2013 Abstracts

Thirty-Fifth Annual Meeting of the American Society for Bone and Mineral Research

Baltimore Convention Center in Baltimore, Maryland, USA October 4–7, 2013

The *Journal of Bone and Mineral Research* (ISSN: 0884-0431 [print]; 1523-4681 [online]) provides a forum for papers of the highest quality pertaining to bone, muscle, and mineral metabolism. Manuscripts are published on the biology and physiology of bone and muscle, relevant systems biology topics (e.g., osteoimmunology), and the pathophysiology and treatment of sarcopenia, and disorders of bone and mineral metabolism. All authored papers and editorial news and comments, opinions, findings, conclusions or recommendations in the *Journal* are those of the author(s) and do not necessarily reflect the views of the *Journal* and its publisher, nor does their publication imply any endorsement.

The JOURNAL OF BONE AND MINERAL RESEARCH (ISSN: 0884-0431), is published monthly on behalf of the American Society for Bone and Mineral Research by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to JOURNAL OF BONE AND MINERAL RESEARCH, Journal Customer Services, John Wiley & Sons Inc., 350 Main St., Malden, MA 02148-5020. **Information for subscribers:** The *Journal of Bone and Mineral Research* is published in 12 issues per year. Institutional subscription prices for 2013 are: Print & Online: US$1024 (US), US$1086 (Rest of World), €787 (Europe), £671 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wileyonlinelibrary.com/tax-vat. The price includes online access to the current and all online back fi les to January 1st 2009, where available. For other pricing options, including access information and terms and conditions, please visit www.wileyonlinelibrary.com/access. **Commercial Reprints:** Beth Ann Rocheleau, Reprints and Eprints Manager, Rockwater, Inc., PO Box 2211, Lexington, SC 29072, USA; Tel: +00 (1)803 359-4578; Fax: +00 (1)803-753-9430; E-mail: asbmr@rockwaterinc.com. For submission instructions, subscription and all other information, visit: http://onlinelibrary.wiley.com/journal/10.1002/%28ISSN%291523-4681

The *Journal of Bone and Mineral Research* is the official journal of the American Society for Bone and Mineral Research, 2025 M Street, NW, Suite 800, Washington, DC 20036-3309, USA. **Advertising:** Address advertising inquiries to Stephen Donohue, Advertising Sales Executive, Wiley Blackwell, 350 Main Street, Malden, MA 02148, (781) 388-8511 (Tel); sdonohue@wiley.com (email). Advertisements are subject to editorial approval and must adhere to ASBMR's advertising policy as specified here: http://onlinelibrary.wiley.com/journal/10.1002/%28ISSN%291523-4681/homepage/advertising_policy.htm. Publication of the advertisements in JBMR is not an endorsement of the advertiser's product or service or the claims made for the product in such advertising. **Disclaimer:** No responsibility is assumed, and responsibility is hereby disclaimed, by the American Society for Bone and Mineral Research, the *Journal of Bone and Mineral Research,* and the Publisher for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of methods, products, instructions or ideas presented in the *Journal*. Independent verification of diagnosis and drug dosages should be made. Discussions, views and recommendations as to medical procedures, choice of drugs and drug dosages are the responsibility of the authors. Advertisers are responsible for compliance with requirements concerning statements of efficacy, approval, licensure, and availability. The *Journal of Bone and Mineral Research* is a **Journal Club™** selection. The Journal is indexed by *Index Medicus, Current Contents/Life Science, CABS (Current Awareness in Biological Sciences), Excerpta Medica, Cambridge Scientific Abstracts, Chemical Abstracts, Reference Update, Science Citation Index,* and Nuclear Medicine Literature Updating and Indexing Service.

GUIDELINES FOR ABSTRACT READERS

The *JBMR*® Supplement 1 Abstracts serves as a compiled version of the Abstracts. Authors submit their own abstracts and are charged a fee to do so. Each abstract must be sponsored by a current ASBMR member. Authors are responsible for the accuracy of the content that they post. Authors are responsible for ensuring compliance with applicable human subject and animal subject procedures. When an abstract is submitted, one person is identified as the Presenting Author, the person who is expected to present the abstract at the ASBMR Annual Meeting.

The ASBMR depends upon the honesty of the authors and presenters and relies on their assertions that they have had sufficient full access to the data to be and are convinced of its reliability. The ASBMR expects that authors and presenters:

- Will disclose any conflicts of interest, real or perceived.
- Should disclose any relationship that may bias one's presentation or which, if known, could give the perception of bias.
- Will affirm, for any study funded by an organization with a proprietary or financial interest, that they had full access to all the data in the study.
- Are responsible for the content of abstracts, presentations, slides, and reference materials.
- Keep the planning, content and execution of abstracts, speaker presentations, slides, abstracts and reference materials free from corporate influence, bias or control.
- Should give a balanced view of therapeutic options by providing several treatment options, whenever possible, and by always citing the best available evidence.
- Should disclose when any commercial product is not labeled for the use under discussion or that the product is still investigational.

The ASBMR:

- Will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.
- Will peer-review the abstracts according to categories, but only to determine which will be selected for oral presentation, for poster presentations or for any awards. Abstracts are not otherwise subject to any quality or content review by ASBMR or *JBMR*®.
- Expects the audience for the Abstracts to be researchers, physicians and other health and allied health professionals.
- Protects the Abstracts by copyright, and prohibits the reproduction, distribution or transmission of the abstracts without the express written permission of ASBMR.
- Embargoes the Abstracts for public release in written, oral and electronic communications until one hour after the abstract has been presented.

Disclaimer. All authored abstracts, findings, conclusions, recommendations or oral presentations are those of the author(s) and/or speaker(s) and do not reflect the views of the American Society for Bone and Mineral Research or imply any endorsement. No responsibility is assumed, and responsibility is hereby disclaimed, by the American Society for Bone and Mineral Research for any injury and/or damage to persons or property as a matter of products' liability, negligence or otherwise, or from any use or operation of methods, products, instructions or ideas presented in the abstracts or at the ASBMR Annual Meeting. Independent verification of diagnosis and drug dosages should be made. Discussions, views and recommendations regarding medical procedures, choice of drugs and drug dosages are the responsibility of the authors and presenters.

TABLE OF CONTENTS

JBMR® Editorial Board

AMERICAN SOCIETY FOR BONE AND MINERAL RESEARCH (ASBMR)

OFFICERS

Lynda F. Bonewald, Ph.D., President
Roberto Civitelli, M.D., President-Elect
Keith Hruska, M.D., Past-President
Brendan Boyce, M.D., Secretary-Treasurer
Dolores Shoback, M.D., Secretary-Treasurer Elect

COUNCILORS

Robert Adler, M.D.	*Term expires 2015*
Peter Ebeling, MBBS, M.D., FRACP	*Term expires 2014*
Dana Gaddy, Ph.D.	*Term expires 2014*
Nancy Lane, M.D.	*Term expires 2013*
Deborah V. Novack, M.D, Ph.D.	*Term expires 2015*
Eric S. Orwoll, M.D.	*Term expires 2013*
Roberto Pacifici, M.D.	*Term expires 2014*
G. David Roodman, M.D., Ph.D.	*Term expires 2013*
Eileen M. Shore, Ph.D.	*Term expires 2015*
Juliet E. Compston, M.D., FRCP	*Ex-Officio 2017*

ASBMR STAFF

Sarah Alcock, *Accountant*
Moira Andersen, *Meetings Associate*
William Braun, *Marketing Associate*
Angela Cangemi, *Program Manager*
Jenny Cano, *Registration Associate*
Sarah Dickey, *Associate*
Ann L. Elderkin, P.A., *Executive Director*
Douglas Fesler, *Associate Executive Director*
Bethel Habte, *Senior Associate*
Melissa Huston, *Director, Event Services*
Jessica Klapstein, *Housing and Ancillary Meetings Manager*
Deborah Kroll, *Director of Development*
Earline Marshall, *Senior Grants Administrator*
Brenda Malottke, *Director of Finance*

ASBMR COMMITTEE MEMBERS AND REPRESENTATIVES

ADVOCACY/SCIENCE POLICY COMMITTEE

Dwight Towler, M.D., Ph.D., *Chairperson*
Laura R. McCabe, Ph.D.
Paola Divieti Pajevic, M.D., Ph.D.
Kenneth G. Saag, M.D., MSc
Robert S. Weinstein, M.D.
Bart O. Williams, Ph.D.
Sylvia Christakos, Ph.D., *Ex-Officio*
Suzanne M. Jan De Beur, M.D., *Ex-Officio*
Robert A. Adler, M.D., *Council Liaison*
Ann L. Elderkin, P.A., *Staff Liaison*
Douglas Fesler, *Staff Liaison*

EDUCATION COMMITTEE

Marian T. Hannan, D.Sc., MPH, *Chairperson*
Charles R. Farber, Ph.D.
Louis C. Gerstenfeld, Ph.D.
Erik A. Imel, M.D.
Yebin Jiang, M.D., Ph.D.
Stavroula Kousteni, Ph.D.
Bruno Camargos, M.D., *Ad Hoc*
Nicola Napoli, M.D., *Ad Hoc*
Nancy Lane, M.D., *Council Liaison*
Angela Cangemi, *Staff Liaison*
Lindsay Schoenle, *Staff Liaison*

ETHICS ADVISORY COMMITTEE

Michael J. Econs, M.D., *Chairperson*
Kristina Akesson, M.D., Ph.D.
Maria-Grazia Ascenzi, Ph.D.
Douglas P. Kiel, M.D., MPH
Laurie K. McCauley, D.D.S., Ph.D.
Tamara J. Vokes, M.D.
Keith A. Hruska, M.D., *Ex Officio*
Lynda F. Bonewald, Ph.D., *Ex Officio*
Eileen M. Shore, Ph.D., *Council Liaison*
Ann L. Elderkin, P.A., *Staff Liaison*
Earline Marshall, *Staff Liaison*
Kirsten Mills, *Staff Liaison*

FINANCE COMMITTEE

Brendan F. Boyce, M.D., *Chairperson*
Daniel D. Bikle, M.D., Ph.D.
Robert D. Blank, M.D., Ph.D.
Mark C. Horowitz, Ph.D.
Majd Zayzafoon, M.D., Ph.D., *Ad Hoc*
Lynda F. Bonewald, Ph.D., *Ex Officio*
Roberto Pacifici, M.D., *Council Liaison*
Ann L. Elderkin, P.A., *Staff Liaison*
Brenda Malottke, *Staff Liaison*

MEMBERSHIP ENGAGEMENT COMMITTEE

Wenhan Chang, Ph.D., *Chairperson*
Cheryl L. Ackert-Bicknell, Ph.D.
Gustavo Duque, M.D., Ph.D.
Deborah L. Galson, Ph.D.
Martin Hewison, Ph.D.
David Karasik, Ph.D.
Robert R. McLean, DSc
Kristy M. Nicks, Ph.D.
Babatunde O. Oyajobi, MBBS, Ph.D.
Lilian I. Plotkin, Ph.D.
Peter R. Ebeling, MBBS, M.D., FRACP, *Council Liaison*
Kirsten Mills, *Staff Liaison*
Bethel Habte, *Staff Liaison*
Sarah Dickey, *Staff Liaison*

MINORITY SUBCOMMITTEE

Sherri-Ann M. Burnett-Bowie, M.D., MPH, *Chairperson*
Jacqueline P. Akech, Ph.D.
Sunday Akintoye, D.D.S.
Sylvia Christakos, Ph.D.
Jeanette N. Keith, M.D.
Kristy M. Nicks, Ph.D.
Roger Zebaze, M.D.
Kirsten Mills, *Staff Liaison*
Bethel Habte, *Staff Liaison*
Sarah Dickey, *Staff Liaison*

YOUNG INVESTIGATOR SUBCOMMITTEE

John R. Hawse, Ph.D., *Co-Chairperson*
Meghan E. McGee-Lawrence, Ph.D., *Co-Chairperson*
Jodi Dowthwaite, Ph.D.
Jessica A. Fowler
Anne Gingery, Ph.D.
Francesco Grassi
Kristie Kapinas
Kristi Milley
Kenneth Philbrick
Benjamin Sinder
Kirsten Mills, *Staff Liaison*
Bethel Habte, *Staff Liaison*
Sarah Dickey, *Staff Liaison*

PROFESSIONAL PRACTICE COMMITTEE

Suzanne M. Jan De Beur, M.D., *Chairperson*
Susan V. Bukata, M.D.
Matthew T. Drake, M.D., Ph.D.
Julie Glowacki, Ph.D.
Robert Pignolo, M.D., Ph.D.
Deborah E. Sellmeyer, M.D.
Emily Margaret Stein, M.D.
G. David Roodman, M.D., Ph.D., *Council Liaison*
Dana Gaddy, Ph.D., *Council Liaison*
Douglas Fesler, *Staff Liaison*
Ann L. Elderkin, P.A., *Staff Liaison*

PUBLICATIONS COMMITTEE

Philip Osdoby, Ph.D., *Chairperson*
Matthew Allen, Ph.D.
Carlos M. Isales, M.D.
Robert L. Jilka, Ph.D.
Moustapha Kassem, M.D., Ph.D.
Paul D. Miller, M.D., FACP
Dolores Shoback, M.D.
Anna Spagnoli, M.D.
Juliet E. Compston, M.D., FRCP, *Ex Officio*
Clifford J. Rosen, M.D., *Ex Officio*
Eric S. Orwoll, *Council Liaison*
Lynn King, *Staff Liaison*

PAST PRESIDENTS

Louis V. Avioli, M.D.	*1979–1980*	Gregory R. Mundy, M.D.	*1996–1997*
Lawrence G. Raisz, M.D.	*1980–1981*	Michael Rosenblatt, M.D.	*1997–1998*
Claude D. Arnaud, M.D.	*1981–1982*	Jane E. Aubin, Ph.D.	*1998–1999*
Stephen M. Krane, M.D.	*1982–1983*	David Goltzman, M.D.	*1999–2000*
William A. Peck, M.D.	*1983–1984*	Robert Marcus, M.D.	*2000–2001*
Paula H. Stern, Ph.D.	*1984–1985*	Robert R. Recker, M.D.	*2001–2002*
B. Lawrence Riggs, M.D.	*1985–1986*	Clifford J. Rosen, M.D.	*2002–2003*
Norman H. Bell, M.D.	*1986–1987*	Robert A. Nissenson, Ph.D.	*2003–2004*
Gideon A. Rodan, M.D., Ph.D.	*1987–1988*	Sylvia Christakos, Ph.D.	*2004–2005*
John G. Haddad, Jr., M.D.	*1988–1989*	Elizabeth Shane, M.D.	*2005–2006*
Armen H. Tashjian, Jr., M.D.	*1989–1990*	Steven R. Goldring, M.D.	*2006–2007*
Frederick R. Singer, M.D.	*1990–1991*	Barbara Kream, Ph.D.	*2007–2008*
Mark R. Haussler, Ph.D.	*1991–1992*	Marc Drezner, M.D.	*2008–2009*
Steven L. Teitelbaum, M.D.	*1992–1993*	Jane B. Lian, Ph.D.	*2009–2010*
Henry M. Kronenberg, M.D.	*1993–1994*	Sundeep Khosla, M.D.	*2010–2011*
Ernesto Canalis, M.D.	*1994–1995*	Keith Hruska, M.D.	*2011–*2012
John P. Bilezikian, M.D.	*1995–1996*		

PAST SECRETARY-TREASURERS

Norman H. Bell, M.D.	*1977–1985*	Andrew F. Stewart, M.D.	*2000–2004*
Gregory R. Mundy, M.D.	*1985–1991*	Marc K. Drezner, M.D.	*2004–2007*
Arnold J. Kahn, Ph.D.	*1991–1997*	Keith A. Hruska, M.D.	*2007–2009*
Steven R. Goldring, M.D.	*1997–2000*	Lynda F. Bonewald, Ph.D.	*2008–2011*

PAST COUNCILORS

John S. Adams, M.D.,	*2009–2012*	Maxine Gowen, Ph.D.	*2000–2003*
Constantine Anast, M.D.	*1980–1982*	Susan Greenspan, M.D.	*2002–2005*
Claude D. Arnaud, M.D.	*1979–1980*	Theresa Guise, M.D.	*2004–2007*
Andrew Arnold, M.D.	*1999–2002*	John G. Haddad, Jr., M.D.	*1982–1985*

Continuing Medical Education Credits

This educational activity has been planned and implemented in accordance with the Essential Areas and policies of the Accreditation Council for Continuing Medical Education (ACCME) through the joint sponsorship of the Institute for the Advancement of Human Behavior (IAHB) and the American Society for Bone and Mineral Research (ASBMR). The IAHB is accredited by the ACCME to provide continuing medical education for physicians.

AMA PRA Statement

The *IAHB designates this educational activity for a maximum of 32.25 AMA PRA Category 1 Credits*™ Physicians should only claim credit commensurate with the extent of their participation in the activity.

Online Evaluation to Receive CME

The online evaluation to receive CME will be available beginning Thursday, October 10. *Please Note*: There will be a $50 fee per application. This fee can be paid when you register for the Annual Meeting or added during the Meeting at the Registration Desk. Should you have questions regarding the online CME evaluation, contact Jillian Davis at +1 (651) 789-3722 or jillian@cmehelp.com.

Meeting Objectives

Upon returning home from the meeting, participants should be able to:

- Discuss the most current and significant advances in biomedical and clinical research in bone and mineral metabolism, specifically in the areas of cancer and bone, personalized medicine, chronic kidney disease, osteoporosis, metabolic bone diseases and therapeutics.
- Better understand the interrelationship among basic research, clinical research and patient care.
- Improve their ability to treat and care for patients through an enhanced knowledge of osteoporosis, other diseases of bone, basic bone biology and its correlation to mineral metabolism.
- Develop new and enhanced strategies for the diagnosis and treatment of patients with disorders of bone and mineral metabolism.

Target Audience

The program is designed for researchers, physicians and other health and allied health professionals with interests in biomechanics, cell biology, dentistry, endocrinology, epidemiology, genetics, internal medicine, metabolism and musculoskeletal research, molecular biology, molecular genetics, nephrology, orthopaedics, pathology, pharmacology, physiology and rheumatics.

Disclosure Policy

The American Society for Bone and Mineral Research is committed to ensuring the balance, independence, objectivity and scientific rigor of all its individually sponsored or industry-supported educational activities. Accordingly, the ASBMR adheres to the requirement set by ACCME that audiences at jointly sponsored educational programs be informed of a presenter's (speaker, faculty, author or planner) academic and professional affiliations, and the disclosure of the existence of any significant financial interest or other relationship a presenter or their spouse has with any proprietary entity over the past twelve months producing, marketing, re-selling or distributing health care goods or services, consumed by, or used on patients, with the exemption of non-profit or government organizations and non-health care related companies. When an unlabeled use of a commercial product, or an investigational use not yet approved for any purpose, is discussed during the presentation, it is required that presenters disclose that the product is not labeled for the use under discussion or that the product is still investigational. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The *On-Site Program* book will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

Disclosure should include any relationship that may bias one's presentation or which, if known, could give the perception of bias. This includes relevant financial relationships of a spouse or partner. Disclosures will be printed in the program materials. These situations may include, but are not limited to:

DISCLOSURE KEY

1) stock options or bond holdings in a for-profit corporation or self-directed pension plan
2) research grants
3) employment (full or part-time)
4) ownership or partnership
5) consulting fees or other remuneration
6) non-remunerative positions of influence such as officer, board member, trustee, or public spokesperson
7) receipt of royalties
8) speaker's bureau
9) other

ABSTRACT-BASED AWARDS

2013 ASBMR Most Outstanding Basic Abstract Award

1005	Leukemogenic Transformation of Hematopoietic Stem Cells by Constitutive Activaton of Canonical Wnt signaling in Osteoblasts	Aruna Kode, Columbia University Medical Center, USA

2013 ASBMR Most Outstanding Clinical Abstract Award

1048	A First-in-Human, Randomized, Double-Blind, Placebo-Controlled, Single-Dose Study of Human Monoclonal Anti-FGF23 Antibody (KRN23) in X-linked Hypophosphatemia	Thomas O. Carpenter, Yale University School of Medicine, USA

2013 ASBMR President's Award

1058	Downregulation of PLCy2/β-catenin Pathway Promotes Activation and Expansion of Myeloid-Derived Suppressor Cells in Cancer	Aude-Helene Capietto, Washington University School of Medicine, USA

2013 ASBMR Felix Bronner Young Investigator Award

1092	Conditional ablation of Cbfβ in different stages of skeletogenesis results in a novel cleidocranial dysplasia mouse model revealing a new role of Cbfβ in postnatal skeletal and tooth development	Joel Jules, University of Alabama at Birmingham, USA

2013 ASBMR Young Investigator Awards

1002	The Cardiovascular Safety of Calcium Supplementation With or Without Vitamin D in Elderly Women: A Collaborative Meta-analysis of Published and Unpublished Trial Level Evidence from Randomised Controlled Trials.	Joshua R. Lewis, University of Western Australia, Sir Charles Gairdner Hospital, Australia
1003	Risk of Non-spine Fractures Among Men and Women with Sarcopenia, Low Bone Mass or Both	Didier Chalhoub, University of Pittsburgh, USA
1004	PTH Release during Exercise Regulates Trabecular Bone Adaptation	Joseph D. Gardinier, University of Michigan, USA
1008	Role Of Muscle Stem Cells During Bone Regeneration	Rana Abou-Khalil, INSERM U781 Colnot Group, France
1010	Loss of Material Properties Due to Diffuse Microdamage in Rat Living Bone Recovers without Osteoclastic Bone Remodeling	Zeynep Seref-Ferlengez, City College of New York, USA
1012	Satellite Cell Populations in Skeletal Muscle, Compromised by Ovariectomy, are Rescued by Daily Bouts of Low Intensity Vibration	Danielle M. Frechette, Stony Brook University, USA
1015	Primary Cilia of Bone Marrow Stromal Cells Mediate Mechanically Induced Osteogenesis	Julia C. Chen, Columbia University, USA

1021	Teriparatide Is Associated with Improved Microarchitecture and Estimated Bone Strength in Premenopausal Women with Idiopathic Osteoporosis: An HR-pQCT Study	Kyle Nishiyama, Columbia University, USA
1024	Systemic Administration of NELL-1, a Wnt/β-Catenin Regulator, Induces Bone Formation in Osteoporotic Mice via Integrinβ1	Aaron W. James, University of California, Los Angeles, USA
1032	Miglustat Normalizes Bone Mass And Improves Bone Microarchitecture In F508del Cystic Fibrosis Mice Through Beneficial Effects on Bone Formation and Resorption	Carole Le Henaff, Inserm Unit 606 and University Paris Diderot, France
1035	The Role of Macrophage Efferocytosis in Prostate Cancer Skeletal Metastasis	Fabiana N. Soki, University of Michigan School of Dentistry, USA
1041	PHOSPHO1: Recognition of roles beyond skeletal mineralization	Karla J. Oldknow, The Roslin Institute, The University of Edinburgh, United Kingdom
1043	Inhibition of AP-1 in specific hypothalamic neurons increases both energy expenditure and bone density in mice	Anna Idelevich, Harvard University, USA
1045	Fetal Stage-Specific Mineral Metabolism in *Hyp* Mice Is Associated with Effects of FGF23 on Placenta	Yasuhisa Ohata, Osaka Medical Center and Research Institute for Maternal and Child Health, Japan
1054	3D-XA-Based Vertebral Finite Element Model for Strength Evaluation in Osteoporosis	Christophe Travert, Arts et Metiers ParisTech, France
1056	Wnt Production of Signaling in Fate Determination and Differentiation of the Skeletal Precursors	Takamitsu Maruyama, University of Rochester Medical Center, USA
1057	Wnt16 Deletion Differentially Affects Cortical and Trabecular Bone: Increased Cortical Bone Resorption, Porosity and Fracture in Wnt16 Knockout Mice	Xianwen Liu, Harvard School of Dental Medicine, USA
1061	Parathyroid Hormone-related Peptide (PTHrP) blockade inhibits the development of bone metastasis and potentiates the effect of zoledronic acid in vitro and in vivo in a mouse model of breast tumor progression	Aimee-Lee Anne Luco, McGill University, Canada
1068	Sclerostin Preserves Cartilage Integrity in Murine Osteoarthritis	Wafa Bouaziz, INSERM U606, France
1073	Osteoclast-secreted Complement Component 3a Stimulates Osteoblast Differentiation	Kazuhiko Matsuoka, National Center for Geriatrics and Gerontology, Japan
1074	RANKL increase ROS and Bone Resorption by Inhibiting FoxO-mediated Catalase Expression	Ha-Neui Kim, University of Arkansas for Medical Sciences, USA
1076	HIF-1α Regulates Bone Formation Following Osteogenic Mechanical Loading	Ryan E. Tomlinson, Washington University in St. Louis, USA
1079	Histology of Atypical Femoral Fractures	Jörg H. Schilcher, Linköping University, Sweden
1082	A Five-Year Longitudinal Study of Site-Specific Changes in Bone Quality in the Calgary Population-Based Cohort: an HR-pQCT Study	Lauren A. Burt, University of Calgary, Canada
1085	Associations of Fetal and Childhood Growth with Bone Mass in School Age Children. The Generation R Study.	Denise H.M. Heppe, Erasmus MC, The Netherlands

1093	NF-κB Family Member Rela/p65 in Chondrocytes Controls Skeletal Growth and Osteoarthritis Development by Inhibiting Chondrocyte Apoptosis	Hiroshi Kobayashi, The University of Tokyo Hospital, Japan
1094	TGF-beta Signaling Regulates Interleukin-36 alpha in Joint Development and Osteoarthritis.	Tieshi Li, University of North Carolina at Chapel Hill, USA
1100	Neonatal Enzyme Replacement Therapy Improves Cervical Spine Bone Architecture and Mineralization in Mucopolysaccharidosis I Dogs	Lachlan J. Smith, University of Pennsylvania, USA
1101	The Transcriptional Cofactor Jab1 is Essential for Mouse Limb Development	Lindsay A. Bashur, Case Western Reserve University, USA
1106	Wnt5a and Wnt5b in osteoblastic niche differentially regulate HSC maintenance and differentiation	Jingjing Cao, Shanghai Jiao Tong University, People's Republic of China
1108	Assessment of Vertebral Fractures in Patients Older than 50 Years with a Recent Non Vertebral Fracture Before and After Introduction of Systematic Vertebral Fracture Assessment (VFA)	Sandrine P.G. Bours, Maastricht University Medical Centre, The Netherlands
1111	β-adrenergic Receptor Antagonists and Fracture Risk: A Meta-analysis of Selectivity, Dose, Gender and Site-specific Effects	Konstantinos A. Toulis, Aristotle University of Thessaloniki, Greece
1113	Alleviation of Radiotherapy-Induced Bone Loss by Parathyroid Hormone Treatment is Associated with Improved DNA Repair in Osteoblasts	Abhishek Chandra, University of Pennsylvania, USA
1114	Manipulation of RANK monomer assembly as a novel anti-resorptive strategy	Julia T. Warren, Washington University in St. Louis School of Medicine, USA

Dietary and Supplemental Calcium Intake and the Risk of Mortality in Older Men: the MrOS Study. Douglas Bauer*[1], Stephanie Harrison[2], Peggy Cawthon[3], Elizabeth Barrett-Connor[4], James Shikany[5], Kristine Ensrud[6], Eric Orwoll[7], Steven Cummings[2]. [1]University of California, San Francisco, USA, [2]San Francisco Coordinating Center, USA, [3]California Pacific Medical Center Research Institute, USA, [4]University of California, San Diego, USA, [5]University of Alabama at Birmingham, Birmingham, AL, USA, [6]Minneapolis VA Medical Center / University of Minnesota, USA, [7]Oregon Health & Science University, USA

Controlled trials suggest that calcium supplement use might increase cardiovascular events and mortality, and one recent observational study also implicated high intake of dietary calcium. As data are scarce in men we assessed dietary calcium intake, use of calcium supplements and mortality among men >65 in MrOS.

At baseline, MrOS participants (N=5967) completed an extensive survey that included dietary calcium intake (Block Food Frequency Questionnaire). Calcium supplements, including multivitamins, were verified by review of pill bottles by trained staff. Mortality during follow-up was confirmed by contacting relatives and blinded central review of death certificates. Calcium intake was analyzed a priori across quartiles. Hazard ratios for total and cardiovascular mortality were estimated with proportional hazards models; final models were adjusted for age, ethnicity, education, BMI, walking speed, total energy intake, health habits, calcium supplement use and clinical center. Additional analyses were stratified by supplement use.

At baseline the mean age ($\pm$ SD) was 74 $\pm$ 6 yr., mean dietary calcium intake was 1142 $\pm$ 590 mg/d, and 65% reported use of calcium supplements. Compared to those with lower total calcium intake (diet plus supplements), men with higher intake were older, thinner, better educated, more likely to be Caucasian, less likely to smoke, and had higher gait speed (p trend<0.05 for all). During 10 years of follow-up 2,022 men died; 687 deaths were attributed to cardiovascular disease. In base models adjusted for age, energy intake and calcium supplement use, those in the lowest quartile of total intake (<621 mg/d) had higher total mortality (RH = 1.19, CI: 1.02, 1.39) compared to those in the highest quartile (>1565 mg/d). After additional adjustment for other potential confounding factors, calcium intake was not associated with total (Figure) or cardiovascular mortality (p trend = 0.51 and 0.79, respectfully). Calcium supplement use was not associated with total (RH = 1.06, CI: 0.96, 1.18) or cardiovascular mortality (RH = 1.00, CI: 0.83, 1.20). Results were similar in analyses stratified by calcium supplement use, and there was no evidence that supplements increased the risk of mortality among those with the highest dietary calcium intake (interaction p value = 0.84)In this large prospective study of older men, total calcium intake, use of calcium supplements and the combination of high dietary calcium intake and supplement use were not associated with total or cardiovascular mortality.

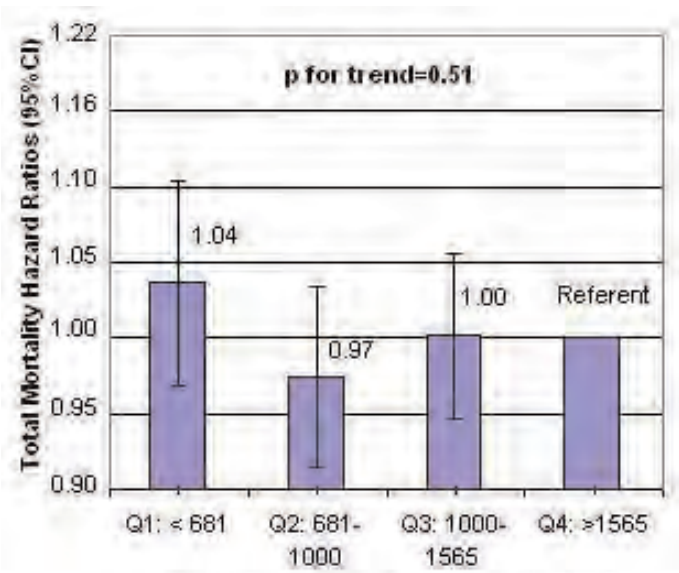

Figure. Adjusted total mortality by quartile of total calcium intake (dietary plus supplements)

The Cardiovascular Safety of Calcium Supplementation With or Without Vitamin D in Elderly Women: A Collaborative Meta-analysis of Published and Unpublished Trial Level Evidence from Randomised Controlled Trials. Joshua Lewis*[1], Lars Rejnmark[2], Kerry Ivey[3], Ross Prentice[4], Richard Prince[5]. [1]University of Western Australia, Sir Charles Gairdner Hospital, Australia, [2]Aarhus University Hospital, Denmark, [3]University of Western Australia, School of Medicine & Pharmacology, Australia, [4]Public Health Sciences Division, Fred Hutchinson Cancer Research Center, USA, [5]Sir Charles Gairdner Hospital, Australia

The use of calcium supplements, predominantly with vitamin D, is an important therapy for the prevention of osteoporosis and its clinical consequences in older women. However the clear benefit on reduction of osteoporosis risk in clinical fracture has been complicated by meta-analyses of cardiovascular disease (CVD) adverse events occurring in RCT's using events that were not properly adjudicated, leading to the concern that more patients on calcium supplements were misreporting more CVD events than the placebo groups, possibly due to reporting stomach ache not heart ache (Lewis et al. JBMR 2012:27; 719–722). This is in addition to concerns over the analysis of different outcomes and the combination of event data from men and women who have different CVD epidemiology presentation and outcomes. The incidence of ischemic heart disease in elderly women lags behind men by up to 20 years for myocardial infarction and is relatively uncommon even in elderly women (Lloyd-Jones D, et al. Circulation 2010;121:e46-e215). To address these concerns we have undertaken a collaborative pre-planned meta-analysis of trials of calcium supplementation with or without vitamin D with primary outcomes of a) all-cause mortality b) adjudicated ischemic heart disease (IHD) hospitalizations or death that include angina, myocardial infarction and chronic ischemic heart disease and adjudicated myocardial infarction as a secondary outcome. MEDLINE, EMBASE and Cochrane Library databases were searched until January 2013, using PRISMA guidelines and we identified19 studies that met the inclusion criteria of; a) randomised controlled trials published in the English language b) women over 50 years of age c) calcium supplementation > 1 year and d) reported all-cause mortality and / or adjudicated cardiovascular outcomes. The trial level relative risk (RR) data for the 4,646 deaths in 59,844 participants yielded a RR of 0.96 (0.91-1.02), P = 0.18 with low heterogeneity (I^2 = 0%) for those randomized to supplements. The trial level RR for the 3,334 ischemic heart disease events in 46,843 participants was 1.02 (0.96-1.09), P = 0.53 (I^2 = 0%) while the trial level RR for the 1,097 myocardial infarction events in 49,048 participants was 1.09 (0.89-1.33), P = 0.21 with low heterogeneity (I^2 = 28%).

The data from this meta-analysis does not support the concept that calcium supplementation with or without vitamin D increase the risk of ischemic heart disease or total mortality in elderly women.

Risk of Non-spine Fractures Among Men and Women with Sarcopenia, Low Bone Mass or Both. Didier Chalhoub*[1], Peggy Cawthon[2], Kristine Ensrud[3], Marcia Stefanick[4], Deborah Kado[5], Eric Orwoll[6], Jane Cauley[7]. [1]University of Pittsburgh, USA, [2]California Pacific Medical Center Research Institute, USA, [3]Minneapolis VA Medical Center / University of Minnesota, USA, [4]Stanford University School of Medicine, USA, [5]University of California, San Diego, USA, [6]Oregon Health & Science University, USA, [7]University of Pittsburgh Graduate School of Public Health, USA

The combination of both sarcopenia (low lean mass and poor muscle function) and low bone mass together on fracture risk has not been studied. We examined the risk of non-spine fractures in older men and women based on both sarcopenia and osteopenia/osteoporosis.

The prospective, longitudinal study data consisted of 1,204 white and black women (mean age=77.6 years) from the Study of Osteoporotic Fractures (SOF) and 5,729 white, black, and Hispanic men (mean age=73.7 years) from the Osteoporotic Fractures in Men (MrOS) study. BMD and appendicular lean mass (ALM) were assessed by DXA (Hologic 2000 for women, Hologic 4500 for men); grip strength by Jamar dynamometry; and walking speed over 6 m. Sarcopenia was based on European Working Group on Sarcopenia in Older Persons definition and included: 1) slowness (gait speed ≤0.8 m/s); 2) weakness (grip strength <30 kg men, <20 kg women); and 3) low lean mass (ALM corrected for height and total fat mass; <20%,"sarcopenic"); ''sarcopenia'' was defined as low lean mass plus either slowness or weakness. Osteopenia/osteoporosis was based on the WHO definition (femoral neck T-score <-2.5, with T-score based on young Caucasian women). Participants were classified into four groups: normal BMD and lean mass (normals) (N=3398 men, 312 women); sarcopenia with normal BMD (N=153 men, 45 women); osteopenia/osteoporosis and no sarcopenia (N=1972 men, 621 women); and sarcopenia with osteopenia/osteoporosis (N= 205 men, 139 women). Non-spine fractures were confirmed by central review of radiographic report over 8 years for women and 9 years for men. Cox proportional-hazards modeling was used to compare the risk of fracture across the four groups. Age adjusted incidence rates of non-spine fractures were calculated.

Men with sarcopenia and osteopenia/osteoporosis had the highest incidence rate of fracture (table). Sarcopenia alone was associated with an increased risk of fracture in men but not women. In men and women, osteopenia/osteoporosis alone was

associated with an increased risk of facture. Women with osteoporosis alone or sarcopenia and osteopenia/osteoporosis had a similar risk of fracture.

Men with both sarcopenia and osteopenia/osteoporosis had almost a two fold higher risk of fracture compared to men with either sarcopenia alone or osteopenia/osteoporosis alone suggesting that the combination of both of these factors may identify men at highest risk.

Table: Hazard ratios (95% confidence interval) and incidence rates (95% confidence interval) per 1000 person years for non-spine fractures in older individuals by sarcopenia, osteopenia/osteoporosis, and sarcopenia-osteopenia/sarcopenia-osteoporosis.

	Normal BMD and lean mass	Sarcopenia alone	Osteopenia/ Osteoporosis alone	Sarcopenia osteopenia/ Sarcopenia osteoporosis
Men				
Hazard ratios				
Age adjusted	1.00	1.6 (1.1, 2.5)	1.8 (1.5, 2.1)	3.2 (2.4, 4.3)
MV adjusted	1.00	1.5 (1.0, 2.3)	1.7 (1.4, 2.0)	3.0 (2.2, 4.0)
Incidence rates				
Age adjusted	9.9 (8.8, 10.9)	15.7 (9.4, 21.9)	17.4 (15.6, 19.3)	30.5 (22.1, 38.8)
Women				
Hazard ratios				
Age adjusted	1.00	1.6 (0.7, 3.6)	3.0 (2.0, 4.4)	3.0 (1.9, 4.8)
MV adjusted	1.00	1.6 (0.7, 3.7)	3.0 (2.0, 4.5)	3.1 (1.9, 5.1)
Incidence rates				
Age adjusted	10.9 (6.9, 14.9)	17.3 (4.5, 30.2)	32.6 (27.9, 37.4)	32.8 (22.9, 42.6)

MV= Multivariate model: Adjusted for age, previous fracture, current smoking, steroid intake, rheumatoid arthritis, alcohol consumption, physical activity, and bisphosphonate (in males).

PTH Release during Exercise Regulates Trabecular Bone Adaptation. Joseph Gardinier*, David Kohn, Fatma Mohamed. University of Michigan, USA

The ability to enhance the structural integrity of bone at a young age reduces the risk of bone fracture as well as the development of musculoskeletal diseases. The structural integrity of bone is constantly adapting in response to dynamic loading and parathyroid hormone (PTH). Although the combination of dynamic loading and intermittent PTH(1-34) treatment can enhance bone adaptation, their distinct influence on bone adaption during exercise has yet to be established. The purpose of this study was to first establish that PTH is released during exercise, and second test our hypothesis that PTH released during exercise regulates bone adaption. In the first experiment, systemic PTH levels were measured following a single bout of exercise. In a second experiment, mice were assigned to sedentary or exercise groups, which were treated for 21 consecutive days with either PTH(7-34), PTH(1-34) or vehicle to determine the influence of PTH on bone adaptation during exercise. In both experiments 16 week old male mice were used and an exercise regimen involving treadmill running at 12 m/min on a 5˚ incline for 30 minutes under approval by the University Committee on Use and Care of Animals. Ex-vivo micro-CT scans of the tibia were taken for trabecular bone analysis, while cortical bone histomorphometry was measured at the tibia mid-diaphysis. Plasma levels of PTH were significantly greater 30 minutes after exercise and returned to baseline 1hr after exercise. Compared to sedentary controls, 3 weeks of exercise significantly increased trabecular bone volume (BV/TV) and thickness, but decreased the structure model index (SMI). PTH(7-34) treatment prior to exercise significantly decreased BV/TV and increased SMI compared to exercise alone. PTH(1-34) treatment alone had no effect on SMI, but significantly increased BV/TV along with the mineralizing surface (MS) and mineral apposition rate (MAR) of cortical bone at the endosteum and periosteum. PTH(1-34) treatment prior to exercise significantly increased endosteal MS and MAR, but periosteal MS was significantly attenuated compared to PTH(1-34) treatment alone. Overall, there is an immediate increase in systemic PTH levels in response to exercise that regulates an increase in trabecular BV/TV and shift in structure. The significant attenuation in BV/TV due to PTH(7-34) treatment prior to exercise demonstrates that bone adaptation during exercise is not only a function of the dynamic loading, but also the release of PTH.

Leukemogenic Transformation of Hematopoietic Stem Cells by Constitutive Activation of Canonical Wnt signaling in Osteoblasts. Aruna Kode*[1], Sanil J Manavalan[1], Ioanna Mosialou[1], Chozha V Rathinam[1], Govind Bhagat[1], Murty Vundavalli[1], Naomi Galili[1], Siddhartha Mukherjee[1], Azra Raza[1], Julie Teruya Feldstein[2], Ellin Berman[2], Stavroula Kousteni[1]. [1]Columbia University Medical Center, USA, [2]Memorial Sloan-Kettering Cancer Center, USA

Osteoblasts have been implicated in self-renewal and expansion of hematopoietic stem cells (HSCs) and the fate of malignant stem cells. However, the molecular basis of these functions remain poorly understood. Here we show that constitutive activation of the Wnt/b-catenin signaling pathway in osteoblast precursors in mice ($\beta cat(ex3)_{osb}$) disrupts hematopoiesis by shifting the differentiation potential of HSC progenitors to the myeloid lineage. As a result, there is accumulation of granulocyte/monocyte progenitors and development of acute myeloid leukemia (AML). This AML phenotype is associated with clonal evolution at the cytogenetic level since common clonal abnormalities could be detected in leukemic blasts from all $\beta cat(ex3)_{osb}$ mice examined. In addition, transplantation of bone marrow cells derived from $\beta cat(ex3)_{osb}$ mice to lethally irradiated wild-type mice recapitulates hematopoietic deregulation with increased myeloid activity and decreased B-lymphopoiesis in recipient animals. A full fledge AML was seen in these mice within 6 weeks following $\beta cat(ex3)_{osb}$ bone marrow transplantation, demonstrating progression towards cells autonomous AML, a hallmark of leukemia. In addition, b-catenin-activated osteoblasts increased proliferation of human HSCs in co-cultures, increased the percentage of early myeloid cells (CD34+/CD33+) but decreased the percentage of late differentiated myeloid cells (CD34+/CD11b+/CD14+) suggesting maturation arrest of the myeloid lineage and accumulation of immature myeloid cells. Consistent with these observations obtained from mice and human cell cultures, malignancy-inducing osteoblasts, detected by nuclear accumulation of β-catenin in bone marrow biopsies, were identified in 38% of patients with myelodysplasia (MDS) or AML. Specifically, β-catenin localized to the nucleus of osteoblasts in 15 of 44 patients with MDS (34%), 9 of 26 patients with AML (34.61%), and 12 of 26 patients (46.1%) with AML that arose from prior MDS. In contrast, β-catenin localized to the cell membrane of osteoblasts of all healthy controls examined. Activation of b-catenin signaling was detected specifically in osteoblasts from the patients with nuclear accumulation of β-catenin in osteoblasts. These findings demonstrate that genetic alterations in osteoblast precursors can induce AML in mice and are associated with AML development in humans. They also provide a molecular basis for the leukemogenic transformation.

The role of the WNT pathway in skeletal maintenance has been extensively studied since the identification of mutations in key signaling WNT mediators (LRP5 and sclerostin) in high and low bone mass phenotypes. However, the identity of the key WNT ligand that signals via LRP5/6 has remained unknown. This study aimed to identify genes with a major effect on the skeleton by studying individuals and families with early-onset osteoporosis or osteogenesis imperfecta (OI). We recruited a Finnish family with severe early-onset and dominantly inherited osteoporosis, characterized by low BMD and vertebral fractures, in 10 individuals. Histomorphometry showed severe low-turnover osteoporosis with low bone formation in two adults and reduced bone remodeling in a 14-year-old boy. A genome-wide microsatellite scan, fine-mapping and targeted next-generation sequencing of the linkage region identified a single novel variant in *WNT1* (p.C218G) segregating with the phenotype. We also ascertained a Laotian Hmong family with two severely affected daughters suffering from recessive OI. After exclusion of mutations in the known OI genes we performed whole-exome sequencing and identified a homozygous nonsense mutation in *WNT1* (p.Ser295*) in both affected children. The mutant $WNT1^{C218G}$ and $WNT1^{S295*}$ proteins were stable and exhibited similar cellular distribution to the wild type (wt) WNT1. In contrast with wt-WNT1, $WNT1^{C218G}$ and $WNT1^{S295*}$ did not induce significant accumulation of active β-catenin in the nucleus. Accordingly, $WNT1^{C218G}$ and $WNT1^{S295*}$ showed significantly reduced capacity to induce canonical WNT signaling in a superTOPFLASH reporter assay. They also had impaired capacity to induce the WNT target gene expression and osteoblast differentiation in vitro. In

expression profiling by RT-PCR we detected *Wnt1* expression in mouse brain, femur and spleen but not in calvarial osteoblasts, osteoclasts or human mesenchymal stromal cells. *Wnt1* was clearly expressed in bone marrow, especially in B-cell lineage and hematopoietic progenitors. Using a Wnt1-Cre crossed with a reporter mice Wnt1 expression was also detected in a subset of osteocytes. Our results suggest altered cross-talk of WNT signaling between hematopoietic and osteoblast lineage cells as the pathogenetic mechanism. These findings indicate that loss-of-function heterozygous or bi-allelic mutations in *WNT1* result in early-onset osteoporosis or OI and identify WNT1 as a key WNT ligand in the regulation of bone mass.

Whole Exome Sequencing Reveals a Pathogenic Mutation in a Kindred with Congenital Kyphosis and Anterior Fontanelle Patency. Philip Giampietro[1], David Sweetser[2], Alex Stoddard[3], Robert Blank*[4], Mark Stephan[5], Cathleen Raggio[6], Kristen Rasmussen[7], Michael Pickart[8], Sarah Sund[4], Ulrich Broeckel[3]. [1]University of Wisconsin Madison/Department of Pediatrics, USA, [2]Massachusetts General Hospital, USA, [3]Medical College of Wisconsin, USA, [4]University of Wisconsin, USA, [5]Madigan Army Medical Center, USA, [6]Hospital for Special Surgery, USA, [7]Marshfield Clinic, USA, [8]Concordia University, USA

Congenital vertebral malformations (CVM) represent defects in formation and segmentation of somites and have an estimated incidence of 0.13-0.50 per 1000 live births. Extreme genetic heterogeneity and the rarity of large families with CVM limit the ability to identify mutations in patterning genes associated with CVM by traditional genetic study designs. We therefore used whole exome sequencing (WES) to study a kindred in which a man and his two daughters suffered from kyphoscoliosis, vertebral body hypoplasia, short lumbar spinal pedicles, and prolonged anterior fontanelle patency. WES was performed using Agilent SureSelect hybridization-based exome capture methodology. Results were filtered to excude all except heterozygous nonsynonymous coding variants with minor allele frequency $< 1\%$. This strategy yielded 21 candidates, with *TLE4* harboring a c.A1318G:p.T440A variant. The functional significance of the *TLE4* variant was demonstrated by a mouse knockout of *Tle4*, the murine homolog. *Tle*$^{-/-}$ mice displayed a profound impairment of bone formation, while Tle$^{+/-}$ mice displayed a similar phenotype to the affected humans, including shortened vertebral pedicles and delayed mineralization of the skull. *TLE4* encodes a transcription factor in a gene family that participates in the determination of hematological cell fate in response to Notch signaling, a critical signaling pathway in somitogenesis. These findings highlight the potential of deep sequncing approaches, particularly when coupled with functional studies in appropriate models, to identify novel genetic determinants of uncommon disorders. While much work remains to be done to fully define the mechanisms by which *TLE4* mutations produce the observed phenotypes, these data nevertheless demonstrate the ability of a deep sequncing strategy to discover previously unknown skeletal genes.

Role Of Muscle Stem Cells During Bone Regeneration. Rana Abou-Khalil*[1], Frank Yang[2], Catia Pereira[1], Shirley Lieu[2], Frederic Relaix[3], Theodore Miclau[2], Ralph Marcucio[4], Celine Colnot[1]. [1]INSERM U781, Université Paris Descartes-Sorbonne Paris Cité, Institut Imagine, Hôpital Necker Enfants Malades, France, [2]Department of Orthopaedic Surgery, University of California at San Francisco, USA, [3]INSERM, UMR-S 787, UPMC Paris VI, Institut de Myologie, Faculté de Médecine Pitié-Salpétrière, France, [4]University of California, San Francisco, USA

Bone has a remarkable and sustained ability to regenerate following injury. Bone regeneration is a highly orchestrated process involving the activation of skeletal stem cells and various other cellular components as well as molecular pathways to insure proper healing. The identity of endogenous skeletal stem cells that contribute to bone regeneration has not yet been greatly elucidated. Periosteum plays an indispensible role in bone regeneration and is a major source of stem cells for cartilage and bone formation. Besides, surrounding soft tissues, such as skeletal muscle, may also procure a source of stem cells and play other functional roles during bone regeneration. Here, we provide evidence for a supporting role for skeletal muscle during bone regeneration specifically through the contribution of satellite cells, the adult muscle stem cells that primarily support muscle regeneration. Using a periosteal graft model, we showed that muscle enhanced periosteal contribution to bone regeneration. Conversely, muscle obstruction, using a porous filter, impaired bone regeneration by decreasing the periosteal activation. We showed the direct cellular contribution of muscle to bone regeneration by transplanting a whole GFP- actin muscle adjacent to a fracture site. By 10 days of bone regeneration, GFP+ chondrocytes were observed within the facture callus. To dissect the identity of muscle-derived stem cells during bone regeneration, we performed lineage analyses using Pax3Cre;R26RLacZ mice (Pax3 being a marker of myogenic lineage) and observed LacZ+-Pax3 derived chondrocytes within the fracture callus, indicating that satellite cells contribute to bone regeneration. Next, we showed that satellite cells are functionally involved in fracture repair. We assessed bone regeneration in Pax7 KO mice that lack Pax7+ satellite cells. We also used tamoxifen inducible Pax7CreER mice crossed with Diphtheria Toxin (DTA$^{f/f}$) mice, therefore ablating Pax7+ satellite cells and causing satellite cell suicide. Satellite cell loss as well as satellite cell depletion severely impaired bone regeneration with a delay in both cartilage and bone deposition. Therefore, for the first time, our results demonstrate the functional role of skeletal muscle during bone regeneration, via the direct contribution of satellite cells, the muscle stem cells, in the process of endochondral ossification in vivo.

1009

Osteocytes, but not osteoblasts, provide the RANKL required for bone remodeling in adult mice: novel insights from Sost-Cre;RANKLf/f mice. Jinhu Xiong*[1], Rajamani Selvam[2], Yiying Wang[2], Marilina Piemontese[2], Melda Onal[3], Priscilla Baltz[2], Stavros Manolagas[1], Charles O'Brien[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]university of wisconsin, USA

The cytokine RANKL is essential for osteoclastogenesis and recent studies have shown that RANKL expressed in Dmp1-Cre transgene-expressing cells is required for cancellous bone remodeling in adult mice. However, the Dmp1-Cre transgene used in those studies is active in both osteocytes and matrix-synthesizing osteoblasts, leaving open the possibility that either or both cell types produce the RANKL required for osteoclast formation in cancellous bone. To distinguish between osteocytes and osteoblasts as sources of RANKL, we created transgenic mice expressing the Cre recombinase under the control of regulatory elements of the Sost gene, which is expressed in osteocytes but not osteoblasts in murine bone. Activity of the Sost-Cre transgene in vivo was determined by crossing Sost-Cre mice with Rosa26R reporter mice, which express LacZ only in cells expressing Cre recombinase. LacZ staining of long bones and vertebrae of these mice, which had also been injected with calcein to identify surfaces undergoing active bone formation, demonstrated that the Sost-Cre transgene is active in osteocytes but not osteoblasts. We then crossed Sost-Cre mice with mice harboring a RANKL conditional allele (RANKLf/f) to delete the gene in osteocytes but not osteoblasts. Quantitative real-time PCR using genomic DNA isolated from osteocyte-enriched cortical bone confirmed that the RANKL gene was reduced by 70% in osteocytes of Sost-Cre;RANKLf/f mice, which displayed normal tooth eruption and were not grossly osteopetrotic. However, at 5 weeks of age, a small increase in spinal bone mineral density (BMD) was observed by DEXA in Sost-Cre;RANKLf/f mice compared with control littermates, and this difference increased progressively with age, so that at 22 weeks there was a 20% increase in vertebral BMD. Analysis by micro-CT at 22 weeks revealed that cancellous bone volume was much higher in femurs and L4 vertebra of Sost-Cre;RANKLf/f mice compared to control littermates. However, femoral cortical thickness was not affected. Consistent with the increase in cancellous bone, osteoclast number on vertebral cancellous bone was dramatically reduced in Sost-Cre;RANKLf/f mice compared with littermates. Moreover, the results obtained in Sost-Cre;RANKLf/f mice were comparable to those observed in Dmp1-Cre;RANKLf/f mice. These findings demonstrate that osteocytes, but not osteoblasts, provide the majority of the RANKL required for cancellous bone remodeling in adult murine bone.

Loss of Material Properties Due to Diffuse Microdamage in Rat Living Bone Recovers without Osteoclastic Bone Remodeling. Zeynep Seref-Ferlengez*[1], Claudy Philemon[1], Oran Kennedy[2], Mitchell Schaffler[1]. [1]City College of New York, USA, [2]New York University, Hospital for Joint Diseases, USA

Introduction: Recent studies show that wear and tear causes bone microdamage at different hierarchical levels, and these have different biological consequences. Typical, linear microcracks are repaired by remodeling that removes and replaces the damaged bone region. Clusters of large numbers of submicron-sized cracks deemed Diffuse damage (DDx) also occur frequently. DDx is not remodeled, thus its long-term consequences are not known. Our recent results show that DDx induced in living bone is reduced over time, suggesting the intriguing idea that small cracks in living bone might be repaired directly. In these studies, we tested this hypothesis by examining whether the microscopic mechanical function list due to DDx is recovered in vivo.

Methods: Under IACUC approval, ulnae of 2 groups of adult female SD rats (n=12, 4-5m.o.) were subjected to in vivo creep loading to a predetermined displacement to induce solely DDx in the diaphyseal cortex. Group 1 rats were euthanized immediately after damage induction in order to assess the 'Acute' effect of DDx on bone elastic modulus (Ei). Group 2: one ulna was damaged with creep loading and rats returned to their cages for 14 days to test whether modulus recovered in DDx regions over time. Cross-sections were cut from DDx regions or equivalent levels from Non-loaded Control ulnae and tissue level Ei was measured within each DDx and Non-Dx Zone using microindentation.

Results: In Controls, Ei was equivalent in all cortex regions (Table 1). In Acute-Loaded ulnae, Ei in DDx Zones was reduced 15.2 $\pm$ 4% compared to non-damaged regions of the same ulna. Ei of cortical regions without damage was the same as

Control bone. After the 14-Day survival period, Ei in previously damaged areas had returned to normal.

Conclusion: The current studies reveal that diffuse damage (clusters of submicron-size cracks) in bone causes a marked and highly localized loss of bone stiffness. Recently we showed histologically that content of diffuse damage induced in living bone is reduced over time. Whether this reduction in microdamage translates to restoration of tissue integrity was not known. Here, we found that local material properties in diffuse damage areas of living bone recovered by 14 days after damage induction. Further studies are needed to elucidate the mechanisms by which this direct repair occurs. Nevertheless, our studies reveal that living bone directly repairs small matrix cracks both structurally and mechanically.

A Myostatin Inhibitor (propeptide-Fc) Increases Muscle Mass but Does Not Alter Bone Density or Strength in Aged Mice. Phonepasong Arounleut[1], Peter Bialek[2], Mohammed Elsalanty[3], Sunil Upadhyay[4], Carlos Isales[4], William Hill[5], Xing-Ming Shi[3], Mark Hamrick*[3]. [1]Georgia Regents University (formally Georgia Health Sciences University), USA, [2]Pfizer Inc., USA, [3]Georgia Health Science University, USA, [4]Georgia Regents University, USA, [5]Georgia Regents University & Charlie Norwood VAMC, USA

Myostatin deficiency is associated with increased muscle mass in mice, dogs, cows, sheep and humans, and mice lacking myostatin have also been observed to show increased bone density in the limb, spine, and jaw. Transgenic overexpression of myostatin propeptide, which binds and inhibits the active myostatin ligand, also increases muscle mass and bone density in mice. We therefore sought to test the hypothesis that inhibition of myostatin using an injectable myostatin propeptide (GDF8 propeptide-Fc) would increase both muscle mass and bone density in aged (24 mo) mice. Mice were injected weekly (20 mg/kg body weight) with recombinant myostatin propeptide-Fc (PRO) or vehicle (VEH; saline) for four weeks. There was no difference in body weight between the two groups after the treatment period but PRO treatment significantly increased mass of the tibialis anterior muscle (+7%) and increased muscle fiber diameter of the extensor digitorum longus (+16%) and soleus (+6%) muscles. Bone volume relative to total volume (BV/TV) of the femur calculated by microCT did not differ significantly between PRO and VEH, and ultimate force (Fu), stiffness (S), toughness (U) measured from three-point bending tests also did not differ significantly between groups. These data suggest that while developmental perturbation of myostatin signaling through either gene knockout or transgenic inhibition may alter both muscle and bone in mice, pharmacological inhibition of myostatin in aged mice has a more pronounced effect on skeletal muscle than on bone. Funding for this research was provided by the Department of the Army (CDMRP093619).

Satellite Cell Populations in Skeletal Muscle, Compromised by Ovariectomy, are Rescued by Daily Bouts of Low Intensity Vibration. Danielle Frechette*, Divya Krishnamoorthy, M. Ete Chan, Benjamin Adler, Clinton Rubin. State University of New York at Stony Brook, USA

The ability of skeletal muscle to regenerate itself following injury is highly dependent on the activation of satellite cells (SC) in the muscle tissue. Chronic disease conditions, including obesity and type II diabetes, experience significant adipose infiltration which can disturb muscle homeostasis and compromise the regenerative process through disrupting SC populations. While the increase in adiposity that parallels menopause is thought to disrupt SC, it has also been proposed that mechanical stimulation suppresses fat accumulation, potentially allowing SC populations to recover. We hypothesized that adipose accumulation in a post-menopausal model (OVX) will decrease SC proportions in muscle, while low intensity vibration (LIV) will provide physical signals anabolic to muscle, reducing adiposity and protecting SC populations. 8w female C57BL/6 mice underwent either OVX or sham surgery (AC, n=10). OVX mice were subject to LIV (V, n=10) for 0.3g at 90Hz for 15min/d and 5d/w, or sham vibrated (O, n=10). At 6w, μCT analysis of the abdomen showed O had greater total abdominal (+43%, $p<0.001$) and visceral (+125%, $p<0.001$) adiposity compared to baseline scans, while LIV treated animals only increased 21% ($p\leq0.05$) and 70% ($p\leq0.005$), respectively. Rate of adipose accretion was significantly higher in O compared to AC ($p<0.005$), but not in V, demonstrating LIV's ability to mitigate adipose accumulation. PPARγ and PPARδ gene expression, mediators of preadipocyte proliferation and adipogenesis activation, were measured in the muscle. Compared to AC, expression levels in O increased 78% and 120%, respectively ($p\leq0.001$), while LIV suppressed expression in V relative to O essentially by half (-52% and -42%, respectively; $p<0.001$). Adipose gene expression was inversely related to the percentage of total SC and activated SC in the hind limb muscles, with total and activated SC populations declining in O compared to AC (-21%; -28%, respectively; $p<0.01$), while V mitigated these declines (-11%, -17%, respectively; $p>0.05$). These results indicate the potential damage of ovariectomy to SC differentiation and/or proliferation. Further, mechanical signals stand as a potential antagonist of adipogenesis in skeletal muscle, which could improve overall muscle homeostasis through maintaining SC populations and improving their ability to respond to detriment.

ERα Signaling in Osterix1 and Prx1 Expressing Cells, Respectively, Mediates the Anabolic Effect of Mechanical Loading in the Murine Periosteum and the Protective Effects of Estrogens on Endocortical Resorption. Srividhya Iyer*[1], Li Han[1], Ha-Neui Kim[2], Semahat Serra Ucer[2], Shoshana Bartell[1], Aaron Warren[3], Julie Crawford[2], Robert Skinner[4], Mark Dallas[5], Mark Johnson[6], Robert Weinstein[1], Robert Jilka[1], Charles O'Brien[1], Maria Jose Almeida[1], Stavros Manolagas[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]Univ. Arkansas for Medical Sciences, & Central Arkansas Veterans Healthcare System, Little Rock, AR, USA, [4]Department of Orthopaedic Surgery, Center for Orthopaedic Research, Univ. Arkansas for Medical Sciences, Little Rock, AR, USA, USA, [5]Department of Oral & Craniofacial Sciences, University of Missouri, Kansas City, MO, USA, [6]University of Missouri, Kansas City Dental School, USA

Targeted deletion of the estrogen receptor (ER) α from pluripotent mesenchymal osteoblast progenitors (using a Cre recombinase driven by Prx1), bi-potential osteoblast precursors (using a Cre recombinase driven by Osx1), or mature osteoblasts and osteocytes (using a Cre recombinase driven by Col1 or Dmp1) has revealed that ERα signaling in Osx1 cells potentiates Wnt/β-catenin signaling and periosteal cell proliferation independently of estrogens. This signaling pathway is required for optimal cortical bone accrual at the periosteum. In addition, ERα signaling in Prx1 expressing cells and their descendants is required for the protective effect of estrogens in the endocortical surface. On the other hand, ERα signaling in Col1 or Dmp1 expressing cells has no effect on bone mass or the effect of mechanical loading. Based on this and evidence that the periosteal response to mechanical loading is compromised in mice with global deletion of the ERα, we investigated here whether ERα signaling in Osx1 cells is indeed required for the osteogenic response of the periosteum to mechanical stimulation. To do this, the right ulnae of 5 month old female ERα-flox;Osx1-Cre and Osx1-Cre littermate control mice (5 animals per group) were loaded at ~2500 microstrains for 3 weeks. At the end of the experiment, bone formation was determined in undecalcified bone sections from the loaded ulnae and the unloaded contralateral ulnae. Loading induced a 2.5 fold increase in mineralizing surface at the periosteum of the loaded, as compared to the unloaded ulnae. The response to loading was completely abrogated in the ERα-flox;Osx1-Cre mice. In addition, we have ovariectomized (OVX) 5 month old ERα-flox;Osx1-Cre mice and examined the effects of OVX 6 weeks later. In difference to the finding that ERα-flox;Prx1-Cre are protected from the loss of cortical bone caused by OVX, ERα-flox;Osx1-Cre and their littermate control mice exhibited indistinguishable loss of femoral BMD by DEXA. These results indicate that the effect of mechanical loading on the periosteum and the protective effects of estrogens on endocortical resorption are mediated by ERα signaling in two distinct cell types of the osteoblast lineage: Osx1 and Prx1 expressing cells, respectively. In the former, ERα is activated by mechanical loading and in the latter by estrogens. Furthermore, these results strongly suggest that Osx1 progenitors residing in the periosteum have mechanosensing properties.

Conditional Disruption of the miR17-92 Cluster in Osteoblasts Impairs Skeletal Growth and Periosteal Response to Mechanical Loading. Chandrasekhar Kesavan*, Jon Wergedal, Subburaman Mohan. Jerry L. Pettis Memorial VA Medical Center, USA

While the role of osteoblast (OB) produced IGF-I in regulating skeletal growth has been well established from mouse conditional knock out (cKO) studies, little is known about the immediate downstream targets of IGF-I signaling in regulating skeletal growth. Because of the established importance of microRNA (miR) in posttranscriptional gene regulation, we evaluated expression levels of several miRs in the bones of IGF-I cKO and WT mice and found reduced expression (2-3 fold, $P<0.05$) of miR20a and 92 in the miR17-92 cluster in the OB-specific cKO mice. Accordingly, treatment of serum-free cultures of OBs with IGF-I caused a 2-3 fold ($P<0.05$) increase in miR20a and 92. Based on these data and the finding that targeted deletion of the miR17-92 cluster produced widespread skeletal defects in E.18.5 embryos and perinatal lethality in mice, we proposed the hypothesis that the miR17-92 cluster is important for skeletal development. MiR17-92 cKO mice were generated by crossing floxed miR17-92 mice with collagen type I Cre mice. At 4 and 8 weeks of age, total body BMC measured by DEXA was reduced by 29% and 24% (both $P<0.01$) respectively in cKO females compared to wild type (WT) control mice. This reduction in BMC was maintained at 12 weeks and was caused by reductions in bone length (10%, $P<0.05$) and cross sectional area (CSA, 18%, $P<0.05$) but not by a vBMD change as measured by pQCT. Male mice also exhibited significant reductions in total body BMC at 4 and 8 weeks of age. Since mechanical loading (ML) by 4 point bending induced a 2-fold increase in miR20a expression and miR17-92 cKO mice showed reduced bone size, we next tested if the miR 17-92 cluster was required for a normal periosteal response to ML. Nine and 7 N (to produce an equivalent amount of mechanical strain) were applied to the right tibia of WT and cKO female mice for a period of 2 weeks (6 days/week) at a 2Hz frequency for 36 cycles once per day by a 4 point bending method which produces a robust periosteal response at the diaphysis. The left tibia was used as an internal control. Two weeks of ML produced a 28%, 38% and 13% increase in CSA, BMC and vBMD, respectively in WT mice. ML-induced changes were significantly less (45-62%) in the cKO mice compared to WT mice. Based on our data, we conclude that the miR17-92 cluster expressed in osteoblasts is regulated by IGF-I and exerts an important role in periosteal bone formation during skeletal development and in response to mechanical strain.

Primary Cilia of Bone Marrow Stromal Cells Mediate Mechanically Induced Osteogenesis. Julia Chen*[1], David Hoey[2], Christopher Jacobs[1]. [1]Columbia University, USA, [2]University of Limerick, Ireland

Osteoporosis is a disease of low bone mass and occurs when the activity of bone-forming osteoblasts is insufficient to counteract that of bone-resorbing osteoclasts. *In vitro* studies have shown that physical stimulation influences the differentiation of bone marrow stromal cells (BMSCs) into osteoblasts. One potential mechanosensor is the primary cilium, which is an antennae-like organelle extending into the extracellular space. Previous *in vitro* studies demonstrate that the osteogenic response of BMSCs to fluid flow is mediated by primary cilia. The objective of this study was to investigate the contribution of BMSCs to bone formation *in vivo,* and the role of primary cilia. Deletion of Kif3A, a subunit of an intraflagellar transport protein, disrupts primary cilia formation, but is embryonic lethal. Therefore, chimeric animals were generated with impaired primary cilia formation only in BMSCs. First, $Kif3A^{fl/fl}$;GFP;$Cre\text{-}ER^{T2}$ donor mice were generated where Kif3A could be deleted by tamoxifen induction of Cre. Wild type mice were irradiated, depleting their original BMSCs, and transplanted with BMSCs from either $Kif3A^{fl/fl}$;GFP (control) or $Kif3A^{fl/fl}$;GFP;$Cre\text{-}ER^{T2}$ (experimental) donors. Injection with tamoxifen induced Cre recombination in animals receiving $Kif3A^{fl/fl}$;GFP;$Cre\text{-}ER^{T2}$ cells, resulting in chimeric experimental animals. Right ulnae were axially loaded at 3N for 120 cycles for 3 days, and left ulnae remained non-loaded. Calcein and alizarin dyes were injected to mark new bone formation. After sacrifice, ulnae were prepared for histological analysis and dynamic histomorphometry. Donor-derived GFP-positive osteocytes were detected in loaded ulnae, indicating that transplanted BMSCs contributed to bone formation. Mineralizing surface (MS/BS), mineral apposition rate (MAR), and bone formation rate (BFR/BS) were measured using dynamic histomorphometry. Mechanical loading resulted in increases in the MS/BS, MAR, and BFR/BS in loaded ulnae compared to non-loaded ulnae for both experimental and control groups. Relative (r) rates were calculated by subtracting nonloaded from loaded values. Compared to controls, animals with disrupted primary cilia in BMSCs had significant reductions in rMS/BS and rBFR/BS of 46% ($p<0.05$) and 53% ($p<0.001$), respectively (Fig. 1). These results demonstrate that BMSCs contribute to mechanically induced bone formation, and primary cilia are important for this process.

Live Imaging of Collagen Assembly and Cell Membrane Dynamics in Osteoblasts and Acceleration of Collagen Assembly by Wnt3a. Erica Perryn*, Patricia Veno, Yongbo Lu, Sarah Dallas. University of Missouri - Kansas City, USA

Type I collagen, the major bone extracellular matrix protein, is composed of heterotrimers of two α1(I) chains and one α2(I) chain, encoded by the COL1A1 and COL1A2 genes. Although the post-translational modifications and intracellular assembly of collagen chains into trimers are well defined, the dynamic processes by which collagen assembles extracellularly are less clear. Previously we described the generation/validation of transgenic mice expressing α2(I)-collagen-GFP driven by the 3.6kb Col1A1 promoter.To gain further insight into collagen assembly, widefield and

confocal live cell imaging were performed on osteoblasts from α2(I)-col-GFP mice. The mice were also crossed with mice expressing a membrane-targeted TdTomato reporter to examine collagen assembly simultaneously with cell membrane dynamics. Live cell imaging showed that collagen assembly is a highly dynamic process involving extensive cell motions which stretched and contracted the fiber network during assembly. A subpopulation of osteoblasts was more active in collagen assembly compared to other cells. Upon addition of ascorbate, GFP-collagen translocated to the periphery of these cells into vesicle-like structures. These vesicles showed extensive intracellular movement to localized regions within the cell and appeared to be involved in the assembly process. Dual imaging of α2(I)-col-GFP/TdTomato osteoblasts showed that early collagen assembly occurred at the cell periphery and that the cell margins extended much further than previously appreciated from DIC imaging, with cell projections extending up to 2-3 cell diameters. Live imaging of α2(I)-col-GFP/mem-TdTomato osteoblasts seeded at low densities on wild type osteoblasts showed GFP-collagen deposition only in areas in which the cell body or cell processes had been, suggesting active placement of collagen by cells rather than diffusion of collagen away from the producing cell. Some cells were able to physically reshape the collagen fiber network by pushing collagen outwards to generate holes resembling lacunae. Treatment with Wnt3a accelerated the collagen assembly process, likely in part through its effect on increasing cell motility and mitosis. These data suggest that collagen assembly is a highly dynamic process involving internal movement of collagen to localized areas of the cell, exertion of forces on the developing fibers via cell motion and physical reshaping of the collagen via cell generated forces.

Further Reduction in the Nonvertebral Fracture Rate Is Observed Following 3 Years of Denosumab Treatment: Results With Up to 7 Years in the FREEDOM Extension. Serge Ferrari*[1], Jonathan D. Adachi[2], Carol Zapalowski[3], Paul D. Miller[4], Jean-Yves Reginster[5], Ove Törring[6], Nadia Daizadeh[3], Andrea Wang[3], Cynthia O'Malley[3], Rachel B. Wagman[3], E. Michael Lewiecki[7]. [1]Geneva University Hospital, Switzerland, [2]McMaster University, Canada, [3]Amgen Inc., USA, [4]Colorado Center for Bone Research, USA, [5]University of Liège, Belgium, [6]Karolinska Institutet, Södersjukhuset, Sweden, [7]New Mexico Clinical Research & Osteoporosis Center, USA

Purpose: Some antiresorptives reduce nonvertebral fracture incidence in the first 3 years of treatment; however, evidence for further reduction of nonvertebral fractures with prolonged therapy is limited. The effects of denosumab (DMAb) treatment for up to 10 years are being evaluated in the 3-year FREEDOM study and its 7-year extension. Here we compare the nonvertebral fracture rate during the first 3 years of DMAb with that in the following 4 years of treatment.

Methods: During the extension, all subjects received 60 mg DMAb Q6M. Here, long-term subjects received 7 years of DMAb (3 years in FREEDOM followed by 4 years in the extension); subjects from the cross-over group received 4 years of DMAb (3 years of placebo in FREEDOM followed by 4 years of DMAb in the extension). Nonvertebral fracture rates for the first 3 years of DMAb were compared with rates in the 4th year of DMAb in each group separately and combined. For the long-term group only, the nonvertebral fracture rate in the first 3 years of DMAb was also compared with the fracture rate during the subsequent 4 years. Adjusted rate ratios (95% CIs) between observational periods were computed via generalized estimating equation (GEE) Poisson regression.

