the number of apoptotic osteoclasts in +/R740S versus +/+ cell cultures, indicating that decreased osteoclast numbers in +/R740S cell cultures were not due to increased cell death. The expression levels of both the pro-apoptotic marker Fas and the anti-apoptotic marker Bcl2 were unexpectedly higher in +/R740S versus +/+ cultures. Besides acidification of extracellular spaces, the V-ATPases are known to play an important role in vesicular trafficking. Our results to date indicate that there is no difference in "a" subunit localization between +/R740S and +/+ cells grown on non-resorbing surface as assessed by immunofluorescence. Future experiments will determine whether the R740S mutation affects vesicular trafficking in osteoclasts. These studies will help to elucidate precise roles of the V-ATPase "a3"subunit in osteoclast maturation and activity.

Live-Cell Microscopy of Osteoclast Precursor Fusion and Osteoclast Fission. Ineke Jansen*[1], Veerle Bloemen[2], Jan Stap[3], Ton Schoenmaker[4], Teun De Vries[5], Vincent Everts[5]. [1]ACTA, The netherlands, [2]Vrije Universiteit Medical Center, The netherlands, [3]Department of Cell Biology & Histology, Netherlands, [4]Dept. of Oral Cell Biology & Periodontology, Netherlands, [5]ACTA, Vrije Universiteit, The netherlands

Purpose: Osteoclasts are specialized cells with the unique capacity to resorb bone. The formation of these cells is a multistep process in which migration is essential for both the precursors and the osteoclast itself. Yet, surprisingly little is known about the dynamics of cell migration throughout the process of osteoclast formation. In this study we investigated the migratory behavior and cell-cell interaction of osteoclast precursors and mature osteoclasts.

Methods: Human peripheral blood mononuclear cells (PBMCs) were cultured with the osteoclastogenic cytokines macrophage colony-stimulating factor (M-CSF) and receptor activator of NF-KB-ligand (RANKL). The cultures were analyzed by live cell microscopy during 96 hours, both after one week and after two weeks of culture. In addition, we analyzed the migratory behavior of mature osteoclasts isolated from rabbits.

Results: At an early stage the osteoclast precursors were actively migrating over relatively long distances and migrated further away from their initial position compared to the later stage. At the two weeks time point, just prior to fusion, the cells were motile, but did not travel long distances. We next monitored isolated osteoclasts and showed for the first time a unique phenomenon: osteoclasts can undergo fission to generate functional multinucleated compartments as well as compartments that contained apoptotic nuclei.

Conclusions: These findings indicate important differences in the dynamics of cell migration during osteoclastogenesis: First, the osteoclast precursor explores the environment in search for fusion partners whereas in a later stage the osteoclast precursor moves in a much more localized area, possibly preparing for an interaction with neighboring cells. The most intriguing observation of dividing osteoclasts suggest that the osteoclast divides into several multinucleated cells in order to simultaneously control bone resorption at different sites and shed apoptotic nuclei to free the cell from non-functional elements. Our observations provide new information on the cellular behavior of multinucleated cells and open a new prospective for controlling bone resorption.

Osteocyte Apoptosis Directly and Indirectly Regulates Osteoclast Formation In Vitro. Lidan You, Axel Guenther, Saja Al-Dujaili*. University of Toronto, Canada

Introduction:

Microdamage is believed to disrupt interstitial fluid flow in bone, thereby reducing solute transport and causing osteocyte apoptosis. Osteocyte apoptosis in microdamage areas was shown to precede increased local osteoclast formation and activity, thereby initiating targeted bone remodeling in vivo. Osteocytes have been demonstrated to release RANKL, M-CSF and VEGF as pro-osteoclastogenic factors in vivo. However, the mechanisms for osteoclast formation and resorption in microdamage areas are unknown. We hypothesize that: a) apoptotic osteocytes localized near microdamage are directly responsible for initiating targeted bone remodeling, and b) apoptotic osteocytes indirectly regulate bone remodeling by sending cues to nearby healthy osteocytes, which then initiate targeted remodeling.

Methods:

We serum-starve MLO-Y4 osteocyte-like cells for 24hr to achieve similar apoptosis effect associated with bone microdamage. Conditioned medium was obtained at 2hr and 24hr post-apoptosis to represent early stages in the initiation of bone remodeling in the following groups:

A) Apoptotic osteocytes (i.e. osteocytes at microdamage)

B) Healthy osteocytes treated with apoptosis conditioned medium (i.e. healthy osteocytes sensing apoptosis cues from microdamage)

C) Healthy osteocyte treated with non-apoptosis conditioned medium (i.e. healthy osteocytes in the absence of microdamage)

We measured soluble concentrations of RANKL, VEGF and M-CSF in conditioned medium, and conditioned medium effect on osteoclast formation/size.

Discussion:

Our findings indicate that both apoptotic osteocytes and apoptosis-conditioned healthy osteocytes are involved in regulating osteoclast formation, as was demonstrated by elevated soluble RANKL and VEGF concentrations in conditioned medium. Moreover, our results suggest that healthy osteocytes near apoptosis are not only responsible for initiating the resorption response, but also for confining osteoclasts to the apoptosis area, thereby creating a ''halo'' around the microdamage. These findings are first to provide a mechanism linking osteocyte apoptosis with bone microdamage, and suggest that osteocyte apoptosis both directly and indirectly regulates the initiation of targeted bone remodeling.

SA0265

Regulation of Osteoclast Formation by Pyruvate Kinase M2. Seong Sik Kim*[1], Ryan Ricofort[2], Eric Serrano[2], Jian Zuo[2], Alan Jenkins[2], John Neubert[2], Mathew Boxer[3], Douglas Auld[4], Craig Thomas[5], Lexie Holliday[2]. [1]Department of Orthodontics, College of Dentistry, Pusan National University, Pusan, Korea., South korea, [2]University of Florida College of Dentistry, USA, [3]NIH Chemical Genomics Center, National Human Genome Research Institute, National Institutes of Health, USA, [4]NIH Chemical Genomics Center, USA, [5]NIH Chemical Genomics Center, National Institutes of Health, USA

Recent studies suggest that a physical link occurs between the vacuolar H^+-ATPase (V-ATPase) and several glycolytic enzymes, and that these interactions are required for assembly of the V-ATPase (1). Given that osteoclasts express very high levels of V-ATPase, this predicts that increases in levels of glycolytic enzymes might be expected during osteoclast formation in order to support V-ATPase assembly. This study was initiated to test this prediction. By quantitative immunoblotting we found that aldolase, glyceraldehyde 3-phosphate dehydrogenase and phosphofructokinase all increased by approximately 10-fold relative to the level of actin during osteoclastogenesis. Because high levels of glycolytic enzymes are expressed in cancer cells and this is associated with a switch from utilization of pyruvate kinase M1 (PKM1) to the use of PKM2, we used an anti-PKM2 antibody in immunoblots to demonstrate high level expression of PKM2 in osteoclasts. RT-PCR was used to confirm the expression of PKM2 and PKM1. A small molecule activator of PKM2 (NCGC00185916-01; ref. 2) at a concentration of 1 micromolar increased the number of osteoclasts (tartrate-resistant acid phosphatase expressing multinuclear cells) formed during differentiation of RAW 264.7 cells stimulated by RANKL and mouse marrow osteoclasts stimulated by calcitriol by from 1.5 to 5-fold. Stimulaton was concentration-dependent with highest stimulation achieved at 1 micromolar of the activator. These data suggest that osteoclastogenesis is associated with expression of increased levels of several glycolytic enzymes and with the expression of PKM2. Osteoclast formation was significantly increased by a small molecule activator of PKM2. The unusual expression of glycolytic enzymes and the presence of PKM2 represent potential therapeutic targets for the treatment of osteoclast-mediated disease processes.

The RANK IVVY$^{535\text{-}538}$ Motif Plays a Critical Role in Tumor Necrosis Factor-α-mediated Osteoclastogenesis by Rendering Osteoclast Genes Responsive to Tumor Necrosis Factor-α. Joel Jules*, Zhenqi Shi, Xu Feng. University of Alabama at Birmingham, USA

Tumor necrosis factor-α (TNF), a proinflammatory cytokine, is implicated in bone loss stemming from various bone disorders, but its precise role in osteoclast (OC) formation remains controversial. While several groups showed that TNF can promote OC formation independent of RANKL, others demonstrated that TNF-mediated OC formation needs permissive levels of RANKL. To address this discrepancy, we independently examined the role of TNF in OC formation in culture dish and bone slices using primary bone marrow macrophages (BMMs). Our data indicate that OC formation in both conditions requires permissive levels of RANKL. Moreover, we show that TNF can stimulate OC formation from BMMs previously exposed to RANKL for as short as 6h. These data indicate that RANKL plays a critical role in TNF-mediated OC formation by priming BMMs into OC lineage. RANKL induces OC formation by activating the expression of numerous genes, including those encoding metallopeptidase 9, carbonic anhydrase 2, cathepsin K and tartrate resistant acid phosphatase. To investigate the molecular basis of the RANKL-mediated lineage commitment, we studied the effect of TNF on the expression of these genes. While TNF alone cannot activate the four genes, TNF is able to do so either in the presence of permissive levels of RANKL or from BMMs previously exposed to RANKL, indicating that the RANKL-mediated lineage commitment involves reprogramming of OC genes into an inducible state. We have previously shown that the RANK IVVY$^{535\text{-}538}$ motif plays a critical role in mediating OC lineage commitment. Hence, we examined whether this motif is involved in reprogramming of OC genes into an inducible state. To this end, we used 2 chimeras: Ch1 & Ch2. Ch1 comprises the human Fas external domain linked to the transmembrane & intracellular domains of normal RANK and Ch2 has inactivating mutations in the IVVY motif. The chimeras were activated by a human Fas activating antibody (Fas-AB), specific to human Fas, without affecting endogenous RANK or Fas. BMMs expressing Ch1 or Ch2 were pretreated with Fas-AB/M-CSF for 18h, followed by TNF/M-CSF for 96h. BMMs expressing Ch1, but not Ch2, formed OCs. More importantly, the expression of the four genes in BMMs expressing Ch1, but not Ch2, was activated by TNF stimulation. Taken together, we conclude that the RANK IVVY motif plays a crucial role in TNF-mediated OC formation by reprogramming of OC genes into an inducible state in which they can be activated by TNF.

Characterization of the V-ATPase *a3*-B2 Subunit Interaction. Norbert Kartner*[1], Yeqi Yao[2], Keying Li[3], Morris Manolson[1]. [1]University of Toronto, Canada, [2]Faculty of Dentisty, University of Toronto, Canada, [3]Faculty of Dentistry, University of Toronto, Canada

V-ATPases are highly expressed in ruffled borders of bone-resorbing osteoclasts, where they play a crucial role in skeletal remodeling. V-ATPases are composed of at least 14 subunits, some of which have multiple isoforms. Mammalian cells have 4 isoforms of the a subunit (a1-a4) and two isoforms of the B subunit (B1 and B2). To discover protein-protein interactions with the a subunit in mammalian V-ATPases, a GAL4 activation-domain fusion library was constructed from an in vitro osteoclast model, RANKL-differentiated RAW 264.7 cells. This library was screened with a bait construct consisting of GAL4 binding-domain fused to the 50 kDa N-terminal cytoplasmic domain of V-ATPase a3 subunit (NTa3), the a subunit isoform that is highly expressed in osteoclasts. One of the prey proteins identified was the V-ATPase B2 subunit, which is also highly expressed in osteoclasts. Further characterization, using affinity pulldowns and solid-phase binding assays, revealed an interaction of apparent high affinity between NTa3 and C-terminal domains of both B1 and B2 subunits. Dual B-binding domains of equal apparent affinity were observed in NTa3, suggesting a possible model for interaction between these subunits in the V-ATPase complex. There did not appear to be any discrimination between binding of B1 or B2 subunits by the four mouse isoforms of the a subunit; however, the a3-B2 interaction appeared to be favored over a1, a2 and a4 interactions with B2, suggesting a

mechanism for the specific subunit assembly of plasma membrane V-ATPase in osteoclasts. We present here a novel model for interaction of the NTa domain with the catalytic headpiece of V-ATPase, which takes into account all known intra-complex interactions with NTa. Further understanding of these interactions could aid in the design of targeted therapeutics for bone loss disorders, such as osteoporosis and rheumatoid arthritis. With this goal in mind, we have used the a3-B2 solid-phase binding assay to screen synthetic chemical compound libraries for inhibitors of the interaction. One inhibitor of the a3-B2 interaction was useful in inhibiting acid secretion by osteoclasts in vitro, suggesting that the a3-B2 interaction is of importance in maintaining V-ATPase proton-translocating activity at the osteoclast ruffled border (see abstract, The benzohydrazide derivative KM91104 inhibits osteoclast mineral resorption at μM concentrations that do not affect osteoclast differentiation or fusion. Crasto et al.).

Patients and mice with mutations reducing the ability of the osteoclasts to secrete acid have osteopetrosis, characterized by defective bone resorption, increased osteoclast numbers, and interestingly normal or even increased bone formation. However, the developmental nature of these phenotypes limits the general applicability of these findings.

To shed light on bone turnover and coupling in osteopetrosis, independent of bone development, we transplanted three-month old mice with hematopoietic stem cells from wt or oc/oc mice, which have defective acid secretion and bone resorption. Changes in bone turnover and structure were investigated in detail during a three month period, which was followed up by a six month study, to allow time for a more drastic change in bone phenotype.

Adult mice were irradiated and transplanted with fetal liver cells from wt or oc/oc mice (Ly5.2 background) by IV injection into wt mice (Ly5.1 background). Engraftment levels were assessed using flow cytometry of the Ly5.2/Ly5.1 ratio. Serum samples were collected every sixth week for measurement of bone turnover markers (CTX-I, PINP, ALP and TRACP 5b). At 12 and 28 weeks the animals were euthanized and bones were collected for histomorphometry, μCT and mechanical tests.

An engraftment level >95% was obtained. The resorption marker CTX-I was reduced in both 3 and 6 month cohorts throughout the timeline, while TRACP 5b was increased in the oc/oc group compared to wt/wt. The bone formation markers PINP and ALP were elevated, when comparing the oc/oc group to wt/wt. μCT analyses of femurs and vertebrae showed a 50% increased bone volume in trabecular and 20% in cortical compartments of oc/oc mice compared to wt. Bone histomorphometry confirms the increased bone volume found in μCT analysis. Furthermore, mechanical tests showed a 35% increase in bone strength in the femoral neck and diaphysis of oc/oc mice compared to wt, as well as a trend in the vertebrae. Bonestrength and volume continue to increase from 3 to 6 months.

In conclusion, we here present data showing that bone formation is uncoupled from bone resorption in adult mice, when the osteoclasts are unable to acidify the resorption lacunae. The observed increase in non-resorbing osteoclasts strongly suggests that bone formation is controlled by the osteoclasts, but not their resorptive activity, and that this uncoupling leads to increased bone quality.

Expression and Activity of Cholinergic Receptors in Osteoclasts. Arik Bar*[1], Alon Bajayo[1], malka Attar[1], Alberta Zallone[2], Itai Bab[1]. [1]The Hebrew University, Israel, [2]University of Bari Medical School, Italy

Acetylcholine receptors have been reported in osteoblasts but not in osteoclasts. In the present study we have systematically scanned mouse bone marrow-derived monocytes and osteoclasts cultures for the expression and activity of these receptors. RT-PCR analysis revealed the absence of mRNA transcripts for neither of the five known muscarinic receptors. mRNA expression was found mainly for the nicotinic acetylcholine receptor (nAChR) α2 and β2 subunits. Quantitative mRNA analysis indicated a marked increase in the expression of these subunits during osteoclastogenesis. In addition, weaker signals were noted for the nAChR γ, δ and α10 subunits in monocytes and β1, δ and β4 in osteoclasts. The presence of α2 and β2 subunits in osteoclasts was confirmed by immunocytochemistry and in vivo immunohistochemistry. To assess the effect of nAChR activation on osteoclastogenesis and bone resorption, osteoclastogenic cultures (grown in the presence of M-CSF and RANKL) were challenged with the cholinergic agonists nicotine or carbamylcholine. Three-day cultures showed a dose dependent increase in the number of TRAP-positive multinucleated cells. The maximal increase (60 %) was at 10^{-8}-10^{-6} M agonist concentration. By contrast, four-day cultures showed a decrease (60 %) in the number of intact osteoclasts at the same agonist dose range. This decrease was associated with a more than 15-fold increase in the number of apoptotic osteoclasts. Resorption analysis on dentine slices demonstrated no effect on pit number, but a 50 % reduction in pit size. Taken together, these data suggest a significant role for nAChR signaling in the inhibition of bone resorption, which results from the early formation of immature osteoclasts and their enhanced death.

Osteoclast Inhibitory Peptide-1 Binding to the FcγRIIB Modulates ITIM and ITAM Signaling in Preosteoclast Cells. Srinivasan Shanmugarajan*[1], Craig C. Beeson[2], Sakamuri Reddy[1]. [1]Charles P. Darby Children's Research Institute, USA, [2]Medical University of South Carolina, USA

Osteoclast inhibitory peptide-1 (OIP-1/hSca) is an autocrine/paracrine inhibitor of osteoclast differentiation, and mice that over-express OIP-1 in osteoclast lineage cells develop an osteopetrosis bone phenotype. We recently demonstrated that OIP-1 binding to the FcγRIIB inhibits osteoclast differentiation, however the underlying molecular mechanism is unclear. Immunoreceptor tyrosine-based activation motif (ITAM)-bearing common γ subunit of FcRs (FcγRI and FcγRIII) and DAP12 are crucial for osteoclast development. Further, Immunoreceptor tyrosine-based inhibitory motif (ITIM) bearing FcγRIIB adapter proteins known to inhibit ITAM signaling in immune cells. Therefore, we examined the OIP-1 inhibition of FcR signaling during osteoclast differentiation. Total cell lysates obtained from the OIP-1 mice derived preosteoclast cells stimulated with RANKL demonstrated increased levels (4-fold) of (ITIM) phosphorylation of FcγRIIB compared to wild-type (WT) mice. In contrast, OIP-1 mouse derived preosteoclasts cells stimulated with RANKL demonstrated inhibition of ITAM phosphorylation of FcRγ but not DAP12. Also, OIP-1 c-peptide treatment to preosteoclast cells obtained from FcγRII$^{-/-}$ deficient mice showed no significant change in the phosphorylation of ITAM. Moreover, evidence suggesting that the tyrosyl-phosphorylated ITIM has affinity with cytoplasmic SH2 domain-containing phosphatases like SHP1, SHP2 and SHIP proteins. Further studies indicate that these inhibitory proteins dephosphorylate tyrosines in ITAM bearing Fc receptors. Total cell lysates obtained from OIP-1 mice derived preosteoclast cells stimulated with RANKL demonstrated a 3-fold increase in phosphorylation of SHP1 but not SHP2. Also, there is no significant change in the levels of phospho-SH2 inositol 5-phosphatases (pSHIP1 and pSHIP2). Interestingly, preosteoclast cells from OIP-1 mice stimulated with RANKL had a 4.5-fold decrease in the levels of ITAM activating phospho-Syk compared to WT mice. These results suggest that cross-regulation of ITIM and ITAM bearing Fc receptors may play a role in OIP-1 suppression of Syk activation and inhibition of osteoclast differentiation. Thus, OIP-1 may have therapeutic utility for bone diseases with high bone turnover.

Peroxiredoxin II Negatively Regulates LPS-induced Differentiation and Bone Resorption. Mijung Yim[1], Hyojung Park*[2]. [1]Sookmyung Women's University, South korea, [2]Sookmyung Women's University, South korea

Lipopolysaccharide (LPS) is pathogen that causes inflammatory bone loss. LPS has been known to induce the osteoclast formation from osteoclast precursors, which mediates NF-kB and other signaling molecules. Recent study showed that peroxiredoxin II (Prx II) is an essential negative regulator of LPS-induced inflammatory signaling. Prx II is a member of antioxidant enzyme family and plays a protective role against oxidative damage caused by reactive oxygen species (ROS). In this study, we investigated the role of Prx II in LPS induced-osteoclast formation using Prx II-deficient mice. We cultured wild-type and Prx II-deficient spleen cells with RANKL for 48 hours and used as osteoclast precursors throughout the study. When 2 types of cell were treated with LPS, as compared to wild-type cells, osteoclast formation was enhanced in PrxII-deficient cells. To gain molecular insight, we examined the effect of PrxII-deficiency on signaling pathways and transcription factors. The expression of NFATc1, a master regulator of osteoclast differentiation, was enhanced in Prx II-deficient cells. Although LPS did not show different activation patterns of IkB, ERK 1/2, p38 MAPK pathways between wild-type and PrxII-deficient cells, LPS increased the expression of proinflammatory cytokines, IL-1 and

IL-6. Furthermore, NO production and iNOS expression is accelerated in PrxII-deficient cells. Also, ROS production is enhanced in PrxII-deficient cells, interestingly, activation of signal transducers and activators of transcription 3 (STAT3) is promoted in PrxII-deficient cells. These results show that PrxII modulates LPS-induced osteoclast differentiation through controlling ROS-related signaling. Consistent with the in vitro result, PrxII-deficient mice showed increased LPS-challenged bone loss. Taken together, PrxII negatively regulates LPS-induced osteoclast differentiation and bone loss. For further study, we continue to make progress in studies about the precise mechanism of Prx II in LPS-induced osteoclastogenesis.