Results: Of 5928 women eligible for the extension, 4550 (77%) enrolled (N=2343 long-term; N=2207 cross-over). In the long-term group, the nonvertebral fracture rate was 1.98 per 100 subject-years during years 1–3 of DMAb (FREEDOM). This rate decreased during year 4 (extension) to 1.43 (rate ratio=0.73; P=0.096), and the rate remained low at 1.45 during years 4–7 (rate ratio=0.74; P=0.016; Table). Similarly for the cross-over group, the fracture rate was 2.20 during years 1–3 of DMAb (extension) and decreased to 1.03 at year 4 (rate ratio=0.48; P=0.004). Combining the long-term and cross-over groups yielded a fracture rate of 2.08 during the first 3 years of DMAb (FREEDOM or extension) that decreased to 1.27 at year 4 (rate ratio=0.62; P=0.002).

Conclusion: Three years of DMAb treatment significantly reduced the nonvertebral fracture rate compared with placebo. When DMAb was continued for an additional 4 years, the fracture rate remained low and was significantly lower than that in the first 3 years of treatment. Contributing factors that might explain this observation include sustained reduction in bone resorption, continued gains in hip BMD and bone mass, decrease in cortical porosity, and increases in cortical/trabecular strength observed with DMAb.

Table. Comparison of Nonvertebral Fracture Rates up to 7 Years of DMAb Treatment

	First 3 Years of DMAb Treatment	4th Year of DMAb Treatment	Years 4–7 of DMAb Treatment
Long-term Subjects (N=2343)	140 Fractures	33 Fractures	119 Fractures
Fracture Rate (95% CI)	1.98 (1.67–2.35)	1.43 (1.02–2.01)	1.45 (1.21–1.74)
Rate Ratio (95% CI)	Referent	0.73 (0.50–1.06)	0.74 (0.59–0.95)
P-value		*P*=0.096	*P*=0.016
Cross-over Subjects (N=1730)	114 Fractures	17 Fractures	
Fracture Rate (95% CI)	2.20 (1.82–2.66)	1.03 (0.64–1.66)	
Rate Ratio (95% CI)	Referent	0.48 (0.29–0.79)	
P-value		*P*=0.004	
Long-term and Cross-over Subjects Combined (N=4073)	254 Fractures	50 Fractures	
Fracture Rate (95% CI)	2.08 (1.83–2.36)	1.27 (0.96–1.67)	
Rate Ratio (95% CI)	Referent	0.62 (0.46–0.83)	
P-value		*P*=0.002	

N = number of subjects who completed FREEDOM (ie, completed their 3-year visit and did not discontinue IP), did not miss >1 dose of IP in FREEDOM, and who enrolled in the extension. In addition, cross-over subjects completed 3 years of the extension and did not miss >1 dose of DMAb during the first 3 years of the extension. Fracture rates and rate ratios were obtained using GEE Poisson models; fracture rates are per 100 subject-years. Rate ratios relative to the first 3 years of DMAb treatment were adjusted for age, total hip BMD T-score, weight, and history of nonvertebral fracture. In addition, the treatment group variable was included in the model for the combined analysis only.

Denosumab Significantly Increases Bone Mineral Density Compared With Ibandronate and Risedronate in Postmenopausal Women Previously Treated With an Oral Bisphosphonate Who Are at Higher Risk for Fracture. Jacques P. Brown*[1], Michael A. Bolognese[2], Pei-Ran Ho[3], Jesse Hall[3], Christian Roux[4], Henry G. Bone[5], Sydney Bonnick[6], Joop van den Bergh[7], Irene Ferreira[8], Prayashi Ghelani[9], Paula Dakin[3], Rachel B. Wagman[3], Christopher Recknor[10]. [1]CHU de Quebec Research Centre & Laval University, Canada, [2]Bethesda Health Research Center, USA, [3]Amgen Inc., USA, [4]Paris Descartes University, France, [5]Michigan Bone & Mineral Clinic, USA, [6]Clinical Research Center of North Texas, USA, [7]VieCuri Medical Centre & Maastricht University, Netherlands, [8]Amgen Inc., United Kingdom, [9]Ovatech Solutions, United Kingdom, [10]United Osteoporosis Centers, USA

Purpose: Low bone mineral density (BMD) is an important and modifiable risk factor for fracture in postmenopausal women with osteoporosis. Denosumab (DMAb), which has a unique mechanism of action, has demonstrated a stronger relationship between BMD increases and antifracture efficacy (new or worsening vertebral and nonvertebral fracture) than bisphosphonate (BP) therapies. There is a clinical need to treat subjects who remain at higher risk for fracture despite current BP therapy. In 2 open-label studies, DMAb significantly increased BMD and decreased bone turnover markers vs a BP, specifically ibandronate (IBN) or risedronate (RIS), in subjects previously treated with, though suboptimally adherent to, a BP. Here we evaluate the effects of DMAb vs a BP (IBN and RIS) to increase BMD in a subset of subjects at higher risk for fracture.

Methods: Both studies were multicenter, randomized, open-label, parallel-group designs in which postmenopausal women ≥55 years were randomized 1:1 to DMAb 60mg subcutaneously every 6 months or a BP 150mg orally every month for 12 months. In this combined post-hoc analysis, higher-risk subjects were identified by meeting ≥1 risk criteria (advanced age, low BMD, prior osteoporotic fracture, high baseline sCTX-1; Table) and the BMD percentage change from baseline in total hip, femoral neck, and lumbar spine at month 12 was calculated.

Results: Subjects from these 2 studies (852 DMAb; 851 BP) had a mean (SD) age of 67 (7.4) years, and mean (SD) T-score at the total hip, femoral neck, and lumbar spine of –1.7 (0.8), –2.0 (0.7), and –2.4 (1.0), respectively. For subjects at higher risk for fracture, denosumab significantly increased BMD at 12 months compared with a BP (IBN and RIS) at the total hip (2.2% vs 0.8%, respectively), femoral neck (1.8% vs 0.3%), and lumbar spine (3.8% vs 1.4%) (p<0.0001 for all; Figure). These results are consistent with the overall study population (treatment-by-risk subgroup interaction p>0.05). In general, AEs and SAEs were similar between DMAb and the comparator BP group.Conclusion: For subjects previously or suboptimally treated with a BP who remain at higher risk for fracture, transitioning to DMAb led to significantly greater increases in BMD at month 12 compared with cycling to another BP. These results in higher-risk subjects are consistent with those obtained in the overall population and support DMAb as an alternative therapeutic option for women at higher risk for fracture.

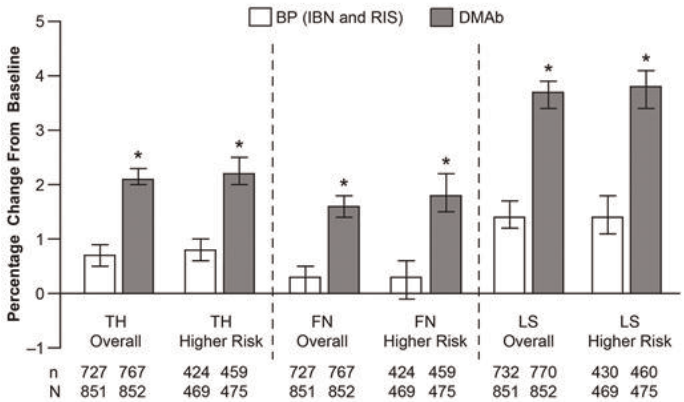
Table. Identification of Subjects at Higher Risk for Fracture

	BP N = 851	DMAb N = 852	All N = 1703
Higher-risk subjects, n (%)	469 (55.1)	475 (55.8)	944 (55.4)
1. Age ≥75 years	150 (17.6)	160 (18.8)	310 (18.2)
2. Baseline BMD T-score ≤–2.5 at total hip or femoral neck	250 (29.4)	245 (28.8)	495 (29.1)
3. Baseline BMD T-score ≤–1.0 at total hip or femoral neck and with prior osteoporotic fracture	256 (30.1)	265 (31.1)	521 (30.6)
4. Baseline sCTX-1 >0.9 ng/mL and BMD T-scores ≤ –2.0 at total hip or femoral neck	17 (2.0)	10 (1.2)	27 (1.6)
Subjects remaining at risk*	319 (37.5)	319 (37.4)	638 (37.5)
Subjects with unknown risk status due to missing data	63 (7.4)	58 (6.8)	121 (7.1)

N=number of subjects randomized. *Subjects who did not meet any of the higher-risk criteria. BP=ibandronate and risedronate; DMAb=denosumab.

Table

Figure. BMD Percentage Change From Baseline at Month 12



Data are least-squares means and 95% CI. Results are based on ANCOVA model adjusting for treatment, time of BMD assessment (study day), treatment by time interaction, baseline BMD value, DXA machine type, and baseline BMD value by DXA machine-type interaction. *p<0.0001 for DMAb vs BP (IBN and RIS). N=number of subjects randomized. n=number of subjects with available baseline and postbaseline BMD data. At risk subjects were subjects who did not meet any of the higher-risk criteria. Higher risk=age ≥75 years, baseline T-score ≤–2.5 at TH or FN, baseline T-score ≤–1.0 at TH or FN and with prior OP fracture, or baseline sCTX-1 >0.9 ng/mL and BMD T-score ≤–2.0 at TH or FN. BP=ibandronate and risedronate; DMAb=denosumab; TH=total hip; FN=femoral neck; LS=lumbar spine.

The DATA Extension Study: 2 Years of Combined Denosumab and Teriparatide in Postmenopausal Women with Osteoporosis: A Randomized Controlled Trial. Benjamin Leder*[1], Alexander Uihlein[2], Joy Tsai[2], Robert Neer[2], Erica Siwila-Sackman[2], Yuli Zhu[2], Katelyn Foley[2], Hang Lee[2], Sherri-Ann Burnett-Bowie[2]. [1]Massachusetts General Hospital Harvard Medical School, USA, [2]Massachusetts General Hospital, USA

Background: Current osteoporosis medications increase bone mineral density (BMD) modestly and reduce, but do not eliminate, fracture risk. Attempts to improve treatment efficacy by combining anabolic agents with bisphosphonates (BPs) have been unsuccessful. In contrast, we recently reported that 12 months of combined denosumab (DMAB) and teriparatide (TPTD) increases BMD more than either drug alone. We now report the effects of this combination over 24-months of treatment.

Methods: 100 postmenopausal women at high fracture risk (age 51-91) who had not used oral BPs in the past 6 months or ever taken parenteral BPs or TPTD were randomized to receive TPTD (20 mcg SC daily), DMAB (60 mg SC every 6 months), or both for 24 months. BMD of the hip, spine and 1/3 distal radius were assessed by DXA. All subjects completing at least 1 post-baseline visit were included in our modified intention-to-treat analysis (n=94) and between-group differences were examined by a longitudinal linear mixed-effects model.

Results: At baseline, subjects were well matched for all clinical characteristics, including BMD at all measured sites. Of the 94 subjects completing at least 1 post-baseline visit, 83 completed all study visits. The 24-month changes in BMD are shown in the figure. PA spine BMD (mean ± SD) increased more in the combination group (12.7 ± 5.1%) than in either the TPTD (9.5 ± 5.9%, P<0.001) or DMAB (8.3 ± 3.4%, P<0.001) groups. Femoral neck BMD also increased more in the combination group (6.4 ± 3.8%) than in the TPTD (2.8 ± 3.6%, P=0.002) and DMAB (4.1 ± 3.8%, P=0.028) groups. Similarly, total hip BMD increased more in the combination group (6.1 ± 2.7%) than in either the TPTD (2.0 ± 3.0%, P<0.001) or DMAB groups (3.2 ± 2.5%, P<0.001). BMD at the 1/3 distal radius increased similarly in the DMAB (2.0 ± 3.7%) and combination groups (2.4 ± 3.1%) but decreased -1.7 ± 4.6% in the TPTD group (P<0.001 for both between-group TPTD comparisons). DMAB alone and TPTD alone produced similar changes at the spine (P=0.831) and femoral neck (p=0.194) but DMAB increased total hip BMD more than TPTD (p=0.005).

Summary and Conclusions: While the improvements in BMD observed after 1 year of therapy are extended in year 2 in all treated groups, the combination of TPTD and DMAB continues to demonstrate superior efficacy compared to TPTD or DMAB treatment alone. DMAB-TPTD co-administration may prove to be an important treatment option in patients at high risk of fracture.

A longitudinal study of Skeletal Histomorphometry in subjects On Teriparatide (TPTD) or Zoledronic acid (ZOL), the SHOTZ study. David Dempster*[1], Hua Zhou[2], Robert Recker[3], Jacques P. Brown[4], Michael Bolognese[5], Christopher Recknor[6], David Kendler[7], E. Michael Lewiecki[8], David Hanley[9], Sudhaker Rao[10], Paul Miller[11], Grattan Woodson[12], Robert Lindsay[2], Neil Binkley[13], Jahangir Alam[14], Valerie A Ruff[14], Boris Janos[15], Kathleen A Taylor[14]. [1]Columbia University, USA, [2]Helen Hayes Hospital, USA, [3]Creighton University, USA, [4]CHU de Québec Research Centre, Canada, [5]Bethesda Health Research, USA, [6]United Osteoporosis Center, USA, [7]Associate Professor University of British Columbia, Canada, [8]University of New Mexico School of Medicine, USA, [9]University of Calgary, Canada, [10]Henry Ford Hospital, USA, [11]Colorado Center for Bone Research, USA, [12], USA, [13]University of Wisconsin, Madison, USA, [14]Lilly USA, LLC, USA, [15]Eli Lilly Canada Inc., Canada

Purpose: Few studies have evaluated progressive effects of osteoporosis therapy using histomorphometric indices; no previous study has directly compared effects of an anabolic vs an antiresorptive agent on bone remodeling in the same individuals over time. Previously we reported contrasting effects of TPTD, an established anabolic agent, and ZOL, a prototypical antiresorptive agent, on bone remodeling based on histomorphometric analysis of bone biopsies after 6 months' therapy. Using a paired-biopsy design, we now extend these observations to month 24.

Methods: SHOTZ is a 2-year trial to assess the biological effects of TPTD and ZOL based on histomorphometric indices and material properties in postmenopausal women with osteoporosis. Subjects from the 12-month randomized study were eligible to enroll in a 12-month extension and assigned open label to their original treatment regimen: TPTD 20 µg/d (sc injection) or ZOL 5 mg/y (IV infusion). Transiliac crest bone biopsies were obtained after tetracycline labeling at month 6 and 24. Here we report dynamic histomorphometric results.

Results: Nineteen subjects had biopsies at both month 6 and 24 (TPTD, n=10; ZOL, n=9). The proportion of samples with tetracycline labels was higher in the TPTD group vs ZOL in all 3 bone envelopes at month 24 and the cancellous envelope at month 6; a similar trend was seen on the endocortex (Table). Mineralizing surface/bone surface (MS/BS), a robust indicator of bone formation especially at low remodeling rates, was significantly higher in the TPTD group in all 3 envelopes at month 6 and 24, except the periosteum at month 6 (Figure). In the cancellous envelope, bone formation rate/BS (BFR/BS) and activation frequency (Ac.f) remained significantly higher at month 24 in the TPTD group. Within-group analyses showed no significant changes in the proportion of samples with labels from month 6 to 24 in either treatment group. No appreciable shifts in dynamic indices were seen in the ZOL group over time. In the TPTD group, MS/BS, BFR/BS and Ac.f remained constant in the cancellous envelope at month 6 and 24 but were reduced in the endocortex at month 24.

Conclusions: This is the first analysis to compare progressive effects of TPTD vs ZOL on bone histomorphometry using paired biopsies. These data reveal histomorphometric characteristics of anabolic vs antiresorptive agents over time and show that the marked difference in the mechanism of action of TPTD and ZOL was maintained for 2 years.

Teriparatide Is Associated with Improved Microarchitecture and Estimated Bone Strength in Premenopausal Women with Idiopathic Osteoporosis: An HR-pQCT Study. Kyle Nishiyama*[1], Ji Wang[1], Polly Young[1], Robert Recker[2], Joan Lappe[3], Serge Cremers[1], X Guo[1], Elizabeth Shane[4], Adi Cohen[5]. [1]Columbia University, USA, [2]Creighton University, USA, [3]Creighton University Osteoporosis Research Center, USA, [4]Columbia University College of Physicians & Surgeons, USA, [5]Columbia University Medical Center, USA

In premenopausal women with idiopathic osteoporosis (IOP), we have previously reported that teriparatide (TPTD; 20 mcg SC daily for 18-24 months) is associated with improved bone density and quality at the central skeleton. In this regard, we documented increases in areal BMD by DXA at the lumbar spine (LS; mean ± SD: 10.8 ± 8.3%) and femoral neck (FN; 7.6 ± 3.4%) as well as in trabecular bone volume fraction measured on paired transiliac biopsies (48 ± 65%). In this analysis, we examined whether TPTD was also associated with improvements in volumetric BMD, bone microarchitecture and estimated bone strength of the peripheral skeleton as assessed by high-resolution peripheral quantitative computed tomography (HR-pQCT, Scanco Medical AG). Premenopausal women (N=20, age 41 ± 5 yrs) with IOP (low-trauma fractures and/or T-scores ≤ 2.5) were scanned with HR-pQCT at the distal radius and tibia at baseline and after 18-months of TPTD. Cortical (Ct) and trabecular (Tb) volumetric BMD and microarchitecture were measured by both standard and individual trabecula segmentation (ITS) techniques, and bone strength was estimated by micro finite element analysis (μFEA). Tb vBMD increased significantly by 2.6% at the radius and 2.5% at the tibia (Table). While Tb number and thickness did not change overall, ITS analysis revealed significant increases in Tb plate bone volume fraction, plate number and thickness at both radius and tibia. While Ct thickness and density did not change, Ct porosity increased at the radius by 17.1%, but not at the tibia. Despite this increase in porosity, whole bone stiffness and failure load estimated by μFEA increased at both radius and tibia and Tb stiffness and failure load increased at the tibia. At the radius, increases in bone volume fraction were associated with increases in LS aBMD (r=0.49, p=0.03) and total hip aBMD (r=0.51, p=0.03). At the tibia, increases in bone volume fraction were associated only with increases in total hip aBMD (r=0.46, p=0.02). In summary, in premenopausal women with IOP, 18-months of TPTD was associated with increases in Tb vBMD, mainly due to improvements in Tb plate microarchitecture. Although cortical porosity increased, cortical density and thickness did not change and estimated bone strength also improved at both radius and tibia. We conclude that TPTD has beneficial effects on both the central and peripheral skeleton in premenopausal women with IOP.

Effect of Romosozumab on Lumbar Spine and Hip Volumetric Bone Mineral Density (vBMD) as Assessed by Quantitative Computed Tomography (QCT). HK Genant*[1], S Boonen[2], MA Bolognese[3], C Mautalen[4], JP Brown[5], C Recknor[6], S Goemaere[7], K Engelke[8], Y-C Yang[9], M Austin[9], A Grauer[9], C Libanati[9]. [1]USCF & Synarc Inc., USA, [2]Leuven University Division of Geriatric Medicine, Belgium, [3]The Bethesda Health Research Center, USA, [4]Centro de Osteopatias Medicas, Argentina, [5]CHU de Québec Research Centre & Laval University, Canada, [6]United Osteoporosis Centers, USA, [7]Ghent University Hospital, Belgium, [8]Synarc Germany, Germany, [9]Amgen Inc., USA

Purpose: Sclerostin is an osteocyte-derived inhibitor of osteoblast activity. Romosozumab, a monoclonal antibody to sclerostin, stimulated bone formation, decreased bone resorption, and increased BMD in postmenopausal women with low bone mass. Here we describe the 12-month effect of romosozumab on lumbar spine (LS) and total hip (TH) BMD, and bone mineral content (BMC) as measured by QCT.

Methods: This international, randomized, placebo (Pbo)-controlled, phase 2 study enrolled postmenopausal women of 55–85 years with LS, TH, or femoral neck T-score ≤–2.0 and ≥–3.5. Measurements with QCT were performed at the "total" LS (mean of L1 & L2 entire vertebral bodies) and TH. Percentage change from baseline in integral and cortical vBMD and BMC, and trabecular vBMD was evaluated for Pbo, subcutaneous teriparatide (TPTD; 20 µg QD), and romosozumab (210 mg QM) at 12 months. Subjects with baseline and ≥1 post-baseline QCT measurements were included in the analyses.

Results: Treatment with romosozumab resulted in significant increases in integral vBMD and BMC at the "total" LS and TH from baseline, and compared with Pbo and TPTD (Figure). TPTD and Pbo were not different at the TH. Differences between romosozumab and TPTD were also observed in the trabecular and cortical bone compartments. Trabecular vBMD increased from baseline with romosozumab and TPTD at the LS and TH (both $p<0.05$). These gains were similar with romosozumab and TPTD at the LS (18.3% vs 20.1%, respectively), but were significantly larger with romosozumab at the TH (10.8% vs 4.2%, $p<0.05$). At the LS, treatment with romosozumab also resulted in significant increases from baseline in cortical vBMD compared with TPTD (13.7% vs 5.7%, $p<0.0001$) and cortical BMC (23.3% vs 10.9%, $p<0.0001$). At the TH, increases with romosozumab treatment from baseline were observed in cortical vBMD (1.1%) and cortical BMC (3.4%), but not with TPTD (–0.9% [cortical vBMD] and 0.0% [cortical BMC]); increases in cortical BMC with romosozumab were significant vs TPTD ($p<0.05$).

Conclusion: Romosozumab significantly increased vBMD and BMC at the "total" LS and TH compared with Pbo and TPTD as assessed by QCT in postmenopausal women with low bone mass. The gains, observed in the trabecular and cortical compartments, support the continued clinical investigation of romosozumab as a potential therapeutic agent for the treatment of women with postmenopausal osteoporosis with established BMD deficits and at increased fracture risk.

Effects of Blosozumab on Estimated Spine and Hip Strength in Postmenopausal Women with Low Bone Mineral Density: Finite Element Analysis of a Phase-II Dosing Study. Tony Keaveny*[1], Stephen Myers[2], Alan Chiang[2], Jahangir Alam[2], Deborah Robins[2], John Krege[2], Adrien Sipos[2], Bruce Mitlak[2], Charles Benson[2]. [1]University of California, Berkeley, USA, [2]Eli Lilly & Company, USA

Blosozumab is a humanized monoclonal antibody targeted to inhibit sclerostin and promote new bone. To determine the effects of subcutaneous blosozumab treatment on non-invasive estimates of spine and hip strength, finite element analysis was performed longitudinally on quantitative CT images in postmenopausal women with low areal BMD (lumbar spine T-score -3.5 to -2.0). These women, mean age 62 years, were a subgroup of patients enrolled in a double-blind, placebo-controlled, randomized, multicenter, 1-year Phase-II dosing study of four treatment groups (all with calcium and vitamin D): placebo, blosozumab 180 mg every 4 weeks, blosozumab 180 mg every 2 weeks, or blosozumab 270 mg every 2 weeks. The study was conducted in accordance with the Declaration of Helsinki and was approved by an ethics committee at each center. To estimate spine and hip strength, finite element analyses were performed for all patients (n=42) who had spine and/or hip CTs at baseline and at either 24 or 52 weeks, using the VirtuOst software (O.N. Diagnostics, Berkeley, CA). A mixed-effect model was used for the statistical analyses. CTs that were technically adequate for interpretation were included in the statistical analyses. After confirming uniformity of the groups at baseline, we found for the placebo group that neither spine nor hip strength changed significantly from baseline. By contrast, in the treated groups, there were statistically significant increases in both spine and hip strength, at both 24 and 52 weeks ($P<0.05$ at least; Table). These effects were substantial in the highest dose group: at the spine, blosozumab increased strength compared to baseline by up to 29.6 % at Week 24 and 37.0% at Week 52, and at the hip, blosozumab increased strength by up to 9.6% at Week 24, and 12.6% at Week 52. At both the spine and hip, these strength changes were associated with statistically significant increases in volumetric BMD of both the trabecular and cortical compartments. Other than mild injection site reactions that were more frequent with blosozumab than placebo, adverse events were similar across all groups. In conclusion, in this Phase-II study, blosozumab increased finite element-estimated spine and hip strength in postmenopausal women with low BMD, displaying a statistically significant positive dose response at both sites.

Systemic Administration of NELL-1, a Wnt/β-Catenin Regulator, Induces Bone Formation in Osteoporotic Mice via Integrinβ1. Aaron James*[1], Jia Shen[1], Omar Velasco[2], Greg Asatrian[2], Choon G Chung[2], Kevork Khadarian[3], Yulong Zhang[4], Le Chang[2], Raghav Goyal[2], Jung Kim[3], Xinli Zhang[1], John Adams[1], Kang Ting[1], Chia Soo[5]. [1]University of California, Los Angeles, USA, [2]Division of Associated Clinical Specialties & Section of Orthodontics, School of Dentistry, USA, [3]Department of Pathology & Laboratory Medicine, David Geffen School of Medicine, USA, [4]Department of Bioengineering, UCLA, USA, [5]Division of Plastic & Reconstructive Surgery, Department of Surgery, University of California, Los Angeles, USA

NELL-1 is a secreted protein that binds Integrinβ1 with known roles in craniofacial development. Nell-1 has recently been implicated in the pathoetiology of osteoporosis, as our laboratory recently described an osteoporotic phenotype of

Nell-1 haploinsufficient mice. While normal during development, senile *Nell-1*$^{+/-}$ mice manifest significant osteoporotic bone loss, with a reduction in the ratio of osteoblast-to-osteoclast cell number and activity, and reduced Wnt/β-catenin signaling.

This study expands on the association between NELL-1 and bone maintenance. First, the expression of Nell-1 was assessed during skeletal aging by qRT-PCR and immunohistochemistry. Next, recombinant human (rh)NELL-1 was systemically delivered by tail vein injection in a mouse model to treat ovariectomy-induced osteoporosis (1.25 ug/mg rhNELL-1 q48 hours, N=6-9 mice per group). Analyses included radiographic (DXA, CT/F18-PET, and postmortem microCT), and histological methods. Finally, MSC and pre-osteoclast cell lines were treated with rhNELL-1 in the setting of Integrinβ1 knockdown, in order to determine the necessity of Integrinβ1 for NELL-1 function.

Results showed that Nell-1 expression levels were inversely associated with skeletal aging – as Nell-1 gene and protein was high in early postnatal development, and decreased with aging (Fig. 1). Next, intravenous injection of rhNELL-1 was performed after induction of osteoporosis. We found that NELL-1 remained detectable in the blood for 24 hours post injection. After osteoporotic induction, intravenous rhNELL-1 was delivered every 48 hours for one month. DXA analysis of the lumbar spine and femur showed that rhNELL-1 injection resulted in a 10% increase in BMD in comparison to control, both osteoporotic and non-osteoporotic animals (Fig. 2). Next, we observed that rhNELL-1 activated Wnt/β-catenin associated gene expression in both osteoblast (M2-10B4) and osteoclast (RAW264.7) cell lines (Fig. 3). Moreover, rhNELL-1 activation of Wnt signaling required expression of the cell surface protein Integrinβ1, as Integrinβ1 siRNA abrogated rhNELL-1 induced Wnt signaling.

In summary, NELL-1 is a pro-osteogenic, anti-resorptive cytokine whose expression is lost with skeletal aging. Our studies suggest that systemic rhNELL-1 treatment is both safe and effective for osteoporotic condition. Moreover, NELL-1 treatment activates Wnt/β-catenin signaling in both osteoblast and osteoclast cell types in an Integrinβ1 dependent manner.

Against All Odds: Results from the ZEST Trial in Long Term Care Residents. Susan Greenspan*, MaryAnne Ferchak, Subashan Perera, David Nace, Neil Resnick. University of Pittsburgh, USA

Background: Although nearly 85% of long term care (LTC) residents have osteoporosis, the pivotal osteoporosis trials have systematically excluded frail, functionally-impaired women. As a result, the vast majority are not treated even though they are at the greatest risk for fracture. The goal of the ZEST trial (Zoledronic acid in frail Elders to STrengthen bone) was to examine the safety and efficacy of a single dose of zoledronic acid in LTC residents.

Methods: This 2-year, double-blind, randomized controlled trial included women residents of a nursing home or assisted living facility, who were not on an antiresorptive agent despite having osteoporosis (BMD or fracture), a vitamin D level >20 ng/dL, and life expectancy of ⩾2 years. We included residents with cognitive impairment, immobility, and multiple diseases and medications. All subjects (or their proxies) provided informed consent, and all received a single dose of zoledronic acid 5 mg or placebo IV, in addition to daily calcium (1200 mg) and vitamin D (800 IU). The primary outcomes were 12-month BMD changes of the hip and spine. Secondary outcomes were 24 month BMD changes, safety and bone turnover markers. We measured BMD in a mobile unit and collected serious adverse events (AE) with an electronic surveillance system. We used linear mixed models for BMD and bone marker analyses.

Results: 181 women were randomized. Mean age was 85.4 and there were no baseline differences between groups in age, BMI, calcium/vitamin D intake, BMD, activities of daily living, or cognitive or mental health status. The active treatment group included more women with diabetes, falls history, anti-seizure medications, and slow gait speed. 92% of subjects completed 12 months; 67% completed 24 months. BMD percent changes at the total hip, femoral neck and spine were significantly greater in the active treatment group compared with the placebo group at 12 and 24 months (all p< 0.01, table), with 12 month absolute differences of 3.2 percentage points at the total hip and 1.8 at the spine. There were no significant differences in serious AEs or deaths.

Conclusions: This trial of single dose zoledronic acid for osteoporosis in cognitively impaired, frail osteoporotic women is the first to demonstrate that it is safe and effective in preserving/improving skeletal integrity over 2 years. Future studies are needed to determine if BMD improvement translates into fracture reduction.

Table: Percent change ± standard error in bone mineral density at the spine, total hip and femoral neck

Skeletal site	Month	Active (N=89)	Placebo (N=92)	P-value (between group difference)
Spine	12	2.9±0.4 **	1.0±0.4 *	<0.01

The Platelet-inhibitor Clopidogrel Increases Risk of Bone Fractures in Stroke Patients. Niklas Jorgensen*[1], Peter Vestergaard[2], Peter Schwarz[3], Helle K. Iversen[4]. [1]Copenhagen University Hospital Glostrup, Denmark, [2]Aalborg University Hospital, Denmark, [3]Glostrup Hospital, Denmark, [4]The Stroke Unit, Department of Neurology, Glostrup Hospital, Denmark

Stroke is one of the leading causes of mortality and morbidity worldwide. In the surviving stroke patient the increased functional dependence and cognitive decline often leads to immobilization. Nearly three-quarters of all strokes occur in people over the age of 65, adding to the risk of osteoporosis in these patients. Balance is often impaired after a stroke increasing the risk of falls and in combination with immobilization and advanced age stroke patients have multiple risk factors for fractures. Finally, most stroke patients receive treatment with the platelet (ADP, $P2Y_{12}$) inhibitor Clopidogrel (Plavix®) which is shown to be associated with increased risk of fractures. The aim of the current study was to investigate the risk of fractures in stroke patients, and to determine whether clopidogrel treatment further increases the risk of fractures.

We investigated the association between clopidogrel use and fracture incidence in a nation-wide cohort study performed within the Danish population of approximately 5.3 million individuals. All subjects who were prescribed clopidogrel during the years 1996 to 2008 were included as exposed subjects (n=77,503), and for each exposed subject three subjects of the same age (same birth year) and gender were randomly selected from the background population as controls (n=232,510). Study endpoint was occurrence of stroke or transient ischaemic attack (TIA). Information on fracture occurrence and a number of confounders was obtained through different registers.

In the clopidogrel treated group 1.2% had a prior haemorrhagic stroke, 9.3% an ischemic stroke and 7.2% a TIA. In the non-clopidogrel treated group the percentages were 0.9% haemorrhagic stroke, 2.6% ischemic stroke and 2.3% TIA. Stroke patients had a significantly increased risk of fractures, both in the group of haemorrhagic stroke (HR: 1.34, $p<0.001$) and ischemic stroke (HR: 1.54, $p<0.001$). Interestingly, also patients with TCI patients had increased risk of fractures (HR: 1.28, $p<0.001$). Clopidogrel users also had an increased risk of fractures, though the contribution of the clopidogrel-treatment (HR: 1.05, p=0.001) was much less than the contribution of the stroke itself.In conclusion, stroke patients have increased risk of fractures due to a number of factors. One of these, treatment with the platelet-inhibitor clopidogrel, is associated with an increase in risk of fractures, though the contribution is minor compared to the stroke itself.

Effects of TZD Use and Discontinuation on Fracture Rates in ACCORD. Ann Schwartz*[1], Haiying Chen[2], Walter Ambrosius[3], Ajay Sood[4], Robert Josse[5], Denise Bonds[6], Adrian Schnall[7], Eric Vittinghoff[1], Douglas Bauer[1], Mary Ann Banerji[8], Robert Cohen[9], Bruce Hamilton[10], Tamara Isakova[11], Deborah Sellmeyer[12], Debra Simmons[13], Monica Stiles[14], Jeff Williamson[2], Karen Margolis[15]. [1]University of California, San Francisco, USA, [2]Wake Forest University Health Sciences, USA, [3]Wake Forest University School of Medicine, USA, [4]Case Western Reserve University, USA, [5]St. Michael's Hospital, University of Toronto, Canada, [6]National Institute of Health, USA, [7]University Suburban Health Center, USA, [8]SUNY Downstate Medical Center & Kings County Hospital, USA, [9]University of Cincinnati College of Medicine, USA, [10]VA Medical Center & University of Maryland School of Medicine, USA, [11]University of Miami, USA, [12]Johns Hopkins School of Medicine, USA, [13]University of Arkansas for Medical Sciences, USA, [14]University of Minnesota, USA, [15]HealthPartners Research Foundation, USA

Trials indicate that thiazolidinediones (TZD) increase fracture risk in women but not men. The fracture effect of discontinuing TZDs is not known. To assess whether TZD use increases fracture risk in men and women and to determine if TZD discontinuation affects fracture risk, we used data from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial designed to test the effect of intensive versus standard glycemia therapy on cardiovascular disease. At participating clinics (54 of 77), non-spine fractures were reported at annual visits and centrally adjudicated. Rosiglitazone was included in the original treatment algorithm for the intensive and standard glycemia therapy groups, and pioglitazone was added in Fall 2007. The intensive glycemia intervention was stopped in February 2008, and the trial ended in June 2009. Participants attended clinic visits every 2-4 months before and after the intensive glycemia intervention was stopped. At each visit, staff recorded the participant's use of diabetes medications, including TZDs, at visit entry and prescribed medications at visit exit. Mean age of the 6,865 included participants was 62.4 (SD 6.6) years; mean BMI was 32.6 (SD 5.3) kg/m^2; and mean duration of diabetes was 11.1 (SD 7.8) years. During mean follow-up of 4.8 (SD 1.5) years, 549 participants experienced at least one confirmed fracture. In proportional hazards models adjusted for age and glycemia randomization assignment, non-spine fracture rate was increased with TZD use and decreased with discontinuation in women, but not men (Table). To our knowledge, this is the first report to assess the effects of TZD discontinuation on fracture. These results confirm previous reports from clinical trials that TZD use increases fracture risk in women, but not men. Attenuation of increased fracture risk in women occurs after TZD use is discontinued.

Table. Adjusted hazard ratios (HR) for non-spine fracture by duration of TZD use and discontinuation

	Women		Men	
	HR	(95% CI)	HR	(95% CI)
Duration of TZD use				
TZD use ≤1yr vs None	1.70*	(1.11, 2.61)	1.44	(0.94, 2.22)
TZD use >1yr vs None	2.18*	(1.56, 3.06)	1.15	(0.82, 1.62)
Time since last TZD use				
Discontinued TZD ≤ 1yr vs Current user	0.70	(0.48, 1.04)	1.22	(0.83, 1.80)
Discontinued TZD >1yr vs Current user	0.58*	(0.39, 0.86)	1.04	(0.69, 1.55)

Estrogen Reduces Bone *sost* mRNA and Circulating Sclerostin Levels in Postmenopausal Women. Matthew Roforth*[1], Koji Fujita[1], Susan Demaray[1], Ulrike McGregor[2], Salman Kirmani[1], Louise McCready[1], James Peterson[1], Matthew Drake[3], David Monroe[4], Sundeep Khosla[5]. [1]Mayo Clinic, USA, [2]King's College, London UK, United Kingdom, [3]College of Medicine, Mayo Clinic, USA, [4]Mayo Foundation, USA, [5]Mayo Clinic College of Medicine, USA

Studies in postmenopausal women have shown that estrogen (E) reduces circulating sclerostin levels (JBMR 26:27, 2011). However, recent studies in mice (JBMR 28:618, 2013) found no significant effects of ovariectomy on serum sclerostin levels and lack of a relationship between circulating sclerostin and *sost* mRNA levels in various bones. To resolve this issue in humans, we measured serum sclerostin and bone *sost* mRNA levels in needle biopsies (1-2 mm diameter) from 20 postmenopausal women (71 ± 5 yr) treated with transdermal estradiol (0.05mg/d) for 3 weeks and 20 untreated control women (73 ± 7 yr). Serum sclerostin levels were 29% lower ($P = 0.008$) in the E-treated compared to the control women. Concomitantly, bone *sost* mRNA levels were reduced by 48% ($P = 0.03$) in the E-treated women. Interestingly, bone *sost* mRNA levels were significantly correlated with serum sclerostin levels in the E-treated ($r = 0.57$, $P = 0.008$), but not in the control women ($r = -0.25$, $P = 0.280$). In addition, mRNA levels of the sclerostin domain-containing protein 1 (*sostdc1*), a sclerostin-related protein that is another Wnt/BMP inhibitor, were also reduced in the bones of the E-treated compared to the control women (by 54%, $P = 0.01$).

We further extended these studies using customized, in-house QPCR analyses to examine the mRNA expression of genes in other pathways related to bone metabolism, as well as the expression of 71 genes linked to SNPs from GWAS studies (Nat Genet 44:491, 2012). Consistent with studies in mice showing that ovariectomy upregulated components of NFκB signaling, leading to impaired osteoblastic bone formation (Nat Med 15:682, 2009), we found significantly reduced mRNA levels of both *NFκB2* and *relB*, along with an overall trend ($P = 0.028$ by cluster analysis) for lower mRNA levels of multiple inflammatory markers in the bone biopsies of the E-treated compared to the control women. Of the 71 GWAS-related genes examined, 14 were modulated *in vivo* by E treatment.

In summary, our studies demonstrate that, in humans, E reduces both bone *sost* mRNA and circulating sclerostin levels. Further, since bone loss following E deficiency is associated with impaired bone formation relative to bone resorption, our findings point to increases in two key inhibitors of Wnt/BMP signaling, sclerostin and sostdc1, along with increased NFκB signaling, as mediating this relative deficit in bone formation in E-deficient postmenopausal women.

Efficacy of a Tissue-nonspecific Alkaline Phosphatase Inhibitor in a Mouse Model of Severe Medial Vascular Calcification. Campbell Sheen*[1], Thangchanthida N. Chhea[1], Anthony B. Pinkerton[2], Michael R. Jackson[2], Jose Luis Millan[3]. [1]Sanford Burnham Medical Research Institute, USA, [2]Conrad Prebys Center for Chemical Genomics, Sanford Burnham Medical Research Institute, USA, [3]Sanford-Burnham Medical Research Institute, USA

Upregulation of tissue-nonspecific alkaline phosphatase (TNAP) in the vasculature occurs in a variety of disorders which manifest medial vascular calcification (MVC). We have previously described a mouse model that overexpresses human TNAP in vascular smooth muscle cells, in an X-linked manner, and consequently causes extensive MVC. Hemizygous overexpressor male mice ($Tagln^{Cre/WT}$; $HprtALPL^{flox/Y}$) exhibit severe cardiac hypertrophy and have a median age of death

of 44 days, whereas the hypertrophy is less pronounced and life expectancy is normal in heterozygous females (*Tagln*$^{Cre/WT}$; *HprtALPL*$^{flox/WT}$). Through medicinal chemistry efforts, we have developed inhibitors of TNAP with drug-like characteristics that have efficacy *in vitro*. Here, we tested one of these inhibitors of TNAP, named SBI-425, to determine whether the compound had efficacy in our *in vivo* model of MVC.

Mice were i.p. injected once daily with either 10 mg/kg SBI-425 or vehicle-only control. Male and female mice were treated from day 7 to day 30 and day 60, respectively. Aortic calcium deposition was measured using acid leeching and a cresolphthalein complexone assay, which showed a significant decrease in calcification in female, but not male, mice. Heart weight to body weight ratios were significantly lower in both male and female treated mice, indicating improvement in cardiac hypertrophy. A separate group of male mice was treated with 10 mg/kg of SBI-425 or control from day 7 until death. This showed that SBI-425 treatment significantly increased the median life expectancy of affected male mice from 44 to 68 days. Possible toxic effects on bone were also evaluated by static and dynamic histomorphometry.Together, these results indicate that SBI-425 can effectively reach and inhibit TNAP in the vasculature, which suggests that it may be an effective treatment for MVC.

PTH 1-84 Targets Bone Vascular Structure and Perfusion in Mice: Impacts of its Administration Regimen and of Estrogen Deficiency. Bernard Roche*, Arnaud Vanden-Bossche, Martin Jannot, Robin Chaux, Luc Malaval, Laurence Vico, Marie-Hélène Lafage-Proust. INSERM U1059-Université de Lyon-Université Jean Monnet, France

Bone vessels functions during bone remodeling are poorly understood. They depend on both vessel network structure and vasomotor regulation. Parathyroid hormone (PTH) is a systemic vasodilator and may modulate microvascularisation. Moreover, while intermittent PTH is anti-osteoporotic, PTH continuous administration can be catabolic for bone. Finally, ovariectomy (OVX) reduces bone perfusion and vessel density in mice. In this context, our working hypotheses were that PTH effects on bone vascularisation 1) depend on its administration regimen and 2) may be impacted by estrogen deficiency. We used 4 month-old female C57BL/6 mice (n=15/group). Tibia bone perfusion was measured in vivo with a Laser Doppler device while systemic blood pressure (BP) and heart rate were monitored. After barium infusion, bone and vascular quantitative histomorphometry was performed on the same tibia. First, a 100µg/kg daily dose of PTH 1-84 was administered for 15 days either as daily Sc injection (iPTH) or continuously (ALZET minipump, cPTH). Compared to untreated controls (CT), iPTH and cPTH both increased bone formation but had opposite effects on bone resorption. iPTH increased bone perfusion (27% vs CT, $p<0.001$), with no difference in BP, while cPTH did not. Although both i- and cPTH were slightly angiogenic, iPTH increased microvessel size by 48%, while cPTH decreased it by 29% ($p<0.001$, vs CT). Second, the vascular effects of a 15d-iPTH treatment (100µg/kg/d) were analysed in OVX mice and compared to sham-operated and OVX CT. In order to asses specificity of PTH effects on vessels, two other anti-osteoporotic drugs were tested in OVX mice: zoledronate which is potentially anti-angiogenic (ZOL, 1 single injection, 70µg/kg) and propranolol (PROP), an anti hypertensive β-blocker, at a dose known to protect bone mass in rodents (5mg/kg/d). No change in bone mass occurred in this time frame. iPTH stimulated bone formation and fully prevented OVX-induced reduction in bone perfusion and vessel density, but with no change in vessel size. ZOL and PROP strongly lowered bone turnover. Surprisingly, ZOL did not further reduce bone vessel density below OVX levels and it prevented, like iPTH, OVX-induced reduction in bone perfusion, while PROP did not. Thus, our integrative approach demonstrates that PTH effects on bone vessel network microstructure and function depend on its mode of administration as well as estrogen status, and that OVX-induced vascular changes are prevented by iPTH.

Parathyroid Hormone Rescues Impaired Tooth Extraction Healing Associated with Bisphosphonates. Junro Yamashita*[1], Laurie McCauley[2], Shinichiro Kuroshima[3]. [1]University of Michigan, USA, [2]University of Michigan School of Dentistry, USA, [3]Nagasaki University, Japan

Osteonecrosis of the jaw (ONJ) is a rare and devastating condition that has emerged in association with antiresorptive therapy. The pathophysiology of ONJ is unknown and no established cure currently exists. The purpose of this study was to determine whether daily PTH administration after tooth extractions would prevent the development of ONJ-like lesions in bisphosphonate-treated rats. Rats were ovariectomized and the combination of alendronate and dexamethasone (Aln/Dex) administered for 12 wks. Tooth extractions (maxillary 2nd molars) were performed and bony defects created in the proximal tibiae to compare osseous healing between the jaw and long bones. Half of the rats received daily PTH injections and the other half saline as vehicle control (VC). Healing of the extraction sites and tibial defects was assessed at 2 wks by microCT and histomorphometric analyses. All rats in the Aln/Dex-VC group developed ONJ-like lesions, while only 30% of rats in the Aln/Dex-PTH group developed ONJ-like lesions. Histomorphometrically, ONJ-like lesions were characterized by the retention of necrotic bone and severe PMN infiltration, while in PTH-treated rats healing occurred with new bone and increased collagen apposition in the extraction wounds. These findings suggest that daily PTH administration prevented the development of ONJ-like lesions. No differences in gross healing in the tibiae were noted between groups. Although the Aln/Dex-VC treatment was not associated with compromised gross healing of the tibiae as found in the oral cavity, histomorphometric analysis showed significantly more necrotic bone in Aln/Dex-VC vs. Aln/Dex-PTH tibiae. PTH administration increased bone mass significantly in the tibial defects regardless of bisphosphonate pretreatment. However, its anabolic effect on osseous wounds was significantly less in the Aln/Dex pretreatment group compared to control. Thus in both the extraction wounds and tibial defects PTH therapy promoted healing by suppressing necrotic bone and increasing bone mass. In this study ONJ-like lesions developed in the tooth extraction wounds but not in the tibial defects in rats on bisphosphonates and steroids. PTH therapy prevented the development of ONJ-like lesions and was more effective in building bone in the absence of bisphosphonate and steroid. These findings suggest daily PTH administration could be effective to prevent ONJ in patients on combination antiresorptive and steroid therapy.

Miglustat Normalizes Bone Mass And Improves Bone Microarchitecture In F508del Cystic Fibrosis Mice Through Beneficial Effects on Bone Formation and Resorption. Carole Le Henaff*[1], Eric Haÿ[2], Caroline Marty[2], Pierre J. Marie[2], Jacky P. Jacquot[1]. [1]EA 4691, SFR CAP-Santé (FED 4231), Université Reims Champagne Ardenne, France, [2]Inserm Unit 606 & University Paris Diderot, France

Male and female patients with cystic fibrosis (CF) show CF-related bone disease characterized by brittle bones. CF patients with the F508del mutation in the transmembrane conductance regulator (*Cftr*) gene display vertebral fractures and subsequent kyphosis, thus accelerating the course of the disease. We recently showed that mice with the F508del mutation in *Cftr* display a severe osteopenic phenotype early on. Using this mouse model, we tested the effect of N-butyldeoxynojyrimicin (miglustat, Zavesca, Actelion), an approved drug for treating bone pathology in type I Gaucher disease which was found to normalize CFTR-dependent sodium and chloride transport in nasal mucosa of F508del cystic fibrosis mice. To this goal, we treated male F508del mice and wild type (WT) littermates by oral administration (gavage) with a low dose (120 mg/kg/day) of miglustat for 28 days. At sacrifice, bone mass and bone microarchitecture were determined by micro-CT analysis, and bone formation and resorption were assessed by histomorphometric analyses in lumbar vertebrae and long bones (femur) after double tetracycline/calcein labelling. At 10 weeks of age, F508del mice showed decreased bone volume, reduced trabecular number and thickness, and increased trabecular separation compared to age-matched WT mice. This phenotype resulted from decreased mineral apposition rate and increased osteoclast surface and number at the two skeletal sites, reflecting decreased osteoblast function and increased bone resorption. Treatment of F508del mice with miglustat normalized trabecular bone volume and microarchitecture parameters in the lumbar spine and femur. This effect was related to correction of the osteoblast function evaluated by the mineral apposition rate, associated with decreased osteoclast surface and number at the two bone sites. Interestingly, miglustat treatment decreased serum IGF-1 level in WT mice, but not in F508del mice. In contrast, miglustat treatment increased serum 17ß-estradiol level in F508del (male) mice but not in WT mice, suggesting that the beneficial effect of miglustat on bone may in part be linked to 17ß-estradiol but not to IGF-1 production. This study provides evidence that miglustat at low dose normalizes bone mass by increasing bone formation and decreasing bone resorption in F508del cystic fibrosis mice and suggests the potential interest of miglustat to treat bone loss in patients with cystic fibrosis related bone disease.

Parathyroid Cyp27b1 Mediates Skeletal Effects of Hyperparathyroidism by Controlling Serum 1,25-dihydroxyvitamin D_3 and Calcium Levels in Mice. Zhiqiang Cheng, Chia-Ling Tu, Alfred Li, Rachel Roston, Nathan Liang, Hanson Ho, Tsui-Hua Chen, Nehal Naik, Daniel Bikle, Dolores Shoback, Wenhan Chang*. Endocrine Unit, VA Medical Center, University of California, San Francisco, USA

Mechanisms underlying skeletal effects of hyperparathyroidism (HPT) remain unclear. Primary HPT (1° HPT) can have anabolic effects on trabecular (Tb) bone whereas secondary HPT (2° HPT) due to 1,25-dihydroxyvitamin D_3 (1,25D) and Ca^{2+} deficiencies is catabolic to bone, suggesting that the skeletal action of PTH depends on changes in 1,25D and Ca^{2+} status. To determine whether increased serum 1,25D (s1,25D) and Ca^{2+} (sCa) levels contribute to skeletal anabolism in 1° HPT, we studied CaSR-Het mice, a 1° HPT mouse model due to heterozygous knockout (KO) of the Ca^{2+}-sensing receptor (CaSR) gene in parathyroid cells (PTCs); Cyp-KO mice, a novel 2° HPT mouse model due to homozygous deletion of Cyp27b1 gene in PTCs; and double KO (CaSR-Het/Cyp-KO) mice. The Cyp-KO mice develop 2° HPT due to a profound reduction in s1,25D (by >70%) and sCa levels (see Table). We compared

serum PTH (sPTH), sCa, and s1,25D levels and Tb bone mass and structural parameters, by micro-computed tomography, in distal femurs of these 3 mouse strains. PTC-specific gene deletion in the mice was confirmed by PCR analyses of genomic DNA and RNA from various tissues. As anticipated, sPTH, sCa, and s1,25D levels were significantly ($p<0.01$) increased in CaSR-Het vs control (Cont) mice (see Table), indicative of 1° HPT. These changes were accompanied by a significantly ($p<0.01$) increased ratio of Tb bone volume (Tb.BV)/total tissue volume (TV) (Tb.BV/TV), Tb number (Tb.N), and Tb thickness (Tb.Th) in CaSR-Het vs control (Cont) mice (see Table), reflecting anabolic effects of 1° HPT. In contrast, Cyp-KO mice developed 2° HPT, as indicated by reduced s1,25D and sCa levels, when compared to Cont mice. Their increased sPTH levels were comparable to those of CaSR-Het mice (see Table). These serum changes were accompanied by catabolic bone effects, reflected by reduced Tb.BV/TV, Tb.N, and Tb.Th (see Table). In CaSR-Het//Cyp-KO double KO mice, concurrent ablation of parathyroid Cyp27b1 significantly ($p<0.01$) decreased sCa and s1,25D levels, despite the presence of their higher levels of sPTH vs those in CaSR-Het mice, and these reduced sCa and s1,25D levels severely blunted the anabolic effects of 1° HPT due to CaSR KO. Our data suggest that the parathyroid Cyp27b1 activity critically mediates skeletal actions of PTH by controlling s1,25D and sCa levels in mice.

Genotype	sPTH, ng/mL	sCa, mg/dL	s1,25D, pM	Tb.BV/TV	Tb.N	Tb.Th, μm
Cont	112 ± 8	9.78 ± 0.04	109.1 ± 14.7	8.7 ± 0.3	3.36 ± 0.11	30.6 ± 0.7

Suppression of Sclerostin by PTH in Osteocytes Contributes to the Coupling of Formation to Resorption in Trabecular Bone in Mouse Models of Primary and Secondary Hyperparathyroidism. Robert Jilka*, Annick DeLoose, Kanan Vyas, Leslie Climer, Robert Weinstein, Charles O'Brien, Stavros Manolagas. Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Osteocytes play a central role in the choreography of bone remodeling by controlling rate-limiting steps of both resorption and formation. However, the role of this cell type in the pathologic bone remodeling associated with primary or secondary hyperparathyroidism is not fully understood. Nonetheless, it is well documented that PTH acts on osteocytes to increase the production of RANKL and suppress the expression of sclerostin. To investigate the contribution of reduced sclerostin production to remodeling balance in hyperparathyroidism, we used C57BL/6 mice overexpressing human sclerostin in osteocytes under the control of a PTH-insensitive DMP1 promoter (DMP1-Sost mice). Administration of a Ca-deficient diet for 4 weeks to 9-mo-old males raised circulating PTH in both genotypes. However, the magnitude of the loss of vertebral BMD by DEXA in DMP1-Sost mice was greater than in wild type (WT) mice (-13.6 ± 3.8% vs. -6.1 ± 5.2%, $P<0.05$). This difference was due, at least in part, to a greater loss of trabecular bone, as determined by μCT. Loss of femoral DEXA BMD was also greater in DMP1-Sost mice, but μCT did not reveal a differentially sensitive site. Ca deficiency caused an equivalent increase in osteoclasts in both genotypes, as evidenced by expression of cathepsin K mRNA in tibial extracts. In contrast, there was no detectable increase in osteocalcin mRNA in DMP1-Sost mice whereas it increased by 2-fold in WT mice, suggesting an increase in osteoblast number in the latter. Hence, the greater bone loss in DMP1-Sost mice may be due to inadequate osteoblastogenesis. Hyperparathyroidism is also associated with peritrabecular fibrosis, thought to be caused by increased numbers of osteoprogenitors that are arrested prior to terminal differentiation. To explore the role of sclerostin in this pathology, we administered 400 ng/g/day of PTH(1-34) by infusion for 5 days. Extensive fibrosis was present in the vertebrae and femora of 9-mo-old wild type mice, but was barely detectable in DMP1-Sost mice. Finally, PTH-induced expression of Wnt target genes including Axin2, Nkd2, and Cx43 was attenuated in DMP1-Sost mice. Collectively, these results reveal that in hyperparathyroid states suppression of sclerostin production by osteocytes and the resulting increase in Wnt signaling contributes to the coupling of bone formation to bone resorption – at least in the cancellous compartment – as well as to the development of peritrabecular fibrosis.

The Role of Macrophage Efferocytosis in Prostate Cancer Skeletal Metastasis. Fabiana Soki*[1], Yeo Won Kim[2], Amy Koh[2], Payam Entezami[2], Sun Wook Cho[3], Serk In Park[4], Sudha Sud[2], Kenneth Pienta[2], Laurie McCauley[1]. [1]University of Michigan School of dentistry, USA, [2]University of Michigan, USA, [3]Seoul National University Hospital, South Korea, [4]Vanderbilt University, USA

Macrophages are implicated in both skeletal homeostasis and tumorigenesis; yet their role in skeletal metastasis is unclear. Macrophage phagocytosis of apoptotic cells is referred to as efferocytosis, and is an integral process by which harmful by-products of dead and dying cells are removed to create a pro-resolving environment. Rapidly growing tumors are accompanied by extensive apoptosis, of which the clearance mechanisms and implications remain unclear. The purpose of this study was to determine the role of macrophages and efferocytosis in prostate cancer skeletal metastasis. *In vivo* experimental approaches employed a chemically inducible macrophage ablation model (i.e. MAFIA mice) in which AP20187 (AP) injections result in fas-induced apoptosis of c-fms (CSF-1 receptor)-positive macrophage lineage cells. Macrophage depletion was optimized, and reduction in mature bone marrow macrophages was validated by FACS analysis ($GR1^{lo}F4/80^{+}CD115^{+}SSC^{int/lo}CD11b^{hi}$ cells ~2.5% in control vs 0.2% in AP-treated). When tumors were co-implanted with neonatal murine vertebrae (vossicles) in AP-treated mafia mice, there was a significant increase in TUNEL positive apoptotic cells (due to inefficient clearance). A significant reduction in tumor growth was noted in tibiae after intratibial tumor inoculations when macrophages were ablated. To evaluate macrophage efferocytosis *in vitro*, immunofluorescence staining was performed to validate and quantify bone marrow macrophage efferocytosis of cobalt chloride-induced apoptotic RM-1 and PC-3 prostate cancer cells. Efferocytosis was increased and to a greater extent when macrophages were co-cultured (5hrs) with prostate cancer cells that were highly apoptotic (>40%) versus low apoptotic (<20%). Concomitantly, milk fat globule-EGF factor 8 (MFG-E8), an efferocytosis facilitator protein, was also increased. Downstream of MFGE8, the SOCS3 (suppressor of cytokine signaling 3) pathway was activated. In addition, CD206+ pro-tumorigenic macrophages (M2) and *IL10* gene expression (encoding interleukin 10) were increased when macrophage lineage cells encountered apoptotic tumor cells. In conclusion, depletion of macrophages hindered tumor growth in bone and phagocytosis via MFG-E8 modulated polarization to M2 tumor associated macrophages. These studies identify a new mechanism by which tumor associated macrophages support prostate cancer growth, and a potential therapeutic target in skeletal metastasis.

Altered TGF-beta signaling contributes to skeletal and extraskeletal manifestations in the Crtap-/- model of recessive Osteogenesis Imperfecta. Ingo Grafe*[1], Tao Yang[2], Stefanie Alexander[3], Erica Paige Homan[3], Caressa Lietman[3], Elda Munivez[3], Ming-Ming Jiang[3], Terry Bertin[3], Yuqing Chen[3], Gautam Sule[3], Mary Ann Weis[4], Yoshihiro Ishikawa[5], Brian Dawson[3], Kuber Sampath[6], Hans Peter Bächinger[5], David Eyre[7], Brendan Lee[8]. [1]Department of Molecular & Human Genetics, Baylor College of Medicine, USA, [2]Van Andel Research Institute, USA, [3]Baylor College of Medicine, USA, [4]University of Washington, USA, [5]Shriners Hospital for Children, USA, [6]Genzyme Corporation, USA, [7]University of Washington Orthopaedic Research Labs, USA, [8]Baylor College of Medicine & Howard Hughes Medical Institute, USA

Osteogenesis Imperfecta (OI) is characterized by low bone mass, fractures and extraskeletal manifestations. Treatment options are limited to symptomatic therapies since the underlying molecular pathomechanisms of OI are not completely understood. Recently, we have shown that mutations in *CRTAP* cause recessive OI. Interestingly, the phenotype of *Crtap-/-* mice overlaps with phenotypes resulting from increased TGFb signaling, including decreased bone mass and increased alveolar airway space in lungs. We hypothesize that the alteration of collagen post-translational modifications in *Crtap-/-* mice results in a dysregulation of matrix-cell signaling which contributes to phenotype manifestation.

Here we show dysregulated TGFb activity in *Crtap-/-* mice, as evidenced by an increased ratio of pSmad2/Smad2 protein and increased expression of TGFb target genes in calvarial bone. Consistent with this, *Crtap-/-* mice carrying a TGFb-luciferase reporter transgene show increased bioluminescence in skeletal tissue compared to WT mice. Furthermore, increased immunostaining of pSmad2 in lungs of *Crtap-/-* mice shows similarly dysregulated TGFb activity in extraskeletal tissues.

To block the increased TGFb activity, we utilized a pan-TGFb neutralizing antibody (1D11, Genzyme) to treat 8 week old *Crtap-/-* mice for 8 weeks (10mg/kg,IP,3x/week). Control antibody treated *Crtap-/-* and WT mice served as controls. MicroCT analysis of L4 vertebrae showed that compared to control *Crtap-/-* mice, 1D11 treatment significantly improved trabecular bone parameters including BS (+91%) and Tb.N (+88%); BV/TV (+193%), Tb.Th (+57%) and Tb.Sp (-58%) were no longer statistically different than WT mice. Similarly significant improvements were also observed at the trabecular bone of femurs. In addition, 1D11 treatment ameliorated the lung phenotype, as demonstrated by a significant reduction of the alveolar airway space.

In summary, we show that dysregulated TGFb signaling is a novel molecular mechanism and important contributor to the bone and lung defects in the *Crtap-/-* model of recessive OI. Given the phenotypic overlap between recessive and dominant forms of OI this mechanism may also contribute to the phenotypes in dominant OI as a common mechanism of disease. These findings could shed new light on the molecular mechanisms of human OI, and potentially may be translated into signaling based therapies to alleviate skeletal as well as extraskeletal manifestations in patients with OI.

NOS-Mediated Vasodilation Causes Immediate Increases in Blood Flow Rate Following Osteogenic Mechanical Loading in Rats. Ryan Tomlinson*[1], Kooresh Shoghi[1], Matthew Silva[2]. [1]Washington University in St. Louis, USA, [2]Washington University in St. Louis School of Medicine, USA

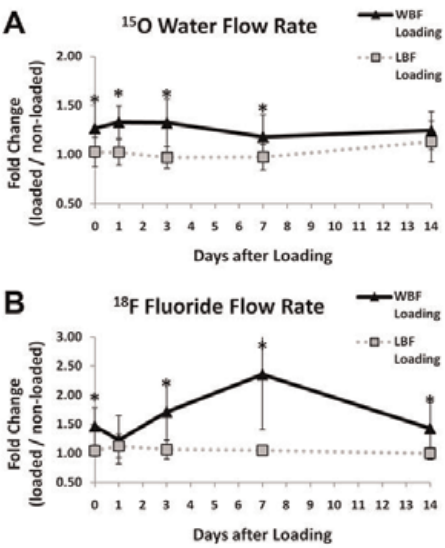
The vascular response following osteogenic mechanical loading is poorly understood. Here, either damaging (WBF) or non-damaging (LBF) axial compression was used to generate woven or lamellar bone formation, respectively, in the adult rat forelimb.

PET imaging was used to evaluate blood flow and fluoride kinetics at the site of bone formation. As early as a few hours after WBF loading, the blood flow rate increased approximately 30%; this significant increase was maintained for 14 days. In contrast, fluoride uptake peaked 7 days after WBF loading, and declined sharply between days 7 and 14. There were no significant changes in blood flow rate or fluoride uptake following LBF loading.

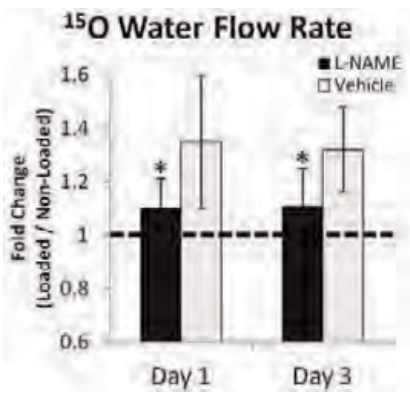
To quantify vasodilation, the area of the anterior interosseous artery was measured following loading. WBF loaded limbs had significantly increased arterial area (+50%) compared to non-loaded limbs at days 1 and 3. By day 7, arterial area was not different between loaded and non-loaded limbs. Similarly, there were no significant differences in arterial area following LBF loading. Since mast cells are a possible effector of vasodilation, mast cell infiltration and Nos2 expression were quantified following loading. Nos2+ mast cells in WBF loaded limbs were significantly increased on days 1 and 3. By day 7, there were no differences between loaded and non-loaded limbs. LBF loading was not associated with increases in Nos2+ mast cells.

L-NAME (N^{ω}-nitro-L-arginine methyl ester), a NOS inhibitor, prevented the expression of Nos2 in mast cells following WBF loading. Additionally, L-NAME treatment abolished the increase in blood flow rate at days 1 and 3, and decreased fluoride uptake at day 3. Finally, L-NAME treatment decreased woven bone formation, with significant decreases in woven bone area (-23%), volume (-27%), and BMD (-26%), compared to vehicle controls.

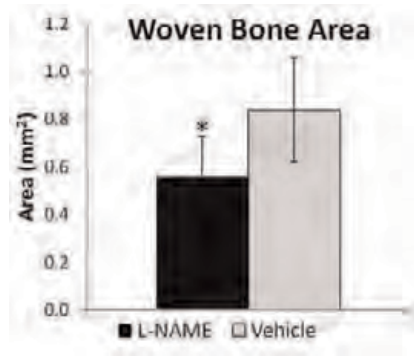
In summary, WBF loading was associated with a rapid and persistent increase in blood flow rate. This increase was mediated by vasodilation associated with mast cells positive for Nos2 in the expanded periosteal region. Treatment with L-NAME blocked the expression of Nos2 as well as the increase in blood flow rate, and ultimately impaired woven bone formation. In contrast, LBF loading was not associated with increases in blood flow rate, vasodilation, or Nos2 expression in mast cells.



15O Water and 18F Fluoride flow rates are temporally regulated following mechanical loading



L-NAME treatment inhibited early increases in blood flow rate following WBF loading



L-NAME treatment was associated with decreased woven bone area by dynamic histomorphometry

Interactions Among Cortical and Trabecular Traits During Growth Provide Insight Into Establishing Whole Bone Mechanical Function in the Lumbar Vertebral Body. Melissa Ramcharan*[1], Meghan Faillace[2], Zoe Guengerich[1], Valerie Williams[1], Karl Jepsen[3]. [1]Mount Sinai School of Medicine, USA, [2]GE Inspection Technologies, USA, [3]University of Michigan, USA

Studying bone as a complex adaptive system will benefit efforts to understand how interactions among cortical and trabecular traits define whole bone mechanical function and to identify genetic and environmental factors that contribute to reduced bone strength. Much is known about cortical and trabecular bone separately, but very little is known about how these traits co-develop during growth to establish bone strength. To study this, we adopted a paradigm which postulates that early variation in one trait is followed by adaptive changes in other traits. We examined temporal changes in bone traits during growth in the vertebral body of three inbred mouse strains, A/J(AJ), C3H/HeJ(C3H) and C57BL/6J(B6). Strains range from a slender to a robust bone phenotype each with widely varying adult trait sets.

Female mice were sacrificed at 1, 4, 7, 10, 14, 28, and 105 days of age (n=10/age/strain). Histological sections of plastic embedded vertebral bodies were imaged along the L3 mid-transverse or L4 mid-coronal plane using fluorescent microscopy. Morphological traits quantified in the transverse plane included total cross-sectional area and cortical area (CtAr). Traits quantified in the coronal plane included percent trabecular bone area (%TBA), trabecular thickness, and anisotropy. Differences in traits relative to age and genotype were determined using a one-way ANOVA and a Tukey's posthoc test ($p<0.05$).

Inter-strain differences in trabecular %TBA and anisotropy observed at 15weeks of age were established as early as 7 days of age. %TBA was highest in B6 mice followed by AJ then C3H mice. Trabecular anisotropy was highest in C3H mice followed by B6 then AJ mice. Also, by 7 days of age, a decrease in %TBA was accompanied by an increase in trabecular anisotropy. This suggests an early restructuring of the trabecular architecture to increase the efficiency of load transfer through the vertebral body. The inter-strain variation in %TBA was retained throughout growth. In contrast, cortical area was highly variable with C3H showing a 135% increase in Ct.Ar between 4 and 15 weeks of age. This suggests an adaptive response of cortical area to the low %TBA present at 4 days of age.

Our results suggest variation in the cortical trait arises from an adaptive response to early genetic variation in trabecular traits. This insight is important for understanding functional bone adaptation and interpreting adaptive changes in bone due to genetic or environment perturbations.

Osteocyte Pericellular Matrix Density Regulates Bone's Anabolic Response to Mechanical Loading. Christopher Price*[1], Tonima Quabili[1], Wei-Ju Tseng[2], X. Sherry Liu[2], Catherine Kirn-Safran[1], Liyun Wang[1]. [1]University of Delaware, USA, [2]University of Pennsylvania, USA

Osteocytes are responsible for detecting mechanical loading and orchestrating the bone's remodeling process. Using fluorescence recovery after photobleaching (FRAP), we have demonstrated significant interstitial fluid flows (50um/s) around the osteocyte cell processes in bone under moderate loading. However, the apparatus by which the osteocyte senses these signals remains unclear. We believe that pericellular matrix (PCM) fibers, which tether the osteocyte cell processes to lacunar wall, constitute the cells' ''sensing antennae''. PCM fibers can be deformed by fluid flow, much like trees are bent under the wind, and may thus allow the transfer of external loading signals to the cells interior and the initiation of biochemical responses. Further, we recently found that the density of the PCM was reduced -34% in mice with deficiency of perlecan (a PCM constituent). We hypothesized that a

reduction in PCM fiber density would reduce bone's sensitivity and anabolic response to mechanical loading.

In this study, we subjected the right tibiae of 3.5-month old perlecan deficient mice (Hypo, N=7) and age-matched control mice (CTL, N=8) to compressive uniaxial-tibial loading (peak load 8.5N at 4 Hz, 5 sessions over 10 days, 5 min/day). The left tibiae served as non-loaded control. Tibiae were scanned in a micro-CT scanner at a resolution of 6um^3/voxel, followed by three-point bending testing.The microCT data showed no significant differences in cortical bone morphology between control tibiae in the CTL and Hypo mice, except for a slightly higher tissue mineral density in the Hypo mice. Loading resulted in an increase in cortical bone polar moment inertia (+6.5%, p=0.02) and a reduction in the cortical porosity (-3.1%, p=0.04) relative to non-loaded tibiae in CTL mice, while no such effects were seen in the Hypo mice (Table 1). Loading also significantly increased tibial stiffness in CTL mice (+ 13.4%, p=0.01), but failed to reach significance in Hypo mice (p=0.19, Table 2). Overall, the hypo mice demonstrated diminished anabolic response to mechanical loading compared with control mice, supporting our original hypothesis. We are currently investigating how the altered PCM fiber density affects bone responses to disuse challenge. These studies will help elucidate the cellular mechanisms underlying bone's intrinsic (in-) sensitivity to mechanical loading, and may provide potential targets to promote bone formation and prevent bone loss.

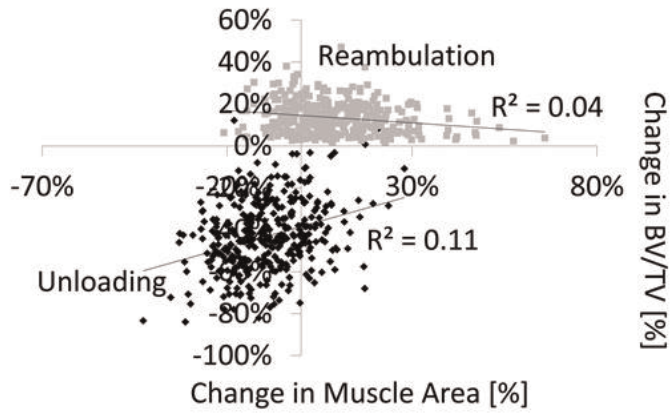
Genotypic and Phenotypic Muscle-Bone Interactions During Unloading/ Reloading. Stefan Judex*[1], Weidong Zhang[2], Leah Rae Donahue[2], Engin Ozcivici[3]. [1]Stony Brook University, USA, [2]Jackson Laboratory, USA, [3]Izmir Institute of Technology, Turkey

The concept of a muscle-bone unit tuned to the magnitude of contractile forces has intuitive appeal, however there is little direct evidence that the relatively few, large-magnitude muscle contractions arising during daily activities dominate skeletal adaptation. Here, we produced a genetically heterogeneous mouse population with large individual differences in mechanosensitivity and tested muscle-bone interactions during 3wk of hindlimb unloading and subsequent 3wk reambulation. Each of the 352 adult mice of the F2 cross of BALB/cByJ and C3H/HeJ were μCT scanned in vivo at baseline and after the two experimental phases. Muscle cross-section area of the upper hindlimb as well as trabecular and cortical morphology of the distal femur and middiaphysis were quantified. DNA was extracted from each mouse and genome wide scans determined quantitative trait loci (QTL) for unloading and reambulation induced changes in tissue quantity of muscle, trabecular, and cortical bone. As expected from this specific mouse population specifically bred for a large range in musculoskeletal mechanosensitivity, the response of all three tissues to the two experimental regimes varied greatly across individuals; from small to large losses during unloading and from continued deterioration to full recovery during reambulation. For instance, unloading resulted in losses of BV/TV between 15-71% while changes during reambulation ranged from -18% to +56%. Averaged across mice, muscle recovered greater losses during reambulation than either trabecular or cortical bone. Changes in muscle area during unloading and reambulation were not correlated with changes in trabecular and cortical quantity (R^2<12%); individuals with the greatest changes in muscle area did not coincide with those that showed the greatest changes in bone. QTL that regulated the magnitude of the response of any given tissue to unloading and reambulation showed little overlap between muscle and trabecular/ cortical bone. These data emphasize the strong influence of genetic variations on the response of the musculoskeletal tissues. The low correlations between morphological changes in muscle and bone, together with the distinct genetic regulation of the response, provide evidence against the hypothesis that bone's response to (un)loading is modulated by muscle forces. They also suggest that the development of physical interventions for musculoskeletal ailments may have to be optimized independently for bone and muscle.



Correlation between muscle area and trabecular BV/TV during unloading and reambulation

PHOSPHO1: Recognition of roles beyond skeletal mineralization. Karla Oldknow*[1], Nik Morton[2], Manisha Yadav[3], Sophie Rajoanah[2], Carmen Huesa[4], Lutz Bunger[5], Derek Ball[6], Mathieu Ferron[7], Gerard Karsenty[8], Vicky MacRae[4], Jose Luis Millan[9], Colin Farquharson[10]. [1]The Roslin Institute, The University of Edinburgh., United Kingdom, [2]QMRI, The University of Edinburgh, United Kingdom, [3]Burnham Institute for Medical Research, USA, [4]The Roslin Institute, The University of Edinburgh, United Kingdom, [5]SRUC, United Kingdom, [6]Heriot-Watt University, United Kingdom, [7]Institut de recherches cliniques de Montreal, Canada, [8]Columbia University, USA, [9]Sanford-Burnham Medical Research Institute, USA, [10]Roslin Institute, University of Edinburgh, United Kingdom

Advances in genetic approaches to bone physiology have expanded our understanding of the mechanisms by which bone and energy homeostasis interact. PHOSPHO1, a bone specific phosphatase is essential for the initiation of bone mineralization. Here we now show that *Phospho1* ablation confers a remarkable protection against obesity and diabetes in mice. To understand the mechanism whereby *Phospho1* impacts metabolism, microarray analysis of osteoblasts, the primary site of *Phospho1* expression was performed. *Esp* (encoding the phosphatase OST-PTP) which controls hormonally active osteocalcin secretion, was 20-fold more highly expressed in *Phospho1*$^{-/-}$ osteoblasts ($p<0.05$). Conversely, *Esp* mRNA was decreased in *Phospho1* overexpressing osteoblasts ($p<0.001$). Unexpectedly, serum levels of uncarboxylated and undercarboxylated osteocalcin were normal suggesting an osteocalcin-independent mechanism of PHOSPHO1 regulated energy metabolism. 120 day-old *Phospho1*$^{-/-}$ mice were hypoglycaemic (wild-type (WT) 9.48 ± 0.31 mmol/L, *Phospho1*$^{-/-}$ 8.30 ± 0.26 mmol/L; $p<0.01$) and showed improved glucose and insulin tolerance compared to WT mice ($p<0.05$). These observations were consistent with the finding of smaller (mg/g BW) subcutaneous (WT 4.51 ± 0.37, *Phospho1*$^{-/-}$ 2.79 ± 0.42; $p<0.01$), mesenteric (WT 13.2 ± 1.34, *Phospho1*$^{-/-}$ 5.56 ± 1.61; $p<0.01$) and epididymal (WT 13.7 ± 1.81, *Phospho1*$^{-/-}$ 6.96 ± 0.58; $p<0.001$) fat deposits noted in *Phospho1*$^{-/-}$ mice at necropsy and confirmed by MRI and CT. Remarkably, *Phospho1*$^{-/-}$ mice resisted the pronounced weight gain (WT 38.0 ± 1.54 g, *Phospho1*$^{-/-}$ 32.4 ± 1.26 g; $p<0.05$) and diabetes (WT 10.3 ± 0.53 mmol/L, *Phospho1*$^{-/-}$ 9.27 ± 0.77 mmol/L; $p<0.05$) exhibited by WT mice when fed a chronic high fat diet (HFD; 14 weeks, 58% kcal as fat) and this was not explained by altered activity. Circulating levels of total and high molecular weight adiponectin were decreased in *Phospho1*$^{-/-}$ mice on both control and HFD, whereas leptin levels were decreased on HFD only ($p<0.05$). Histology revealed smaller epididymal adipocytes, decreased fat content, decreased pancreatic islet number and increased mitochondria number in brown fat ($p<0.05$). However, no differences were observed in brown fat specific genes including *Ucp1* suggesting canonical thermogenesis does not underlie metabolic protection. Our findings indicate *Phospho1* deficiency improves the metabolic profile of mice in vivo and confers resistance to obesity and diabetes most likely through a primary effect on bone metabolism/turnover.

Loss of Cbl PI3K Interaction Alters the Composition of Hematopoietic Stem Cells and Osteoclast Precursor Cells in Bone Marrow in Association with Increased SDF-1 Production by CAR Cells. Naga Suresh Adapala[1], Sierra Root[2], Joseph Lorenzo[3], Hector Aguila[3], Archana Sanjay*[3]. [1]Department of Orthopedic Surgery, University of Connecticut Health Center, USA, [2]Department of Immunology, University of Connecticut Health Center, USA, [3]University of Connecticut Health Center, USA

Cbl functions as E3 ubiquitin ligase and adaptor protein in osteoclasts (OCs) and osteoblasts. One major function of Cbl involves the regulation of phosphatidyl inositol kinase (PI3K) activity. Tyrosine phosphorylation in the Y^{737}EAM motif is essential for Cbl-PI3K interaction. Substitution of phenylalanine for tyrosine 737 (YF) abrogates Cbl-PI3K interaction. We reported that mice harboring the YF mutation (YF mice) have increased OC numbers with defective bone resorption. This results in mild osteopetrosis, possibly due to perturbed spatiotemporal distribution of PI3K activity. To explore the origin of the increased OCs in YF mice, we performed FACS analysis and found that YF mice had 2-fold more OC precursors ($CD3^-CD45R^-NK.1.1^-CD11b^{lo}$ $CD115^{hi}$) in their bone marrow (BM). The granulocyte macrophage progenitors (GMP) progenitors which give rise OCPs were increased by 1.2 fold in YF mice while the numbers of common myeloid progenitors (CMP) and megakaryocyte-erythroid progenitors (MEP) were comparable to wild type. We have previously shown that levels of a chemokine, stromal derived factor-1 (SDF-1) are increased in YF BM. SDF-1 plays a crucial role in the initiation and maintenance of hematopoietic niches, and promotes OCP recruitment. By FACS analysis we demonstrated that expression of SDF-1 and its receptor CXCR4 is increased in YF derived GMPs and OCPs. Additionally, migration of YF derived OCPs towards a SDF-1 gradient was increased (WT 10.2% + 1.5; YF 17.8% + 1.8 $p < 0.0008$). Together, these data provide a mechanism for the increase in the number of OCPs in YF mice. Further analysis of the non-hematopoietic compartment revealed that the number of CXC12 abundant reticular (CAR) cells, which are the major source of SDF-1 in BM was significantly increased in YF mice and treatment of BM cells with a PI3K inhibitor attenuated SDF-1 expression. SDF-1 promotes B-cell development and selective ablation of SDF-1 in adult BM stromal cells resulted in expansion of hematopoietic stem cells (HSCs). We found that YF BM had a 1.6 fold decrease in HSCs ($Lin^-Sca1^+c\text{-}Kit^+$) as well as a decrease in common lymphoid progenitors (CLP) and T cells (CD3+) but an increase in B cells (B220+). These results demonstrate that the composition of the BM milieu in the YF mice is perturbed by their increased production of SDF-1. We conclude that Cbl-PI3K interaction has an important role in maintaining the balance of cellular components within the BM microenvironment.

Inhibition of AP-1 in specific hypothalamic neurons increases both energy expenditure and bone density in mice. Anna Idelevich*[1], Kazusa Sato[2], Glenn Rowe[3], Francesca Gori[4], Roland Baron[5]. [1]Harvard University, USA, [2]Harvard School of Dental Medicine, USA, [3]Harvard Medical School, USA, [4]Harvard School of Dental Medicine, Massachusetts General Hospital, USA, [5]Harvard School of Medicine & of Dental Medicine, USA

It has been recognized that the regulation of bone homeostasis and energy metabolism, once thought to be self-governing, may be coordinated by common neuronal relays. ΔFosB, a natural splice isoform of FosB and antagonist of AP1 transcriptional activity, increases both energy expenditure and bone formation, in a transgenic mouse model or following viral-mediated gene delivery into the ventral hypothalamus (VHT). Several VHT neurons forming the Ventromedial and Arcuate nucleai, have been previously implicated in the regulation of energy metabolism including AgRP, CART, POMC, NPY and SF1 neurons. The aim of the present study was to identify the individual AP-1 responsive VHT neuronal circuits that mediate the metabolic, skeletal or both effects.For this purpose,we generated Cre-inducible lentiviral vectors that express AP1 antagonists: ΔFosB, Δ2ΔFosB and DNJunD, as well as AP-1 agonist: FosB. The expression of these factors was restricted to specific neuronal types via stereotaxic delivery into the VHT of transgenic mice expressing Cre-recombinase under the control of the neuron-specific promoters, including AgRP-Cre, CART-Cre and SF1-Cre. Energy expenditure was assessed using calorimetric and monitoring system (CLAMS), whereas bone density was evaluated by micro-CT. Despite the classically divergent functions of anorexigenic CART and orexigenic AgRP neurons in feeding behavior and energy balance, AP-1 inhibition in either CART or AgRP neurons resulted in a consistent increase in energy expenditure and bone density. Moreover, all AP-1 antagonists in either of the three neuron-specific expression systems displayed a similar phenotype of lower weight gain and smaller fat pads with smaller adipocytes. Stimulation of AP-1 transcriptional activity via overexpression of full length FosB reversed the metabolic phenotype induced by AP-1 blockade, resulting in contrastingly lower energy expenditure and higher fat gain.

This study demonstrates that: 1) The induction of high energy expenditure and high bone density by ΔFosB in the VHT results from its antagonistic activity to AP-1 and 2) Selective inhibition of AP-1 in only one of AgRP, CART or SF1 neuron subtypes is sufficient to stimulate total body metabolism, decrease fat and increase bone density. These findings suggest that bone and energy are at least in part under common neuronal control and these effects are mediated by a central factor common to and/or affecting several hypothalamic neurons.

Expression of Glucose Transporter-4 by the osteoblast is required for global glucose metabolism. Zhu Li*[1], Julie Leslie[2], Guang William Wong[1], Barbara Kahn[3], Ryan Riddle[1], Thomas Clemens[2]. [1]Johns Hopkins University School of Medicine, USA, [2]Johns Hopkins University, USA, [3]Harvard Medical School, USA

Recent studies have identified the osteoblast as a major insulin responsive cell that regulates global energy metabolism by secreting hormones such as osteocalcin that alter insulin secretion and sensitivity. However, little is known of the major fuel requirements of osteoblasts. In this study, we examined the oxidation of glucose and fatty acids after insulin stimulation. Whereas oxidation of ^{14}C-oleate was decreased by insulin treatment, metabolism of ^{14}C-glucose was dose-dependently increased. Classical insulin responsive cells express glucose transporters (Glut) that facilitate the uptake of hexoses to be stored or metabolized. Primary mouse osteoblasts expressed Glut1 and Glut3 at low levels whereas Glut4 mRNA increased 6-fold during the course of osteoblast differentiation, compatible with the increased uptake of glucose during matrix production and mineralization. Insulin treatment induced Glut4 translocation to the plasma membrane in association with increased 2-deoxy-glucose uptake. Disruption of this transporter in osteoblasts *in vitro* eliminated insulin-stimulated glucose uptake, reduced proliferation and diminished measures of osteoblast maturation (Alkaline phosphatase and Alizarin red staining). *In vivo*, Glut4 was expressed by osteoblasts, osteocytes and chondrocytes at levels approaching those observed in adjacent skeletal muscle. To determine the importance of Glut4 in bone, we generated mice lacking Glut4 in osteoblasts/osteocytes (Glut4 Ob-KO). Glut4 Ob-KO mice were viable, exhibited normal linear growth, and had cortical and trabecular bone architecture indistinguishable from control littermates. Remarkably, however, Glut4 Ob-KO mice exhibited increased peripheral adiposity in association with mild hyper-insulinemia but marked insulin resistance measured by ITT. Quantitative PCR analysis of gene expression profiles in the liver and adipose of Glut4 Ob-KO mice revealed that insulin sensitivity was not altered in these tissues, suggesting that resistance to insulin was the result of decreased Glut4-mediated uptake of glucose in bone. Based on these observations, we conclude that the osteoblast-lineage contributes to the clearance of glucose in response to insulin and likely functions in the regulation of whole body metabolism beyond the secretion of osteocalcin.

Fetal Stage-Specific Mineral Metabolism in *Hyp* Mice Is Associated with Effects of FGF23 on Placenta. Yasuhisa Ohata*[1], Miwa Yamazaki[1], Masanobu Kawai[1], Kanako Tachikawa[1], Tomoko Koinuma[1], Kazuaki Miyagawa[2], Akihito Kimoto[1], Masahiro Nakayama[1], Noriyuki Namba[3], Hironori Yamamoto[4], Keiichi Ozono[5], Toshimi Michigami[1]. [1]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [2]Osaka University, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]University of Jin-ai, Japan, [5]Osaka University Graduate School of Medicine, Japan

We previously reported that human placenta expresses α-Klotho, which is required for fibroblast growth factor (FGF)23 signaling. Here we investigated the roles of FGF23 in mineral metabolism at the fetal stage using *Hyp* mice with high levels of circulating FGF23. *Hyp* and wild-type (WT) females were mated with WT males, and the mothers and their male fetuses were analyzed. Despite hypophosphatemia in *Hyp* mothers, serum phosphate (Pi) levels in fetuses were comparable among the 3 groups: *Hyp* and WT fetuses from *Hyp* mothers and WT fetuses from WT mothers. FGF23 levels in *Hyp* mothers were elevated. FGF23 levels were about 20-fold higher in *Hyp* fetuses than in *Hyp* mothers. WT fetuses from *Hyp* mothers exhibited low levels of FGF23, as did fetuses from WT mothers, suggesting that FGF23 does not cross the placenta or is rapidly degraded after its transfer. In kidneys of *Hyp* fetuses, although the expression of *Slc34a1* and *Slc34a3* was decreased and that of *Cyp24a1* was increased, the levels of Pi in amniotic fluids were comparable among the 3 groups. The feto-maternal interface of the placenta both in WT mouse and normal human expressed FGFR1 as well as α-Klotho. An antibody against the phosphorylated

FGFR (Y653/Y654) positively immunostained the interface, and so did an antibody against early growth response-1 (EGR-1), a target gene of FGF signaling. These observations indicated that these areas seemed to be receptive to FGF signaling. The expression of FGFR1 and α-Klotho in the placenta led us to hypothesize that FGF23 may exert its effects on the placenta and regulate mineral metabolism at the fetal stage. To test this hypothesis, we compared placental gene expression among WT fetuses from WT mothers and WT and *Hyp* fetuses from *Hyp* mothers. In *Hyp* fetuses, *Cyp24a1* expression was elevated in the placenta. To examine whether this increase in the placental expression of *Cyp24a1* was caused by an elevated level of FGF23, we performed *ex vivo* experiments using an organ culture of placentas from WT mice. In the organ culture of placentas, treatment with the plasma from *Hyp* mothers increased the expression of *Cyp24a1*, which was abolished by the addition of the anti-FGF23 neutralizing antibody. The direct injection of recombinant FGF23 into WT placentas induced the placental expression of *Cyp24a1* and *Egr-1*. These results indicate that the placenta is a target of FGF23, which may play a role in fetal vitamin D metabolism.

Bone Marrow Adipogenesis. Mark Horowitz*[1], Ryan Berry[2], Jackie Fretz[1], Tracy Nelson[2], Chris Church[2], Casey Doucette[3], Nancy Troiano[2], Joshua VanHoutan[2], Ormond MacDouglad[4], Clifford Rosen[5], Matthew Rodeheffer[2]. [1]Yale University School of Medicine, USA, [2]Yale University, USA, [3]Maine Medical Center Research Institute, USA, [4]University of Michigan, USA, [5]Maine Medical Center, USA

Adipocytes were identified in the bone marrow (BM) more than a century ago, but unlike adipose tissue in other depots, these cells have never been considered more than ''fillers'' for other ''more important'' BM cells. ''Yellow'' fatty marrow replaces ''red'' hematopoietic/osteogenic marrow within the long bones of humans. However, little is known about the origin, differentiation and function of BM adipocytes or their relationship to adipocytes in other depots.We have found that both rosiglitazone feeding and BM reconstitution following irradiation induces BM adipogenesis. BM adipocytes can be visualized through new techniques using osmium staining with quantitation by micro-CT or confocal imaging of BM plugs or frozen sections to assess morphology and expression of adipocyte genes.Experiments show that B6 mice, which have low BMD have few marrow adipocytes, which increase with calorie restriction and high fat diet (HFD). In contrast, C3H mice have high BMD and many adipocytes, which increase with HFD.Lineage tracing shows that BM adipocytes express adiponectin as rosiglitazone feeding of adiponectin-cre:mT/mG mice; in which expression of Cre recombinase from a promoter of interest (adiponectin) results in permanent removal of the targeted dTomato (mT) cassette and expression of the membrane targeted eGFP (mG) cassette, resulting in flipping from a dTomato+ to an eGFP+ cell; results in eGFP+ BM adipocytes. Using Vav1-cre:mT/mG mice we show that hematopoietic BM cells are Vav+, while none of the adipocytes express Vav. In contrast, using Pdgfra-cre:mT/mG mice we show that a subpopulation of BM adipocytes are Pdgfra+.Reconstitution of irradiated mice with mT/mG, Vav1-cre:mT/mG, Pdgfra-cre:mT/mG, or adiponectin-cre:mT/mG BM yields unlabeled LipidTox+ adipocytes, indicating that BM adipocytes do not arise from donor cells. Supporting this finding, white adipose tissue progenitors (Lin-Pdgfra+CD29+CD34+Sca-1+CD24+) are not found in isolated BM cells by FACS. Reconstitution of mT/mG mice with B6 BM results in dTomato+ adipocytes, indicating that BM adipocyte progenitors (AP) are present in the irradiated host. These experiments suggest that: A non-hematopoietic precursor cell resides in a BM ''niche'' giving rise to BM adipocytes; MAT can contribute to systemic metabolism through expression of adiponectin; BM AP are different than AP in other depots; These data are the first to define genetic markers in BM adipocyte progenitors *in vivo*.

Bone Specific Deletion of *Fgfr1* in Hyp Mice Partially Corrects the Hypophosphatemic Rickets Phenotype. Zhousheng Xiao*, Jinsong Huang, Li Cao, Yingjuan Liang, L. Darryl Quarles. The University of Tennessee Health Science Center, USA

Osteoctyes regulate phosphate and vitamin D homeostasis through the release of the Fgf23 hormone. Recent studies suggest that activation of Fgfr1 signaling underlies the increased Fgf23 levels in *Phex* mutant *Hyp* mice. To directly test the role of Fgfr1 in osteocytes, we conditionally deleted *Fgfr1* in *Hyp* osteocytes by crossing male *Dmp1*-Cre;*Fgfr1*$^{null/+}$ mice with female *Fgfr1*$^{flox/flox}$;*Hyp* mice. We characterized ''wild-type'' littermates (*Fgfr1*$^{flox/+}$), conditional homozygous *Fgfr1* null (*Fgfr1*$^{Dmp1\text{-}cKO}$) mice with intact *Phex* lacking *Fgfr1*, *Hyp* mice with intact *Fgfr1* lacking *Phex*, and conditional homozygous *Fgfr1* knockout mice lacking *Phex* (*Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp*). Mice were born with the expected Mendelian frequency. T*here were no differences in survival between these 4 genotypes*. *Dmp1*-Cre resulted in a 70% decrease of *Fgfr1* transcripts in bone. The gross appearance, *bone mineral density (BMD), periosteal mineral apposition rate (MAR), trabecular bone volume (BV/TV) and cortical thickness (Ct.Th) of Fgfr1*$^{Dmp1\text{-}cKO}$ mice were *indistinguishable from wild-type mice. However,* loss of *Fgfr1* in osteocytes resulted in a 30% reduction in *Fgf23* transcripts and a significant decrease in *Phex*, *Mepe*, *Sost* and *Dmp1*, but not *Ocn* or *Opn* transcripts in bone of *Fgfr1*$^{Dmp1\text{-}cKO}$ mice. Serum Fgf23 concentrations were reduced 2-fold, but no alterations in serum PTH, calcium, or phosphate concentrations were observed *in Fgfr1*$^{Dmp1\text{-}cKO}$ mice. In contrast, the tail length and body size of compound *Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp* mice were intermediate to wild-type and *Hyp* mice. In addition, compared to Hyp mice, compound *Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp* mice showed significant increments in *BMD, BV/TV, Ct.Th, and MAR,* suggesting partial rescue of the *Hyp* phenotype. *Concordant with the improved bone parameters, s*erum Fgf23 decreased from 3899 to 885 pg/ml and serum phosphate increased from 7.2 mg/dl to 10.2 mg/dl in *Hyp* and *Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp* mice, respectively. The reductions in circulating FGF23 levels were greater than the decrease in FGF23 mRNA expression in bone of *Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp* mice. In conclusion, conditional deletion of *Fgfr1* in osteocytes results in significant reductions of serum Fgf23 concentrations in both wild-type and *Hyp* mice, indicating that Fgfr1 signaling plays a role in regulating Fgf23 production in bone. Further studies are needed to determine the mechanisms underlying the residual FGF23 transcription and disproportionate reductions in circulating concentrations in *Fgfr1*$^{Dmp1\text{-}cKO}$;*Hyp* mice.

A First-in-Human, Randomized, Double-Blind, Placebo-Controlled, Single-Dose Study of a Human Monoclonal Anti-FGF23 Antibody (KRN23) in X-linked Hypophosphatemia. Thomas Carpenter*[1], Erik Imel[2], Mary Ruppe[3], Thomas Weber[4], Mark Klausner[5], Margaret Wooddell[6], Tetsuyoshi Kawakami[6], Takahiro Ito[6], Xiaoping Zhang[6], Jeffrey Humphrey[6], Karl Insogna[1], Munro Peacock[7]. [1]Yale University School of Medicine, USA, [2]Indiana University School of Medicine, USA, [3]The Methodist Hospital, USA, [4]Duke University Medical Center, USA, [5]Kyowa Hakko Kirin, USA, [6]Kyowa Hakko Kirin Pharma Inc, USA, [7]Indiana University Medical Center, USA

Purpose: X-linked hypophosphatemia (XLH) is an inherited metabolic bone disease characterized by short stature and skeletal deformities. XLH is caused by mutations of *PHEX* resulting in abnormally elevated serum FGF23, which causes low serum phosphorus (P) and inappropriately normal 1,25 dihydroxyvitamin D (1,25D) levels. A Phase 1 study was conducted with a human monoclonal anti-FGF23 antibody (KRN23) to measure changes in biochemical markers and to assess its safety and tolerability in adult patients with XLH.

Methods: Thirty-eight adults with XLH and baseline FGF23 ⩾ 30 pg/mL were randomized to receive single doses of KRN23 or placebo via intravenous (IV) (0.003 to 0.3 mg/kg) or subcutaneous (SC) (0.1 to 1.0 mg/kg) routes. Dose-escalation occurred after establishing safety of the prior dose. Biochemistry, pharmacokinetics, pharmacodynamics, and immunogenicity were assessed at baseline and at various time points up to Day 50 postdosing. Changes from baseline values for each dose level were compared with placebo as least squares means.

Results: Twenty-two subjects were in the IV arm (17 KRN23, 5 placebo), and 16 in the SC arm (12 KRN23, 4 placebo). Baseline age, sex, weight, and height were comparable in all groups. Serum P and renal threshold maximum for phosphate reabsorption (TmP/GFR) were lower than reference ranges in all subjects. Single doses of either IV or SC KRN23 increased serum P, TmP/GFR and 1,25D compared to placebo for higher doses. Peak serum P effects occurred later with SC (8-15 days) than with IV dosing (0.5-4 days). Duration of effect on P was dose-related, greater with SC than IV, and persisted beyond 29 days with SC. No meaningful changes in serum calcium, serum parathyroid hormone, or urinary calcium excretion occurred. Adverse events (AEs) occurred with higher frequency in patients receiving KRN23 (82% IV and 83% SC) compared to those receiving placebo (40% IV and 50% SC). AEs considered related to the study drug occurred in 6 patients (4 in IV dose groups [24%] and 2 in SC groups [17%]). There were no SAEs, and no changes in safety biochemistries, ECGs, or renal sonograms. Single-dose administration of KRN23 was safe and well-tolerated; no patient developed anti-KRN23 antibodies.

Conclusions: Blocking FGF23 activity with KRN23 is a novel treatment for XLH. Single IV or SC doses increased serum P and TmP/GFR, with effects lasting for more than 4 weeks with SC dosing.

Introduction: Selective serotonin receptor inhibitors (SSRIs), proton pump inhibitors (PPIs) and glucocorticoids (GCs) are associated with increased fracture risk. The objective of this study is to assess patterns of fractures over 5 years among GLOW participants.

Methods: GLOW comprises women ⩾55 years of age, enrolled in 615 primary care practices (17 sites, 10 countries). Self-administered surveys, mailed at baseline, 12, 24, 36 and 60 months, sought data on patient characteristics, risk factors, and use of estrogens, SSRIs, PPIs, GCs and anti-osteoporosis medication (AOM). Multivariable regression calculated odds ratios (ORs) and 95% confidence intervals (CIs). Adjustment was made for age, fracture between age 45 and enrollment into the study (baseline), and baseline use of anti-osteoporosis medication.

Results: 9347 subjects were never treated with SSRIs, GCs, PPIs, estrogen or AOM; 2715 women were on PPIs, 5304 on GCs and 1149 on SSRIs at some point between baseline and year 2. SSRI use was the only therapy associated with a statistically significant increase in overall, clinical spine and non-hip-non-vertebral (NHNV) fractures (Table). GCs were significantly associated with spine fractures. PPIs, while not statistically significant, were associated with NHNV fractures.

Introduction: Selective serotonin receptor inhibitors (SSRIs), proton pump inhibitors (PPIs) and glucocorticoids (GCs) are associated with increased fracture risk. The objective of this study is to assess patterns of fractures over 5 years among GLOW participants.

Prevention of Bone Loss in Breast Cancer Survivors on Aromatase Inhibitors: Results of the REBBeCA II Trial. Susan Greenspan*[1], Subashan Perera[1], Karen Vujevich[1], Gisberta van Londen[2], Adam Brufsky[2], Barry Lembersky[2], Shannon Puhalla[2]. [1]University of Pittsburgh, USA, [2]Magee-Womens Hospital, USA

Background: Aromatase inhibitors (AIs) including anastrozole, letrozole, and exemestane are routinely used for adjuvant treatment of postmenopausal women with hormone receptor positive breast cancer. Because AIs inhibit peripheral conversion of androgens to estrogen, women have a marked reduction in estrogen leading to accelerated bone loss and fractures. Little data are available on the impact of an oral bisphosphonate in women with low bone mass (not osteoporosis) who are on these commonly used AIs. The goal of the REBBeCA II trial (Risedronate's Effect on Bone in women with Breast CAncer II) was to examine the prevention of bone loss with the oral bisphosphonate risedronate in breast cancer survivors on an AI.

Methods: This 2-year randomized, double-blind, placebo-controlled trial included postmenopausal women over age 55 with breast cancer on an AI who had low bone mass, were not treated with a bisphosphonate in the previous year, and had no illness or were on no medications known to affect bone and mineral metabolism. Subjects provided informed consent and were randomized to risedronate 35 mg once weekly or placebo. All received daily calcium (up to 1200 mg daily) and vitamin D (800 IU). The primary outcomes were 24 month changes in spine, total hip and femoral neck bone mineral density (BMD), analyzed using linear mixed models.

Results: Of the 109 randomized, 77% were on anastrozole, 15% on letrozole and 8% on exemestane. Mean age was 64.2 years and there were no baseline differences between the groups in age, BMI, calcium/vitamin D intake or BMD. 87% completed 24 months. The BMD percent changes at the spine, total hip, and femoral neck showed significant increases in the active treatment group compared to the placebo group at 12 and 24 months (table), with 24 month absolute difference of 3.9 percentage points at the spine and 3.2 at the total hip. The medication was well tolerated and there were no significant differences in serious adverse events or deaths.

Conclusions: The oral bisphosphonate risedronate maintained/improved skeletal integrity over 2 years during a time of accelerated bone loss in breast cancer survivors on AIs.

Table: Percent change ± standard error in bone mineral density at the spine, total hip and femoral neck

Skeletal site	Month	Active (N=55)	Placebo (N=54)	P-value (between group difference)

Pathogenesis of Cortical Deficits and Decreased Bone Stiffness after Kidney Transplantation. Kyle Nishiyama[1], Sapna Iyer[2], Lucas Nikkel[3], Chiyuan Zhang[1], Elzbieta Dworakowski[1], Serge Cremers[1], Bin Zhou[1], Donald McMahon[4], X Guo[1], Elizabeth Shane[4], Thomas Nickolas*[4]. [1]Columbia University, USA, [2]University of California San Diego, USA, [3]Columbia University Medical Center, USA, [4]Columbia University College of Physicians & Surgeons, USA

Fracture risk is more than 4-fold higher after kidney transplantation than in the general population. We reported that hyperparathyroidism (HPT) is associated with progressive cortical (Ct) losses in patients with chronic kidney disease. As HPT commonly persists after kidney transplantation, we hypothesized that Ct deficits would worsen, would be directly associated with HPT and elevated bone turnover markers, and would lead to impaired bone strength. We scanned the distal radius and tibia by high-resolution peripheral quantitative CT (HRpQCT, Scanco Medical) in 31 patients (22 men, 9 women; age 52±13 years) within 2 weeks of, and 1 year after transplantation. Ct porosity (CtPo) was quantified by indexing the Ct region of interest to the baseline image and endocortical losses at follow-up were quantified as CtPo. Whole bone stiffness and failure load were estimated using finite element analysis. Intact PTH and markers of bone formation (BSAP, osteocalcin, P1NP) and resorption (CTX and Trap5b) were measured at 3, 6 and 12 months post-transplantation and were time-averaged. Mixed linear models adjusted for baseline bone measures were used to determine longitudinal changes. At 1 year, 74% of patients had HPT (PTH>65 pg/mL). At the radius, Ct density decreased by 2.2±1.8%, thickness by 2.2±0.8% and area by 2.5±0.8% (all $p<0.05$); CtPo increased by 78±9% ($p<0.01$) and trabecular area by 0.4±1.8% ($p=0.06$). Stiffness and failure decreased by 3.1±1.3% and by 3.4±1.4% (both $p<0.05$) respectively. At the tibia, Ct density decreased by 1.9±0.6% and thickness by 1.1±0.5% (both

p<0.05); CtPo increased by 30±5% (p<0.05). Changes in stiffness and failure load were not significant. At 1 year, greater CtPo was significantly associated with lower Ct density, thickness and area, and whole bone stiffness and failure load (all p<0.001). Correlations between bone metabolic markers and changes in Ct measures, stiffness and failure load were strongest at the radius (Table). Decreases in stiffness and failure load were strongly associated with higher levels of PTH (r= -0.45, p<0.05) and remodeling markers (Osteocalcin and Stiffness r= -0.70; Osteocalcin and Failure Load r= -0.64, both p<0.001). In conclusion, persistent HPT and elevated bone turnover after transplantation drive progressive Ct deterioration and decreased bone stiffness. Further studies are needed to determine whether mitigating the adverse effects of HPT on cortical bone will protect against fracture.

Circulating Sclerostin is Negatively Associated with Cortical BMD, PINP, Estradiol and IGF-1. Jennifer Walsh*, Fatma Gossiel, Margaret Paggiosi, Richard Eastell. University of Sheffield, United Kingdom

Sclerostin is produced by osteocytes and inhibits osteoblast function through the Wnt signalling pathway. It may be an important mediator of the skeletal response to loading.

We measured serum sclerostin in 170 healthy men and women ages 16-18, 30-32 and over 70, to determine 1) how sclerostin varies with age and gender, 2) whether it correlates with BMD by DXA and BMD and microarchitecture assessed by HR-pQCT, 3) whether it correlates with bone formation markers and IGF-1.

Sclerostin was measured using an ELISA from BioMedica (Austria). Sclerostin was not normally distributed so non-parametric tests were used (Kruskal-Wallis for group comparisons and Spearman's rank for correlation).

Sclerostin did not differ between men and women (mean (95% CI); men 27.9 (25.0 to 30.9), women 25.1 (22.4 to 27.8) pmol/l). It was higher in adults aged over 70 than in younger adults (mean (95% CI); ages 16-18 22.0 (17.8 to 26.3), ages 30-32 22.6 (20.8 to 24.5), ages 70+ 35.5 (32.5 to 38.5) pmol/l (p<0.001)).

Sclerostin was not correlated with BMD by DXA at the spine or hip. At the distal radius, sclerostin was negatively correlated with total BMD (r -0.30, p <0.001), cortical BMD (r -0.32, p<0.001), cortical thickness (r -0.35, p<0.001) and trabecular thickness (r -0.17, p<0.05), but positively correlated with total area (r 0.20, p<0.01). At the distal tibia, sclerostin was negatively correlated with total BMD (r -0.17, p <0.05) and cortical BMD (r -0.24, p<0.001).

Sclerostin was negatively correlated with PINP (r -0.23, p <0.001), and IGF-1 (r -0.47, p <0.001). It was negatively correlated with estradiol in women (r -0.51, p<0.001), but not in men.

These results support the role of sclerostin as an inhibitor of bone formation. The DXA and HR-pQCT result suggest that it is more strongly associated with cortical bone density than trabecular properties. Estradiol may influence sclerostin secretion through direct actions on osteocytes, and previous studies show that estrogen receptors interact with mechanical strain to control the skeletal response to loading. IGF-1 is an important regulator of bone formation and muscle mass. It is possible that IGF-1 is associated with sclerostin via muscle mass and hence bone loading, or that it influences sclerostin secretion directly.

Serum Estradiol Levels are Inversely Associated with Cortical Pore Size in Older Men – The MrOS Sweden Study. Liesbeth Vandenput*[1], Maria Nilsson[2], Daniel Sundh[3], Magnus Karlsson[4], Mattias Lorentzon[5], Dan Mellstrom[6], Claes Ohlsson[7]. [1]University of Gothenburg, Sweden, [2]Department of Clinical Chemistry, Sahlgrenska University Hospital, Sweden, [3]Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [4]Skåne University Hospital Malmö, Lund University, Sweden, [5]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [6]Sahlgrenska University Hospital, Sweden, [7]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

It has been firmly established that estradiol (E2) plays a fundamental role in the maintenance of skeletal health in men. Serum E2 levels associate not only with bone mineral density (BMD) and BMD loss but are also predictors of incident fracture risk in older men. Yet, the role of E2 for trabecular and cortical bone microstructure, measurable by high-resolution peripheral quantitative computed tomography (HRpQCT), still remains unknown.

Therefore, we examined the associations between serum levels of E2, testosterone (T) (both analyzed by gas chromatography-mass spectrometry) and sex hormone-binding globulin (SHBG) and HRpQCT-derived bone parameters at the tibia in older men (n=438, mean 80.1 years of age) participating in the prospective population-based MrOS Sweden cohort.

In regression analyses adjusted for age, height and weight, serum E2 associated inversely with both cortical porosity (standardized beta= -0.11, p<0.05) and cortical pore diameter (beta= -0.14, p<0.01). Serum T associated only moderately with cortical pore diameter (beta= -0.10, p=0.04), whereas SHBG was not associated with any of these cortical microstructural parameters. Interestingly, multiple linear regression models including serum E2, T, and SHBG and adjusted for age, height and weight demonstrated that only serum E2 associated independently with both cortical porosity (beta= -0.11, p=0.01) and cortical pore diameter (beta= -0.14, p<0.01). In addition, serum E2 associated with the cortical pore diameter distribution (beta= -0.13, p<0.01). In similar analyses, serum E2, T and SHBG were not associated with any of the trabecular microstructural parameters such as trabecular bone volume/total volume (BV/TV), trabecular number and trabecular thickness.

In conclusion, serum E2 levels are inversely associated with cortical pore size in older men. This might indicate, as previously suggested, that serum E2 is more important for cortical than trabecular bone structure in older subjects. A recent study indicated that bone loss in elderly subjects is mainly due to loss of cortical and not trabecular bone. In addition, it has been proposed that the age-related increase in cortical porosity is a major determinant of cortical bone strength. We propose that serum E2 may modulate cortical bone strength by affecting the cortical pore size, and, thus, indirectly may influence fracture risk.

3D-XA-Based Vertebral Finite Element Model for Strength Evaluation in Osteoporosis. Christophe Travert*[1], Anabela Darbon[2], Nicolas Vilayphiou[3], Helene Follet[4], Jean-Baptiste Pialat[5], Wafa Skalli[6]. [1]Arts et Metiers ParisTech, France, [2]EOS imaging, France, [3]INSERM UMR1033, Université de Lyon & Hospices Civils de Lyon, France, [4]INSERM, UMR1033; Universite De Lyon, France, [5]INSERM U1033, Team1, Université de Lyon & Hospices Civils de Lyon, France, [6]Arts et Metiers ParisTech, Fra

CT-scan-based Finite Element Models (FEM) have been proposed to evaluate vertebral strength and fracture risk. The main limitation of such approach in routine osteoporotic diagnosis is the cost of CT-scan. Developing an accurate FEM which is deployable at a large scale is still a challenge. Approaches have been proposed to build a FEM using 2D Bone Mineral Density (BMD) measurements, such as DXA or the EOS system in dual energy. However, specific algorithms are required to estimate the BMD distribution in such models.

The purpose of this study is to develop a method to estimate 3D BMD distribution from 2D BMD measurements and evaluate its impact on vertebral strength estimation.

Lumbar spine segments (6 donors aged 80 ± 9 years) have been imaged with the EOS low dose X-ray device in dual energy to provide frontal and lateral BMD images of the spine segments, and to build 19 3D-XA vertebral FEMs (fig. 1). In addition, they have been scanned with a calibration phantom to build CT-based FEMs. In the CT FEM, geometry was obtained by segmentation. A specific meshing technic was developed to obtain regular hexahedral meshes while respecting shape accuracy. Material properties were assigned to each element of the model using published relationship between volume BMD and Young modulus. A convergence analysis was performed to select appropriate mesh refinement. For the 3D-XA FEM, 3D geometry was reconstructed using the pair of EOS images and the same meshing technic was used. A generic BMD distribution was first associated to this mesh from an independent vertebral model database, then element BMD values were adjusted to insure image similarity between the dual energy images and virtual images derived from this estimated BMD distribution. Average vertebral body volume BMD and

BMD distribution in 27 areas of the 3D-XA FEMs were compared to CT-scan. Vertebral strength was estimated in anterior compression on CT and 3D-XA FEM for comparison.

Average vertebral body BMD was estimated by the EOS model with a root mean square error (RMSE) of 13mg/cm^3 with no significant bias. In the 27 areas, RMSE was 40mg/cm^3. The failure load of the CT and 3D-XA FEM were 3217 $\pm$ 1294 N and 3346 $\pm$ 1337 N respectively, with R^2 = 0.91 and RMSE = 409 N between the two FEMs (fig. 2).Although these results should be confirmed by experimentations *in vitro* and *in vivo*, 3D-XA FEM appears as a good alternative to CT-based FEM. They could help osteoporotic fracture risk assessment in clinical routine.

Bone gain with unexpected elevated bone resorption by activating canonical Wnt/βcatenin signaling in osteocytes. Xiaolin Tu*[1], Kevin McAndrews[1], Meloney Cregor[1], Munro Peacock[2], Makoto M. Taketo[3], Lilian Plotkin[1], Teresita Bellido[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University Medical Center, USA, [3]Department of Pharmacology, Graduate School of Medicine, Kyoto University, Japan

Osteocytes orchestrate the response of osteoblasts and osteoclasts to mechanical and hormonal stimuli by modulating Wnt signaling. Moreover, deletion from osteocytes of βcatenin, the obligatory transducer of canonical Wnt signaling, leads to low bone mass and high resorption. However, the consequences of activating canonical Wnt/βcatenin signaling in osteocytes are unknown. To address this question, we generated mice expressing a dominant active (da) form of βcatenin in these cells (daβCat^{Ot}), by crossing Catnb$^{lox(ex3)}$ mice, in which the phosphorylation sites required for βcatenin degradation are flanked by loxP sites, with DMP1-8kb-Cre mice. daβcat^{Ot} mice display no gross skeletal abnormalities at birth, exhibit tooth eruption, and live up to 1 year. These features contrast with those of daβcat$^{Ob/Ot}$ mice expressing the same da βcatenin in both osteoblasts and osteocytes (Col1-2.3kb-Cre), which lack tooth eruption due to decreased resorption and die after weaning. At 4 months, daβcat^{Ot} mice showed denser bones by X-ray and increased total, spinal, and femoral BMD (142, 152 and 128%, compared to control Catnb$^{lox(ex3)}$ littermates). Distal femur μCT revealed increased BV/TV and trabecular number (499 and 469%), decreased trabecular separation (71%), with no changes in trabecular thickness. In contrast to daβcat$^{Ob/Ot}$ mice that exhibit decreased bone resorption, daβcat^{Ot} mice display high resorption with 4.3- and 2.5-fold increase in CTX at 2 and 4 months, respectively, vs controls. Circulating alkaline phosphatase was also increased 4- and 3-fold at 2 and 4 months, respectively; but osteocalcin was similar to controls. Gene expression analysis of bones (L4) revealed the expected upregulation of Wnt target genes (lef1, BMP4, Cx43, axin2 and Smad6). Similar to daβcat$^{Ob/Ot}$ mice, OPG expression in daβcat^{Ot} mice was high (>4-fold). However, RANKL expression was also high (>9-fold) resulting in increased RANKL/OPG ratio; and MCSF expression was also increased. Moreover, Runx2 and alkaline phosphatase expression was markedly increased in daβcat^{Ot} mice, but osteocalcin expression was not different. Thus, activation of canonical Wnt/βcatenin signaling in osteocytes increases bone remodeling with a positive balance in favor of bone gain. These findings establish unexpected converse changes in resorption by activating canonical Wnt/βcatenin signaling in osteocytes vs osteoblasts/osteocytes; and high resorption by either activating or deleting βcatenin in osteocytes.

Wnt Production of Signaling in Fate Determination and Differentiation of the Skeletal Precursors. Wei Hsu, Takamitsu Maruyama*, Ming Jiang. University of Rochester Medical Center, USA

The Wnt signal transduction pathway controls development of various stem cell types essential for proper formation of multiple organs. In the skeleton, Wnt signaling regulates bone formation and remodeling through modulation of osteoblasts, chondrocytes and osteoclasts. Genetic inactivation of *CTNNB1* encoding β-catenin further indicates its important function in the determination of mesenchymal cell fate. We have recently identified *Gpr177*, the mouse orthologue of *Drosophila Wls*/*Evi*/*Srt* essential for Wnt sorting and secretion. The protein encoded by *Gpr177* exhibits an ability to regulate the intracellular trafficking of Wnt proteins in signal-producing cells. Human genetic analysis further reveals that *Gpr177* is a susceptibility locus for bone-mineral-density and osteoporosis. To determine the unknown function of this gene in skeletogenesis, we have generated four different mouse models with Gpr177 deficiency in various skeletal cell types. The loss of Gpr177 severely impairs development of the craniofacial and body skeletons, demonstrating its requirement for intramembranous and endochondral ossifications, respectively. Defects in the expansion of skeletal precursors and their differentiation into osteoblasts and chondrocytes suggest that Wnt production and signaling mediated by Gpr177 cannot be substituted. Mesenchymal but not osteoblast production of Wnt is essential for development of the skeletal precursors into osteoblast lineage. However, Wnt proteins produced by chondrocytes are necessary for the chondrogenic lineage. Our findings not only identify the sources of Wnt essential for osteogenesis and chondrogenesis, but also reveal the function of Gpr177 in modulating the interplay of Wnt signals across distinct cell types. However, the disruption of Wnt secretion does not result in mesenchymal cell fate change. The discrepancy is likely attributed to the dual role of β-catenin in cell adhesion and signaling as the loss of Gpr177 would not interfere with cell-cell interaction. To test the possible involvement of β-catenin-mediated cell adhesion regulating the lineage commitment of mesenchymal cells, we have created mice with disruption of only the transcriptional activity of β-catenin required for Wnt signal transduction. Without interfering with cell adhesion, these mutants permit a definitive assessment of β-catenin as a master transducer of Wnt signaling, leading to a new mechanism underlying mesenchymal cell fate determination mediated by β-catenin.

Wnt16 Deletion Differentially Affects Cortical and Trabecular Bone: Increased Cortical Bone Resorption, Porosity and Fracture in Wnt16 Knockout Mice. Xianwen Liu*[1], Kenichi Nagano[2], Hiroaki Saito[2], Roland Baron[3], Francesca Gori[4]. [1]Harvard School of Dental Medicine, Sichuan University, USA, [2]Harvard School of Dental Medicine, USA, [3]Harvard School of Medicine of Dental Medicine, USA, [4]Harvard School of Dental Medicine, Massachusetts General Hospital, USA

Wnt16 has recently emerged as a determinant of cortical bone thickness, bone mineral density, bone strength, and fracture risk in several GWAS studies (Medina-Gomez *et al.* PLoS Genet. 2012, Zheng *et al.* PLoS Genet. 2012). Decreased cortical bone density is associated with non-vertebral osteoporotic fractures but the mechanisms by which cortical bone mass is regulated remain largely unknown. To examine the role of Wnt16 in bone homeostasis, we analyzed Wnt16$^{-/-}$ mice. Micro-CT and bone histomorphometry show a marked decrease in cortical bone thickness in both Wnt16$^{-/-}$ male (-22.73% $\pm$7.21%) and female (-25.62% $\pm$4.75%) compared to WT littermates. Notably, cortical bone porosity was significantly increased in both male (+29.11%$\pm$15.32%) and female (+38.56%$\pm$14.19%) Wnt16$^{-/-}$ mice compared to WT littermates and approximately 30% of Wnt16$^{-/-}$ mice developed spontaneous long

bone fractures. The endocortical surface showed a marked increase in osteoclast numbers and surface, with no changes in osteoblast (OB) numbers. In sharp contrast with the changes in cortical bone, a small but significant increase in trabecular bone volume was observed in Wnt16$^{-/-}$ mice, with no changes in other histomorphometric parameters. Analysis of femur cortical bone showed that the decrease in cortical bone mass was associated with a significant increase in sclerostin and a decrease in OPG, leading to a marked increase in the RANKL/OPG ratio. Accordingly, Wnt16 deletion results in a marked increase in osteoclastogenesis in vitro. Importantly, Wnt16 is a potent regulator of non-canonical Wnt signaling as indicated by the significant reduction in JNK and c-JUN phosphorylation levels seen with Wnt16 deletion. The opposite was true in Wnt16 treated osteoblasts. Furthermore, activation of Topflash reporter assay, increased expression of Wnt target genes including TCF1 and Axin2, ß-catenin and phosphorylated LRP6 levels seen in OBs treated with Wnt16 protein, imply that Wnt16 also signals via or indirectly affects canonical Wnt signaling. These data demonstrate that Wnt16 has a crucial role in cortical bone homeostasis. Deletion of Wnt16 specifically affects cortical bone in mice, increasing sclerostin and RANKL/OPG ratio and leads to increased resorption and porosity and decreased thickness. These findings provide a novel insight into the mechanism by which cortical bone homeostasis is regulated in mice and may help explain the link between Wnt16, bone mass and fractures in humans.

Downregulation of PLCγ2/β-catenin pathway promotes activation and expansion of Myeloid-Derived Suppressor cells in cancer. Aude-Helene CAPIETTO*[1], Seokho Kim[2], Deborah Novack[2], Roberta Faccio[2]. [1]Washington University School of Medicine, USA, [2]Washington University in St Louis School of Medicine, USA

Myeloid-derived Suppressor Cells (MDSC) promote tumor dissemination by mainly suppressing anti-tumor T-cell responses in many cancers. Although the mechanism of T-cell inhibition is well-established, the pathways leading to MDSC accumulation in bone marrow and secondary lymphoid organs remain unclear. We found that downregulation of PLCγ2 signaling in tumor-bearing mice induces aberrant expansion of MDSC in the bone marrow, spleen and tumor site. To analyze whether MDSC promote tumorigenesis in PLCγ2-/- mice, we adoptively transferred MDSC isolated from PLCγ2-/- or WT mice into subcutaneous tumor-injected WT mice. Animals receiving PLCγ2-/- MDSC displayed greater expansion of MDSC in the spleen and increased tumor burden compared to mice receiving WT MDSC. Furthermore, PLCγ2-/- MDSC were more efficient than WT cells to suppress CD8+ T-cell proliferation, via increased ROS and NO production. Mechanistically, PLCγ2-/- MDSC display reduced β-catenin levels and its rescued expression decreases MDSC expansion and tumor growth in PLCγ2-/- mice. In addition, the deletion of β-catenin in myeloid cells (LysM-Cre/β-cat.cKO), including MDSC, led to enhanced tumor growth and a 2-fold increase in MDSC compared to control mice. By contrast, constitutive β-catenin activation in myeloid cells (LysM-Cre/β-cat.CA) decreased tumor growth while MDSC percentage was reduced compared to control mice. Consistent with a role for β-catenin in MDSC during tumor progression, its expression was reduced in tumor-bearing WT mice compared to tumor-free animals. The relevance of the PLCγ2/β-catenin axis is further documented in MDSC from pancreatic cancer patients which show reduced phospho-PLCγ2 and β-catenin expression levels compared to healthy controls. Importantly, aberrant expansion of MDSC in tumor bearing hosts is also likely to contribute to bone metastatic dissemination, even in the context of osteoclast blockade. Consistent with this hypothesis, PLCγ2-/- mice display increased bone tumor burden compared to WT animals despite reduced osteoclast differentiation and function. The elevated rate of tumor growth in bone is due to impaired CD8+ T-cell responses and correlates with greater accumulation of MDSC in spleen of PLCγ2-/- mice. In conclusion, we show that downregulation of PLCγ2/β-catenin pathway occurs in mice and humans, leading to MDSC-mediated tumor expansion. Our data also implicates MDSC as new modulators of bone metastases.

Adult-onset deletion of β-catenin in 10kbDmp1-expressing cells prevents intermittent PTH-induced bone gain. Alexander Robling[1], Rajendra Kedlaya*[1], Paola Divieti Pajevic[2]. [1]Indiana University, USA, [2]Massachusetts General Hospital & Harvard Medical School, USA

PTH is a potent calcium-regulating factor with anabolic and catabolic properties. Bone cells express PTH receptors, but the cellular responses to PTH in bone are incompletely understood. Wnt signaling has recently been implicated in the osteoanabolic response to the hormone. Whereas downstream nodes of the canonical Wnt pathway itself, and canonical Wnt-responsive transcriptional mechanisms are altered by PTH treatment, it is less clear whether the Wnt pathway is required for the anabolic action of PTH. We have found that the Wnt co-receptor Lrp5 is not required for intermittent PTH (iPTH) effects, and others have reported that the cytoplasmic tail of Lrp5 does not undergo phosphorylation in response to PTH treatment, whereas that of Lrp6 does. Whether Lrp6 is required for PTH effects in bone is less clear, partly because Lrp6$^{-/-}$ mice die at birth and are precluded from study. We sought to better understand the role of Wnt signaling in iPTH-induced bone metabolism by targeting and disabling β-catenin—a downstream facilitator of canonical Lrp5/Lrp6 signaling—during iPTH treatment. Male mice homozygous for the floxed loss-of-function β-catenin allele (loxP in introns 1 and 6) were raised with and without the tamoxifen-inducible 10kbDmp1-CreERt2 transgene. At 12 wks of age, the mice were given DEXA scans then treated with 3 doses of tamoxifen (20 mg/kg) or corn oil, spaced 7 days apart, to induce recombination of the β-catenin alleles. Two days after beginning tamoxifen/oil treatment, the mice were given daily injection of 30 ug/kg human PTH 1-34 or vehicle control. After 4 wks of treatment, the mice were given a second DEXA scan and sacrificed. Tamoxifen treatment in had a small but significant effect on bone mass in the presence of PTH or vehicle. PTH increased whole body BMD by 7.5% in control (oil-treated) mice, compared to a 1.6% increase in BMD among control mice receiving vehicle. In mice receiving tamoxifen (conditional β-catenin KO), BMD was unchanged by vehicle treatment. PTH treatment in these mice was not effective in improving bone mass, and significantly exacerbated bone loss in the spine. In summary, the anabolic action of iPTH appears to require funcitonal β-catenin in Dmp1-expressing cells. Because signaling pathways other than Wnt/Lrp5/6 effects β-catenin (e.g., PKA, mTor), it is unclear whether the deficit in PTH signaling observed in β-catenin mutant mice extends from Wnt or from an alternate pathway.

Continuous PTH Infusion Increases Trabecular but Not Cortical Bone in Cyclooxygenase-2 Knockout Mice. Shilpa Choudhary*[1], Ernesto Canalis[2], Adam Harris[1], Douglas Adams[1], Renata Rydzik[1], Carol Pilbeam[1]. [1]University of Connecticut Health Center, USA, [2]St. Francis Hospital & Medical Center, USA

Intermittent PTH *in vivo* increases bone mass, while continuous PTH infusion causes bone loss. *In vitro,* continuous PTH inhibits osteoblast differentiation in marrow stromal cells but can stimulate differentiation if COX-2 expression or activity is absent. We examined the impact of COX-2 knockout (KO) on continuous PTH infusion *in vivo*. Three-mo old male wild type (WT) and KO mice (n=6-7/group) were infused with vehicle or hPTH 1-34 (40 μg/kg/d) via ALZET pump for 21 days. Measurements included % change in femur BMD; distal femur trabecular and midshaft femur cortical morphometry by μCT; distal femur trabecular histomorphometry; serum analyses; and tibial mRNA expression. Data were analyzed by 2-way ANOVA. Both WT and KO mice were hypercalcemic after infusion but did not lose weight. PTH infusion decreased femur bone mineral density (BMD) in WT mice and increased BMD in KO mice. By μCT, PTH decreased femur trabecular bone volume fraction (BV/TV) 50% in WT mice and increased BV/TV 60% in KO mice. In addition, PTH decreased trabecular connectivity density 73% in WT femurs and increased connectivity density 100% in KO femurs. In WT femurs, PTH decreased trabecular number 34% and increased trabecular spacing 56%. In KO femurs, PTH increased trabecular number 16% and decreased spacing 14%. Similarly, by histomorphometry, PTH decreased trabecular BV/TV 54% in WT femurs and increased trabecular BV/TV 68% in KO femurs. In contrast to the effects seen in trabecular bone, no statistical difference was observed in cortical parameters with PTH. There was a trend for PTH to increase cortical porosity 2-fold in KO but not WT femurs. Consistent with its effects on trabecular bone, PTH increased serum osteocalcin, a marker of bone formation, only in KO mice (7.6-fold). CTX, a serum marker of bone resorption, was increased by PTH similarly in WT (1.9-fold) and KO mice (1.7-fold). PTH also increased *Osteocalcin* mRNA only in KO tibiae (8.6-fold) but increased *Rankl*/*Opg* expression similarly in WT and KO tibiae (3.8-fold and 3.0-fold, respectively). In addition, expression of inhibitors of Wnt signaling, *Dkk-1* and *Sost,* was significantly lower in KO compared to WT tibiae after PTH infusion. In summary, COX-2 absence prevented trabecular, but not cortical, bone loss secondary to PTH infusion. These data suggest that prostaglandins produced by COX-2 do not enhance PTH-stimulated resorption but can suppress PTH-stimulated osteoblast differentiation.

Parathyroid Hormone-related Peptide (PTHrP) blockade inhibits the development of bone metastasis and potentiates the effect of zoledronic acid in vitro and in vivo in a mouse model of breast tumor progression. Aimee-Lee Luco*[1], Jiarong Li[1], Benoit Ochietti[2], Ibtihal Fadhil[2], Anne Camirand[2], Monzur Murshed[1], Andrew Karaplis[1], Richard Kremer[3]. [1]McGill University, Canada, [2]McGill University Health Center, Canada, [3]McGill University, Royal Victoria Hospital, Canada

Using conditional ablation of PTHrP in mammary epithelial cells in the PyVMT model of breast tumor progression, we previously demonstrated that PTHrP has a major role in breast cancer initiation, growth and metastasis outside the skeleton. Here we investigated its role on the development of skeletal metastasis alone and in combination with the potent bisphosphonate zoledronic acid (ZA).First isolated tumor cells from control (PyVMT-PTHrP$^{flox/flox}$-Cre^{-}) and homozygous (PyVMT-PTHrP$^{flox/flox}$-Cre^{+}) animals were examined *in vitro and in vivo* in the presence of a monoclonal antibody (mAb) against PTHrP1-33 and ZA alone or in combination. *In vitro* cell growth was reduced by over 80% in PTHrP ablated cells or by mAb treatment of control cells (IC50 2µg/ml).Treatment with ZA resulted in a dose dependent inhibition of growth(IC50 $5x10^{-5}$M) and the combination of the mAb and ZA was additive .Next we examined the effect of PTHrP inhibition alone and in combination with ZA following intra-tibial injection of isolated tumor cell into the right tibia.500 000 control or PTHrP ablated breast tumor cells were injected intra-tibially in 8 week old wild type female FVB mice and treated with either control IgG, mAb(200 ug subcutaneously, every 2 days), ZA (2.5 µg/week) or a combination(n=10/group). Three weeks following tumor cell injections the mice were sacrificed, blood collected, X-rays(Faxitron) taken for osteolysis scoring and tumor weight determined by subtracting weight of the injected limb from weight of the contro-lateral limb. Bones were embedded in plastic for histomorphometric analysis of tumor burden. Mice injected with control cells had the largest tumor weight, tumor burden and osteolytic score. Animals injected with PTHrP ablated cells had over 80% reduction in tumor weight and volume compared to control animals($p<0.001$). Combination of ZA and PTHrP ablation or ZA combined with mAb administration resulted in an almost complete inhibition of tumor growth within bone and was significantly superior than PTHrP ablation or ZA alone($p<0.05$). In summary our data demonstrate that PTHrP blockade has a direct effect on tumor growth of breast cancer cells *in vitro and in vivo* and potentiates the effect of ZA with almost complete inhibition of tumor growth within bone. Our data lend support to the "seed and soil" hypothesis and the rational of targeting both the tumor cells and the bone microenvironment in order to eradicate the development of skeletal metastasis.

Continuous PTH Treatment Induces Bone Loss through T Cells Produced IL17. Jau-Yi Li*, Michael Reott, Qun Dai, Jonathan Adams, M. Neale Weitzmann, Roberto Pacifici. Emory University School of Medicine, USA

Hyperparathyroidism in humans and continuous PTH treatment (cPTH) in mice stimulate bone resorption and cause bone loss by regulating RANKL/OPG production by stromal cells (SCs) and osteoblasts. Reports have shown that T cells markedly potentiate the bone catabolic effect of cPTH by inducing CD40 signaling in SCs through their surface receptor CD40L. In addition, cPTH stimulate T cells to secrete the osteoclastogenic cytokine TNF, a factor that potentiates the osteoclastogenic activity of RANKL. A search for additional mechanisms by which T cells potentiate cPTH induced bone loss revealed that in vivo cPTH treatment for 2 weeks increased by ~2-3 fold the frequency of Th17 cells in the BM. Th17 are a highly osteoclastogenic population of CD4+ cells defined by the capacity to produce IL-17, a potent inducer of RANKL and TNF production. Accordingly, we found cPTH to cause a 2-3 fold increase in intracellular IL-17A and a 4 fold increase in the expression of the Th17-inducing transcription factors RORα and RORt, in BM CD4+ T cells. To investigate the contribution of Th17 to cPTH induced bone loss 16 week-old WT mice were treated with vehicle or cPTH (80mg/kg/day subcutaneously for 2 weeks) alone or in combination with mouse IL-17 neutralizing antibody (mIL-17 Ab) or isotype matched irrelevant Ab (Irr.Ig). We found that treatment with mIL-17 Ab decreased by ~ 50% the loss of trabecular bone volume (as measured by mCT), the increase in bone resorption (as measured by serum CTX) and the formation of osteoclasts in cultured of bone marrow cells induced by cPTH treatment. By contrast, treatment with Irr Ig did not antagonize the bone catabolic effects of cPTH. Measurement of serum P1NP, a marker of bone formation, showed that neither mIL-17 Ab nor Irr.Ig blunted the increase in serum P1NP (a marker of bone formation) induced by cPTH. Furthermore, mIL-17 Ab completely blocked the increase in SC production of TNFa and RANKL induced by cPTH, while Irr. Ig had no effects, thus demonstrating that cPTH stimulates SC osteoclastogenic function through T cell produced IL17. In summary, these findings demonstrate that cPTH polarizes the differentiation of CD4+ cells toward the Th17 subset. Moreover, increased T cell production of IL-17 is a novel mechanism by which cPTH stimulates bone resorption and causes bone loss.

Marked Increases in Cortical Porosity After Kidney Transplantation Especially Near the Endocortical Surface: An HR-pQCT Study. Kyle Nishiyama*[1], Yves Pauchard[2], Lucas Nikkel[3], Sapna Iyer[4], Steven Boyd[5], Elizabeth Shane[6], Thomas Nickolas[6]. [1]Columbia University, USA, [2]University of Western Ontario, Canada, [3]Columbia University Medical Center, USA, [4]University of California San Diego, USA, [5]University of Calgary, Canada, [6]Columbia University College of Physicians & Surgeons, USA

We reported that hyperparathyroidism (HPT) in chronic kidney disease patients results in progressive increases in cortical porosity (Ct.Po), which may contribute to their increased fracture risk. While most kidney transplant patients have persistent HPT, it is unclear whether Ct.Po worsens after transplant or whether changes in Ct.Po are confined to specific cortical (Ct) regions, such as the endocortex. Defining the Ct region of interest (ROI) in longitudinal high-resolution peripheral quantitative CT (HRpQCT) studies with current analytical methods is challenging since changes at the Ct surface may confound changes in Ct.Po. Our objective was to compare image registration methods for assessment of changes in Ct.Po in patients undergoing first time kidney transplant. We assessed post-transplant bone resorption with CTX and used HRpQCT (Scanco Medical) to scan the distal radius and tibia in 31 patients (22 men; age: 52 ± 13yrs) at transplant and after 1 year. Baseline and 1 year images were aligned using a fully automated, intensity-based image registration framework. We compared 3 methods to define the Ct ROI and quantify changes in Ct.Po: (1) Ct bone was independently defined in baseline and 1 year scans; (2) Ct bone was defined as the common ROI in baseline and 1 year scans; and (3) Ct ROI for both baseline and 1 year scans was indexed to the baseline cortex. Data are expressed as median percent change (IQR) and all are significant ($p<0.01$). By independently defined ROI, Ct.Po increased 10.4% (3.8, 26.0) at the radius and 10.3% (0.6, 14.4) at the tibia. By common ROI, Ct.Po increased 10.8% (0.6, 22.8) at the radius and 4.8% (0.0, 17.5) at the tibia. By indexed ROI, Ct.Po increased 74.6% (38.8, 112.1) at the radius and 27.1% (16.8, 35.4) at the tibia. The increase in Ct.Po with indexed ROI was significantly greater than for other methods ($p<0.001$). In contrast to other methods, indexed ROI was the most sensitive at detecting resorption-associated changes in Ct.Po, even at low CTX levels (Figure). These results indicate that intracortical porosity increases throughout the cortex after transplant. This increase is particularly marked at the endocortical surface, likely through endocortical cancellization, and is driven by increased resorption rates. These results demonstrate that image registration is essential to quantify regional changes in Ct.Po. The effects of increased Ct.Po on skeletal fragility in transplant recipients require further study.

Fracture History of Healthy Premenopausal Women is Associated with a Prevailing Reduction of Cortical Microstructural Components at the Distal Radius. Thierry Chevalley*[1], Jean-Philippe Bonjour[2], Bert van Rietbergen[3], Serge Ferrari[4], Rene Rizzoli[4]. [1]University Hospitals of Geneva Division of Bone Diseases, Switzerland, [2]University Hospital of Geneva, Switzerland, [3]Department of Biomedical Engineering, Netherlands, [4]Geneva University Hospital & Faculty of Medicine, Switzerland

Purpose: To determine in healthy premenopausal women which bone structural components of distal radius are the most closely associated with a history of fracture. Methods: Measurement of radial areal bone mineral density (aBMD) by DXA, microstructural components by high-resolution quantitative peripheral computerized tomography (HR-pQCT) and strength variables by micro Finite Element Analysis (μFEA) were made in 196 healthy premenopausal women aged 45.9±3.7 (±SD) years with (FX, n=96) and without (NO-FX, n=100) a history of fracture.

Results: In the whole group the mean radial metaphysis aBMD T-Score was not significantly different from zero. In the FX as compared to the NO-FX group, the differences in T-Scores after adjustment for age, height, weight, menarcheal age, calcium and protein intakes, and physical activity were for: radial metaphysis aBMD, -0.24 (P=0.005); for distal radius microstructure components: cortical volumetric (v) BMD, -0.38 (P=0.0009); cortical thickness, -0.37 (P=0.0001); cross-sectional area (CSA), +0.24 (P=0.034); endosteal perimeter, +0.28 (P=0.032); for strength estimates: stiffness: -0.15 (P=0.030); failure load: -0.14 (P=0.044); apparent modulus: -0.28 (P=0.006). T-scores of trabecular volumetric BMD and thickness did not significantly differed between the FX and the NO-FX groups. Differences in T-scores for cortical vBMD and cortical thickness remained significant after further adjustment to radial metaphysis aBMD (P=0.035 and P=0.003, respectively) and to CSA (P=0.009 and P=0.0007, respectively). The Figure below illustrates the fracture risks (OR, 95% CI) for 1 SD decrease in various radius measurements, after adjustment for all confounding factors. After additional adjustment to radial metaphysis aBMD, ORs for cortical vBMD and cortical thickness remained significant: 1.63 (CI: 1.05-2.54, P=0.031) and 2.58 (CI: 1.36-4.86, P=0.004), respectively.

Conclusions: In healthy premenopausal women, a history of fracture is associated with reduced T-Scores in the distal radius, the greatest deficit being measured in cortical thickness. A reduction of one SD in cortical thickness is associated with about 2.5 fold increased risk of fracture. This finding strengthens the notion that, in healthy women, fractures occurring before the menopause are associated with a substantial degree of bone structural fragility. The strategy of individual prevention of postmenopausal osteoporosis should take into acount this important risk factor.

Denosumab Reduces Hip Cortical Porosity in Women With Osteoporosis. Roger M Zebaze*[1], Cesar Libanati[2], Michael R McClung[3], Jose R Zanchetta[4], David L Kendler[5], Arne Høiseth[6], Andrea Wang[2], Ali Ghasem-Zadeh[1], Ego Seeman[1]. [1]Austin Health, University of Melbourne, Australia, [2]Amgen Inc., USA, [3]Oregon Osteoporosis Center, USA, [4]Instituto de Investigaciones Metabólicas, Argentina, [5]University of British Columbia, Canada, [6]Curato Røntgen, Norway

Purpose: Cortical thickness, area, mass, and porosity are determinants of bone strength and so, contribute to nonvertebral fracture risk. Cortical porosity is a marker of structural decay associated with an exponential worsening in bone fragility and is the result of unbalanced and accelerated intracortical remodeling upon Haversian canal surfaces. Canals enlarge, coalesce, and fragment the cortex. Reducing remodeling will limit worsening of porosity but for individuals already at increased risk for fracture, reducing porosity is preferred. Using multi detector computer tomography (MDCT) hip images from the FREEDOM study, we previously reported that hip cortical mass and thickness improved over 3 years of denosumab (DMAb) administration. We postulated that this could be explained by infilling of porosity in the inner cortical region adjacent to the medullary canal. Here, we used a subset of these images to evaluate changes in hip porosity.

Methods: FREEDOM was a 3-year, randomized, double-blind trial that enrolled postmenopausal women with a lumbar spine or total hip T-score <–2.5 but not <–4.0 at both sites. Women received placebo (Pbo) or 60 mg DMAb every 6 months. Percentage porosity in both the compact and the trabecularized (outer and inner transitional zones) cortical volumes of the subtrochanter region were measured using StrAx1.0 software (Zebaze et al., *Bone* 2013) from MDCT hip images obtained at baseline and year 3 (Pbo n=22; DMAb n=28).

Results: The percentage volume occupied by porosity at baseline was 72% in the inner transitional zone adjacent to the medullary compartment, 37% in the outer transitional zone, and 29% in the compact-appearing cortex. Cortical porosity correlated positively with serum CTX (p=0.017) and negatively with hip strength estimated using finite element analysis (p=0.027). DMAb reduced porosity compared with baseline and Pbo at year 3 across the entire cortex (Figure) and in each compartment, reaching treatment effect (DMAb–Pbo) improvements of –1.8% (inner transitional zone), –5.6% (outer transitional zone), and –7.9% (compact-appearing cortex) (all p<0.001).

Conclusions: This is the first report of the response of hip porosity *in vivo* to pharmacological therapy. Since reductions in cortical porosity equate to increased mineralized bone matrix mass and both are relevant to strength, these improvements are expected to contribute to the observed reductions in nonvertebral fractures associated with DMAb administration.

Total Body Lean Mass and Fat Mass Differentially Affect Hip BMD and Strength Index in Women and Men But Are Not FRAX Independent Risk Factors for Fracture: A Large Clinical Cohort Study. William Leslie*[1], Eric Orwoll[2], Carrie Nielson[2], Suzanne Morin[3], Sumit Majumdar[4], Helena Johansson[5], Eugene McCloskey[6], Anders Oden[7], John Kanis[8]. [1]University of Manitoba, Canada, [2]Oregon Health & Science University, USA, [3]McGill University, Canada, [4]University of Alberta, Canada, [5]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [6]University of Sheffield, United Kingdom, [7]Consulting statistician, Sweden, [8]University of Sheffield, Belgium

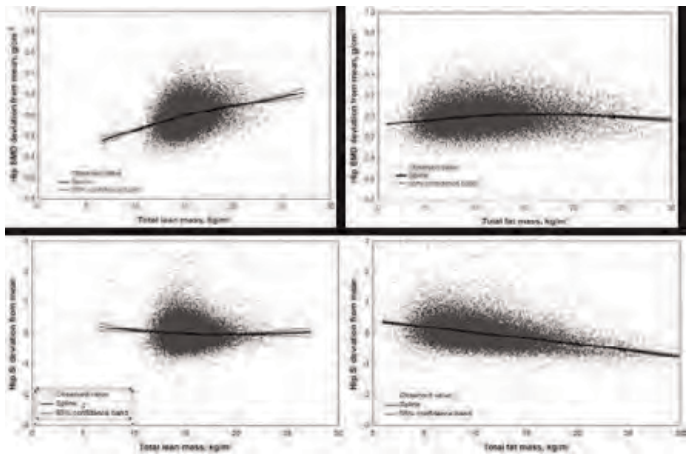
Background: Although increasing body weight has been regarded as protective against osteoporosis and fractures, there is accumulating evidence that fat adversely affects skeletal health compared with lean tissue.

Objective: To examine skeletal health parameters in women and men as a function of estimated total body lean and fat mass.

Methods: 40,050 women and 3,600 men age ⩾50 y at the time of baseline DXA testing (Lunar Prodigy; GE Healthcare) with FRAX probabilities were identified in a clinical database from Manitoba, Canada. Major osteoporosis fractures (MOF) and hip fractures (HF) were obtained via linkage to a population-based repository. Total body lean and fat mass in kg and kg/m^2 were estimated using non-linear prediction equations based on weight, sex and DXA fat percent from abdomen and hip (modified from Leslie WD: JCD 2009;12:428). Hip BMD, strength index (SI), cross sectional area (CSA) and cross sectional moment of inertia (CSMI) were calculated using Advanced Hip Analysis (enCore version 13.6; GE Healthcare). Generalized additive models (cubic splines with 4 df) and Cox proportional hazards models with multivariable adjustments were used to study the independent contributions of lean and fat mass on BMD, SI and fracture risk.

Results: During mean 5-years observation, incident MOF occurred in 2505 women and 180 men (626 and 45 HF). Increasing lean mass was associated with near-linear increases in hip BMD, CSA and CSMI for both women and men, while increasing fat mass showed a minor initial increase that plateaued without further gain. In contrast, SI was relatively unaffected by increasing lean mass but showed a continuous linear decline with increasing fat mass (predicting higher fracture risk). All findings were similar in men and women, without significant sex interactions. There was no evidence that lean mass, fat mass or SI consistently affected risk of MOF or HF after adjustment for FRAX covariates or FRAX scores (with or without BMD).

Conclusions: Skeletal adaptation to increasing lean mass was associated with greater BMD but neutral effects on SI, whereas increasing fat mass had neutral effects on BMD but adversely affected SI. Despite predictions of higher fracture risk, greater fat mass was not independently associated with an observed increased risk of fractures. FRAX robustly predicted fractures and was not affected by variations in body composition.