SA0276

Spontaneous Rythmic Fluctuations of Osteoclasts Intracellular pH. Raif Musa-Aziz, Priscilla Morethson*. University of Sao Paulo, Brazil

Large amounts of acid are secreted into the resorption lacuna by the osteoclasts to promote bone mineral dissolution. This extracellular acidification is mediated by a vectorial proton secretion, one of the key elements of the osteoclast activity (Bruzzaniti A & Baron R, 2006) and may have an impact on osteoclast pH regulation. The vacuolar H^+-ATPase is the known mechanism related to the proton secretion; however, other proteins, such as Na^+/H^+ exchanger, the voltage-gated proton channel and a proton-coupled chloride transporter (CLC-7), are also expressed in osteoclasts and may be implicated in the proton secretion process. The role of the aforementioned mechanisms and their interplay during the osteoclast proton secretion are still poorly understood.

This work was performed to evaluate which are the mechanisms involved with proton transport at the osteoclast plasma membrane and their function in the intracellular pH (pHi) regulation. To address these questions, we worked with freshly isolated osteoclasts from long bones or osteoclast-like (OCL) cells generated from bone marrow precursor cells (using M-CSF and RANK-L) of Wistar rats. The cells were plated on glass or plastic coverslips in α-MEM + 10% FBS, pH 7.4, placed in a 5% CO_2 incubator at 37°C. At the time of the experiments, osteoclasts and OCL-cells were identified by their morphology using enhanced contrast microscopy and, for some experiments, a further confirmation of the cell phenotype was done by cytochemistry for TRAP or immunocytochemistry for calcitonin receptor. The pHi was measured using the probe BCECF. The emitted fluorescence ratios (R) after excitation of intracellular BCECF at 490 and 440 nm (R = 490/440) were converted to pHi using the high-K^+ nigericin technique. The experiments were performed in the presence of standard HEPES solution free of CO_2/HCO_3^-, pH 7.4, 37°C, without perfusion (''basal conditions'').

Under these conditions, our preliminary data show that the osteoclasts exhibit cyclic pHi variations characterized by repeated periods of spontaneous acidification and alkalinization. These cyclic pHi variations seem to be regular, with a frequency of 14.5 ± 1.1 min, n=11, and an amplitude—difference between maximal and minimal pHi—of 1.59 ± 0.02 pH units, n=3.

Our data suggest that, at ''basal conditions'', osteoclasts do not maintain a constant pHi but, instead, these cells seem to exhibit an oscillatory pHi pattern that may be independent of any stimulus or acid challenge.

P62, PKCzeta and NF-kappaB Signaling in Human Osteoclasts: a Link With Paget's Disease of Bone. Estelle Chamoux*[1], Martine Bisson[2], Laetitia Michou[3], Jacques Brown[4], Sophie Roux[2]. [1]Centre Hospitalier Universitaire Sherbrooke, Canada, [2]University of Sherbrooke, Canada, [3]Centre De Recherche Du Chuq-Chul, Canada, [4]Laval University, Canada

In Paget's Disease of Bone (PDB), osteoclasts (OCs) are larger, more numerous and more active than healthy ones. PDB has been linked to mutations of the sequestosome1 (SQSTM1) gene encoding the protein p62. The most prevalent p62 P392L mutation promotes an active OC phenotype, with a basal and constitutive activation of PKCζ and NF-κB (Chamoux et al, Mol Endocrinol 2009). However, the mechanisms by which the P392L mutation alters p62-associated pathways remain to be investigated. In the present work, OCs generated from cord blood monocytes were transfected with vectors containing the wild-type or mutated p62 gene. Using immunoprecipitations, we determined that p62 associates time-dependently with IκB and that significant degradation of IκB occurs after RANKL stimulation, an effect enhanced by the over-expression of p62WT but prevented by a preincubation with MG-132, a proteasome inhibitor. However, in cells expressing the $p62^{P392L}$ variant, increased expression of IκB was detected in non-stimulated cells, which remained relatively high in the presence of MG132. In addition, we showed that p62/IκB interactions were less consistent in these cells, thus indicating that the p62 mutation may alter the function of p62 in NF-κB signaling by decreasing its capacity to bind IκB, and thus to shuttle this factor towards the proteasome. In order to reconcile these results with our previous observations showing that $p62^{P392L}$ expression lead to over-active OCs, we evaluated the role of PKCζ as a potential intermediate between p62 and NF-κB. The use of a myristoylated PKCζ inhibitor prior to RANKL stimulation significantly decreased NF-κB activation in non-transfected OCs. Moreover, the PKCζ inhibitor abolished both the baseline and RANKL-induced increase in NF-κB activation observed in OCs expressing $p62^{P392L}$ but had only limited effects in $p62^{WT}$-expressing cells, and tended to decrease the area of bone resorbed by $p62^{P392L}$-expressing OCs. Thus, our results suggest that the reduced proteasomal degradation of IκB and the increased PKCζ activation both contribute to the resulting NF-κB activation. While the P392L mutation in p62 renders the proteasomal pathway inefficient, it over-activates the PKCζ pathway leading to uncontrolled NF-κB functions and increased bone resorption. The present study highlights for the first time a double function of p62 and clearly points out the importance of PKCζ in the phenotypic changes specific to the P392L mutation in human OCs.

The Dynamin GTPase-induced Dephosphorylation of Pyk2 is Mediated by PTP-PEST and Regulates Osteoclast Bone Resorption. Pierre Eleniste*[1], Angela Bruzzaniti[2]. [1]Indiana University-Purdue University Indianapolis, USA, [2]Indiana University School of Dentistry, USA

Osteoporosis is a bone disease that affects millions of people worldwide and is characterized by low bone mass and structural deterioration of bone tissue, which increases the risk of bone fracture, frailty, morbidity and mortality. Excessive bone loss is caused by the activity of osteoclasts which degrade the bone matrix. The specific aim of this study is to identify and characterize the signaling proteins in osteoclasts that regulate the bone resorbing activity of these cells. The non-receptor tyrosine kinase Pyk2is highly expressed in osteoclasts, and mice lacking Pyk2 have an increase in bone mass due to impairment in the cytoskeletal organization and bone resorbing activity of osteoclasts. Following integrin activation, Pyk2 is activated by phosphorylation at Y402, which is necessary for its full kinase activity, and consequently for osteoclast spreading and bone resorption. We previously reported that the GTPase dynamin regulates osteoclast bone resorption in part by leading to the dephosphorylation of Pyk2 at Y402, thus decreasing Pyk2's kinase activity and its ability to bind to Src and downstream signaling proteins. In the current study we examined the intracellular mechanism by which dynamin leads to the dephosphorylation of Pyk2. We report that Pyk2 associates with dynamin via a unique mechanism involving Pyk2's N-terminal domain, most likely its FERM domain, and dynamin's plextrin homology domain. In addition, Pyk2 dephosphorylation requires dynamin's GTPase activity since expression of specific dynamin mutants that have either reduced affinity for GTP or exhibit defective GTPase activity significantly rescue Pyk2-Y402 phosphorylation. Moreover, we find that Pyk2 phosphorylation is rescued in the presence of chemical inhibitors of the tyrosine phosphatases and we identified PTP-PEST as a major phosphatase involved in the dynamin-mediated dephosphorylation of Pyk2. Together, our studies suggest that dynamin and PTP-PEST associate with Pyk2 and regulate the cyclic phosphorylation and dephosphorylation of Pyk2, which is critical for integrin signaling, podosome turnover and osteoclast attachment, migration and bone resorbing activity. Understanding the role of Pyk2 and dynamin and the intracellular mechanism that regulates osteoclast function may lead to the identification of novel therapeutic targets for the treatment of bone-related diseases such as osteoporosis.

Evidence that Sclerostin is a Locally Acting Regulator of Osteoblast to Osteocyte Transition and a Master Regulator of Mineralization. Gerald Atkins*[1], Asiri Wijenayaka[1], Katie Welldon[1], Peter Rowe[2], David Findlay[1], Hui Peng Lim[1]. [1]University of Adelaide, Australia, [2]University of Kansas Medical Center, USA

Sclerostin is a product of mature osteocytes embedded in mineralised bone and is a negative regulator of bone mass and osteoblast differentiation. The identity of the cells that respond to sclerostin has not been identified, although the localized expression of sclerostin implies that it may have local paracrine or autocrine activities. We tested the hypothesis that sclerostin would regulate the behaviour of the cells actively involved in mineralisation, the late osteoblast or pre-osteocyte. First, long-term cultures of differentiating human primary osteoblastic cells (HO) were exposed to chronic levels of recombinant sclerostin. Significant inhibition of in vitro mineralization occurred in a dose-dependent manner. Analysis of gene expression revealed that sclerostin decreased the expression of mature osteocyte markers, DMP1 and that of SOST itself, whereas the expression of the pre-osteocyte marker E11 was increased. E11 expression was also increased by sclerostin in the MLO-Y4 osteocyte cell line. To separate possible effects on immature cells, primary HO were cultured for 5 weeks, a process that served to differentiate the cells to a post-proliferative and more uniformly mature, pre-osteocyte stage. Cultures were then exposed acutely to sclerostin and gene expression analysed. These cells were exquisitely sensitive to sclerostin and concentrations of 1 – 50 ng/ml consistently increased the expression of E11, while decreasing the expression of the mature markers DMP1 and SOST. Concomitantly, the expression of MEPE was increased by sclerostin, at both the mRNA and protein levels and PHEX mRNA was decreased. This implies that mature osteocytes, by virtue of their expression of sclerostin, are able to impede differentiation of pre-osteocytes as well as alter levels of key regulators of bone mineralization. Consistent with this, MEPE protein levels were increased by sclerostin and immunostaining revealed that sclerostin promoted an increase in the levels of the MEPE-ASARM peptide, shown previously to bind to and inhibit the growth of nascent bone mineral. Our results suggest that sclerostin acts through regulation of the PHEX/MEPE axis and behaves as a master regulator of physiological bone formation, in a local paracrine fashion. The regulation by sclerostin that we have identified of both pre-osteocyte and osteocyte activity is consistent with its localization in the bone and its established role in the inhibition of bone formation.

Effect of Intermittent PTH (1-34) Treatment on Osteocyte Lacunae in Ovariectomized Rats. Donald Kimmel*[1], Susan Candell[2], Tiffany Fong[3], Jack Coats[4], Mohammed Akhter[5], Thomas Wronski[6]. [1]Kimmel Consulting Services, USA, [2]Xradia Inc., USA, [3]Xradia Inc, USA, [4]Xradia, USA, [5]Creighton University Osteoporosis Research Center, USA, [6]University of Florida, USA

Parathyroid hormone (PTH) increases serum calcium by several mechanisms including osteocyte (Ocy) activity that may release mineral from bone and increase Ocy lacunar (Ocy.La) size. The purpose of this work is to quantify Ocy.La density and volume in mineralized bone tissue of PTH-treated rats by 3D Xray microscopic imaging.

Female rats aged 13wks were ovariectomized (OVX) (N=24). After 6wks, rats were treated subcutaneously for 16wks with 0 [Veh] or 0.05 mg/kg PTH (1-34) (Bachem) 5d/wk. Tibiae and L2 vertebrae (L2V) were fixed in 10% PO4-buffered formalin for 24hrs, then stored in 70% ethanol. Histomorphometric studies showed typical PTH-related increases in proximal tibial cancellous bone volume and bone formation rate. L2V (4/grp) were trimmed of posterior and transverse processes, leaving whole L2 body (L2VB) samples measuring 12mm diameter X 8mm long. These were scanned (5μm pixel resolution [PR]; 125μm^3 voxel resolution [VR]) with a 3D Xray microscope (XCT-200). 3D images were reconstructed and a 1.5mm diameter subregion (0.5-1.3mm distal to the cranial growth plate) rich in trabecular bone was identified and re-scanned (0.9μm PR; 0.729μm^3 VR). 3D images were reconstructed and multiple 0.9μm PR 2D slices from each rat were reviewed (Figures). While Ocy.La were more visible in some (Fig 2) than others (Fig 1), automated quantitation of Ocy.La density and volume by segmentation software could not be completed due to insufficient resolution. Blind-coded, randomized 2D slices from all rats were ranked [0-3 semi-quantitative scale (Figs 1 and 2)] independently by all authors for Ocy.La visibility. Combined scores (mean $\pm$ SD) were respectively, 0.63 ± 0.46 [Veh] and 2.23 ± 0.50 [PTH] ($P < .001$, Mann-Whitney U).

The semi-quantitative data indicate that each author considered Ocy.La more visible in PTH than Veh rats, perhaps suggesting that Ocy.La are larger in PTH rats than in Veh rats. We also conclude that while images acquired at 0.9μm PR seem acceptable for qualitatively evaluating Ocy.La, images with better than 0.9μm PR are required to facilitate automated analysis of Ocy.La density and volume by segmentation software. Trabecular bone rich specimens from all rats, cut from plastic-embedded L2VBs and measuring 2mmX2mmX8mm, are being re-scanned at 0.125μm^3 VR (0.5μm PR), a resolution that was previously proven sufficient to allow automated analysis of Ocy.La properties in human bone.

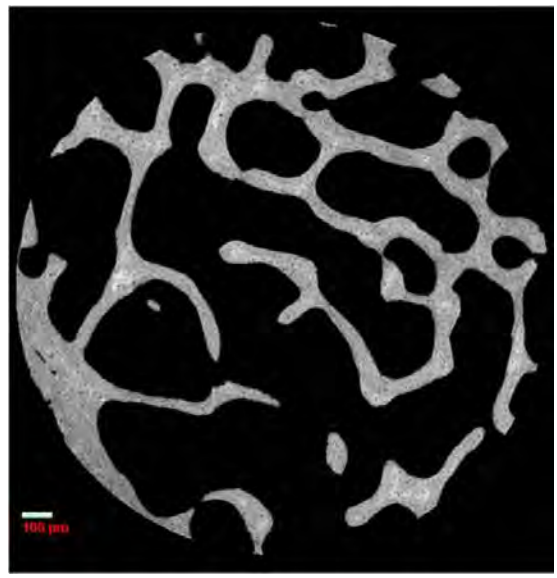

Fig. 1. 2D Xray microscopic image of rat vertebral trabecular bone. Few Ocy.La are visible (Rank=0).

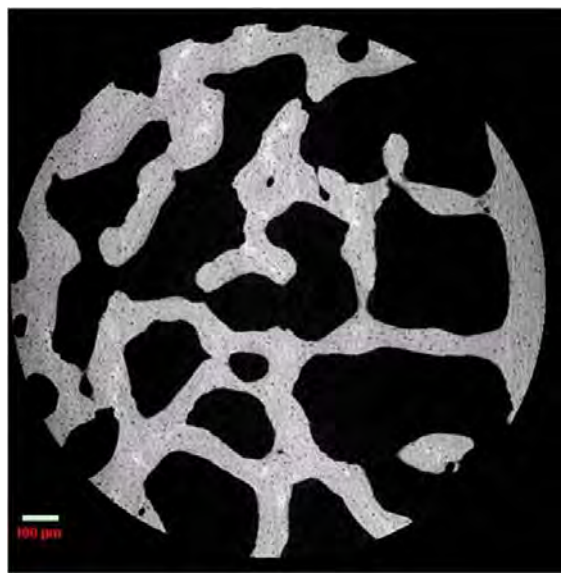

Fig. 2. Many Ocy.La are visible (black dots) (Rank=3).

Association of Changes in Serum Levels of Intact Parathyroid Hormone with Changes in Biochemical Markers of Bone Turnover and Bone Mineral Density: A 10-year Follow-up of the Taiji Cohort. Noriko Yoshimura*[1], Shigeyuki Muraki[1], Hiroyuki Oka[1], Hiroshi Kawaguchi[2], Kozo Nakamura[3], Toru Akune[1]. [1]University of Tokyo, Japan, [2]University of Tokyo, Faculty of Medicine, Japan, [3]The University of Tokyo, Japan

The aim of this 10-year prospective cohort study is to evaluate changes in the serum levels of intact parathyroid hormone (iPTH) in the general population, and to assess the association of these changes with changes in biochemical bone-turnover markers (BTMs) and bone mineral density (BMD). We randomly selected 400 individuals (aged 40–79 years; 50 men and women in each of 4 age groups) from a list of registered residents of Taiji in 1993 (baseline). The BMD and various serum markers, namely, iPTH, total osteocalcin (OC), beta-C-terminal cross-linking telopeptide of type I collagen (beta-CTX), and N-terminal cross-linking telopeptide of type I collagen (NTX), were measured in the lumbar spine and femoral neck of the participants, at baseline and in the 10-year follow-up survey. The blood and BMD examinations could be performed at both time points in 317 of the 400 subjects (79.3%; 149 men and 168 women). The mean (standard deviation) serum levels of iPTH at baseline were 26.9 (11.0) pg/mL in men and 28.8 (12.6) pg/mL in women. Six individuals (1 man and 5 women) whose iPTH levels were higher than 65 pg/mL (65.02-79.1 pg/mL) at baseline were included in the follow-up analysis. After 10 years, the mean iPTH levels were 32.1 (12.3) pg/mL in men and 32.3 (12.9) pg/mL in women. The serum iPTH levels tended to increase over 10 years in both genders ($p < 0.0001$ in men, $p = 0.059$ in women). Multivariate regression analysis after adjustment for age, body mass index (kg/m^2), and menstrual status in females (0: normal menstruation, 1: irregular, 2: menopause) at baseline revealed that the changes in the serum iPTH levels were significantly positively associated with the changes in the levels of total OC (men: $\beta = 0.25$, $p = 0.002$; women: $\beta = 0.19$, $p = 0.03$), beta-CTX (men: $\beta = 0.44$, $p = 0.000$; women: $\beta = 0.27$, $p = 0.002$), and NTX in women ($\beta = 0.22$, $p = 0.01$). Multivariate regression analysis after adjustment for the above-mentioned confounders revealed a significant inverse relationship between changes in the serum iPTH levels and changes in the BMD of the femoral neck in women ($\beta = -0.19$, $p = 0.02$). An increase in the serum iPTH levels was found to be related to an increase in all BTM levels in both genders, with the exception of NTX in men. These findings confirmed that the serum iPTH levels were associated with bone metabolism, while they had a limited effect on changes of BMD over 10 years.

SA0293

Is Bone Turnover Adequately Suppressed in Osteoporotic Patients, Treated with Bisphosphonates, in Daily Practice? Danielle Eekman*[1], Ben A.C. Dijkmans[2], Willem Lems[3], Annemieke C. Heijboer[2], Irene E.M. Bultink[2]. [1]VU University Medical Center, The netherlands, [2]VU University Medical Center, Netherlands, [3]Vrije Universiteit Medical Centre, The netherlands

Purpose: In patients with osteoporosis persistence is generally poor. It has been suggested that monitoring therapy by measurement of bone turnover markers (BTM) after 3 months of anti-resorptive therapy might improve persistence.

Methods: We investigated serum bone marker levels in two groups. The first group consisted of patients newly diagnosed with osteoporosis and starting treatment with bisphosphonates. We observed which proportion shows a decrease of BTM of $\geqslant 30\%$ (the least significant change). Serum levels of procollagen type 1 N-terminal propeptide (P1NP) and C-terminal crosslinking telopeptide (CTX) were determined before the start of treatment and after > 2 months of treatment. Secondly, P1NP and CTX levels were measured cross sectionally in a group of patients who were already treated with bisphosphonates for $\geqslant 3$ months. We observed which proportion reached the biological goal of therapy, BTM in the lower half of the normal premenopausal range. We also measured P1NP and CTX in a reference population of 34 healthy premenopausal women.

Results: In the first group 32 patients were included (23 women) mean age 66. During a mean treatment period of 4 months the P1NP and CTX level decreased significantly with 50% and 63% respectively. In 26 patients (81%) levels of both markers decreased with $\geqslant 30\%$. In 6 patients bone turnover was not adequately decreased, probably related to non-compliance (1), prednisone use (1), alcohol abuse (1), decreased mobility (1), paraproteinemia (1) and low calcium intake (1).

In the second group 96 patients were included, mostly women, aged 67. In 95% the serum P1NP levels and CTX levels were in the lower half of the premenopausal range. In 6 of the 7 patients with a level above the premenopausal range a possible explanation could be found: non-adherence (1), non-compliance (2), immobility (1), rheumatoid arthritis (1) and polymyositis and phenytoin use (1).