Hip BMD (upper) and SI (lower) for lean mass index (left) and fat mass index (right) in women

Protein-Coding Less-Common Variants Are Associated with BMD: An Exome-Chip Meta-Analysis of Adult Caucasians. Karol Estrada[1], Ching-Ti Liu[2], Chia-Ho Cheng[3], Carolina Medina-Gomez[4], Yanhua Zhou[2], Ling Oei[5], Albert Hofman[5], Carola Zillikens[5], David Karasik[6], Andre Uitterlinden[7], L. Adrienne Cupples[2], Douglas Kiel[8], Fernando Rivadeneira[9], Yi-Hsiang Hsu*[10]. [1]Analytic & Translational Genetics Unit, Massachusetts General Hospital, USA, [2]Dept. Biostatistics, School of Public Health, Boston Univ., USA, [3]Hebrew SeniorLife Institute for Aging Research, USA, [4]Erasmus Medical Center, The Netherlands, [5]Erasmus University Medical Center, The Netherlands, [6]Hebrew SeniorLife; Bar Ilan University, USA, [7]Rm Ee 575, Genetic Laboratory, The Netherlands, [8]Hebrew SeniorLife, USA, [9]Erasmus University Medical Center, The Netherlands, [10]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

We previously reported 56 novel genome-wide significant loci for BMD, but these loci focus on common (MAF>5%) SNPs and only explain 5% of the BMD variance. Recent studies suggest that less-common variants in protein-coding and regulatory regions may contribute to the susceptibility of common disorders. The availability of the "exome-chip" with 235,933 less-common protein-coding variants (with functional implication as non-synonymous, splice sites and stop altering SNPs) provides a feasible way to identify less-common coding variants of diseases. We conducted an exome-chip meta-analysis for BMD to identify (1) novel coding variants (with predicted deleterious function) that associated with BMD; and (2) coding variants (with predicted deleterious function) that may responsible for the 56 BMD loci. 6,348 Framingham Heart Study (FHS) participants and 2,427 Rotterdam Study (RS) Caucasian participants (58.7% female) were genotyped with Illumina exome-chip. We found 78% of genotyped variants with MAF $\leq$ 1% and 16% monomorphic. To identify novel less-common coding variants (MAF $\leq$ 1%) associated with BMD, we performed two gene-based burden tests (allele-count and "SKAT" tests) in each study, adjusting for age, age^2, sex, weight, genetic ancestry and estrogen use (in FHS females only). A meta-analysis was then used to combine results from two studies. We identified novel associations ($p < 5x10^{-5}$) with LS BMD (*DYRK4, KIAA1324L, SGM2*) and FN BMD (*PPP4R2*), although none of them achieved genome-wide significance ($p < 4.2x10^{-6}$, Bonferroni correction). To identify functional coding variants that may responsible for the 56 BMD loci, we performed regression analyses in each study adjusting for the same set of covariates and followed by an inverse-variance fixed-effect meta-analysis. The most significant association was found for a reported missense SNP V667M in the *LRP5* gene ($p < 8.9x10^{-4}$ with LS BMD). Other strongly associated missense deleterious SNPs were also found (i.e. N501H in *LRP4* and A745V in *LRP5* with LS BMD). In summary, this is the first exome-chip meta-analysis conducted for BMD in which we focus on less-common coding variants with functional implication. We identified novel less-common coding variants associated with BMD as well as deleterious variants in previously identified BMD loci. A large-scale exome-chip meta-analysis with an additional ~20,000 samples is underway to increase the statistical power of identifying less-common coding variants for BMD.

Sclerostin Preserves Cartilage Integrity in Murine Osteoarthritis. Wafa Bouaziz*[1], Thomas Funck-Brentano[2], Hilène Lin[3], Caroline Marty[2], Dominique Come[2], Eric Hay[4], Martine Cohen-Solal[5]. [1]INSERM U606, France, [2]Univ Paris Diderot, Sorbonne Paris Cité, Lariboisière Teaching Hospital, France, [3]INSERM UMR-606, France, [4]INSERM 4606, France, [5]Centre Viggo Petersen, France

Purpose: Sclerostin is a Wnt inhibitor produced by mineralizing cells such as osteocytes and hypertrophic chondrocytes. Sclerostin may regulate cartilage homeostasis by inhibiting Wnt pathways in osteoarthritis. Here, we assessed the effect of Sclerostin in osteoarthritic cartilage using Sost-deficient mice.

Methods: 10 week-old Sost-KO and wild type (WT) mice underwent partial transsection of the meniscus (Mnx). Mice were sacrificed at 4, 6 or 9 weeks after Mnx to analyze 1) bone volume (BV/TV) at the medial femoral condyle, 2) osteophyte volume (microCT), 3) cartilage damage (OA score) and 4) expression of matrix proteins. The role of Sclerostin in chondrocyte metabolism was analyzed in primary murine chondrocyte cultured with Wnt3a and Sclerostin (RT-PCR and WB). Proteoglycan content was quantified in the culture supernatant by a colorimetric assay and GAG accumulation by Alcian blue staining. We further investigated the role of JNK pathway using SP600125 inhibitor.

Results: Sclerostin was only expressed in the calcified cartilage and osteocytes and was enhanced in OA. At any time, cartilage was preserved in Sost-KO mice despite a markedly high BV/TV. Mnx resulted in a higher OA score in Sost-KO mice than in WT at Week 4 (6.66 $\pm$ 0.57 vs 3.25 $\pm$ 0.95, $p<0.05$) and Week 6 (11 $\pm$ 1 vs 7 $\pm$ 0,81, $p<0.05$), along with increased type X collagen and Adamts-4 expressions, suggesting an enhanced chondrocyte catabolism. However, osteophyte volume was not affected by the lack of Sclerostin at Week 4 (0.033 $\pm$ 0.019 vs 0.024 $\pm$ 0.01, p: NS) and at Week 6 (0.023 $\pm$ 0.01 vs 0.02 $\pm$ 0.01, p: NS).In primary chondrocytes, Wnt3a reduced the proteoglycan release and this was rescued by Sclerostin. Wnt3a increased

the expression of Adamts-4 & -5, MMP-3 & -13 and type X collagen, while this effect was totally abolished by Sclerostin through a mediation of the canonical pathway. Moreover, Wnt3A promoted the phosphorylation of JNK which was inhibited by Sclerostin. We further investigated whether Sclerostin-induced inhibition of JNK affects chondrocyte anabolism. Interestingly, in Wnt-induced chondrocytes, Sclerostin rescued the accumulation of GAG and the expression of the anabolic genes when JNK pathway was inhibited.

Conclusions: Lack of Sclerostin results in cartilage damage and disrupts the anabolic/catabolic balance in OA. Sclerostin inhibits both Wnt canonical and non canonical JNK pathway preserving the chondrocyte metabolism. These data suggest an important role of Sclerostin in cartilage integrity in OA.

Acute Increase in Bone Formation Following Sclerostin Antibody Treatment Is Consistent With Activation of Bone Lining Cells in Aged Ovariectomized Rats. Michael S Ominsky*, Steve Kaufman, Dave Cordover, Gwyneth Van, Irene Soto, Qing-Tian Niu, Rogely W Boyce. Amgen Inc., USA

To investigate if the acute increase in bone formation in response to sclerostin antibody (Scl-Ab) is associated with an increase in osteoblast number, unbiased stereological methods were used to estimate the total number of RUNX2-positive (RUNX2+) cells immediately adjacent to the cancellous bone surface (lining cells and osteoblasts) and in the peritrabecular stroma (osteoprogenitors) in vertebrae from rats following a single dose of Scl-Ab.

Aged ovariectomized (OVX) rats were given a single dose of vehicle (Veh) or 100 mg/kg Scl-Ab (Scl-Ab VI) (n = 5/group) and vertebrae (L6 and T9) were collected at 168 hours post-injection. Xylenol orange, calcein green, and alizarin were given on days –3, 2, and 5, respectively. L6 vertebrae were processed undecalcified and osteoid (OS/BS) and mineralizing (MS/BS) surfaces were estimated based on calcein and alizarin labels. The physical fractionator, a stereological estimator not previously applied to bone, was used to estimate the total number of RUNX2+ cells in T9 vertebrae. The physical fractionator provides estimates of total cell number independent of size, shape, or orientation using physical disectors, paired consecutive thin sections constituting a 3-dimensional probe in which cells are counted. T9 vertebrae were decalcified; processed in paraffin; exhaustively sectioned at 3 μm, collecting $1/80^{th}$ of the sections as disector pairs; and immunostained for RUNX2. Using AutoDisector® software (Visiopharm), sections were aligned and $1/50^{th}$ of the cancellous tissue area was sampled as matched fields of view in the paired sections; cells were then counted using the disector counting principle.

Despite a 280% and 65% increase in OS/BS and MS/BS, respectively, after Scl-Ab treatment, the total number of RUNX2+ cells directly adjacent to the bone surface was not increased compared with Veh treatment (Scl-Ab = 269,200 ± 65,293; Veh = 251,600 ± 29,711). The total number of peritrabecular RUNX2+ osteoprogenitor cells was also similar in both groups (Scl-Ab = 57,600 ± 9,633; Veh = 60,000 ± 18,547).

These data indicate that the acute increase in bone formation following Scl-Ab treatment is not associated with an increase in surface-associated RUNX2+ cells or osteoprogenitor cells. These data are consistent with Scl-Ab-mediated activation of lining cells into matrix-producing osteoblasts.

An End-product of Tryptophan Degradation is a Potential Anabolic Treatment for Osteoporosis. Christopher Vidal*[1], Sandra Bermeo[1], Wei Li[2], Krishanthi Gunaratnam[3], Chai Lim[4], Guilles Guillemin[4], Gustavo Duque[5]. [1]University of Sydney, Australia, [2]University of Sydney, Nepean Clinical School, Australia, [3]Sydney Medical School-NepeanLevel 5 South Block, Australia, [4]Mcquarie University, Australia, [5]Ageing Bone Research Program, University of Sydney, Australia

New anabolic treatments for osteoporosis are highly needed. Inhibiting gut-derived serotonin increases bone formation in oophorectomized mice. However, the role of the alternative pathway of tryptophan degradation, the kynurenine pathway(KP), in bone metabolism has not been explored. Stimulation of KP with interferon gamma in mesenchymal stem cells (MSC) has an osteogenic effect. Similar effect is observed in MSC treated with picolinic acid(PA), an end product of KP. In this study, we investigated the effect of PA treatment to rescue osteoporosis in vivo. Nine-month-old oophorectomised (OVX) and SHAM C57BL/6 mice (n=24/group) were treated with PA(0.25, 0.5 and 1 g/kg/day) in drinking water for 6 weeks. Mice treated with water were used as controls. After treatment, we performed bone phenotyping using μ-*CT,* histology and histomorphometry. Serum was collected for analyses of minerals, calciotropic hormones, and pharmacokinetics. RNA and proteins were assessed for osteogenic markers and MSC cultured ex vivo. Serum PA reached therapeutic levels in the treated groups in a dose-dependent manner, with no difference in body weight or water consumption. Serum concentrations of nine minerals, duodenal Zn, PTH and VitD did not differ between the groups showing that the effect of PA on bone is independent of Zn absorption in the gut or changes in calciotropic hormones. Quantitative μCT showed a significant increase in bone volume (~+5% femoral BV/TV; $p<0.05$) and trabecular number (~+20%; $p<0.05$) with a decrease in trabecular separation (~-15%; $p<0.05$) in PA treated SHAM and OVX mice. Similar gains were observed at the lumbar spine. Histology showed a significant increase in Ob number in PA-treated mice ($p<0.01$). Mineral apposition rate(MAR) was higher in both trabecular and cortical bone with higher mineralization being observed in PA treated mice. Ex-vivo MSC in osteogenic conditions showed higher mineralization and bone forming units in treated mice compared to controls. Higher levels of the osteogenic genes Runx2 (~+2.5 fold) and osteocalcin (~+2.0 fold) were observed in all the PA-treated groups ($p<0.05$). In conclusion, PA treatment improves bone mass and microarchitecture in both OVX and SHAM mice. PA had an osteo-anabolic effect through the expression of osteogenic genes with no cross-related effects on mineral absorption or calciotropic hormones. PA was well tolerated and absorbed without any side effects making it an ideal treatment for osteoporosis.

High Fat Diet Rapidly Suppresses B Lymphopoiesis by Diminishing the Supportive Capacity of the Bone Marrow Niche. Benjamin Adler*[1], Danielle Green[1], M. Ete Chan[1], Clinton Rubin[2]. [1]Stony Brook University, USA, [2]State University of New York at Stony Brook, USA

The bone marrow (BM) niche is the primary site of hematopoiesis, and cues from this microenvironment are critical to the normal maintenance and mobilization of hematopoietic stem cells as well as the differentiation of their progeny such as B lymphocytes. Obesity increases lifetime susceptibility to a host of chronic diseases, and has been linked to defects in leukocyte differentiation and function. The central role of BM health in B lymphopoiesis and the changes BM experiences due to obesity lead us to hypothesize that a high fat diet (HFD: 60% Kcal from fat) will impair B cell development. Seven week old male C57Bl/6J mice were fed either a high fat (HFD) or regular chow (RD) diet. Bone marrow was analyzed using flow cytometry after 2 days, 1 week and 6 weeks to characterize B cells (B220+) in the early stages of obesity (n=10). B cells were not changed after 2d of HFD, but within 1w B cell proportions were reduced by -10% and by 6w by -25% in HFD compared to RD ($p<0.05$). Using RT-PCR, BM RNA was evaluated for the expression of Il-7, Ebf1 and Pax5, representing sequential stages of commitment to the B cell lineage. At 2d, despite no decrease in B220+ cells, the expression of Il-7 and Ebf1 were reduced by -20% ($p=0.08$) and -11% ($p=0.06$), strong trends indicating the initiation of B cell suppression occurs at the early stages of B cell development. Pax5, which is expressed in cells further along in B cell commitment, was not significantly impacted at 2d (-9%). Meanwhile the expressions of Il-7, Ebf1, and Pax5 were reduced by -19%, -20% and -16% after 1w, and -23%, -29% and -34% after 6w in HF animals ($p<0.05$ for all). Il-7 is a critical factor in the early B lineage which is secreted by supportive cells in the BM niche, and whose binding to IL-7r+ common lymphoid progenitors initiates Ebf1 expression and B cell commitment. Here we report for the first time that BM Il-7 expression, and by extension B cell differentiation, are rapidly impaired by HFD. The trend towards suppressed expression of Il-7 following only 2d of HFD demonstrates how susceptible the BM niche is to changes in diet and fat phenotype. Ultimately, it is still unclear whether this susceptibility is to the dietary insult itself, rapid accretion of adiposity, or both. These data provide developmental insight into the etiology of obese leukocyte defects and are striking for the speed with which B lymphopoiesis is harmed following initiation of HFD.

Inflammatory and Non-inflammatory Actions of Activated NLRP3 Inflammasome Culminate in Skeletal Abnormalities. Sheri Bonar[1], Cynthia Brecks[1], Sung Yeop Jeong[2], Marcus Watkins[3], Matthew McGeough[4], Chang Yang[5], Deborah Novack[3], Ernestina Schipani[6], Hal Hoffman[4], Roberto Civitelli[3], Gabriel Mbalaviele*[3]. [1]Washington University in St. Louis, USA, [2]Washington University School of Medicine, USA, [3]Washington University in St. Louis School of Medicine, USA, [4]University of California, San Diego, USA, [5]Washington University in St Louis School of Medicine, USA, [6]Indiana University School of Medicine, USA

Activating missense mutations in the NOD-like receptor (NLR) family, pyrin domain-containing 3 gene (*NLRP3*) in humans is associated with skeletal manifestations, including abnormal growth plate development, low bone mass and short stature. Accordingly, knock-in mice globally expressing a constitutively active NLRP3 allele exhibit growth plate dysplasia, severe osteopenia, and stunt growth. To gain insights into the cellular mechanisms of NLRP3 actions, we employed Cre/*LoxP* technology to generate mice expressing active NLRP3 in myeloid cells using LysM-Cre ($NLRP3^{LysM}$). $NLRP3^{LysM}$ mice are phenotypically undistinguishable from mice globally expressing active NLRP3, as they develop systemic inflammation, are significantly smaller, and are osteopenic due to increased osteoclastogenesis relative to wild type (WT) mice. To further characterize the impact of NLRP3 activation specifically in the osteoclast cell lineage, we engineered mice in which the active *Nlrp3* mutant is driven by cathepsin K-Cre ($NLRP3^{CatK}$). Intriguingly, $NLRP3^{CatK}$ mice also exhibit low bone mass, but there is no systemic inflammation and no evidence of

increased osteoclastogenesis. Interestingly, osteoclasts from NLRP3^{CatK} bone marrow macrophages form more resorption pits on bone slices *in vitro* than WT cells, suggesting a role of the NLRP3 inflammasome in osteoclast bone-resorbing activity. Intriguingly, growth plate development is normal in NLRP3^{LysM} mice and NLRP3^{CatK} mice, suggesting that NLRP3 activation in myeloid cells does not affect growth plate development. Consistent with a chondrocyte autonomous action, activation of NLRP3 in chondrocytes driven by type II collagen-Cre (NLRP3^{Col2}) does not cause systemic inflammation, but leads to disorganized growth plate associated with massive chondrocyte death in the center of the epiphysis. Collectively, these data indicate that the NLRP3 inflammasome regulates skeletal development and remodeling in inflammatory and non-inflammatory conditions.

Osteoclast-secreted Complement Component 3a Stimulates Osteoblast Differentiation. Kazuhiko Matsuoka*[1], Masako Ito[2], Kyoji Ikeda[1], Sunao Takeshita[1]. [1]National Center for Geriatrics & Gerontology, Japan, [2]Nagasaki University Hospital, Japan

In bone remodeling, "coupling" of resorption to subsequent formation plays a pivotal role; however, information on the mechanisms and signaling molecules that link osteoclasts to osteoblasts is scarce. The objective of the present study is to identify a candidate coupling factor from the conditioned medium (CM) of mature osteoclasts.

We have established a co-culture system in which increasing number of osteoclasts stimulates the differentiation of calvaria-derived primary osteoblasts, as determined by alkaline phosphatase (ALP) activity. The stimulation of ALP activity was mimicked by adding the CM from mature osteoclasts in a dose-dependent manner. The ALP-stimulating activity was purified through several steps of ion chromatography, and was identified as complement component 3a (C3a) by LC-MS/MS.

The results of microarray and qRT-PCR analyses revealed the expression of C3 gene markedly increased during osteoclast differentiation, and the cleavage product C3a was detected by ELISA in the CM of mature osteoclasts, but not of bone marrow macrophages. Retroviral expression of C3a itself stimulated osteoblast differentiation, while an antagonist of the C3a receptor (SB290157) inhibited the stimulation of ALP activity by the osteoclast CM.

The involvement of C3a in the coupling process in vivo was investigated in OVX model, where bone formation is stimulated secondarily to accelerated resorption. We reasoned that since coupling of resorption to formation is stimulated in OVX (with a net decrease in bone mass), if C3a is involved, the secondary stimulation of bone formation is inhibited when blocked C3a receptor by SB290157, resulting in an acceleration of net bone loss. Ten-week-old *ddY* mice, sham or OVX operation, were given daily i.p. injections of SB290157 for 6 days. OVX was associated with significant increases in the expression of C3 gene in bone as well as C3a concentrations in the bone marrow. Bone histomorphometic analysis at the proximal tibia revealed the stimulation of BFR/BS following OVX was completely suppressed by simultaneous administration of SB290157. This was associated with an exacerbation of bone loss following OVX, as determined by microCT scanning.We conclude that mature osteoclasts express C3 gene and secrete C3a, that acts on osteoblast lineage cells to stimulation their differentiation. Thus, osteoclast-secreted C3a may function in the relay from osteoclasts to osteoblasts as a candidate of coupling factor.

RANKL increase ROS and Bone Resorption by Inhibiting FoxO-mediated Catalase Expression. Ha-Neui Kim*[1], Shoshana Bartell[2], Li Han[2], Aaron Warren[3], Srividhya Iyer[2], Julie Crawford[4], Haibo Zhao[2], Charles O'Brien[2], Stavros Manolagas[2], Maria Jose Almeida[2]. [1]Univ. Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]Univ. Arkansas for Medical Sciences, & Central Arkansas Veterans Healthcare System, Little Rock, USA, [4]Univ. Arkansas for Medical Sciences, Little Rock, USA

RANKL stimulates reactive oxygen species (ROS) formation, which in turn promotes osteoclast differentiation, activity, and survival. In several cell types, the FoxO family of transcription factors decreases ROS by up-regulating the expression of several antioxidant enzymes. Here, we investigated the role of FoxOs in osteoclastogenesis and bone resorption. We report that serum starvation of bone marrow-derived osteoclast progenitors promoted nuclear translocation of FoxOs and FoxO-mediated transcription. On the other hand, treatment of the osteoclast progenitors with RANKL for 1 h abrogated the nuclear translocation of FoxOs, as determined in Western blot of nuclear extracts. Stimulation of FoxO-mediated transcription by serum depletion or transfection of FoxO1, FoxO3 or FoxO4 plasmids was also inhibited by RANKL, as measured by the activity of a FoxO-luc reporter plasmid in Raw264.7 macrophages. In addition, RANKL decreased protein levels of FoxO1, FoxO3, and FoxO4. To determine the significance of these findings to the in vivo situation, we used mice in which FoxO1,3,4 were specifically deleted (FoxO1,3,4ΔOc) or FoxO3 was overexpressed (FoxO3TgOc) in the osteoclast lineage, using LysM-Cre knock-in mice. Bone marrow-derived macrophages from FoxO1,3,4ΔOc mice exhibited greater proliferation, higher ROS levels and osteoclastogenesis in response to RANKL, and decreased expression of the FoxO-target gene catalase as compared to cells from FoxO1,3,4 flox littermate controls. Cells from the FoxO3TgOc mice exhibited the opposite phenotype when compared to their respective LysM-Cre controls. Moreover, FoxO1,3,4ΔOc mice had higher levels of ROS in the bone marrow and lower vBMD and cancellous bone volume in vertebrae and femora, as well as decreased femoral cortical thickness. The low bone mass phenotype was associated with increased CTx levels in the serum and high mRNA expression of TRAP and catK in bone, as well as with high osteoclast number in histological sections of vertebrae. Administration of catalase to 4 week old FoxO1,3,4ΔOc mice for 6 weeks prevented the decrease in bone mass. Once again, FoxO3TgOc mice had the opposite phenotype to that of the FoxO1,3,4ΔOc mice: increased bone mass associated with decreased resorption markers and osteoclast numbers in bone. These results demonstrate that attenuation of FoxO activation and thereby catalase expression is a seminal mechanism by which RANKL increases ROS generation and bone resorption.

Connective Tissue Growth Factor (Ctgf) is a Novel Notch Target Gene in Osteoblasts and Osteocytes. Ernesto Canalis*, Anna Smerdel-Ramoya, Stefano Zanotti. St. Francis Hospital & Medical Center, USA

Ctgf, a member of the CCN family of proteins, is required for skeletal development and adult skeletal homeostasis. Ctgf regulates the activity of signaling molecules in the bone environment, and previous studies revealed newly discovered interactions between Ctgf and Notch, a molecule with a key role in osteoblastic cell fate and function. In the present study, we explored whether Notch regulated Ctgf expression in the skeleton. Calvarial osteoblasts were obtained from *Rosa^{Notch}* mice, where the Notch intracellular domain is expressed under the control of the *Rosa26* promoter following the excision of an intervening *loxP* flanked STOP cassette. Osteoblasts from *Rosa^{Notch}* mice were transduced with an adenoviral vector expressing Cre under the control of the CMV promoter to activate Notch or with a control vector. Activation of Notch signaling induced canonical target genes of the *Hes* and *Hey* families. Furthermore, Notch increased Ctgf mRNA by ~7 fold, an effect that was sustained for up to 2 weeks of culture. Notch induced the newly transcribed Ctgf hnRNA nearly 3 fold indicating a transcriptional level of regulation. The half-life of Ctgf transcripts was 2.5 hours in transcriptionally arrested *Rosa^{Notch}* control osteoblasts, and in the context of Notch activation, indicating that Ctgf mRNA stability was not altered by Notch. The effect of Notch on Ctgf transcription was mediated by canonical signaling, since it was lost in the context of Rbpjk/Csl (required for canonical signaling) downregulation by RNAi. Downregulation of *Hes* and *Hey* genes did not preclude the induction of Ctgf by Notch suggesting that *Ctgf* is a direct Notch target gene. To ensure that the induction of Ctgf by Notch was physiological, wild type osteoblasts were cultured on wells coated with the Notch ligand Delta-like 1 (Dll1), which induced Ctgf mRNA and hnRNA by 1.5 to 2 fold. In addition, Notch induced Ctgf mRNA by 2 to 9 fold in femurs and calvariae from *Rosa^{Notch}* mice crossed with transgenics expressing Cre under the control of the *Osterix*, *Osteocalcin*, *Type I a1 collagen* or *Dentin matrix protein 1* promoter. This demonstrates that Notch induced Ctgf in undifferentiated and differentiated osteoblasts and osteocytes *in vivo*. These results establish Ctgf as a new and direct target of Notch signaling in osteoblasts and osteocytes suggesting that Ctgf may mediate selected actions of Notch in osteoblasts.

HIF-1α Regulates Bone Formation Following Osteogenic Mechanical Loading. Ryan Tomlinson*[1], Matthew Silva[2]. [1]Washington University in St. Louis, USA, [2]Washington University in St. Louis School of Medicine, USA

HIF-1α is a factor typically associated with angiogenic gene transcription under hypoxic conditions. In addition, HIF-1α has been shown to associate with β-catenin, potentially inhibiting downstream activation of Wnt target genes. Importantly, both angiogenesis and Wnt signaling are differentially regulated following osteogenic mechanical loading. To clarify the role of HIF-1α in this process, mice lacking HIF-1α in the osteoblast lineage (ΔHIF-1α) or wild type (WT) mice were subjected to damaging or non-damaging mechanical loading, producing woven or lamellar bone, respectively.

ΔHIF-1α mice produced less woven bone than WT mice 7 days after damaging mechanical loading, with significant decreases in woven bone volume (-22%) and extent (-21%), but no changes in woven bone BMD. These decreases in woven bone formation were precipitated by a significant decrease in vascularity (-35%), as measured by immunohistochemistry against vWF. Additional immunohistochemistry was used to show that osteocytes, rather than osteoblasts, are the main bone cell expressing HIF-1α following damaging loading.

Following non-damaging mechanical loading, both ΔHIF-1α and WT mice had increased lamellar bone formation in loaded limbs compared to non-loaded limbs, with significant increases in Ec.MS/BS, Ps.MS/BS, Ps.MAR, and Ps.BFR/BS. Importantly, loaded limbs from ΔHIF-1α mice had greater increases in both Ps.MAR and Ps.BFR/BS than WT loaded limbs. However, ΔHIF-1α mice also had increased baseline mineralization, demonstrated by increased periosteal bone formation in non-loaded limbs compared to WT non-loaded limbs.

In summary, ΔHIF-1α mice produced less woven bone following damaging mechanical loading, but generated additional lamellar bone following non-damaging mechanical loading. The diminished response to damaging loading was attributed to the role of HIF-1 as a pro-angiogenic transcription factor, since angiogenesis is required for optimal bone formation after stress fracture. The increased bone formation following non-damaging loading was attributed to decreased binding of HIF-1α to β-catenin, a process that disrupts Wnt signaling associated with periosteal bone apposition. These results demonstrate that HIF-1α is a factor that regulates bone formation following osteogenic mechanical loading.

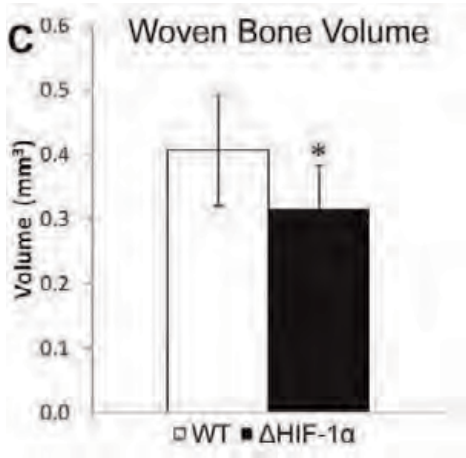

Figure 1 – Loading-induced woven bone formation is impaired in dHIF-1a mice

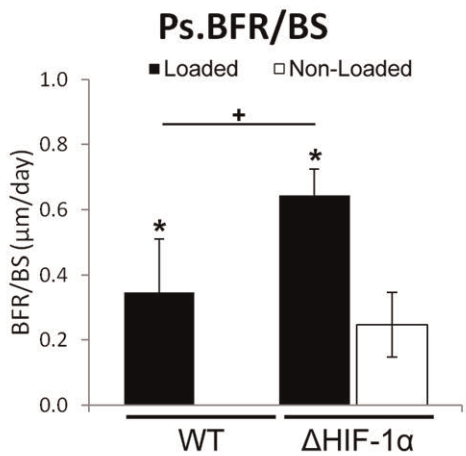

Figure 2 – Loading-induced lamellar bone formation is increased in dHIF-1a mice

R-spondin 3 Is a Negative Regulator of Bone Formation. Kei Yamana*[1], Hiroaki Saito[1], Kenichi Nagano[1], Riku Kiviranta[1], Francesca Gori[2], Roland Baron[3]. [1]Harvard School of Dental Medicine, Harvard Medical School, USA, [2]Harvard School of Dental Medicine, Massachusetts General Hospital, USA, [3]Harvard School of Medicine & of Dental Medicine, USA

Wnt ligands function with an entourage of receptors, co-receptors, agonists and antagonists that either enable or prevent Wnt signaling activation. Although activation of canonical Wnt signaling exerts a positive action on bone homeostasis, not all aspects of how it regulates bone homeostasis are clear. R-spondins (Rspos) consist of 4 cysteine-rich secreted glycoproteins essential in development. Although the mechanism of action of these proteins in mammals is not clear, the general consensus is that they potentiate canonical Wnt signals and thereby should exert a positive influence on bone formation and bone mass.

To test this hypothesis, and since Rspo3 is highly expressed in skeletal elements during development and is associated with bone density in GWAS studies, we investigated the biological function of Rspo3 in bone. Rspo3 is expressed in MEFs and in primary calvarial osteoblasts (OBs) and its expression increases during OB differentiation. While global deletion of Rspo3 results in embryonic lethality, Rspo3+/- mice develop normally and are healthy. In contrast to our expectations, Rspo3 haplo-insufficiency led to a striking increase (11X) in bone formation rate (BFR) and a 3X increase in mineral apposition rate in both female and male mice and at several time points. Accordingly, trabecular bone mass was significantly increased. Preliminary studies indicate that Rspo1 null mice develop high bone mass as well, suggesting that the increase in bone mass also apply to other members of the R-spondin family. In vitro studies in MEFs and calvarial OBs confirm that deletion and haplo-insufficiency of Rspo3 results in increased OB differentiation. Remarkably, lack of Rspo3 leads to activation of canonical Wnt signaling as indicated by reporter gene activity and increased expression of canonical Wnt target genes, activated β-catenin and phosphorylated LRP5/6. In addition, Wnt3a decreases while Dkk1 increases Rspo3 expression suggesting a feedback loop regulating Rspo3 and thereby canonical Wnt signaling. Finally, deletion of one allele of Dkk1 or overexpression of Dkk1 in Rspo3+/- mice aggravates or normalizes the Rspo3+/- bone phenotype, respectively, confirming activation of canonical Wnt signaling in these mice.

Thus, although R-spondins are believed to potentiate canonical Wnt signaling, our findings reveal a novel and unexpected function of this component of the Wnt signaling pathway as negative regulators of bone formation and homeostasis.

Fracture Healing Via Periosteal Callus Formation Requires Macrophages for Both Initiation and Progression of Endochondral Ossification. Allison Pettit[1], Liza Raggatt*[1], Martin Wullschleger[2], Kylie Alexander[3], Roland Steck[4], Simranpreet Kaur[5], Andy Wu[5]. [1]Mater Medical Research Institute, Australia, [2]The University of Queensland & RBWH, Australia, [3]Center for Clinical Research, Australia, [4]Queensland University of Technology, Australia, [5]The University of Queensland, UQ-CCR, Australia

The importance of inflammation to the initiation of fracture repair is established. Macrophages have been implicated in these inflammatory events but there has been little consideration of their possible roles beyond this. Our discovery that bone tissues contain resident macrophages (osteomacs) that exert pro-anabolic influence exposed a novel role for macrophages in bone biology. This included demonstration of a critical role for osteomacs in promoting intramembranous ossification during bone healing. Macrophage distribution throughout fracture healing was investigated using immunohistochemical staining with a panel of macrophage and bone cell marker antibodies in samples collected from a clinically relevant fracture model (MouseFix) that repairs via endochondral callus formation. Macrophage functional contributions during endochondral callus formation were determined using inducible in vivo macrophage depletion (Mafia transgenic mice) in the same fracture model. We confirmed macrophages were prominent during both the inflammatory and early anabolic phases and extended this through identification of 3 macrophage subpopulations including inflammatory macrophages and osteomacs. We showed that macrophages persist throughout later healing phases, but at reduced frequency, with enrichment of osteomacs at sites of bone formation. Notably, inflammatory macrophages were scattered within foci of mesenchymal condensation during the initiation of endochondral ossification. They were also located at the chondro-osseous junction, preceding osteoclast invasion into cartilage matrix. Depletion of macrophages initiating at the time of surgery resulted in catastrophic failure of fracture healing including persistence of hematoma and absence of granulation tissue. Delayed macrophage depletion commencing at the transition to early anabolism resulted in significant reduction in soft callus area (greater than 50%, $p = 0.002$). A significant positive correlation was observed between residual callus size and efficiency of macrophage depletion ($r = 0.6$). These observations provide the most compelling evidence to date regarding the necessity of macrophages in the initiation of fracture repair and establish their direct functional contribution to anabolic mechanisms during endochondral callus formation. Our accumulating data implicating macrophages in both endochondral and intramembranous ossification mechanism solidifies this pathway as a key cellular mechanism in bone biology.

Histology of Atypical Femoral Fractures. Jörg Schilcher*[1], Per Aspenberg[1], Olof Sandberg[2]. [1]Linköping University, Sweden, [2]Department of clinical & experimental medicine, Linköping University, Sweden

Background: The pathophysiology behind bisphosphonate-associated atypical femoral fractures remains unclear. Histological findings at the fracture site itself might provide important clues. So far only one case has been published describing the histological appearance of the fracture.

Methods: Between 2008 and 2013, bone biopsies from the fracture sites were collected from 8 patients with 4 displaced and 4 undisplaced atypical femoral fractures. Seven female patients reported continuous bisphosphonate use for an average of 10 years. One patient was a man, not using bisphosphonates. Laboratory parameters were obtained, and the patients were followed until union. The bone biopsies were evaluated histologically and with micro-computed tomography.

Results: The 4 undisplaced fractures engaged the whole cortical thickness and comprised a 160 to 200 μm wide, meandering fracture gap filled with amorphous necrotic material. Active resorption and remodeling was common in the close vicinity of the fracture, but seldom reached into the fracture gap. In some areas, the bone adjacent to the gap appeared to undergo fragmentation and disintegration, possibly due to abrasion. Loose bone fragments could be found in the fracture gap in all cases. Where fragments had loosened, defects occurred in the underlying bone. Woven bone was common adjacent to the fracture gap, and appeared to have been formed in the

defects caused by abrasion. Periosteal and endosteal callus was found in all cases. Far away from the fracture, large areas of osteonal bone with only empty osteocyte lacunae were found in some samples.

Figure 1 shows a fracture gap (x) with amorphous material (+). A fragment of lamellar bone is about to loosen. White arrows indicate a thin layer of amorphous material between this fragment and the intact bone. Black arrows indicate resorption cavities near the fracture.

Discussion: Atypical femoral fractures show signs of increased remodeling in the vicinity of the fracture gap. The narrow width of the gap and its necrotic contents suggest that micromotion leads to strains between the fracture fragments that precludes survival of ingrowing cells. Moreover, there seemed to be continuous mechanical fragmentation of the bone at the crack, and replacement of fragmented areas with woven bone. Thus, it appears that the fracture line is not static, but moves in the bone over time, like the changes in the course of a meandering river.

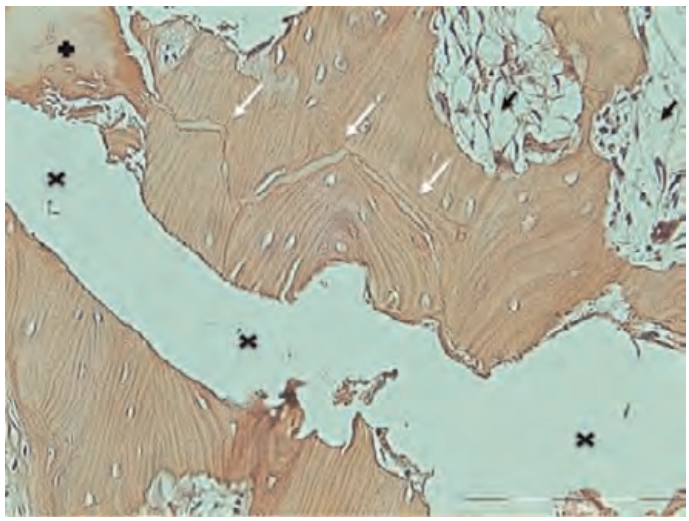

Figure 1. See text

Effect of Teriparatide on Healing of Incomplete Atypical Femur Fractures. Angela M. Cheung*[1], Jonathan Adachi[2], Aliya Khan[3], Robert Bleakney[4], Earl Bogoch[5], Rowena Ridout[6], Heather McDonald-Blumer[7], Lianne Tile[8], Savannah Cardew[9], Khalid Syed[8], Jessica Chang[8], Judite Scher[8], Hanxian Hu[8], Suzanne Morin[10], Alexandra Papaioannou[11], Sophie Jamal[12], Robert Josse[13]. [1]University Health Network-University of Toronto, Canada, [2]St. Joseph's Hospital, Canada, [3]McMaster University, Canada, [4]Mount Sinai Hospital, Canada, [5]St. Michael's Hospital, Canada, [6]Toronto Western Hospital, Canada, [7]University of Toronto, Canada, [8]University Health Network, Canada, [9]Women's College Hospital, Canada, [10]McGill University, Canada, [11]Hamilton Health Sciences, Canada, [12]The University of Toronto, Canada, [13]St. Michael's Hospital, University of Toronto, Canada

Background: With increased awareness of atypical femur fractures (AFFs), incomplete non-displaced AFFs are diagnosed more frequently. Optimal therapy for these fractures is unclear. We describe a case series of 22 patients with incomplete AFFs treated with teriparatide (TPD) therapy.

Methods: These 22 patients are part of our larger Ontario AFF Cohort Study. All satisfied the criteria set forth by the ASBMR Task Force for the definition of AFF. Baseline demographic characteristics including BMD at the lumbar spine, total hip and femoral neck were collected. We assessed radiographic fracture healing using CT scans and plain radiographs, measuring depth of the lucency line through the cortex and degree of extension around the circumference every 6 months for up to 2 years (recommended duration of TPD therapy for osteoporosis in Canada). Progression / regression of fracture line up to last follow-up were noted. Pain, mobility and any surgical intervention were noted. We summarized our results using descriptive statistics.

Results: All 22 patients were postmenopausal women (68% Caucasian, 32% Southeast/South Asian): mean age 65.9 years (range 26.0 - 80.8 yrs), mean BMI 28.4 kg/cm2 and mean serum 25-hydroxyvitamin D 110 nmol/L at diagnosis. All had normal ionized calcium and intact PTH. 17 (77%) had bilateral AFFs (12 had a complete AFF surgically fixed on the contralateral side and 5 had bilateral incomplete AFFs), and 5 (23%) had unilateral incomplete AFF. Average length of bisphosphonate use was 12.0 years (range 3.4-28.7 yrs). Mean BMD T-scores at the LS, TH and FN were -1.76, -1.16 and -1.78, respectively. Average duration of TPD was 18.8 months (range: 1-36 months). Of the 22 patients, 3 underwent prophylactic surgical repair (2 due to debilitating pain/progression and 1 due to patient/physician preference). Of the remaining 19 patients, follow-up imaging was available for 15 patients with 19 incomplete AFFs. Of these 19 incomplete AFFs, 2 had healed, 5 were healing, 12 were stable, and none had worsened at last follow-up. However, 4 patients developed new lucency lines in the same femur as their original incomplete AFF despite teriparatide therapy.

Conclusions: Teriparatide may promote healing of incomplete non-displaced AFFs. However, a randomized placebo-controlled trial is urgently needed to definitively answer this question.

Beyond 10 yrs Prediction of Fragility Fracture by DXA in Women. The OFELY study. Elisabeth Sornay-Rendu, François Duboeuf, Stephanie Boutroy, Roland Chapurlat*. INSERM UMR1033, Université de Lyon, France

Low bone mineral density (BMD) is a major determinant of fragility fractures (Fx) but its very long term prediction is poorly documented. In the OFELY study, we analyzed the risk of Fx over 20 yrs and more particularly beyond 10 yrs in women aged 40 yrs and more at the inclusion. BMD was measured at baseline at the spine, hip and forearm in 868 women (mean age 59 $\pm$ 10 years, 78% postmenopausal) using dual-energy X-ray absorptiometry (DXA). All peripheral and vertebral fragility Fx, were confirmed by radiographs and prospectively registered. During a median follow-up of 19.7 yrs (IQ :2.8), 245 women sustained one or more incident fragility Fx (first Fx: vertebral n=65, peripheral n=180). Each SD decrease of BMD at the femoral neck (FN) , total hip, spine and ultradistal (UD) radius was associated with an increased risk of fragility Fx with an odds ratio [95% CI] of 1.49 [1.23-1.79], 1.54 [1.32-1.82], 1.47 [1.28-1.67] and 1.72 [1.45-2.04] respectively, after adjustment for age, prior Fx, parental hip Fx, treatment at baseline or during follow-up (hormone replacement therapy, bisphosphonates, etc ...) and duration of follow-up. Women who sustained Fx beyond 10 years (Fx 10-20, n=109) were younger compared with those in the first10 years (Fx 0-10, n=136) ($p<0.0001$). After adjusting for age, Fx 10-20 had greater grip strength and spine BMD and used more often HRT, compared with Fx 0-10 ($p=0.01$ to 0.02). The risk of Fx 10-20 was significantly increased with adjusted OR of 1.35 [1.06-1.72], 1.39 [1.12-1.72], 1.30 [1.09-1.56] and 1.67 [1.32-2.08] for each SD decreased of FN, total hip, spine and UD, in the same order of Fx 0-10 (OR 1.61 [1.25-2.08], 1.69 [1.37-2.13], 1.67 [1.39-2.00] and 1.79 [1.45-2.17] respectively). Parental hip Fx was associated with an increased risk of Fx 10-20 but contrasting with Fx 0-10, Fx 10-20 were not associated with lower grip strength, falls and previous Fx at baseline after adjusting for age. In conclusion, low BMD in women aged 40 yrs or more is significantly associated with an increased risk of fracture beyond 10 years independently of age and other predictors of fractures. The prediction conferred by baseline BMD did not decline with time.

A Five-Year Longitudinal Study of Site-Specific Changes in Bone Quality in the Calgary Population-Based Cohort: an HR-pQCT Study. Lauren Burt*[1], Anne-Laure Ménard[2], Heather Macdonald[3], David Hanley[1], Steven Boyd[1]. [1]University of Calgary, Canada, [2]Ecole Polytechnique of Montréal, CHU Ste-Justine Research Center, Canada, [3]University of British Columbia, Canada

Age-related bone loss measured by dual-energy X-ray absorptiometry (DXA) occurs at a rate of 1-2% per year, but the age at which bone loss occurs varies with skeletal sites and imaging modalities. Age-related bone loss measured with high-resolution peripheral quantitative computed tomography (HR-pQCT) may differ from DXA measurements. In our population-based cohort we aimed to compare subject-specific longitudinal age-related bone changes in different skeletal sites using two imaging modalities.

Women (N=112, 60-85 yrs) from the Calgary cohort of the Canadian Multicentre Osteoporosis Study (CaMos) participated in a 5-year follow-up study. Areal bone mineral density (aBMD) at the lumbar spine (LS), femoral neck (FN) and total hip (TH) were obtained from DXA (Hologic, USA) scans of L1-L4 and the left hip. The non-dominant radius and left tibia were scanned using HR-pQCT (Scanco Medical, Switzerland). Total volumetric BMD (Tt.BMD), cortical BMD (Ct.BMD), trabecular BMD (Tb.BMD) and cortical porosity (Ct.Po) were assessed using standard and automated segmentation methods. Finite element analysis (FEA) estimated apparent bone strength. Repeated measures ANOVA assessed age-related bone change over time. T-tests compared differences between skeletal sites and imaging modalities.

Over 5-years, DXA-derived aBMD decreased between 4% (FN) and 6% (TH) whereas HR-pQCT-derived Tt.BMD declined between 3% (tibia) and 7% (radius) ($p<0.05$). At the radius, Tb.BMD decreased 6% and Ct.BMD 4% ($p<0.01$). However, at the tibia Tb.BMD did not change significantly ($p>0.05$) and Ct.BMD decreased by 5% ($p<0.01$). The greatest age-related change was in Ct.Po; Ct.Po increased by 53% at the radius and 33% at the tibia ($p<0.01$). Preliminary FEA results revealed a loss in radial apparent bone strength of 3% ($p<0.05$). Comparisons between skeletal sites indicated that age-related changes in Tt.BMD and Ct.Po were larger at the radius than tibia ($p<0.05$). Similarly, age-related aBMD changes were greater at the TH than LS ($p<0.01$).

Our 5-year longitudinal HR-pQCT study is the longest population-based cohort study, demonstrating age-related skeletal changes in women over 60 yrs. Age-related changes differed according to imaging modality (DXA vs HR-pQCT) and skeletal sites: more bone loss occurred at the radius than tibia. Whether this holds true for men will be the subject of our continued study. Further understanding of age-related changes bone quality will enhance our ability to assess bone health with HR-pQCT.

Inflammatory Markers and Risk of Hip Fracture in Older Women: The Study of Osteoporotic Fractures. Kamil Barbour*[1], Li-Yung Lui[2], Kristine Ensrud[3], Teresa Hillier[4], Marc Hochberg[5], Jane Cauley[6]. [1]CDC, USA, [2]California Pacific Medical Center Research Institute, USA, [3]Minneapolis VA Medical Center / University of Minnesota, USA, [4]Kaiser Center for Health Research, USA, [5]University of Maryland School of Medicine, USA, [6]University of Pittsburgh Graduate School of Public Health, USA

Cytokines play a major role in bone remodeling *in vitro* and in animal models, with evidence supporting the involvement of inflammatory markers in the pathogenesis of osteoporosis. Moreover, there is evidence showing that high levels of inflammatory makers may increase bone loss in predominantly older women. However, few studies have examined the association between inflammatory marker levels and risk of hip fracture, the most serious consequence of osteoporosis. We used a case-cohort design nested in a cohort of 4709 white women from the Study of Osteoporotic Fractures at year 10 (1997-1998) to determine if high levels of inflammation increase the risk of hip fracture, and whether this association is mediated by frailty, physical function, calciotropic hormones, renal function, and bone mineral density (BMD). We randomly selected 1171 to serve as the random subcohort (mean age 80.1 $\pm$ 4.2 years) plus the first 300 women with incident hip fracture after the Year 10 examination. The median (interquartile range (IQR)) study follow-up time was 6.3 (3.7, 6.9) years. We examined inflammatory marker levels in quartiles as their distribution was shown to be skewed. In multivariable models, the hazard ratio (HR) of hip fracture for participants with the highest levels (quartile 4) of 4 inflammatory markers compared with those with lower levels (quartiles 1, 2, and 3) was 1.33 (95% confidence interval [CI], 0.97-1.82) for interleukin-6 (IL-6), 1.13 (95% CI, 0.83-1.54) for IL-6 soluble receptor (SR), 1.52 (95% CI, 1.11- 2.08) for tumor necrosis factor (TNF) SR1, and 1.05 (95% CI, 0.75-1.45) for TNF SR2. Among participants with 2 and $\geq$3 of 4 markers in the highest quartile, the HR of hip fracture was 1.50 (95% CI, 1.06-2.11) and 1.42 (95% CI, 0.87-2.31), in comparison with participants with 0 or 1 marker(s) (p trend = 0.03). After individually adjusting for 6 potential mediators, cystatin-C (a biomarker of renal function) attenuated the dose-response relationship the most (p trend=0.24); even greater than BMD (p trend=0.16). Based on findings from this and our prior study, older women with higher levels of inflammatory markers are at increased risk of hip fracture in part due to their reduced renal function.

Table. Hazard ratios (95% CIs) of hip fracture, according to number of high* inflammatory markers

	0, 1 (Ref)	2	≥3	P trend

Bone Material Strength Measured by *In Vivo* Microindentation is Compromised in Postmenopausal Women with Type 2 Diabetes Mellitus. Joshua Farr*[1], Shreyasee Amin[1], L. Joseph Melton[1], Louise McCready[1], Sundeep Khosla[2]. [1]Mayo Clinic, USA, [2]Mayo Clinic College of Medicine, USA

Type 2 diabetes mellitus (T2DM) is an established, independent risk factor for fracture. Moreover, recent evidence suggests that fracture risk is higher for a given femoral neck BMD T-score and age in patients with T2DM as compared to non-diabetics (JAMA 305:2184, 2011). These observations have led to the notion that bone "quality" (i.e., bone material properties) is abnormal in T2DM, leading to reduced bone strength for a given bone mass. To rigorously test this hypothesis *in vivo*, we used an innovative hand-held microindentation instrument (Osteoprobe®) to directly measure the bone material strength (BMS) of the midshaft of the tibia in a case-control study of 30 postmenopausal women (mean age $\pm$ SD: 65.5 $\pm$ 8.1 yrs, range: 50–80 yrs) diagnosed with T2DM for at least 10 yrs and 30 age-matched, non-diabetic women. In addition, we measured serum hemoglobin A1c (HbA1c) as well as bone density at the radius, spine, hip, and total body by DXA and microarchitecture at the distal radius and tibia by HRpQCT. Compared to controls, women with T2DM had significantly lower tibial BMS, both unadjusted and following adjustment for BMI (–10.5%, P<0.001), but showed no differences in cortical or trabecular bone microarchitecture at the distal radius and tibia as well as in BMD at any site. Importantly, BMS of the tibia was negatively correlated with HbA1c in women with T2DM (r=–0.41, P=0.026; Fig. A) but not in controls (r=–0.09, P=0.626; Fig. B). BMS of the tibia was not significantly correlated with any of the DXA- or HRpQCT-derived bone parameters.

These findings represent the first demonstration, using a direct *in vivo* measure of BMS, of compromised bone quality in women with T2DM. By contrast, HRpQCT and DXA were not able to differentiate between women with or without T2DM. Given the lack of associations between BMS and bone density or microarchitecture, our data suggest that these BMS measures may reflect a unique component of bone quality that could serve to better identify individuals at risk for fragility fractures. Our finding of an inverse relationship between HbA1c and BMS in women with T2DM supports this possibility, and may reflect the detrimental effects of prolonged hyperglycemia on bone material properties. Our study also points to the need to further define the factors that regulate bone material properties in T2DM, which could lead to novel insights into the pathophysiological basis and possible prevention of the fractures observed in these patients.

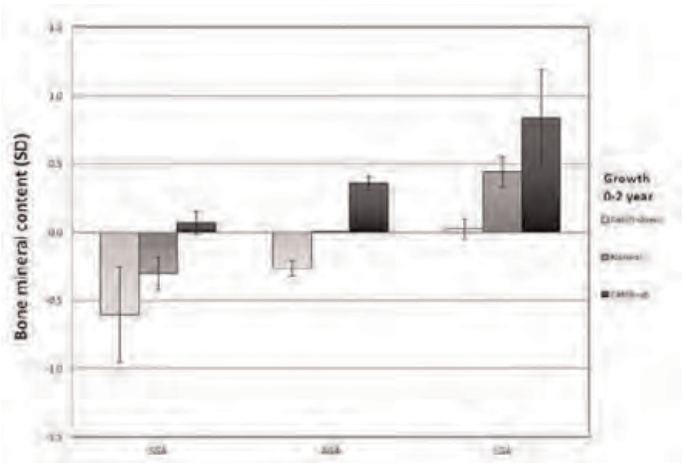
Associations of Fetal and Childhood Growth with Bone Mass in School Age Children. The Generation R Study. Denise Heppe*[1], Carolina Medina-Gomez[2], Albert Hofman[3], Fernando Rivadeneira[4], Vincent W.V. Jaddoe[5]. [1]Erasmus MC, The Netherlands, [2]Erasmus Medical Center, The Netherlands, [3]Department of Epidemiology Erasmus Medical Center, Netherlands, [4]Erasmus University Medical Center, The Netherlands, [5]Generation R Erasmus Medical Center, Netherlands

Fetal growth restriction, as indicated by low birth weight, leads to lower bone accrual in children and peak bone mass acquisition in adults. We aimed to assess how different patterns of fetal and childhood growth influence bone properties at school age. In 5,431 children, participating in a prospective birth cohort study, we measured fetal growth by ultrasound during the second and third trimesters, and childhood growth at birth, 1, 2, 3 and 4 years of age. We measured total body bone mineral density (BMD) by dual-energy x-ray absorptiometry (DXA) at the median age of 6.0 (IQR 0.37) years and analyzed bone parameters after body size correction. As compared to children born with normal birth weight, the bone mineral content (BMC) and bone area (BA) were all lower in small (<10^{th} percentile) for gestational age (SGA) children and higher in large (>90^{th} percentile) for gestational age (LGA) children. SGA children with normal postnatal growth in the first two years had -0.30 SD (95%CI -0.42, -0.18) lower BMC, -0.35 SD (95%CI -0.47, -0.24) lower BA and -0.21 SD (95%CI -0.36, -0.06) lower BMD than children born with normal birth weight and normal growth in the first 2 years. No differences in BMD, BMC or BA were seen in SGA children with catch-up growth in the first two years (>0.67 SD increase in weight) and LGA children with catch-down growth (<-0.67 SD decrease in weight). Conditional growth analysis showed that all fetal and childhood growth measures, except birth length, were positively associated with BMC, BA and BMD (all with P <0.05). Birth length was positively associated with BMC and BA, not BMD (both with P <0.001). Overall, childhood growth exerted a larger influence on bone parameters than fetal growth did. The strongest effect of growth during the first years of life was seen for weight and height on BMC (ß 0.25 SD, 95%CI 0.23, 0.27 and ß

0.31 SD, 95%CI 0.29, 0.33 per SD increase, respectively). Results were less prominent on BMD, probably due to positive relations with both BMC and bone size (BA). We conclude that fetal and childhood growth influence bone mineral accrual, particularly in the first postnatal years. Compensatory growth in the first postnatal years may eradicate the consequences of slower fetal growth rates on bone development.



BMC by Growth periods

The Oral Small Molecule Phenamil Regulates BMP Signaling and Prevents Ovariectomy-Induced Osteoporosis. Aaron James*[1], Choon G Chung[2], Greg Asatrian[2], Omar Velasco[2], Daniel Halperin[3], Kye Won Park[4], Georgina Bayani[2], Kevork Khadarian[2], Xinli Zhang[1], Kang Ting[1], Peter Tontonoz[3], Chia Soo[5]. [1]University of California, Los Angeles, USA, [2]Division of Associated Clinical Specialties & Section of Orthodontics, UCLA School of Dentistry, USA, [3]Department of Pathology & Laboratory Medicine, David Geffen School of Medicine, USA, [4]Sunkyunkwon University, Korea, Korea, democratic people's republic of, [5]Division of Plastic & Reconstructive Surgery, Department of Surgery, University of California, Los Angeles, USA

Introduction: Phenamil is a non-toxic, small molecule that induces *in vitro* osteogenesis via downregulation of the BMP (bone morphogenetic protein) antagonist Smurf1 (SMAD ubiquitin regulatory factor 1). Moreover, phenamil plays a role in regulating the balance of osteogenesis versus adipogenesis via Trb3 (Tribbles homolog 3)-dependent promotion of BMP action. No prior studies have reported anabolic effects of phenamil *in vivo*. Here, we sought to determine if oral administration of phenamil would induce bone formation in osteoporotic and non-osteoporotic mice.

Methods: Wildtype mice underwent ovariectomy (OVX) or SHAM surgery, followed immediately by feed supplemented with Phenamil (50 mg / kg diet) or control. Analysis was performed by weekly Dual-energy X-ray absorptiometry (DXA), post-mortem high-resolution micro computed tomography (microCT), histology and immunohistochemistry. N=20 mice in total were split evenly into treatment groups and were followed for four weeks post-OVX. All analyses were performed on the lumbar spine.

Results: As expected, OVX induced significant bone loss among mice treated with control feed. Remarkably, maintenance of bone mineral density (BMD) was observed when OVX mice were treated with Phenamil feed (*$p<0.01$ in comparison to control feed) (Fig. 1A). MicroCT showed a significant increase in bone volume (BV) (Fig. 1B) and fractional bone volume (BV/TV) when either sham or OVX mice were treated with Phenamil feed (*$p<0.05$ in comparison to control feed), also observed in microCT 3D coronal reconstructions (Fig. 1C). Non-significant trends toward increased trabecular bone thickness and trabecular bone number were observed among Phenamil treated groups.

Conclusions: This study shows for the first time that the small molecule phenamil induces bone formation *in vivo*, and helps to counteract ovariectomy induced bone loss. As phenamil is a non-toxic derivative of amiloride (an FDA approved potassium sparing diuretic), these finding are highly translatable to clinical use.

Bone Marrow Stromal Cell Proliferation in Mice Lacking NFATc1 in Mature Osteoclasts. Julia Charles*[1], Jonathan Quang[2], Kelly Tsang[3], Antonios Aliprantis[4]. [1]Brigham & Women's Hospital & Harvard School of Medicine, USA, [2]Boston University School of Medicine, USA, [3]Brigham & Women's Hospital, USA, [4]Brigham & Women's Hospital & Harvard School of Public Health, USA

Nuclear Factor of Activated T Cells c1 (NFATc1) is a key transcription factor in osteoclast (OC) differentiation where it drives expression of osteoclast-specific genes in precursor cells. Although the role of NFATc1 in OC formation is well described, little is known about the function of NFATc1 in mature OCs. To address this, $Nfatc1^{fl/fl}$*Ctsk-Cre*$^{+}$ ($Nfatc1^{\Delta OC/\Delta OC}$) mice were generated, in which *Nfatc1* is deleted in mature OCs. These mice were compared to $Tnfrsf11a^{fl/fl}$*Ctsk-Cre*$^{+}$, in which the gene encoding Receptor activator of nuclear factor kB (RANK) is knocked out in OCs ($Rank^{\Delta OC/\Delta OC}$). Both $Nfatc1^{\Delta OC/\Delta OC}$ and $Rank^{\Delta OC/\Delta OC}$ mice are runted and toothless with an increase in calcified cartilage in the long bones. In contrast to $Rank^{\Delta OC/\Delta OC}$ mice, which largely lack OCs, abnormally large, multinucleated OCs are present in the bones of $Nfatc1^{\Delta OC/\Delta OC}$ mice. Strikingly, in $Nfatc1^{\Delta OC/\Delta OC}$ mice, bone marrow hematopoietic elements are replaced with spindle shaped stromal cells. In contrast, $Rank^{\Delta OC/\Delta OC}$ mice do not display expansion of stromal cells and normal appearing hematopoietic cells occupy the residual marrow space. The expanded bone marrow stromal cells in $Nfatc1^{\Delta OC/\Delta OC}$ mice are likely of the osteoblast (OB) lineage, as they differentiate into OBs ex vivo and support osteoclastogenesis. To exclude that the stromal cell proliferation phenotype could be due to unanticipated deletion of the conditional *Nfatc1* allele by *Ctsk-Cre* in OBs, we also crossed $Nfatc1^{fl/fl}$ with *Osx-Cre* and *Prx1-Cre*, which are expressed in OBs and limb mesenchymal progenitors, respectively. Neither $Nfatc1^{fl/fl}$*Osx-Cre*$^{+}$ nor $Nfatc1^{fl/fl}$*Prx1-Cre*$^{+}$ recapitulates the $Nfatc1^{\Delta OC/\Delta OC}$ phenotype. To test if OCs are required for the stromal proliferative phenotype, mice doubly deficient for *Nfatc1* and *Rank* in mature OCs ($Nfatc1^{\Delta OC/\Delta OC}Rank^{\Delta OC/\Delta OC}$) were examined. RANK-deficiency completely rescued the stromal proliferative phenotype, with $Nfatc1^{\Delta OC/\Delta OC}Rank^{\Delta OC/\Delta OC}$ mice demonstrating an identical bone phenotype to $Rank^{\Delta OC/\Delta OC}$ mice. In summary, deficiency of NFATc1 in mature OCs results in a high bone mass phenotype with effacement of the marrow space by OB lineage stromal cells and enlarged OCs, a constellation of pathologic findings reminiscent of fibrous dysplasia. We hypothesize that NFATc1 in mature OCs regulates the expression of a factor that either promotes stromal cell proliferation or drives stromal cells to differentiate into OBs.

Absence of the αvβ3 Integrin and the ITAM Protein, DAP12, Causes Severe Osteopetrosis. Wei Zou*[1], Jean Chappel[2], Steven Teitelbaum[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

Osteoclastic bone resorption depends upon the cell's ability to organize its cytoskeleton via the αvβ3 integrin and osteoclastogenic cytokines. Ligand occupancy of αvβ3 induces phosophorylation of the ITAM-bearing adaptor protein, DAP12, which we have established is essential for osteoclast function, in vitro. Like those deleted of only αvβ3, however, DAP12-/- mice exhibit only a slight increase in bone mass. Alternatively, DAP12-/- mice, also lacking another ITAM protein, FcRγ, are severely osteopetrotic, establishing that FcRγ compensates for DAP12 deficiency in the bone-resorbing polykaryons. Here we show that despite the mild phenotype of single gene deletion, β3/DAP12 double-deficient (β/D) mice are severely osteopetrotic. In contrast, mice with combined deletion of β3 and FcRγ exhibit no skeletal abnormalities. Bone marrow macrophages, derived from β/D mice, precursors normally express osteoclast differentiation markers when exposed to M-CSF and RANKL but the derivative TRAP+ cells fail to multinucleate and have a more severe phenotype than those lacking either αvβ3 or DAP12. β/D mice also express normal endogenous FcRγ , indicating that absence of the integrin precludes compensation for DAP12 deficiency by FcRγ. Consistent with this hypothesis, overexpression OSCAR, the co-receptor which activates FcRγ, rescues spreading and function of DAP12-/-, but not β/D osteoclasts. These data indicate αvβ3 is an essential partner of FcRγ/OSCAR and in fact, the three proteins associate under the influence of cytoskeleton-organizing cytokines. OSCAR, activated in bone-residing osteoclasts also phosphorylates Syk, a tyrosine kinase which is essential for organization of the osteoclast cytoskeleton. We found that MCSF induces Syk phosphorylation in DAP12 deficient osteoclast transduced with OSCAR, but not in β/D osteoclasts. Thus αvβ3, FcRγ and OSCAR form a cytoskeleton-activating complex required to compensate for DAP12 deficiency.

CSF-1 in Osteocytes and Late Osteoblasts Controls Major Aspects of Bone Remodeling. Sherry Abboud Werner*[1], Diane Horn[1], Yves Gorin[1], Roberto Fajardo[2], Jean Jiang[1], Marie Harris[1], Stephen Harris[1]. [1]University of Texas Health Science Center at San Antonio, USA, [2]UT Health Science Center, San Antonio, USA

CSF-1 is a key factor in regulating bone remodeling. The precise source of CSF-1 that controls this remodeling process is unknown. Osteocytes express CSF-1 and its receptor. Viable osteocytes are essential for bone remodeling through cell-cell contact and secretion of factors that regulate osteoblasts and osteoclasts. Increased oxidative stress contributes to osteocyte death and correlates with bone loss during aging. The NADPH oxidase Nox4 is constitutively active and is a major source of reactive oxygen species (ROS) in bone. CSF-1 decreases Nox4 expression, suggesting that CSF-1 protects against oxidant stress. Little is known regarding the role of CSF-1 and Nox4 in osteocytes and oxidant stress-induced alterations in skeletal tissues. To examine CSF-1/Nox4 biologic effects, DMP1Cre-CSF-1cKO (CSF-1cKO) mice that lack CSF-1 in late osteoblasts/osteocytes were generated. Bones from WT and CSF-1cKO mice were examined for bone phenotype using μCT and histomorphometry; Nox4 and 4-HNE (marker of oxidant stress) expression were determined using immunohistochemistry. In parallel, bones from CSF-1KO mice with global CSF-1 deficiency were examined and enriched osteocytes from CSF-1KO mice were analyzed for apoptosis, gap junction function, NADPH oxidase activity and Nox4 protein by Western blot. WT osteocytes were treated with CSF-1 and examined for NADPH oxidase activity. CSF-1cKO bone phenotype showed a modest increase in bone mass, decreased osteoclasts and elevated Nox4 and 4-HNE expressing osteocytes. CSF-1cKO mice also showed reduced bone formation rate that would predispose to bone loss/fracture with age. Similarly, osteopetrotic CSF-1KO mice showed osteocyte defects including apoptosis, associated with increased Nox4 expression/activity as well as 4-HNE and DHE fluorescence and reduced Cx43 expression required for osteocyte function. Cultured CSF-1KO osteocytes were also predisposed to apoptosis and showed elevated NADPH oxidase activity/Nox4 protein and reduced gap junction function compared to WT osteocytes. Notably, CSF-1 inhibited NADPH oxidase activity in WT osteocytes. Taken together, studies indicate a novel link between CSF-1, Nox4-derived ROS and osteocyte survival/function and that CSF-1 deficiency in osteocytes regulates bone remodeling. Results reveal new mechanisms by which CSF-1/oxidative stress regulate osteocyte homeostasis and suggest therapeutic targets for improving osteocyte viability crucial for bone strength and longevity.

Deletion of ERβ in Early Osteoprogenitor Cells Leads to a Doubling of Trabecular Bone Volume. Kristy Nicks*[1], Koji Fujita[1], Daniel Fraser[1], Ulrike McGregor[2], Meghan McGee-Lawrence[1], Jennifer Westendorf[1], David Monroe[3], Sundeep Khosla[4]. [1]Mayo Clinic, USA, [2]King's College, London UK, United Kingdom, [3]Mayo Foundation, USA, [4]Mayo Clinic College of Medicine, USA

While the role of ERα in regulating bone metabolism has been extensively studied, ERβ has been largely dismissed as a relevant modulator of bone mass. However, all previous studies have used an ERβ KO mouse that expressed transcript variants of ERβ and also involved global deletion of ERβ; the latter resulted in systemic hormonal changes (e.g., increased IGF-I levels) that confounded interpretation of the skeletal phenotype. Thus, we used a mouse model with flox sites ($ER\beta^{fl/fl}$) that, upon cleavage with Cre, led to a complete deletion of ERβ (Antal et al. PNAS 105:2433, 2008) specifically in mature osteoblasts (Col 2.3 Cre) or in early osteoprogenitors (Prx-1 Cre). In 3-month old female mice, ERβ deletion using the Col 2.3 Cre resulted in a 9% increase in spine ($P < 0.05$) and 7% increase in femur ($P < 0.01$) BMD relative to control (Cre alone) mice. More detailed studies using the Prx-1 Cre mice revealed that ERβ deletion in early osteoprogenitor cells resulted in a 93% increase ($P < 0.001$) in trabecular BV/TV by μCT at the femoral metaphysis; by contrast, cortical thickness at the femur mid-shaft was unchanged in the KO mice. Bone histomorphometric analysis demonstrated a 54% increase in osteoblast numbers ($P = 0.001$) but no changes in osteoclast numbers or eroded surfaces in the ERβ KO mice, consistent with ERβ deletion in osteoblasts leading to enhanced bone formation. To determine potential underlying mechanism(s), we isolated RNA from the femur metaphysis of $PrxCre//ER\beta^{fl/fl}$ and controls and utilized customized, in-house QPCR analyses of 240 genes related to bone metabolism, including genes reflecting 17 pre-specified pathways. Genes in the pathways were analyzed using a cluster analysis (O'Brien Umbrella Test) which tests for concordant changes in multiple genes in the pathway. Highly regulated pathways in the ERβ KO mice included adipogenesis (decreased, $P = 0.007$), autophagy (decreased, $P = 0.0008$), and oxidative stress (decreased, $P = 0.005$), suggesting that deletion of ERβ resulted in modulation of several pathways related to bone formation. In summary, our data demonstrate that deletion of ERβ in osteoblast lineage cells, in the absence of all splice variants, results in increased trabecular bone mass associated with increased osteoblast numbers and modulation of multiple pathways related to bone formation. These findings also suggest that pharmacological inhibition of ERβ in bone may provide a novel anabolic approach to treat osteoporosis.

1091

Deletion of gp130 in Osteocytes Blocks PTH Anabolic Effect. Therese Standal*[1], Rachelle Johnson[2], Narelle McGregor[2], T. John Martin[2], Natalie Sims[2]. [1]St Vincent's Institute for Medical Research, Melbourne & Department of Cancer Research & Molecular Medicine, Trondheim, Norway, [2]St. Vincent's Institute of Medical Research, Australia

In exerting its anabolic effect on bone, PTH acts via its receptor (PTH1R) to increase osteoblast proliferation and differentiation and to inhibit apoptosis. Members of the IL-6/gp130 superfamily of cytokines are rapidly upregulated by PTH in the osteoblast lineage, and share similar gene targets, such as inhibiting osteocytic sclerostin. This study addresses whether gp130 signaling in osteocytes is needed for PTH's anabolic effect.

Male mice with conditional deletion of gp130 in osteocytes (Dmp1-Cre gp130f/f) and littermate controls (Dmp1-Cre gp130w/w) were treated with PTH(1-34) (30ug/kg s.c. 5x/week for 5 weeks). In w/w mice this treatment doubled osteoblast number / bone perimeter (p=0.001), and significantly increased osteoid surface / bone surface (BS) (p=0.009), osteoblast surface /BS (p=0.001) and mineralizing surface /BS (p=0.03). However in f/f mice, PTH treatment changed none of these parameters. Serum N-terminal propeptide of type I collagen (P1NP) levels were increased by 30% (p= 0.006) with PTH treatment in w/w mice, but were not modified in PTH-treated f/f mice. The only effect of PTH common to both w/w and f/f mice was to increase trabecular mineral apposition rate to the same extent in each. This suggests that the mineralization response to PTH is retained in some differentiated osteoblasts in f/f mice, but that PTH does not increase osteoblast proliferation and differentiation in

the absence of osteocytic gp130. Osteoclast number neither differed in number or size between the two groups, nor changed in response to PTH.

Since the PTH-induced increase in osteoblast number was completely blocked in the f/f mice, we investigated whether knockdown of gp130 in osteocytes influenced PTH1R expression in bone. Indeed, in f/f femurs gp130 mRNA levels were reduced by 44% ($p < 0.001$) and PTH1R mRNA reduced by 47% compared to w/w femurs ($p=0.03$). This was supported by *in vitro* data, where C57Bl/6 and gp130f/f primary osteoblasts were infected with lentiviral cre. In cre-infected gp130f/f osteoblasts both gp130 and PTH1R mRNA were 52% ($p=0.008$) and 84% ($p=0.03$), respectively, lower than in infected C57Bl/6 cells.In conclusion, osteocytic gp130 is required for PTH to increase osteoblast number and bone forming surfaces, and to maintain PTH1R expression in the osteoblast lineage.

Conditional ablation of Cbfβ in different stages of skeletogenesis results in a novel cleidocranial dysplasia mouse model revealing a new role of Cbfβ in postnatal skeletal and tooth development. Joel Jules*, Mengrui Wu, Wei Chen, Junqing Ma, Guochun Zhu, Fei Tian, Matthew McConnell, Christie Paulson, Yi-Ping Li. University of Alabama at Birmingham, USA

RUNX/Cbfβ complexes are critical for skeletogenesis, but not only is the role of Cbfβ in postnatal bone formation and disease unclear, but also the pathogenesis of cleidocranial dysplasia (CCD), a human disease of Runx2 deficiency characterized by short stature and defective cranial bones and clavicle, is largely unknown due to the embryonic lethality of Cbfβ deficiency. Toward this end, we used the Cre-loxp system to delete Cbfβ by conditional knockout (CKO) at different stages of differentiation and in different tissues. First, we used the Twist2-Cre mice to restrict Cbfβ in mesenchymal progenitors. Twist2-Cre;$Cbf\beta^{f/f}$ mice died at birth and were dwarfism with defective skeleton. Notably, Runx2 expression was not affected by Cbfβ CKO, but osteoblast and chondrocyte genes were repressed. To explore the role of Cbfβ in cartilage, we used Col2a-Cre mice to excise Cbfβ in chondrocytes. Col2a-Cre;$Cbf\beta^{f/f}$ mice lived to adulthood with dwarfism and severe bone defects but normal cranial bones. There was drastic reduction in the expression of Indian hedgehog (Ihh), critical for chondrocyte differentiation, and its target gene cyclin D1, and chondrocyte genes in these mice, indicating that Cbfβ regulates chondrocyte biology during postnatal cartilage development partly by regulating chondrocyte genes. We then explored the role of Cbfβ in bone formation by restricting its expression in the osteoblast lineage using Col1-Cre mice. Col 1-Cre;$Cbf\beta^{f/f}$ mice lived to adulthood with dwarfism and severe bone defects. Osteoblast, but not chondrocyte, genes were repressed in Col1 CKO mice, indicating that Cbfβ regulates osteoblastogenesis during postnatal skeletogenesis partly by regulating osteoblast genes. Given the separate effects of Cbfβ in chondrocytes and osteoblasts, we used the Osx-Cre mice to collectively excise Cbfβ in odontoblasts/osteoblasts/chondrocytes. Osx-Cre;$Cbf\beta^{f/f}$ mice also lived to adulthood with severe bone defects but recapitulated the clinical features of CCD. Notably, Osx-Cre;$Cbf\beta^{f/f}$ also had defective mandible, mandibular and teeth, critical CCD features. We then revealed that Cbfβ interacted with Runx1 and Runx2 in distinct regions of the growth plate to mediate postnatal skeletogenesis. Overall, we showed that Cbfβ regulates both osteoblasts and chondrocytes during postnatal skeletogenesis, and its deletion via Osx-Cre leads to a novel CCD mouse model mimicking human CCD. Significantly, these findings may assist in developing new therapies for CCD.

1093

NF-κB Family Member Rela/p65 in Chondrocytes Controls Skeletal Growth and Osteoarthritis Development by Inhibiting Chondrocyte Apoptosis. Hiroshi Kobayashi*[1], Makoto Hirata[2], Shozo Itoh[2], Taku Saito[3], Haruhiko Akiyama[4], Ung-Il Chung[5], Hiroshi Kawaguchi[6]. [1]The University of Tokyo Hospital, Japan, [2]The University of Tokyo, Japan, [3]University of Tokyo, Graduate School of Medicine, Japan, [4]Kyoto University, Japan, [5]University of Tokyo Schools of Engineering & Medicine, Japan, [6]University of Tokyo, Faculty of Medicine, Japan

The NF-κB family of transcription factors plays crucial roles in a variety of cell functions. Here we examined the role of NF-κB family member Rela/p65 in chondrocytes during skeletal growth and osteoarthritis (OA) development. In the mouse limb cartilage, Rela/p65 was expressed ubiquitously in chondrocytes of various differentiation stages. We then examined the skeletal growth of conditional knockout mice at several differentiation stages by mating *Prx1-Cre*, *Col2a1-Cre,* and *Col10a1-Cre* transgenic mice, respectively, with mice homozygous for a floxed *Rela* allele (*Rela*$^{fl/fl}$). *Prx1-Cre*;*Rela*$^{fl/fl}$ and *Col2a1-Cre*;*Rela*$^{fl/fl}$ mice exhibited limb shortening, whereas *Col10a1-Cre*;*Rela*$^{fl/fl}$ mice exhibited normal skeletal growth, suggesting an important role of Rela/p65 at the early stage of chondrocyte differentiation. Expressions of the early differentiation markers: *Sox9, Col2a1, aggrecan* in the culture of *Prx1-Cre*;*Rela*$^{fl/fl}$ articular chondrocytes were comparable to those of the control *Rela*$^{fl/fl}$ littermates. However, the cell number was decreased in the *Prx1-Cre*;*Rela*$^{fl/fl}$ chondrocyte culture, as well as by the *Rela* knockdown through siRNA in the mouse chondrogenic ATDC5 cell culture. Although the growth plate chondrocytes of *Col2a1-Cre*;*Rela*$^{fl/fl}$ mice showed normal proliferation determined by BrdU uptake, they exhibited enhanced apoptosis determined by Tunel staining. Next, to examine the function of Rela/p65 in the OA development, time-specific conditional knockout mice of *Rela* in cartilage were generated by mating tamoxifen (TM)-inducible *Col2a1-Cre* transgenic mice (*Col2a1-Cre*^{TM}) with the *Rela*$^{fl/fl}$ mice. TM was injected to 7-week-old mice, and the OA model was created surgically in knee joints one week after the injection. Eight weeks after the surgery, OA development was enhanced in *Col2a1-Cre*^{TM};*Rela*$^{fl/fl}$ mice as compared to the control *Rela*$^{fl/fl}$ littermates, with acceleration of chondrocyte apoptosis at the frontline of degraded articular cartilage. In the *ex vivo* culture of *Prx1-Cre*;*Rela*$^{fl/fl}$ articular chondrocytes, the TNF-α-induced apoptosis was more enhanced than in the *Rela*$^{fl/fl}$ culture. Microarray analysis between the two genotype chondrocytes predicted 10 anti-apoptotic genes under the TNF-α induction, in which expressions of Traf2 and c-Iap1,2 were confirmed to be suppressed in the *Prx1-Cre*;*Rela*$^{fl/fl}$ chondrocytes by real-time RT-PCR. In conclusion, Rela/p65 in chondrocytes controls skeletal growth and OA development by inhibiting chondrocyte apoptosis.

TGF-beta Signaling Regulates Interleukin-36 alpha in Joint Development and Osteoarthritis. Tieshi Li*[1], Lara Longobardi[1], Timothy Myers[2], Joseph Temple[1], Alessandra Esposito[1], Anna Spagnoli[1]. [1]University of North Carolina at Chapel Hill, USA, [2]University of North Carolina, USA

TGF-β type II receptor (Tgfbr2) signaling plays an essential role in joint development and homeostasis. By combining laser-capture microdissection for RNA sampling with microarrays we found that in the joint interzone of mice in which the Tgfbr2 signaling is conditionally inactivated in limb mesenchyme (Tgfbr2Prx1KO), the inflammatory cytokine interleukin-36 alpha (IL36α) is up-regulated more than 40-fold compared to control (Tgfbr2flox/flox). The upregulation of IL36α in Tgfbr2Prx1KO was confirmed by immunohistochemistry and evaluated throughout joint development. IL36α has been reported to be involved in psoriasis and more recently, increased levels have been found in the inflamed joints of patients with different forms of arthritis. To determine the interplay between IL36α and Tgfbr2 signaling in osteoarthritis (OA) we have generated mice in which we have induced a conditional inactivation of Tgfbr2 in post-natal life (tamoxifen-induced inactivation at P3) named Prx1CreERT2;Tgfbr2lox/lox mice. We have found that Prx1CreERT2;Tgfbr2lox/lox mice progressively develop severe knee OA starting as early as P31, at P3M they show loss of Safranin O staining and by P14 months they demonstrate total loss of knee articular cartilage, severe subchondral bone sclerosis, osteophytes formation and severe synovitis. We found that in Prx1CreERT2;Tgfbr2-lox/lox mice, IL36α was up-regulated in articular cartilage, subchondral bone, superficial layer of meniscus and synovial membrane, such expression proceeded along with the progression of OA and was especially found in areas affected by OA. Elevated expression of IL36α was also found in the arthritic knee joints of mice subjected to a destabilization of medial meniscus (DMM) as a murine model of post-traumatic OA. In DMM, expression of IL36-α correlated with the severity of OA progression although interestingly up-regulation seems to be lower than the one found in Prx1CreERT2;Tgfbr2lox/lox mice. Furth more, the expression of IL36α showed an age-dependent increase in knee articular cartilage and this trend appeared opposite to Tgfbr2's expression that decreased with age. Our findings indicate that inactivation of Tgfbr2 signaling in pre-natal and postnatal limbs induces up-regulation of the inflammatory cytokine IL36α and such up-regulation was associated with severe OA progression. Our studies open novel perspective for the prevention and treatment of OA by manipulating the TβRII/ IL36 α axis.

Lower Limb Geometrical Parameters in the Pathogenesis of Bisphosphonate-Associated Atypical Femur Fractures. Suzanne Morin*[1], Benoit Godbout[2], Michelle Wall[3], Laetitia Michou[4], Andrew Karaplis[1], Etienne Belzile[5], Louis-Georges Ste-Marie[6], Thomas Moser[7], Jacques deGuise[8], Jacques P. Brown[9]. [1]McGill University, Canada, [2]Centre de Recherche du Centre Hospitalier de l'Université de Montreal, Canada, [3]McGill University Health Center Research Institute, Canada, [4]Université Laval, Canada, [5]Laval University, Canada, [6]CHUM, Canada, [7]Université de Montreal, Canada, [8]Centre de Recherche du Centre Hospitalier Université Montreal, Canada, [9]CHU de Québec Research Centre, Canada

Background: Atypical femur fractures (AFF) arise in the subtrochanteric and diaphyseal regions. Because of this unique distribution, we hypothesized that patients with AFF demonstrate specific geometrical variations of their lower limb whereby baseline tensile forces applied to the lateral cortex are higher and might favor the appearance of these rare stress fractures, when exposed to bisphosphonates.

Methods: Subjects exposed to bisphosphonates who sustained AFF, as defined by the ASBMR task force, were recruited. Using the EOS™ low irradiation 2D-3D X-Ray scanner, bilateral lower extremities examinations were obtained in the upright weight-bearing position. EOS™ permits 3D surface images of high resolution from simultaneous two-plane images. We compared the participants' leg geometrical

parameters to those of reference cohorts and also examined differences between women who sustained diaphyseal versus subtrochanteric AFF. For each subject with AFF, we are currently enrolling age- (± 5 yrs), sex-, height- (± 6 cm) and cumulative bisphosphonate exposure- (±2 yrs) matched controls without femur fracture. Conditional logistic regression models will be constructed to estimate the effect of selected geometric parameters on AFF.

Results: We identified 25 subjects (21 women; mean age 67 SD [9] yrs; 23 Caucasian) with AFF and an average cumulative duration of use of bisphosphonate of 10.6 SD [4.6] yrs). There were 40 AFF: 15 subjects had bilateral AFF; 15 AFF were complete and 25 were incomplete; 28 were diaphyseal and 12 subtrochanteric. Bilateral AFF occurred in the identical region of the femurs in 75% of subjects. We documented differences in geometrical parameters of the lower limb in subjects with AFF compared to those reported in normal populations (Table 1). Compared to women with diaphyseal fractures (n=11), those with subtrochanteric fractures (n=5) had a lesser femur neck-shaft angle (123.0˚ SD [3.3] versus 129.2˚ SD [7.1]; $p < 0.05$), longer femoral offset (4.2 SD [0.2] cm versus 3.7 SD [0.6] cm; $p < 0.05$), and tended to have less pronounced femur bowing in frontal plane (- 2.7˚ SD [5.6] cm versus -4.2˚ SD [3.3]; p= 0.60).

Conclusion: Our analyses, though limited by sample size, support that subjects with AFF exhibit femur geometry that results in higher tensile mechanical load on the lateral femur, particularly in women with subtrochanteric fractures; this may play an important role in the pathogenesis of AFF.

Early Diagnosis of Atypical Femoral Fracture Using DXA by Extending Femur Length. Malachi McKenna*[1], Susan van der Kamp[2], Eric Heffernan[2]. [1]St. Michael's Hospital, Ireland, [2]St. Vincent's University Hospital, Ireland

Introduction: The Task Force Report of the ASBMR 2010 listed five major criteria, all of which must be present, to make a diagnosis of AFF: located on the femoral shaft anywhere between lesser trochanter and the supracondylar flare, non-comminuted, transverse or short oblique, incomplete on lateral surface only or complete with a medial spike, and as a consequence of minimal or no trauma. The Task Force also listed minor criteria, such as: localized periosteal reaction of lateral cortex with ''beaking'' or ''flaring''. Since AFF often have a prodrome of pain and tenderness at the fracture, there is window of opportunity for early detection. McKiernan has demonstrated that incomplete AFF may be detected using DXA scan by extending the length of the femur image.

Methods: Patients over 50 years of age presenting for routine DXA who had been taking bisphosphonates therapy in excess of 5 years had an extended hip scan performed bilaterally using an array mode. We extended femur length from default of approximately 15.3 cm up to 22 cm, in order to view the extra length of the femoral shaft. Images were viewed independently by two observers. If abnormalities were noted in the lateral aspect of the femur, namely ''flare'' or ''beaking'', then patients were referred for a plain X-ray of pelvis with imaging of lateral femur.

Results: Over 16 month spell, 257 patients had an extended DXA imaging. Patients were predominantly women; Alendronate and Risedronate accounted for 89% of treatments. At the time assessment, the prevalence of DXA-based diagnosis of osteoporosis at any site was 56%. A suspected abnormality on the DXA was noted in 19 of 257 (7.4%). On X-ray, 7 (2.7%) showed no abnormality, 7 (2.7%) showed evidence of AFF, and 5 (2.0%) showed an additional abnormality (an osteochondroma, an abnormal lucency, and 3 cases of cortical thickening). Of the 7 cases with X-ray evidence of AFF, 5 had a periosteal flare and 2 had a visible fracture line. The latter patients were referred for orthopedist opinion, and both subsequently had elective insertion of an intramedullary nail. On multivariable analysis, duration of bisphosphonate therapy was the only factor associated with diagnosis of AFF (OR=1.35, 95%CI=1.04-1.76, p=0.026).

Conclusion: Extended DXA imaging of the lateral femur shaft permits early detection of AFF. We noted a prevalence of AFF of 2.7% in patients on bisphosphonate therapy over 5 years.

Pamidronate Treatment of Pediatric Burns Attenuates Muscle Breakdown. Elisabet Borsheim[1], David Herndon[1], Matthew Cotter[1], Gordon Klein*[2]. [1]University of Texas Medical Branch & Shriners Burns Hospital, USA, [2]University of Texas Medical Branch, USA

Acute intravenous administration of pamidronate to burned children has been shown to preserve bone mass for up to 2 yr. However, inasmuch as these children also suffer from muscle wasting, likely a result of elevated production of endogenous glucocorticoids, it is unclear whether treating the bone with pamidronate is associated with any secondary benefits to muscle. To address this question we studied burned pediatric patients who were enrolled in a double-blind placebo-controlled study of acute pamidronate infusion and its effect on bone mass who also underwent infusion with deuterated phenylalanine tracer alone and on the same day in combination with unlabelled amino acids and who also had a vastus lateralis muscle biopsy and arterial and venous blood sampling. All studies were done during the acute hospitalization. We measured incorporation of tracer into muscle and calculated fractional synthetic rate (FSR), rate of appearance of phenylalanine from muscle into the blood (Ra), and net balance (NB) of phenylalanine in muscle as arterio-venous difference X blood flow/100 ml leg volume. FSR rose in response to amino acid infusion in placebo subjects (n=3) but did not rise in those receiviing pamidronate (n=4), F=11.55, p=0.014 by one-way ANOVA. Ra, a measure of muscle breakdown, was 246.8 + 166.4 (SD) nmol/min/100 ml leg volume in the controls (n=7) and 112.1 + 53.9 in the pamidronate group (n=10), p=0.0375 by two-tailed t test. NB was -61.7 + 73.2 nmol/min/100 ml leg volume in the controls (n=7) and 132.6 + 190.5 in the pamidronate group (n=10), p=0.024 by two-tailed t test. Thus pamidronate treatment not only prevents post-burn bone loss but these data suggest that it may also indirectly attenuate muscle breakdown and that treatment of bone loss may confer indirect muscle-sparing effects.

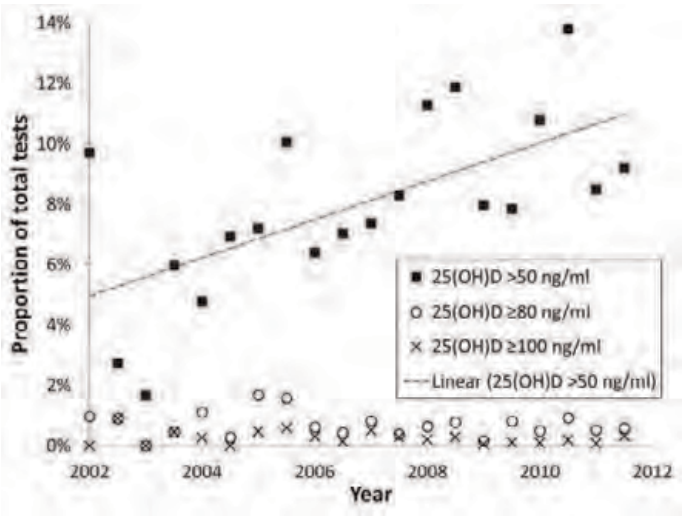
Incidence of Vitamin D Toxicity: A Population-Based Study in Olmsted County, Minnesota. Daniel Dudenkov*[1], Barbara Yawn[2], Sara Oberhelman[1], Philip Fischer[1], Ravinder Singh[1], Steven Cha[1], Julie Maxson[1], Stephanie Quigg[1], Tom Thacher[1], Tom Thacher[1]. [1]Mayo Clinic, USA, [2]Olmsted Medical Center, USA

Background: Hypervitaminosis D and associated toxicity may complicate vitamin D supplement use. The initial finding in almost all reported cases of vitamin D toxicity is hypercalcemia. Our objective was to determine the incidence trend of hypervitaminosis D and its association with hypercalcemia in Olmsted County, Minnesota.

Methods: We identified all serum 25-hydroxyvitamin D [25(OH)D] measurements >50 ng/ml (hypervitaminosis D) in persons residing in Olmsted County, MN during a 10-year interval (2002-2011), through the Rochester Epidemiology Project databases. The date of the first value >50 ng/ml was considered the index date for incidence determination. Hypercalcemia (serum calcium >10.1 mg/dl or ionized calcium >5.3 mg/dl) was considered associated with hypervitaminosis D if measured within 3 months of 25(OH)D measurement.

Results: Of 20,308 total 25(OH)D measurements, 1885 (9.3%), 133 (0.7%), and 44 (0.2%) unique persons had 25(OH)D values >50, ⩾80, and ⩾100 ng/ml, respectively. The incidence of hypervitaminosis D increased from 10 per 100,000 in 2002 to 260 per 100,000 in 2011. The increase in incidence was greater in persons age ⩾65 years and in females. The proportion of 25(OH)D values >50 ng/ml increased from 2002 to 2011, but the proportion of 25(OH)D values ⩾80 and ⩾100 ng/ml did not increase. Of 960 with serum calcium measured within 3 months of 25(OH)D value, 180 (19%) had hypercalcemia. The greatest serum 25(OH)D of 364 ng/ml was associated with the greatest serum calcium of 17.5 mg/dl. This person had been taking vitamin D 50,000 IU four times daily for several weeks. When this subject was excluded, serum 25(OH)D values were not significantly related with serum calcium values (r=-0.01; p=0.70) or with the risk of hypercalcemia [OR=0.93 (95% CI 0.50-1.7) for 25(OH)D⩾80, and OR 0.94 (0.35-2.5) for 25(OH)D ⩾100 ng/ml]. The incidence of hypercalcemia between 2002 and 2011 did not change.

Conclusion: The incidence of hypervitaminosis D has increased between 2002 and 2011 without an increase in extreme 25(OH)D values. Hypercalcemia was common but its relationship with hypervitaminosis D was not established.



Hypervitaminosis D in Olmsted County, MN from 2002-2011

Bone Turnover Markers and Prediction of Fracture in a 15-year Follow-Up Study of Elderly Women. Kaisa Ivaska*[1], Fiona McGuigan[2], Karl Obrant[3], Paul Gerdhem[4], Kristina Akesson[5]. [1]University of Turku, Finland, [2]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [3]University Hospital, Sweden, [4]Karolinska Institutet, Sweden, [5]Skåne University Hospital, Malmö, Sweden

High level of bone turnover is associated with increased fracture risk, but the information on how long time markers can predict fractures is limited. The aim of this study was to investigate whether bone markers are associated with long-term fracture risk in the elderly.

Fracture prediction was evaluated in the population-based OPRA cohort of 1044, 75-year-old women. Bone turnover markers (CTX, PINP, TRACP5b, bone-specific ALP, serum and urinary osteocalcin) were measured at baseline and prospective fractures were recorded and verified for the mean of 15.0 years (range 13.4 – 17.0 years). The ability of baseline bone markers to predict fracture was estimated by Cox proportional hazard ratios for 5 years, 10 years and for the entire follow up of mean 15 years.

The number of women who sustained at least one fracture of any type was 214 at five years, 399 at ten years and 524 at the end of the follow-up. By the end of the follow-up 195 women sustained a hip fracture, 214 women a vertebral fracture and 453 women a FRAX fracture (hip, spine, forearm or shoulder). Mortality at five, ten and fifteen years was 10%, 29% and 57%, respectively. During the 5-year follow up, women in the highest tertile for bone markers (particularly CTX and urinary osteocalcin) had significantly higher risk for sustaining any fracture, FRAX fracture or vertebral fracture when compared to women in the lowest tertile. The hazard ratios for fracture were 1.5 - 2.0 ($p<0.05$), depending on the marker. Baseline bone markers were not significantly associated with fracture risk for the follow-up period of 10 years, and the predictive ability of bone markers was further attenuated when the follow-up time was continued for up to 15 years. However, women in the middle tertile of baseline formation markers appeared have lower long term risk for sustaining vertebral fractures than those in the low or high tertile (hazard ratios 0.6-0.7, $p<0.05$). Baseline bone markers were not associated with the risk for hip fracture at any of the evaluated time points.

In conclusion, increased levels of bone turnover markers are associated with increased probability of fracture, particularly in first five years following the measurement. The ability of a single measurement of bone marker to predict fractures in elderly women attenuates over time and is not significant for long follow-up time of 10 - 15 years.

Neonatal Enzyme Replacement Therapy Improves Cervical Spine Bone Architecture and Mineralization in Mucopolysaccharidosis I Dogs. Lachlan Smith*[1], Joseph Chiaro[1], Patricia O'Donnell[1], Eileen Shore[1], Neil Malhotra[1], Dawn Elliott[2], Katherine Ponder[3], Mark Haskins[1]. [1]University of Pennsylvania, USA, [2]University of Delaware, USA, [3]Washington University in St Louis, USA

Mucopolysaccharidosis I (MPS I) is a lysosomal storage disorder characterized by deficient α-L-iduronidase activity, leading to the accumulation of poorly degraded dermatan and heparan sulfate glycosaminoglycans (GAGs). Clinical presentation includes significant cervical spine disease, leading to spinal cord compression and kypho-scoliosis. Using the authentic MPS I canine homolog, we showed previously that MPS I dogs have significantly lower trabecular bone volume and mineralization in the cervical vertebrae from as early as 3-months-of-age, and abnormal persistence of growth plate cartilage at 12-months-of-age. The purpose of this study was to determine whether neonatal enzyme replacement therapy (ERT, currently in clinical use), alone or in combination with oral simvastatin (ERT+S), could attenuate cervical spine bone disease in MPS I.

Four groups were studied (all n=5): normal controls; MPS I untreated; MPS I ERT treated; MPS I ERT+S treated. Treatments commenced at 1-week-of-age, and all animals were euthanized at 12-months-of-age. C2 vertebrae were excised, trabecular bone imaged using microCT, and standard morphometric parameters and BMD determined. Vertebrae were processed for paraffin histology to evaluate presence of growth plate cartilage.

Untreated MPS I dogs had significantly reduced BV/TV (49% of normal), Tb.Th (74% of normal), and BMD (61% of normal), and increased Tb.Sp (1.5-fold normal) (all $p<0.05$, Figure). ERT treated dogs had improved BV/TV (85% of normal), Tb.Th (95% of normal), Tb.Sp (1.2-fold normal), and BMD (89% of normal), none significantly different from normal and all significantly greater the untreated MPS I. ERT+S treated dogs showed similar, but not greater, improvements. Histological assessment of GAG and collagen revealed growth plate remnants in all five untreated MPS I vertebrae, in two ERT treated vertebrae, and in one ERT+S treated vertebra. In all normals, growth plates were absent.

These results show that neonatal ERT effectively attenuates vertebral bone disease in MPS I dogs. There is evidence that simvastatin has anti-inflammatory properties and can stimulate BMP signaling, however, in this study supplementation with simvastatin provided minimal additional benefits over ERT alone. Future work will seek to further elucidate the underlying pathogenesis of bone and disc disease in MPS, with the goal of developing new therapeutic strategies.

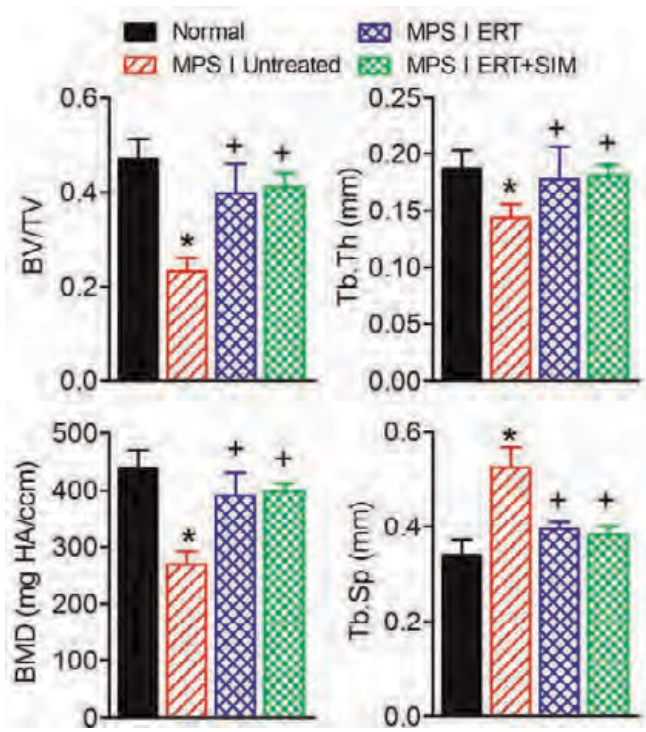

Figure: MicroCT analysis results. *$p<0.05$ vs normal; +$p<0.05$ vs untreated MPS I

The Transcriptional Cofactor Jab1 is Essential for Mouse Limb Development. Lindsay Bashur*, Dongxing Chen, Bojian Liang, Zhijun Chen, Shunichi Murakami, Guang Zhou. Case Western Reserve University, USA

The transcriptional cofactor Jab1 controls cell proliferation, apoptosis, and differentiation in many developmental processes by regulating the activity of various transcription factors. However, the physiological role of Jab1 in skeletal development is still poorly understood. To determine the role of Jab1 during early limb development, we developed a novel *Jab1^{floxlflox};Prx1-Cre* conditional knockout (*cKO*) mutant mouse model in which *Jab1* was deleted specifically in the osteochondroprogenitor cells of limb buds. *Jab1 cKO* mutant mice displayed drastically shortened limbs at birth, strikingly mirroring phocomelia, a devastating human birth defect with severe limb truncation. Real time RT-PCR analysis revealed no significant changes in the expression of chondrocyte differentiation markers *Sox9* and *Col2a1* in E11.5 *Jab1 cKO* mutant limb buds. At E12.5, *Jab1 cKO* mutant mice and wild-type littermates exhibited no gross morphological differences. However, the short limb defect became apparent in *Jab1 cKO* mutants at E14.5 and increasingly worsened thereafter. By E18.5, *Jab1 cKO* mutant mice exhibited significantly shorter limbs with: very few hypertrophic chondrocytes, disorganized chondrocyte columns, much smaller primary ossification centers, significantly increased apoptosis, but normal proliferation. The expression of *Sox9*, *Col2a1*, and *Col10a1* were all down-regulated in E15.5 and E18.5 *Jab1 cKO* mutant long bones by real time RT-PCR, indicating impaired chondrogenesis. Immunohistochemistry revealed decreased expression of both Sox9 and BMP signaling downstream effector phopho-Smad1/5, in *Jab1 cKO* mutants. Furthermore, in a well-established micromass culture model of early limb mesenchyme cells, Alcian blue staining showed a significant decrease in chondrogenesis in *Jab1 cKO* micromasses. The expression of Sox9 and its downstream targets *Col2a1* and *Aggrecan*, and also the BMP downstream targets *Col10a1*, *Ihh* and *Id1*, were all significantly decreased in *Jab1 cKO* micromasses. This suggests that Jab1 positively regulates Sox9 and BMP signaling during early limb development. In conclusion, the deletion of *Jab1* in early limbs inhibits chondrocyte differentiation and cell survival, consequently leading to a phocomelia-like phenotype in mice. Thus, Jab1 is a novel and essential regulator of limb development *in vivo*, and our *Jab1 cKO* mice can serve as an excellent model for elucidating the pathogenesis of and developing therapeutic interventions for phocomelia.

TAK1 Regulates SOX9 Expression and is Essential for Postnatal Development of the Growth Plate and Articular Cartilages. Jennifer Jonason[1], Lin Gao*[1], Tzong-Jen Sheu[1], Yufeng Dong[1], Michael Zuscik[2], Edward Schwarz[1], Matthew Hilton[3], Regis O'Keefe[1]. [1]UNIVERSITY OF ROCHESTER, USA, [2]University of Rochester School of Medicine & Dentistry, USA, [3]University of Rochester Medical Center, USA

TGF-β-activated kinase 1 (TAK1) is a MAP3K that mediates non-canonical TGF-β and BMP signaling. During the embryonic period, TAK1 is essential for cartilage and joint development as deletion of *Tak1* in chondro-osteo progenitor cells leads to severe chondrodysplasia with defects in both chondrocyte proliferation and maturation. Here, we designed experiments to address the role of TAK1 in committed chondrocytes during early postnatal development. Using the *Col2a1-CreER^{T2}; Tak1$^{f/f}$* mouse model, we induced deletion of *Tak1* at postnatal day 7 and characterized the skeletal phenotypes of these mice at one and three months of age. Mice with chondrocyte-specific *Tak1* deletion exhibited severe growth retardation and disorganized growth plate cartilage with reduced chondrocyte proliferation. Strikingly, the articular cartilage of these mice exhibited reduced proteoglycan and Type II Collagen content in zones of uncalcified cartilage. Consistent with these observations, we found reduced *Col2a1* and *Acan* gene expression, but increased *Mmp13* and *Adamts5* gene expression, in articular chondrocytes isolated from the *Tak1*-deficient mice as well as in *Tak1$^{f/f}$* primary sternal chondrocytes infected, *in vitro*, with adenovirus encoding Cre recombinase. Additionally, expression of the SOX trio of transcription factors, SOX9, SOX5, and SOX6, was decreased in chondrocytes both *in vivo* and *in vitro* upon deletion of *Tak1*. It is well established that BMP signaling regulates SOX9 expression in chondrocytes, but the precise mechanism by which it does so is unclear. We, therefore, designed experiments to determine whether TAK1 is a downstream effector of BMP-mediated SOX9 expression. We found that BMP2 induced *Sox9* gene expression and promoter activation in chondrocytes, but that these effects were suppressed upon deletion of *Tak1* or inhibition of TAK1 kinase activity. TAK1 affects both canonical and non-canonical BMP signal transduction and we found that both of these pathways contributed to BMP2-mediated *Sox9* promoter activation. Specifically, *Smad1* or *Atf2* gene silencing via siRNA suppressed *Sox9* promoter activation in response to BMP2 treatment. Finally, we found that ATF2 directly binds the *Sox9* promoter in response to BMP2 signaling and that this effect is dependent upon TAK1 kinase activity. These novel findings establish that TAK1 is essential for BMP2-mediated *Sox9* gene expression and the postnatal development of normal growth plate and articular cartilages.

***Hox* genes, critical regulators of embryonic skeletal development, are required for adult fracture healing.** Danielle Rux*[1], Ilea Swinehart[1], Aleesa Schlientz[1], Kenneth Kozloff[2], Steven Goldstein[3], Deneen Wellik[4]. [1]University of Michigan, USA, [2]University of Michigan Department of Orthopaedic Surgery, USA, [3]University of Michigan Orthopaedic Research Lab, USA, [4]University of Michigan Medical Center, USA

The *Hox* genes are critical regulators of embryonic skeletal development. Loss of function mutations in any one of the 13 paralogous groups (*Hox1-13*) leads to regionally-restricted malformations of the axial skeleton and the limbs. Specifically, loss of *Hox11* function results in severe mispatterning of the sacrum and of the skeletal elements of the limb zeugopod (tibia/fibula, radius/ulna). We show that *Hox11* is expressed in the mesenchyme of the developing limb bud, but is surprisingly excluded from the condensing chondrocytes that will become the zeugopod elements. Instead, it is expressed highly in the perichondrium and periosteum up to E18.5. Previous studies have suggested that *Hox* genes may continue to function after embryonic development. Our lab shows significant evidence that this is the case. First, we show that *Hox11* expression persists in periosteal fibroblast populations of the limb skeleton during post-natal and adult stages. Further, we demonstrate that cell populations expressing *Hox* increase dramatically after fracture injury. Expression is especially high in the fibroblast cells expanded from the periosteal surface of the bone to encase the fracture callus suggesting a role for *Hox* in early mesenchymal differentiation. Using *Hox11* compound mutants (mutant for three of four alleles that function in zeugopod development), we show that loss of *Hox* function disrupts the endochondral ossification process during fracture repair. In contrast, intramembranous bone formation appears to proceed normally. Loss of *Hox11* function leads to significant perturbation of the fracture healing process. In *Hox11* compound mutants, the fracture gap is not bridged until several weeks after controls are fully bridged, and remodeling is incomplete even five months after fracture. Cartilage formation is decreased in *Hox11* compound mutants during early stages of repair, but osteoblast and osteoclast formation is comparable to controls. These results indicate a novel role for *Hox* genes in fracture repair. Further study may shed new light on the differential patterning of mesencymal progenitor cells during fracture repair and the role *Hox* genes play in this process.

Cells Expressing Type 2 Collagen Are Self-renewing Multipotent Mesenchymal Progenitors during Postnatal Bone Development. Noriaki Ono*, Wanida Ono, Henry Kronenberg. Massachusetts General Hospital, USA

In skeletal development, matrix-producing osteoblasts and hematopoiesis-supporting stromal cells are constantly generated to drive bone growth. Although cells expressing osterix (Osx) in the embryonic perichondrium (PC) are implicated as the transient source of these cells, how they are replenished during postnatal bone development is not well understood. Type 2 collagen (Col2) is expressed by chondrocytes within and at the periphery of the growth cartilage adjacent to the PC. To test the hypothesis that Col2$^+$ cells are earlier progenitors upstream of Osx$^+$ cells, we first performed fate mapping using a Col2-cre recombinase that activates a Rosa26 tomato reporter. The majority of osteogenic perichondrial cells at embryonic day 13.5 (E13.5) were descendants of Col2$^+$ cells. Furthermore in postnatal bone, a great majority of osteocalcin (Oc)-GFP$^+$ osteoblasts and Cxcl12-GFP^{high} stromal cells were derived from Col2$^+$ cells. Second, to unravel the difference between Col2$^+$ and Osx$^+$ cells at specific points during embryogenesis, a pulse-chase experiment was conducted using an inducible cre recombinase (Col2-CreER, Osx-CreER) with a single tamoxifen injection. Col2$^+$ cells appeared earlier than Osx$^+$ cells, and only Col2$^+$ yielded a number of red cells at postnatal day 0 (P0) upon E11.5 injection. Next, the mice received tamoxifen at E13.5 and were analyzed a week later at birth. While initially present within the PC, Osx-descendants disappeared from newly generated PC. In contrast, although initially absent from the PC, Col2-descendants robustly contributed to the PC. The majority of Osx-descendants disappeared by P21. Third, to test whether postnatal Col2$^+$ cells also behave as early progenitors, the mice received tamoxifen at P3 and were chased for up to 6 months. Osx$^+$ cells gave rise to osteoblasts for the first month. However, as the chase extended, they disappeared from the metaphysis, while they became increasingly present as stromal cells in the diaphysis. In contrast, Col2$^+$ cells continued to yield osteoblasts for the entire chase period. The fraction of Col2-descendants among Oc-GFP$^+$ osteoblasts increased progressively from 4.3% to 46% during the first month of chase. Col2$^+$ cells also became Cxcl12^{high} stromal cells and adipocytes in bone marrow. These data indicate that both embryonic and postnatal Col2-expressing cells are self-renewing multipotent progenitors that continue to become chondrocyte, osteoblast and stromal lineage-cells during bone development.

Progenitor-Derived VEGFA Regulates the Fate and Population Dynamics of Osteoblast Precursor Cells in Bone Development and Maintenance. Agnes Berendsen*, Bjorn Olsen. Harvard School of Dental Medicine, USA

Vascular endothelial growth factor A (VEGFA) is expressed by multiple cell types in the skeleton and is most commonly known as an important regulator of angiogenesis. We previously reported a novel function for VEGFA in controlling the balance between osteoblast/adipocyte differentiation in osteoblast precursor cells. Here, we further uncovered the cellular and molecular mechanisms involved in the VEGF-dependent regulation of the fate and population dynamics of osteoblast precursor cells. Conditional deletion of *Vegfa* in osteolineage cells using the *Osx* promoter to drive expression of Cre recombinase resulted in a reduced size and thickness of the craniofacial as well as the long bones in mice at birth. This loss of bone mass progressively worsened with age and furthermore a dramatic increase in marrow fat was detected in bones of 6-week-old *Vegfa* CKO mice. Use of the Cre reporter transgene tdTomato revealed that the marrow adipocytes were derived from osterix-expressing progenitor cells, thus pointing towards cell autonomous mechanisms of VEGF-dependent control of cell fate. Conditional knockdown of VEGF receptor 2 in addition to knockdown of VEGFA in osterix-expressing progenitor cells further reduced the bone density in adult mice, confirming that VEGF signaling in progenitor cells is required for their differentiation into mature osteoblasts. Interestingly, reduced expression of VEGF receptor 2 in addition to VEGFA in progenitor cells did not affect the marrow fat content in bones of 6-week-old mice, suggesting differential VEGF-dependent molecular mechanisms controlling the differentiation into osteoblast and adipocyte cell lineages. Immunohistochemistry revealed that the number of osterix-expressing cells during vascular invasion into the primary ossification centers of developing bones was reduced in the limbs of *Vegfa*-CKO mice. As elegant pulse-chase studies recently demonstrated that the turnover of osteoblast progenitor cells and mature osteoblasts in bones is a highly dynamic process, our data therefore suggest that VEGFA is one of the key mediators in regulating the fate and dynamics of the osteoblast precursor cell population serving the demands of both development and maintenance of the skeleton.

Wnt5a and Wnt5b in osteoblastic niche differentially regulate HSC maintenance and differentiation. Jingjing Cao*, Yong Wan, Zhengju Yao, Xizhi Guo. Bio-X Institutes, Shanghai Jiao Tong University, China

The hematopoietic stem cells (HSC) are mostly maintained in the endosteal and vascular niche in bone marrow. Osteoblasts are key components of the endosteal niche for HSC. Recent studies have indicated that non-canonical Wnt signaling from N-cad^{+} osteoblasts maintains HSCs quiescence in the endosteal niche. However which non-canonical Wnt ligand from osteoblastic cells performs the role is still unknown. To address this question, we first blocked the Wnt secretion from osteoblasts through conditional inactivation of *Wntless* using *Col1 (3.6kb)-Cre*. We found that blocking Wnts from the osteoblasts resulted in higher proportion of HSC, impaired B cell development and increased percentage of myeloid cells in bone marrow. Our study showed that *Wnt5a* and *Wnt5b* were highly expressed in osteoblasts of the postnatal bones. When *Wnt5b* was overexpressed in osteoblasts by generating transgenic mice *Col1a1-Wnt5b*, the frequency and number of HSC were decreased in bone marrow while HSC subsequent differentiation was not disturbed compared to the control. In contrast, overexpression of *Wnt5a* in osteoblasts of transgenic mice *Col1a1-Wnt5a* led to defective B lymphopoiesis and augmented myeloid development. Although the HSC frequency was not changed in the *Col1a1-Wnt5a* mice, the absolute HSC number was decreased due to the decline of bone marrow cellularity. Taken together, these results indicate that non-canonical Wnts in osteoblasts are important in HSC maintenance and differentiation. Wnt5a prefers to regulate HSC differentiation including B lymphopoiesis and myeloid differentiation, and Wnt5b intends to regulate HSC maintenance rather than HSC differentiation.

Prediction of vertebral fracture by Trabecular Bone Score in elderly women of The Rotterdam Study. Biljana Atanasovska*[1], Ling Oei[2], Carolina Medina-Gomez[3], Natalia Campos[1], Karol Estrada[4], Albert Hofman[5], Berengere Aubry-rozier[6], Carola Zillikens[7], Andre Uitterlinden[8], Edwin Oei[9], Didier Hans[6], Fernando Rivadeneira[2]. [1]Erasmus MC, The Netherlands, [2]Erasmus University Medical Center, The Netherlands, [3]Erasmus Medical Center, The Netherlands, [4]Analytic & Translational Genetics Unit, Massachusetts General Hospital, USA, [5]Department of Epidemiology, Erasmus Medical Center, Netherlands, [6]Lausanne University Hospital, Switzerland, [7]Department of Internal Medicine, Department of Epidemiology, Netherlands, [8]Rm Ee 575, Genetic Laboratory, The Netherlands, [9]Department of Radiology, Netherlands

Aim: The trabecular bone score (TBS) reflects the microarchitecture of the vertebral bones and can be extracted from dual-energy X-ray absorptiometry (DXA) images of the lumbar spine. We aimed to examine the ability of TBS to predict the risk of prevalent and incident vertebral fracture in a large population based study of Dutch elderly women.

Methods: This study included a selection of 2760 women from the three Rotterdam Study cohorts (RS-I, RS-II and RS-III). DXA scans (GE-Lunar Prodigy, Madison) and BMD of the lumbar spine were measured in RS-I during the third follow-up (mean age 75.5 SD=6.0 years), in RS-II during the first follow-up (mean age 69.2 SD=7.4 years) and RS-III during the baseline visit (mean age 58.0 SD=7.1 years). TBS were calculated centrally by Lausanne University Center blinded to clinical parameters and outcomes using the TBS iNsight software (Medimaps, Pessac). Radiographic vertebral fractures were available for RS-I (McCloskey-Kanis; n=845, 53 cases) and RS-III (Optasia quantitative morphometry; n=1272, 221 cases). Incident clinical vertebral fractures occurring during follow-up (mean 3.0 SD 0.1 years) after DXA were extracted from computerized records of the general practitioners and hospital registries for RS-I (mean age 76.6 SD=5.4 years) and RS-II (mean age 69.2 SD=7,3 years) participants, (combined n=1484, 21 events). Logistic- and Cox-regression models corrected for age, height and weight were used to obtain risk estimates per SD decrease in TBS for prevalent and incident vertebral fractures, respectively.

Results: Correlation between TBS and LS-BMD was low (Pearson rho 0.25-0.30) across studies ($p<0.001$). Both TBS and BMD mean levels are significantly lower in fracture cases than non-cases ($P<0.05$). Lower TBS scores were associated with increased risk for prevalent vertebral fractures in both RS-I (OR 1.71 95%CI [1.29-2.27]; P=0.0002) and RS-III (OR 1.27 95%CI [1.08-1.48]; P=0.004), respectively per SD decrease. The combined analysis of incident vertebral fractures in RS-I and RS-II was also suggestive of increased risk per SD decrease in TBS score (HR 1.48 95%CI [0.96-2.29]; P=0.08). Adjustment for lumbar spine BMD did not affect the risk estimates.

Conclusion: Trabecular bone scores are strongly associated with prevalent vertebral fractures independent of BMD. Despite the borderline statistical significance our results are indicative of TBS being also predictive for incident vertebral fractures in women.

Assessment of Vertebral Fractures in Patients Older than 50 Years with a Recent Non Vertebral Fracture Before and After Introduction of Systematic Vertebral Fracture Assessment (VFA). Sandrine Bours*[1], Piet Geusens[2], Willem Lems[3], Robert Van der Velde[4], Tineke Van Geel[5], Joop Van Den Bergh[6]. [1]Maastricht University Medical Centre, The Netherlands, [2]University Hasselt, Belgium, [3]Vrije Universiteit Medical Centre, The Netherlands, [4]Viecuri MC, Netherlands, [5]Maastricht University, The Netherlands, [6]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands

Purpose: To compare the prevalence of vertebral fractures (VF) in patients evaluated at fracture liaison services (FLS) in the Netherlands because of a recent non-vertebral fracture, before and after the implementation of the new (2011) Dutch CBO guideline (1) for osteoporosis and fracture prevention.

Material and methods: This study was performed at the FLS of 3 hospitals in the Netherlands (VU MC Amsterdam, Maastricht UMC, VieCuri MC). DXA measure-

ments were performed at the lumbar spine and hip. Patients were classified according to the lowest value of T-score in total hip, femoral neck, or lumbar spine: osteoporosis as a T-score of -2.5 or less, osteopenia as a T-score between -2.5 and -1.0, and normal BMD as a T-score of -1.0 or higher. Non-vertebral fractures were classified according to Center in hip, major, minor and finger/toe fractures (2). Vertebral fractures were diagnosed using VFA (or spine X-ray) according to the method described by Genant (3). A VF was diagnosed if impression was > 20% at the anterior, mid or posterior location of the vertebral body.

Results: We evaluated 1400 patients, 730 pre- and 670 post-guideline (mean age 65.9 and 66.5 years; 71.6% and 73.6% women respectively). The percentage of patients with a normal BMD, osteopenia and osteoporosis were not significantly different (16.9%, 56.0%, 27.1% pre- and 18.2%, 51.6%, 30.2% post-guideline). Imaging of the spine increased from 16.5% in the pre- to 95.4% in the post-guideline group ($p<0.0001$). In the pre-guideline group, 8.4% had a VF and in 8.1% a VF could be excluded, in the post-guideline group, these percentages were 25.8% and 69.6% ($p<0.0001$). Of the fully assessed patients in the post-guideline group (n=639), 27.1% had one or more newly diagnosed VFs; 42.2% of the patients with a hip fracture, 34.1% with a major fracture, 23.0% with a minor fracture and 26.8% with finger/toe fractures. 33.2% of patients with osteoporosis had a VF, 26,6% of patients with osteopenia and 18.5% of patients with a normal BMD.

Conclusion: Overall, systematic implementation of VFA revealed a newly diagnosed VFs in 25% of all patients that present with a non-vertebral fracture at the FLS, which was significantly higher than before introduction of the guideline. VFs were more prevalent in patients with hip and major fractures and in patients with osteoporosis but were newly diagnosed in all subgroups, regardless of non-vertebral fracture classification or BMD result.

Differentiating Osteoporotic Vertebral Fractures from Scheuermann's Disease using Different Radiological Assessment Methods for Osteoporotic Vertebral Fractures: The Rotterdam Study. Ling Oei*[1], Stephan Breda[2], Guirong Jiang[3], Salih El Saddy[2], Ater Makurthou[2], Felisia Ly[2], Martha Castano-Betancourt[1], Albert Hofman[2], Erwin Waarsing[2], Dennis Black[4], John Schousboe[5], Frank van Rooij[2], Joyce Van Meurs[1], Andre Uitterlinden[6], Maria Zillikens[2], Fernando Rivadeneira[1], Edwin Oei[2]. [1]Erasmus University Medical Center, The Netherlands, [2]Erasmus MC, Netherlands, [3]University of Sheffield, United Kingdom, [4]University of California, San Francisco, USA, [5]Park Nicollet Clinic University of Minnesota, USA, [6]Rm Ee 575, Genetic Laboratory, The Netherlands

Osteoporotic vertebral fractures are a major health issue and should be diagnosed accurately. An important radiological differential diagnosis is Scheuermann's disease. The radiographic assessment of osteoporotic vertebral fractures with quantitative morphometry (QM) evaluates vertebral height loss and is unable to distinguish fractures from non-fracture deformities with vertebral height loss, such as Scheuermann's disease. In contrast, it is said that vertebral fracture assessment with the algorithm based qualitative (ABQ) method is able to systematically rule out non-fracture deformities. Our aim was to evaluate how ABQ and QM assessments perform on independently ascertained cases of radiological Scheuermann's disease. Two independent groups of trained research assistants applied the algorithm based qualitative (ABQ) or software-assisted QM (SpineAnalyzer® software to measure vertebral height ratios which includes Genant's classification of shape and severity of deformities). These methods for osteoporotic vertebral deformities were compared on cases of radiological Scheuermann's disease, which were diagnosed by an independent third reader group who applied the criteria by Sørensen and Sachs (three or more adjacent wedged vertebral bodies each of at least 5 degrees, endplate irregularities [including Schmorl's nodes] and thoracic kyphosis greater than 45 degrees). Complete data was available for 2,311 lateral spine radiographs (T4-L4) from the population-based Rotterdam Study (42.7% men, age 46-89). Radiographic Scheuermann's disease was present in 4.2% (95% CI: 3.4%-5.0%; n=96) of the sample. Of these participants with radiographic Scheuermann's disease, QM scored 71.9% (95% CI: 62.9%-80.9%; n=69) as having osteoporotic vertebral deformities, while ABQ classified only 8.3% (95% CI: 2.8%-13.8%; n=8) as having osteoporotic fractures. Although we cannot exclude that radiographic Scheuermann's disease and osteoporotic vertebral fractures may co-exist, general consensus is that radiographic Scheuermann's disease and osteoporotic vertebral fractures are two different entities that should be diagnosed differentially. In conclusion, accurate vertebral fractures diagnosis is needed to identify patients with high risk for future fractures to optimize patient management. The inability of QM to rule out non-fracture deformities explains in part the higher number of osteoporotic vertebral deformities misclassified when applying QM as scoring method compared to ABQ.

Incidence of and Risk Factors for Clinical Fractures in Patients with Systemic Lupus Erythematosus and Matched Controls: a Population-based Study in the United Kingdom. Irene Bultink*[1], Nicholas Harvey[2], Arief Lalmohamed[3], Cyrus Cooper[4], Willem Lems[5], Tjeerd Van Staa[6], Frank De Vries[7]. [1]VU University Medical Center, The Netherlands, [2]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [3]Division of Pharmacoepidemiology & Clinical Pharmacology, Utrecht University, Netherlands, [4]University of Southampton, United Kingdom, [5]Vrije Universiteit Medical Centre, The Netherlands, [6]Clinical Practice Research Datalink, United Kingdom, [7]Pharmacoepidemiology & Clinical Pharmacology, Utrecht University, Netherlands

Background: Systemic lupus erythematosus (SLE) has been associated with an increased risk of low bone mineral density and fractures. However, data on absolute fracture risk and risk factors associated with clinical fractures are very scarce.

Objective: To estimate incidence rates of clinical fractures in patients with SLE and relative risks compared with matched controls, and to evaluate risk factors associated with fractures in SLE.

Methods: We conducted a population-based cohort study using the Clinical Practice Research Datalink (from 1987 to 2012). Each SLE patient (n=4343) was matched with up to 6 controls (n=21780) by age and gender. Fracture type was stratified according to WHO definitions into osteoporotic fracture (clinical spine, hip, forearm, or humerus) and non-osteoporotic fracture. Cox proportional hazards models were used to calculate relative rates (RR) of fracture, and time interaction terms to evaluate fracture timing patterns. Incidence rates of fractures in SLE patients, stratified by age, gender, type of fracture, disease duration, and therapy variables, were compared with fracture rates in controls.

Results: Mean age was 46.7 years. Follow-up duration was 6.4 years in SLE patients and 6.6 years in matched controls. Overall, SLE patients had an increased risk of any fracture compared to controls, after adjustment for confounders (adj RR 1.22; 95% confidence interval (CI) 1.05-1.42, and the risk further increased with a longer disease duration. Glucocorticoid (GC) use in the previous six months raised the risk of any fracture (adj RR 1.27; 95% CI 1.02-1.58), but was not further increased with higher cumulative GC exposure. A similar pattern was found for osteoporotic fracture, but did not reach statistical significance (adj RR 1.23; 95% CI 0.91-1.67). Cerebrovascular events, seizures, and (as expected) previous osteoporotic fractures were identified as significant predictors for any and osteoporotic fractures (table 1).

Conclusions: SLE patients in the United Kingdom have an increased risk of clinical fractures compared to age- and sex-matched controls. GC use in the previous six months and longer disease duration are important factors associated with the increased fracture risk in SLE. In addition, special attention should be paid to lupus patients with neuropsychiatric organ damage or a history of osteoporotic fractures since these subgroups of patients are at high risk of the occurrence of (subsequent) fractures.

Table 1. Risk of fracture within SLE patients (n=4343), stratified according to organ damage. (reference = no risk factor)

	Any fracture		Osteoporotic fracture	
	Events	Adj RR (95% CI)*	Events	Adj RR (95% CI)*
Cognitive impairment	5	1.67 (0.68-4.08)	4	2.25 (0.82-6.16)
Seizures	34	**2.01 (1.41-2.86)**	22	**2.81 (1.80-4.40)**
Cerebrovascular event	55	**1.49 (1.12-2.00)**	35	**1.77 (1.22-2.57)**
Renal disease	54	1.30 (0.96-1.75)	32	1.35 (0.91-2.00)
Previous osteoporotic fracture	172	**4.26 (3.49-5.18)**	95	**3.85 (2.92-5.07)**
Diabetes	21	1.39 (0.89-2.17)	11	1.33 (0.72-2.45)
Malignancy	50	1.23 (0.91-1.68)	28	1.22 (0.81-1.84)

*Adjusted for: previous fracture, use of glucocorticoids, antimalarials, calcium/vitamin D supplements, benzodiazepines, and proton pump inhibitors in the previous 6 months.

β-adrenergic Receptor Antagonists and Fracture Risk: A Meta-analysis of Selectivity, Dose, Gender and Site-specific Effects. Konstantinos Toulis*[1], Karla Hemming[2], Stavros Stergianos[3], Krishnarajah Nirantharakumar[2], John Bilezikian[4]. [1]Aristotle University OF Thessaloniki, Greece, [2]Department of Public Health, Epidemiology & Biostatistics, University of Birmingham, Birmingham, UK, United Kingdom, [3]Department of Internal Medicine, Sundsvall Hospital, Sweden, [4]Columbia University College of Physicians & Surgeons, USA

Aim: To determine by meta-analysiswhether β-adrenergic blockers (βBs) reduce fracture risk and whether the effect, if demonstrable, is dependent upon selectivity, dose, gender, or fracture site.

Methods: A literature search was performed in electronic databases MEDKINE, EMBASE and reference sections of relevant articles to identify eligible studies. Adjusted estimates of fracture risk (ES) were pooled across studies using fixed or random-effects (RE) meta-analysis as appropriate. Dose-related effects were evaluated using meta-regression. To explore the relative efficacy of β1-selective blockers in comparison to non-selective βBs, adjusted indirect comparison was performed.

Results: A total of sixteen studies (seven cohort and nine case-control studies), involving 1,644,570 subjects, were identified. The risk of any fracture was found to be significantly reduced in subjects receiving βBs as compared to control subjects (16 studies, RE pooled effect size (ES) = 0.86, 95% CI: 0.78 - 0.93, I^2 = 87%). In a sensitivity analysis limited to those studies deemed to be most robust, the βB effect to reduce fracture risk was sustained (4 studies, pooled ES = 0.79, 95% CI: 0.67 - 0.94, I^2 = 96%). The risk of a hip fracture was lower in both women and men receiving βBs [women: pooled ES = 0.86, 95% CI: 0.80 - 0.91, I^2 = 1 % and men: pooled ES = 0.80, 95% CI: 0.71 - 0.90, I^2 = 0%). Similar risk reductions were found for clinical vertebral and forearm fractures, although statistical significance was not reached. The reduction in risk did not appear to be dose-related (test for a linear trend *p*-value: 0.150). Using adjusted indirect comparisons, it was estimated that β1-selective agents were significantly more effective than non-selective βBs in reducing the risk of any fracture (6 studies, β1-selective blockers versus non-selective βBs: RE pooled ES = 0.82, 95% CI = 0.69 - 0.97).

Conclusions: The findings suggest thatthe risk of fracture is approximately 15% lower in patients treated with βBs compared to controls independent of gender, fracture site, and dose. This risk reduction might be attributable to the effects of β1-selective blockers. Assuming that the lifetime risk of any osteoporotic fracture at the age of 50 is approximately 30%, 1 osteoporotic fracture would have been prevented with every 30 patients treated with βBs.

Aging Alters Bone-Fat Reciprocity and MPC Engraftment In Vivo. Lakshman Singh, Elizabeth Russell, Jung-Hoon Kim, Qijun Chen, Frederick Johnson, Robert Pignolo*. University of Pennsylvania, USA

Bone marrow derived mesenchymal progenitor cells (MPCs) play an important role in bone homeostasis. Age-related changes occur in bone resulting in a decrease in bone density and a relative increase in adipocity. Although *in vitro* studies suggest the existence of an age-related lineage switch between osteogenic and adipogenic fates, stem cell and microenvironmental contributions to this process have not been elucidated *in vivo*. In order to study the effects of MPC and microenvironmental aging on functional engraftment and lineage switching, bone marrow transplantation (BMT) was performed under non-myeloablative conditions in young and old recipients, with donor MPCs derived from young and old green fluorescent protein (GFP) transgenic mice. Our results from syngeneic transplantations show that engraftment of MPCs was primarily a function of cell intrinsic aging. Robust engraftment by young MPCs was observed in the marrow, bone-lining region and in the matrix of young recipients. No engraftment, however, was observed in young recipients transplanted with MPCs derived from old GFP transgenic mice and significantly lower engraftment was seen at the same sites in old recipients transplanted with old MPCs. The absence of engraftment observed in old into young transplants was mitigated by myeloablation with concomitant reversal of splenic sequestration, resulting in engraftment of old MPCs in as little as 4 hours post-transplantation. Differentiation of transplanted MPCs strongly favored adipogenesis over osteogenesis in old recipients irrespective of MPC donor age, suggesting that microenvironmental alterations that occur with aging in vivo are predominately responsible for MPC lineage switching. These data indicate that aging alters bone-fat reciprocity and engraftment of mesenchymal progenitors, with important implications for the treatment of age-related osteoporosis as well as transplant biology.

Alleviation of Radiotherapy-Induced Bone Loss by Parathyroid Hormone Treatment is Associated with Improved DNA Repair in Osteoblasts. Abhishek Chandra*[1], Tiao Lin[1], Ji Zhu[2], Beom Huh[1], Allison Altman[1], Sarah Hagan[1], Keith Cengel[1], Xiaowei Liu[1], Ling Qin[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, School of Medicine, USA

Radiation damage to tumor-adjacent bones is a well-recognized late effect of radiotherapy, resulting in a spectrum of bone changes from mild osteopenia to osteoradionecrosis. Since radiation primarily causes bone atrophy, we propose that PTH, an anabolic agent for bone formation, should preserve bone structure and strength against radiation damage. In this study, 3-month-old rats were focally irradiated at the proximal metaphyseal region of right tibiae by a unique SARRP irradiator that replicates clinical focal radiotherapy with an accuracy of 1 mm resolution(8 Gy at day 1 and 3), designed to mimic the dose to the hip during hypofractionized radiation protocols for prostate cancer. Rats were then administered daily with vehicle (n=9) or PTH(1-34, 60 μg/kg, n=9) for 4 weeks. μCT scans revealed a significant 20% decrease in trabecular bone volume (BV) in irradiated tibiae compared to the contralateral tibiae in the vehicle group, mainly due to a 17% decrease in trabecular number (Tb.N). 3D registration of μCT images before and after radiation confirms that some trabecular elements were lost after radiation while almost all elements were preserved and thickened after 4 weeks in non-irradiated tibiae. Finite element analysis indicates that this microstructural deterioration resulted in a 57% decrease in trabecular bone stiffness. Conversely, PTH injections remarkably increased BV,Tb.N, and stiffness in both non-irradiated and irradiated trabecular bone to a similar level and preserved all trabecular elements in the irradiated bone. Histological analysis indicates that radiation caused apoptosis in osteoblasts, leading to 70% fewer viable and functional osteoblasts on the trabecular bone surface compared to the non-irradiated control, while PTH injections increased their number and protected them from cell death. In vitro experiments replicated in vivo observations that a single dose (8 Gy) of X-ray radiation resulted in an 18% apoptotic rate in osteoblastic cells after 2 days and that PTH treatment abolished this deleterious effect via a beta-catenin-dependent pathway. PTH did not affect the production of reactive oxygen species (ROS) by radiation. Using a gamma-H2AX foci assay that detects DNA double-stranded breaks (DSBs), we demonstrate that PTH promotes DSB repair in osteoblasts. Taken together, our data demonstrate a strong radioprotective effect of PTH on bone integrity and a novel role of PTH in regulating DSB repair machinery and chromatin remodeling.

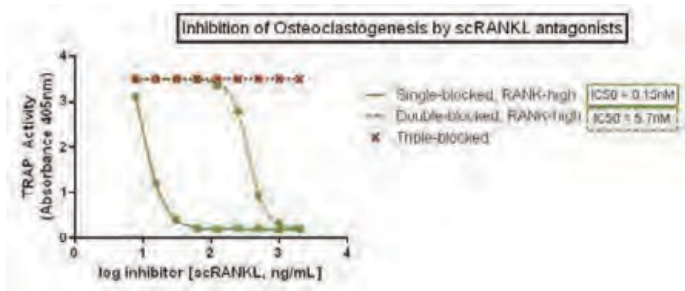
Manipulation of RANK monomer assembly as a novel anti-resorptive strategy. Julia Warren*[1], Christopher Nelson[2], Lawrence Yu[2], Daved Fremont[2], Steven Teitelbaum[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University in St. Louis, USA

The interaction of receptor activator of NF-kB ligand (RANKL) with its receptor RANK is essential for the differentiation and function osteoclasts (OCs). RANKL exists as a homotrimer, with classical models of receptor activation assuming trimeric clustering of receptor as necessary for signal transduction. We have designed a novel single-chain RANKL (scRANKL) construct to test the assumption that trimeric clustering of RANK is necessary for downstream signaling, and to function as a competitive antagonist of this pathway. scRANKL consists of all three RANKL monomers connected by short protease-resistant linkers, enabling individual manipulation of each RANK binding site and assessment of the receptor clustering state necessary for downstream signaling. We used our co-crystal structure of RANK/RANKL to design mutations in RANKL that abolish binding to RANK. After inserting these variants at one scRANKL site, to create a single-blocked ligand capable of recruiting only two RANK receptors, we still observe OC formation, although only at high ligand concentration. In contrast, double-blocked scRANKL does not form OCs. Hence, dimeric engagement of RANKL by RANK is sufficient and necessary for downstream signaling in the OC. Although double-blocked scRANKL may potentially antogonize RANK/RANKL signaling, it competes poorly with endogenous RANKL due to loss of receptor avidity. Therefore, we identified mutations in RANKL, using yeast surface display, that dramatically increase its affinity for RANK. Concurrently, we sorted for loss of binding to OPG, the RANKL endogenous decoy receptor, with the hypothesis that this trait would allow scRANKL to more efficiently function as a competitive antagonist, in vivo. When inserted at the intact RANK binding sites in single- or double-blocked scRANKL (termed "single-blocked, RANK-high" or "double-blocked, RANK-high"), these novel constructs are highly efficient competitive antagonists of wild-type RANKL-induced osteoclastogenesis. Our work demonstrates that the manipulation of RANK receptor oligomerization, and the subsequent blockade in signaling, may provide a novel avenue to develop anti-resorptive drugs. Additionally, the design of single-chain TNFSF ligands with individually manipulated receptor binding sites can more broadly inform our knowledge of how these receptors, with diverse biological functions, initiate signal transduction.



Inhibition of Osteoclastogenesis by scRANKL Antagonists

WNT16 is a Novel Osteoblast-Derived Paracrine Regulator of Osteoclastogenesis, Cortical Bone Mass and Fracture Susceptibility. Sofia Moverare Skrtic*[1], Petra Henning[2], Anna Börjesson[2], Klara Sjögren[2], Sara Windahl[3], Hanna Isaksson[4], Emma Eriksson[5], Farasat Zaman[5], Lars Sävendahl[6], Ulf Lerner[7], Claes Ohlsson[1]. [1]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [2]Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [3]Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, [4]Division of Solid Mechanics, & Department of Orthopedics, Lund University, Lund, Sweden, [5]Karolinska Institutet, Sweden, [6]Department of Women's & Children's Health, Karolinska Institutet, Pediatric Endocrinology Unit, Stockholm, Sweden, [7]University of Umea, Sweden

We have previously identified a missense variant in the *WNT16* gene associated with cortical bone thickness and forearm fracture risk in humans. To determine the mechanisms of action for WNT16 in the regulation of cortical bone mass, *Wnt16*$^{-/-}$ mice were evaluated. Although *Wnt16*$^{-/-}$ mice were born healthy, 46% exhibited spontaneous tibia diaphyseal fractures before 11 weeks of age.

Computed tomography (CT) analyses of tibia revealed a pronounced reduction of cortical volumetric BMD (-21.4 $\pm$ 1.2%, $P < 0.01$) and cortical bone thickness (-13.1 $\pm$ 1.9%, $P < 0.01$) in *Wnt16*$^{-/-}$ mice compared to wild type (WT) mice. Analysis of cortical bone composition using Fourier Transform Infrared Spectroscopy demonstrated reduced mineral to matrix ratio (-18.6 $\pm$ 4.0%, $P < 0.01$) and collagen maturity (-7.3 $\pm$ 2.3%, $P < 0.05$). In contrast, the trabecular bone volume (BV/TV) as analyzed by μCT was normal in *Wnt16*$^{-/-}$ mice. *Wnt16* mRNA measurements and immunohistochemistry of WT mice revealed abundant and specific WNT16 expression in cortical bone. Primary cultured osteoblasts, but not osteoclasts, expressed high *Wnt16* mRNA levels.

Cell cultures isolated from *Wnt16*$^{-/-}$ mice did not show any major differences in osteoblast differentiation, nor was RANKL induced osteoclastogenesis in bone marrow macrophages from *Wnt16*$^{-/-}$ mice affected, suggesting that WNT16 does not exert cell autonomous effects. Importantly, recombinant WNT16 protein dose-dependently inhibited RANKL induced osteoclastogenesis associated with decreased mRNA levels of the osteoclast specific genes *Acp5, Ctsk* and *Nfatc1* and decreased bone resorption measured by CTX release. These findings are consistent with that the number of osteoclasts was increased in the cortical bone of *Wnt16*$^{-/-}$ mice ($P < 0.01$).

Endogenous *Wnt16* mRNA levels in calvarial osteoblasts were increased by Oncostatin M (+273 $\pm$ 61%, $P < 0.01$). Oncostatin M induced osteoclastogenesis in co-cultures of calvarial osteoblasts and bone marrow macrophages was enhanced when the osteoblast were from *Wnt16*$^{-/-}$ mice, suggesting that WNT16 is involved in a negative feed-back loop of Oncostatin M induced osteoclastogenesis.In conclusion, WNT16 is a novel osteoblast-derived regulator of osteoclastogenesis, cortical bone mass and fracture susceptibility. We propose that WNT16 is expressed by osteoblasts in cortical bone and is a crucial regulator of cortical bone mass, and thereby fracture susceptibility, acting as a paracrine inhibitor of osteoclastogenesis.

Treatment With Anti-sclerostin Antibody Restores Endosteal Osteoblasts in Osteocyte-specific Gsα-KO Mice. Keertik Fulzele*[1], Christopher Dedic[2], Xiaolong Liu[2], Paola Divieti Pajevic[1]. [1]Massachusetts General Hospital; Harvard Medical School, USA, [2]Endocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA

Intermittent PTH and sclerostin antibodies are potent anabolic agents for osteoporosis treatment, both of which increase osteoblasts numbers to build new bone. How the new osteoblasts are recruited in response to these treatments is not clear. Previously, in-vivo lineage tracing experiments showed that intermittent PTH administration increases osteoblast numbers by converting bone lining cells (BLC) into mature osteoblasts (JBMR; 27(10):2075–84). Histological analysis of mice lacking the stimulatory subunit of G-proteins (Gsα) in osteocytes (DMP1-GsαKO), unexpectedly revealed lack of endosteal osteoblast (endo-OB) those could be observed under light microscope. Gsα-deficient osteocytes also showed a dramatic increase in sclerostin expression as assessed by quantitative PCR and immunohistochemistry. Because PTH is a potent suppressor of sclerostin expression and can also convert BLC into mature osteoblasts, we hypothesized that treatment with anti-sclerostin antibody may restore the endo-OB in the mutant mice. To confirm the contribution of Gsα signaling in osteocytes in the maintenance of endo-OB, we also generated mice lacking Gsα in mature osteoblasts using osteocalcin-Cre (OC-GsαKO). OC-GsαKO mice also showed increased sclerostin expression in osteocytes. Interestingly endo-OB were present in OC-GsαKO mice but were fewer, thinner, and disorganized as compared to control littermates. Taken together this data indicated that Gsα signaling in osteocytes plays an important role in the maintenance of endo-OB. We next treated DMP1-GsαKO and control mice with anti-sclerostin antibody (25 mg/kg, 2 times per week) for 4-weeks. Upon the antibody treatment, the endo-OB reappeared in the DMP1-GsαKO mice to a comparable level to that of the vehicle treated control littermates. In control mice, E11/gp38 positive osteocytes were observed in parallel with the endo-OB with higher dendrite density towards the endo-OB. In DMP1-GsαKO mice, E11/gp38 positive osteocytes were lacking dendrites and were randomly scattered throughout the bone matrix. After treatment with anti-sclerostin antibody, DMP1-GsαKO mice showed increased E11/gp38 positive osteocytes near the endosteal bone surface and endo-OB. However, whether the appearance of E11/gp38 positive osteocytes is a cause or effect of appearance of endo-OB is not clear. Taken together, this data suggest that young osteocytes regulate endo-OB, at least in part, by secretion of sclerostin.

GATA4 Regulates Bone Mineralization Via Estrogen Receptor-Dependent and -Independent Pathways. Alejandro Garcia*[1], Miriam Guemes[2], Stephanie Runke[2], Diana Rigueur[2], Gustavo Miranda-Carboni[2], Karen Lyons[1], Susan Krum[2]. [1]University of California, Los Angeles, USA, [2]UCLA, USA

Osteoporosis is a disease characterized by low bone mass that leads to an increased risk of fragility fractures. The biggest risk factor for osteoporosis is being a post-menopausal woman. Estrogens play a role in almost all cells and tissues in the body, but how tissue specificity occurs is largely unknown. We have identified GATA4 as a transcription factor expressed in osteoblasts and recruited to estrogen receptor alpha (ERα) binding sites near osteoblast-specific genes that control differentiation and tissue specificity. GATA4 binding precedes that of ERα and is necessary for histone modifications associated with recruitment of ERα to binding sites. Bone mineralization decreases in calvarial osteoblasts following GATA4 knockdown are both dependent and independent of 17β-estradiol (E2*)* activity. Microarray analysis, followed by qPCR and immunoblots, of wildtype vs. GATA4 knockdown showed that GATA4 regulates TGFβ and BMP signaling. GATA4 knockdown decreases the expression of BMPs -3, -4, and -6 and R-SMADs -3 and -5, proteins known to induce osteoblast differentiation. Furthermore, there is an increase in I-SMAD expression, especially Smad6. In the absence of GATA4, TGF-β signaling, which has been shown to inhibit expression of bone-specific genes, is increased. *In vivo* deletion of GATA4, driven by Cre-recombinase in osteoblasts (Col2.3-Cre, 2.3 kb fragment of the rat Col1a1 gene) results in low birth weight, stunted intrauterine long bone growth and perinatal lethality. Taken together, the data support that GATA4 has both E2-dependant and independent effects regulating osteoblast function and bone development. Understanding of the role of GATA4 to regulate the tissue specificity of estrogen-mediated osteoblast gene regulation and estrogen-independent bone differentiation may help in therapeutics of post-menopausal osteoporosis.

Glucocorticoids Stimulate Osteocyte Autophagy in Mice but Suppression of Autophagy in Osteocytes does not Accentuate their Negative Impact on the Skeleton. Marilina Piemontese*[1], Melda Onal[2], Jinhu Xiong[3], Yiying Wang[1], Rajamani Selvam[1], Stuart Berryhill[1], Li Han[3], Erin Hogan[1], Robert Weinstein[3], Stavros Manolagas[3], Charles O'Brien[3]. [1]University of Arkansas for Medical Sciences, USA, [2]university of wisconsin, USA, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Glucocorticoid excess decreases bone mass and strength but the mechanisms remain unclear. Autophagy is a lysosome-based recycling pathway that promotes the turnover of cellular components and can promote cell survival under stressful conditions. Recent studies have shown that glucocorticoids stimulate autophagy in an osteocytic cell line. These studies suggest the possibility that autophagy may oppose the negative actions of glucocorticoids on osteocytes and that in the absence of autophagy, the impact of glucocorticoids on the skeleton might be increased. To address this possibility, 6-month-old mice lacking the Atg7 gene, which is essential for autophagy, specifically in osteocytes (Dmp1-Cre;Atg7f/f) and their control littermates (Atg7f/f) were implanted with pellets releasing vehicle or prednisolone and examined after 28 days. Prednisolone elevated conversion of LC3 form I to form II in osteocyte-enriched cortical bone of Atg7f/f mice, demonstrating that glucocorticoids stimulate autophagic flux in osteocytes in vivo. However, prednisolone did not stimulate LC3 conversion in cortical bone in Dmp1-Cre;Atg7f/f mice, confirming suppression of autophagy in the osteocytes of these mice. Comparison of the vehicle treated groups revealed that suppression of autophagy in osteocytes reduced cortical bone thickness, cancellous bone volume, osteoblast number, and osteoclast number but increased cortical bone porosity as well as oxidative stress in the bone microenvironment. In Atg7f/f mice, prednisolone reduced femoral cortical thickness, increased cortical porosity, reduced bone strength, reduced osteoblast number and increased oxidative stress. Similar changes were observed in Dmp1-Cre;Atg7f/f mice with the exception that prednisolone did not reduce osteoblast number, which was already reduced by Atg7deletion. Similarly, prednisolone reduced the bone formation rate in Atg7f/f mice, but not in Dmp1-Cre;Atg7f/f mice, which already displayed a significant reduction in this parameter. Taken together, these results demonstrate that although glucocorticoids stimulate autophagy in osteocytes, suppression of autophagy in this cell type does not accentuate the negative impact of glucocorticoids on the skeleton. Thus stimulation of autophagy in osteocytes does not appear to be an important defense mechanism opposing the negative effects of glucocorticoids on the skeleton.