Conclusion: Our data illustrate that a decrease in bone turnover greater than the LSC can be observed in the majority (81%) of newly treated patients. Of chronically treated patients 95% have a BTM in the premenopausal range. In most patients an explanation for inadeqauate suppression of bone turnover was available. Monitoring treatment effect with bone turnover markers is in daily practice is feasible, and might be an additive tool in improving compliance.

Is Isolated serum 25-Hydroxyvitamin D Measurement to assess Vitamin D Nutritional Status Clinically Relevant? Nayana Parikh*, Tarlisha Eskridge, Leila Idi, Shijing Qiu, Sudhaker Rao. Henry Ford Hospital, USA

There has been growing interest in assessing vitamin D nutrition (VDN) in patients in general and those with bone & mineral disorders in particular. However, there are no guidelines for screening in the general population. Nevertheless, the number of 25-OHD measurements has increased exponentially in the last 2 years especially the number with isolated 25-OHD measurements. The clinical relevance of such practice is yet to be established. Accordingly, we reviewed serum 25-OHD testing in the lab over 5 years to determine the prevalence of 25-OHD measurements with and without simultaneous measurement of serum PTH levels and the relationship between the two, and develop guidelines for appropriate interpretation of serum 25-OHD levels in clinical practice.

Methods: We included all measurements from 2005 to 2009 for both PTH and 25-OHD. The relevant data are summarized in the Table.

Results: While the number of PTH testing remained relatively constant over the 5 years, the number of 25-OHD measurements increased by 9 folds, mostly in the last 2 years. More importantly, the number of isolated 25-OHD measurements as a fraction of total 25-OHD measurements increased from 28% in 2005 to 80% in 2009, again mostly in the last 2 years. However, the fraction of 25-OHD tests <30 ng/ml, a consensus cut-off for optimal VDN, remained constant throughout the 5 year period. There was the expected significant inverse relationship between 25-OHD and PTH both within each year and for the entire cohort, without significant difference between the 5 yearly slopes.

Conclusions: The exponential increase in 25-OHD measurements suggests increased awareness of VDN among clinicians. However, the relevance of isolated 25-OHD measurement without PTH may overestimate vitamin D depletion (because of seasonal or recent vitamin D deficiency) and the need for pharmacologic vitamin D supplementation. Further studies are needed to determine the clinical implications of an isolated 25-OHD measurement to assess VDN.

Measurement	2005	2006	2007	2008	2009
PTH Tests (Total #)	10937	12810	15426	17149	18209
25-OHD Tests (Total #)	7530	11762	19644	35687	64993

Serum Levels of Cathepsin K and Bone Turnover Markers are Decreased in Patients with Type 2 Diabetes. Pedro Rozas*[1], Rebeca Reyes[2], Antonia García-Martín[3], Maria Dolores Perez-Avilés[3], Mariela Vasavsky[3], Manuel Munoz-Torres[4]. [1]Hospital General, Spain, [2]Bone Metabolic Unit., Spain, [3]Bone Metabolic Unit. Endocrinology Division. San Cecilio University Hospital., Spain, [4]University Hospital, Spain

Background: Studies of bone resorption in diabetes are limited, and the results are conflicting. Aim: To analyse serum levels of bone turnover markers (BTM), cathepsin K, PTH-i and 25 OH vitamin D in patients with type 2 diabetes mellitus (T2DM) and the relationship with bone mineral density (BMD). To compare BTM and cathepsin K levels between T2DM and controls. Patients and methods: Case-Control study including 133 subjects, 78 patients with T2DM and 55 healthy controls. Lumbar spine and femoral BMD were measured by dual X-Ray absorptiometry (Hologic QDR 4500). We measured: bone alkaline phosphatase (b-ALP) (OCTEIATM IDS Ltd Boldon UK), osteocalcin (OC) (DiaSorin, Stillwater, Minnesota USA; tartrate resistant acid phosphatase (TRAP) (Bone TRAP ® Assay IDS Ltd); CTX (Elecsys ß Cross-Laps,Roche Diagnostics SL, Barcelona, Spain); Serum cathepsin K levels by ELISA (Biomedica Medizinprodukte GhbH & Co KG Wien, Austria). PTH-i (Intact PTH, Roche Diagnostics SL); 25 OH vitamin D (25-Hydroxyvitamin D 125I RIA DiaSorin). Results: Mean age was 56,7$\pm$ 6,8 yr (57.8$\pm$ 6.4 and 55,1$\pm$ 7,1 in T2DM and control group respectively; p=0.024). Among the T2DM patients (n=78), 47.2% were females (n=35) and 52.8% males (n=43). Serum levels of bone resorption markers were lower in T2DM compared with controls (TRAP: T2DM 1.39$\pm$0.99 UI/l vs controls 1.85$\pm$0.81 UI/l, p<0.05; CTX: T2DM 0.20$\pm$0.12 ng/ml vs controls 0.33$\pm$0.15 ng/ml, p<0.05). There were no differences in bone formation markers (b-ALP: T2DM 14.83$\pm$6.5 ug/L vs controls 12.96$\pm$6.73 ug/L, p 0.11; OC: T2DM 1.48$\pm$1.25 ng/ml vs controls 1.45$\pm$1.2 ng/ml, p 0.91). In the subgroup of patients where cathepsin K serum levels were measured (27 T2DM, 11 controls), T2DM presented lower levels although this difference was not significant (T2DM 4.36$\pm$5.46 pmol/l vs controls 6.56$\pm$10.13 pmol/l, p 0.39). PTH-i serum levels were lower in T2DM (PTH-i: T2DM 38.35$\pm$18.20 pg/ml vs controls 50.22$\pm$18.99 pg/ml, p<0.05). T2DM have lower levels of 25 OH vitamin D with respect to controls, although differences were not significant (T2DM 17.81$\pm$11.14 ng/ml vs controls 21.30$\pm$11.05 ng/ml, p 0.07). In T2DM there was a negative correlation between CTX levels and BMD at different sites (p<0.001). Conclusions: T2DM patients have lower levels of bone resorption markers and PTH-i compared with controls. Cathepsin K serum levels seem to be lower in T2DM, although larger studies are needed to clarify this significance of this finding.

Assessment of Tibial and Radial Peripheral Quantitative Computed Tomography: Precision Measurements. Charles Wisniewski*, Giulia Rinaldi, Nithya Setty, Meryl Leboff. Brigham & Women's Hospital, USA

Purpose: Peripheral Quantitative Computed Tomography (pQCT) measures true volumetric (3-dimensional) bone mineral density (vBMD) at the radius and tibia, with minimal radiation exposure. In addition, this technique discriminates cortical and trabecular compartments and cortical thickness. Assessment of the reproducibility of pQCT depends on the machine, technician and testing procedures. Sources of imprecision not related to the instrument are inexact repositioning of the subject in follow-up scans, anatomic site, reference line placement and movement artifacts. Methods: To determine the reproducibility of pQCT, we performed 3 repeated measurements in normal subjects ages 22-35 years within 2 months at the tibia (N=18) and at the radius (N=20) using pQCT (XCT 3000, Stratec, Germany). To minimize extremity movement and discomfort, customized arm and leg holders were used (Bone Diagnostic Inc, WI). We determined the percent coefficient of variation (%CV; standard deviation divided mean BMD times 100) and the least significant change (LSC; root mean square standard deviation times 2.77 for a 95% confidence level) for total area, total density and cortical thickness at each site (4% and 33% radius and 4% and 38% tibia), for trabecular density at the distal sites and for cortical density at the proximal sites of both limbs. Results: At all the tibial sites and proximal radius, the reproducibility (%CV) ranged from 0.34% to 2.41% (Tables 1 and 2). In contrast, the %CV at the 4% metaphyseal site at the radius was $>$ 5% in total area and density; %CV and LSC measures improved when cross sectional area (CSA) at the 4% radial site was within ± 10 mm^2 on repeated measures for each subject (J Musculoskelet Neuronal Interact. 2009 Jan-Mar;9(1):18-24) (Table 2). Cortical thickness at all sites, except at the radial 4%, showed a %CV below 1% and LSC of 0.082-0.42 (Tables 1 and 2). Conclusions: These data show that pQCT is a precise technique for measurements of vBMD and skeletal compartments of the extremities, but the 4% metaphyseal, radial site has the greatest variability. Thus, with standardized measurement procedures, pQCT is a valuable and precise clinical research tool for assessment of the therapeutic benefits of new treatment interventions on bone.

Combination of Bone Mineral Density and Trabecular Bone Score for vertebral fracture prediction in secondary osteoporosis. Sophie Bréban*[1], Sami Kolta[2], Karine Briot[3], Simon Paternotte[4], Mirieme Ghazi[4], Jacques Fechtenbaum[2], Maxime Dougados[4], Christian Roux[5]. [1]Cochin HospitalParis Descartes University, France, [2]Centre D'Evaluation, Des Maladies Osseuses, France, [3]Cochin Hospital, France, [4]Paris Descartes University, Cochin Hospital,Rheumatology Department, France, [5]Hospital Cochin, France

Rationale and objective: The relationship between decreased BMD and fracture risk is less clear in secondary osteoporosis than in post menopausal osteoporosis. The Trabecular Bone Score (TBS) is determined from a grey-level analysis of Dual X-ray Absorptiometry image and is thought to provide non quantitative information on bone. The aim of this study was to test the combination of TBS and BMD for vertebral fracture risk detection in a rheumatoid arthritis (RA) population treated (CS) or not (NCS) with glucocorticoids. Patients: 140 women aged 55.9 $\pm$ 14.0 years, with RA since 15.2 $\pm$ 10.2 years; 94 were receiving glucocorticoids (mean dose of 6.7 $\pm$ 4.7 mg/day) and 129 a disease modifying drug. Lumbar spine and hip BMD (g/cm^2) were assessed by DXA and TBS was applied to anteroposterior image of lumbar spine. Vertebral fractures from T4 to L4 were evaluated using Vertebral Fracture Assessment (VFA) software on DXA device.

Results: Mean spine and hip Tscores were -0.9 $\pm$ 1.4 and -1.6 $\pm$ 1.0, and -0.8 $\pm$ 1.5 and -1.5 $\pm$ 1.1, in patients with and without CS respectively. There was no difference in BMD between both groups, but TBS was 1.19 $\pm$ 0.11 and 1.23 $\pm$ 0.09 in CS and NCS groups respectively (p=0.03). TBS was significantly correlated to spine and hip BMD in all groups (r=0.52 to 0.61; p$<$0.0003). The vertebral fractures prevalence was 16.7% in the whole population, 23.9% in NCS group and 13.0% in CS group. In the whole population, the Area under the Curve (AUC) in the vertebral fracture risk prediction was higher in the TBS model (0.736) compared to the BMD model (0.670 for spine BMD; 0.705 for hip BMD; 0.708 for femoral neck BMD). We calculated a threshold of TBS (1.173) which corresponds to the best sensitivity (75%) and specificity (66%) according to ROC curves. Among patients without osteoporosis (n=97), 13 had vertebral fractures and 8 of them had a TBS lower than 1.173. Conclusion: Trabecular Bone Score provides additional information compared to BMD alone in vertebral fracture risk assessment, in RA population, with or without glucocorticoids. The bone parameters assessed by TBS need to be identified.

Comparison of a Prototype and Current DXA Whole Body Phantoms Provide Inconsistent Relationships. Cassidy Powers*[1], Bo Fan[2], Colin Miller[3], John Shepherd[2]. [1]Bone & Breast Density Group, University of California San Francisco, USA, [2]University of California, San Francisco, USA, [3]BioClinica, Inc. (formerly Bio-Imaging Technologies, Inc.), USA

PURPOSE: This study was conducted to determine if available whole body phantoms give consistent cross-calibration and quality control relationships between two DXA systems.

METHODS: A BioClinica whole body phantom prototype, the Hologic Whole Body Phantom (each containing an aluminum skeleton), and the BioImaging Variable Composition Phantom (VCP) were scanned 10 times (BioClinica and Hologic) and 5 times in three configurations (VCP) on the Lunar Prodigy and Hologic Discovery DXA scanners using whole body mode (smartscan off). Analysis was performed using Hologic Apex v3.0 (Hologic, Inc.) and Encore v13.2 (GE Healthcare, Inc.) software. Whole body and subregion ROIs were used on the BioClinica and Hologic phantoms to provide BMD, total mass, fat mass, lean mass, percent fat (pfat), BMC and area values. A centered subregion ROI was used to find pfat values for the VCP. Precision was described using means, SDs and %CVs.

RESULTS: The best precision was found using the Hologic WB phantom on both DXA systems. The total mass was very precise for both the BioClinica (17407.08 $\pm$ 42.03g, 16893.05 $\pm$ 53.40g) and Hologic (29147.17 $\pm$ 28.67g, 28274.97 $\pm$ 77.79g) phantoms. The Discovery produced better precision for BMD (0.98 $\pm$ 0.01, 1.10 $\pm$ 0.01) and area (516.44 $\pm$ 10.76, 651.21 $\pm$ 9.08) measures for the BioClinica and Hologic phantoms. It also gave better precision for total fat, lean, mass, and pfat for BioClinica (6413.86 $\pm$ 70.88, 10484.64 $\pm$ 81.01, 17407.08 $\pm$ 42.03, 36.84 $\pm$ 0.41, respectively). Total BMC (489.55 $\pm$ 7.58, 699.88 $\pm$ 6.07) was more precise on the Prodigy. The assumed single-point cross calibration between the Discovery and Prodigy was in good agreement for mass, BMD, and BMC, but soft tissue variables differed from 6.7 % (lean) to 18.0% (pfat) depending which phantom was used. However, the VCP showed a significant offset (7.4%) between the systems for pfat that could not have been predicted by the other two phantoms. Although small (n$\leq$30) in vivo cross calibration populations would provide some adjudication, the power is generally too poor to discern these calibration differences.

CONCLUSIONS: None of the phantoms tested were shown to be superior to the others. A universal standard of accuracy is greatly needed to determine truth in calibration for whole body DXA bone and soft tissue results. However, the phantoms may be useful for evaluation of consistent calibration on a single instrument.

Reducing Unneccessary BMD Testing in Healthy Women at Menopause. Gillian Hawker*[1], Susan Jaglal[2], Jacob Cancino-Romero[1], Arielle Mendel[1], Samra mian[1], Esther Waugh[1], Sophie Jamal[3]. [1]Women's College Hospital, Canada, [2]University of Toronto, Canada, [3]The University of Toronto, Canada

Purpose: Bone mineral density (BMD) testing rates are highest in women at menopause, when fracture risk is low. No BMD testing guidelines exist for this group. Thus, we determined risk factors for low BMD and their ability to discriminate those with/without low BMD in this group.

Methods: Women aged 40-60 years having their first BMD at an academic centre were assessed for osteoporosis (OP) risk factors and spine and hip BMD by dual x-ray absorptiometry. Risk factors were: age, weight, physical activity, smoking, alcohol, caffeine and calcium intake, age at menarche, parity, breastfeeding and menopausal status, and family/personal history of fracture > age 40. We excluded women with medical conditions linked to OP. Using logistic regression and bootstrap technique, we determined the model that best discriminated (using area under the curve, AUC) women with/without low BMD (any site t-score ≤ -2.0). For ease of use, continuous risk factors were then dichotomized at cut-points that best discriminated women with/without low BMD. We compared the AUC of these models with that of the Osteoporosis Self-Assessment Tool (OST score=[weight(kg)-age(yrs)]x 0.2), developed to identify women 65+ years for BMD testing.

Results: Of 958 healthy women sent for a first BMD test, 944 with complete data were included; 87/944 (9.2%) had low BMD. Low BMD was significantly associated with older age, > years post menopause, lower weight, prior fracture, older age at menarche, and physical inactivity in adolescence. In multivariable analysis, older age, lower weight, > years post menopause, and prior fracture were significant independent predictors of low BMD (AUC 0.75 versus OST AUC 0.70, p=0.01). Dichotomizing weight (≤71/>71 kg), years post menopause (≥2 /<2), and age (>52/≤52) gave similar discrimination (AUC=0.745). Using the 4 dichotomous risk factors and setting sensitivity to detect low BMD at 95%, 258 women with normal BMD and 4 with low BMD would *not have been* recommended for testing. None of the 944 women had OST scores < -3 (high OP risk); 41 *with low* BMD and 205 *without low* BMD had OST scores between 1 and -3 (moderate OP risk). Using an OST score ≤1 to recommend testing would identify only 47.1% with low BMD.

Conclusions: In healthy women at menopause <10% had low BMD, supporting the need for guidance about testing. Assessment of 4 risk factors was superior to the OST in discriminating women with versus without low BMD.

The Influence of Exogenous Fat and Water on Lumbar Spine Bone Mineral Density in Healthy Volunteers. KYU-NAM KIM*. Ajou University, South korea

Background Changes in human body composition can affect the accuracy of spine bone mineral density (BMD) measurements. The purpose of this study was to evaluate whether fat and water in the soft tissue of the abdomen influence lumbar spine BMD measurements obtained using dual energy X-ray absorptiometry (DEXA).

Methods Healthy volunteers (10 male, 10 female) had duplicate BMD measurements on the same day before and after placement of the following 3 materials in the abdominal area: lard 900g, 1.5cm thick; oil 1.4 liters in a vinyl bag; and water 1.2 liters in a vinyl bag. Duplicate BMD measurements were also made using the Hologic anthropomorphic spine phantom under the same conditions.

Results In the case of human participants, following the placement of exogenous water to mimic extracellular fluid (ECF), there was a significant decrease in lumbar spine BMD (-0.012 g/cm^2, P = 0.006); whereas, placement of exogenous lard and oil to mimic abdominal fat, produced a slight increase in lumbar spine BMD (0.006 g/cm^2, P = 0.301; 0.008 g/cm^2, P = 0.250, respectively). The average percentage of lumbar spine BMD change with and without exogenous lard, oil, and water increased 0.51% and 0.67% and decreased 1.02%, respectively. Using the phantom, BMD decreased with placement of both lard (-0.002g/cm^2, P = 0.699) and water (-0.006 g/cm^2, P = 0.153); however, there was no difference in BMD after oil placement (0 g/cm^2, P = 0.870). Differences in lumbar BMD between lard and oil, representing solid fat and liquid fat respectively, were not significant (P = 0.607).

Conclusions These results suggest that in cases where changes in fat and ECF volume are similar, ECF exerts a greater influence than fat on DXA lumbar BMD measurements.

Which Limb to Scan? Revisiting the Relationship Between Skeletal and Functional Limb Dominance. Benjamin Weeks, Belinda Beck*. Griffith University, Australia

Purpose: The typical referral for clinical or research bone densitometry requests a ''non-dominant'' limb exam. While hand dominance reliably predicts upper extremity skeletal dominance, our experience suggests that functional dominance does not predict lower limb skeletal dominance. In the absence of a single reliable technique to determine lower extremity functional dominance, the extrapolation of the upper extremity rule is widespread; to the extent that scanning devices such as densitometers are generally designed to facilitate scanning of the left hip rather than the right to accommodate the preponderance of right handed individuals in the population. The aim of the current work was to determine the true nature of the association between functional and skeletal dominance of the lower limb. The ultimate goal is to establish a simple and reliable determinant of lower extremity skeletal dominance. Methods: 100 healthy men and women (age 32.5 ±10.2 years) were recruited for anthropometry and bilateral hip densitometry (BMD; Norland XR-800), calcaneal quantitative ultrasonometry (BUA; QUS-2, Quidel) and tibial peripheral quantitative computed tomography (cortical and trabecular density and area, cortical width and stress strain indices [SSI]; XCT3000 Stratec). Side dominance questionnaires and physical tasks were completed including the Waterloo Footedness Questionnaire(Revised) (WFQ-R), hop distance test, step test, handedness and footedness questions, and side preference for a number of common postures (e.g. folding arms). Correlation analyses and chi square tests with crosstabs were run on all bone and functional dominance parameters using SPSS(17). Results: Significant negative relationships were found for handedness and WFQ-derived dominance with femoral neck BMD dominance (r = -0.35, p = 0.01 and r = -0.32, p = 0.03 respectively), as well as arm folding dominance with tibial SSI dominance at the 14% site (r = -0.62, p = 0.003). While significance was not reached for other measures, a consistent trend for lower limb skeletal dominance in the functionally non-dominant limb was observed for 70% of all bone parameters. Conclusions: Contrary to conventional thinking, the functionally dominant lower extremity exhibits lower bone mass than the functionally non-dominant lower limb. Findings bring into question the standard practice of scanning left lower extremity regions of right handed individuals when skeletally non-dominant lower limb measures are desired.