Effects of Age on Molecular Pathways Regulating Bone Formation in Humans: A Key Role for Notch and Rorβ Signaling. Matthew Roforth*[1], Koji Fujita[1], Ulrike McGregor[2], Salman Kirmani[1], Louise McCready[1], James Peterson[1], Matthew Drake[3], David Monroe[4], Sundeep Khosla[5]. [1]Mayo Clinic, USA, [2]King's College, London UK, United Kingdom, [3]College of Medicine, Mayo Clinic, USA, [4]Mayo Foundation, USA, [5]Mayo Clinic College of Medicine, USA

Despite extensive studies in mice, there is currently little information on the molecular pathways contributing to age-related bone loss in humans. In part, this stems from the difficulty of obtaining trephine bone biopsies (~5-7 mm diameter) in normal volunteers. Thus, we used the standard clinical approach hematologists employ for bone marrow aspirates and biopsies to obtain needle biopsies (1-2 mm diameter) from the posterior iliac crest in 20 young (30±5 yr) and 20 old (73±7 yr) women. We coupled this to customized, in-house QPCR analyses of 288 genes related to bone metabolism, including genes reflecting 17 pre-specified clusters/pathways (e.g., Wnt targets) and 71 genes linked to SNPs from GWAS studies (Nat Genet 44:491, 2012). Genes in pre-specified pathways were analyzed using a cluster analysis (O'Brien Umbrella Test) which tests for concordant changes in multiple genes in the pathway.

One of the most highly upregulated pathways in the old women was Notch (P = 0.003), which is known to modulate age-related bone loss in mice (Nat Med 14:306, 2008). Individual significant (P<0.05) gene changes in this pathway were *hes1* (1.6x), *hey1* (1.8x), *heyL* (1.5x), and *Jag1* (1.2x). In addition, recent studies have identified retinoic acid receptor-related orphan receptor β (*Rorβ*) as an important regulator of osteogenesis that is markedly upregulated in bone marrow mesenchymal cells from aged versus young mice (JBMR 27:891, 2012). *Rorβ* itself (1.6x) as well as multiple *Rorβ* target genes (P = 0.001 for the pathway) were also upregulated in the biopsies from the old women. Both Notch and Rorβ signaling inhibit runx2 activity, thereby potentially blocking osteoblast differentiation. Interestingly, a panel of stem cell markers was significantly upregulated with aging (P = 0.022), including *nestin* (2.0x), *CD146* (1.4x), and *nanog* (1.3x), suggesting that activation of Notch and Rorβ signaling may result in a block in osteoblast differentiation with resultant expansion of the stem cell pool within bone.Of the 71 GWAS genes, 11 were significantly altered with aging, most notably *mmp7* (4.0x). Other individual gene changes of interest with aging included *rankl* (1.6x) and *fgf23* (2.0x).In summary, we describe a novel approach coupling needle biopsies of bone to customized QPCR analyses to study genes/pathways regulating bone metabolism in humans. Our work validates, in humans, several pathways associated with age-related bone loss in mice, including Notch and Rorβ signaling.

Low trunk muscle density is associated with prevalent vertebral fractures in older adults. Dennis Anderson*[1], Brett Allaire[1], Alexander Bruno[2], Serkalem Demissie[3], Douglas Kiel[4], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]Harvard-MIT, USA, [3]Boston University School of Public Health, USA, [4]Hebrew SeniorLife, USA

Low x-ray attenuation (low density) of muscles in CT scans, indicative of fat accumulation within muscle, has been associated with reduced strength and physical performance in older adults. In addition, low density of the trunk muscles is associated with increased prevalence of back pain and increased hyperkyphosis, while low density of the thigh muscles is associated with increased risk of incident hip and non-vertebral fractures, independent of BMD. However, the association of muscle density with vertebral fractures (VF) has not been previously examined.

To test whether density of the trunk muscles is associated with prevalent VF we conducted a cross-sectional study of 267 subjects (44 with moderate/severe prevalent VF, 223 with no VF) ⩾50 years old from the community-based Framingham Heart Study CT cohort. Muscle density (in Hounsfield Units) was determined from axial CT scans at the L3 level of the spine. Logistic regression models were performed to determine the associations between prevalent VF and muscle density, adjusting for age, sex and vertebral body integral vBMD. Odds ratios for VF were calculated for overall muscle density (weighted average of all muscles), and for specific muscle groups.

Cases with prevalent VF were similar in age to controls without VF (68.3±9.7 vs. 66.2±10.1 yr, p=0.209), but had lower vertebral vBMD (0.130±0.040 vs. 0.163±0.044 g/cm^3, p<0.001) and lower overall trunk muscle density (34.3±9.5 vs. 39.4±8.2 HU, p=0.003). After adjusting for age, sex, and BMD, 1 SD lower trunk muscle density was associated with more than double the odds for prevalent VF (Table). When examined individually, lower density of the rectus abdominis, latissimus dorsi and external oblique muscle groups were associated with prevalent VF (p<0.05), while lower density of erector spinae and multifidus did not achieve significance (p<0.10).

Low trunk muscle density is associated with prevalent VF, independent of age, sex and BMD. Overall muscle density had the strongest association, while some muscle groups had weaker associations, which may indicate that VF is associated with a general loss of muscle quality or function rather than declines in a specific muscle group. These results, in conjunction with previous reports that low muscle density is an independent risk factor for incident non-vertebral fractures, provide strong motivation for future studies examining the contribution of trunk muscle density to the risk of incident VF.

Table. Association between muscle density at L3 and prevalent VF, expressed as odds ratio per 1SD reduction, adjusted for age, sex and vertebral BMD.

	OR (95% CI)	p-value
Overall Muscle Density (All Muscles Combined)	2.16 (1.23-3.99)	**0.009**
Rectus Abdominis	1.69 (1.04-2.77)	**0.034**
Latissimus Dorsi	2.08 (1.39-3.19)	**<0.001**
External Oblique	1.64 (1.08-2.54)	**0.023**
Erector Spinae	1.49 (0.99-2.24)	0.054

Protein Intake is Protective Against Grip Strength Loss in Adults: The Framingham Osteoporosis Study. Kelsey Mangano*[1], Robert McLean[2], Marian Hannan[3], Douglas Kiel[4], Virginia Casey[4], Shivani Sahni[2]. [1]Institute for Aging Research, Hebrew SeniorLife, Harvard Medical School, USA, [2]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [3]HSL Institute for Aging Research & Harvard Medical School, USA, [4]Hebrew SeniorLife, USA

Rationale: Muscle function is progressively lost with aging and has been linked to unfavorable health outcomes. Previously, dietary protein intakes were associated with improved lean muscle mass; however, the role of protein with muscle strength remains unclear. Further, the relation between type of dietary protein and muscle function has yet to be elucidated. Objective: To determine the longitudinal associations of types of dietary protein with grip strength among Framingham Offspring participants. Methods: Grip strength (kg) was measured by isometric hand dynamometer (3 trials/hand) and the maximum value across trials was used at baseline (1999-2002) and at follow-up (2005-2007) among 1,564 men and women. Longitudinal change in grip strength, presented as % change per year, was calculated from baseline to follow-up. Usual intakes (g/d) of total, animal and plant protein were assessed in 1995-98 via food frequency questionnaire. Multivariable linear regression was used to assess the association of dietary protein (energy adjusted; residual method) with change in grip strength. Least squares-adjusted mean strength was calculated for quartiles of energy-adjusted protein intake and linear trend was tested. Models were adjusted for baseline age, sex, height, BMI, health status (self-reported: excellent, good, fair; poor), physical activity (PASE) menopause status (>1y post-menopausal y/n), baseline grip strength (kg) and total energy intake (kcal/d). Animal and plant protein were adjusted for each other. Results: Mean age was 59.5±9.3y (range 29-86). Mean protein intakes (g/d) were 79±28 (total), 55±23 (animal) and 24±9 (plant); mean baseline grip strength was 32.6 ± 12.7kg. Average follow up was 5.8±1.1y; mean grip strength loss was -0.08±6.0% per year (absolute change: -0.3±1.6kg/y). A positive association between dietary protein and % change grip strength was observed for all dietary protein types (total protein: β=0.020, p=0.03; animal protein: β=0.019, p=0.04; plant protein: β=0.089, p=0.002); where for 1g greater intake of total protein grip strength increased 0.65kg per year. Similar protective trends were observed with protein quartiles; however, only results for plant protein reached statistical significance (Figure). Conclusions: Similar protective patterns were observed across type of dietary protein with change in grip strength. These results suggest greater intake of dietary protein may be beneficial in preventing muscle strength loss over time.

Exercise During Growth as an Independent Predictor of Cortical Bone Size and Strength in Older Swedish Men. Martin Nilsson*[1], Claes Ohlsson[1], Magnus Karlsson[2], Dan Mellstrom[3], Mattias Lorentzon[4]. [1]Centre for Bone & Arthritis Research At the Sahlgrenska Academy, Sweden, [2]Skåne University Hospital Malmö, Lund University, Sweden, [3]Sahlgrenska University Hospital, Sweden, [4]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden

Purpose: We have previously reported an association between exercises during youth and increased areal bone mineral density in older men (Nilsson, M. et al. Ost. Int. Nov, 2008). The aim of this study was to investigate if exercise during growth was associated with cortical bone geometry and whole bone strength in weight-bearing bone in older men.

Methods: Cortical bone geometry at the tibia and radius was measured by peripheral quantitative computed tomography (pQCT) (XCT-2000, Stratec), whereas finite element analysis of the ultra distal tibia and radius was performed, using measurements from a high-resolution 3D pQCT device (XtremeCT, Scanco). The study was performed in 600 men, 79.9 ± 3.4 (mean ± SD) years old, from the Gothenburg part of the MrOS Sweden five-year follow-up study. A standardized questionnaire was used to collect information about previous and current exercise.

Results: A linear regression model (including age, height, weight, calcium intake, smoking, levels of exercise during growth, and current exercise) revealed that levels of exercise during growth (10-20 years) was independently associated with periosteal circumference (β=0.09, $p<0.01$), cortical thickness (β=0.15, $p<0.001$) at the tibia and total bone strength (estimated ultimate failure load (β=0.13, $p<0.01$) and stiffness (β=0.13, $p<0.01$)) at the ultra distal tibia. Current exercise was independently associated with endosteal circumference (β=-0.11, $p<0.01$), cortical thickness (β=0.13, $p<0.01$) at the tibia and total bone strength (estimated ultimate failure load (β=0.09, $p<0.05$) and stiffness (β=0.09, $p<0.05$)) at the ultra distal tibia. Current or previous exercise was not associated with the corresponding measurements at the radius.

Conclusion: In this large cohort of elderly men, exercise during growth was independently associated with larger periosteal circumference, and higher bone strength, whereas current exercise was independently associated with lower endosteal contraction and bone strength at the tibia. These findings indicate that exercise during growth can increase the cortical bone size via periosteal expansion while exercise at old age can decrease endosteal bone loss in weight-bearing bone in older men.

FR0023

Long-term Exercise Intervention in Older Adults: 4-Year Follow-up of a Randomized Controlled Trial of Music-Based Multitask Training (Jaques-Dalcroze Eurhythmics). Andrea Trombetti*, Mélany Hars, François Herrmann, René Rizzoli. Division of Bone Diseases, Geneva University Hospitals & Faculty of Medicine, Switzerland

Long-term prospective controlled data supporting the efficacy of exercise to prevent physical decline in old age are scarce. In a 1-year randomized controlled trial [1], we showed that a 6-month music-based multitask exercise program (i.e., Jaques-Dalcroze eurhythmics) improved gait and balance, and reduced falls in older adults. We conducted a 4-year extension of this trial aimed at assessing the effects of long-term practice of the multitask exercise regimen.

We planned a long-term follow-up extension of a 1-year randomized controlled trial in which 134 community-dwellers aged ⩾65 years at increased risk of falls received an immediate or a delayed 6-month music-based multitask exercise program, with outcomes assessed at baseline, 6-month, and 1-year. Four years following original trial enrolment, 52 subjects (baseline mean ± SD age, 75 ± 8 years) who i) have maintained exercise program participation through the 4-year follow-up visit (long-term "intervention group", n=23) or ii) have discontinued participation following original trial completion ("control group", n=29) were studied. They were reassessed in a blind fashion, using the same procedures.

At 4 years, linear mixed-effects models showed significant gait (gait speed, P=0.006) and balance (unipodal stance time, P=0.015) improvements in the intervention group, compared with the control group. Also, intervention subjects did better on Timed Up & Go, Five-Times-Sit-to-Stand and hand grip strength tests, than controls ($P<0.05$, for all comparisons). Furthermore, the exercise program had a protective effect on falls (relative risk, 0.69; 95% confidence interval, 0.5 to 0.9; P= 0.008).

This 4-year extension of a randomized controlled trial suggests that long-term maintenance of a music-based multitask exercise program later in life is a promising strategy to prevent age-related physical decline. This exercise regimen promotes both compliance and adherence in older adults.

Height Age Correction of Pediatric DXA: Illustration of its Importance. Katherine Madson*[1], Gary S Gottesman[1], Fan Zhang[2], Michael Whyte[1]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]Shriners Hospital for Children, USA

Pediatric bones change size and shape with growth, and this dynamism poses challenges when measuring bone mineral density (BMD) in children by dual-energy x-ray absorptiometry (DXA). Additionally, DXA measures "areal" BMD (gm/cm^2), not true volumetric BMD (gm/cm^3), and is therefore influenced significantly by bone size (length and width). Age-, gender-, and race-specific healthy control ranges help to interpret pediatric BMD, but DXA BMD Z scores still under- or over-estimate bone density in children who have less or more than average height, respectively. Until recently, a simple way to correct pediatric BMD for height was unavailable. Then, in 2012, one equation each for pre-teenage boys and girls was published[(1)] that corrected for height variation thus improving pediatric DXA interpretation.

Here, beginning July, 2012, we prospectively analyzed our DXAs for all pre-pubertal patients to assess the importance of height correction. Our Hologic Discovery-A densitometer software uses the normative data of Kelly et al[(2)] and Kalkwarf et al[(3)]. We studied 61 consecutive patients (boys n=30) undergoing DXA and interpreted the BMD Z scores for both chronologic age (CA-Z) and then "height age" (HA-Z). Interpretable data were available for L1-L4 spine CA-Z n=61 and HA-Z n=59, and for total hip CA-Z n=50 and HA-Z n=48. In the total hip, non-usable data occurred from surgical metal and an older age reference range. Most patients had metabolic bone disease, thus heights were shorter than in the normal population.

Individual spine and hip BMD Z score differences were defined as HA-Z minus CA-Z. We pooled the data for boys and girls after no gender difference was identified by ANCOVA (spine p=0.77; hip p=0.27). Next, linear regression for the patients with height Z score (HT-Z) within -2 to +2 was used to evaluate the correlation between BMD Z score difference versus HT-Z for spine and hip, respectively. We found negative correlations: Spine HA-Z – CA-Z = -0.40 x HT-Z, r^2=0.75 ($p<0.0001$) and total hip HA-Z – CA-Z = -0.407 x HT-Z, r^2=0.879 ($p<0.0001$). Thus, the further the HT-Z deviated from average (Z=0), the greater the HA-Z correction (Figure).

Our data illustrate how height correction can have importance when interpreting pediatric DXA.

RANKL Inhibition Improves Long Bone and Vertebral Bone Properties in Moderately Severe Type IV Osteogenesis Imperfecta Brtl Mice. Patricia Collin-Osdoby*[1], Tarpit Patel[2], Michael Brodt[2], Linda Rothe[2], Chun Ya Han[3], Marina Stolina[4], Matthew Silva[5], Paul Kostenuik[4], Joan Marini[6], Philip Osdoby[1]. [1]Washington University in St. Louis, USA, [2]Washington University, USA, [3]Amgen, USA, [4]Amgen Inc., USA, [5]Washington University in St. Louis School of Medicine, USA, [6]National Institute of Child Health & Human Development, USA

Brtl mice contain a glycine substitution (G349C) in half of their type I collagen a1(I) chains and exhibit key characteristics typical of moderately severe human Type IV osteogenesis imperfecta (OI). Thus, Brtl mice have a smaller body size, reduced cortical and trabecular bone volumes, abundant osteoclasts, matrix insufficiency, and brittle bones prone to fracture. While bisphosphonates have proven useful as anti-resorptive drugs to reduce the severity of OI-related bone loss in humans and animal models, new therapeutics are being sought for improved OI skeletal management. Here, we investigated the potential benefits of inhibiting RANKL-stimulated osteoclast bone resorption in the Brtl OI mouse. Male littermate Brtl and wild-type (WT) mice were injected with RANK-Fc (10 mg/kg) twice weekly from 5 to 8 weeks of age (the time of peak OI phenotype in Brtl mice), after which serum and bones were collected for analysis. Serum CTXI and OC bone turnover marker levels, which were significantly higher in Brtl vs. WT mice, were markedly reduced along with TRACP5b by RANK-Fc treatment in both Brtl and WT mice. Consistent with this, microCT analysis of femoral and tibial bones showed that RANK-Fc treatment had little effect on cortical bone but dramatically suppressed trabecular bone resorption and increased BV/TV, Tb Th, BMD, and TMD. Bone marrow compartments were noticeably smaller due to excess bone present in RANK-Fc treated Brtl and WT mice. Similarly, microCT analyses of BV/TV, Tb. N, and BMD in vertebral bones (L4, L5), which all were lower in Brtl vs. WT mice, were each significantly increased following RANK-Fc treatment. Biomechanical 3-point bending tests of long bones revealed that RANK-Fc increased the rigidity (stiffness) and brittleness of WT and/or Brtl femoral bones, and produced only slight improvements in Brtl bone toughness or resistance to fracture. Vertebral crush tests of L4 and L5 vertebrae demonstrated that stiffness, resistance to deformation, and maximal force to crush, which all were lower in Brtl vs. WT vertebral bone, increased in Brtl and WT vertebrae following RANK-Fc treatment. We conclude that RANK-Fc inhibition of osteoclast-mediated bone turnover improves multiple structural and biomechanical properties of vertebral and long bones in Brtl OI mice. Further studies may indicate if RANKL inhibition will be a useful therapeutic alternative to bisphosphonates for improving bone properties and limiting bone loss in human OI.

Treatment with a soluble bone morphogenetic protein Type 1A receptor (BMPR1A) fusion protein increases bone formation and bone mass in a mice subjected to hindlimb unloading. Miranda Van Vliet*[1], Rachel Ellman[1], Daniel Grasso[1], Daniel Brooks[1], Christine Conlon[1], Jordan Spatz[2], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]Harvard-MIT Division of Health Sciences & Technology (HST), USA

Previous work has shown that RAP661, a soluble murine BMPR1A–fusion protein, binds to BMP2/4 BMP2 and BMP4 with high affinity, preventing downstream signaling. Further, Baud'huin et al (PNAS 2012) showed that treatment of intact and ovariectomized mice with RAP661 led to increased bone mass, improved bone microarchitecture and strength, via increased bone formation and reduced resorption. In this study, we tested the effects of RAP661 on disuse-induced bone loss caused by 21 days of hindlimb unloading (HLU) via tail suspension vs. cage controls (CON). Adult female C57BL6/J mice (12 wks old) were assigned to one of four groups (n=10 each): CON-VEH; CON-RAP661; HLU-VEH; and HLU-RAP661. Mice were injected subcutaneously with VEH or RAP661 (4.5 mg/kg, Acceleron Pharma, Cambridge, MA) 2x/week for duration of study. Leg BMD declined in the HLU-VEH group (-5.3 $\pm$ 1.3%), whereas it was unchanged in HLU-RAP661 (-0.3 $\pm$ 0.9%, $p<0.05$ vs HLU-VEH). Additionally, leg BMD increased significantly more in CON-RAP661 than CON-VEH (10.2$\pm$0.6% vs 4.4$\pm$0.8%). In the femur, trabecular and cortical bone microarchitecture was worse in the HLU-VEH compared to CON-VEH mice, whereas RAP-661 treatment led to improved Tb.BV/TV, Tb.Th and midshaft Ct.Th in both the HLU and CON groups ($p<0.05$). In 3-pt bend testing, both CON and HLU animals treated with RAP661 showed either no change or increases in mechanical properties. Specifically, HLU-RAP661 had 21% greater failure load ($p<0.05$) compared to their VEH-treated counterparts. Dynamic histomorphometry indicated that treatment with RAP661 led to significant increases in mineralizing surface and mineral apposition rate, resulting in a 3.5-fold and 5-fold increase in bone formation rate in the RAP661-treated CON and HLU animals vs. VEH groups, respectively. RAP661-treated mice had a similar number of osteoblasts but significantly fewer osteoclasts than VEH-treated animals in both the CON and HLU groups. Altogether these findings suggest that treatment with the soluble BMPR1A fusion protein RAP661 may be useful for maintenance of skeletal integrity in the setting of disuse-induced bone loss.

Cartilage-specific RUNX2 Activity Regulates Endochondral Bone Formation and Articular Cartilage Homeostasis. Jennifer Jonason[1], Donna Hoak*[1], Tzong-Jen Sheu[1], Fanxin Long[2], Regis O'Keefe[1], Matthew Hilton[3]. [1]University of Rochester, USA, [2]Washington University School of Medicine, USA, [3]University of Rochester Medical Center, USA

RUNX2 is a transcription factor critical for normal endochondral bone formation. *In vivo* and *in vitro* evidence suggest that RUNX2 is required for chondrocyte maturation and terminal differentiation. To date, however, *in vivo* studies have been limited to global deletion of *Runx2* or RUNX2 overexpression in chondro-osteoprogenitor cells preventing investigation of RUNX2 function solely in chondrocytes. Here, we examined the effects of RUNX2 gain-of-function (GOF) specifically in committed chondrocytes during endochondral bone development and in postnatal articular chondrocytes using the tamoxifen-inducible *Col2a1-CreER^{T2}* transgene in combination with *Rosa-Runx2^{flf}* alleles. Overexpression of RUNX2 was induced at E13.5 for all developmental studies and at P14 for all postnatal studies. Histological examination and in situ hybridization analyses of the humeri at E14.5 and E15.5 reveal an early onset of hypertrophy and terminal maturation in the RUNX2 GOF mutants compared to controls. By E15.5, the overall length of the mutant limbs is significantly shorter than that of the controls and by E18.5, the length of the mutant hypetrophic zone is decreased compared to controls suggestive of accelerated progression through terminal differentiation. Additionally, at E18.5, the RUNX2 GOF mutants have enhanced TUNEL staining indicative of increased chondrocyte apoptosis throughout all regions of the growth plate. Surprisingly, no histopathological signs of osteoarthritis (OA) are observed four months following induction of RUNX2 overexpression in postnatal animals. The amount of uncalcified cartilage is reduced, however, in the RUNX2 GOF mutants compared to controls and the number of hypertrophic chondrocytes in the calcified cartilage zone is increased. RUNX2 GOF articular cartilage exhibits decreased *Col2a1* and *Prg4* expression, however, there is no evidence of cartilage fibrillation, cell cloning, chondrophyte/osteophyte formation or subchondral bone sclerosis in these mice. This mild phenotype was unpredicted since it has been well documented that RUNX2 expression is increased in both mouse and human osteoarthritic cartilage and is a target of many signaling pathways known to be dysregulated in OA. Altogether, these data confirm a role for RUNX2 in chondrocyte maturation and terminal differentiation during endochondral bone development and in the maintenance of the articular cartilage, but suggest that overexpression of RUNX2 alone is insufficient to cause OA.

Forkhead protein FoxC1 regulates chondrogenic genes expression by modulating Ihh/Gli2 signaling. Michiko Yoshida*[1], Kenji Hata[2], Sachiko Iseki[3], Teruko Takano-Yamamoto[4], Toshiyuki Yoneda[5], Riko Nishimura[2]. [1] Division of Orthodontics & Dentofacial Orthopedics, Graduate School of Dentistry, Tohoku University, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]Section of Molecular Craniofacial Embryology, Graduate School, Tokyo Medical & Dental University, Japan, [4]Tohoku University, Japan, [5]Indiana University School of Medicine, USA

Endochondral ossification is a unique and complex biological event that is harmoniously and sequentially regulated by several transcription factors. However, the mechanism by which these transcriptional networks control endochondral ossification is still elusive. To address this, we attempted to identify a novel chondrogenic transcription factor(s) by performing gene-cloning by combination of mouse genetics and microarray. As a result, we isolated FoxC1 as a specific transcription factor in cartilage development. In situ hybridization analysis revealed a strong expression of FoxC1 in resting and proliferating chondrocytes. Mutations in FOXC1 cause Axenfeld-Rieger syndrome (ARS), which is associated with skeletal malformations including developmental delay and cleft palate. Furthermore, FoxC1 deficient mice showed impaired cartilage development. We therefore examined the effects of FoxC1 on the expression of chondrogenic genes. We found that FoxC1 overexpression in mouse primary chondrocytes up-regulated Ihh target genes such as PTHrP and Gli1. ChIP assay and DNA pull-down assay showed that FoxC1 directly bound to FoxC1 consensus binding site (CTAAATAAC) present in PTHrP and Gli1 gene promoter. Interestingly, FoxC1 enhanced PTHrP and Gli1 expression induced by Ihh or Gli2, an Ihh signaling transcriptional mediator. In contrast, dominant negative-Foxc1 inhibited expression of PTHrP, Gli1, Col10a1, Osx and ALP induced by Ihh. Co-immunoprecipitation experiment showed a physical interaction between FoxC1 and Gli2. Moreover, FoxC1 significantly increased the DNA binding of Gli2 to the Ihh target gene promoter as determined by ChIP assay. These data collectively suggest that FoxC1 controls expression of chondrogenic genes through stimulating Ihh/Gli2 function.

We next investigated the pathological role of *FOXC1* mutations using F112S mutant identified in ARS. F112S inhibited the transcriptional activity of wild-type FoxC1 and Ihh- dependent PTHrP expression. Of note, F112S retained binding activity to PTHrP gene promoter but lost the function interacting with Gli2. Consistently, F112S diminished Gli2 function compared with wild-type FoxC1. These data suggest the possibility that loss of functional interactions with Gli2 partially account for the pathophysiology of ARS caused by F112S mutation. In conclusion, FoxC1 regulates expression of chondrogenic genes in association with Gli2, and consequently modulates chondrogenic action of Ihh/Gli2 signaling.

Sirt6 regulate proliferation and differentiation of the postnatal growth plate chondrocyte via Ihh signaling. Jinying Piao*[1], Kunikazu Tsuji[2], Hiroki Ochi[3], Morita Sadao[4], Daisuke Koga[5], Atsushi Okawa[5], Shu Takeda[6], Yoshinori Asou[2]. [1]Graduate School, Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Japan, [3]Laboratory of Veterinary Microbiology, Nippon Veterinary & Life Science University, Japan, [4]Department of Rehabititation Medecine, Tokyo Medical & Dental Univrsity, Japan, [5]Department of Orthopedics Surgery, Tokyo, Medical & Detal University, Japan, [6]Keio University, Dept. of Nephrology, Endocrinology & Metabolism, Japan

Members of the sirtuin family of NAD-dependent deacetylases promote longevity in multiple organisms. Sirt6 null mice exhibit growth retardation, and aging-like phenotypes, including osteopenia and lordokyphosis. However, as Sirt6 null mice die young, the role of Sirt6 in cartilage metabolism is unclear. The aim of this study was to investigate the Sirt6 signal pathway in cartilage metabolism. Sirt6 gene was shown to be expressed in primary epiphyseal chondrocytes (EC) and the chondrocyte-like cell line ATDC5. At birth, Sirt6 null mice showed dwarfism. Two weeks after birth, growth retardation was more apparent in Sirt6-/-, with reduced proliferating zone and hypertrophic zone in the growth plate (GP), delayed ossification of secondary ossification center and decreased primary spongiosa. PCNA expression was reduced in GP chondrocytes in Sirt6-/- mice. When Sirt6 expression was knocked down by siRNA in vitro, mRNA expression of cyclin D1 and D2 was reduced in both EC and ATDC5 cells. In contrast, the expression of these genes was enhanced by overexpression of Sirt6 in ATDC5 cells. The number of TUNEL positive cells was comparable in GP between Sirt6-/- and littermates. Immunohistological analysis revealed the expression of Col2 and Col10 was reduced in GP with impaired expression of Indian hedgehog (Ihh) in Sirt6-/- mice. mRNA expression of these genes was also reduced in EC derived from Sirt6-/- mice. When Sirt6 was knocked down in EC and ATDC5 cells, the expression of Col2al, Col10a1, Ihh and its downstream genes were also reduced. We further examined the action of Sirt6 on chondrocyte biology using ATDC5 cells to determine the status of Hh signaling activity. Impaired expression of Col2a1 and Col10a1 by Sirt6 silencing was rescued by administration of purmorphamine, a Hh signal agonist. Conversely, the administration of nicotinamide mononucleotide, a key NAD+ intermediate, enhanced Col10a1 expression together with increased expression of Ihh and Gli1, and these effects were clearly cancelled by Sirt6 silencing. The effect of Sirt6 knockdown was partially ameliorated by activation of ATF4, the positive regulater of Ihh expression. ChIP assay using EC revealed that ATF4 binding to the Ihh promoter was markedly decreased by Sirt6 knockdown. In conclusion, Sirt6 directly controls proliferation and differentiation of chondrocytes. Furthermore, Sirt6 positively regulates chondrocyte differentiation via the ATF4 -Ihh axis.

β-catenin Signaling Regulates Endochondral Ossification through Bmp2 Signaling. Jennifer Jonason[1], Yongchun Zhang*[1], Debbie Dao[2], Donna Hoak[1], Tzong-Jen Sheu[1], Matthew Hilton[3], Regis O'Keefe[1]. [1]University of Rochester, USA, [2]University of San Francisco, USA, [3]University of Rochester Medical Center, USA

The Wnt/β-catenin signaling pathway regulates endochondral bone formation and is essential for skeletal development. Genetic models using β-catenin gain-of-function (GOF) and loss-of-function (LOF) in mesenchymal progenitor cell populations have shown that β-catenin promotes osteoblast differentiation while inhibiting chondrogenesis. For this reason, the role of β-catenin signaling in committed chondrocytes during endochondral bone formation is only more recently emerging. The current studies used a tamoxifen-inducible *Col2Cre^{ERT2}* transgene in combination with *β-catenin$^{f(exon3)/+}$* and β-*catenin$^{f/f}$* alleles to induce chondrocyte-specific either β-catenin GOF and LOF following administration of tamoxifen at stage E13.5. In the gain of function model chondrocytes had increased expression of BMP-2 and the MAP3K TAK1. These mice had accelerated development of the secondary ossification center, early cartilage vascular canal formation, and enhanced perichondrial bone formation. The opposite phenotype was observed in the LOF model. *In vitro* assay shows that Bmp2 transcription and BMP-2 secretion are increased in the β-catenin GOF chondrocytes. The differentiation of osteoprogenitors was accelerated in co-cultures with β-catenin GOF chondrocytes further showing that chondrocyte secreted factors regulate bone formation. We also performed experiments *in vivo* to examine the potential role for chondrocyte β-catenin GOF in growth plate chondrocyte maturation, terminal differentiation and primary bone formation. In the growth plate, chondrocyte β-catenin GOF resulted in delayed terminal chondrocyte differentiation and reduced formation of the primary medullary bone center. To examine a potential role of non-canonical BMP signaling, β-catenin GOF chondrocytes were crossed with TAK1$^{f/f}$ mice. We observed partial rescue of the delayed chondrocyte terminal differentiation. Altogether our findings suggest that β-catenin expression in chondrocytes has important effects on the terminal differentiation of chondrocytes. Furthermore, we show that the effects are context specific with acceleration of terminal differentiation in the secondary center and delay in the growth plate.

CCN3 Participates in Bone Regeneration as an Inhibitory Factor. Yuki Matsushita*[1], Kei Sakamoto[1], Kiyoshi Harada[1], Tokutarou Minamizato[2], Akira Yamaguchi[1]. [1]Tokyo Medical & Dental University, Japan, [2]Graduate School of Biomedical Science, Nagasaki University, Japan

To explore the expression profile of genes involved in bone regeneration, we conducted microarray analysis using a bone regeneration model in mice, and identified CCN3 as one of the most upregulated genes at the early stage of bone regeneration. CCN3 is a matricellular protein that belongs to the CCN family of genes. CCN3, a member of the CCN protein family, inhibits osteoblast differentiation *in vitro*. However, the role of CCN3 in bone regeneration has not been well elucidated. In this study, we investigated the role of CCN3 in bone regeneration. We identified *Ccn3* gene by microarray analysis as a highly expressed gene at the early phase of bone regeneration in a mouse bone regeneration model. We confirmed the upregulation of *Ccn3* at the early phase of bone regeneration by RT-PCR, western blot, and immunofluorescence analyses. *Ccn3* transgenic mice, in which *Ccn3* expression was driven by 2.3-kb *Col1a1* promoter, showed osteopenia compared with wild-type mice, but *Ccn3* knockout mice showed no skeletal changes compared with wild-type mice. We analyzed bone regeneration process in *Ccn3* transgenic mice and *Ccn3* knockout (KO) mice by microcomputed tomography and histological analyses. Bone regeneration in *Ccn3* KO mice was accelerated compared with that in wild-type mice. The mRNA expression levels of osteoblast-related genes (*Runx2, Sp7, Col1a1, Alpl, Bglap*) in *Ccn3* KO mice were upregulated earlier than those in wild-type mice, as demonstrated by RT-PCR. Phosphorylation of Smad1/5 was highly upregulated at bone regeneration sites in *Ccn3* KO mice compared with wild-type mice. The number of CFU-Alpl significantly increased in cultures of *Ccn3* KO mice compared with that in wild-type mice, suggesting that the number of osteoprogenitors was greater in the bone marrow of *Ccn3* KO mice than that of wild-type mice. Bone regeneration in *Ccn3* transgenic mice showed no significant changes compared with that in wild-type mice. Collectively, the present study demonstrates that CCN3 appears at an early stage of bone regeneration, and that it participates in bone regeneration as an inhibitory factor. These results indicated that the use of counteracting agents against CCN3 is a potential strategy to develop new bone regeneration therapies.

Loss of the E3 Ubiquitin Ligase Von Hippel Lindau (VHL) in Limb Bud Mesenchyme causes dwarfism and tumors of the soft tissue. Laura Mangiavini*[1], Christophe Merceron[2], Tremika Leshan Wilson[1], Rita Gerard-O'Riley[1], Amato J Giaccia[3], Ernestina Schipani[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine; Inserm, UMRS 791-LIOAD, Centre for Osteoarticular & Dental Tissue Engineering, Group STEP ''Skeletal Tissue Engineering & Physiopathology'', Nantes, France, USA, [3]Stanford University, USA

Adaptation to low oxygen tension is a critical event in fetal development. The hypoxia inducible factor-1 (HIF-1) and HIF-2 are essential mediators of the homeostatic responses that allow hypoxic cells to survive and differentiate. Our working hypothesis is that gradients of oxygen control organ size and shape during development by regulating the HIF signaling pathway. Along these lines, we have demonstrated that HIF-1 is an indispensable survival and differentiation factor for fetal chondrocytes, whereas HIF-2 is not necessary for fetal growth plate development. VHL is the E3 ubiquitin ligase that targets HIFs to the proteasome for degradation in normoxia, and it is also a tumor suppressor gene. In this study we analyzed the role of VHL in the context of endochondral bone formation.

We conditionally deleted VHL in whole limb bud mesenchyme by using the Cre-loxP system. Mutant mice were born with the expected mendelian frequency, but they died three-four weeks later. Prenatally, mutant cartilaginous elements lacking VHL were short and misshapen. This phenotype was due, at least in part, to a delayed transition from proliferation to hypertrophy, and from hypertrophy to bone marrow cavity formation. Moreover, chondrocyte proliferation rate was impaired.

Postnatally, VHL deficient chondrocytes underwent massive cell death that eventually caused to the collapse of the growth plate, and was paradoxically associated to a dramatic increase of trabecular bone, expansion of the bone marrow stroma and dilated bone marrow blood vessels.

In addition, VHL deficiency caused massive fibrosis in the synovial space associated to partial destruction of articular surface cartilage. More strikingly, in about 70% of the analyzed mice, loss of VHL led to the formation of fibroblastic

tumors of the soft tissue, which aggressively invaded and destroyed the surrounding cartilaginous, muscular and bony structures.

In double mutant mice lacking both VHL and HIF-2 in limb bud mesenchyme, synovial fibrosis was partially corrected; though fibroblastic tumors were still detectable in at least 46% of the cases. Conversely in VHL/HIF-1 double mutants, these tumors were no longer present.

Taken together, our findings demonstrate that loss of VHL in mesenchymal cells controls size and shape of the skeletal elements, and its loss causes HIF-1 dependent aggressive fibroblastic tumors of the soft tissue.

Osteonectin/SPARC Single Nucleotide Polymorphism (SNP) Alters Trabecular Bone and is Targeted by miRNA-433. Neha Dole*[1], Kristina Kapinas[2], Catherine B Kessler[1], Anne Delany[1]. [1]University of Connecticut Health Center, USA, [2]University of Massachusetts, Worcester, USA

Osteonectin is an extracellular matrix protein that regulates collagen fibril organization and promotes osteoblast differentiation and survival. Osteonectin-null and haploinsufficient mice are osteopenic. Genetic factors impact bone mass, and polymorphisms in selected genes involved in bone remodeling have been associated with bone density. Previously, haplotypes consisting of 3 SNPs in the 3' untranslated region (UTR) of osteonectin, at cDNA bases 1046C/G, 1599G/C and 1970T/G, were associated with bone mass in a cohort of men with idiopathic osteoporosis. Specifically, haplotype A (1046C_1599G_1970T) was found at a higher frequency in severely affected osteoporosis patients, whereas haplotype B (1046C_1599C_1970T) was found at a higher frequency in less affected patients and healthy controls. We postulated that SNPs in the osteonectin 3' UTR modulate its expression and may affect bone mass.

To determine whether SNPs affected gene expression, Luciferase reporter constructs containing 6 different human osteonectin 3' UTR haplotypes were transfected into hFOB1.19 cells (human fetal osteoblast cell line). Constructs containing haplotype A had the lowest reporter gene expression, whereas constructs containing haplotype B had higher expression. Since the difference between haplotypes A and B is SNP 1599G/C, our results suggest that SNP 1599G, in haplotype A, could decrease osteonectin expression and may impact bone mass.

We found that SNP 1599 was within a potential binding site for microRNA (miR)-433. In hFOB1.19 cells transfected with haplotype A or B reporter constructs and miR-433 inhibitor, an increase in luciferase activity was observed for the haplotype A construct, but not for haplotype B. This suggests that 1599G, in haplotype A, allowed targeting of osteonectin by miR-433, whereas 1599C, in haplotype B, interfered with miR-433 targeting.

To determine whether the SNP at 1599 could affect skeletal phenotype in vivo, we replaced the mouse osteonectin 3' UTR with the human osteonectin haplotype A or B 3' UTR, using a knock-in strategy. Western blot analysis demonstrated that long bones from haplotype A mice had 3 fold less osteonectin compared with haplotype B. Preliminary microCT data suggest that trabecular thickness in the femur of haplotype A mice is less than that in haplotype B. Overall, SNP 1599 in the osteonectin 3' UTR regulates its expression and affects trabecular bone. miR-433 targeting of osteonectin likely plays a role in this process.

The Novel Interplay of Anemia and Hypoxia in the Control of FGF23 Expression. Erica Clinkenbeard*[1], Taryn Cass[2], Tim Lahm[3], Mircea Ivan[3], Kenneth White[4]. [1]Indiana University-Purdue University Indianapolis, USA, [2]Department of Medical & Molecular Genetics, Indiana University, USA, [3]Department of Medicine, Indiana University, USA, [4]Indiana University School of Medicine, USA

Patients with autosomal dominant hypophosphatemic rickets (ADHR) carry either R176Q/W or R179Q/W mutations within the FGF23 $_{176}$RXXR$_{179}$/S$_{180}$ proteolytic cleavage motif, resulting in the stabilization of the bioactive hormone. We previously found that hypophosphatemia with elevated FGF23 can be induced through iron deficiency anemia in ADHR knock-in mice, which parallels the late onset disease observed in some ADHR patients. Low iron can cause hypoxic responses due to decreased oxygen delivery, leading to activation of hypoxia inducible factor 1 (HIF1α) and adaptive changes in gene expression. We now show that during iron deficiency, erythropoietin (EPO), a known HIF target, was significantly up-regulated in ADHR and WT mice, and rats placed in a hypobaric chamber for two weeks maintained normal iron, but had increased serum total FGF23 (6-fold; $p<0.05$). Based upon these data, we hypothesized that during anemia/hypoxia, FGF23 is stimulated via a common pathway involving HIF1α. By chelating iron with deferoxamine (DFO) in UMR106 cells, HIF1α protein increased and translocated to the nucleus. This activation in UMR106 and also in U2OS cells, coincided with 6-fold and 3-fold increases in FGF23 ($p<0.05$) and VEGF mRNAs, respectively. To determine whether cis-regulatory elements were responsible for induction of FGF23, the FGF23 promoter was cloned into a luciferase vector (FGF23-pGL4). Cotransfection of this construct with a constitutively active HIF1α increased luciferase activity versus controls: 4-fold in UMR106 ($p<0.001$); 5-fold in U2OS ($p=0.003$); and 8-fold in HEK293 ($p=0.02$) cells. Further, HIF1α knockdown using both siRNA and shRNA prevented the accumulation of cellular HIF1α protein upon treatment with DFO. In HIF1α knockdown cells, or upon transfection of an FGF23 promoter construct with targeted mutation of proximal HIF response elements (native: 5′-[A/G]CGTG-3′ to: 5′-CAATG-3′), DFO- or HIF1α-dependent FGF23 expression was abolished. In summary, our data demonstrate that FGF23 expression increases during anemia/hypoxia are downstream of HIF1α activation. Taken together, these findings provide a novel mechanism for FGF23 induction arising in rare and potentially in common disorders of phosphate metabolism.

Characterization of FGF23-dependent Egr-1 Cistrome in the Mouse Renal Proximal Tubule. Martin Zhang, Anthony Portale, Farzana Perwad*. University of California San Francisco, USA

The transcription factor, early growth response 1 (egr-1), is a biomarker for activation of the extracellular signal regulated kinase 1/2 (ERK1/2) signaling pathway by fibroblast growth factor 23 (FGF23). In the *Hyp* mouse, ERK1/2 signaling is constitutively activated by excess circulating FGF23. We and others have shown in *Hyp* mice that blockade of FGF23-dependent ERK1/2 signaling suppresses egr-1 expression, improves hypophosphatemia,and reverses1,25-dihydroxyvitamin D ($1,25(OH)_2D$) deficiency. To test whether egr-1 itself mediates the renal phosphaturic response to FGF23, we administered FGF23 to egr-1 null and normal mice. In mice lacking egr-1 expression, the hypophosphatemic response to FGF23 was blunted by 78% when compared to FGF23-treated normal mice. Using genome-wide chromatin-immunoprecipitation (ChIP) and sequencing, we demonstrated rapid binding of egr-1 to regulatory DNA elements in the kidney of FGF23-treated normal mice. We identified egr-1 binding to 8,708 specific genomic regions (active regions) that were unique in FGF23-treated mice compared with 114 active regions in vehicle-treated mice. Using in-depth *in silico* analysis, specific active regions were assigned to several genes responsible for sodium-dependent phosphate (Na/Pi) cotransport (*Npt2a, Npt2c, NHERF1, NHERF2*) and for $1,25(OH)_2D$ metabolism (*cyp27b1,cyp24a1,Vdr*). Binding of egr-1 protein to these specific active regions occurred only in FGF23-treated mice. These data suggest that the phosphaturic effect of FGF23 is mediated, atleast in part, by activation of the transcription factor, egr-1. Thus, we have identified novel FGF23-dependent egr-1 cistromes associated with specific genes that mediate Na/Pi cotransport and $1,25(OH)_2D$ synthesis in the kidney.

Genetic Rescue of Glycosylation-deficient Fgf23 in the Galnt3-null Mouse. Shoji Ichikawa*[1], Amie Gray[1], Erica Clinkenbeard[2], Kenneth White[1], Michael Econs[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University-Purdue University Indianapolis, USA

Fibroblast growth factor 23 (FGF23) is a peptide hormone that inhibits renal reabsorption of phosphate and biosynthesis of 1,25-dihydroxyvitamin D. The subtilisin-like proprotein convertase recognition sequence (^{176}RHTR$^{179}\downarrow$) in FGF23 is protected by *O*-glycosylation through activity of ppGalNAc-T3 (GALNT3). Thus, inactivating GALNT3 mutations make mature FGF23 more susceptible to proteolysis, thereby reducing levels of circulating intact hormone and leading to hyperphosphatemic familial tumoral calcinosis.

However, it is unknown whether glycosylation is only necessary for FGF23 secretion or also affects FGF23 activity. To delineate the role of glycosylated Fgf23, we used two mutant mice for the present study: Galnt3 knockout mice, a model of familial tumoral calcinosis, and autosomal dominant hypophosphatemic rickets (ADHR) knock-in mice carrying a human ADHR FGF23 mutation (R176Q). The two lines of mice were crossed to generate five genotypes: wild type, Galnt3 knockout mice, ADHR mutant mice, and ADHR/Galnt3 double mutant mice that are Galnt3 null and either heterozygous or homozygous for the R176Q ADHR mutation.

Compared to same-sex wild-type controls, serum intact Fgf23 was significantly lower in all mice lacking Galnt3, regardless of Fgf23 genotype; however, Fgf23 levels were not affected in the ADHR mutant mice with normal Galnt3. In contrast to intact Fgf23 levels, total Fgf23 production at the mRNA and protein (13-16 fold) levels were significantly higher in Galnt3 knockout mice with wild-type Fgf23 alleles. However, the increase in total Fgf23 protein was almost completely normalized in the ADHR/Galnt3 double mutants (1-2 fold). Serum phosphorus levels were higher in Galnt3 knockouts, but lower in ADHR mutant mice. Interestingly, serum phosphorus levels in ADHR/Galnt3 double mutant mice remained normal even with lower intact Fgf23.

Thus, the Fgf23 ADHR mutation biologically 'cancelled out' the need for glycosylation by Galnt3 in vivo and was sufficient to maintain normal phosphorus levels in the absence of Galnt3, suggesting that glycosylation is only necessary for proper secretion of Fgf23. Furthermore, the ability of ADHR mutant mice to regulate phosphorus with less intact Fgf23 suggests that the mutant protein may be more potent.

Phosphate Restriction Extends the Life of Uremic Rats with Established Vascular Calcification. Eduardo Slatopolsky[1], Jane Finch*[2], Sarah Zhang[2], Helen Liapis[2], Cynthia Ritter[2]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

Numerous studies have demonstrated the role of hyperphosphatemia in the pathogenesis of secondary hyperparathyroidism, cardio-vascular disease and the progression of renal failure. The purpose of this study was to determine if, in rats with chronic kidney disease (CKD) and severe vascular calcification, a significant reduction in phosphate intake could prolong the life of these animals. CKD was induced by 5/6th nephrectomy. A group of normal rats served as control (NC). All rats were fed a high phosphate diet containing 1.4% phosphorus (P) and 0.8% calcium (Ca). After 3 months, a portion of rats from both groups were sacrificed. Compared to NC rats, the serum P in uremic rats increased from 5.9 $\pm$ 0.34 to 10.3 $\pm$ 0.76 mg/dl; the Ca x P increased from 56.7 to 94.3 mg^2/dl^2. Aortic calcium content also increased from 0.5 $\pm$ 0.06 (NC) to 46.2 $\pm$ 14.2 mg/mg dry wt (uremic). Uremic rats also exhibited positive aortic staining for von Kossa, RUNX2 and osteopontin. The remaining uremic rats were divided into the following 3 groups: uremic+1.4%P diet (UHP-6M); uremic+1.4%P+4%sevelamer (a phosphate binder; UHP+Sev); and uremic+a very low P diet (0.1%P, 0.3%Ca; ULP). After 3 additional months, the serum P in the UHP-6M group was 12 $\pm$ 1.35 vs 6.96 $\pm$ 0.82 (UHP+Sev), 3.69 $\pm$ 0.23 (ULP) and 3.9 $\pm$ 0.3 mg/dl (NC-6M). Mortality in the UHP group was 71.4%, and was reduced to 37.5% by treatment with sevelamer, and further reduced to 5.9% by the low P diet. Positive staining for aortic von Kossa, RUNX2 and osteopontin was increased in UHP-6M rats. P-restriction inhibited this. PTH decreased from 6574 $\pm$ 1641(UHP) to 289 $\pm$ 70 pg/ml in the ULP rats. FGF-23 also decreased from 22,244 $\pm$ 4049 (UHP) to 1079 $\pm$ 162 pg/ml (ULP). Cardiac perivascular fibrosis, cardiomyocyte size were significantly reduced by the low phosphate diet. In addition, glomerulosclerosis, renal interstitial fibrosis and severe interstitial inflammation were also greatly reduced in rats on the low phosphate diet compared to the high phosphate diet. These studies clearly demonstrate that a significant reduction in mortality in uremic rats with severe vascular calcification can be achieved by intensive control of phosphate restriction.

Role of PTH/PTHrP Receptor Signaling in Osteocytes in Ovariectomy-Induced Osteopenia. Jenna Garr*[1], Dean Marengi[1], Vaibhav Saini[2], Xiaolong Liu[1], Paola Divieti Pajevic[3]. [1]Massachusetts General Hospital, USA, [2]MGH, Harvard Medical School, USA, [3]Massachusetts General Hospital & Harvard Medical School, USA

Over 200 million women worldwide suffer from post-menopausal osteoporosis; understanding the cellular and molecular mechanisms of this disease will aid development of better treatments. Parathyroid Hormone (PTH), an endogenous regulator of skeletal homeostasis, is the only FDA-approved anabolic agent to treat osteoporosis. Using microCT and histomorphometric analyses, we previously reported that mice lacking PTH receptor (PTHR1) expression in osteocytes (OcyPPRKO) have a significant increase in trabecular and cortical bone parameters as compared with control at 12 weeks of age. Moreover, when subjected to intermittent or continuous PTH injections, OcyPPRKO failed to display anabolic or catabolic effects, respectively. To investigate the role of PPR signaling in osteocytes in ovariectomy-induced osteopenic mice, ovariectomy (OVX) was performed on 10-week-old OcyPPRKO and control females. The skeletal phenotype of OcyPPRKO was compared to control at two and four weeks post OVX. MicroCT analysis of the distal femur showed a significant decrease in trabecular bone following OVX in both OcyPPRKO and control mice, as compared to sham-operated. These results indicate that PTHR1 signaling in osteocytes does not play a role in OVX-induced osteopenia. As expected, cortical parameters were not changed in either group following OVX. To investigate the role of PTHR1 signaling in osteocytes in the anabolic effect of PTH, we subjected OcyPPRKO and control OVX groups to intermittent PTH administration. Briefly, mice were injected daily with 80 ug/Kg hPTH(1-34) for 4 weeks. At the end of the treatment period, bones were collected and analyzed both histologically and by microCT. Interestingly, PTH induced an anabolic response, as assessed by a significant increase in BV/TV%, conn-density and Tb thickness, in both control and OcyPPRKO mice. Our data suggest that the mechanism of action of PTH in the setting of OVX-induced osteopenia is distinct from its anabolic effect in gonadal-intact animals. Further studies are ongoing to elucidate the cellular and molecular mechanisms of the anabolic effects of PTH.

EphrinB2 reverse signaling in osteoblasts is required for normal bone material strength and increased bone formation in response to parathyroid hormone (PTH). Farzin Takyar[1], Christina Vrahnas[1], Stephen Tonna[1], Blessing Crimeen-Irwin[1], Patricia Ho[1], T J Martin[1], Natalie Sims*[2]. [1]St. Vincent's Institute, Australia, [2]St. Vincent's Institute for Medical Research, Australia

PTH stimulates osteoblastic expression of ephrinB2, and pharmacological inhibition of its interaction with EphB4 impairs late stage osteoblast differentiation. EphrinB2/EphB4 signals can occur in two directions and it remains unknown whether the effect of this interaction is mediated by ephrinB2 (reverse) or EphB4 (forward) signaling. Osteoblastic EphB4 signaling may also inhibit osteoblast differentiation due to activation by ephrinB2 expressed in the osteoclast lineage. To define the role of osteoblastic ephrinB2 signaling in bone formation we assessed the response to anabolic PTH in mice with osteoblast-specific deletion of the ephrinB2 signaling domain (Osx1Cre+EfnB2f/f) compared to littermate controls.

8-week-old male Osx1Cre+EfnB2f/f and control mice (n=7-12) were treated with PTH (30μg/kg; 5x/week) or vehicle for 4 weeks and samples, including flushed femora for RNA analysis, were collected 1 hr after the last injection. Femora were analyzed by microCT, quantitative real time PCR and reference point indentation; tibiae were analyzed by dynamic histomorphometry.

In untreated mice, while osteoblast numbers were not significantly altered in Osx1Cre+EfnB2f/f mice compared to controls, collagen1α1 and runx2 mRNA levels were significantly higher in Osx1Cre+EfnB2f/f femoral cortical bone compared to controls (2-fold and 6-fold, respectively). Conversely, mRNA levels of osteocalcin and sclerostin were significantly lower (both <50% of control) confirming a block in osteoblast differentiation, as previously reported in female Osx1Cre+EfnB2f/f mice. In addition, cortical thickness, cortical tissue mineral density and bone material stiffness were all significantly lower (each by ~10%, $p<0.05$) in OsxCre+EfnB2f/f mice compared to controls.

PTH treatment of control mice significantly increased osteoblast surface (by 244%), increased trabecular and periosteal mineral apposition rates (by 26% and 96%), and decreased sclerostin mRNA levels (to <50%), as expected. However, in Osx1Cre+.EfnB2f/f mice, the PTH-induced increase in osteoblast surface was significantly reduced to 50% of that observed in control mice. No increase in periosteal or trabecular MAR was observed in Osx1Cre+EfnB2f/f mice, nor was any reduction in sclerostin mRNA detected.

These data indicate that ephrinB2 reverse signaling is required for normal cortical growth, and that PTH-induced osteoblast differentiation and mineralization requires ephrinB2 reverse signaling within the osteoblast lineage.

Pdlim7 (LMP) Knock-Out Mice Display a Significant Decrease in Trabecular Bone Volume. Manjula Viggeswarapu*[1], Matthew Gary[2], Colleen Oliver[3], Mesfin Teklemariam[4], Sreedhara Sangadala[1], F. Louisa Titus[5], Scott. D. Boden[6]. [1]Emory University School of Medicine, USA, [2]Department of Neurosurgery, Emory University, USA, [3]VA Medical Center, USA, [4]Department of Orthopaedics, Emory University, USA, [5]VA Medical Center, Decatur, USA, [6]Department of Orthopaedics, Emory University School of Medicine, USA

Rat and human LMP-1 were described by our group as osteoinductive proteins whose overexpression induces bone formation in rats and rabbits and enhances BMP-2 efficacy in vitro. In order to understand the systemic role of LMP during development and maturation, Knock-out (KO) mice were generated using ES cell technology. To characterize the skeletal phenotype, mice were sacrificed at 18 or 26 weeks. Weight and height were measured at euthanasia. Cardiac puncture was performed to obtain serum for analysis of serum chemistry. To assess trabecular and cortical bone structure we analyzed femurs and spines from WT, Heterozygous (Het) and KO LMP mice by micro computed tomography. In vitro osteoblastogenesis was performed using whole bone marrow stromal cells (BMSCs) from femurs of WT, Het and KO LMP mice.

The LMP KO mice weighed significantly less at 18 and 26 weeks-old and were shorter in length at 18 weeks-old compared to their WT counter parts (p= 0.001). Compared to WT, 18 week female KO mice, had a significant decrease in trabecular BV of 25% (p=0.04) and Tb.Th of 11% (p=0.02); there was a trend for decreased trabecular BV/TV of 23% (p=0.06) and cortical volume of 6% (p=0.06). In the 26 week female KO mice, there was a decrease in the trabecular BV of 45% (p=0.001), BV/TV of 41% (p=0.001), and Th.N. of 9% (p=0.04) and cortical volume of 8% (p=0.001). At the spine, the 26 week Female KO mice, had a significant decrease in vertebral trabecular BV/TV of 25% (p=0.001) and Tb.Th of 8% (p=0.005) in the KO mice. In the male KO mice, there was no statistically significant difference in any of the analyses of the femora or vertebrae at 18 or 26 weeks. The 26 week KO mice had normal serum chemistries; serum turnover markers were unchanged compared with WT. BMSC cultures from 18 week Het mice grown under osteogenic conditions formed a reduced area of mineralization (AOM) compared with cells from WT mice (p=0.04); cells from KO mice also formed less AOM.

We present here the development of the first LMP KO mouse. We conclude that LMP is an important determinant of mouse weight and length, female bone density and marrow stromal cell propensity for mineralization. We speculate that these may be due to altered responsiveness to BMP-2, an important determinant during development. Further research is needed to elucidate other phenotypic differences as well as to determine the mechanism causing the reduced body size and gender specific bone loss of LMP KO mice.

SH3BP2 "Cherubism" Gain-of-Function Mutation Exacerbates Inflammation and Bone Erosion in Murine Collagen-Induced Arthritis Model. Tomoyuki Mukai*[1], Shu Ishida[1], Teruhito Yoshitaka[2], Yoshitaka Morita[3], Keiichiro Nishida[4], Yasuyoshi Ueki[2]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri-Kansas City, School of Dentistry, USA, [3]Kawasaki Medical University, Japan, [4]Okayama University, Japan

SH3BP2 is a signaling adapter protein in which gain-of-function mutations result in cherubism. Cherubism is an autosomal dominant craniofacial disorder in children characterized by the extensive growth of fibrous lesions containing a large number of TRAP-positive multinucleated cells, resulting in facial swelling and jaw bone destruction. Analysis of the mouse model of cherubism demonstrated that homozygous mutants exhibit TNF-α-dependent inflammatory bone destruction in joints due to enhanced TNF-α production in macrophages as well as to increased RANKL-induced osteoclastogenesis. However, it remains unclear whether SH3BP2 is involved in the pathogenesis of other common forms of inflammatory bone diseases than cherubism. In this study, we examined the role of SH3BP2 gain-of-function mutation in the development of arthritis using murine collagen-induced arthritis (CIA) model. Wild-type (WT) and SH3BP2 "cherubism" mutation heterozygous knock-in (KI/+) mice on C57BL/6 background were immunized with chicken type II collagen in complete Freund's adjuvant. Clinical arthritis scores (max=16) were evaluated by visual inspection of the paws up to 56 days. Synovial inflammation and bone erosion were evaluated by histological analysis. To analyze focal bone erosion and systemic bone loss, bone properties of talus and proximal tibia were examined by micro CT. The incidence of arthritis was increased in KI/+ mice compared to WT mice (50.0% vs. 27.3%, n=10–11). Arthritis score in KI/+ mice was higher than WT mice (7.20 ± 4.09 vs. 4.33 ± 0.58 at day 28). The higher arthritis score in KI/+ mice continued toward the end of inspection (8.00 ± 4.00 vs. 1.00 ± 1.73 at 56 days). Histological analysis showed that synovial inflammation and bone erosion in KI/+ mice were more severe than those in WT mice. Micro CT analysis revealed that bone volume reduction of talus in KI/+ was greater than that in WT mice (6.81 ± 8.85% and 1.73 ± 3.34% reduction from control mice of each genotype, respectively). Furthermore, bone volume/tissue volume of tibia was more reduced in KI/+ compared with WT (57.9 ± 15.0% and 23.8 ± 19.0% reduction from control mice of each genotype, respectively). Taken together, gain-of-function mutation in SH3BP2 increased the incidence and severity of arthritis accompanied by more severe bone destruction in murine CIA model. These data suggest a potential role of SH3BP2 in the pathogenesis of common inflammatory bone diseases such as rheumatoid arthritis.

In Vivo Pharmacologic Modulation of Bone Marrow Microenvironmental Signals Promotes Long-Term Hematopoietic Stem Cell Function. Julianne Smith*[1], Alexandra Goodman[2], Laura Calvi[1]. [1]University of Rochester School of Medicine, USA, [2]University of Rochester School of Medicine & Dentistry, USA

Osteolineage cells (OBs) and the bone marrow (BM) vasculature constitute hematopoietic stem and progenitor cell (HSPC) niches. We previously demonstrated that OB-activation by Parathyroid Hormone (PTH) expands HSPCs. To test if the vasculature is also modulated by PTH, we assessed whether PTH expands BM endothelial structures. In a murine model of intermittent PTH treatment, PTH increased microvessels and vascular area in hindlimb BM as well as CD31+ Sca1+ BM endothelial cells (ECs). This PTH effect is OB-dependent since ECs were increased in transgenic mice with osteoblastic activation of the PTH receptor. PTH increased expression of the proangiogenic signal VEGF-A in OBs in vitro and strongly increased VEGF-A protein within endosteal cell populations in vivo. To determine the functional relevance of VEGF-A signaling in PTH-dependent microenvironmental activation and HSPC regulation, we used the anti-VEGF-A monoclonal antibody bevacizumab (αVEGF) in combination with PTH in vivo. αVEGF significantly decreased the PTH-mediated expansion of ECs, restoring it to control, without blocking the bone anabolic action of PTH, suggesting that PTH-dependent EC expansion in the BM is VEGF-A mediated. Surprisingly, αVEGF further increased the PTH-induced expansion of phenotypic and functional BM HSPCs. This effect persisted and was further enhanced by secondary transplantation. To examine whether co-administration of PTH and αVEGF expands long term HSPCs at the expense of hematopoietic progenitor and precursor maturation, acute hematopoietic recovery from chemotherapeutic injury was measured. The peripheral blood of PTH and αVEGF treated mice recovered similarly to that of controls and was restored to normal levels, suggesting no impairment of the short term HSPC compartment. Together our data demonstrate that blocking VEGF-A in PTH-initiated vascular remodeling enhances expansion of long-term HSPCs. Both fibroblast growth factor 2 (FGF2) and VEGF-A are proangiogenic signals involved in bone remodeling. VEGF-A promotes endothelial sprouting and permeability while FGF2-stimulated blood vessels are less cell-permeable. Moreover, FGF2 is reported to expand marrow HSPCs. PTH simultaneously increased FGF2 and VEGF-A in OBs in vitro. We speculate that αVEGF therapy permits dominance of PTH-induced FGF2 actions leading to preferential long-term HSPC expansion. These data also demonstrate the validity of niche manipulation for therapeutic targeting of specific HSPC subsets.

EphrinB2/EphB4 Mediates the Actions of IGF-I Signaling in Regulating Vascularization during Endochondral Bone Formation. Yongmei Wang*[1], Alicia Menendez[2], Chak Fong[3], Daniel Bikle[4]. [1]Endocrine Unit, University of California, San Francisco/VA Medical Center, USA, [2]Endocrine Unit, University of California, San Francisco/San Francisco VA Medical Center, USA, [3]Endocine Unit, University of California, San Francisco/San Francisco VA Medical Center, USA, [4]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA

Ephrin B2 and its receptor EphB4 are critical in regulating vessel morphogenesis as well as mediating osteoblast (OB) and osteoclast differentiation and communication. Our previous studies demonstrated that both global insulin-like growth factor-I (IGF-I) knockout (KO) mice and cartilage-specific IGF-I receptor (IGF-IR) KO mice had impaired vascular invasion during endochondral bone formation, but the mechanism remained unknown. In the current study, we investigated the role of IGF-I signaling in regulating the vascularization process in endochondral bone formation with particular attention to the role of ephrin B2/EphB4.

Immnohistochemical localization demonstrated that ephrin B2 was expressed in the endothelial cells and pericytes in the vessels in the long bones. IGF-I treatment (50 mg/kg BW/day, 2 weeks) increased the number of vessels and the expression of ephrin B2 in the vessels of the chondro-osseous junctions in the tibia of wild-type mice (WT, 12W). In the global IGF-I KO mice, the expression of ephrin B2 was significantly decreased in the vessels of the tibia when compared to the WTs. To further investigate the role of IGF-I signaling in regulating vascularization, we generated mice with IGF-IR null mutation in the prehypertrophic chondrocytes (PHC), osteoprogentors and perichondium (osxIGF-IRKO, floxed IGF-IR mice X osterix promoter driven cre-recombinase). Histology showed that osxIGF-IRKO (3W) had delayed secondary ossification center (SOC) formation and fewer vessels in the (SOC) and chondro-osseous junctions in the tibia compared to controls. This was further confirmed by immunohistochemistry (IHC) using an antibody against CD31. IHC further showed

that ephrin B2 was expressed in chondrocytes, OBs, endothelial cells and pericytes in the tibia of the controls, but the expression was abolished in the tibia of the osxIGF-IRKO as was that of VEGF in these cellsThese results were confirmed by qRTPCR demonstrating that the mRNA (long bones, marrow flushed out) levels of ephrin B2 and EphB4 were significantly decreased in the osxIGF-IRKO (45% and 42% of the control, respectively). Our data indicate that IGF-I signaling in PHC, osteoprogenitors and perichondrium stimulates ephrin b2 production, which in turn to promotes vascularization in the primary and secondary ossification centers during endochondral bone formation.

IGF-I – Estrogen Cross Talk is Essential for Cortical Bone Response to Mechanical Loading in Mice. Bhat Chetan*[1], Subburaman Mohan[2], Jon Wergedal[2], Chandrasekhar Kesavan[2]. [1]JLP VA Medical Center, USA, [2]Jerry L. Pettis Memorial VA Medical Center, USA

The adaptive remodeling of the skeleton to mechanical strain is predicted to be mediated by the integrated actions of a number of signaling pathways including IGF-I, Wnt, integrin and estrogen. We recently demonstrated that osteoblast (Ob)-derived IGF-I is essential for mechanical loading (ML) induced new bone formation (BF) in mice. Based on the findings that estrogen receptors are involved in Ob mechanotransduction and based on the well established cross talk between estrogen and IGF-I signaling pathways to modulate biological responses, we proposed the hypothesis that the ML induced increase in IGF-I expression functionally interacts with estrogen signaling pathway to determine the amount of new BF in response to ML. To test this, we performed sham or partial-ovariectomy (p-OVX) on a 5 week-old heterozygous IGF-I knockout (H-IGF-I KO) mice in which one copy of the IGF-I gene is disrupted in type I collagen producing Obs by Cre/loxP technology and corresponding wild type (WT) littermate controls. At 10 weeks, a 10N axial load was applied on the right tibia of WT or H-IGF-I KO sham or p-OVX mice for a period of 2 weeks (3 days/week). The left tibia was used as an internal control. Partial estrogen loss in the WT mice resulted in a (5%) reduced BMD at the mid-diaphysis (P=0.08, ANOVA, LSD Pos-hoc test) when compared to the sham group. Micro-CT analysis of the loaded region revealed that 2 weeks of ML caused a 8-10% and a 11-12% ($p<0.05$ vs. unloaded bones) increase in cortical vBMD and cortical thickness (Cth), respectively, in the WT sham, WT p-OVX and H-IGF-I KO sham groups. In contrast, the magnitude of cortical vBMD (4%, P=0.11) and Cth (6%, $P<0.05$) responses were reduced by >50% in H-IGF-I KO p-OVX mice compared to the other 3 groups ($p<0.05$, LSD Post- Hoc test). The interaction between genotype and estrogen deficiency on the ML-induced cortical bone response was significant ($p<0.05$) by two-way ANOVA. 2 weeks of axial loading (AL) also induced trabecular (secondary spongiosa site) bone response as reflected by significant increases in trabecular BV/TV (15-18%) and thickness (18-23%) in all four groups of mice. Conclusions: 1) Partial loss of estrogen or IGF-I did not affect the ML induced cortical or trabecular bone response to AL 2) Partial loss of both estrogen and IGF-I significantly reduced cortical but not the trabecular bone response to ML, thus suggesting that IGF-I and estrogen cross talk to regulate the cortical bone response to ML.

Ovariectomy Induces Short-Term Hemopoietic Stem Cell Expansion through T Cells. Jau-Yi Li*[1], Jonathan Adams[1], Laura Calvi[2], M. Neale Weitzmann[1], Roberto Pacifici[1]. [1]Emory University School of Medicine, USA, [2]University of Rochester School of Medicine, USA

Estrogen deficiency expands bone marrow (BM) hemopoietic stem and progenitor cells (HSPCs) and mature blood lineages but neither the involved mechanism nor the affected HSPC populations are known. Since T cells contribute to ovariectomy (ovx) induced bone loss, we investigated the role of T cells in the HSPC expansion induced by ovx. Ovx increased the number of HSPCs (Lin-Sca-1+c-Kit+ cells) by ~2 fold and host survival after BM transplantation by ~4 fold in WT mice and T cell reconstituted-T cell deficient mice. By contrast ovx had no effects on HSPCs expansion and survival after BM transplantation in T cells deficient mice. Analysis of SLAM receptor expression on HSPCs and competitive repopulation assays demonstrated that ovx specifically expands short-term HSCs (ST-HSCs) without exhausting long-term HSCs (LT-HSCs) in T cell replete mice but not in T cell null mice. To determine whether the capacity of estrogen deficiency to induce HSPC expansion might be exploited in a clinical setting, we assessed the effects of the complete estrogen antagonist ICI 182,780 on the survival of mice undergoing myeloablative BM transplantation using limiting number of donor cells. We found that treatment of either donor or recipient mice with ICI 182,780 improved by 2-3 fold host survival after BM transplantation. Mechanistic studies revealed that ovx expands ST-HSPCs and improves host survival after BM transplantation through a dual role of the T cell costimulatory molecule CD40L. This surface receptor is required for ovx to stimulate T cell production of Wnt10b, a Wnt ligand that activates Wnt signaling in HSPCs and stromal cells (SCs). Moreover, CD40L is required for ovx to increase SC production of the hemopoietic cytokines IL-6, IL-7 and GM-CSF. Attesting to the relevance of CD40L and Wnt10b, ovx failed to expand ST-HSPCs and survival after BM transplant in CD40L null mice and in animals lacking global or T cell expression of Wnt10b. In summary, T cell expressed CD40L and the resulting increased production of Wnt10b and hemopoietic cytokines by T cells and SCs respectively, play a pivotal role in the mechanism by which ovx regulates hemopoiesis. The data suggest that anti-estrogens may represent pharmacological targets for promoting HSPC expansion and survival after BM transplant.

Inhibition of TGF-β Signaling in Osteoblasts Leads to Activation of SOST and AXIN, Scoliosis-like Pathological Defects in Mice. Hsin-chiu Ho*[1], Shen-chin Hsu[2], Shanshan Shi[3], Eric Beier[3], Yongchun Zhang[3], Tzong-Jen Sheu[3], Mo Chen[4], Min-jon Lin[5], Wei Hsu[3], J. Edward Puzas[6]. [1]Wan-Chuan Clinics, Fangliao General Hospital, Taiwan, [2]Chung Shan Medical University Hospital Dept of Pharmacy, Taiwan, [3]University of Rochester, USA, [4]Columbia University, USA, [5]Chung Shan Medical University Dept of Biomedical Sciences, Taiwan, [6]University of Rochester School of Medicine, USA

TGF-β signaling can regulate Wnt/β-catenin pathways, which is crucial in modulating chondrocyte maturation during endochondral bone formation. Previously, using TGF-β receptor II conditional knockout mice with different skeletal tissue-specific targeting cre mice, they all showed skeletal malformation. However, the genetic evidence between WNT and TGF-β pathways cross-talk remains undefined. In this study, we used TGF-β reporter SBE-lucRT mice and WNT reporter TOP-GAL mice to identify what tissues had the active TGF-β and Wnt signals. Interestingly, we found the strongest TGFβ and Wnt reporter activity converges in Calvaria and spine. To delineate the coordination of TGF-β and Wnt signaling in these tissues, we generated Col-1 cre Tgfbr2 conditional knockout mice ($Tgfbr2^{Col1}$) and analyzed changes in histology, gene expression and bone density. Deletion of the Tgfbr2 gene in osteoblasts resulted in up-regulation of SOST, Mmp13, and Axin expression. Histological analysis showed end-plate cartilage degradation, vertebral distortion, scoliosis-like, and decreased vetebral bone mass in 2-month-old Tgfbr2Col1 mice. To determine if up-regulation of SOST and Axin expression is responsible for $Tgfbr2^{Col1}$-induced scoliosis, we generated Tgfbr2/SOST and Tgfbr2/Axin2 double KO mice. Deletion of the SOST gene significantly alleviates scoliosis-like pathological changes observed in 1- and 2-month-old $Tgfbr2^{Col1}$ mice, while deletion of the Axin2 gene reversed scoliosis-like phenotype in 2-month-old $Tgfbr2^{Col1}$ mice. These changes were confirmed by histomorphometric analysis and μ-ct imaging evaluation. In this study, we demonstrate that inhibition of TGF-β signaling and downstream WNT signaling in osteoblast leads to a progressive Scoliosis-like phenotype in mice and. SOST and Axin2 are critical downstream target genes of TGF-β signaling during scoliosis development.