Bone Density and Bone Size in Older Men and Women Assessed by High Resolution pQCT: Contributions of Growth, Consolidation and Aging. Richard Eastell[1], Margaret A. Paggiosi[2], Jennifer Walsh*[2]. [1]University of Sheffield, United Kingdom, [2]NIHR Bone Biomedical Research Unit, United Kingdom

Bone size and density are major determinants of bone strength. HR-pQCT (Xtreme CT, Scanco) measures size-independent volumetric density (vBMD) and structure. The aims of this study were to 1) identify gender differences in bone density and size in older men and women, 2) determine the contributions of growth, consolidation and aging to bone density and size in older men and women 3) identify site-specific changes in bone density and size with aging. We conducted a cross-sectional observational study of 171 male and female healthy volunteers ages 16-18 (end of growth), 30-32 (peak bone mass) and >70 (aging). We measured BMD at the spine and hip with DXA, and the distal radius and tibia with HR-pQCT. HR-pQCT results were analysed by ANOVA with gender, age group and gender*age group interaction as fixed factors. ANOVA with linear contrast was used to compare groups and differences between groups. The table shows subject characteristics, DXA BMD and selected HR-pQCT results.

Radius total density was similar in older men and women, and was similar in men and women at the end of growth and peak bone mass. Density decreased with aging in men and women (M -18%, W -20%, $p<0.001$). Radius cortical perimeter was greater in older men than older women, and was also greater in men at the end of growth and peak bone mass ($p<0.001$). Cortical perimeter increased with aging in men and women (M 10%, W 6%). Cortical perimeter increased from the end of growth to peak bone mass in men, but not women (M 7%, W -1%, $p<0.05$).

Tibia total density was higher in older men than older women ($p<0.001$). Density decreased with aging in men and women (M -14%, W -23%, $p<0.001$). Women had slightly lower peak density, and greater loss with aging. Tibia cortical perimeter was higher in older men than older women, and was also higher in men at the end of growth and peak bone mass ($p< 0.001$). However, cortical perimeter did not differ by age in men or women.

We conclude: 1) radius vBMD does not differ by gender, 2) older men have larger radius size than women due to greater size at the end of growth and a gender-specific increase between the end of growth and peak bone mass, 3) older women have lower tibia vBMD than men due to lower peak values and greater loss with aging, 4) older men have larger tibia size than women due to greater size at the end of growth, 5) weight-bearing and non-weight-bearing bones differ in density and size variation due to gender and age.

Detection of Vertebral Fractures in Lateral Scout Views from Computed Tomography Using Statistical Models of Shape and Appearance. Jane Haslam[1], Yoo Mee Kim[2], Douglas Kiel[3], Elizabeth Samelson[3], Joes Staal[4], Peter Steiger*[5], Mary Bouxsein[2]. [1]Optasia Medical Ltd, United Kingdom, [2]Beth Israel Deaconess Medical Center, USA, [3]Hebrew SeniorLife, USA, [4]Optasia Medical Ltd., United Kingdom, [5]Optasia Medical, USA

Purpose: Vertebral fractures (VFx) are underdiagnosed worldwide. New methods that improve reliable VFx assessment are needed. Thus, the aim of this study was to develop and test algorithms which detect osteoporotic vertebral fractures in lateral CT scout view images.

Methods: Subjects included 50 men and 50 women (aged 50-87 yrs, mean 70 yrs) selected from the Framingham Heart Study Offspring and Third Generation cohorts. Vertebral shape was captured by a non-radiologist on CT lateral scout views from T4 – L4 using a novel semi-automated software tool (SpineAnalyzer, Optasia Medical), which captures vertebral shape with 95 points per vertebra. Scout films were also read by two trained radiologists using Genant SQ scores. Machine learning techniques were used to develop classification algorithms (or classifiers) for automatically detecting vertebral fractures given vertebral shape, for two definitions of VFx: 1) SQ grades 1-3 vs. grade 0, and 2) SQ grades 2-3 vs. grades 0-1. The classifiers were evaluated against consensus SQ readings for each definition of VFx in terms of their equal error rates (EERs), area under the Receiver Operator Characteristic (ROC) curve, and kappa score. Classifier testing was performed using ''leave one out'' cross-validation in order to give very nearly unbiased performance estimates.

Results: Based on radiologists' consensus SQ readings 977 vertebrae were normal and 44 fractured: 25 grade 1 (mild), 16 grade 2 (moderate) and 3 grade 3 (severe). For the two definitions of VFx, classifiers yielded EERs of 8.7% and 0.7%, areas under the ROC curves of 0.97 and 0.998, and maximum kappa scores of 0.57 (95% CIs: 0.42-0.71) and 0.83 (0.70-0.97) respectively. In comparison, for SQ 1-3 vs. SQ 0, radiologist inter-reader kappa scores were 0.56-0.59. For SQ 2-3 vs. SQ 0-1 radiologist inter-reader kappa scores were 0.68-0.72.

Conclusions: These initial results indicate the potential feasibility of developing algorithms which allow non-radiologist operators to use vertebral shape measurements, determined using a highly automated algorithm, to distinguish VFx in lateral CT scout view images. The algorithms' agreement with ''gold-standard'' SQ scores is similar to the agreement between experienced radiologists for the same data-set. These data provide strong rationale to validate the results on a larger data-set.

Effects of Antiresorptive Agents on Bone Micro-Architecture Assessed by Trabecular Bone Score in Women Age 50 and Older: The Manitoba Prospective Study. Marc-Antoine Krieg*[1], Andrew Goertzen[2], William Leslie[2], Didier Hans[3]. [1]University Hospital, Switzerland, [2]University of Manitoba, Canada, [3]Lausanne University Hospital, Switzerland

Antiresorptive agents such as biphosphonates induce a rapid increase of BMD during the 1st year of treatment and a partial maintenance of bone architecture. Trabecular Bone Score (TBS), a new grey-level texture measurement that can be extracted from the DXA image, correlates with 3D parameters of bone micro-architecture.

AIM: To evaluate the longitudinal effect of antiresorptive agents on spine BMD and on site-matched spine micro-architecture as assessed by TBS.

METHODS: From the BMD database for Province of Manitoba, Canada, we selected women age >50 with paired baseline and follow up spine DXA examinations who had not received any prior HRT or other antiresorptive drug. Women were divided in two subgroups: (1) those not receiving any HRT or antiresorptive drug during follow up (=non users) and (2) those receiving non-HRT antiresorptive drug during follow up (=users) with high adherence (medication possession ratio >75%) from a provincial pharmacy database system. Lumbar spine TBS was derived by the Bone Disease Unit, University of Lausanne, for each spine DXA examination using anonymized files (blinded from clinical parameters and outcomes). Effects of antiresorptive treatment for users and non-users on TBS and BMD at baseline and during mean 3.7 years follow-up were compared. Results were expressed % change per year.

RESULTS: 1,150 non-users and 534 users met the inclusion critera. At baseline, users and non-users had a mean age and BMI of [62.2 ± 7.9 vs 66.1 ± 8.0 years] and [26.3 ± 4.7 vs 24.7 ± 4.0 Kg/m^2] respectively. Antiresorptive drugs received by users were bisphosphonates (86%), raloxifene (10%) and calcitonin (4%). Significant differences in BMD change and TBS change were seen between users and non-users during follow-up ($p<0.0001$). Significant decreases in mean BMD and TBS (-0.36 ± 0.05 % per year; -0.31 ± 0.06 % per year) were seen for non-users compared with baseline ($p<0.001$). A significant increase in mean BMD was seen for users compared with baseline ($+1.86 \pm 0.0$ % per year, $p<0.0018$). TBS of users also increased compared with baseline ($+0.20 \pm 0.08$ % per year, $p<0.001$), but more slowly than BMD.

CONCLUSION: We observed a significant increase in spine BMD and a positive maintenance of bone micro-architecture from TBS with antiresorptive treatment, whereas the treatment naïve group lost both density and micro-architecture. TBS seems to be responsive to treatment and could be suitable for monitoring micro-architecture.

Measuring Bone Quality using Peripheral Quantitative Computed Tomography at the Tibia in Individuals with SCI: Reproducibility and Methodological Considerations. Lora Giangregorio[1], Deena Lala*[1], Kayla Hummel[1], Christopher Gordon[2], B. Catharine Craven[3]. [1]University of Waterloo, Canada, [2]McMaster University, Canada, [3]Toronto Rehabilitation Institute, Canada

Background: Measurements of trabecular connectivity and hole size can be obtained at the radius using the Stratec pQCT device despite the limited resolution. There are no reports of the same pQCT-based trabecular structure measurements at the tibia. It would be important to establish whether they could be measured reliably, particularly in individuals with low BMD.

Objective: To investigate the reproducibility of bone structure measurements in individuals with spinal cord injury (SCI) obtained using peripheral quantitative computed tomography (pQCT).

Design: Cross-sectional study

Participants/methods: Eleven individuals with SCI (C5-L1) were recruited to participate; 1 was excluded due to contractures. Mean (±SD) age was 43 (10) years and years post injury was 18 (14). pQCT scans were performed twice on the same day at the ultra-distal tibia, with repositioning between scans. The following bone structure variables were determined using in-house software: average and maximum hole size [mm^2]; connectivity index; average cortical thickness [mm]; bone volume to total volume (BVTV) ratio. For each outcome, the root mean squared coefficients of variation (RMSCV) were calculated.

Results: Mean (±SD) and RMSCV (in %) for bone structures variable were: average hole size 9.5 (9.7) mm^2, 7.0%; maximum hole size 663.1 (253.0) mm^2, 5.4%; connectivity index 0.16 (0.06), 2.9%; cortical thickness 0.94 (0.1) mm, 1.8%; BVTV 0.28 (0.12), 0.7%. Variability observed across participants may be attributable to factors such as age, impairment (AIS) or duration of injury. Potential sources of within subject variability include variations in positioning, or movement during scanning.

Conclusions: Although pQCT is a novel and feasible tool for measuring tibia bone structure, the RMSCV for some variables may necessitate multicentre studies with large sample sizes to determine treatment efficacy.

Reliability of Semi-Automated Vertebral Morphometry Measurements using Lateral Scoutviews from Computed Tomography. Yoo Mee Kim*[1], Serkalem Demissie[2], Rahel Eisenberg[1], Douglas Kiel[3], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]Boston University School of Public Health, USA, [3]Hebrew SeniorLife, USA

The presence of vertebral fracture (VFx) is among the strongest risks for future fracture. Despite this, underdiagnosis and undertreatment of VFx is a well-known problem worldwide. New methods are needed to improve the accuracy and efficiency of identifying VFx. Thus, the aim of this study was to determine intra- and inter-reader reliability of vertebral morphometry measurements performed using a new semi-automated algorithm that is based on shape-based statistical modeling (SpineAnalyzer, Optasia Medical, Cheadle, UK). Methods: 100 subjects (50 men and 50 women, aged 50-87 yrs, mean: 70.3±8.9 yrs) were selected from the Framingham Heart Study Offspring and Third Generation Multi-Detector Computed Tomography Study. Two non-radiologist readers independently assessed vertebral morphometry from the CT lateral scoutviews for T4-L4 at 2 time points. Deformities were classified as mild (≥20%), moderate (≥25%) or severe (≥40%) based on Genant's criteria. Intraclass correlation coefficients (ICCs), root mean squared CV (RMS-CV) and kappa (k) statistics were used to assess reliability. Results: Four subjects were excluded due to poor image quality. Of 1248 individual vertebrae from T4-L4 in 96 subjects, 1246 were analyzed. The time per subject needed to conduct morphometry measurements averaged 5 min 22 sec (range: 3:13 to 9:06 min:sec). Intra- and inter-reader ICCs for anterior, mid and posterior vertebral heights for all vertebral levels combined were excellent, ranging from 0.96 to 0.98. ICCs were also excellent at distinct spinal regions (T4-9, T10-12, and L1-4), ranging from 0.87 to 0.96. Intra- and inter-reader RMS-CV ranged from 2.5 to 3.9% and 3.3 to 4.4%, respectively. Based on morphometry measurements alone, Reader A and B identified 51-52 and 46-59 subjects, with at least one prevalent VFx, respectively. Examining all vertebral levels together, we found good intra- (k =0.59 to 0.69) and inter-reader agreement (k= 0.67) for VFx defined by a deformity of ≥ 20%. Conclusions: This new semi-automated method for assessing vertebral morphometry has excellent intra- and inter-reader reliability for vertebral height measurements on lateral CT scoutviews, and requires less time than conventional 6-point morphometry. Reliability for VFx assessment was comparable to previous reports for SQ grading by radiologists. Altogether, this semi-automated technique using CT lateral scoutviews is a convenient and reproducible method to facilitate assessment of VFx.

SA0313

Vertebral Bone Loss Quantified by Normalised Mean Vertebral Area in Lateral Radiographs. Erik B Dam[1], Mads Nielsen[2], Martin Lillholm*[3]. [1]Nordic Bioscience & CCBR-Synarc, Denmark, [2]University of Copenhagen, Denmark, [3]Nordic Bioscience, Denmark

Osteoporosis drug trials often use incident vertebral fractures as markers of disease progression and treatment efficacy. The purpose of this study was to investigate bone loss through a continuous measure of vertebral area as a supplement to established progression markers.

The case-control study population consisted of 126 postmenopausal women; a subset of the community recruited PERF study. Case and control groups were matched with respect to age, height, weight, and BMD. Fracture status at baseline and follow-up (6.3 years) was determined from lateral radiographs by an experienced radiologist using Genant's semi-quantitative method. All subjects were fracture-free at baseline and the 101 controls remained fracture-free. The 25 cases developed at least one incident fracture in the lumbar region. The lumbar vertebrae had the corner and mid points marked using a computer tool. The vertebral bone area was calculated as the area of the hexagon defined by the six points. Radiographic scaling invariance was approximated through normalization with the square of the average width of vertebrae (T12-L5). Width was defined as the distance between the midpoints of the anterior and posterior heights. The normalised average vertebral area of the lumbar region was defined as the mean of the six areas. This area was calculated at baseline and follow-up for all 126 subjects. Results are given as mean ± SEM and significance tested using the Wilcoxon ranksum test for unpaired samples and the signed variant for paired.

The mean vertebral areas for the case group at baseline and follow-up and were 0.83 ± 0.01 and 0.77 ± 0.01, $p=1\times10^{-5}$. Similarly for the control group at baseline and follow-up: 0.84 ± 0.01 and 0.82 ± 0.01, $p=2\times10^{-12}$. The difference between cases and control was significant at follow-up $p=2\times10^{-5}$ whereas the difference between cases and controls at baseline was not p=0.35. The average vertebral bone area loss was significantly larger for the case group, $p=7\times10^{-12}$.

Several intuitive results were confirmed: The matched case and control groups had comparable vertebral bone area at baseline. Both groups individually suffered significant bone area loss from baseline to follow-up and the case group with fractures lost significantly more bone area than the fracture-free control group. Most promising is, however, the significant bone area loss in the fracture-free control group – a continuous and significant progression that is not registered by fracture readings.

SA0314

Preliminary Comparison of FRAX™ (excluding BMD) with FRAX™ (including BMD calcaneal QUS T-Score) Screening Tool for Estimating Long-term Fracture Risk. Simon Dyall[1], Daphne Bird[1], Ian Drysdale*[2], Heather Hinkley[2]. [1]British College Osteopathic Medicine, United Kingdom, [2]British College of Osteopathic Medicine, United Kingdom

The aims of this study were to compare FRAX™ (excluding BMD) with FRAX™ (including calcaneal QUS T-Score) predictions for fracture risk and assess the ability of each to predict actual fracture over the long-term (10 years). Osteoporosis remains a major public health concern and accurate assessment of the associated bone fracture risk should enable appropriate targeting of vulnerable individuals with interventions intended to reduce this risk. Fracture risk may be predicted using simple non-invasive screening techniques that ensure patient safety at relatively low cost such as quantitative ultrasound (QUS) or the WHO fracture risk assessment tool, FRAX™, an algorithm of hip and other major osteoporotic fracture risk over 10 years.

180 Caucasian females, aged 40 to 79 at baseline were randomly selected from a cohort of 900 subjects screened using calcaneal QUS (McCue Cubaclinical). Relevant patient details were retrospectively entered into the FRAX™ assessment tool, either with or without BMD calcaneal QUS T-score, and indices of fracture risk were compared. Subjects completed a follow up questionnaire to ascertain details of any fracture and level of trauma within the subsequent 10 years, and fragility fractures were abstracted. Scores were classified into low, medium and high risk based on FRAX™ criteria, and the results analysed by Chi-squared statistic.

The FRAX™ scores were significantly different when calculated with and without BMD ($P<0.05$), and although not significant the Chi-squared analysis indicated a far closer relationship between fragility fracture and high risk with BMD QUS T-score (P=0.08 vs. P=0.93). Furthermore, ten year follow up (mean 10.1 years) revealed that 26 of the 180 subjects sustained fragility fractures, 9 of which were predicted by FRAX™ (18%) and 13 by FRAX™ (with BMD) (28%). There were two spine fractures which were in the high risk category for both techniques, of the 17 wrist fractures 5 were in the high risk category for FRAX™ and 8 for FRAX™ (with BMD), the hip fracture was predicted by both techniques as was one of the two elbow fractures.

It should be noted that the predictive ability of the techniques may have been confounded by increased interim use osteoporosis treatments taken following the initial screen. However, these preliminary findings suggest that the addition of calcaneal QUS T-score improves the ability to predict fragility fractures in women.

Prognosis of Fracture Risk by Quantitative Ultrasound Measurement and Bone Mineral Density. Nguyen Nguyen[1], Jacqueline Center[1], John Eisman[1], Tuan Nguyen[1], Mei Chan*[2]. [1]Garvan Institute of Medical Research, Australia, [2]Osteoporosis & Bone Biology, Australia

Quantitative ultrasound measurement (QUS) or bone mineral density (BMD) has been shown to predict fracture risk in women. However, whether a combination of QUS and BMD can improve the predictive value of fracture remains unclear. In this study, we sought to determine whether the combined use of calcaneal QUS and BMD measurements could improve the accuracy in fracture risk prediction, and to develop a nomogram based on the predictive model to predict the 5-year and 10-year fracture risk for individual men and women.

The study was designed as a population-based prospective investigation, which involved 407 women and 421 men aged 62-89 year, who had been followed for a median of 13 years (range 11-15 years) during the period of 1994-2009. BMD was measured at femoral neck by DXA using GE Lunar DPX-L densitometer and BUA was measured at the calcaneus using CUBA sonometer. The Cox's proportional hazards regression model was used to assess the association between fracture risk and the predictive variables. Reclassification analysis was used to compare the prognostic performance of the model including age, BMD and fall with the model including BUA.

During the follow-up period, 18% men (n=77) and 38% women (n = 154) had sustained a fragility fracture. Each standard deviation decrease in BUA was associated with a hazard ratio [HR] of fracture 1.86 (95%CI, 1.57-2.27) in women and 1.50 (95% CI, 1.19-1.94) in men. After adjustment for BMD, BUA remained significantly associated with fracture risk in women and men with reduced magnitude (HR 1.57, 95%CI, 1.26-1.95 in women; HR 1.32, 95% CI, 1.03-1.69 in men). For the model with BUA and BMD combined, the AUC increased from 0.71 to 0.74 in women, and from 0.695 to 0.697 in men. Reclassification analysis also yielded a total net reclassification improvement (NRI) of 9.7% (p = 0.02) and 3% (p = 0.69) for women and men respectively. Overall, 21% of women and 33% of men were reclassified into a different risk category.

Based on the estimated parameters of the final model (i.e. BUA, BMD fall and age), two nomograms were constructed for predicting fracture risk for an individual man and woman. These results suggest that calcaneal QUS was significant and independent predictor of fracture risk in both men and women. The combination of QUS and BMD in form of a nomogram can enhance the accuracy of categorizing individuals according to their risk of fracture, supporting the potential role of QUS in the prognosis of fracture.

Association Between Fat and Lean Distributions with Bone Mineral Density in KNHANES. Woong-Hwan choi[1], Sangmo Hong*[2]. [1]Hanyang university hospital department of internal medicine, South korea, [2]Hanyang University, South korea

It is uncertain whether obesity is protective or harmful to bone. There were many limitations due to collinearitis between BMD, Fat mass, muscle mass, and body weight in ths studies for role of fat to BMD.

The aim of this study was to define the role of muscle and fat distributions to BMD.

We analyzed body composition and BMD data of 1172 Male and 1546 female from KNHANES IV. Body composition and BMD were measured by DXA. Metabolic syndrome (Mets) modified to define any two of four factors except waist circumference by IDF definition due to conventional Mets has collinearity with central obesity. The relations of [Appendicular lean/Trunk lean; AM] for muscle, [Appendicular fat /Trunk lean; AF] for subcutaneous fat, [Trunk fat/Trunk Lean; CO] for central obesity, age, body weight (BW) and Mets with sub-total BMD analyzed by multiple regressions. We also generated the Z score of each factors by LMS method with LMS chartmaker pro 2.3.