Atypical Femoral Fractures: Radiographic and Histomorphometric Features in 19 Patients. Aliya Khan*[1], Angela M. Cheung[2], O. Ahmed Khan[3], Zohair Rahman[4], Ken Pritzker[5], Brian Lentle[6]. [1]McMaster University, Canada, [2]University Health Network-University of Toronto, Canada, [3]Oakville Bone Centre, Canada, [4]McMaster, Canada, [5]University of Toronto, Canada, [6]University of British Columbia, Canada

Purpose: This study describes characteristics and histomorphometric and radiographic features of atypical femoral fractures (AFF) as seen in 19 cases referred for evaluation.

Methods: All patients referred for evaluation of AFF were reviewed. Patients meeting the ASBMR criteria for AFF were further evaluated and tetracycline labelled bone biopsies were completed. Radiographs were reviewed by a musculoskeletal radiologist.

Results: All fracture lines were transverse or short oblique and 15 of 19 patients demonstrated thickened cortices on xray. We report 19 cases of AFF in patients on long term bisphosphonate (BP) therapy. 14 of 19 fractures occurred without a fall or direct trauma to the femur with 5 cases occurring after a fall from standing height. All patients were female; average age was 65 years (range 23-80 years). 4 of the 19 cases were of Chinese descent, 4 were East Indian, with 11 being Caucasian. Average BP durations of use was 9.8 years (range 6-15 years). 9 of 19 patients were on alendronate alone, 2 patients were on risedronate alone, 6 patients on a combination and 1 patient on a combination of pamidronate and alendronate. 1 patient was on a combination of alendronate and denosumab. Prodromal thigh or groin pain was seen in 12 of the 19 patients for 1 to 15 months prior to fracture. Proton pump inhibitor use was present in 6 patients. 2 patients were on prednisone for rheumatoid arthritis and 2 patients on prednisone for asthma. 1 patient had a diagnosis of osteogenesis imperfecta type IV with a history of multiple fragility fractures and had experienced a femoral fracture after 12 years of IV pamidronate with features consistent with an AFF. All patients had 25OH Vit D levels > 50nmol/L. 18 of the patients with radiographic features of AFF had been on a bisphosphonate for > than 6 years. 1 patient had been on alendronate for 5 months. 8 of 19 patients had bilateral femoral fractures.

Summary: A large number of patients with radiographic features of an AFF had evidence of mineralization abnormalities on tetracycline labelled bone biopsy. Decreased osteoid surface and mean mineralized trabecular width was seen in 6 of 11 biopsies. Diffuse label was noted in 5 of 11 biopsies. Mineralization abnormalities

were noted in a significant number of patients with radiographic features of AFF (See Table 1). All of the women had normal or mildly reduced serum vitamin D levels.Conclusion: Histomorphometric features seen on bone biopsy in women sustaining an AFF in association with long term bisphosphonate use included evidence of mineralization abnormalities and decreased bone formation. 1 patient had features of decreased bone formation and mineralization abnormalities with only 5 months of bisphosphonate exposure. Improved understanding of the pathophysiology leading to these fractures may be gained with further histomorphometric data in larger numbers of patients.

FGF23 neutralization improves bone quality and osseointegration of titanium implants in chronic kidney disease mice. Ningyuan Sun*[1], shiwen zhang[2], Huawei Zou[2], Victoria Shalhoub[3], Reinhold Erben[4], Quan Yuan[5], Beate Lanske[5]. [1]Chn, [2]State Key Laboratory of Oral Diseases, West China Hospital of Stomatology, Sichuan University, China, [3]Amgen Inc., USA, [4]University of Veterinary Medicine, Austria, [5]Harvard School of Dental medicine, USA

Chronic kidney disease (CKD) has become a worldwide public health problem with its growing prevalence. FGF23, a phosphaturic hormone, increased significantly at the very early stage of CKD, and was found to be independently associated with the mortality and morbidity of CKD patients, including chronic kidney disease–mineral and bone disorder (CKD-MBD) and increased bone fracture risk. Our previous study showed that CKD impairs the osseointegration of titanium implants. The aim of this study was to evaluate whether FGF23 neutralization could improve the bone quality and osseointegration of titanium implants. Chronic renal insufficiency was induced by 5/6 nephrectomy in adult female mice. They were treated with FGF23 neutralizing antibody (FGF23 Ab 5mg/kg body weight) 3 times a week. Experimental titanium implants were inserted in the distal end of the femurs 2 weeks later. After 2-week healing, mice were sacrificed for samples collection. All mice were survived during the experimental period. FGF23 neutralization did not alter serum BUN, but significantly decreased serum PTH, and increased the Vitamin D and calcium levels. Histomorphometric analysis of the tibiae showed a significantly improvement of bone parameters. FGF23 neutralization also increased the fracture toughness of the tibiae as qualified by a three-point bending test. Although there is no significant change of bone-implant contact ratio, the strength of osseointegration, as evaluated by a biomechanical push-in test, was significantly improved by FGF23 neutralization. In summary, our findings indicate that FGF23 neutralization improves bone quality and osseointegration of titanium implants in chronic kidney disease mice, suggesting FGF23 is a key factor in the CKD related bone diseases.

Beneficial Effects of PTH(1-84) in Hypoparathyroidism as Determined by Microarchitectural Texture Assessment (TBS): a 4-year Experience. Barbara Silva*[1], Natalie Cusano[2], Chiyuan Zhang[3], Dinaz Irani[1], Jim Sliney Jr[1], Zachary Lenane[3], Laura Beth Anderson[3], Stephanie Boutroy[4], Didier Hans[5], Mishaela Rubin[3], John Bilezikian[2]. [1]Columbia University Medical Center, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]Columbia University, USA, [4]INSERM U1033 & Université de Lyon, France, [5]Lausanne University Hospital, Switzerland

We have shown that PTH(1-84) is a safe and effective treatment of hypoparathyroidism (HypoPT) for up to 4 yrs. BMD increases at the lumbar spine (LS) and remains unchanged at the hip. Yet, the effect of PTH(1-84) on skeletal microstructure over 4 yrs of PTH exposure is unknown. Trabecular bone score (TBS) is a quantitative estimate of trabecular microarchitecture that correlates with measures of bone microstructure by μCT and HRpQCT. In this study, we examined the effect of PTH(1-84) on TBS over a 4-yr period, with attention also to the possibility of sex-specific differences.

We studied 39 HypoPT subjects treated with PTH(1-84) for at least 2 and up to 4 yrs. Site-matched LS TBS data were extracted from the DXA image (Hologic) using TBS iNsight software. Linear mixed model for repeated measures was performed to assess the % change in TBS relative to baseline. Sex-specific differences were evaluated by using sex as a covariate in the model.

The mean age was 48 ± 2 yrs. Study subjects were pre- (PreM; n=18) and postmenopausal (PostM; n=10) women and men (n=11). PreM women were younger (PreM: 38 ± 2; PostM: 59 ± 2; Men: 54 ± 4 yrs; $p<0.001$) and had lower calcium levels (PreM: 8.2 ± 0.2; PostM: 9.0 ± 0.2; Men: 8.5 ± 0.2 mg/dl; p=0.06). Men had a longer duration of the disease (PreM: 12 ± 3; PostM: 16 ± 5; Men: 28 ± 5 yrs; p=0.02). At baseline, mean TBS was normal at 1.429 ± 0.020 (normal ≥ 1.35). TBS, while within normal limits, was lower in PostM (1.358 ± 0.036) than in PreM women (1.441 ± 0.032; p=0.09) or men (1.473 ± 0.034; p=0.04). In the entire cohort, PTH improved TBS at 2 yrs ($+1.4 \pm 0.7\%$; p=0.057), which plateaued after this time point, reaching a mean gain of $1.5 \pm 0.8\%$ at 4 yrs (p=0.04). Differences in the % change of TBS among the groups were seen at 18 months (p=0.04). While TBS remained unchanged in PostM women and men, it increased in PreM women by $2.1 \pm 1.0\%$ (p=0.04) at 18 months, and $2.6 \pm 1.0\%$ (p=0.01) at 2 yrs, plateauing thereafter (Fig). A positive correlation between the % change in TBS and LS BMD was noted at 6, 12, 30 and 36 months (r= 0.3-0.5; $p<0.05$).

TBS is normal in HypoPT subjects. Treatment of HypoPT with PTH(1-84) for up to 4 yrs improves TBS in PreM women, and preserves it in PostM women and men. The results suggest that microstructural improvements due to PTH(1-84) treatment of HypoPT can be monitored by TBS, that they are more apparent in younger individuals, and provide additional confirmation of the safety of the long-term treatment with PTH(1-84).

Figure: Percent change in TBS in PreM (A) and PostM (B) women, and Men (C) on PTH(1-84) therapy for 4 years

CDC73/HRPT2 mutations and parafibromin immunohistochemistry in a large series of sporadic parathyroid carcinomas and atypical adenomas. Filomena Cetani*[1], Chiara Banti[2], Elena Pardi[2], Liborio Torregrossa[3], Simona Borsari[2], Federica Saponaro[2], Massimo Rugge[4], Gianmaria Pennelli[4], Mariarosa Pelizzo[5], Mauro Papotti[6], Marco Volante[6], Guido Gasparri[7], Paolo Miccoli[3], Claudio Marcocci[1]. [1]University of Pisa, Italy, [2]Department of Clinical & Experimental Medicine, University of Pisa, Italy, [3]Department of Surgical, Medical & Molecular Pathology, University of Pisa, Italy, [4]Department of Medicine, University of Padova, Italy, [5]Department of Medical & Surgical Sciences, Italy, [6]Department of Clinical & Biological Sciences, University of Torino, Italy, [6]Department of Clinical & Biological Sciences, University of Torino, Italy, [7]Department of Surgical Sciences, University of Torino, Italy

The histological diagnosis of parathyroid carcinoma (PC) is restricted to lesions showing perineural invasion, full thickness capsular invasion with growth into adjacent tissues, vascular invasion or metastasis. A subset of parathyroid tumors (atypical adenomas, AA) show pathologic features of PC, such as trabecular growth, fibrous bands, marked cellular atypia, increased mitotic activity, without the above criteria of malignancy. In some cases the distinction between AA and PC may be difficult at histology, and it might be that AA could be an early stage of PC.

Mutations of the *CDC73*/*HRPT*2 gene and/or loss of expression of its protein product, parafibromin (PF), have been detected in up to 70% of metastatic PC. To further investigate the involvement of *HRPT2*/*CDC73* gene in the pathogenesis of PC and AA we studied 80 patients with apparently sporadic primary hyperparathyroidism (PHPT) (58 PC and 22 AA). Mutational analysis of the *CDC73*/*HRPT*2 coding and splite site regions was performed in 40/58 PC and all 22 AA, and PF immunostaining in all PC and 21/22 AA.

Parathyroid cancer. CDC73/*HRPT2* mutations were found in 13 out of 40 (32.5%) PC, 5 were germline. Loss of PF staining (<5% positive cells) was observed in 11 of 13 mutated and 7 of 27 (25.9%) non-mutated samples. Of the 18 samples not tested for *CDC73*/*HRPT2* mutations 7 were negative and 11 positive at PF staining. Long term follow up was available in 35 patients: Twenty-one died because of PC and 12 of them carried a *CDC73*/*HRPT2* mutation; of the 11 patients still alive only 1 carried a *CDC73*/*HRPT2* mutation (p=0.01). By combining the different patterns of *CDC73*/*HRPT*2 mutation and PF staining we found that 18 out of 21 who died for PC had *CDC73*/*HRPT2* mutation and/or loss of PF staining; on the other hand 10 out 11 patients with PC who are still alive showed neither the mutation nor loss of PF staining (P<0.0001).

Atypical adenoma. A *CDC73*/*HRPT2* germline mutation associated with loss of PF staining was found in 1 out of 22 (4.5%) AA; loss of PF staining was observed in 14/21 (66.7%) non-mutated samples. Twenty-one patients, including the one carrying the mutation (with a follow up of 9 yrs), have been cured by surgery, and 2 have persistent/recurrent PHPT. The latter patient's tumors showed retained PF staining.

The present data suggest that patients with PC, whose primary tumor carry a *CDC73*/*HRPT2* mutation and/or loss of PF staining might have a more aggressive PC, since all but three died for the disease. Conversely, the absence of the mutation and the retained PF staining suggest a more being course of PC, since 10 of the 11 patients with these histologic features are still alive.

FR0175

Changes in Bone Turnover Markers and Bone Mineral Density with Recombinant Human Parathyroid Hormone, rhPTH(1-84), in Hypoparathyroidism: Potential Utility as Surrogate Endpoints for Monitoring - the REPLACE Study. John Bilezikian*[1], Tamara Vokes[2], Jeffrey Rothman[3], Bart Clarke[4], Michael Mannstadt[5], Hjalmar Lagast[6], Dolores Shoback[7]. [1]College of Physicians & Surgeons, Columbia University, USA, [2]University of Chicago, USA, [3]Staten Island University Hospital, USA, [4]Mayo Clinic College of Medicine, USA, [5]Massachusetts General Hospital & Harvard Medical School, USA, [6]NPS Pharmaceuticals, Inc., USA, [7]University of California-San Francisco Veterans Affairs Medical Center, USA

Hypoparathyroidism is a rare disorder characterized by hypocalcemia and absent or inappropriately low levels of PTH. Bone mineral density (BMD) is abnormally increased while bone turnover is very low. A phase III, randomized, multicenter, double-blind, placebo (PBO)–controlled study (REPLACE) was performed to determine whether treatment with rhPTH(1-84) could restore mineral homeostasis and lead to reduction of the large doses of oral calcium (Ca) and active vitamin (Vit D) generally required for management. Patients were randomized to receive daily subcutaneous injections of 50 µg rhPTH(1-84), which could be increased to 75 µg and then to 100 µg if needed, or PBO for 24 weeks. Responders were defined as patients whose oral Ca and active Vit D could be reduced by ≥50% from baseline at Week 24 while maintaining serum Ca levels: 53.3% of patients in the rhPTH(1-84) group vs. 2.3% in the PBO group ($P<0.001$) achieved this primary endpoint. We now report the effects of rhPTH(1-84) on bone turnover markers (BTMs) and BMD according to whether or not patients achieved the primary endpoint.

At baseline, mean BTMs were low normal and BMD was above average in both rhPTH(1-84) and PBO groups. At Week 24, BTMs rose to significantly higher levels after rhPTH(1-84) as compared to the PBO group, regardless of whether patients met the primary endpoint, ($P\leq0.001$ vs. PBO; Table). At Week 24, all BTMs were higher in patients who met the primary endpoint vs those who did not. BMD was reduced more towards normal in both groups of patients treated with rhPTH(1-84) than in those given PBO.

Results indicate that in patients with hypoparathyroidism, treatment with rhPTH(1-84) leads to an increase in bone remodeling, as indicated by increased BTMs and a decrease towards normal in BMD. This endpoint was reached even in those patients who did not meet the primary endpoint of the REPLACE trial (≥50% reduction in Ca and active Vit D). The results suggest that BTMs and BMD may serve as surrogate endpoints and might prove useful for monitoring bone remodeling activity in patients who receive rhPTH(1-84) for the treatment of hypoparathyroidism.

Table. Mean Change From Baseline in BTMs at Week 24†

	rhPTH(1-84)		Placebo
	Primary Endpoint Achieved n=40	Primary Endpoint Not Achieved n=42	n=44
BTMs:			
BSAP (µg/L)	23.9*	16.2*	0.23
s-CTx (ng/L)	874*	702*	9.70
Osteocalcin (µg/L)	27.1*	24.2*	−0.44
P1NP (µg/L)	348*‡	238*	2.48

BSAP, bone-specific alkaline phosphatase; s-CTx, serum carboxy-terminal telopeptide of type I collagen; P1NP, procollagen type I amino-terminal propeptide.
*P≤0.001 vs. Placebo.
‡P=0.03 vs. subjects who did not achieve primary endpoint.

Parathyroid Hormone Regulates Bone Microstructure: Reciprocal Changes After Treatment of Hyper- and Hypoparathyroid Subjects. Natalie Cusano*[1], Mishaela Rubin[2], Barbara Silva[3], Chiyuan Zhang[2], Wen-Wei Fan[1], Megan Romano[1], Laura Beth Anderson[2], Jim Sliney Jr[3], John Bilezikian[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA, [3]Columbia University Medical Center, USA

In primary hyperparathyroidism (PHPT) and hypoparathyroidism (HypoPT), improvements are seen in some abnormal bone indices after parathyroidectomy (PTX) and PTH therapy, respectively. However, direct comparisons *between* hyper- and hypoparathyroid microskeletal parameters following reversal of the abnormal parathyroid state have not yet been made. To this end, we studied 11 subjects with PHPT and HypoPT at baseline and 1 yr after intervention with high resolution peripheral quantitative computed tomography (HRpQCT, Scanco Medical AG). Subjects were matched for sex, race and menopausal status. There were 7 postmenopausal women and 4 men in both cohorts, all Caucasian. The mean age (± SD) was similar (PHPT: 63 ± 15 vs HypoPT: 57 ± 13 yrs; p=0.3). Baseline (10.8 ± 0.7 vs 8.7 ± 0.8 mg/dL; p<0.001) and 1 yr (9.3 ± 0.5 vs 8.3 ± 0.7 mg/d; p<0.001) serum calcium were higher in PHPT subjects. There was a trend toward longer duration of disease in the HypoPT subjects (7 ± 11 vs 19 ± 17 yrs; p=0.07), but no differences between groups with respect to height, weight, BMI, or 25-hydroxyvitamin D.

At baseline, at the radius, total volumetric (vBMD), cortical (Ct), and trabecular (Tb) density as well as Ct area and thickness (Ct.Th), Tb bone volume fraction and Tb number were all lower in the PHPT cohort, while Tb separation was higher. At the tibia, vBMD, Ct vBMD, inner Tb density (Dinn), and Tb thickness were lower in PHPT subjects (see Table for all results). One yr after PTX in PHPT subjects and initiation of PTH(1-84) in HypoPT subjects, there were significant *within group* differences at the tibia in both cohorts and at the radius in the HypoPT cohort. Comparing the response *between groups*, in general there were reciprocal changes at both the radius and tibia with the tibia showing the greatest change: total (p=0.004), cortical (p=0.005), and trabecular area (p=0.002), total vBMD (p=0.003), Ct.Th (p=0.004), Ct vBMD (p=0.007), and Dinn (p=0.03).

We have demonstrated reciprocal changes in bone density and geometry in PHPT and HypoPT subjects before and after therapy using high resolution imaging. The changes are mostly present at the weight-bearing site of the tibia. These results suggest that correction of PTH excess or deficiency is associated with a reversal of abnormalities and gives further direct evidence for PTH's critical role in regulating skeletal microstructure.

Table. Baseline and 1 year changes in cortical (Ct) and trabecular (Tb) HRpQCT parameters in subjects with PHPT and HypoPT after intervention (PTX and start of PTH therapy, respectively)

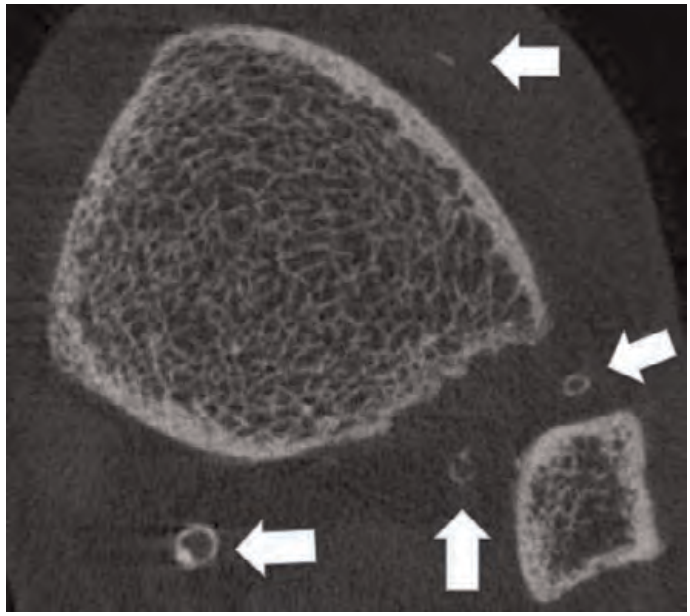
FR0180

Assessment of Osteovascular Interactions by HR-pQCT: Links Between Lower Leg Arterial Calcifications and Renal Osteodystrophy. Janina Patsch*[1], Mafo Kamanda-Kosseh[2], Serge Cremers[2], Elzbieta Dworakowski[2], Chiyuan Zhang[2], Donald McMahon[3], Elizabeth Shane[3], Thomas Nickolas[3]. [1]Medical University of Vienna, Austria, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA

Vascular calcifications (VC) are common in patients with chronic kidney disease (CKD) and are associated with increased risk of cardiovascular disease and fracture. Methods typically used to quantify severity of VC are associated with considerable radiation doses, which limits clinical investigation of bone-vascular interactions. High-resolution peripheral quantitative CT (HR-pQCT, SCANCO Medical AG) measures true volumetric BMD (vBMD) and trabecular and cortical microarchitecture at the distal radius and tibia with low radiation dosages (3 μSv per scan), and can also detect VC. We hypothesized that peripheral arterial calcifications detected by HR-pQCT would be inversely associated with vBMD and microarchitecture in patients with CKD. We enrolled patients with CKD stages 2+3 (n=18), 4+5 (n=14), hemodialysis (HD, n=16) and an age-, sex- and race- matched reference group with normal kidney function (n=21). Tibia HR-pQCT scans were reviewed for lower leg arterial calcifications (LLAC) and a semi-automated, image-processing algorithm was applied. This included image downscaling, removal of bone volume, and detection of remaining focal hyperdense areas by dual threshold seed-point segmentation. LLAC mass was expressed in mg hydroxyapatite (mgHA). Relationships between LLAC and eGFR, cortical and trabecular vBMD and microarchitecture, PTH, and markers of bone formation (BSAP, osteocalcin, P1NP) and resorption (CTX, TRAP5b) were assessed. Analyses were adjusted for kidney function. Mean age was 65 ± 9 (± SD) years, 57% were male and 45% were Black. Compared to the reference group, LLAC was 3.2 mgHA higher in patients with CKD stages 4+5 and 8.8 mgHA higher in patients on HD (both $p<0.05$). LLAC was inversely associated with total density (r= -0.30, $p<0.05$) and trabecular thickness (r= -0.30, $p<0.03$) at the radius, and with total (r= -0.30, $p<0.05$) and cortical density (r= -0.30 $p<0.05$), and cortical thickness (r= -0.20, $p<0.05$) at the tibia. LLAC was positively associated with BSAP (r= 0.40, $p<0.05$). In summary, LLAC measured by HR-pQCT was higher in patients with advanced CKD, was inversely associated with vBMD at both radius and tibia, and was directly associated with the bone formation marker, BSAP. These findings suggest that HR-pQCT may prove to be a useful technology to investigate the pathogenesis of associations between the cardiovascular system and the skeleton in CKD and other diseases.



Vascular calcifications in a CKD patient visualized by HR-pQCT

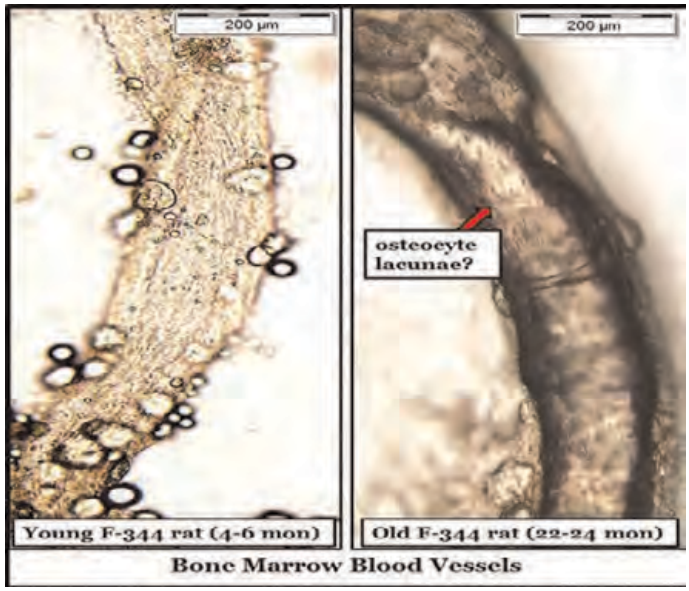
Does a Progressively Hostile Marrow Microenvironment Ossify Bone Marrow Blood Vessels and Contribute to Bone Microvascular Dysfunction?. Rhonda Prisby*[1], Ashley Bice[2], Arun Kumar[3]. [1]University of Delaware, USA, [2]University of Delaware, Department of Kinesiology & Applied Physiology, USA, [3]University of Delaware, Department of Medical Laboratory Sciences, USA

BACKGROUND: With aging, diaphyseal blood flow transitions from a centrifugal to a centripetal direction. In old rats, reduced vasodilator capacity of the femoral principal nutrient artery (PNA) coincided with diminished bone and marrow blood flow (Prisby et al., 2007; Dominguez et al., 2010). However, can declines in nutrient artery function solely account for the age-related reversal in direction of diaphyseal flow? Atherosclerosis occurs in bone marrow arteries (Brenneise & Squier 1985). Yet, it is presumed that systemic atherosclerosis and arteriosclerosis contribute to declines in skeletal perfusion (Brenneise & Squier 1985; Shao et al., 2011). We examined diaphyseal bone marrow blood vessels and assessed the influence of the marrow microenvironment on vascular function.

METHODS: Femoral bone marrow blood vessels and PNAs were isolated from young (4-6 mon; n=7) and old (22-24 mon; n=7) male Fischer-344 rats. Bone and bone marrow blood vessels (n=3-4/age) were analyzed by FT-IR. In addition, femoral PNAs were cannulated to assess vasodilation to acetylcholine (10^{-9} – 10^{-4} M) in the presence and absence of marrow.

RESULTS: Body mass was higher ($p<0.05$) in old (429 ± 14 g) vs. young (363 ± 12 g) rats while marrow mass did not differ between groups (58 ± 15 mg & 35 ± 10 mg, respectively). Bone marrow blood vessel ossification seemed evident at both ages, but accounted for the majority of the microvascular network in old rats. Morphologically, these vessels resembled bone tissue such that osteocyte lacunae appear present on the vessel surface (see Figure). FT-IR analysis revealed that old bone marrow blood vessels have FT-IR spectra which show that the mineral-to-matrix ratio, carbonate-to-phosphate ratio area and crystallinity peak area are similar to old bone. As expected, endothelium-dependent vasodilation was diminished ($p<0.05$) in old age. Strikingly, in the presence of the marrow, vasodilation was reduced by 41% ($p<0.05$) and 39% ($p=0.07$) in young and old rats, respectively.

CONCLUSION: These data suggest that bone marrow presumably represents a progressively toxic microenvironment, whereby it induces vascular dysfunction and ossification. Ossification of bone marrow blood vessels may result in "microvascular dead space" and coupled with reduced vasodilator capacity of the nutrient arterial system may account for the age-related declines in bone perfusion and centripetal nature (i.e., from the cortices towards the marrow) of diaphyseal flow.



ossified bone marrow vessel

Potential Role of Leptin and BMP2 in Osteocyte Regulation of Muscle Mass and Function in the Adult Skeleton and With Age. Jeffrey Gorski*[1], Nichole T. Huffman[1], Leticia Brotto[1], Mark Dallas[1], Anne Breggia[2], Sridar V. Chittur[3], Jian Huang[1], Chenglin Mo[4], Ying Liu[1], Nabil G. Seidah[5], Clifford Rosen[2], Marco Brotto[1], Lynda Bonewald[1]. [1]University of Missouri - Kansas City, USA, [2]Maine Medical Center, USA, [3]Center for Functional Genomics, University of Albany, SUNY, USA, [4]University of Missouri-Kansas City, USA, [5]Clinical Research Institute of Montreal, Canada

MBTPS1 (SKI-1 or S1P) is a serine protease that regulates the transcription of genes in cultured bone cells such as *COL11* and *FBN* and osteocyte markers *PHEX* and *DMP1* by activating membrane bound transcription factors like SREPB-1, ATF-6, and CREB-H. To determine the role of this protease in vivo, cKO mice were generated by crossing floxed MBTPS1 with DMP1 Cre mice. We previously showed that at 15-20 wks, cKO mice have a 20% higher body weight compared to controls (p=0.034). But, no significant differences were found in bone size and morphology, BMC, and ash weight, or in whole body or abdominal fat. MBTPS1 cKO mice are larger due to a general gain in skeletal muscle mass (for example, +12.3% for cKO soleus muscles, p=0.03). MBTPS1 cKO muscles also contracted with more force and histologically exhibited features of regenerating muscle. To identify the mechanism responsible, MBTPS1 protein analyses, food intake measurements, osteocyte microarray data, and serum biomarker analysis on blood samples were performed at 40 wks of age. Immunoblotting of muscle extracts revealed that MBTPS1 protein was unchanged in knockouts and controls (n=3). Despite differences in body mass, cKO and control littermates had equivalent food intake. Whole genome arrays of isolated bone cells enriched for osteocytes (n=4) showed that MBTPS1 deficiency significantly reduced expression of 230 genes including osteocyte markers such as *PHEX*, *DMP1, MEPE,* and *SOST* as well as *BMP2*, *BMP3*, *BMP4*,*TGFb2* and *TGFb3*. Leptin was significantly increased in serum in cKO mice compared with littermate controls (7176 vs. 3575 pg/ml, p=0.018). Interestingly, serum leptin and BMP2 in cKO mice correlated directly (leptin, r^2=0.89, p=0.001) and inversely (BMP2, r^2=0.58, p=0.028) with overall body weight when analyzed by linear regression (Fig. 1). These data provide new evidence of bone-muscle crosstalk and suggest that osteocytes play a key role in regulating muscle mass and contractile force. We propose a model in which osteocytes normally inhibit the growth and differentiation of skeletal muscle by secreting BMPs, negative regulators of myogenic differentiation of primary satellite cells. With reduction of MBTPS1 in osteocytes, this repressive signaling is abrogated and elevated circulating leptin stimulates differentiation of muscle precursor cells. Further characterization should prove useful in identifying targets for the treatment of sarcopenia, muscle atrophy, and muscle myopathies.

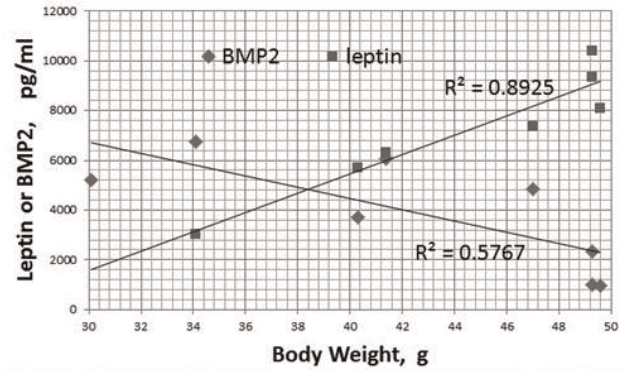

Figure 1: Serum leptin and BMP2 correlate directly and inversely, respectively, with body weight of MBTPS1 conditional knockout mice.

Fig. 1: Serum leptin and BMP2 correlate directly and inversely, respectively, with body weight

Neuroskeletal Signaling In The Regenerating Zebrafish Fin: Remote Inhibition of Osteoblast Function via Disruption of Cholinergic Signaling. Anthony Recidoro, Amanda Roof, Brandon Ausk, Sundar Srinivasan, Edith Gardiner, Ted Gross, Steven Bain, Christopher Allan, Ronald Kwon*. University of Washington, USA

Disruption of the nervous system (e.g., via brain, spinal cord, or peripheral nerve injury) has been widely associated with aberrant bone function. Zebrafish are small, optically accessible, genetically manipulable vertebrates whose tail fins possess a remarkably simple neuroskeletal structure (~18 bone rays each with several intra-/inter-ray nerves, Fig 1A). The capacity for zebrafish to undergo rapid bone regeneration following fin amputation confers unique opportunities to examine neuroskeletal signaling within a highly tractable experimental system.

In this study, we developed a model of cholinergic disruption in the regenerating tail fin using intramuscular injections of Botuliunum toxin B (BTxB). The tail fin is muscularized only at the base. By administering BTxB into the base, we were able to examine remote effects of BTxB at the distal tip while minimizing the influence of impaired muscle near the regenerate (Fig 1B). BTxB resulted in multi-faceted effects on bone regeneration in adult zebrafish (9dpa, ~30mm S.L.). For example, BTxB fish exhibited a significant decrease in the % length of bone regrowth compared to saline controls (sal: 74.8±8.1%, btx: 35.2±4.6%, $p<0.001$ for treatment, n=5). The degree of inhibition was significantly more pronounced in the middle of the regenerate compared to the dorsal/ventral regions ($p<0.05$ for region:treatment), suggesting that the trophic influence of fin base nerves can be spatially focused to distinct fin regions. We also found that bone ray bifurcations were significantly reduced in BTxB fish (sal: 9.4±1.0, btx: 6.7±0.3 $p<0.05$), indicating a role for the nervous system in guiding bone patterning. Finally, when fish were calcein stained, we found that BTxB dramatically decreased osteoblast activity in regenerating bone. Interestingly, the effects of BTxB appeared to be spatially restricted within individual rays, as evidenced by marked differences in osteoblast activity between adjacent rays (Fig 1C). This suggests a potential role for intra- and/or inter-ray nerves in mediating the effects of nerve disruption in the fin base on osteoblast activity in the distal tip. Collectively, these studies demonstrate the capacity for focal cholinergic disruption to remotely alter bone regeneration in a multi-faceted manner. Given the genetic and optical tools for dissecting neural pathways in zebrafish, this model provides a powerful platform for identifying novel mechanisms underlying neural control of bone growth.

Muscle-Bone Interactions during Multiple Hindlimb Unloading and Reambulation Cycles. Sarah Manske*[1], Surabhi Vijayaraghavan[1], Alyssa Tuthill[1], Jean Olivier Brutus[1], Shikha Gupta[2], Stefan Judex[1]. [1]Stony Brook University, USA, [2]State University of NY, Stonybrook, USA

Exposure to single and multiple bouts of hindlimb unloading (HLU) causes rapid deterioration of the musculoskeletal system. We recently showed that after single or multiple exposures to 2wk HLU and 4wk of reambulation (RA), neither hindlimb muscle cross-sectional area (MCSA) nor distal femur bone volume fraction (BV/TV) recovered to the level of age-matched controls, regardless of the previous number of exposures to unloading. Here, we hypothesized that extending the RA period between multiple bouts of HLU can mitigate the loss of muscle and bone upon subsequent unloading cycles and enhance long-term recovery. Ninety 16wk-old female mice (double cross of BALB and C3H strains) were exposed to 3x(3wk HLU and 3wk RA) (3W), 3x(3wk HLU and 9wk RA) (9W) or no unloading (C). *In vivo* micro-CT scans tracked changes in distal femur bone and upper hindlimb MCSA through each HLU/RA cycle and long-term recovery at 62wk. Finite element models of the metaphyseal region were constructed to assess stiffness. Animal activity was monitored pre- and post-HLU via infrared beams over 24h periods. We found that increasing the RA period yielded greater recovery between HLU bouts, however 9W had greater rates of loss in the final two HLU periods than 3W for MCSA, BV/TV and stiffness (Figure 1). Due to these differences in rates of loss, 3W and 9W mice reached similar absolute values of MCSA, BV/TV and stiffness at the end of each HLU period after adjusting for initial values indicating that lengthened RA periods did not protect the musculoskeleton when exposed to multiple bouts of HLU. Long-term, MCSA fully recovered in both groups at 62wks. In contrast, BV/TV did not normalize to control levels over the same duration ($p<0.05$ for 3W and trend for 9W). Stiffness also reflected this trend. The lack of BV/TV recovery was consistent with the drop in the percent load carried by trabecular bone in 3W vs C. Mean loss of stiffness moderately correlated with MCSA over all three HLU periods ($R^2 = 0.32$), similar to stiffness vs MCSA in the first two RA periods ($R^2 = 0.31$). Addition of activity levels did not enhance the association between muscle and bone. These results indicate that both muscle and bone desensitize in response to multiple bouts of HLU. As the magnitude of the muscle and bone response to HLU and RA across individuals did not correlate well and activity levels were a poor predictor for recovery, it is unlikely that bone changes were primarily a result of muscle loading.

Visualizing the Skeletal Response to Resistance Exercise. Thomas Lang*[1], Isra Saeed[2], Julio Carballido-Gamio[2], Roy Harnish[2], Lynda Frassetto[2], Tim Streeper[2], Jean Sibonga[3], Stuart Lee[3], Joyce Keyak[4], Peter Cavanagh[5]. [1]University of California, San Francisco, USA, [2]UC San Francisco, USA, [3]NASA, USA, [4]Department of Radiological Sciences, University of California, Irvine, USA, [5]University of Washington, USA

Understanding the skeletal effects of resistance exercise depends on our ability to delineate the spatially heterogeneous response of bone to the load distributions from contractions of different muscles. Densitometric analyses may obscure these patterns by averaging data from tissues that vary in their mechano-responses. To quantify heterogeneity in the response of the hip to resistance exercise, we carried out pre- and post-training quantitative computed tomography (QCT) (GE vCT 64, 120 kVp/150 mAs, 2.5 mm slice thickness) in 15 subjects (age range 25-55 years, 6 males, 9 females) performing two different types of resistance training for 16 weeks. Group A (N=7) performed 4 sets each of squats and deadlifts (SQDL) and Group B (N=8) performed 4 sets each of standing hip abductions and adductions (ABADD). Subjects exercised three times weekly, and the daily load was adjusted to their maximum effort. To examine the exercise-related changes on a per voxel basis, we used voxel-based morphometry (VBM) (1). Briefly, all vQCT images were registered onto an anatomic template, creating a single atlas of pre- and post-exercise images. The BMD change was computed per voxel in the atlas, and a cluster of voxels was tested for statistically significant pre- to post-training change (paired t-test) if it included 25 contiguous voxels which changed by ≥ 10 mg/cm^3. We also computed whole bone strength using finite element modeling (FEM) with stance and fall loading conditions (2), and cortical and trabecular BMD and cortical tissue volume using analytic techniques published previously (3). Figure 1 shows the effects of SQDL and ABADD exercise detected by VBM. For both groups, there were only changes in cortical bone. SQDL produced focal regions of increased BMD in the femoral neck, which were localized to the trochanter for ABADD. Table 1 shows results for FEM and vQCT. While SQDL increased femoral neck cortical vBMD and volume, as well as hip strength in stance loading, ABADD increased only trochanteric cortical volume. In conclusion, we observed differential patterns of proximal femoral response to SQDL and ABADD exercise. This study suggests that VBM and vQCT can quantify the subtle and spatially heterogeneous effects on bone of different types of muscle contractions.

Selective RARγ agonist blocks heterotopic ossification and promotes skeletal muscle repair. Agnese Di Rocco*, Kenta Uchibe, Maurizio Pacifici, Masahiro Iwamoto. Children's Hospital of Philadelphia, ARC, USA

Skeletal muscles can be damaged or injured for a variety of reasons such as overuse and trauma. Repair/regeneration of severely damaged and/or degenerated muscle tissue is still quite challenging and often result loss of functionality of the muscle tissue.

Heterotopic ossification (HO) is a pathological bone formation in the soft tissue. Since majority of HO occurs in the skeletal muscle, HO has been linked with muscle degeneration for a long time. We have recently reported that selective agonists for retinoic acid receptor gamma (RARγ agonist) effectively blocks HO in the fibrodysoplasia ossificans progressiva like model mouse (FOP like model). In this model, we locally injected cardiotoxin as an inducer of inflammation and muscle degeneration. In control, skeletal muscle tissue around HO was heavily degenerated. Interestingly, RARγ agonist not only blocked HO but also prevented muscle degeneration. The observation suggests that the beneficial effect of RARγ agonist on skeletal muscle could be an indirect effect by blocking HO or direct effect on skeletal muscle tissue. We tested the latter possibility.

In the first experiment, we created a critical round-shape defect in tibialis anterior-muscle of 6 weeks old wild type mice and examined the effect of RARγ agonist. In control, the defects were mostly filled with scar and adipose tissues. In contrast,

RARγ agonist treatment not only reduced the size of the defect but also decreased adipose and fibrous tissue in the defect.

To study the role of RARγ in muscle repair, we injected carditoxin into tibialis anterior-muscles of RARγ-null or wild type littermates and analyzed histology at 2 weeks. In wild type, the initially damaged region was completely replaced with new muscle fibers. RARγ-null mice however still contained necrotic tissue and inflammatory cells. To further study the role of retinoid signaling in muscle regeneration, we examined distribution of retinoid signaling in RARE-Lac-Z reporter mice after muscle laceration. Lac-Z positive area started to appear 4 days after injury, and it can still be detected at day 7.

All together our results indicate that (1) RARγ is an endogenous regulator of muscle repair and (2) its activation using a selective agonist not only decreases skeletal muscle degeneration, but also accelerates muscle regeneration. Thus, selective RARγ agonists may be useful to treat variety of muscle problems ranging from local injury to systemic myopathy.

CKMM Polymorphism Is Associated with Physical Fitness Test Scores In Military Recruits. Courtney Sprouse*[1], Laura Tosi[1], Jason Lipof[2], Mai Abdel-Ghani[3], Hugo Clifford[2], Kirsten Norrell[2], Nathanael Leo[2], Victoria Rentas[4], Heather Gordish-Dressman[1], Joseph Devaney[1], Karen Kelly[5]. [1]Children's National Medical Center, USA, [2]George Washington University, USA, [3]George Mason University, USA, [4]Howard University, USA, [5]Naval Health Research Center, USA

Introduction: Muscle-specific Creatine Kinase (CKMM), an isozyme of creatine kinase, is abundant in skeletal muscle. CKMM is thought to play an integral role in maintaining energy homeostasis by providing a steady supply of creatine phosphate, which is critical for sustaining the Ca^{2+}-ATPase channel in the sarcoplasmic reticulum. It has been suggested that a genetic variant in the 3'-untranslated region of CKMM gene, rs8111989, contributes to individual differences in physical performance. We hypothesized that rs8111989 might be predictive of physical fitness test (PFT) scores in military recruits.

Methods: We studied 172 male military infantry recruits undergoing basic training. PFT measures included three-mile run-time and number of pull ups/sit-ups achieved in two minutes. BMI, body weight, smoking status and a total PFT score were calculated. DNA extracted from whole blood was genotyped using a Taqman genotyping assay from Life Technologies. Statistical analysis: Hardy- Weinberg equilibrium (HWE) was determined using a ^{2}-test to compare the observed genotype frequencies to those expected under HWE. Normality of each quantitative trait was tested using the Shipiro-Wilk normality test. Mean measurements were compared to SNP genotypes (dominant model: TT vs. CT/CC) using analysis of covariance (ANCOVA) methods, followed by Sidak post hoc analysis to control for multiple comparisons.

Results: Participants with two copies of the TT allele had higher PFTS for all three measures of physical fitness: run time, pull ups, and total physical fitness test score. Specifically run time scores were TT [n = 97]: 82 $\pm$ 10 PFTS versus CC/CT [n = 79]: 78 $\pm$ 11 PFTS; p = 0.0370, pull-ups scores were TT [n = 97]: 78 $\pm$ 11 PFTS versus CT/CC [n = 79]: 65 $\pm$ 21; p=0.0496. Total physical fitness scores were TT [n = 97]: 250 $\pm$ 31 PFTS versus CC/CT [n = 79]: 238 $\pm$ 31PFTS; p=0.0173. There was no association with BMI, body weight, number of sit-ups, and smoking status.

Discussion: We demonstrated an association between physical performance and variation in the CKMM gene (rs8111989). Two copies of the common allele were associated with faster run time PFT score, number of pull-ups, and total PFT score. Our study supports the findings of Heled et al. (2007) who found that individuals with the TT genotype were more likely to be high responders to exercise protocols.

FR0195

Effects of Vitamin D Supplementation on Neural Plasticity, Serum Brain-derived Neurotrophic Factor (BDNF) and Functional Performance in Older Adults: A 10-week Double-Blinded, Placebo Controlled Randomised Trial. Robin Daly*, Stephanie Pirotta, Dawson Kidgell. Centre for Physical Activity & Nutrition Research, Deakin University, Australia

Vitamin D has direct effects on muscle modulated by specific VDRs present in muscle tissue, but VDRs are also located in the brain and CNS, including the primary motor cortex (M1) which is responsible for controlling movement. Thus it is possible that the beneficial effects of Vit D on neuromuscular function may be mediated by changes in neural plasticity (eg. the ability of the brain to adapt and strengthen neural connections). Transcranial magnetic stimulation (TMS) is a non-invasive technique that allows an objective assessment of neurophysiological changes such as corticomotor plasticity and altered synaptic activity, and thus provides direct evidence of changes in the responsiveness of the human corticospinal tract. The aim of this 10-wk double-blinded, placebo controlled trial was to examine the effects of Vit D on: 1) corticomotor excitability and plasticity; 2) serum brain-derived neurotrophic factor (BDNF), a neurotrophin involved in regulating synaptic plasticity and neurogenesis, and 3) muscle strength, power and function. Healthy adults aged 60+ yrs with serum 25OHD <60 nmol/L were randomized to 2000IU/d Vit D3 (n=13) or a matched placebo group (n=13). Single and paired-pulse TMS applied over the M1 was used to assess changes in motor evoked potentials (MEPs) and short-interval intracortical inhibition (SICI), as a measure of corticomotor excitability and inhibition, respectively, by recording EMG responses to stimulation from the wrist extensors. Muscle strength (leg extension), power (stair climb), function (TUG, four square step test), serum 25OHD and BDNF were assessed. 96% of the participants completed the trial; supplement compliance was similar between the groups (98% Vit D; 89% placebo, P=0.13). Serum 25OHD increased by 34 nmol/L in the Vit D group with no change in the controls (-1.2 nmol/L). After 10-weeks, treatment with Vit D resulted in an increase in muscle strength (8-11%) and a reduction in cortical excitability (MEP amplitude) and intracortical inhibition (all $P<0.05$). However, these changes were not significantly different from those observed in the controls. There was no effect of Vit D on muscle power, function or serum BDNF. While the lack of significant between group differences may relate to the sample size, the reduction in excitability and inhibition suggests that Vit D may improve the efficacy of neural transmission within the corticospinal pathway, and thereby facilitate motor output and improve muscle performance.

FR0196

Effect of 1 year of whole-body vibration therapy on muscle density and volume in postmenopausal women: the Vibration Study. Miranda Boggild*[1], Marta Erlandson[2], George Tomlinson[1], Eva Szabo[1], Lubomira Slatkovska[2], Lora Giangregorio[3], Cathy Craven[1], Shabbir Alibhai[1], Angela M. Cheung[5]. [1]University of Toronto, Canada, [2]University Health Network, Canada, [5]University Health Network-University of Toronto, Canada

Purpose: Whole-body vibration (WBV) therapy has been proposed as a potential therapy for reducing sarcopenia (or age-related skeletal muscle loss) and its negative consequences (such as frailty, functional impairment and increased risk of fracture). Previous meta-analyses suggest WBV therapy may improve muscle strength and balance in the elderly. The purpose of this study was to explore whether WBV therapy increases muscle density and volume as measured by high-resolution peripheral quantitative computed tomography (HR-pQCT) in the Vibration Study.

Methods: The Vibration Study is a 1-year 1: 1: 1 randomized controlled trial comparing 0.3g 30-Hz WBV, 0.3g 90-Hz WBV and control in 202 healthy postmenopausal women with low bone density (T-score -1 to -2.5). The WBV intervention groups were asked to stand on a 30- or 90-Hz WBV platform daily for 20 minutes; all participants received calcium and vitamin D. The primary outcome of the study was trabecular volumetric bone density at the distal tibia. For this secondary research question, we analyzed muscle density and volume in HR-pQCT distal tibia scans at baseline and 1-year in a blinded fashion. Our primary analysis was intention-to-treat, run separately for muscle density and volume; using linear regression, we compared change from baseline between WBV groups, adjusting for the baseline measurement.

Results: Compared to no WBV therapy, 0.3g 30- or 90-Hz WBV therapy had no significant effect on muscle density or muscle volume at the distal tibia after 1 year. The mean change in muscle density from baseline to 1 year was 0.39 (SD 1.5) mgHA/cm^3 in the 30-Hz WBV group, 0.18 (SD 1.6) mgHA/cm^3 in the 90-Hz WBV group, and 0.38 (SD 1.5) mgHA/cm^3 in the control group (p = 0.8). The mean change in muscle volume from baseline to 1 year was 77.6 (SD 550) mm^3 in the 30-Hz WBV group, 209.2 (SD 796) mm^3 in the 90-Hz WBV group, and 79.4 (SD 675) mm^3 in the control group (p = 0.5). Per-protocol, sensitivity, and subgroup analyses revealed no significant effects of WBV on muscle density or volume.

Conclusion: In this secondary exploratory analysis, one year of daily low magnitude whole-body vibration therapy at 30- or 90-Hz had no significant effect on muscle density or volume at the distal tibia in postmenopausal women.

Keywords: sarcopenia, whole-body vibration, muscle density, muscle volume, postmenopausal women, HR-pQCT

Intermittent PTH Increases Bone Formation but Not Bone Mass in Osteopenic Mice Lacking Gsa in Osteoblasts. Rhiannon Chubb[1], Partha Sinha[1], Piia Aarnisalo[2], Rachelle Johnson[3], Ingrid Poulton[3], Min Chen[4], Lee Weinstein[4], Natalie Sims[3], Henry Kronenberg[1], Joy Wu*[5]. [1]Massachusetts General Hospital, USA, [2]University of Helsinki & Helsinki University Central Hospital, Finland, [3]St. Vincent's Institute of Medical Research, Australia, [4]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [5]Stanford University School of Medicine, USA

Parathyroid hormone is an important regulator of osteoblast function and is in clinical use as the only anabolic therapy currently approved for the treatment of osteoporosis. The parathyroid hormone (PTH) receptor (PPR) is a G protein-coupled receptor that signals via multiple G proteins including Gsα. Ablation of Gsα in the osteoblast lineage during embryonic development using osterix-driven Cre recombinase (GsαOsxKO mice) resulted in fractures at birth. GsαOsxKO mice do not survive past weaning, but administration of doxycycline to delay expression of Cre recombinase until birth yields mice with postnatal ablation of Gsα in the osteoblast

lineage (P-GsαOsxKO mice). We have previously reported that P-GsαOsxKO mice have markedly reduced trabecular and cortical bone, with normal serum calcium, phosphate, and PTH levels. Furthermore, expression of sclerostin, a canonical Wnt inhibitor that is suppressed by PTH and upregulated in the absence of Gsα, is significantly increased in P-GsαOsxKO osteocytes, suggesting efficient removal of Gsα in the osteoblast lineage. To determine the role of Gsα in the anabolic response to recombinant PTH administration, we administered daily PTH(1-34) (80 mg/kg/day) to male and female P-GsαOsxKO mice and controls, beginning at 8 weeks of age. Vehicle-treated P-GsαOsxKO mice had markedly reduced trabecular bone volume and cortical thickness relative to controls. After 4 weeks of PTH treatment, trabecular bone volume was increased in female control mice, but this was completely abrogated in P-GsαOsxKO mice. In both male and female mice, PTH treatment significantly increased trabecular thickness (measured by both microCT and histomorphometry); this effect was also observed in P-GsαOsxKO mice. In addition, osteoblast surface, osteoblast numbers and bone formation rate were each significantly increased to a similar extent in both P-GsαOsxKO and control mice treated with PTH. Osteoclast surface was slightly increased by PTH treatment only in P-GsαOsxKO mice, and while this did not reach statistical significance, trabecular number was significantly reduced in P-GsαOsxKO but not control mice treated with PTH, suggesting a bone resorption response. Together these data indicate that the anabolic effect of intermittent PTH treatment on overall trabecular bone volume is blunted by deletion of Gsα in osteoblasts. Surprisingly, however, PTH is capable of stimulating osteoblast differentiation and bone formation even in the absence of osteoblastic Gsα. This suggests a Gsα-independent pathway of PTH anabolic action on osteoblast differentiation.

Semaphorin 3A regulates bone homeostasis through sensory nerve system. Toru Fukuda*[1], Ren Xu[2], Hiroki Ochi[1], Satoko Sunamura[1], Tsuyoshi Sato[3], Shinsuke Shibata[1], Chenshan Ma[2], Cheng Xu[2], Ayako Kimura[2], Yoshinori Asou[2], Mitsuhiro Enomoto[2], Hideyuki Okano[1], Atsushi Okawa[2], Hiroshi Ito[1], Shu Takeda[1]. [1]Keio University School of Medicine, Japan, [2]Tokyo Medical & Dental University, Japan, [3]Saitama Medical University, Japan

Semaphorin 3A (Sema3A) is a secreted and membrane bound proteins originally discovered in the nervous system, which are involved in repulsive axon guidance during nervous system development. Previous studies have demonstrated that global Sema3A-knockout (KO) mice have multiple developmental defects including low bone mass due to bone-anabolic action of Sema3A. However, osteoblast-specific Sema3A-KO mice had normal bone mass, even though the expression of Sema3A in bone was substantially decreased. In contrast, mice lacking Sema3A in neurons had low bone mass similar to global Sema3A-KO mice, indicating that neuron-derived Sema3A is responsible for the bone abnormalities independent of the local effect of Sema3A in bone. Indeed, sensory innervations of trabecular bone were significantly decreased in neuron specific Sema3A-KO mice, whereas sympathetic innervations of trabecular bone were unchanged. Moreover, ablating sensory nerves decreased bone mass in wild-type mice, whereas it did not deteriorate low bone mass phenotype in neuron specific Sema3A-KO mice, further indicating the essential role of sensory nervous system in normal bone homeostasis. In summary, this study demonstrates that Sema3A regulates bone remodelling indirectly by modulating sensory nerve development and sensory neurons are indispensable for bone development and homeostasis.

TSC1 Deletion in Neural Crest-derived Cells Leads to Excess Craniofacial Bone Formation through the Expansion of Osteoblast Lineage Cells. Fang Fang*[1], Dongye Yang[1], Yuan Zhu[1], Fei Liu[2]. [1]University of Michigan, USA, [2]University of Michigan School of Dentistry, USA

Conflicting *in vitro* results were reported about the regulation of mTOR on osteogenesis. To study the role of mTOR signaling in bone homeostasis *in vivo*, we deleted TSC1, a negative regulator of mTOR signaling, with P0-Cre, which targets neural crest-derived (NCD) cells that generate majority of the craniofacial bones. Despite the low deletion efficiency (43%) in NCD bones shown by qPCR, μCT analysis demonstrated strikingly increased bone mass in all NCD bones such as frontal, nasal, and zygomatic bones. This mimicked the sclerotic lesions in craniofacial region of 40% of the Tuberous Sclerosis patients, in which mutations in TSC1 or TSC2 cause the disease. The thickness of frontal but not parietal (mesoderm derived) bone in conditional knockout (CKO) mice dramatically increased (1.25, 1.8, 2.09 and 2.83 folds at 1, 2, 3 and 12 month respectively, $p<0.05$, n=5-13) comparing to their control littermates (CTR). TRAP staining showed comparable osteoclast number in the frontal bone of CKO mice, which excluded the contribution of altered osteoclastogenesis. After the IP injection of rapamycin, inhibitor of mTOR, at 1mg/kg every the other day from 1 to 8.5 week, calvaria thickness increase in CKO mice was completely rescued. To perform lineage-tracing experiment, we crossed CTR and CKO mice to R26 reporter mice and found 3-fold increase in P0-Cre targeted NCD cells (lacZ positive) in both metopic suture and frontal bone of 7-day-old CKO mice. Importantly, rapamycin treatment (from birth to day 7) rescued the increase in lacZ staining in CKO bone. Interestingly, osteocyte density in CKO mice frontal bone was significantly higher than that of CTR at one month of age (1547 *vs.* 1072 cells/mm^2, $p<0.05$, n=5-6). In addition, mRNA expression of osteocalcin (OCN), an osteoblast specific marker, increased 50% in the frontal bone of 7-day-old CKO mice, further suggesting an increase in osteoblast lineage cells. *In vitro*, although we observed increased phospho-S6 and -4EBP1 expression, indication of enhanced mTOR signaling, in primary frontal osteoblasts of CKO mice, osteoblast differentiation was not affected, shown by the comparable Alkaline Phosphatase/Alizarin Red Staining and expression of osteoblast markers (OCN, BSP, Col1A1 and Runx2). Altogether, our findings suggest that enhanced mTOR signaling in NCD cells can increase bone mass through the enlargement of osteoblast population, which may be responsible for the hyperostosis observed in Tuberous Sclerosis patient.

The Presence of Either Cdc42 or Rac1 is Required for the Crosstalk between Osteoblasts and Adipocytes. Carina Wuerfel, Carla Sens, Christine Hoffmann, Inaam Nakchbandi*. Max-Planck Institute of Biochemistry & University of Heidelberg, Germany

Both RhoGTPase cdc42 and rac1 regulate cell division, migration and polarization, and are involved in the transfer of extracellular signals into the cells. Because of its importance knockout mice die during embryonal development. Because both RhoGTPases mediate effects required for osteoblast differentiation we examined their roles in osteoblasts.

Using the cre-lox*p* system we evaluated the effect of deleting cdc42 using the osterix promoter. There was a significant decrease in BMD in 3-week-old conditional knockout (cKO) mice (15%). Bone histomorphometry revealed a significant decrease in osteoblast numbers (29%). Isolated calvarial osteoblasts showed decreased differentiation. Interestingly, the number of adipocytes was significantly increased in the bone marrow (9-fold). This was not due to deletion of cdc42 in bone marrow cells because transplantation of cKO bone marrow into CT mice did not result in increased adipocytes. Coculturing cKO osteoblasts and CT bone marrow resulted in increased adipocytes. In line with these findings markers of adipocyte differentiation were significantly increased in cKO bone marrow (1.5 to 4-fold). These data suggest a direct effect of cdc42 in osteoblasts on adipocyte differentiation. In order to determine whether this was due to an upregulation of rac1 we first deleted rac1 in osteoblasts using the osterix promoter. This resulted in a significant decrease in BMD associated with a decrease in osteoblast numbers on bone histomorphometry (11 and 40%). Isolated osteoblasts showed significantly decreased differentiation *in vitro*. Cocultures of cKO osteoblasts with CT bone marrow resulted in a significant increase in adipocytes. This suggests that the absence of rac1 decreases osteoblast and increases adipocyte differentiation. In double cKO animals however, the decrease in BMD as well as osteoblast number *in vivo* and differentiation *in vitro* were not associated with an increase in adipocyte. Neither Runx2 nor a change in osteocyte numbers seemed to be responsible for this effect.

These data suggest that both rac1 and cdc42 are required for osteoblast differentiation, but that adipocyte differentiation is increased only if one of these two molecules is still present. Thus, the signals originating from the osteoblasts and resulting in adipocyte differentiation require the expression of at least one of these two molecules. This establishes a role for RhoGTPases in the crosstalk between osteoblasts and adipocytes.

FR0226

N-cadherin Restrains the Anabolic Action of Parathyroid Hormone via Interference with Lrp6/β-catenin Signaling. Leila Revollo*[1], Jin Norris[2], Gabriel Mbalaviele[3], Roberto Civitelli[3]. [1]Washington University, Division of Bone & Mineral Diseases, USA, [2]Washington University in St Louis, USA, [3]Washington University in St. Louis School of Medicine, USA

Interaction between PTHR1 and Lrp6 has been linked to the anabolic action of PTH. Since N-cadherin negatively regulates Wnt/β-catenin signaling by interaction with Lrp5/6 in osteoblasts, we hypothesized that N-cadherin may affect PTH-induced anabolic response by interfering with Lrp6 signaling. We tested our hypothesis in mice with a deletion of the N-cadherin gene (*Cdh2*) in osteoblasts ($Cdh2^{flox/flox}$*::Osx-Cre;* cKO). $Cdh2^{flox/flox}$ *and Osx-Cre* mice were used as control. Mice were treated with human PTH (80μg/kg bw, sc, 5x/week, 4 weeks) and changes in bone mass and architecture determined by μCT imaging. PTH increased trabecular thickness and bone volume/tissue volume in cKO to a significantly larger extent than in either control group, suggesting that N-cadherin restrains PTH anabolic effect. Co-immunoprecipitation experiments with bone marrow stromal stem cells (BMSC) from control mice show that PTHR1 interacts with Lrp6 but not Lrp5 or N-cadherin. Intriguingly, this interaction is sharply enhanced by exposure to PTH in cKO BMSC; whereas PTH has minimal effect on Lrp6/PTHR1 complexes in control cells. Confirming β-catenin activation, PTH stimulates Tcf/Lef transcriptional activity and pharmacological inhibition of PKA attenuates this effect. PTH stimulation of Tcf/Lef target genes is enhanced in N-cadherin-ablated BMSC compare to control cells. We have previously shown β-catenin up-regulation by PTH in bone. Indeed, in BMSC PTH promotes β-catenin phosphorylation at the C-terminus, an event shown to favor β-catenin stabilization and Tcf/Lef transcription. Accordingly, this phosphorylation is

hindered by a PKA inhibitor, suggesting that PTH activates β-catenin via PKA. Importantly, cKO BMSC exhibit larger and prolonged β-catenin C-terminus phosphorylation in response to PTH relative to control cells. Thus, absence of N-cadherin in osteoblasts enhances PTHR1/Lrp6 interaction in response to PTH, and leads to larger PTH-induced β-catenin stabilization via PKA-dependent phosphorylation at C-terminus sites. As others have shown that LRP6 is involved in PTH anabolic effect, we propose that N-cadherin modulates PTH-induced bone formation by functioning as a "buffer" for Lrp6, thus modulating Lrp6/PTHR1 interaction and consequently the intensity and duration of β-catenin signaling by PTH. Since N-cadherin is down-regulated as osteoblasts differentiate, this action may serve as a mechanism to restrain osteoblast precursor recruitment from uncommitted cells.

Trabecular bone loss in Gα11 transgenic mice is characterized by decreased bone formation and increased osteoclastogenesis. Ariana Dela Cruz*[1], Michael Mattocks[1], Kim S. Sugamori[1], Marc Grynpas[2], Jane Mitchell[1]. [1]University of Toronto, Canada, [2]Samuel Lunenfeld Research Instituteof Mount Sinai Hospital, Canada

$G\alpha_{11}$ is a member of the heterotrimeric Gq protein family that mediates phospholipase C-dependent signaling downstream of G protein-coupled receptors including the parathyroid hormone 1 receptor (PTH1R). We previously demonstrated that the potent glucocorticoid dexamethasone increases $G\alpha_{11}$ protein expression in osteoblasts and can therefore enhance parathyroid hormone (PTH) signaling through the phospholipase C pathway. To identify how increased osteoblastic expression of $G\alpha_{11}$ affects bone, we generated transgenic mice that overexpress $G\alpha_{11}$ in osteoblasts (G11-Tg) driven by the 3.6kb Col1A1 promoter.

We found that G11-Tg mice overexpressed $G\alpha_{11}$ by 2-6 fold selectively in calvaria, vertebrae, long bone, and bone marrow stromal cells (BMSCs) compared to WT controls. DEXA scans revealed significant reductions in BMD in male and female G11-Tg mice aged 3- to 20-weeks. Furthermore, microCT scans showed that bone volume and microarchitecture parameters were decreased in 8-week old G11-Tg mice trabecular bone, while cortical bone was not changed. The functional consequence of decreased G11-Tg trabecular bone was assessed by vertebral compression testing, showing that G11-Tg vertebrae exhibited reduced biomechanical strength. Consistent with our microCT data, three-point bending tests displayed no differences in normalized cortical bone strength from G11-Tg mice compared to WT controls. These data indicate that $G\alpha_{11}$ over-expression preferentially affects the trabecular bone compartment.

To explore the cellular basis for the trabecular bone loss seen in G11-Tg mice, static and dynamic histomorphometry were performed. Bone resorption parameters including osteoclast number and surfaces were significantly increased, whereas osteoblast numbers were not altered. However, we found that G11-Tg rates of mineral apposition and bone formation were significantly decreased. In an *in vitro* assay to assess osteoblast differentiation, we assessed osteoblasts derived from BMSC cultures of G11-Tg mice and found increased expression of mRNA encoding osteoclast inducting proteins, M-CSF and RANKL, as well as the gene encoding MMP-13, a collagen degrading enzyme.

In summary, our results suggest that osteoblastic over-expression of $G\alpha_{11}$ results in a dual mechanism of trabecular bone loss by promoting induction of bone-resorbing osteoclasts and decreasing bone formation rate.

Prostaglandin E2 Regulates Osteoblastic Niche Selectively for Hematopoietic Progenitors through Induction of Osteopontin via EP4 Receptor. Yuko Kawano*[1], Mari Sato[1], Noboru Asada[1], Chie Fukui[1], Kanako Wakahashi[1], Hiroki Kawano[1], Kentaro Minagawa[1], Akiko Sada[1], Satoshi Uematsu[2], Shizuo Akira[2], Toshimitsu Uede[3], Shuh Narumiya[4], Toshimitsu Matsui[1], Yoshio Katayama[5]. [1]Hematology, Department of Medicine, Kobe University Graduate School of Medicine, Japan, [2]Laboratory of Host Defense, WPI Immunology Frontier Research Center, Osaka University, Japan, [3]Division of Molecular Immunology, Institute for Genetic Medicine, Hokkaido University, Japan, [4]Department of Pharmacology, Kyoto University Graduate School of Medicine, Japan, [5]Hematology, Dept. Med., Kobe Univ., Japan

The regulation of osteoblastic niche in bone marrow (BM) microenvironment is crucial for the maintenance of hematopoietic stem/progenitor cells (HSCs/HPCs). The mobilization of HSCs/HPCs to the circulation is triggered by their release from the niche, and the cytokine G-CSF is widely used for this purpose in clinic. Because G-CSF administration causes fever and back pain and because these symptoms are ameliorated with NSAIDs, we investigated the role of PGE2 in osteobalstic niche regulation. First, HPC mobilization by G-CSF (125μg/kg/dose, every 12 hours, 8 divided doses) was significantly augmented in PGE syntase-1-deficient mice (42% increase), and strongly inhibited by exogenous administration of PGE2 (6mg/kg/day for 2 weeks) to wild-type (WT) mice (by 52%). The inhibitory effect of PGE2 was completely abrogated in PGE2 receptor EP4-deficient mice, and the chimeric model generated by the reciprocal BM transplantation revealed it was EP4 in microenvironment, but not in hematopoietic cells, that was critical for this effect. Since PGE2 did not change the CXCL12 behavior, we speculated that PGE2 increased another anchor in the niche, osteopontin (OPN). Immunofluorescence staining demonstrated clear upregulation of OPN by PGE2 and/or G-CSF in endosteum, which was abolished in EP4-/- mice. Indeed, the inhibitory effect of PGE2 on HPC mobilization was canceled partially in OPN-/- mice and almost completely in anti-OPN antibody-treated WT mice. To confirm the induction of OPN by PGE2 directly, we fractionated non-hematopoietic (CD45-CD31-Ter119-) cells isolated from femur into three populations, i.e. Sca-1+ALCAM- immature mesenchymal cells, Sca-1-ALCAM- preosteoblasts, and Sca-1-ALCAM+ mature osteoblasts that are most potent to maintain quiescent HSCs in vitro. PGE2 upregulated OPN protein 2-fold in Sca-1+ALCAM- immature mesenchymal cells in cultures, and more dramatically (6-fold) in Sca-1-ALCAM- preosteoblasts, as assessed by flow cytometry. In sharp contrast, no OPN induction was observed in Sca-1-ALCAM+ mature osteoblasts. In contrast to HPCs, the mobilization of long-term repopulating HSCs was not altered in PGE2-treated WT mice, indicating that PGE2 does not modulate HSC niche. Collectively, the results suggest that PGE2 regulates osteoblastic niche selectively for HPCs through the induction of OPN via EP4 receptor. Thus, PGE2/EP4/OPN pathway may be an important pharmacological target to modulate the function of BM microenvironment.

Rejuvenating Bone Fracture Repair. Gurpreet Baht*[1], Benjamin Alman[2]. [1]University of Toronto, Hospital for Sick Children, Canada, [2]Hospital for Sick Children, Canada

The capacity for tissues to repair and regenerate diminishes with age. In vivo bone repair and in vitro differentiation of bone marrow stromal cells to osteoblasts is more efficient in young animals than old animals. We sought to determine the effect of animal age, cell age, and matrix age on bone regeneration and osteoblast differentiation. Fracture repair and osteoblast differentiation were more efficient and more robust in young mice (4 months) than in old mice (18 months). Exposure to a youthful circulatory system by via heterochronic parabiosis rejuvenated aged fracture repair and aged osteoblast differentiation. When osteoblasts were ablated in the old heterochronic host, bone regeneration capacity and osteoblastogenesis were completely ablated. Conversely, removal of osteoblasts from young partners did not affect rejuvenation of old, heterochronic mice. Transplantation of young bone marrow rescued fracture repair and osteogenic potential in a mechanism which again required osteoblasts from the host animal but not osteoblasts from the donor animal. Tissue culture methods were used to rescue the age-dependent decrease in osteogenic potential. Western blot analysis from cell lysates identified a decrease in β-catenin during rescue. In vivo, β-catenin was found to be elevated upon fracture; however, β-catenin was elevated further in old calluses relative to young calluses and remained elevated throughout repair. Because β-catenin regulation is critical during mesenchymal commitment to an osteochondral lineage, its dysregulation in old bone may be contributing to the impaired fracture healing observed. Transplantation of young, wildtype bone marrow was not able to rejuvenate fracture repair in old mice in which β-catenin levels could not be modulated. Pharmacologic reduction of β-catenin during early fracture repair improved bone regeneration in old mice. These data demonstrate that the circulatory system carries within it a "youth factor" which originates, in part, from the bone marrow. This youth factor is able to rejuvenate bone repair and osteoblast differentiation through modulation of β-catenin. Agents which modulate β-catenin can improve the quality of fracture repair and osseous integration of implants in the aging population.

Sirt1 in osteoblast progenitors expressing Osterix1 promotes cortical bone mass accrual. Srividhya Iyer*[1], Li Han[1], Shoshana Bartell[1], Aaron Warren[1], Julie Crawford[2], Rafael de Cabo[3], Stavros Manolagas[1], Maria Jose Almeida[1]. [1]Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]Experimental Gerontology, NIA, NIH, Baltimore, MD, USA

Sirt1, a nicotinamide adenine dinucleotide+ class III histone deacetylase, associates with several non-histone regulatory proteins in mammalian systems and regulates age-related processes including, cancer, glucose metabolism, apoptosis, mitochondrial biogenesis, and defense against oxidative stress. Sirt1 deletion in mesenchymal cells expressing Prx1 attenuates their differentiation and decreases both cortical and cancellous bone in aged mice. In contrast, Sirt1 deletion in mature Col1a1 expressing osteoblasts decreases only cancellous bone. Notably, in either model, the bone phenotype is restricted to females. Here we have deleted the Sirt1 floxed (f) allele in osteoprogenitors and their descendants using the Osx1-Cre transgene. Sirt1 mRNA was reduced by ~90% in Osx1-Cre expressing cells from the $Sirt1^{f/f}$;Osx1-Cre mice compared to Osx1-Cre littermate controls. Bone marrow cultures from the $Sirt1^{f/f}$;Osx1-Cre mice had decreased numbers of colony forming unit of osteoblasts and adipocytes. High density cultures of adherent bone marrow cells exhibited reduced mineralization and decreased expression of osx1, runx2, col1 and osteocalcin. In addition, osteoprogenitor cells from $Sirt1^{f/f}$;Osx1-Cre mice exhibited increased apoptosis, as determined by caspase 3 activity. Stimulation of Sirt1 by two synthetic compounds (provided by GlaxoSmithK-

line), on the other hand, increased osteoblast differentiation in Sirt1 replete, but not deficient, bone marrow cultures. Strikingly, stimulation of osteoblast differentiation in bone marrow-derived osteoprogenitor cells by the Sirt1 activators was attenuated in cells lacking ERα, consistent with published evidence that Sirt1 and ERα interact in other cell types. Furthermore, female, but not male, $Sirt1^{f/f}$;Osx1-Cre mice had reduced cortical thickness in femur as well as in vertebra, as determined by microCT at 3 months of age. The vertebral cancellous bone volume (BV/TV) was unaffected; albeit, there was a small decrease in trabecular thickness in both femur and vertebra at this age. In addition, markers of oxidative stress, including reactive oxygen species levels in bone marrow, as well as phospho-$p66^{shc}$ in vertebral lysates were elevated in $Sirt1^{f/f}$;Osx1-Cre mice. Collectively, these results demonstrate that Sirt1 in Osx1 cells (not mesenchymal progenitors or mature osteoblasts) promotes accrual of cortical bone in females, perhaps in part by potentiating ERα signaling.

Analysis of αSMA-labeled Progenitor Cell Commitment Identifies Notch Signaling as an Important Pathway in Fracture Healing. Brya Matthews*[1], Danka Grcevic[2], Liping Wang[3], Yusuke Hagiwara[3], Douglas Adams[3], Ivo Kalajzic[3]. [1]University of Connecticut Health Center, Department of Reconstructive Sciences, USA, [2]University of Zagreb, Croatia, [3]University of Connecticut Health Center, USA

Fracture healing is a complex process that involves coordinated cellular responses, but characterization of specific cell populations in this process has been limited. We identified alpha smooth muscle actin (αSMA) as a marker of periosteal progenitor cells that contribute to fracture healing.