In men, BMD (R2=0.275) had positive relations with AM (B=0.193) and BW (B=0.006) but had negative correlations with AF (B=-0.229), CO (B=-0.111), and Mets (B=-0.016). BMD (R2=0.258) of ⩾50 yr men only showed relation with CO (B=-0.187) and BW (B=0.006). Z score of BMD (BMDz, R2=0.251) showed relations with Z score of AF (AFz, B=-0.027), AMz (0.009), BWz (B=0.059) and Mets (B=-0.025) but Coz had no relation with BMDz. In ⩾50yr men, BMDz (R2=0.237) showed negative correlation with COz (B=-0.014) and AFz (B=-0.014), but AMz and Mets had no relation with BMD of ⩾50yr men. In women, BMD (R2=0.322) had negative relations with AF (B=-0.095), CO (B=-0.045), age (B=-0.002) and Mets (B=-0.009), and positive relations with AM (0.135) and BW (B=0.005). In ⩾50 women, BMD (R2=0.202) only had relation with CO (B=-0.043), BW (B=0.004), age (B=-0.004) and AM (B=1.124) but AF had no relations with BMD. BMDz (R2=0.219) in women had negative relations with AFz (B=-0.128), and COz (B=-0.096), and positive relations with AMz (B=0.135) and BWz (B=0.524). In ⩾50yr women, BMDz (R2=0.177) only had relation with COz (B=-0.098), BWz (B=0.457) and AMz (B=0.087) and AFz had no relations with BMDs.

We found that central obesity and subcutaneous fat had negative effects to bone except ⩾50 women. And muscle mass had relations with BMD, but its significant was disappeared (in men) or weaken [in women AMz B=0.131(<50yr) → 0.087(⩾50yr)] in older subjects.

SA0318

Association of calcaneal QUS BMD and DEXA BMD at the femoral neck, lumbar spine and whole body in American Indian Men and Women. Maureen Murtaugh*, Molly McFadden, Khe-ni Ma, Tracy Frech, Laurie Moyer-Mileur, Martha Slattery, Tom Greene. University of Utah, USA

Little information is available about bone density, osetoporosis, and fracture risk in American Indian populations in the United States. The feasibility of dual energy s-ray absorptiometry (DEXA) screening among American Indian populations living in remote areas of reservations is met with challenges including cost, radiation exposure, and proximity to a DEXA table. Quantitative ultrasound (QUS) is attractive because it is portable, non-invasive, and does not involve exposure to radiation. Anecdotal reports from Alaska Native healthcare providers suggested that BMD estimated by QUS had a high false positive rate for osteopenia and osteoporosis determined by DEXA at the hip. Therefore, we explored the association of QUS measures as a predictor of DEXA measured BMD (g/cm^2) at the femoral neck, lumbar spine and whole body in American Indians living in the southwest. Participants were recruited randomly from the Education and Research Toward Health (EARTH) study to fill age and gender strata. Bone density of the hip, lumbar spine (L1-L4) and whole body were measured using a Hologic Discovery W DEXA machine following standard protocols in 925 men and women. Bone density at the heel was estimated using a Hologic Sahara QUS device in men and women ranging from 18 to 81. We explored the association of estimates of BMD from QUS as a predictor of femoral neck BMD using linear regression analyses stratified by gender. Calcaneal BMD, estimated using QUS, accounted for approximately 26% of the variation of femoral neck, lumbar spine and whole body BMD in women. In men, 15% of the variation of femoral neck BMD but only 4% of lumbar spine BMD and 8% of whole body BMD was explained by QUS BMD. A joint model including age, BMI and QUS BMD accounted for 51% of the variation in measured femoral neck BMD in women and 37% in men (Table 1). Associations with spine and whole body were lower, particularly among men. Using speed of sound (SOS), broadband ultrasound attenuation (BUA) and quantitative ultrasound index (QUI) in place of QUS BMD, resulted in similar associations with DEXA BMD at the three sites. In separate regression models, mean differences between estimates of BMD from calcaneal QUS vs. DEXA at the femoral neck, spine and whole body were systematically related to BMI, suggesting a BMI-dependent bias (Table 2). Population characteristics may be an important consideration in the utility of calcaneal QUS in estimation of BMD and bone health screening.

Table 2: DEXA minus Calcaneal QUS BMD (N=925)

		Femoral Neck	Spine	Whole Body
Gender	BMI	Mean ± SE

Bone Density Following Long-Duration Spaceflight and Recovery. Shreyasee Amin*[1], Sara Achenbach[1], Elizabeth Atkinson[1], Elisabeth Spector[2], HJ Hartnett[2], L. Joseph Melton[1], Sundeep Khosla[3], Jean Sibonga[4]. [1]Mayo Clinic, USA, [2]Wyle Integrated Science & Engineering Group, USA, [3]College of Medicine, Mayo Clinic, USA, [4]NASA-Johnson Space Center, USA

Rapid bone loss in the weight-bearing skeleton is well recognized during long-duration spaceflight, but the implications on long-term bone health remain unclear. How bone mineral density [BMD] in US crew members serving on long-duration missions in space [US crew] compare with what would be expected had they not been exposed to microgravity, is unknown.

We therefore examined the observed changes in BMD (g/cm^2) among 28 US crew (immediately post-flight and following ~12 months recovery) relative to comparable age- and gender-expected changes derived from 348 men (age range at baseline: 22-90 yrs) and 351 women (range: 21-93 yrs) representing an age-stratified, random sample of the adult community population. BMD measurements (Hologic QDR 2000) were made at the total hip, lumbar spine, ultradistal and midshaft radius, and total body (sites also measured in US crew). Men were measured at baseline, 2, and 4 yrs; women were measured at baseline, 1, 2, and 4 yrs. Linear mixed effects models were used to predict follow-up BMD using baseline BMD, age, gender, and follow-up time, adjusting for the fact that most people were measured more than once. Models including body mass index (BMI) or lean mass were also considered. In US crew (24 men, age range at pre-flight scan: 36-53 yrs; 4 women, age: 41-53 yrs), BMD was measured pre-flight, immediately post flight and at ~12 months post-flight using Hologic QDR 2000, QDR 4500 and Discovery scanners. The majority had pre- and post-flight BMD on similar machines. Immediate post-flight BMD was performed a median of 6 (range: 3-33) days after return, with a median flight duration of 167 (range: 95-215) days. 22 men and 4 women had a scan within 6-18 months post-flight; median days from landing to ~12 months scan was 376 (range: 184-534) days.

The table shows the predicted and observed BMD and rates of change immediately and ~12 month post-flight for US crew. Findings were similar using prediction models which included BMI or lean mass. Due to microgravity exposure, the observed immediate post-flight BMD at all sites was significantly lower than predicted. However, at ~12 months post-flight, BMD at most sites in US crew were still lower than would be expected had they not been exposed to microgravity.

These findings have implications on potential long-term adverse effects on bone health of US crew serving on long-duration spaceflight missions.

	Mean BMD (g/cm²) (% change in BMD per month) [95% Confidence Interval]					
BMD Site	Immediate Post Flight			~12 Month Post Flight		
	Predicted	Observed	p-value	Predicted	Observed	p-value
Total Hip	1.082 (-0.00) [-0.05, 0.04]	1.012 (-0.87) [-1.04, -0.71]	<0.001	1.086 (0.01) [-0.01, 0.02]	1.062 (-0.10) [-0.15, -0.06]	<0.001
Spine	1.078 (0.12) [0.10, 0.13]	1.028 (-0.48) [-0.61, -0.34]	<0.001	1.086 (0.05) [0.05,0.06]	1.068 (-0.03) [-0.01, 0.03]	0.004
Ultradistal Radius	0.519 (-0.02) [-0.05, -0.00]	0.511 (-0.21) [-0.34, -0.09]	0.01	0.512 (-0.07) [-0.07, -0.06]	0.517 (-0.02) [-0.07, 0.02]	0.03

25-Hydroxyvitamin D-Levels in Community-Dwelling Postmenopausal Women Differ Between Swiss Mountain and Plain Areas During Winter. Jotinder Schuematschek-Kainth*[1], David Kissner[1], Albrecht Popp[1], Günter Menz[2], Raphael Kessler[3], Matthias Stahl[4], Christoph Senn[1], Spiros Arampatzis[1], Antonella Berlingieri[1], Romain Perrelet[1], Kurt Lippuner[1]. [1]Osteoporosis Policlinic, University of Bern, Switzerland, [2]Hochgebirgsklinik Davos, Switzerland, [3]HFR Tafers, Switzerland, [4]Kantonsspital Olten, Switzerland

Background: Adequate vitamin D supply plays a critical role in the maintenance of optimal musculoskeletal health. Since dietary vitamin D sources are scarce, sunlight exposure is an important determinant of Vitamin D status which therefore could differ among geographic regions. Little is known about differences in vitamin D status between plain and mountain areas in Switzerland, a country where 25% of the population lives in mountain sites.

Methods: In 150 randomly selected, community-dwelling women, aged 65-80 years, from 3 different regions, serum levels of 25-hydroxyvitamin D (25[OH]D) were assessed using the DiaSorin LIAISON "25-OH Vitamin D Total Assay" kit (Diasorin, Stillwater, MN, USA). One third of the women were living in a mountain area (Davos, 1600 m.a.s.l., n=50), one third in a plain rural area (Tafers, 651 m.a.s.l., n=50) and one third in a plain urban area (Olten, 396 m.a.s.l., n=50). All blood samples were taken during wintertime (February). Current intake of vitamin D supplements were recorded.

Results: Mean ($\pm$ SD) 25(OH)D levels were highest in Davos (49.9 $\pm$ 24.7 nmol/L), followed by Tafers (43.4 $\pm$ 23.6 nmol/L) and Olten (38.9 $\pm$ 19.2 nmol/L, p=0.015 vs. Davos). The respective rates of women with vitamin D inadequacy (<75nmol/L), insufficiency (<50 nmol/L) and deficiency (<22.5 nmol/L) were: 90%, 64%, and 20% (overall population), 84%, 56%, and 10% (Davos), 88%, 68%, and 18% (Tafers), and 98%, 68%, and 30% (Olten). The rates of inadequacy and deficiency were significanly higher in Olten than in Davos (p=0.015). One third of the women indicated to take current vitamin D-supplements in all three areas.

Conclusions: In Switzerland during wintertime, the prevalence of vitamin D inadequacy in community-dwelling postmenopausal women was high despite intake of supplements. People living in mountain areas may have some advantage over those in plain areas, possibly due to higher sun exposure.

A Bout of Resistance Exercise Increased Osteoprotegerin in Healthy Young Men. Katherine Brooke-Wavell*[1], James King[1], Stephen Burns[2], David Stensel[1]. [1]Loughborough University, United Kingdom, [2]National Institute of Education, Singapore

Purpose: The binding of receptor activator nuclear factor κB ligand (RANKL) to its receptor promotes osteoclast differentiation, activation and attachment to bone. The soluble decoy receptor osteoprotegerin (OPG) binds to RANKL, preventing the binding of RANKL to RANK, so reducing or preventing bone resorption. In vitro studies have reported increased production of OPG, and reduced production of RANKL, in response to loading. Increases in OPG have also been reported in humans following endurance running but there is little information as to the effects of resistance exercise. The purpose of the study was thus to determine whether a bout of resistance exercise influences serum OPG.

Methods: Participants were 16 healthy young men, who each completed a resistance exercise trial, and a control trial, in random order. The resistance exercise trial consisted of 3 sets of 12 repetitions of 10 resistance exercises, at 80% of 12-repetition maximum. During the control trial participants undertook sedentary activity in the laboratory. Food intake was matched for 48 hours before, and during the trials. A venous blood sample was collected before exercise and after 2.5 hours (30 minutes after the exercise bout). Changes in plasma volume were estimated from haemoglobin and haematocrit concentrations. OPG was analysed using a commercially available enzyme immunoassay from serum in seven participants and plasma in nine. Comparisons between trials were made with paired t-tests and repeated measures analysis of variance.

Results: Participants' mean +/- SD age was 24.1 +/- 3.2 y, height 1.79 +/- 0.06m and weight 77.6 +/- 9.3 kg. Resting OPG concentration did not differ between control and exercise trials (2.9 +/- 0.7 versus 3.2 +/- 0.9 pmol/l respectively). Changes in plasma volume did not differ between trials (p=0.591). OPG increased by mean (standard error) 7.3 (4.0) % after the exercise trial but decreased by 5.1 (3.6) % after the control trial. This difference between trials was statistically significant (p=0.040).

Conclusion: A bout of resistance exercise of an intensity that may be expected to increase bone mineral density increased serum OPG in healthy young men. The OPG/RANKL/RANK system may be involved in bone response to mechanical loading.

Age-related Cortical Bone Loss and Fracture Patterns in the Neolithic Community of Çatalhöyük, Turkey. Sabrina Agarwal[1], Bonnie Glencross*[2]. [1]University of California, USA, [2]University of Toronto, Canada

The Neolithic (from 10,000 to 5,000 cal BC) is broadly characterized by population increase, sedentism, crowding and the adoption of an agricultural lifestyle. Typically prehistoric populations that follow a change in subsistence and lifestyle, show a decline in health as indicated by disruptions in bone remodeling, low cortical bone mass for age, poor bone quality and fragility fracture. The focus of this study is to examine age and sex-related patterns of cortical bone loss as well as skeletal fragility fracture in a Neolithic archaeological skeletal sample from Çatalhöyük, Turkey. Using metacarpal radiogrammetry, a method with specific advantages for investigating cortical bone loss in archaeological remains, 50 adult metacarpals (f=28 m=22) were examined. Measurements of total bone width (TW) and medullary width (MW) were taken and used to calculate cortical thickness (CT) and cortical index (CI). These parameters were then standardized for comparison with historic and modern European data. Çatalhöyük males and females demonstrate an inverse relationship where CI decreases as age and MW increase. Analyses indicate statistically significant age-related change in MW, CT and CI amongst the oldest females. Further, both Çatalhöyük males and females have significantly more compact bone across the entire adult life course than males and females from a medieval historic sample while maintaining similar amounts of compact bone in comparison to recent Europeans. Despite age-related loss of bone, no typical fragility fractures are observed. We discuss possible growth and lifestyle factors at Çatalhöyük that may have contributed to improved skeletal strength and reduction in the risk of fragility fracture, and the implications for understanding age-related bone loss in modern populations.

Dietary Patterns and Bone Health in Women. Sarah McNaughton[1], Tikky Wattanapenpaiboon[1], John Wark*[2], Caryl Nowson[1]. [1]Centre for Physical Activity & Nutrition Research, School of Exercise & Nutrition Sciences, Deakin University, Australia, [2]Royal Melbourne Hospital, Australia

Increasingly, measures of dietary patterns have been used to capture the complex nature of dietary intake. Dietary patterns have been shown to be associated with health but few studies have investigated the impact of specific dietary patterns on bone health. The aim of this study was to examine the association between dietary patterns and measures of bone health in a sample of Australian women aged 18-65 years (n=527) recruited through the Twin and Sister Bone Research Program at the Royal Melbourne Hospital.

Bone mineral density (BMD; g/cm^2) at the lumbar spine (L2-L4) and total hip was measured from site-specific scans and total body bone mineral content (BMC; g) was measured from a total body scan using dual energy X-ray absorptiometry. Diet was assessed using a 4-day food diary. Dietary patterns were identified using principal components analysis (PCA). Scores were calculated based on the amount of each food consumed in the pattern and the weightings determined by the PCA. Participants were categorised into quintiles according to the scores. Analysis was conducted using generalised estimating equation methods and adjusted for clustering associated with twin and sister pairs and covariates.

PCA revealed 5 dietary patterns. Pattern 1 was characterised by high consumption of refined cereals, soft drinks, hot chips, sausages and processed meat, vegetable oils, beer and takeaway foods and low consumption of other vegetables, vegetable dishes, tea, coffee, fruit, wholegrain breads and breakfast cereals. This pattern was significantly inversely associated with total body BMC (adjusted for age, height, energy intake, physical activity, smoking, education and calcium intake). Each quintile increase in consumption of this pattern was associated with a 0.7% lower total body BMC. Pattern 4 (high consumption of legumes, seafood, seeds, nuts, wine, rice and rice dishes, other vegetables and vegetable dishes and low consumption of bacon and ham) was directly associated with BMD at both sites and total BMC in adjusted models. Each quintile increase was associated with an average higher bone density of 0.2% at the hip, 0.3% at the spine and 0.6% with total body BMC. The remaining dietary patterns, including those containing dairy foods, were not consistently associated with BMD or total body BMC.

This study identified specific dietary patterns associated with BMD and total body BMC among women and potential food-based strategies for improving bone health.

Evidence for an Association Between Seasonal Fluctuation of 25(OH)D and Serum C-telopeptide (CTx): Preliminary Evidence from the D-FINES study. Andrea Darling*[1], Fatma Gossiel[2], Rosemary Hannon[2], Debra Skene[1], Jacqueline Berry[3], Richard Eastell[2], Susan Lanham-New[1]. [1]University of Surrey, United Kingdom, [2]University of Sheffield, United Kingdom, [3]University of Manchester, United Kingdom

The purpose of this study was to assess whether there is a difference in bone resorption by degree of seasonal change in 25(OH)D and whether this varies by ethnicity. In the recent D-FINES study, (Vitamin D, Food Intake, Nutrition and Exposure to Sunlight in Southern England, 2006-2007), a subset of n=65 from the 293 participants (South Asian (n 30) and Caucasian (n 35)) had blood taken in four seasons for determination of 25(OH)D and serum c-telopeptide (sCTX). sCTX was measured using an electrochemiluminescent immunoassay (Roche cobas e411). Seasonal fluctuation of 25(OH)D was assessed by calculating differences between the winter (nadir) and summer (peak) 25(OH)D. For ease of interpretation these changes were expressed as positive values. This enabled investigation of the absolute change in 25(OH)D but not its direction. This variable was then split into quartiles within ethnicity. The dependent variables were absolute concentration of sCTX in each season as well as summer to winter change in sCTX. ANCOVA was run with absolute summer and winter 25(OH)D status, age, BMI, socioeconomic status, physical activity, and dietary calcium as covariates. In the Asian group there was no clear trend between degree of seasonal fluctuation and absolute sCTX. Indeed, only the autumn data was statistically significant (F=5.93; p= 0.01) and with no consistent pattern among the quartiles. No data were significant for change in summer to winter sCTX in Asians or Caucasians despite a trend in both ethnic groups for lower sCTX in the middle quartiles relative to the highest and lowest. Last, in Caucasians, there was a non-statistically significant ($p>0.05$) inverse trend between cycling of 25(OH)D and absolute serum C-telopeptide levels. These data suggest lower bone resorption in all seasons in Caucasians with increased cycling, and a reduction in sCTX between summer and winter in both ethnic groups in the middle quartile relative to the other quartiles. As the values were covariate adjusted, these findings are not likely to be due to other variables. However, it must be borne in mind that these results are only trends, which is likely due to the small numbers of subjects. Further research is required to analyse banked urine samples from the D-FINES study (n 293) which would enable us to see if these results are statistically significant with increased statistical power.The D-FINES study was funded by the UK Food Standards Agency. All views are those of the authors alone

Middle-aged Men with Dietary Intake of Omega-3 Long Chain Polyunsaturated Fatty Acids above the Median have Higher Bone Mass for Age. Nour Makarem*[1], Jason DeGuire[1], Catherine Vanstone[1], Suzanne Morin[2], Hope Weiler[1]. [1]McGill University, Canada, [2]McGill University Health Centre, Canada

Background: Dietary eicosapentaenoic (EPA) and docosahexaenoic acid (DHA) are associated with improved bone health in postmenopausal women and in animals, but evidence is scarce in men.

Objective: To determine if the dietary intake of EPA and DHA and their subsequent levels in erythrocytes are associated with higher BMD in healthy middle aged men.

Methods: This analysis represents the first 27 participants in a cross-sectional sample of healthy men between 37 and 53 years. Measures included: anthropometry, dietary intake of EPA and DHA using the validated Harvard/Willett food frequency questionnaire (FFQ), assessment of serum 25-hydroxy vitamin D using an automated immunoassay (Liaison, Diasorin), and assessment of BMD at the whole body, spine, total left hip and femoral neck using DXA. The Paffenbarger physical activity questionnaire was used to capture total and weight-bearing activity. BMD of

participants with dietary intake of EPA and DHA below (group 1: G1) and above (group 2: G2) the median was compared using t-tests. The results were then confirmed with a multiple regression analysis using EPA and DHA intake, calcium intake, serum 25-hydroxy vitamin D, height, and BMI as independent variables and whole body BMD and spine, hip, and femoral neck BMD z-scores as the dependent variables.

Results: There were no differences between the groups for age (G1: 43.6 ± 1.3 vs G2: 45.9 ± 1.4 y, P=0.259), BMI (G1: 25.7 ± 1.2 vs G2: 28.1 ± 1.1 kg/m^2, P=0.149), serum 25-hydroxy vitamin D (G1: 67.0 ± 6.6 vs G2: 67.0 ± 5.0 nmol/L, P=0.497), or calcium intake (G1: 1255 ± 116 vs G2: 1169 ± 103 mg/d, P=0.584). By design, mean intakes of EPA plus DHA were higher in group 2 (P=0.009). Group 2 had higher BMD for whole body (P=0.019), spine (P=0.012), and femoral neck (P=0.040), but not total hip (P=0.074) plus higher BMD z-scores at the spine (P=0.005), total hip (P=0.033), and femoral neck (P=0.016). Multiple regression analysis confirmed that EPA and DHA intake was the only significant independent predictor of whole body BMD (P= 0.014) and regional BMD z-scores (P<0.024).

Conclusion: These data suggest that men with higher intakes of EPA and DHA have improved bone health. This is consistent with evidence from other population groups. Future investigation using a larger sample will include assessment of EPA and DHA using erythrocyte membrane fatty acid analyses, confirm present results, and provide clarification as to whether benefits are also evident for the hip BMD.

	Group 1	Group 2	P-value
Whole Body BMD (g/cm^2)	1.268 ± 0.037	1.380 ± 0.025	0.019

Temporal Trends and Determinants of Longitudinal Change in 25-Hydroxyvitamin D Levels in a Population-based Study. Claudie Berger*[1], Lisa Langsetmo[2], Nancy Kreiger[3], Linda Greene-Finestone[4], Christopher Kovacs[5], Brent Richards[6], Nick Hidiroglou[7], Kurtis Sarafin[7], K. Shawn Davison[8], Jonathan Adachi[9], Jacques Brown[8], David Hanley[10], David Goltzman[11]. [1]McGill University, Canada, [2]Canandian Multicenter Osteoporosis Study, Canada, [3]University of Toronto, Canada, [4]Public Health Agency of Canada, Canada, [5]Memorial University of Newfoundland, Canada, [6]Jewish General Hospital, McGill University, Canada, [7]Health Canada, Canada, [8]Laval University, Canada, [9]St. Joseph's Hospital, Canada, [10]University of Calgary, Canada, [11]McGill University Health Centre, Canada

Vitamin D plays a clear role in skeletal health and in other diseases. We examined vitamin D intake, sun-exposure, and body mass index (BMI) and subsequent changes in serum 25(OH)D over a five-year period among CaMos participants in 2 centres.

We studied 481 women and 213 men aged 30+ years with available 25(OH)D levels drawn in 2000-02 (year 5) and 2005-07 (year 10). Blood samples were all analyzed in the same laboratory using Diasorin Liaison. Our main outcome was change in serum 25(OH)D levels (nmol/L). Potential predictors were vitamin D intake from supplements and drugs (year 10 and change), BMI (year 10 and change), and sun exposure. We used multiple linear regression adjusting for sex, age, season of blood draw, centre (Quebec City and Calgary), and physical activity. Interactions between change in vitamin D intake and season of blood draw and centre were considered.

Vitamin D supplement intake was 174.3 (SD=279.3) IU/day at year 5 and 336.9 (SD=408.6) IU/day five years later. Average BMI increase was 0.27kg/m^2 (95% CI: 0.10; 0.44). More than two-thirds of participants reported direct sunlight exposure (>30 minutes) as never or seldom at both time points, while 7.6% reported regular or frequent exposure. 66% of the participants had both draws done in the same season. Average difference between year 5 and 10 in 25(OH)D levels was 3.24 (1.64; 4.83) nmol/L. Those who had their blood drawn in the same season showed an average increase of 3.6 (1.6; 5.7) nmol/L and those who had them drawn in a different season showed a trend toward an increase with a mean of 2.5 (-0.2; 5.1) nmol/L. At year 5, only 33.3% of men, 32.4% of women, and 32.7% overall had 25(OH)D levels >75 nmol/L. By year 10, 38.4% of men, 42.7% of women and 39.6% overall had levels >75nmol/L. Increase in vitamin D supplements, older age, and being from Quebec city were among the variables associated with an increase in 25(OH)D levels over time. BMI (year 5 or change) was not associated with changes in 25(OH)D levels.

The results, in a longitudinal population-based cohort, indicate a trend toward increasing 25(OH)D levels over the 5-year period. This trend appears to be due to changes in vitamin D intake but indicate that more than 400 IU per day will be required to increase levels in the population above 75nmol/L.

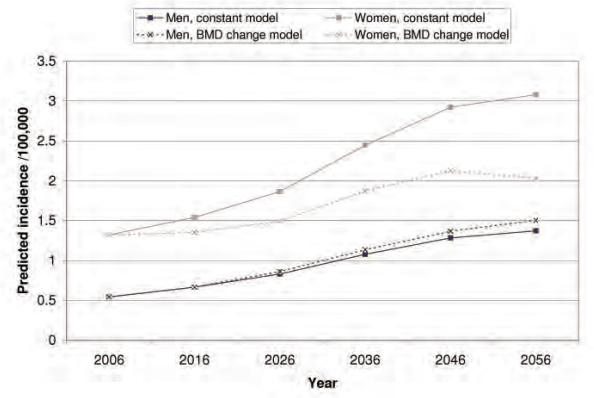
50 Year Predicted Changes in BMD Distribution and Hip Fracture Incidence in Canada. Lisa Langsetmo*[1], David Hanley[2], Claudie Berger[3], Nancy Kreiger[4], Christopher Kovacs[5], Alexandra Papaioannou[6], David Hanley[2], K. Shawn Davison[7], Jerilynn Prior[8], Robert Josse[9], David Goltzman[10]. [1]Canandian Multicenter Osteoporosis Study, Canada, [2]University of Calgary, Canada, [3]McGill University, Canada, [4]University of Toronto, Canada, [5]Memorial University of Newfoundland, Canada, [6]Hamilton Health Sciences, Canada, [7]Laval University, Canada, [8]University of British Columbia, Canada, [9]St. Michael's Hospital, University of Toronto, Canada, [10]McGill University Health Centre, Canada

Background: The age distribution in the Canadian population is expected to change over the next 50 years, with a consequent increase in the burden of hip fracture. Our objective was to predict the burden of hip fracture based on estimated distribution of age and bone mineral density (BMD) over the period 2006-2056 assuming a) sex-age-specific fracture rates remain constant and b) sex-age-specific fracture rates change according to changes in sex-age-specific BMD.

Methods: Study participants (2590 men, 5740 women) were members of CaMos, an on-going population-based cohort study of Canadians ages ⩾ 25 years. We assessed the distributions of BMD at baseline (1995-1997) and year 10 (2005-2007), as well as the mean 10-year longitudinal rate of change by sex and five-year age categories. We assumed constant peak bone mass and constant sex-age-specific rates of change to forecast the future distribution of BMD. Multiple imputation was used to account for missing data. Our base fracture model assumed the sex-age-specific hip fracture rates remain constant over time. Our second model incorporated the expected changes in BMD together with the established relationship between BMD and hip fractures to estimate a predicted fracture rate. Future population age distributions were based on Statistics Canada forecasts.

Results: For men over 50 years, the mean total hip BMD was 0.997 g/cm^2 in 2006, 0.979 g/cm^2 with same BMD distribution but 2056 age weights, and 0.963 g/cm^2 using the predicted 2056 age and BMD distribution. For women over 50 years, the mean total hip BMD was 0.858 g/cm^2 in 2006, 0.833 g/cm^2 using the same BMD distribution and 2056 age weights, and 0.880 g/cm^2 using the predicted 2056 age and BMD distribution. Assuming constant rates, the crude incidence rate of fracture over 50 years would increase by 153% in men and 133% in women, due to estimated changes in age (see Figure). Assuming the predicted changes in BMD distribution, the crude incidence rate of fracture over 50 years would increase by 177% in men, but would increase by only 54% in women.

Conclusion: A simple model based on age alone predicted decreases in mean BMD in both men and women, as well as dramatic increases in hip fracture incidence between 2006 and 2056. However, the predicted increases in hip fracture due to changes in age distribution may be partially mitigated by secular increases in BMD in women, but not in men.



Figure

Association Between Beta-blocker use and Fracture Risk: the Dubbo Osteoporosis Epidemiology Study. Shuman Yang*[1], Nguyen Nguyen[2], Jacqueline Center[2], John Eisman[2], Tuan Nguyen[2]. [1]Garvan Institute, Australia, [2]Garvan Institute of Medical Research, Australia

Mice treated with beta-blockers (BB) had increased bone mass. Low bone mass is a predictor of fracture risk. The present study sought to examine the association between BB use and fracture risk in elderly men and women.

Data from 3536 participants (1293 men) aged 50 years and above in the Dubbo Osteoporosis Epidemiology Study were analyzed. Baseline characteristics of participants were obtained at the initial visit which had taken place between 1989 and 1993. Bone mineral density (BMD) at the lumbar spine and femoral neck was measured by dual energy X-ray absorptiometry (GE-LUNAR Corp, Madison, WI). Two hundred and seventy (21%) men and 451 (20%) women had been on BB, as ascertained by direct interview and verification with medication history. The incidence of fragility fractures was ascertained during the follow-up period (1989-2008). Propensity score analysis was used to adjust for potential differences in covariates between BB users and non-BB users.

During the follow-up period, 237 men and 681 women had sustained a fragility fracture. As expected, men and women with a fracture were older and had lower BMD than those without a fracture. Men who used only beta-blocker had a significantly lower risk of fracture than those not on beta-blocker (odds ratio [OR]: 0.63; 95% CI: 0.43-0.92). A similar trend was observed in women, but it was not statistically significant (0.96; 0.77-1.21). These associations did not change after adjusting for age, BMD and common risk factors. A combination of the use BB and thiazide was non-significantly associated with lower fracture risk in both sexes (0.94; 0.37-2.47 for men and 0.95; 0.61-1.49 for women). Men on BB had higher BMD at the femoral neck (0.96 versus 0.92 g/cm^2, $P<0.01$) after adjustment for propensity score.

These data suggest that use of beta blockers was associated with reduced fracture risk in men, and the association is likely to be mediated by BMD. Given the high prevalence of osteoporosis and hypertension in the general population, this finding raises the possi-
bility that these anti-hypertensive agents may have materially affected osteoporosis in many populations with high incidence of hypertension, such as the US, Europe and Japan.

SA0334

BMD Enhances Clinical Risk Factors in Predicting Ten-Year Risk of Osteoporotic Fractures in Chinese Men: The Hong Kong Osteoporosis Study. Cora Bow*[1], Shirley Tsang[2], Sze Sze Soong[1], Siu Ching Yeung[1], Annie Kung[3]. [1]Department of Medicine, The University of Hong Kong, Hong kong, [2]University of Hong Kong, Peoples republic of china, [3]Department of Medicine, University of Hong Kong, Hong kong

Introduction: Clinical risk factors with or without bone mineral density (BMD) measurements are increasingly recognized as reliable predictors of absolute fracture risk. Clinical risk factors may be population specific. The purpose of this prospective study was to determine the risk factors for osteoporotic fractures and to predict the 10-year risk of fractures in Southern Chinese male population.

Materials and Methods: This is a part of the Hong Kong Osteoporosis Study. 1,525 community-dwelling, treatment-naive Southern Chinese men aged 50 or above were recruited. Baseline demographic characteristics and clinical risk factors were obtained, and BMD at the spine and hip were measured. Subjects were prospectively followed for incident low trauma fractures. Ten-year risks of major osteoporotic fracture and hip fracture were calculated using Cox proportional hazards models.

Results: The mean age of subjects was 68 $\pm$ 10 years. After 3.5 $\pm$ 3 (1–14) years of follow-up, 36 non-traumatic incident fractures were reported. The incident rates for osteoporotic fractures and hip fractures were 676/100,000 and 132/100,000 person-years respectively. The most significant predictors of osteoporotic fracture were history of fall (odds ratio 14.5) and fragility fracture (odds ratio 4.4). Other predictive factors included outdoor activity <60 minutes per day, body mass index (BMI) < 20 kg/cm^2, difficulty bending forward, use of walking aid, and age $\geq$ 65 years. Each SD reduction in BMD at spine or hip was associated with 1.7 to 2.6-fold increase in fracture risk. Subjects with 5 or more clinical risk factors had an absolute 10-year risk of osteoporotic fracture of 6.2%, which increased to 18.2% if they also had total hip BMD T-score $\leq$ -2.5. Addition of BMD information (total hip T-score $\leq$ -2.5) significantly enhanced fracture risk prediction when compared to clinical risk factors only (omnibus test p=0.001). Men with multiple risk factors and low BMD T-scores have a higher absolute fracture risk, while men with no risk factors and normal BMD have a lower fracture risk than that predicted by FRAX.

Conclusions: Clinical risk factors are population specific and the addition of BMD measurement to risk factor assessment improves fracture risk prediction in Southern Chinese men.

SA0335

Clinical Utility of Combined Femoral Neck and Lumbar Spine Bone Mineral Density Measurements in the Individualized Prognosis of Fracture. Tuan Nguyen*[1], Nguyen Nguyen[1], Steven Frost[2], Dana Bliuc[1], Jacqueline Center[1], John Eisman[1]. [1]Garvan Institute of Medical Research, Australia, [2]University of Western Sydney, Australia

Femoral neck bone mineral density (FNBMD) has been used as the principal predictor of fracture risk in men and women, even though more than 50% of women and ~70% of men who fracture do not have low FNBMD. Lumbar spine BMD (LSBMD) has also been used in the prognosis of fracture risk, but there is a concern over its predictive value due to degenerative change that affects spinal BMD measurement. The present study sought to address that question by examining the contribution of FNBMD and LSBMD to the prediction of fracture.

The Dubbo Osteoporosis Epidemiology Study was designed as a community-based prospective study, with 1358 women and 858 men aged 60+ years as at 1989. Baseline measurements included femoral neck bone mineral density (FNBMD and LSBMD), prior fracture, a history of falls and body weight. The Cox's proportional hazards model was used to assess the contributions of BMD and clinical risk factors to the prediction of fracture risk.

During the follow-up period, 426 women and 149 men had sustained a low-trauma fracture. There were 77 first hip fractures in women and 26 in men. For predicting any fracture and hip fracture, LSBMD was not a significant and independent predictor in the presence of FNBMD. The area under the ROC (AUC) of the model including FNBMD, age, prior fracture and falls was 0.75; when LSBMD was added to the model the AUC was still 0.75. For hip fracture, the AUC value of the model with FNBMD and the model combined FNBMD and LSBMD were the same of 0.85. When the lower value of either LSBMD or FNBMD was used in the model, these results remained unchanged. Further re-classification analysis revealed that while the use of lower LSBMD did not improve the AUC over and above that of FNBMD, value of LSBMD was useful in ruling out fracture (i.e., increase specificity by ~17% to 38%).

These data suggest that although lumbar spine BMD may not be an independent predictor of fracture risk, its use in conjunction with femoral neck BMD could be useful for ruling out fracture cases, particularly hip fracture. This "ruling-out" utility can be very valuable in the individualization of fracture prognosis.

Creation of an Electronic Order Set to Improve the Care of Patients with Osteoporotic Fractures. Beatrice Edwards*[1], Andrew Bunta[2], Nikolas Kazmers[3], Kenzie Cameron[4], Lidia Andruszyn[3], Nicole Dillon[3], Gabrielle Edwards[3], Allison Hahr[5], Mark Williams[6]. [1]Northwestern University Medical School, USA, [2]Northwestern University Feinberg School of Medicine, USA, [3]Northwestern University, USA, [4]Division of Internal Medicine, Northwestern University, USA, [5]Division of Endocrinology, Northwestern University, USA, [6]Division of Hospital Medicine, Northwestern University, USA

Background: Patients with osteoporotic fractures are rarely assessed and treated for osteoporosis

Goal: creation of Information technology based intervention to assist physicians in providing medical care for osteoporosis to individuals hospitalized with fractures.

Methods: Study conducted at Northwestern Memorial Hospital (NMH) Chicago from Jan 2008- Dec 2009. Physician focus groups explored attitudes about osteoporosis and secondary prevention in patients with fractures. Physicians provided feedback on their ideal EMR intervention in order to improve care of patients with fractures. Information technology: based on physician recommendation a Powerchart (Cerner) based order set was created for clinical use. Creation of list of patients hospitalized with fractures was performed via text "parsing". Parsing is the visual recognition of specific terms in radiologic report. Terms searched included: fractures, compression deformity, and insufficiency fracture. A list of patients with fractures was created. Exclusion: patients under the age of 50 yrs, with metastatic cancer, other metabolic bone disorders, or CKD stage 5 . Dissemination: conferences were held for medical staff and trainees on secondary prevention of osteoporosis and review of the order set (4 sessions) Evaluation: Medical records of patients hospitalized in the Medicine service were reviewed for the following 9 months. Monthly treatment rates were calculated

Results: Four focus groups were conducted with six physicians per group, participants were General Internal Medicine (N= 10) Hospital Medicine (n=14). All were attendings at NMH. Physicians noted that lack of radiologist emphasis on presence of fracture, time constraints, competing demands, need for brief hospitalization, and lack of IT-based reminders limited their ability to provide care for such patients. 278 cases were reviewed, diagnosis and anti-resorptive treatment rate varied from 2-12%, mention of need for outpatient osteoporosis care with PCP varied from 3-14% over the next 12 months. Figure 1 Pelvic fractures were readily identfied and treated (n=14/21, 67%)

Conclusion: The creation of an order set was recommended by clinicians but rarely used in practice. Low level of clinician/radiologist awareness, competing demands, need for brief hospitalizations, limit clinicians' ability to address osteoporosis in practice. Other interventions must be explored in an effort to overcome this gap in medical care.

SA0337

Has the Cost Burden of Incident Fractures Changed Over Time? A Longitudinal Analysis from 1996-2008. Colleen Metge*[1], Mahmoud Azimee[1], Lisa Lix[2], Suzanne Morin[3], Patricia Caetano[4], William Leslie[1]. [1]University of Manitoba, Canada, [2]University of Saskatchewan, Canada, [3]McGill University Health Centre, Canada, [4]Manitoba Health, Canada

Cost-of-illness (COI) analysis is used to evaluate the economic burden of illness in terms of health care resource (HCR) consumption and production losses. Incidence-based COI is useful when considering fracture prevention measures and post-fracture management from a cost distribution perspective.

AIM: To estimate costs over time related to incident fractures in older women and men and to describe the incremental costs of fracture in Canada.

METHODS: We used the Population Health Research Data Repository for Manitoba—a comprehensive collection of databases including physician visits, hospitalization and pharmaceutical prescriptions—to identify incident fractures (Apr 1997-Mar 2007) and HCR costs (Mar 1996-Apr 2008). An incidence approach was used to count fracture numbers by site/mechanism (hip, wrist, spine, humerus, other and trauma) and sex in Manitobans aged 50 y and older; a bottom-up approach was used to estimate costs (quantity x unit costs) in the year pre- and post-fracture. Incremental fracture-related costs were calculated as the difference between the year pre- and post-fracture. Costs were expressed in constant dollars (2006 CDN) and evaluated for linear trends over time.

RESULTS: Over the 10 years, adjusted post-hip fracture costs in women changed minimally for hospitalization ($24,863 to $20,085, -1.6% per y, p=.12) and personal care home residence ($11,980 to $12,485, +1.7% per y, p=.15), significantly for physician costs ($2,149 to $3,447, +6.7% per y, p<.0001) and drug costs ($792 to $1974, +14.3% per y, p<.001); home care costs did not change significantly over time ($3,456 to $3,433, -0.5% per y, p=.55). Total costs in the year post-hip fracture were stable in women (+0.1% per y, p=.87) and men (-0.6% per y, p=.58). Incremental costs (the difference between pre- and post-hip fracture costs) increased significantly for physician services (p<.001) and decreased significantly for drug costs (p<.001) in both women and men. Total incremental cost changes over time were variable and depended on type of fracture and sex (see Table); a significant reduction was seen for wrist fractures in women (-4.4% per y, p<.001) with increases for trauma fractures in women (+7.9% per y, p=.003) and men (+8.4% per y, p=.018).

CONCLUSION: Post-fracture costs have changed over time in a site-dependent manner. Identifying projected cost-of-illness including health care resource use will help to estimate the future cost burden of fracture.

		Hip	Wrist	Spine	Humerus	Other	Trauma
	N=	5217	6295	2128	3326	15997	924
Women	Annual % Change	+0.3%	-4.4%	+1.3%	-0.5%	+2.6%	+7.9%
	p for Linear Trend	0.801	<.001	0.484	0.792	0.255	0.003
Men	Annual % Change	-1.3%	-0.4%	-4.8%	-0.6%	+1.7%	+8.4%
	p for Linear Trend	0.659	0.915	0.189	0.769	0.338	0.018

Ontario Osteoporosis Strategy: Three Year Evaluation of Quality Indicators. Gillian Hawker[1], Susan Jaglal*[2], Cathy Cameron[1], Ruth Croxford[3]. [1]Women's College Hospital, Canada, [2]University of Toronto, Canada, [3]Institute for Clinical Evaluative Sciences, Canada

Purpose: In February 2005, the Ontario Osteoporosis Strategy was launched to address the gaps in care with the overall goal to reduce fractures, morbidity, mortality and costs from osteoporosis through an integrated and comprehensive approach aimed at health promotion and disease management in the population. The province of Ontario, Canada has 11 million inhabitants. The purpose of this research is to evaluate the impact on health system indicators after the first 3 years of implementation of the strategy. Methods: A literature review followed by a Delphi process was used to identify and refine quality indicators for osteoporosis and post-fracture care. Quality indicators using administrative data sources were selected for the three year evaluation due to data availability. Data sources included hospital discharge abstracts and emergency department visits to identify fractures; physician billings for BMD testing and drug plan data which only includes individuals 65 years and older. Time trends for each indicator were calculated from 2002 to 2008. Indicators examine fracture rates, BMD testing, treatment rates and adherence. Results: For the primary indicator, fracture rate there was no significant change in fracture rates between 2002 and 2008. The rate of BMD testing was constant over the time period with a greater proportion of patients at "high risk" being tested. The number of BMD tests was constant at about 500,000 per year until 2008 when it dropped to 480,000. The indicator BMD testing one year after a fracture showed an increasing proportion among those who fractured from 2002 to 2007. In 2005 12.7% of hip fracture patients had a BMD test compared to 16.6% in 2007 compared to 24.9% in 2005 and 26.5% in 2007 for wrist fractures. However, over the time period there was no difference in one year adherence rates among those 66+ years who initiated an osteoporosis medication. Conclusions: In the first three years of implementation of the Ontario Osteoporosis Strategy the emphasis was on improving post-fracture care where fracture clinic coordinators were placed in high volume hospitals. This 3 year evaluation suggests that the strategy is successful in targeting these high risk individuals for osteoporosis care. More time is needed before conclusions can be drawn about the impact on fracture rates.

Questionnaire Survey to Validate an Educational Program Intended for Orthopaedic Surgeons to Improve the Management of Severe Osteoporosis. Irene Cerocchi*[1], Giuseppina Resmini[2], Antonio Capone[3], Giovanni Iolascon[4], Alfredo Nardi[5], Umberto Tarantino[6]. [1]PTV Foundation - University of Tor Vergata, Italy, [2]Treviglio Hospital, Italy, [3]University of Cagliari, Italy, [4]Second University of Naples, Italy, [5]Rovigo General Hospital, Italy, [6]Azienda Ospedaliera PTV, Italy

The GOST (Management of Severe Osteoporosis in Traumatology) project was intended for orthopaedic surgeons, whose knowledge about osteoporosis and fragility fractures is known to be often poor and superficial, as widely documented in the literature. During 18 educational events the 510 participants were invited to fill in a questionnaire both at the beginning and at the end of the course, in order to verify if its structure and content had brought an improvement in the understanding of osteoporosis and related arguments. The questionnaire was made of 36 multiple choice questions: 7 about basic science, 12 about the clinical aspects of osteoporosis and metabolic bone diseases, 7 about diagnostic tools, 6 about pharmacological therapy and 4 about surgical treatment. There was an overall improvement of 18,77%, and for each question the percentage of right answers was higher at the end of the course compared to the beginning. The data obtained were also compared based on the subject treated. The best results were achieved in the clinical field (62,76% right answers before versus 84.64% after the meeting, with a 21,88% improvement). The percentage of right answers increased by 20,84% in the diagnosis field, and by 16,83% and 16,81% for the questions about medical treatment and basic science, respectively. The lower percentage of improvement in the surgical field (12,21%) was probably due to the already good knowledge about bone implants and the treatment of osteoporotic fractures, as the courses were attended by orthopaedic surgeons only. Moreover, the finality of the educational events was to focus on the biological, clinical and therapeutical aspects of osteoporosis, that are usually poorly considered by surgeons, who tend to focus on the surgical treatment of the fracture, often forgetting the pathophysiology, characteristics and consequences of poor bone quality. In conclusion, the GOST courses proved to be an useful tool in the improvement of orthopaedic knowledge about effective diagnosis and management of metabolic bone diseases.

What was the FRAX® Value the Day Before the Fracture? Karine Briot*[1], Frédéric Sailhan[2], Antoine Babinet[2], JP Courpied[2], Philippe Anract[2], Christian Roux[1]. [1]Paris Descartes University, Rheumatology Department, Cochin hospital, France, [2]Paris Descartes University, Orthopaedics Department, Cochin hospital, Paris, France, France

Rationale and objectives

FRAX® is a fracture prediction algorithm to determine a patient's absolute fracture risk, and to select patients who should receive the highest priority for treatment. FRAX® calculates the 10-year probability of hip (H-FRAX®) and major osteoporotic (clinical spine, forearm, hip and shoulder) fractures (MO-FRAX®). The aim of this study was to calculate the FRAX® in a population of patients with a recent fracture.

Patients and methods

We calculated the FRAX® with femoral neck BMD for all the patients hospitalized for low trauma hip and major osteoporotic fracture over 1 year from February 2009. Bone mineral density (BMD) was measured by DXA and the number of vertebral fractures (VF) were defined using vertebral fracture assessment (VFA) performed during the same exam. The FRAX® was calculated from the data of the day before the fracture, without taking into account the current fracture. All the patients receiving an anti-osteoporotic treatment were excluded.

Results

435 patients were hospitalized over 1 year in the Orthopaedic Department for a non traumatic non vertebral fracture. 134 were excluded because of cognitive disorders, poor general health and ongoing antiosteoporotic treatment and 59 because of non major osteoporotic fracture. Assessment was thus performed in 242 patients (75.2 $\pm$11 years); 134 with hip and 108 with other major osteoporotic fractures (clinical spine fractures excluded). Mean femoral neck T score was -2.3 ($\pm$1.1), and 53% of patients were osteoporotic according to spine and/or hip T scores. Mean MO-FRAX® in patients with incident MO fractures was 13.5 $\pm$9.5% and 44.6% and 62% had a MO-FRAX® $\leq$10% and 15% respectively. Mean H-FRAX® in patients with a hip fracture was 7.2 $\pm$5.8% and 28.2% and 50% had a FRAX® $\leq$3 and 7% respectively. Prevalence of VF by VFA was 42.2% and 50.7% in patients with MO and hip fracture respectively, and 6.3% of these VF were known. Adding these prevalent fractures in the FRAX® calculation increases it to 11.5 % and 22.1% for hip and MO fracture.

Conclusion: this study suggests that following the threshold, 25 to 60 % of patients with recent fracture would not have been detected by the FRAX® before their fracture. Adding prevalent vertebral fracture in the calculation increases the scores, and thus VFA tool should be consider for fracture prediction improvement.

Decreased Risk Of Vertebral Fracture Is Associated With Low-Moderate Amount Of Alcohol Intake In A Random Sample Of Mexicans. Laura Paola Bernal-Rosales*[1], Patricia Clark[2], Juan O Talavera-Piña[3], Margarita Deleze[2], Fidencio Cons-Molina[4]. [1]Hospital Infantil de México "Federico Gómez", Mexico, [2]Laboratorios Clinicos De Puebla, Mexico, [3]Centro Médico Nacional Siglo XXI, Mexico, [4]Unidad de Diagnóstico de Osteoporosis, Mexico

Purpose: The present study analyzed the potential risk factors in a random sample of Mexicans with vertebral fractures. Methods: A total of 820 subjects were evaluated (406 women and 414 men) aged 50 and over. The sample was randomized and stratified according to four age groups (50–59, 60–69, 70–79, and those over 80) from both sexes.A questionnaire containing information on demographic characteristics, gynecologic history, lifestyle habits, calcium intake, alcohol intake, and physical activity was applied to all participants. Lateral X-rays of the lumbar and thoracic spine and BMD by DXA were obtained in all cases. The protocol was submitted and approved by the Institutional Review Board and written consent was obtained from all participants once the implications of their participation in the study was explained in detail and before the application of questionnaires and/or interviews. A bivariate analysis was performed to estimate the odds ratio and the 95% confidence interval for every risk factor related with the presence of a vertebral fracture; this was followed by a multivariate analysis where each variable was adjusted by the rest of them in a global index. Results: The average age for study group was 69.3 years. Age, gender, and physical inactivity were related to vertebral fracture as follows: age of 70–79 years (OR=2.40, IC95% 1.04–5.68), age over 80 years (OR=6.83, IC95% 3.15–15.16), sedentary lifestyle (OR=1.63, IC95% 0.97–2.72) and female gender (OR=2.28, IC95% 1.40–3.73). A low and moderate intake of alcohol (1–40 g/day) was protective factor for vertebral fracture (OR=0.51, IC95% 0.30–0.87). In the multivariate analysis, low and moderate consumption of alcohol remained as a protective factor (OR=0.56, IC95% 0.33–0.92). Conclusion: Moderate alcohol consumption (1–40g/day) presented a protective effect for vertebral fracture, and, as other studies have showed, an association between the age and gender was observed as risk factors of vertebral fracture.

SA0347

Effects of Cigarette Smoke Cadmium on Urine Calcium Excretion in Postmenopausal Women. Maryka Bhattacharyya, Shahram Bozorgnia*. Medical College of Georgia, USA

Low-level cadmium (Cd) exposure in humans is significantly correlated with decreased bone density and increased susceptibility to fractures. In addition, cigarettes are a major source of Cd exposure, with individual smokers having blood Cd concentrations up to 10-fold above those of non-smokers. As part of a larger project, this study investigates if the Cd component of cigarettes is associated with increased calcium excretion from the kidneys of persons who smoke. Eighteen postmenopausal women who smoke cigarettes and 11 non-smokers were studied. From each participant, 2 blood and 11 urine samples were collected over 7 weeks: the first 3 weeks during which smokers smoked at their customary rate; the next 4 days when all smokers ceased smoking; the next 4 weeks when smokers, to different degrees, returned to their previous smoking status. Blood was collected at the beginning and end of the 7 weeks. A first-of-morning (FOM) urine specimen was collected 1- to 2-times per week during the 7 weeks. Smoking status was documented with a daily diary and verified with a carbon monoxide breath test. Analyses included blood Cd concentration (CdB), urine Cd concentration (CdU), and urine calcium concentration (CaU). Results demonstrate that mean values of CdB and CdU were significantly higher in smokers than non-smokers (3.5-fold and 2.6-fold, respectively, $p<0.05$). In addition, prior to smoking cessation, Cd exposure did not increase mean levels of Ca in FOM urine, with 57$\pm$7, 60$\pm$14, and 54$\pm$10 mg Ca per sample for high-Cd smokers (CdB, 1.0-2.7 ng Cd/ml, n=9), lower-Cd smokers (CdB, 0.5-0.9 ng Cd/ml, n=8), and non-smokers (CdB, 0.2-0.6 ng Cd/ml, n=11), respectively (mean $\pm$ SE). However, effects of smoking cessation, measured longitudinally in each subject, did depend upon Cd exposure. During 4 days of smoking cessation, FOM CaU decreased in lower-Cd smokers (-16$\pm$5 mg Ca), showed no change in high-Cd smokers (3$\pm$4 mg Ca), and increased in non-smokers (32$\pm$14 mg Ca). These results indicate that subjects with higher CdB values maintained elevated levels of CaU during the short period of smoking cessation, while CaU values decreased in the lower Cd group. For subjects taking Ca supplements, effects of smoking cessation on CaU were also diminished. Results confirm smoking as a significant source of cadmium exposure and demonstrate that the Cd component of cigarettes may maintain elevated calcium excretion by the kidney, which may play a direct role in osteoporosis.

SA0348

Should Risk of Osteoporosis Restrict Weight Control for Other Health Reasons Among Postmenopausal Women ? - 10-year Follow-up Study. Joonas Sirola*[1], Toni Rikkonen[2], Marjo Tuppurainen[3], Risto Honkanen[4], Heikki Kröger[3]. [1]University of Eastern Finland / Kuopio, Finland, [2]University of Eastern Finland, Campus of Kuopio, Finland, [3]Kuopio University Hospital, Finland, [4]University of Kuorio, Finland

Introduction: High body mass index (BMI) is a risk factor for several morbidities but may be protective against osteoporosis. The aim of the present study was to investigate the effects of overweight and obesity on postmenopausal co-morbidity.

Methods: 1970 Finnish women from the OSTPRE cohort were measured with DXA of femoral neck (FN) and lumbar spine (LS) at baseline (1994) and at 10-year follow-up (2004). Women were categorized according to BMI into normal (under 25 kg/m^2), overweight (25-29 kg/m^2) and obese (over 30 kg/m^2). Weight change (WC) during the follow-up was categorized into tertiles: 1) < 1 kg 2) 1-6.2 kg 3) > 6.2 kg. The definition of osteoporosis in the present study was 10-year follow-up FN or LS T-score under -2.5 SD or under -2.0 SD + low trauma energy follow-up fracture. Information about other co-morbidities was based on self-reports. The end-point morbidities were not allowed to be present at baseline. The risk of each co-morbidity was obtained with multivariate logistic regression, adjusted for age, alcohol intake and smoking.

Results: The incidence of co-morbidities during the follow-up were: hypertension (HT) 25.7 %, cardiac insufficiency 6.2 %, coronary artery disease (CAD) 10.3 %, stroke 5.0 %, diabetes mellitus (DM) 7.3 %, osteoarthritis (OA) 22.3 %, breast cancer (BC) 2.8 %, depression 2.8 %, osteoporosis (OP) 8.2 %, chronic back pain (BP) 17.1 % and poor self-rated health (SRH) 4.3 %. Obesity / overweight predicted higher 10-year risk of HT (OR=2.6 / OR=1.7, $p<0.001$ compared to normal BMI), CAD (OR=1.6, $p<0.05$ / OR=1.2, p=NS), DM (OR=11.7 / OR=5.3, $p<0.001$), OA (OR=1.4, $p<0.05$ / OR=1.1, p=NS), BP (OR=1.6, p=0.007 / OR=1.2, p=NS) and poor SRH (OR=2.4, $p<0.05$ / OR=1.5, p=NS) and lower risk of OP (OR=0.13 / OR=0.41, $p<0.001$). The combined 10-year risk for any co-morbidity significantly associated with BMI, other than SRH and OP, was 2.2 for obese and 1.7 for overweight women (p=0.001). In

comparison to the third WC tertile, the first had 1.8 and 2.6 times ($p<0.001$) and the second 1.6 and 2.9 times ($p<0.05$) lower risk of having HT and BC, respectively.

Conclusions: The health related risks of obesity, especially DM, outweigh its protective effects on bone health. Weight loss has no significant effect on OP but may protect from HT and BC. Patients with BMI under 25 kg/m^2 should be screened for OP, because the risk is over two times higher than the reduction in combined risk of HT, CAD, DM, BP and OA.

Assessing Bone Health in Adult Premenopausal Females in Karachi - A Preliminary Report from Pakistan. Aysha Khan*, Farhan Dar, Romaina Iqbal, Imran Siddiqui, Farooq Ghani. Aga Khan University, Pakistan

Objective: To assess the bone health status in healthy females by using biochemical markers of bone metabolism

Material and Methods:

Study Design: A cross- sectional study.

Place and Duration: The study was conducted at Section of Chemical Pathology, Department of Pathology & Microbiology, The Aga Khan University Hospital, Karachi, Pakistan, from November 2007 to June 2008.

Methodology: 174 healthy premenopausal female volunteers were recruited through convenient, non-purposive sampling after informed consent. Females taking vitamin D or calcium supplements or any medicine or disease altering bone turnover were excluded. A questionnaire addressing the demographic details was filled; NTx, 25OHD and iPTH were measured in blood in fasting. NTx value >19 nMBCE/L was considered high bone turnover. 25OHD levels were stratified as deficient <20 ng/ml, 21-29 ng/m insufficient, and >30 ng/ml sufficient. Plasma iPTH level of > 87 pg/ml was considered high. Data was analyzed using the Statistical Package for Social Sciences SPSS (Release 16.0, standard version, copyright SPSS). A p-value of <0.05 was treated as significant.

Results: Mean age and BMI of the participants was 29.06 ± 6.89 (18 – 48 years) and 23.12 ± 4.58 (13.84 – 41.2) kg/m^2 respectively. 82.8% of the females were identified as D deficient, 16.1% had insufficient levels and 1.1% had optimal levels. High bone turnover as depicted by NTx was seen in 36.8% cases. Secondary hyperparathyroidism was present in 25.9% volunteers while others had blunted PTH response. NTx associated with 25OHD ($r = 0.198$; P-value=0.009); 25OHD associated with iPTH ($r = –0.199$; P=0.009). Major determinant of high serum NTx were 25OHD, sun exposure and purdah observation. High bone turnover coexists with both low 25OHD (hypovitaminosis D; <30ng/ml) and optimal 25OHD (>30ng/ml).

Conclusion: Vitamin D deficiency is highly prevalent in adult females. Bone turnover is high regardless of vitamin D status. There is a need to develop strategies to understand further, the bone biomechanics and bone quality for Pakistani females.

Comparison Between Logistic Regression and Artificial Neural Networks for Morphometric Vertebral Fractures Risk Assessment: New Data from GISMO Lombardia Database. Cristina Eller Vainicher*[1], Ivana Santi[2], Marco Massarotti[3], Luca Pietrogrande[4], Matteo Longhi[5], Valter Galmarini[6], Giorgio Gandolini[7], Maurizio Bevilacqua[8], Iacopo Chiodini[1], Enzo Grossi[9]. [1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinco Milano, Italy, [2]Istituto Geriatrico ASP IMMeS e Pio Albergo Trivulzio Milano, Italy, [3]IRCCS Humanitas Clinical Institute, Italy, [4]Ospedale S.Paolo - Università degli Studi di Milano, Italy, [5]IRCCS Galeazzi Milano, Italy, [6]AO Fatebenefratelli e Oftalmico Milano, Italy, [7]Don C. Gnocchi Foundation IRCCS Milan, Italy, [8]Ospedale L. Sacco - Polo Universitario, Italy, [9]Centro Diagnostico Italiano, Italy

Background: There is growing interest in the development of algorithms, like FRAX™, using traditional statistical approach, for predicting osteoporotic fractures. Nevertheless, some studies suggest their poor sensitivity. Artificial Neural Networks (ANNs), computer algorithms inspired by the highly interactive processing of the human brain, could represent an attractive alternative to this approach. So far, no reports have investigated the ability of ANNs in predicting osteoporosis fracture.

Aim: To evaluate the capacity of ANNs, compared with Logistic Regression (LR), to recognise patients with or without morphometric vertebral fractures (MVF+ and MFV- respectively) on the basis of classical bone osteoporotic risk factors and other clinical information.

Methods: We compared the prognostic performance of ANNs with that of LR in predicting MFV in 372 female patients affected with postmenopausal osteoporosis (MVF+ n=176; MVF- n=196), described by 42 independent variables. ANNs where allowed to choose the relevant input data automatically (Twist system-Semeion).

Results: 18 variables were selected, as most relevant, among 42 by TWIST system. Using this set of variables the mean sensitivity of LR and ANNs in test data sets was 35.8% and 72.47% respectively, the mean specificity was 76.53% and 78.50% respectively, the overall accuracy was 56.17% and 75.48% respectively.

Age, BMI, years since menopause, smoking habit, hypertension, dislipydemia, calcium intake, bone mineral density, family history of femoral fracture, resulted to be the most relevant variables for the best performing model.

Conclusions: ANNs showed a better performance than LR in predicting the presence of MVF, in particular ANNs showed a higher sensitivity in respect with LR. These results suggest a promising role of ANNs in the development of algorithm for predicting osteoporotic fractures.

Differences in Skeletal and Non-Skeletal Factors in a Diverse Sample of Men With and Without Type 2 Diabetes Mellitus. Ann Schwartz[1], Gretchen Chiu[2], Julia Dixon[2], Andre Araujo*[2]. [1]University of California, San Francisco, USA, [2]New England Research Institutes, USA

Purpose: While fracture risk is higher in patients with type 2 diabetes mellitus (T2DM), patients with T2DM tend to have higher bone mineral density (BMD) than their non-diabetic counterparts. These observations motivate comparisons of both skeletal and non-skeletal factors in subjects with and without T2DM.

Methods: The Boston Area Community Health/Bone (BACH/Bone) Survey is a population-based cross-sectional survey of skeletal health in a random sample of 1,219 Boston men aged 30-79 y. Diabetes status, age and race/ethnicity were obtained via self-report. BMD and body composition were measured by DXA. Physical function was assessed via a composite physical function score derived from walk and chair stand tests. Grip strength was measured with a hydraulic hand dynamometer. Multivariate linear regression was used to examine the association of T2DM status with skeletal and non-skeletal factors.

Results: Of the 1137 men with complete data included in this analysis, the mean age was 48 y. Prevalence of T2DM was 12.5%, with an average duration of disease of 7.4 y. Of the skeletal factors considered, only lumbar spine BMD was significantly higher in men with T2DM. Of the non-skeletal factors considered, both the composite physical function score and maximum grip strength were significantly lower in men with T2DM. As shown in the table, skeletal factors were no longer significantly associated with T2DM status in multiple regression models. Non-skeletal factors including appendicular lean mass, arms lean mass, and maximum grip strength were negatively associated with T2DM after adjustment.

Conclusion: These results suggest that non-skeletal factors such as body composition and muscle strength, which may influence fall risk, could explain higher fracture rates among patients with T2DM.

		T2DM		
Subgroup	Outcomes	β	SE	p-value
Skeletal Factors	Femoral neck BMD (g/cm^2)	-0.01	0.02	0.46
	Lumbar spine BMD (g/cm^2)	0.01	0.02	0.56
Non-Skeletal Factors	Lean mass (kg)	-0.54	0.82	0.51
	Appendicular lean mass (kg)	-1.04	0.50	0.04
	Arms lean mass (kg)	-0.42	0.15	0.006
	Legs lean mass (kg)	-0.62	0.37	0.097
	Composite score	-0.48	0.26	0.07
	Maximum grip strength (kg)	-3.02	1.25	0.02

Gender Differences in Factors Associated with Falls in a Population-Based Cohort Study in Japan: The ROAD Study. Shigeyuki Muraki*[1], Toru Akune[1], Hiroyuki Oka[1], Kozo Nakamura[2], Hiroshi Kawaguchi[3], Noriko Yoshimura[1]. [1]University of Tokyo, Japan, [2]The University of Tokyo, Japan, [3]University of Tokyo, Faculty of Medicine, Japan

Fall is the most serious factor for fractures in the elderly; therefore, it is important to identify subjects with factors associated with fall. The objective of the present study was to determine factors associated with falls in elderly men and women. From the 3,040 participants in the ROAD study, the present study analyzed 1,180 subjects aged more than 60 years from the mountainous and coastal cohorts (431 men and 749

women; mean age, 71.7 years). At the baseline, physical ability was estimated by measuring grip strength, 6-m walking time, normal step length (NSL), and chair stand time. Further, vertebral fracture (VFx) was assessed by lateral radiographs of the lumbar spine. Lumbar spondylosis and knee osteoarthritis (OA) were defined as a Kellgren/Lawrence grade of ≥3. Falls during the preceding year were evaluated by a self-reported questionnaire. During 1 year, 63 men (14.7%) and 153 women (20.5%) fell once or several times. In men, logistic regression analysis without adjustment revealed that NSL and radiographic VFx at the baseline were significantly associated with falls (odds ratio [OR], 0.94 and 2.21; 95% confidence interval [CI], 0.90–0.99 and 1.19–4.00, respectively), but grip strength, 6-m walking time, chair stand time, knee OA, and lumbar spondylosis were not associated with falls (OR: 0.98, 1.01, 1.03, 0.77, and 1.13; 95% CI: 0.94–1.02, 0.91–1.10, 0.96–1.10, 0.36–1.54, and 0.66–1.94, respectively). Multiple logistic regression analysis after adjustment for age revealed that NSL and radiographic VFx were independently associated with falls (OR, 0.94 and 2.08; 95% CI, 0.89–0.98 and 1.08–3.88, respectively). In women, logistic regression analysis without adjustment revealed that grip strength and knee OA were significantly associated with falls (OR, 0.96 and 1.52; 95% CI, 0.92–0.99 and 1.05–2.20, respectively), but 6-m walking time, NSL, chair stand time, VFx, and lumbar spondylosis were not associated with falls (OR: 1.03, 0.99, 1.02, 1.47, and 1.23; 95% CI: 0.97–1.08, 0.94–1.03, 0.98–1.05, 0.86–2.42, and 0.86–1.75, respectively). Multiple regression analysis after adjustment for age revealed that grip strength and knee OA were independently associated with falls (OR, 0.95 and 1.56; 95% CI, 0.91–0.99 and 1.05–2.30, respectively). In conclusion, this study revealed distinct factors associated with falls in men and women. In men, NSL and VFx were associated with falls, whereas in women, grip strength and knee OA were associated with falls.

Lack of Association Between Osteoporosis and Coronary Artery Disease in Korean Men and Women. Se Hwa Kim[1], Soo-Kyung Kim[2], Deok-Kyu Cho[1], Yun-Hyeong Cho[1], Sun-Ok Song*[1]. [1]Kwandong University College of Medicine, Myongji Hospital, South korea, [2]Pochon CHA University College of Medicine, South korea

Background: Coronary artery disease (CAD) and osteoporosis are major causes of morbidity and mortality in the elderly. The aim of this study was to investigate whether osteoporosis or osteoporotic fractures was associated with CAD independent of traditional risk factors. Subjects and Methods: Study population consisted of Korean men and women who underwent coronary angiography. The following clinical and demographic parameters were recorded: age, sex, body mass index (BMI), hypertension, diabetes mellitus, coronary artery disease, smoking status. Bone mineral density (BMD) and T-L spine lateral X-ray were taken. Of 485 patients, 250 were taken T-L spine lateral X-ray to assess the vertebral fractures and BMD was assessed using dual energy X-ray absorptiometry (DXA) in 110 patients. Results: Patients were grouped according to the BMD (normal, osteopenia, and osteoporosis). Patients with vertebral fractures were regard as osteoporosis group. Patients with osteoporosis were older and had lower BMI than those with normal or osteopenia. There were not significant differences between three groups in respect to diabetes mellitus, hypertension, hypercholesterolemia, BMD. Prevalence of CAD was not different between the 3 groups. However, prevalence of CAD involving more than 2 coronary arteries in patients with osteoporosis or vertebral fractures was higher than in patients with normal BMD (26% vs. 56% in women, 36% vs. 69% in man). In the logistic regression analysis showed that age and diabetes mellitus were independently associated with CAD. Conclusions: Age and diabetes mellitus were independent predictors of CAD in our study population. However, osteoporosis or vertebral fracture did not show any association with CAD in Korean men and women.

Modification of the Osteoporosis Patient Assessment Questionnaire Using Item Response Theory Methods. April Naegeli*[1], Russel Burge[1], Steven Watts[1], Timothy Stump[2], Deborah Gold[3], Stuart Silverman[4]. [1]Eli Lilly & Company, USA, [2]Indiana University School of Medicine, USA, [3]Duke University Medical Center, USA, [4]Cedars-Sinai/UCLA, USA

The purpose of this study was to develop a modified version of the Osteoporosis Patient Assessment Questionnaire (OPAQ 3.0) that reduces respondent burden and specifically assesses the impact of osteoporosis on physical function and mobility for use in clinical trials evaluating drug therapy for the prevention of vertebral fracture.

This study was conducted using the Multiple Outcomes of Raloxifene Evaluation (MORE) trial database. At baseline, 1478 patients were administered the OPAQ 2.0. The OPAQ 2.0 is an 18-domain, 60-item patient reported outcome (PRO) measure used in clinical trials to evaluate health-related quality of life in patients with fractures related to their osteoporosis. Items were evaluated based on the application of a unidimensional, polytomous Item Response Theory (IRT) model and clinical relevance founded on expert judgment. Dimensionality was assessed with a factor analysis considering eigenvalues. A large drop from the first to second eigenvalue with the rest following the scree plot was indicative of a unidimensional scale. Items were retained based on their relatedness to the underlying construct and ability to discriminate through analysis of Item Information and Item Characteristic Curves, respectively. All analyses were conducted using Mplus statistical software.

OPAQ 3.0 contains 6 domains with 21 items retained from OPAQ 2.0: walking and bending (6 items), sitting and standing (3 items), transfers (4 items), backache and pain (2 items), fear of falls (3 items), and independence (3 items). Slight modifcations to item wording and response options were necessary to improve clinical relevance and to capture descriptions as depicted by patients with osteoporosis.

OPAQ 3.0 was developed based on clinical trial responses to OPAQ 2.0 to decrease respondent burden by reducing the number of items from 60 to 21, and to assess the impact of osteoporosis, specifically on physical function and mobility. Next steps for OPAQ 3.0 include confirmation of content validity, and evaluation of psychometric properties (factor structure, reliability, validity, and responsiveness) in targeted clinical trial patient populations for drug therapy aimed to prevent fracture related to osteoporosis.

Obesity in Adolescence and Bone Strength in Adulthood. Kirsti Uusi-Rasi*[1], Marika Laaksonen[2], Olli Raitakari[3], Jorma Viikari[4], Mika Kähönen[5], Harri Sievänen[1]. [1]UKK Institute for Health Promotion Research, Finland, [2]University of Helsinki, Finland, [3]University oh Turku, Finland, [4]University of Turku, Finland, [5]University of Tampere, Finland

While obese children have been reported to have lower bone mass for a given weight, obese adults have greater bone mineral density compared with normal weight adults. In this prospective cohort study we evaluated differences in bone cross-sectional size and density in relation to the age of gaining excess body mass.

328 women from the population-based cohort of The Young Finns Study were divided into 4 groups by body mass index (BMI) at the age of 12-15 years (healthy body weight, C-, or overweight/obese, C+) and 24 years later (healthy weigh in adulthood A-, or overweight/obese in adulthood A+). Of 162 overweight women, 49 had been obese since childhood (C+A+) and 113 had gained extra weight in adulthood (C-A+). Of 166 healthy weight women, 24 had been overweight in childhood (C+A-) and 142 had always been healthy weight (C-A-).

Total cross-sectional area (ToA, mm^2) and cortical (shaft CoD, mg/cm^3) and trabecular (distal TrD, mg/cm^3) bone density of the radius and tibia were measured with pQCT at the mean age (SD) of 38 (1.5) years. Between-group differences were evaluated with analysis of covariance.

Mean body height was 166 (6) cm without between-group differences. In healthy weight groups, mean body mass was similar being 62 (6) and 61 (6) kg, but those women who had been obese since childhood weighted more than women who had become obese in adulthood, the mean weights being 89 (18) and (80 (10) kg, respectively. Childhood obesity was associated with larger ToA especially at the tibia, whilst obesity in adulthood predicted higher TrD and lower CoD (Table).

Childhood obesity was associated with larger cross-sections at long bone diaphyses and distal tibia, but not distal radius. Being obese since childhood or gaining excess weight in adulthood may lead to lower cortical and higher trabecular density both at weight-bearing and nonweight-bearing bones. In contrast, it seems that temporary obesity in adolescence, while being associated with increased bone size, may lead to lower trabecular density.

	C-A+, n=113	C+A+, n=49	C+A-, n=24	p for group differences
Distal radius TrD	2.7 (-1.6 to 6.9)	3.4 (-2.3 to 9.0)	-3.5 (-11.7 to 4.3)	0.073
Distal radius ToA	1.4 (-3.0 to 5.8)	2.3 (-3.5 to 8.0)	4.1 (-3.8 to 11.3)	0.450
Radial shaft CoD	-0.7 (-1.4 to -0.2)	-0.9 (-1.6 to 0)	0.0 (-1.2 to 0.9)	0.002

Serum 25-Hydroxyvitamin D Levels, Mortality and Risk of Non-spine and Hip Fractures in Older White Women: Data from the Study of Osteoporotic Fractures. Marc Hochberg*[1], Li-Yung Lui[2], Dennis Black[3], Jane Cauley[4], Peggy Cawthon[2], Kristine Ensrud[5], Lisa Fredman[6], Teresa Hillier[7], Steven Cummings[8]. [1]University of Maryland School of Medicine, USA, [2]California Pacific Medical Center Research Institute, USA, [3]University of California, San Francisco, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]Minneapolis VA Medical Center / University of Minnesota, USA, [6]Boston University School of Public Health, USA, [7]Kaiser Center for Health Research, USA, [8]San Francisco Coordinating Center, USA

Objective: The associations between low serum vitamin D levels and mortality and fracture risk are inconsistent. The objective of the current analysis was to determine whether low serum levels of 25-hydroxyvitamin D (25[OH]D) were associated with higher mortality and an increased risk of non-spine, including hip, fractures in older white women. Methods: Serum 25(OH)D levels were measured by liquid chromatography-tandem mass spectroscopy in frozen specimens from 5915 white women (mean [SD] age: 76.7 [4.8] years) who completed Visit 4 in the Study of Osteoporotic Fractures between August 1992 and July 1994. Cox proportional hazards models were used to test the association of serum 25(OH)D levels, as either a continuous or categorical variable, with all-cause mortality, and the incidence of non-spine and hip fractures; results are expressed as hazard ratios (HR) with 95% confidence intervals (CI).Results: Mean (SD) serum 25(OH)D level was 23.2 (11.7) ng/ml; quartiles were defined as <=16, 17-22, 23-28 and >=29 ng/ml. 3199 women died during a mean 11.1 (4.5) years of follow-up. There was a significant trend for increasing mortality in lower quartiles of 25(OH)D in age-adjusted but not multivariate (MV)-adjusted models (Table). Women in the lowest quartile of serum 25(OH)D levels had a significantly increased risk of mortality in age-adjusted models compared with women in Q2-4 combined: HR 1.10 (1.02, 1.19). This association was stronger with shorter length of follow-up: HR 1.29 (1.10, 1.51) and 1.15 (1.04, 1.27) after 5 and 10 years of follow-up, respectively. 2174 women sustained a non-spine fracture, including 768 with a hip fracture, over a mean 8.7 (5.0) years of follow-up. Lower serum 25(OH)D levels were significantly associated with a decreased risk of both non-spine and hip fractures in both age- and MV-adjusted models as a continuous but not as a categorical variable (Table). There was a significant trend for decreasing hip fracture risk in lower quartiles of 25(OH)D levels in MV-adjusted models (Table). Similar results were found when data were analyzed using clinically relevant cutpoints (deficient, insufficient and sufficient) for 25(OH)D levels.Conclusion: These data suggest a relationship between low serum 25(OH)D levels and an increased risk for all-cause mortality while, paradoxically, providing evidence for a reduced risk of hip fractures in these older white women with lower 25(OH)D levels.

The Effect of Biological Aging On Bone Mineral Density and Fracture. Kyoung Min Kim*[1], Kwang Joon Kim[2], Su-Jin Park[3], Gadi Jogeswar[3], Jami Ajita[3], Yumie Rhee[4], Sung-Kil Lim[5]. [1]Yonsei University, South korea, [2]Severance Hospital, South korea, [3]Yonsei university colleage of medicine, South korea, [4]IUMS, Yonsei University, College of Medicine, South korea, [5]Yonsei University College of Medicine, South korea

Introduction: Bone mineral density is influenced by the dynamics of aging, inflammation and bone remodeling processes. Admittedly, chronological age (CA) being a major determinant of BMD. However, this CA simply measures the amount of time that has gone by since birth. Thus, CA provides only limited information about matters such as declining functional capacity and other properties we associate with aging. Therefore, several previous reports have tried to search the correlations between telomere length, as a marker of biological aging, and BMD. Purpose : We sought to identify the useful candidate biomarkers of aging for evaluation of individual biological capacity, and using these to develop an equation measuring biological age (BA), then to investigate the relationships between individual biological aging with BMD. Results : Among 4763 men and 5275 women aged 39~70 years-old, we selected 1509 subjects who met the normality criteria of each biochemical variables. Variables showing significant correlations (correlation coefficient >0.15, $p<0.05$) with CA were selected. 5 variables were selected including systolic blood pressure (SBP), forced expiratory volume in 1 s (FEV1), glycosylated hemoglobin (HbA1c), red blood cell count(RBC) and waist/hip ratio(W/H). Then, Biological aging calculating equation was obtained by multiple regression analysis with using these 5 variables. We calculated each one's BA and the differences between these two ages (BA-CA, Biological Aging Score(BAS)). Individual BAS showed significant correlations with glucose metabolism, pulmonary function, hematological variables, lipid profile and anthropometric parameters after adjusting CA. However, BAS was not associated with BMD, osteoporosis or fracture after adjusting CA unlikely other clinical parameters. Conclusions : No association was observed between BAS and BMD in Korean. This finding can tell us that BMD will be strongly afftected by not BA but CA, the time after birth.

Better Skeletal Microstructure Confers Greater Mechanical Advantages in Chinese-American Women than Caucasian Women. Xiaowei Liu*[1], Marcella Walker[1], Bini Zhou[1], Donald McMahon[2], Julia Udesky[1], George Liu[3], John Bilezikian[2], X Guo[1]. [1]Columbia University, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]New York Downtown Hospital, USA

Despite lower areal BMD (aBMD) by DXA, Chinese-American (CH) women have fewer fractures (Fx) than Caucasian (CA) women. We hypothesized that better skeletal microstructure in CH women could account for this paradox. To address this hypothesis, we applied individual trabeculae segmentation (ITS), a novel image analysis technique, and micro finite element analysis (μFEA), to high-resolution peripheral quantitative computed tomography (HR-pQCT) images of premenopausal CH and CA women.

Age was similar (36 ± 7 *vs.* 35 ± 4), but height (64 ± 2 *vs.* 65 ± 3 inches; p=0.02) and weight (125 ± 22 *vs.* 139 ± 38 lbs; p=0.03) were lower in the CH (n=46) *vs.* CA (n=49) group. aBMD by DXA did not differ at the spine, hip and 1/3 radius. ITS analysis was applied to trabecular sub-volumes of HR-pQCT (XtremeCT, Scanco Medical; voxel size 82 μm) images at the distal radius (DR) and distal tibia (DT) to quantify trabecular plate- and rod-microarchitecture. Remarkably, CH women had 94% (DR) and 80% (DT) higher plate bone volume fraction (pBV/TV) and 20% (DR) and 18% (DT) higher plate number density (pTb.N) as compared to CA women ($p<0.0001$). In contrast, rod-like characteristics {*i.e.* the amount and number of trabecular rod (rBV/TV and rTb.N)} were similar. Thus, the plate/rod ratio was much greater in CH than in CA trabecular bone. Additionally, plate thickness (pTb.Th) was 9% (DR) and 4% (DT) greater in CH women ($p<0.001$). Plate-rod and plate-plate junction densities (P-R & P-P Junc.D), parameters indicating the trabecular network connections, were 37% and 56% (DR) and 29% and 49% (DT) greater in CH women ($p<0.01$). These striking differences in trabecular bone translate into 55%-69% (DR, $p<0.001$) and 29%-54% (DT, $p<0.05$) higher Young's and shear moduli in the CH vs. CA groups, as estimated by μFEA of HR-pQCT images. Moreover, although CH women have 9% (DR, p=0.03) and 6% (DT, p=0.08) smaller bone size than CA women, thicker cortices (18% and 10% higher in CH vs. CA, $p<0.05$) and more plate-like trabecular bone lead to 14% (DR) and 8% (DT) greater whole bone stiffness ($p<0.05$).

Greater microstructural advantages in CH, as shown by these results, may help to account for lower Fx rates in CH women as compared to CA women.

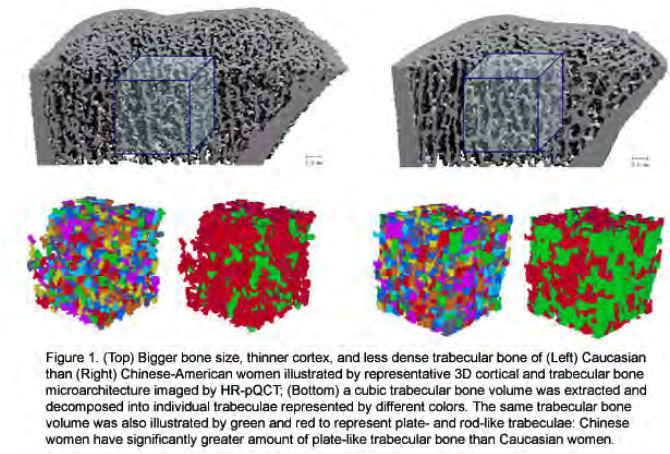

Figure 1. (Top) Bigger bone size, thinner cortex, and less dense trabecular bone of (Left) Caucasian than (Right) Chinese-American women illustrated by representative 3D cortical and trabecular bone microarchitecture imaged by HR-pQCT; (Bottom) a cubic trabecular bone volume was extracted and decomposed into individual trabeculae represented by different colors. The same trabecular bone volume was also illustrated by green and red to represent plate- and rod-like trabeculae: Chinese women have significantly greater amount of plate-like trabecular bone than Caucasian women.