To identify and trace cells in periosteum we used αSMA promoter-driven inducible Cre (αSMACreERT2) combined with a Cre-activated fluorescent reporter Ai9 to generate SMA9 mice. Tibial fractures were performed after tamoxifen-induced labeling of cells, and the SMA9+ population was characterized during the early stages of fracture healing by histology, flow cytometry and gene expression profiling.

Histology indicated that SMA9+ periosteal cells expanded after fracture, and by day 6 were contributing to chondrocytes and osteoblasts within the callus. Periosteal cells from labeled unfractured bone, or periosteum/fracture callus from fracture day 2 and 6 were isolated for flow cytometry or cell sorting for RNA extraction. Over 95% of SMA9+ cells were negative for hematopoietic and endothelial lineage markers. The frequency of mesenchymal stem cell markers such as Sca1 increased after fracture (9% unfractured SMA9+ cells, 26% at day 6). Gene expression profiling showed that proliferation genes and cytokines/chemokines were upregulated 2 days after fracture. By fracture day 6, genes involved in matrix production and remodeling, including chondrocyte markers Col2a1 and aggrecan, and osteoblast markers alkaline phosphatase and bone sialoprotein were elevated. Genes associated with muscle contraction and Notch signaling were downregulated after fracture. Given that Notch signaling is an important developmental pathway in bone, but its role in fracture healing is undefined, we examined the effect of forced Notch activation in SMA9+ mesenchymal progenitor cells *in vitro*. Cre-mediated activation of Notch signaling in SMA9+ cells from periosteal or bone marrow stromal cell cultures reduced or blocked differentiation into osteogenic, chondrogenic and adipogenic lineages.

This is the first study to characterize a defined population of mesenchymal progenitor cells that actively participate in bone repair. We found that down-regulation of Notch signaling may be important for commitment of SMA9+ cells to mature lineages. Further characterization of these cells could potentially reveal mechanisms for recruitment or expansion of progenitor cells to improve bone healing.

Combined Deficiency of Prolyl Hydroxylase (PHD) 1 and PHD3 Increases Mesenchymal Stem Cell Number and Regulates the Hematopoietic Stem Cell Niche. Steve Stegen*[1], Satish Khurana[2], Nick van Gastel[1], Sophie Torrekens[1], Karen Moermans[1], Peter Carmeliet[3], Catherine Verfaillie[2], Geert Carmeliet[4]. [1]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, [2]Interdepartmental Stem Cell Institute, KU Leuven, Belgium, [3]Laboratory of Angiogenesis & Neurovascular Link, Vesalius Research Center, VIB, & Laboratory of Angiogenesis & Neurovascular Link, Vesalius Research Center, KU Leuven, Belgium, [4]Katholieke Universiteit Leuven, Belgium

Several distinct cell populations of the bone microenvironment are critical for hematopoietic stem cell (HSC) maintenance including mesenchymal stem cells (MSC), osteolineage cells and endothelial cells. Pharmacological block of the 3 prolyl hydroxylase domain enzymes (PHD), which regulate hypoxia signaling, has recently been reported to increase the number of quiescent HSCs. These compounds have previously been described to enhance bone mass by increasing the number of blood vessels. In this study we investigated the specific contribution of PHD1 and PHD3 on bone as well as HSC niche by genetic means.

Inactivation of both PHD1 and PHD3 (*Phd1/3* dKO) has no effect on most of the skeletal parameters including bone length, growth plate morphology, mineralized bone mass or the number of osteoblasts or osteoclasts, suggesting that PHD2 can compensate for these functions. However, several observations indicate that PHD1 and PHD3 specifically regulate the HSC niches in the bone/bone marrow. First, *Phd1/3* dKO osteoblasts produce more unmineralized bone matrix *in vivo*, without a change in dynamic mineralization parameters. Moreover, sorted osteoblasts ($Lin^-CD45^-CD31^-Sca1^-CD51^+$) displayed increased expression of genes coding for HSC supporting factors, including Osteopontin, CXCL12, Annexin A2, VCAM-1 and Angiopoietin-1. Secondly, *Phd1/3* deletion increases the number of MSC shown by a higher number of $Lin^-CD45^-CD31^-Sca1^+$ or $Lin^-CD45^-Nestin^+$ cells and supported by increased osteoblast colony forming units detected *in vitro*. In addition, sorted MSC ($Lin^-CD45^-CD31^-Sca1^+$) expressed increased levels of Osteopontin, CXCL12, Annexin A2, VCAM-1 and Angiopoietin-1. Thirdly, the number of blood vessels is increased shown by immunohistochemistry and the number of $Lin^-CD45^-CD31^+$ cells. Of note, opposite to the general accepted paradigm, the increased vascularity in *Phd1/3* dKO mice was not associated with increased bone mass, further supporting the concept that the primary role of PHD1 and PHD3 in bone is related to the control of the HSC niche by influencing multiple cell types. The changes in the HSC niches were linked to an increase in the frequency of primitive HSCs ($CD150^+CD48^-KLS$ cells) expressing more CXCR4 and showing improved competitive repopulation ability.

Taken together, this study indicates that PHD1 and PHD3 regulate the number and expression profile of osteolineage and endothelial cells constituting the HSC niche and control HSC number without affecting bone mass.

FR0246

Effects of Blockade of Endogenous Gi Signaling in Endothelial Lineage Cells on Bone Formation in a Heterotopic Ossification Model. Liping Wang*[1], Dylan O'Carroll[2], Xuhui Liu[3], Theresa Roth[2], Abbott Marcia[2], Hubert Kim[3], Bernard Halloran[4], Robert Nissenson[5]. [1]VA Medical Center, San Francisco, USA, [2]Endocrine Unit, VA Medical Center & Departments of Medicine & Physiology, University of California, USA, [3]Orthopedic Surgery, UCSF, USA, [4]VA Medical Center (111N), USA, [5]VA Medical Center & University of California, San Francisco, USA

Heterotopic ossification (HO) recapitulates normal endochondral bone formation in atypical locations. However, the precise lineage of progenitor cells forming HO lesions remains unknown. Current studies have revealed that endothelial lineage cells (ECLs) are a likely cellular source that contributes to HO through an endothelial-mesenchymal transition (EMT) mechanism. Since signaling through the G protein Gi is required for ECL motility, we hypothesized that blockade of endogenous Gi signaling in ECLs would prevent HO formation. We induced HO by injecting rhBMP-2 (1.5 μg in hydro gel) in quadriceps muscle in 12-16 week old littermate control and Tie2.PTX mice that expression of pertussis toxin (PTX) gene, driven by the endothelial-selective Tie2 promoter. Bone formation within HO lesions was evaluated by μCT 2 weeks after BMP injection. A sexually dimorphic responsiveness to BMP was observed. BMP-induced HO was detectable by uCT in about 50% of male mice (control, 7/14; Tie2.PTX, 8/20) and in about 90% of female mice (control, 10/11; Tie2.PTX, 8/9). Moreover, expression of PTX in ECLs significantly reduced the bone volume (BV) of HO lesions by 77.1% in male mice (control, 0.35 ± 0.14 mm^3; Tie2.PTX, 0.08 ± 0.03 mm^3, $p<0.05$) and by 76.7% in females (control, 0.90 ± 0.31 mm^3; Tie2.PTX, 0.21 ± 0.08 mm^3, $p<0.05$). In addition, the orthotopic bones were assessed by μCT and histomorphometry at the distal femur. Expression of PTX in ECLs did not change bone mass and structure in male Tie2.PTX mice, but significantly increased trabecular BV/TV by 31.6% ($p<0.01$), trabecular thickness by 13.6% ($p<0.01$), mineral appositional rate by 30.6% ($p<0.05$), and bone formation rate by 65.2% ($p<0.01$) in females. This result is strikingly similar to previous findings that blockade of Gi signaling in mature osteoblasts stimulates trabecular bone formation in female but not male mice. Lineage tracing of ECLs in adult Tie2.GFP mice showed that the GFP^+ cells appeared both inside and at the surfaces of bone tissue within the BMP-induced HO lesions and in the orthotopic bones. Collectively, the above findings suggest that ECLs are an important source of osteogenic cells during bone formation. Blockade of endogenous Gi signaling in ECLs prevents formation of ectopic bone and stimulates osteogenesis in orthotopic bones. Targeting of Gi protein coupled receptors in ECLs may be a novel therapeutic strategy in states of abnormal bone formation such as osteoporosis and HO.

FR0248

Vinculin Regulates Osteoclast Function. Tomohiro Fukunaga*, Wei Zou, Steven Teitelbaum. Washington University in St. Louis School of Medicine, USA

Osteoclastic bone resorption depends upon the cell's ability to form sealing zones (actin rings) by organizing its cytoskeleton via the αvβ3 integrin and osteoclastogenic cytokines. Because vinculin is an actin-binding cytoskeletal protein, we asked if it participates in skeleton degradation. Thus, we mated Vinculin(fl/fl) mice with those expressing cathepsin K-Cre (CtsK-*VCL*) to delete the gene in mature osteoclasts or with lysozyme M-Cre (LysM-*VCL*) mice to delete Vinculin in all osteoclast lineage cells. Vinculin-deficient precursors normally express osteoclast differentiation markers when exposed to M-CSF and RANKL. However, vinculin-deficient osteoclasts, expressing either Cre recombinase, cultured on bone, are small and have the "crenated" appearance characteristic of those with dysfunctional cytoskeletons. In

keeping with this conclusion, the same cells form small actin-rings and fail to effectively resorb bone as demonstrated by pit formation and CTx analysis. In keeping with inhibited resorptive function, both of CtsK-*VCL* and LysM-*VCL* mice exhibit an approximate doubling of bone mass with no change in osteoclast number *in vivo*. Vinculin functions by interacting with other proteins. To clarify the mechanism how vinculin regulate osteoclast function, we transduced WT and various mutant vinculin into LysM-*VCL* macrophages and differentiated them into osteoclast. While WT vinculin completely rescues osteoclast spreading and actin-ring formation on bone, mutant P878A which lose the ability to bind Arp2/3, also completely rescues LysM-*VCL* osteoclast function. Surprisingly, actin and paxillin binding site deletion (VCL 1-880) mutant significantly increases actin-ring area ($P<.01$). However, (VCL A50I) which blocks binding with Talin and Talin binding site deletion (VCL 811-1066) mutants fail to rescue osteoclast spreading and actin-ring formation. Thus, vinculin binding Talin, but not Arp2/3 and paxillin, is critical for osteoclast function.

Deletion of the Glycoprotein130 Co-Receptor in Osteoclasts Reduces Cortical Bone Formation. Rachelle Johnson*, Narelle McGregor, Holly Brennan, Ingrid Poulton, T John Martin, Natalie Sims. St. Vincent's Institute of Medical Research, Australia

The glycoprotein130 (gp130) co-receptor transduces signals in response to Interleukin-6 (IL-6) family cytokines. It is abundantly expressed in bone cells, including osteoclasts, osteoblasts and osteocytes. Studies have suggested that IL-6 signalling stimulates osteoclast activity through direct action on the osteoclast, but the role of osteoclastic gp130 in bone remodeling is not known. To determine the contribution of osteoclastic gp130 signalling to bone turnover, the gp130 transmembrane domain was conditionally deleted in osteoclasts under the control of CathepsinK-Cre recombinase and the bone phenotype of male and female mice was assessed.

Prior to phenotypic analysis, osteoclasts from *CtkCre.gp130w/w* and *CtkCre.gp130fl/f* mice were generated *in vitro* and significant knockdown (by 31%, $p<0.0001$) was confirmed in floxed cells by qPCR. Significantly longer femora were detected in *CtkCre.gp130fl/f* male mice at 6, 12 and 26 weeks of age. This was associated with increased growth plate width at 6 weeks, which could relate to gp130 deletion due to CtkCre expression in hypertrophic chondrocytes, as previously reported.

Femoral and vertebral trabecular bone volumes were normal in *CtkCre.gp130fl/f* mice compared to *CtkCre.gp130w/w* controls at 6, 12 and 26 weeks. However, histomorphometric analyses revealed a significant reduction in trabecular osteoblast number (by 38%, $p<0.05$) and mineralising surface (by 17%, $p<0.05$) in 12-week old male *CtkCre.gp130fl/f* mice, and increased osteoclast length ($p<0.05$) in both males (13%) and females (22%).

In cortical bone, osteoclastic deletion of gp130 significantly inhibited periosteal bone formation rate (by 68%, $p<0.0001$), reducing both double-labeled surface (by 75%, $p<0.008$) and mineral apposition rate (by 45%, $p<0.05$) resulting in reduced cortical thickness at 12 weeks. This lower level of bone formation was associated with reduced cortical bone size ($p<0.01$) on the periosteal (8%) and endocortical surfaces (11%) in male but not female mice at 26 weeks, contrary to the larger cortical bone phenotype reported with osteocytic deletion of gp130. Since IL-6 and IL-11R global knockout mice exhibited a similar reduction in cortical width, we also assessed these strains for periosteal bone formation, which was reduced in similar extent (by 94% in IL-6, $p<0.01$; by 65% in IL-11R, $p<0.05$) to the *CtkCre.gp130fl/f* mice. These data suggest that IL-6 and IL-11 signalling maintain periosteal growth in male mice through osteoclastic gp130.

The Rho GEF Def6 is a Novel, RANKL-independent in vivo Suppressor of Osteoclastogenesis and Bone Resorption under Inflammatory Conditions. F. Patrick Ross, Nikolaus Binder*, Benjamin Schatz, Alessandra Pernis, Steven Goldring. Hospital for Special Surgery, USA

Differentially Expressed in FDPC6 cells (Def6) is a guanine nucleotide exchange factor (GEF) for Rho family GTPases. Def6 null mice are osteoporotic, with 50% lower TV/BV than wild-type (WT) animals. Treatment of *Def6*$^{-/-}$ bone marrow macrophages (BMMs) with low levels of M-CSF and RANKL induces rapid formation of many large TRAP-positive osteoclasts (OCs); under similar conditions WT cells yield only TRAP-positive mononuclear precursors. Thus, Def6 suppresses osteoclastogenic (OCg) signals. In line with this hypothesis, expression of the OC marker genes *NFATc1, CathK and CTR* is up-regulated earlier and more robustly in *Def6*$^{-/-}$ cultures. Retroviral transduction of Def6 into *Def6*$^{-/-}$ BMMs reverses enhanced OC formation and gene expression, while its over-expression in WT precursors suppresses their capacity for OCg. When mice lacking *Def6*$^{-/-}$ are bred with TCR transgenic animals the progeny develop inflammatory arthritis with marked bone erosions and raised levels of IL-17 and IL-21, potent inducers of TNFα. Given these facts, we studied the impact of TNFα on OCg by *Def6*$^{-/-}$ BMMs. Treatment of *Def6*$^{-/-}$ precursors with TNFα alone results in robust OC formation and raised mRNA levels of prototypical OC genes, while WT counterparts developed few mature OCs, with smaller increases in expression of the same genes. To exclude the potential presence in the cultures of stromal cells, which express RANKL in response to TNFα, we repeated the studies, including BMM isolation and culture, in the continuous presence of osteoprotegerin (OPG), an endogenous high affinity RANKL-binding protein. As expected, presence of the inhibitor completely abolished RANKL-induced OCg by WT and *Def6*$^{-/-}$ BMMs. Critically, OPG presence failed to alter TNFα-induced OC formation in *Def6*$^{-/-}$ BMMs, confirming that the cytokine's ability to induce OCg is RANKL independent. Supracalvarial TNFα injections in WT and *Def6-/- mice* confirmed the enhanced capacity of TNFα to induce bone resorption in vivo. Next, we asked if TNFα regulates Def6 expression and found that, like RANKL, it reduces levels of the GEF. Finally, since Def6 has cytoplasmic and nuclear actions in T-cells, we expressed HA-tagged Def6 retrovirally in BMMs to study its cellular localization during OCg and find the protein in both locations in BMMs and OCs. In summary, Def6, likely via a combination of cytoplasmic and nuclear actions, acts as a novel, RANKL-independent suppressor of OCg under inflammatory conditions in vitro and in vivo.

High Bone Mass in Mice Lacking Cx37 Due to a Cell-autonomous Defect in Osteoclast Differentiation and Fusion. Rafael Pacheco Da Costa*[1], Drew M Brown[2], Iraj Hassan[2], Surajudeen Bolarinwa[2], Meloney Cregor[2], Rejane Reginato[3], Angela Bruzzaniti[4], Teresita Bellido[4], Matthew Allen[4], Lilian Plotkin[4]. [1]Indiana University/Universidade Federal de Sao Paulo - Brazil, Brazil, [2]Dept. Anatomy & Cell Biology, USA, [3]Department of Morphology & Genetics, Federal University of São Paulo, Brazil, [4]Indiana University School of Dentistry, USA

Connexin (Cx) 37 is a gap junction protein expressed in osteoblasts, osteocytes and osteoclasts. However, the role of Cx37 on bone cell function has not been investigated. Newborn Cx37$^{-/-}$ or Cx37$^{+/-}$ mice exhibit normal cartilage and calcified tissue compared to wild type Cx37$^{+/+}$ mice, as evidenced in histological whole body preparations stained with alcian blue/alizarin red. However, Cx37$^{-/-}$ male mice (N=10-14) exhibit increased spinal BMD (10-12%) at 3-5 months of age. Femoral BMD was also increased (7-10%) at 3-4 months of age. In addition, Cx37$^{-/-}$ mice exhibit higher BV/TV and trabecular number, and lower trabecular thickness in L4, measured by μCT at 5 months of age. On the other hand, Cx37 deletion did not affect cortical bone geometry at the femoral midshaft. *Ex vivo* cultures of non-adherent bone marrow cells from Cx37$^{-/-}$ mice in the presence of sRANKL and MCSF for 5 days showed a 5-fold decrease in osteoclasts compared to cultures established with Cx37$^{+/+}$ cells. In addition, Cx37$^{-/-}$ osteoclasts are 5.6-fold smaller and exhibit lower number of nuclei per cells (10.5 versus 6.6 for Cx37$^{+/+}$ and Cx37 $^{-/-}$, respectively). Moreover, expression of cathepsinK, TRAP, RANK, and calcitonin receptor, markers of osteoclast number and activity, were decreased in Cx37$^{-/-}$ cells. Cx37 absence also decreased expression of DC-STAMP, NFATc1, and Atp6v0d2, genes associated with osteoclast fusion and function. On the other hand, non-adherent bone marrow cells from Cx37$^{-/-}$ mice exhibit a 2-fold increase in the expression of CD11b, a marker of osteoclast precursors. However, the ability of MLO-Y4 osteocytic cells to support osteoclast differentiation was not reduced by silencing Cx37 using shRNA. These results are consistent with a direct effect of Cx37 deletion on the differentiation of osteoclast precursors. The mineralization potential of bone marrow cells cultured in the presence of 50μg/ml ascorbic acid and 10mM β-glycerophosphate for 14d was not changed, as evidence by similar alizarin staining. Further, osteocalcin levels were similar in vertebrae bone lysates or in the circulation in Cx37$^{+/+}$ or Cx37$^{-/-}$ mice. These results suggest that Cx37 deletion does not alter osteoblast function. Thus, Cx37 deletion increases bone mass by inhibiting osteoclast differentiation, raising the possibility that intercellular communication via Cx37 channels among mononuclear osteoclast precursors is required for triggering cell fusion and differentiation.

Cx43 Scaffolding Cytoplasmic Domain Restrains Bone Resorption but is Dispensable for the Anabolic Action of Intermittent PTH Administration. Rafael Pacheco Da Costa*[1], Iraj Hassan[2], Xiaolin Tu[3], Rejane D Reginato[4], Eduardo Katchburian[4], Teresita Bellido[3], Lilian Plotkin[3]. [1]Indiana University/Universidade Federal de Sao Paulo - Brazil, Brazil, [2]Dept. Anatomy & Cell Biology, USA, [3]Indiana University School of Medicine, USA, [4]Department of Morphology & Genetics, Federal University of São Paulo, Brazil

Connexin (Cx) 43 channels mediate intercellular communication in bone. In addition, through its cytoplasmic domain, Cx43 serves as a scaffold, facilitating intracellular signaling. Loss-of-function studies showed that mice lacking Cx43 in osteoblastic cells exhibit high RANKL/OPG expression and increased osteoclasts, reduced Sost and increased bone formation, and a defective anabolic response to intermittent PTH. However, Cx43 domains responsible for these functions have not been identified. To investigate the role of Cx43CT domain, we generated Cx43$^{stop/fl}$ mice, in which one allele of the gene is truncated at aminoacid 258 rendering a mutant that forms functional channels but lacks the scaffolding ability; and the other allele is the full length Cx43flox (fl). Female 18-week-old Cx43$^{stop/fl}$ mice exhibit 30% lower

cancellous (L5) BV/TV, decreased trabecular number and increased trabecular separation (μCT) compared to $Cx43^{fl/fl}$ control littermates, suggesting that truncated Cx43 acts as dominant negative for the full length molecule. To explore the molecular basis of this phenotype, we examined gene expression by qPCR in vertebral bone (L6). OPG level was decreased without changes in RANKL, leading to a 6-fold higher RANKL/OPG ratio in $Cx43^{stop/fl}$ mice than in controls. MCSF levels were also 2-fold higher. Consistently, calcitonin receptor expression was 4-fold increased and TRAP expression was also higher but without reaching significance. On the other hand, osteocalcin and alkaline phosphatase levels were not changed and collagen1a1 expression was 2-fold higher. Further, circulating levels of CTX were 30% higher in $Cx43^{stop/fl}$ mice than in controls. Remarkably, loss of osteocytic Cx43flox allele by crossing $Cx43^{stop/fl}$ mice with DMP1-8kbCre mice reversed the effect of truncated Cx43. Thus, $Cx43^{stop/fl}$;DMP1-8kbCre mice have higher BV/TV and trabecular number and lower trabecular separation, associated with reduced Sost expression; and reduced RANKL/OPG ratio, calcitonin receptor, and CTX, compared to $Cx43^{stop/fl}$ littermates. In spite the differences under basal conditions, all mice responded in similar fashion to daily PTH injections (100ng/g for 14d) with increased BMD, BV/TV, and osteocalcin and collagen1a1 expression in the spine. Thus, Cx43 scaffolding cytoplasmic domain is responsible for Cx43 antiresorptive function and for maintaining Sost levels that restrain bone formation, but is dispensable for the skeletal anabolic action of intermittent PTH.

FR0263

Induction of osteoclast-rich osteopetrosis leads to uncoupled formation and resorption, while induction of osteoclast-poor osteopetrosis does not. Christian Thudium*[1], Carmen Flores[2], Ilana Moscatelli[2], Annemarie Brüel[3], Jesper Thomsen[4], Karoline Natasja Stæhr Gudmann[1], Ellen Hauge[5], Morten Karsdal[1], Johan Richter[2], Kim Henriksen[1]. [1]Nordic Bioscience A/S, Denmark, [2]Lund University, Sweden, [3]University of Aarhus, Denmark, [4]Aarhus University, Denmark, [5]Aarhus University Hospital, Denmark

Osteopetrosis due to lack of acid secretion by osteoclasts is characterized by abolished bone resorption, increased osteoclast numbers, but normal or even increased bone formation. In contrast, osteoclast-poor osteopetrosis appear to have less osteoblasts and reduced bone formation, indicating that osteoclasts are important for bone formation.

To shed light on the role of the osteoclast in mediating bone formation in adult mice, we transplanted irradiated skeletally mature three-month old wt mice with hematopoietic stem cells (HSCs), to generate either an osteoclast rich or osteoclast poor osteopetrosis model. We used HSCs from 1) oc/oc mice (acidification deficient and non-resorbing), 2) HSCs from RANK KO (osteoclastogenesis impaired) mice, and 3) compared to wt control HSCs.

Briefly, 12 weeks old mice were lethally irradiate with 950 cGy and transplanted with 2x106 fetal live cells from either oc/oc, RANK KO or wt mice. The mice were followed for 15 weeks and serum samples were drawn every two weeks and analyzed for TRACP5b and CTX-I. At termination bones were isolated analyzed using μCT, dynamic histomorphometry, and mechanical testing.

TRACP5b, a marker of osteoclast number, showed an increase (125%) in oc/oc and a 50% decrease in Rank KO recipients, while the bone resorption marker CTX-I was similarly decreased (20%) in both groups. Both oc/oc and Rank KO recipients developed a mild osteopetrotic phenotype, however, the osteoclast-rich oc/oc recipients showed a higher trabecular bone volume (40%), and increased bone strength (66%) in trabecular bone, while RANK KO recipients showed a trend (16% and 19%) towards an increase compared to wt recipients. In cortical bone, similar but smaller effects on bone volume and strength were observed in both osteopetrosis groups. Furthermore, oc/oc recipients had increased bone formation rate in the trabecular compartment of the vertebrae (54%) compared to wt recipient controls, and these changes were not observed in RANK KO recipients.

In summary, we here present in vivo data showing that maintaining non-resorbing osteoclasts, as opposed to removing the osteoclasts, leads to increased bone formation, bone volume and ultimately higher bone strength *in vivo*. These data strongly indicate that the osteoclasts are sources of anabolic molecules for the osteoblasts, and thereby play an important role in maintaining bone turnover independently of their resorptive capacity.

Novel Models Of Osteoporosis In Transgenic Mice Overexpressing Human RANKL. Vagelis Rinotas[1], Alexandra Niti[1], Romain Dacquin[2], Nicolas Bonnet[3], Serge Ferrari[4], Pierre Jurdic[5], Eleni Douni*[6]. [1]BSRC Alexander Fleming, Greece, [2]ENS de Lyon, France, [3]University Geneva Hospital-Department of Internal Medecine Specialities, Switzerland, [4]Geneva University Hospital & Faculty of Medicine, Switzerland, [5]Ecole Normale Superieure de Lyon, France, [6]Agricultural University of Athens/ BSRC Al. Fleming, Greece

Receptor activator of nuclear factor-κB ligand (RANKL) is a central regulator of bone remodeling by mediating osteoclast-induced bone resorption. Overproduction of RANKL is implicated in a variety of degenerative bone diseases such as osteoporosis and its specific inhibition effectively reduces the incidence of fractures in postmenopausal women. We have recently generated transgenic mice overexpressing human RANKL (TghuRANKL) in order to model human RANKL-mediated pathologies. To achieve a correct pattern of human RANKL expression in the mouse, a 200kb genomic fragment containing the whole human RANKL gene was used as a transgene. Quantitative bone analysis revealed a mild phenotype in the low copy number Tg5516 line displaying trabecular bone loss as well as reduced biomechanical properties at 3 months of age. A more severe osteoporotic phenotype was identified in the high copy Tg5519 line developing trabecular bone loss, severe cortical bone porosity, and decreased bone strength by the age of 3 months. The numbers of osteoclasts at the cortical surfaces as well as serum markers of bone turnover were significantly increased in Tg5519 mice. Moreover, this transgenic line also displayed active bone formation and significantly increased serum alkaline phosphatase levels, indicating increased bone remodeling. The observed phenotypes developed in both sexes, whereas the levels of human RANKL expression were correlated with bone resorption and disease severity. Notably, TghuRANKL mice rescued the osteopetrotic phenotype of mutant mice expressing an inactive form of endogenous RANKL, showing that the human RANKL protein is fully active in the mouse. Interestingly, treatment of TghuRANKL mice with known anti-resorptive drugs effectively inhibited bone resorption proving the significance of such mice in preclinical evaluation studies of novel anti-osteoporotic compounds. These novel human RANKL transgenic models of osteoporosis represent a unique tool for understanding the pathogenic mechanisms in bone resorption as well as for the preclinical evaluation of novel inhibitors that target human RANKL and osteoclasts.

Comparative Analysis of the Specificity of Available Osteoclast Lineage Cre-Drivers and Identification of Novel Osteoclast Lineage Selective Genes. Megan Weivoda*[1], Katharina Jähn[2], Matt Prideaux[3], Ming Ruan[1], Sundeep Khosla[4], Lynda Bonewald[5], Merry Jo Oursler[1]. [1]Mayo Clinic, USA, [2]University Medical Center Hamburg-Eppendorf, Germany, [3]University of Missouri-Kansas City, USA, [4]Mayo Clinic College of Medicine, USA, [5]University of Missouri - Kansas City, USA

Osteocytes express certain osteoclast genes including cathepsin K (CTSK) and tartrate resistant acid phosphatase (TRAP) to remodel mineralized matrix in response to lactation. The CTSK and TRAP promoters are commonly used to drive Cre recombinase (Cre) expression to knockdown genes in osteoclasts. Activation of these promoters in osteocytes by lactation may lead to Cre expression and subsequent gene deletion in osteocytes, complicating the findings in osteoclast specific knockdown experiments. The goal of this study was to assess the tissue specificity of genes used to drive Cre expression in the osteoclast lineage and to identify novel gene candidates to selectively target osteoclasts. Expression of genes used to drive Cre in the osteoclast lineage was compared in osteocytes isolated from lactating female mice to virgin female osteocytes, bone marrow, and bone marrow-derived osteoclasts. Microarrays performed on virgin and lactating mouse osteocytes were analyzed in comparison to osteoclasts to reveal potential candidate genes for new osteoclast specific Cre models; identified targets were validated by qPCR. Osteoclast specificity of Cre driver genes and novel targets were assessed in a cDNA tissue library. Consistent with published data, lactation increased CTSK and TRAP expression in osteocytes. Osteoclasts expressed 7-fold and 8-fold higher levels of CTSK and TRAP, respectively, as compared to osteocytes isolated from lactating mice. Lactation did not significantly alter expression of CD11b, cFms, LysM, RANK, or Vav1, promoters of which have been used to drive Cre expression in the osteoclast lineage. Analysis of these genes in a cDNA tissue library showed that CD11b, cFms, and CTSK have greater specificity for the osteoclast lineage. In contrast, LysM, RANK, TRAP, and Vav1 revealed more heterogeneity in tissue expression. Microarray identified OSCAR and OC-STAMP as highly expressed in osteoclasts compared to virgin or lactating osteocytes. Validation by qPCR showed 20 and 54-fold increases, respectively, in comparison to lactating osteocytes. Moreover, OSCAR and OC-STAMP were highly restricted to the osteoclast lineage. These data suggest that although lactation induces CTSK expression in osteocytes, CTSK remains a good model for gene knockdown in the osteoclast lineage in virgin mice. This work also suggests that the development of OSCAR and OC-STAMP Cre models may be promising tools for highly specific gene deletion in the osteoclast lineage.

FR0271

Deletion of the cell-adhesion mediator PODXL in early osteoclast precursors leads to a high bone mass phenotype in female, but not male mice: A role for PODXL in the localization of active Rac1 in osteoclasts. Megan Weivoda*[1], Muzaffer Cicek[1], Ashok Kumar[2], Ming Ruan[1], Larry Pederson[1], Christine Hachfeld[1], Michael Hughes[3], Kelly McNagny[3], Merry Jo Oursler[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic College of Medicine, USA, [3]University of British Columbia, Canada

Podocalyxin (PODXL) is a mediator of cell adhesion expressed by the hematopoietic lineage. Due to the role of PODXL in adhesion, we hypothesized that PODXL may regulate osteoclast precursor fusion. We crossed PODXL floxed mice with Vav-Cre mice to obtain male and female mice with PODXL deleted in early osteoclast progenitors (Vav/PODXL^{del}). L4 vertebrae from 17-week mice were assessed by μCT and histomorphometry; femurs were assessed by pQCT. Bone marrow was cultured with RANKL and M-CSF and examined for osteoclast differentiation and cell signaling. Bones from Vav/PODXL^{del} mice exhibited increased osteoclast numbers. Unexpectedly, female, but not male, Vav/PODXL^{del} mice exhibited a high bone mass phenotype. Female L4 vertebrae had significant increases in BV/TV, TbN, and TbTh, and decreased TbSp. BMD and CTh were significantly increased in female femurs as measured by pQCT. To uncover the reason for the high bone mass despite elevated osteoclast numbers, we examined osteoclast functions *in vitro*. Vav/PODXL^{del} bone marrow cultured on tissue culture plastic produced TRAP^{+}, multinucleated osteoclasts. Although Vav/PODXL^{del} osteoclasts were capable of adhering to bone surfaces, they failed to form resorption pits on bovine bone chips *in vitro*; this was true of osteoclasts derived from both male and female mice. The fact that osteoclasts derived from male Vav/PODXL^{del} mice fail to resorb bone *in vitro* similarly to female derived Vav/PODXL^{del} osteoclasts suggests that the lack of an altered bone phenotype in males is due to endocrine influences. Consistent with the retained ability to bind bone surfaces, activation of the integrin $\alpha_v\beta_3$ was not impaired. While active Rac1 was localized to discrete membrane regions in wild type osteoclasts, Vav/PODXL^{del} osteoclasts exhibited diffuse Rac1 activation. Adenoviral infection of osteoclast precursors with constitutively active Rac1 restored resorption pit formation by Vav/PODXL^{del} osteoclasts *in vitro*. Together, these data suggest that PODXL is required for optimal Rac1 activity in the osteoclast and PODXL deletion leads to impaired osteoclast bone resorption due to improper localization of active Rac1. This phenotype may be evident in female mice due to estrogen-mediated decreases in Rac1 activity. Resolution of the mechanism by which PODXL regulates localization of active Rac1 in osteoclasts may provide new avenues to pursue to suppress bone resorption while preserving the anabolic influences of osteoclasts.

Diacylglycerol kinase ζ (DGKζ) is a critical regulator of bone homeostasis via modulation of DAG levels in osteoclasts. Ali Zamani*[1], Pamela Hesker[2], Roberta Faccio[3]. [1]Department of Orthopedics, Washington University, St. Louis, Missouri, USA, [2]Washington University in St Louis School, USA, [3]Washington University in St Louis School of Medicine, USA

Osteoclasts (OCs) are instrumental component in the pathogenesis of rheumatoid arthritis (RA) and osteoporosis. Our lab has previously shown that PLCγ2 is a critical modulator of OC differentiation and inflammation. Despite the critical role of PLCγ2 in both bone and immune cells in the context of RA, its high homology with the more ubiquitously expressed PLCγ1, rendering PLCγ2 specific targeting difficult. In contrast, diacylglycerol (DAG), a downstream product of PLCγ2 catalytic activity to control PLCγ2-mediated events in OC, is strictly controlled by tissue specific diacylglycerol kinases (DGKs). This high level of specificity makes DGKs an attractive target for therapeutic interventions. Among 10 different DGK isoforms, our data indicate that DGKζ is the most highly expressed isoform in macrophages and OC. Consistent with the role of DAG in PLCγ2-mediated events in OC, DGKζ deficiency, which leads to DAG accumulation, results in a substantial osteoporotic bone phenotype in vivo. 6 week old DGKζ -/- mice exhibit a very sparse trabecular pattern with 5 fold less trabecular volume/bone volume (BV/TV), along with thinning and erosion of the cortical bone, compared to WT mice. The number of periosteal OCs is also significantly increased in DGKζ -/- mice (nOC WT 8 ± 3; nOC DGKζ-/- 25 ± 2). This in vivo phenotype is maintained with age. Similarly, in vitro, DGKζ -/- bone marrow macrophages form more numerous OC than WT with high or low doses of RANKL stimulation. DGKζ-/- cells express higher levels of early OC differentiation markers (NFATc1, TRAP and CTSK) and display significant upregulation of fusion markers (DC-STAMP and ATP6V0D2). In addition, DGKζ-/- OC also show enhanced resorption activity when equal numbers of WT and KO DGKζ OC plated on bone for 24hrs. These data indicate that DGKζ is a critical regulator of bone homeostasis in vitro and in vivo. Mechanistically, DGKζ-/- OC precursors exhibit enhanced proliferation in response to M-CSF stimulation, which is reflected by increased CyclinD1 and p-pRb levels. Furthermore, the osteoclastogenic transcription factor c-Fos is also elevated in DGKζ-/- cells in response to M-CSF. To our knowledge, this is the first report that implicates the lipid kinase DGKζ as a novel critical regulator of bone homeostasis via modulation of DAG levels in the osteoclasts and positions DGKζ as a potential new therapeutic target for pathological bone loss.

Novel Role of the Alternative NF-κB Pathway in Regulating Osteoclast Mitochondrial Biogenesis Distinct from Osteoclast Differentiation. Rong Zeng*[1], Chang Yang[2], Deborah Novack[2]. [1]Washington University in St. Louis, USA, [2]Washington University in St Louis School of Medicine, USA

Osteoclasts (OCs) are mitochondria-rich multinucleated cells specialized for the energy-intensive role of degrading bone matrix. We have previously shown that the alternative NF-κB pathway, controlled by the kinase NIK and mediated by the transcription factor subunit RelB, regulates OC differentiation and function. However, direct functional target genes of RelB controlling OC resorption have not been identified. In skeletal muscle, an unknown stimulus activates the alternative NF-κB pathway, and allows RelB to positively and directly regulate its target, PGC-1β, a transcription co-factor to PPARγ, important for controlling metabolism and mitochondria biogenesis in many metabolically active cell types, including OCs. Thus we hypothesize that the RANK-activated alternative NF-κB pathway in OCs directly controls mitochondrial biogenesis and its associated metabolic roles via PGC-1β, but may be independent from OC differentiation. In our studies, OC precursors from relb-/-, nik-/-, and CatK.NT3 (constitutively active NIK transgene driven by the Cathepsin K promoter) mice were cultured under osteoclastogenic conditions (in the presence of M-CSF and RANKL). Expression of PGC-1β and mitochondrial oxidative phosphorylation genes (for ATP synthesis) were significantly impaired in relb-/- and nik-/- OCs, as measured by qRT-PCR and immunoblotting. Furthermore, when total DNA (nuclear and mitochondrial) was extracted to quantitate relative mitochondrial copy numbers (CN), relb-/- and nik-/- OCs had deficient mitochondrial CN compared to WT. Examination of mitochondrial function with a Seahorse XF Flux Analyzer revealed that relb-/- and nik-/- OCs had a reduction in basal and maximum oxygen consumption rates. CatK.NT3 OCs showed increased mitochondrial CN and respiration rate. CatK.NT3 and relb-/- mutants showed abnormal mitochondrial morphologies by transmission EM. Mechanistically, Chromatin IP and luciferase assays suggest that RelB directly regulates PGC-1β transcription in OCs, making PGC-1β the likely mediator of the mitochondrial phenotypes. Retroviral overexpression of PGC-1β in relb-/- cells rescues mitochondrial defects but not OC differentiation or function, while overexpression of NFATc1 rescues OC differentiation but not mitochondrial or bone resorption defects. We conclude that mitochondrial biogenesis in OCs is regulated by the alternative NF-κB pathway, via PGC-1β, in a pathway distinct from osteoclastogenesis that contributes to bone resorption.

RANKL/M-CSF-PI3K-Akt signaling in osteoclast differentiation and function is regulated via the direct interaction between G protein α subunit and Class IA PI3K. Mengrui Wu*, Wei Chen, Yi-Ping Li. The University of Alabama at Birmingham, USA

Current bone resorption inhibitors are effective but far from ideal because of side effects (*e.g.,* jaw osteonecrosis and increased bone fragility). Thus, there is a compelling need for better therapeutic agents in osteoclast-related bone diseases. The critical role of Phosphatidylinositol 3-kinase (PI3K), especially class IA PI3K, in osteoclast differentiation and function, has been established. Class IA PI3K is comprised of a regulatory subunit (p85/p55) and a catalytic subunit (p110α/β/δ). p110α is more abundant and important than p110β or δ in osteoclasts. Thus, we searched for candidate regulators of PI3K using an anti-p110α antibody co-immunoprecipitation approach. By co-immunoprecipitation, we demonstrated that guanine nucleotide binding protein α 13 (Gna13) was interacting with p110α, but not p85 or Csf1r. Knockdown of Gna13 *in vitro* and osteoclast-specific knockout of Gna13 *in vivo* increased osteoclast differentiation and function via PI3K/Akt signaling. The Gna13 mutant mice exhibit severe osteoporosis phenotype. Gna13 deficiency increased the formation of huge osteoclasts with more nuclei and larger actin rings. The average nuclei number of osteoclasts and the average size of actin rings were increased in the absence of Gna13 (by 100% and 300%, respectively). On the other hand, overexpression of the constitutively active form of Gna13 (Gna13 Q226L) in monocytes/macrophages blocked pre-osteoclast fusion by 85% and disturbed actin ring formation. Osteoclast-specific genes, Ctsk and NFATc1, were increased in Gna13-deficient osteoclasts (by 50% and 200%, respectively)and decreased in Gna13 Q226L-overexpressed osteoclasts (by 70% and 90%, respectively). Gna13 deficiency increased AKT phosphorylation and overexpression of Gna13 Q226L inhibited AKT activation, but the phosphorylation of Erk1/2, c-jun and p38 was not affected. Ctsk secretion and bone resorption were also increased in Gna13-deficient osteoclasts (by 200% and 200%, respectively) and decreased in Gna13 Q226L-overexpressed osteoclasts (by 80% and 90%, respectively). In summary, we demonstrated that Gna13 negatively regulates RANKL/M-CSF Class IA PI3K/AKT signaling by interacting with p110α, so as to inhibit osteoclast fusion and function. This is the first report of an endogenous interaction between G protein α subunit and PI3K and its biological role. Our study indicates that the constitutively active form of Gna13 could be a new therapeutic target of osteoclast-related bone diseases.

FR0275

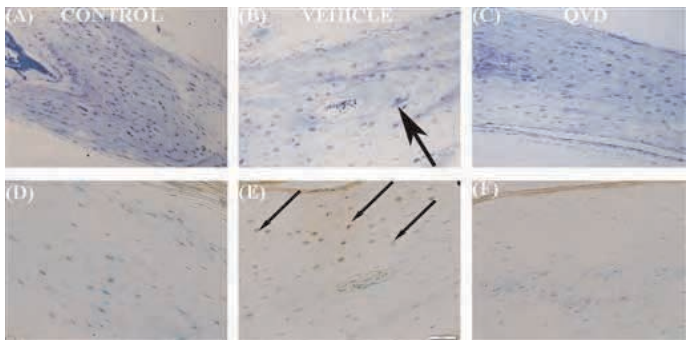
Activation of intracortical resorption in mouse long bone by acute placement of focal microdamage by in vivo indentation is controlled by osteocyte apoptosis. Oran Kennedy*[1], Anaya Philip[2], Jelena Basta Pljakic[2], Mitchell Schaffler[2]. [1]New York University, Hospital for Joint Diseases, USA, [2]City College of New York, USA

Introduction: Intracortical remodeling in bone removes and replaces microdamage. This process is known to include osteocyte apoptosis near sites of damage. In vivo fatigue loading of rat ulnae has been widely used to study this phenomenon [1,2]. The ability to scale down this approach for use in mice, and take advantage of genetic technologies, would be very valuable. However, this has proven difficult due to size issues. We previously showed that indentation which places microdamage in living cortical mouse bone, can activate a focal remodeling response [3]. Here, we use a pan-caspase inhibitor (QVD) to test whether the remodeling response is mediated by osteocyte apoptosis in this system.

Methods: We used a 50 µm conical indenter (Reference Point Indentation, Active Life Scientific, CA) to generate acute focal microdamage beneath the indenter tip in C57Bl/6 mouse tibiae [4]. Mice (n=6/group, IACUC approved) were assigned to 1 of 3 groups: Control, Indent+VEH or Indent+QVD. Under anesthesia, focal damage was placed on the anterior surface of the right limb at the level of the tibiofibular junction. The cortex at this site is sufficiently thick for indentation. Animals were sacrificed at 14 days – the resorption phase for the remodeling response to microdamage. Tibiae were examined by histology and IHC staining for apoptosis (Caspase 3).

Results and Discussion: Focal damage sites were highly consistent among all groups. Indentation/focal microdamage did not evoke a periosteal woven bone response, nor was there evidence of focal soft tissue inflammation. Intracortical remodeling was activated in the microdamage zone below indentation sites in Indent+VEH animals (Fig 1B). Such remodeling sites were absent from Indent+QVD and Control bones (Fig 1A,C). IHC analyses showed strong positive staining for caspase-3 in osteocytes at the indentation-remodeling sites in Indent+VEH animals (Fig 1E), but not in Indent+QVD and Control animals (Fig 1D,F).

Conclusion: We show that remodeling can be activated in mouse bone by acute focal microdamage placement with in vivo microindentation. Moreover, this remodeling response was completely abrogated when osteocyte apoptosis is inhibited by a pan-caspase inhibitor. These results show the damage-remodeling pathway in this acute microdamage model is the same as for fatigue microdamage, and identifies a powerful new approach for using mouse models to interrogate the regulatory role of osteocyte apoptosis in bone remodeling.



Sections stained either with toluidine blue (A-C) or for caspase-3 (D-F) from each treatment group

Disruption of Connexin 43 Channel Function in Osteocytes Differentially Reduces Bone Mass and Impairs the Tibial Anabolic Response to Load. Jean Jiang*. University of Texas Health Science Center at San Antonio, USA

Connexin (Cx) 43 plays an important role in bone function and development. Targeted deletion of Cx43 in osteoblasts or osteocytes results in increased osteocyte apoptosis, osteoclast recruitment, and reduced bone mass and strength. We and others have shown that the Cx43 hemichannel (HC) in osteocytes is a major portal for the release of bone-modulating factors (i.e. prostaglandins, ATP, etc) in response to mechanical stimulation. Interestingly, recent studies showed that knocking out Cx43 enhanced the anabolic responses of the bone to mechanical loading. Cx43 forms both gap junctions (GJ) and HCs; however, a significant amount of Cx43 is also retained in the cytoplasm of osteocytes. In order to determine the relative contributions of Cx43 GJs versus HCs in osteocytes, two transgenic mouse models driven by a 10 kb-DMP-1 promoter with the overexpression of dominant negative Cx43 mutants were generated - the Cx43 (R76W) mutant which blocks GJ but not HC function and the Cx43(?130-136) mutant that inhibits both GJ and HC activity. Immunohistochemistry showed predominant expression of these two mutants in osteocytes in situ. Dye transfer and dye uptake analyses confirmed the dominant negative function of these two Cx43 mutants on GJs and HCs in osteocytes isolated from transgenic mice. Both Cx43(R76W) and Cx43(?130-136) mice ranging from 2 to 6 month old showed a decrease in BMD, compared to wild-type controls. Fifteenweek-old mice subjected to tibial loading (11N, 1800 cycles at 2 Hz and 5 days/week for 2 weeks)showed a significant increase in BV/TV in wild-type control mice; however, this anabolic effect was completely abolished in both Cx43 transgenic mouse models. Moreover, after mechanical loading, tibia of R76W mice showed lower BV/TV thannon-loaded controls, suggesting non-coupling of resorption and formation. The compromised anabolic response to mechanical loading in transgenic mice was further confirmed by an increased osteoclast number by histomorphometry analyses, while a reduced osteoclast number was observed, as expected, for wild-type control mice. These results suggest that Cx43 GJs in osteocytes are critical for maintaining normal bone mass, but that HCs or overexpression of HCs as in the R76W mutant may increase resorption. In summary, normal expression of both GJs and HCs are responsible for mediating the anabolic response of mechanical loading on bone tissues by reducing osteoclast numbers.

Osteocytes release microvesicles that regulate osteoblast function. Patricia Veno*, Matt Prideaux, Vladimir Dusevich, Lynda Bonewald, Sarah Dallas. University of Missouri - Kansas City, USA

Microvesicles (100-1000nm) and exosomes (50-100nm) are membrane-bound particles released by cells that provide a novel mechanism for intercellular communication through targeted delivery of their contents including proteins, mRNAs and microRNAs. We have developed transgenic mice expressing a membrane-targeted GFP in osteocytes, driven by the Dmp1 promoter (Dmp1-mem-GFP), which allows visualization of microvesicle shedding. Confocal microscopy showed abundant spherical GFP+ve microvesicles deposited around osteocytes in the calvaria, long bones and alveolar bone of neonatal and adult Dmp1-mem-GFP mice. GFP-positive microvesicles persisted in adult bone matrix even after osteocytes had stopped expressing Dmp1-GFP. Live imaging of Dmp1-mem-GFP positive osteocytes in situ within their bone matrix in calvarial organ cultures revealed shedding of vesicles from the cell body and dendrites. Some osteocytes appeared to extend their dendrites beyond the limits of their canaliculi to shed microvesicles into vascular channels. To further understand their function in bone, microvesicles were purified from osteocyte-enriched primary cultures of Dmp1-mem-GFP calvarial cells and from IDG-SW3 cells (a late osteoblast cell line that differentiates into mature osteocyte-like cells) for characterization by TEM and Western blotting. Western blotting showed that the contents of the microvesicles reflected the differentiated state of the parent cells, with microvesicles from 7 day cultures of IDG-SW3 and primary Dmp1-mem-GFP calvarial cell cultures expressing early osteocyte markers (E11/gp38 and a high MW form of MEPE) and microvesicles from 4 week old cultures expressing these early markers as well as the late osteocyte marker, sclerostin. Sclerostin was enriched in the microvesicle compartment compared to whole cell lysate and was strongly down regulated by PTH treatment. Treatment of undifferentiated IDG-SW3 cells or Dmp1-mem-GFP calvarial cells with microvesicles from late differentiated (mature osteocyte-enriched) cultures resulted in a strong induction of alkaline phosphatase and induction of Dmp1-GFP expression within 48h as well as increased expression of E11/gp38, suggesting regulation of osteoblast function and acceleration of differentiation towards an early osteocytic phenotype. These data suggest that osteocytes shed microvesicles containing bone regulatory proteins which may induce differentiation of osteoblasts and potentially have effects on distant tissues.

Inhibition of Osteocyte Apoptosis Prevents Extensive Trabecular Bone Loss Caused by Unloading in the Long Bone of Mice. Pamela Cabahug*[1], Robert Majeska[1], Damien Ladier[2], Alyssa Tuthill[3], Stefan Judex[3], Mitchell Schaffler[1]. [1]City College of New York, USA, [2]The City College of NY, USA, [3]Stony Brook University, USA

Osteocyte apoptosis is required to activate bone remodeling in fatigue microdamage, estrogen withdrawal and disuse. In cortical bone, inhibition of apoptosis prevents the onset of osteoclast resorption due to these challenges, showing that regulated osteocyte death controls remodeling. Bone loss in mouse compact bone during estrogen loss or disuse is small and confined to endocortical surfaces, but trabecular bone loss due to disuse is extensive. We asked whether inhibiting osteocyte apoptosis (OtAp) would be effective in preventing such major bone loss. Our goals were to evaluate the effects of unloading on the trabeculae of long bone and determine if inhibition of OtAp prevents the onset of bone resorption due to unloading. Methods: C57BL/6J mice (4 mo-male, n=6/group) were hindlimb unloaded (HLU) by tail suspension. A group was HLU for 5 days to find acute effects on OtAp. Treatment groups were HLU for 14 days. These were: 1) HLU+Vehicle, 2) HLU+Ap inhibitor (ApInh = pan caspase inhibitor, QVD), 3) Veh and 4) ApInh treated cage control (CC) groups. Analyses were performed from distal femurs. Ot Ap was assessed using IHC staining for activated caspase-3. The proportion of positively stained Ots were expressed as a percentage of total Ot numbers (%Casp+Ot). Corresponding regions of contralateral femurs were scanned with a µCT to evaluate changes in bone architecture. The same femurs were sectioned undecalcified and used to measure resorption activity (% eroded surface, %ErS). ANOVA with post-hoc Mann-Whitney U test were used and significance reported at $p<0.05$. Results: %Casp+Ot after 5 days of HLU nearly quadrupled from baseline, and remained highly elevated at 14 days of HLU. This increase was prevented in HLU mice given the apoptosis inhibitor (Fig 1).

For the HLU+Veh animals, %ErS more than doubled. However, apoptosis inhibition prevented this increase (Fig 2). Most significantly, apoptosis inhibition completely prevented the loss of bone volume caused by 14 days of HLU (Fig 3). Conclusion: Our results show that apoptosis inhibition prevents the dramatic and rapid cancellous bone loss caused by disuse. Inhibiting OtAp was highly effective in preventing cancellous bone loss caused by hindlimb unloading thus indicating that selectively targeting osteocyte death may be a powerful strategy in combating disuse osteoporosis.

PTH upregulates RANKL and MMP13 expression through direct actions on osteocytes, but MMP13 is derived from non-osteocytic cells. Jesus Delgado-Calle*, Xiaolin Tu, Amy Sato, Meloney Cregor, Kevin McAndrews, Lilian Plotkin, Teresita Bellido. Indiana University School of Medicine, USA

Activation of PTH receptor signaling in osteocytes is sufficient to increase bone mass and the rate of bone remodeling, two recognized skeletal actions of PTH. Whereas increased bone mass can be explained by downregulation of the osteocyte-specific bone formation inhibitor SOST, the mechanism by which osteocytes mediate bone resorption induced by PTH remains unclear. We report here that the expression of RANKL and MMP13, two genes involved in PTH-induced resorption, is elevated in transgenic mice with constitutive activation of the PTH receptor in osteocytes (DMP1-8kb-caPTHR1 mice). RANKL and MMP13 expression is also increased in bones (L4) from 4 month-old control mice injected with PTH (100ng/g) daily for 1 month. In contrast, PTH elevation did not increase RANKL or MMP13 expression in bones from mice with conditional deletion of the PTHR1 in osteocytes (cKO-PTHR1^{Ot} mice), generated by crossing PTHR1flox mice with DMP1-8kb-Cre mice. These findings demonstrate that regulation of RANKL and MMP13 requires direct actions of PTH on osteocytes. Osteocytes are the main source of RANKL; however, this cytokine is also expressed in other cells of the osteoblastic lineage. And, MMP13 is expressed by cells of both osteoblastic and osteoclastic lineage. Therefore, we next examined whether PTH regulates these genes directly in osteocytes using ex vivo and in vitro approaches. Long bone diaphyses of 1 month old mice devoid of marrow were digested with collagenase to remove bone surface cells. Remaining bone pieces were enriched in osteocytes as evidenced by 50-100 fold increase in Sost expression compared to undigested bones. Addition of PTH (100 nM) for 4h to these bone organ cultures increased the expression of RANKL in littermate control bones but not in bones from cKO-PTHR1^{Ot} mice. In contrast, PTH did not change MMP13 expression in osteocyte-enriched bones from either mouse strain. Moreover, PTH (or the stable cAMP analog DBA) also increased RANKL but not MMP13 expression in MLO-A5 osteocytic cells. These results demonstrate that PTH regulates the expression of RANKL but not of MMP13 in osteocytes. Taken together, these findings demonstrate that PTH regulation of the RANKL and MMP13 genes is exerted through direct hormonal actions on osteocytes. However, the origin of these pro-resorptive genes differs. Whereas RANKL is derived from osteocytes, the source of MMP13 is of non-osteocytic nature and must require crosstalk between osteocytes and other bone cells.

Osteocytes are Key to the Formation and Maintenance of Mineralized Bone. Yinshi Ren*[1], Shuxian Lin[2], Xianglong Han[3], Baozhi Yuan[4], Yan Jing[1], Ying Liu[1], Marc Drezner[4], Paul Dechow[2], Min Liu[5], Jian Feng[6]. [1]Baylor college of dentistry, Texas A&M Health Science Center, USA, [2]Baylor College of Dentistry, USA, [3]Baylor College of Dentistry, Texas A&M University, Biomedical Sciences, USA, [4]University of Wisconsin, USA, [5]Amgen Inc., USA, [6]Texas A&M Health Science Center, USA

The theory that osteoblasts (Obs) regulate mineralized bone formation is a cornerstone of bone biology. However, the role that the osteocyte (Ocy), the most abundant bone cell, may play in bone formation remains speculative. Thus, we tested if the Ocy does, in fact, have a role in this vital function. Using SEM and FITC (a fluoresce dye filling in Oycs and dendrites), we documented a close association between Ocy maturation and the degree of bone mineralization. Quantitative data revealed that the mature Ocy cell volume was 50% reduced, and the volume vacated by the reduced cell body in the matrix was replaced by mineral. Confocal microscopic examination of DAPI nuclear stained bone, previously labeled with calcein/alizarin red revealed not only mineral deposition surrounding Ocy matrix, but also at the mineralization front surrounding cananiculae. For the Ocy to play such a central role in formation of mineralized bone, access to a mineral source is critical. Yet, it is widely believed that there are few blood vessels in bone. However, we demonstrated high vessel density and numerous dendritic connections between the vessels and Ocys. Moreover, a dye injection into the rabbit abdominal aorta revealed dye in the Ocy bodies and their dendrites in < 2 minutes, indicating a rapid exchange and delivery of mineral between capillaries and Ocys. The vital Ocy role in mineralization was further demonstrated in *Dmp1* mice, where Obs failed to form Ocys; where b-catenin levels are >10-fold higher than WT; and the mice are osteomalacic. Moreover, in the offspring of mice obtained by crossing *Dmp1*-Cre and *Catnb*$^{\Delta ex3}$ mice, the elevated b-catenin levels recaptured an osteomalacia phenotype similar to*Dmp1* KO mice except without the FGF-23 abnormalities.

Currently, imbalances of Obs and osteoclasts are implicated in osteoporosis, although neither cell is embedded in bone matrix where Ocys likely play a key pathological role. To test this hypothesis, we evaluated patients with osteoporosis and ovariectomized (OVX) rats demonstrating distinct Ocy changes from a spindle to a round shape with >50% increase in Ocy volumes and reductions of Ocy numbers. Unexpectedly, there were sharp reductions of blood vessels in Ovx rat bones. Administration of Sclerostin antibody to Ovx rats reversed these changes, leading to bone mineral recovery. Our studies suggest that the Ocys, but not Obs, are the key cells building and maintaining bone mineralization, as such, defective Ocy function may underlie osteomalacia and possibly osteoporosis.

Quantification of Lower Leg Arterial Calcifications by High-Resolution Peripheral Quantitative Computed Tomography. Janina M Patsch*[1], Martin A. Zulliger[2], Nicolas Vilayphiou[3], Elizabeth Samelson[4], Daniel Cejka[1], Danielle Diarra[1], Gundula Berzaczy[1], Thomas Link[5], Michael Weber[1], Christian Loewe[1]. [1]Medical University of Vienna, Austria, [2]Former employee of SCANCO MEDICAL AG, Switzerland, [3]SCANCO MEDICAL AG, Switzerland, [4]Hebrew SeniorLife, Harvard Medical School, USA, [5]University of California, San Francisco, USA

High resolution peripheral quantitative computed tomography (HR-pQCT) is an in-vivo research tool primarily designed for the assessment of bone geometry, bone mineral density and bone microarchitecture of the ultradistal extremities. Vascular calcifications are frequently observed as incidental findings on HR-pQCT images and the interplay between vasculature health and bone health, is an emerging field of research. Nevertheless, quantitative analysis of vascular calcifications captured by HR-pQCT has not been performed yet. The objectives of our study were therefore to validate a quantitative tool for the assessment of lower leg arterial calcifications (LLAC) found in HR-pQCT scans and to test method reliability in the clinical setting. For validity assessment of our novel method, we recruited forty-six subjects with chronic kidney disease on hemodialysis with a mean age of 59 ± 13 years to undergo HR-pQCT of the ultradistal lower leg. As a standard of reference for quantitative assessment of vascular calcifications, we acquired MDCT scans of the heart and performed Agatston, mass, and volume scoring. HR-pQCT scans were graded for motion artifacts. The presence or absence of vascular calcifications in HR-pQCT scans was determined by visual assessment. If calcifications were detected in HR-pQCT scans, images were downscaled to a voxel size of 250µm to enhance comparability with MDCT. Subsequently, tibial and fibular bone volume was subtracted and lower leg arterial calcifications (LLAC) were detected and outlined by a semi-automated, dual-threshold seed-point segmentation. LLAC mass was calculated as the product of voxel-based LLAC volume and mean LLAC density. We used two-way random intra-class correlation (ICC) for reliability assessment of LLAC analyses by HR-pQCT on repeated image analysis of fourteen scans. Comparing lower leg arterial calcifications (LLAC) by HR-pQCT and coronary artery calcifications (CAC) by MDCT, there were significant positive correlations between LLAC mass and CAC as measured by Agatston score, mass score, and volume score (Spearman's rho=0.6;$p<0.01$). The ICC was 1.0. Our study indicates that lower leg arterial calcifications (LLAC) are quantifiable by HR-pQCT, which should facilitate quantitative research on osteo-vascular interactions. Associations with coronary artery calcifications (CAC) need to be confirmed in patients with normal kidney function, functional cardiovascular parameters and clinical outcomes.

Trait variances capture the micro-structural basis of bone fragility better than trait means. Yohann Bala*[1], Sandra Iuliano-Burns[2], Ali Ghasem-Zadeh[2], Xiao-Fang Wang[3], Qingju Wang[2], Roger Zebaze[2], Ego Seeman[2]. [1]University of Melbourne, Dept. of Medicine, Australia, [2]Austin Health, University of Melbourne, Australia, [3]University of Melbourne, Austin Health, Australia

High Resolution peripheral Quantitative Computerised Tomography (HR-pQCT) is a noninvasive method of image acquisition that quantifies cortical and trabecular microstructure. However, the use of fixed thresholds introduces errors as most voxels contain both bone and void. The void lowers the threshold which allocates porous cortical bone to the trabecular compartment underestimating cortical porosity and mass, and over estimated trabecular bone mass and so underestimates an individuals fracture risk. Non-threshold based segmentation allocates voxels by their anatomical location, not attenuation, and quantifies all voxel void and matrix volumes, rather than erroneous disregarding voxels 'tainted' by partial volume effects. We hypothesized that expressing microstructure as a continuum or frequency distribution curve of voxels containing differing volumes of void and bone matrix better discriminates women with and without forearm fracture and controls.

HR-pQCT images obtained in 33 women (57 ± 9 years) with forearm fractures and 53 aged-matched controls were analysed using Strax 1.0 and a DEXA scans of the lumbar spine (LS) and the femoral neck (FN). StrAx1.0 automatically segments bone from background and cortex into its compact appearing cortex, outer and inner transitional zones. Voxels were classified according their relative bone matrix and void volumes. Sensitivity and specificity was evaluated using the area under a receiver-operating curve (AUC).

aBMD did not discriminate cases from controls (AUC = 0.58 at LS, 0.53 at FN. Ct. and Tb.vBMD discriminated with AUCs of 0.69 and 0.63, respectively, $p<0.05$. However, the proportion of voxels containing 50-70%, 70-95% and >95% mineralized bone was the best discriminant (AUC 0.63 to 0.87) with the voxels containing 50-70% of mineralized bone in the outer transitional zone the most sensitive discriminant (AUC 0.87 and $p<0.05$ vs. Ct.vBMD and Tb.vBMD) associated with an OR (95% CI) for fracture of 11.20 (2.77-52.65) (Fig).

Fragility fractures are associated with heterogeneous abnormalities in cortical microstructure quantifiable by analysing trait variance, not means and expressing this as a frequency distribution of individual voxel contents.

Associations Between Biomarker-Calibrated Protein Intake and Bone Health in the Women's Health Initiative. Jeannette Beasley*[1], Andrea Lacroix[2], Joseph Larson[2], Charles Eaton[3], Marian Neuhouser[2], Lesley Tinker[2], Ying Huang[2], Rebecca Jackson[4], Karen Johnson[5], Linda Snetselaar[6], Ross Prentice[2]. [1]Einstein College of Medicine, Yeshiva University, USA, [2]Fred Hutchinson Cancer Research Center, USA, [3]MHRI, USA, [4]The Ohio State University, USA, [5]University of Tennessee Health Science Center, USA, [6]University of Iowa, USA

OBJECTIVE: The effects of dietary protein intake on bone health are controversial. This study examined the relation between protein intake with bone mineral density (BMD) and fracture within the Women's Health Initiative (WHI).

METHODS: The WHI recruited 161,806 women aged 65-79 into the WHI-Observational Study (OS) and WHI-Clinical Trial (CT) between 1993 and 1998. Fractures were collected annually (WHIOS) or semi-annually (WHI-CT) by questionnaire through 2011. BMD was measured at baseline and 6 years among 10,833 women using dual-energy x-ray absorptiometry. Protein and energy intake were assessed via the WHI Food Frequency Questionnaire and calibrated using regression equations established based on biomarkers of protein and energy intake. Cox (fracture) and linear (BMD) regression models were adjusted for confounders including age, race/ethnicity, and body mass index.

RESULTS: Median calibrated protein intake was 14% of energy. Women consuming 20% higher calibrated protein were 9% less likely to have a hip fracture (95% CI= 1%-15%). Each 20% increase in calibrated protein was associated with higher BMD for total body (mean 6-year change 0.004 g/cm2, 95% CI = 0.001- 0.007 g/cm2) and hip (0.003 g/cm2, 95% CI= 0.001-0.005 g/cm2). CONCLUSION: Higher protein intake was associated with reduced risk of hip fracture and better maintenance of BMD over time. These data suggest higher protein intake may be an intervention target for preserving bone health.

Low Serum Concentration of Vitamin E Is Associated With Increased Risk of Hip Fracture in the Elderly. A NOREPOS Case-Cohort Study. Kristin Holvik*[1], Clara Gjesdal[2], Grethe Tell[3], Guri Grimnes[4], Ellen Apalset[3], Berit Schei[5], Rune Blomhoff[6], Karl Michaelsson[7], Haakon E. Meyer[8]. [1]Norwegian Institute of Public Health, Norway, [2]Department of Rheumatology, Haukeland University Hospital, Norway, [3]Department of Global Public Health & Primary Care, University of Bergen, Norway, [4]University Hospital of Northern Norway, Norway, [5]Department of Public Health & General Practice, Norwegian University of Science & Technology, Norway, [6]Department of Nutrition, Institute of Basic Medical Sciences, University of Oslo, Norway, [7]Uppsala Clinical Research Center, Sweden, [8]Norwegian Institute of Public Health/ University of Oslo, Norway

The increased oxidative stress associated with ageing influences the formation and survival of bone forming and bone resorbing cells. Vitamin E, of which α-tocopherol is the most abundant form in human tissues, is a plant-derived lipid soluble substance with potent antioxidant properties. The relation between vitamin E concentrations in blood and risk of hip fracture has not previously been investigated in a population-based study. We aimed to study the association between α-tocopherol levels in serum and risk of hip fractures in elderly men and women in Norway, the population with the world's highest hip fracture incidence.

In the Norwegian Epidemiologic Osteoporosis Studies (NOREPOS), we performed a case-cohort analysis in 21,774 men and women aged 65-79 years (mean 72 y) who underwent baseline examinations in four population-based health studies during 1994-2001. Data on incident hip fractures occurring up to 10.7 years of follow-up were retrieved from electronic patient administrative systems. Frozen serum samples from baseline were analyzed in participants who suffered a hip fracture during follow-up (n=1179; 307 men and 872 women) and in sex-stratified random samples from baseline (n=1447, including 89 of those who later suffered a hip fracture). α-tocopherol in serum was determined by high pressure liquid chromatography (HPLC)-fluorescence detection. Cox proportional hazards regression adapted for the case-cohort design was performed with adjustment for age, sex, and study center.

Median (25, 75-percentile) serum α-tocopherol concentration was 30.0 (22.6, 38.3) µmol/l. A linear inverse relation between serum α-tocopherol levels and hip fracture was observed, with hazard ratio (HR) 1.12 (95% CI 1.04-1.20) per 10 µmol/l lower serum α-tocopherol. HR of hip fracture in the lowest (<22.6 µmol/l) compared with the highest (>=38.3 µmol/l) quartile of serum α-tocopherol was 1.53 (95% CI 1.18-1.97). The trend was linear across quartiles ($p<0.001$). Additional adjustment for body mass index, cigarette smoking, month of blood draw, and length of education yielded similar results.

In conclusion, low serum concentrations of α-tocopherol were associated with increased risk of hip fracture in both men and women.

FR0327

Markers of Bone Turnover for Prediction of Fracture: a Meta-analysis. Eugene McCloskey*[1], Anders Odén[2], John Kanis[3], Helena Johansson[4]. [1]University of Sheffield, United Kingdom, [2]WHO Collaborating Centre, University of Sheffield, United Kingdom, [3]University of Sheffield, Belgium, [4]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden

The IOF/IFCC has recently recommended s-PINP and s-CTX as the primary candidates for markers of bone turnover. The aim of this analysis was to update and summarise the clinical performance of these two markers in the prediction of fracture.

The study comprised an updated systematic review to document the performance characteristics of s-PINP and s-CTX in fracture risk prediction in untreated

individuals in prospective cohort studies. Cross-sectional and case-control studies were excluded as were studies that did not provide separate data for incident hip fractures. Eight potentially eligible publications were identified and six included in meta-analysis, since one publication did not have numerical info and two publications studied the same cohort. Three publications were available for the meta-analysis of s-PINP and six for the meta-analysis of s-CTX.

Higher values of both markers were associated with future fracture risk, with no differences between genders so that data in men and women were combined. For example, the hazard ratio per SD increase in s-PINP (gradient of risk: GR) was 1.23 (95% CI: 1.09-1.39) for any fracture. There was also a significant association between s-CTX and risk of any fracture, GR 1.18 (95% CI: 1.08-1.29). For the outcome of hip fracture, association between s-CTX and risk of fracture was slightly higher 1.23 (95% CI: 1.04-1.47).

There is a modest but significant association between bone turnover markers and risk of future fractures. Whether this predictive ability remains significant following adjustment for other risk factors is unknown.

Atypical Femoral Fracture Risk Factors: A Population-based Case-control Study. Annette Adams*[1], Fei Xue[2], Jean Wang[1], Richard Dell[3], Cathy Critchlow[2]. [1]Kaiser Permanente Southern California, USA, [2]Amgen, Inc., USA, [3]Kaiser, USA

Purpose: To identify risk factors for atypical femoral fractures (AFF) among women enrolled in a large integrated health care organization.

Methods: Subjects in this population-based case-control study were female, aged ⩾45 years, had a qualifying fracture between 2007-2011, and ⩾6 months enrollment in the health plan prior to fracture/index. Cases had an AFF, as validated by physician review, and were compared to subjects comprising 2 control groups: 1) other subtrochanteric/diaphyseal fractures (subtroch group), and 2) "classic" femoral neck or intertrochanteric hip fractures (hip group). Cases and controls were optimally matched 1:1 on index date ±6 months and medical center. Potential risk factors included demographic characteristics, clinical factors, bisphosphonate (BP) use characteristics, and other pharmacologic exposures up to 3 years prior to index.

Results: Overall, 115 AFF cases were matched to 107 subtroch and 115 hip fracture control subjects. Compared to the subtroch group, AFF cases were younger (median age 70 vs. 80 years, $p<0.01$), more likely to be Asian (vs. White, OR 13.0; 95% CI 3.1-54.8), to have an osteoporosis diagnosis prior to index (OR 2.5; 95% CI 1.2-4.9), and to be using BPs at index (OR 6.4; 95% CI 3.0-13.4). AFF cases also used BPs for longer durations (median 6.6 vs. 2.0 years, $p<0.01$), with risk increasing monotonically from OR 5.8 (95% CI 1.9-17.2) for use <4 years to OR 13.3 (95% CI 4.2-42.2) for use ⩾8 years (p for trend<0.01). Compared to the hip group, younger age (median age 70 vs. 83 years, $p<0.01$), Asian race (vs. White, OR 11.7; 95% CI 3.6-37.9), osteoporosis diagnosis (OR 2.1; 95% CI 1.1-3.9), active use of BPs at index (OR 6.8; 95% CI 3.2-14.2), and longer duration of use of BPs (median 6.6 vs. 2.4 years, $p<0.01$) were independent predictors of AFF status. AFF risk increased from OR 3.3 (95% CI 1.3-8.8) for <4 years of BP use to 10.5 (95% CI 3.6-30.8) for ⩾8 years use (p for trend<0.01).

Conclusion: Our findings suggest that subjects with AFF differ from subjects with other subtroch and classic hip fractures with regard to age, race, and patterns of BP use prior to fracture. The pathophysiology of AFF fractures continues to be investigated, and our findings may provide additional insight into the role of potentially modifiable risk factors such as BP use.

FR0350

Long-Term Height Loss and Low BMI Strongly Predict Hip Fracture among 16,009 Women and Men Aged 70-79 Years. A NOREPOS Study. Haakon E. Meyer*[1], Siri Forsmo[2], Grethe S. Tell[3], Kristin Holvik[4], John Eisman[5], Anne Johanne Søgaard[6]. [1]Norwegian Institute of Public Health/University of Oslo, Norway, [2]Norwegian University of Science & Technology, Norway, [3]University of Bergen, Norway, [4]University of Oslo, Norway, [5]Garvan Institute of Medical Research, Australia, [6]Norwegian Institute of Public Health, Norway

We aimed to study the predictive power of height loss and low body mass index (BMI) on the risk of hip fracture in elderly women and men.

We used data from seven regional population based health studies carried out in the period 1995- 2002. All studies were part of the Cohort of Norway (CONOR) collaboration with similar data collection, including standardized height and weight measurements. The current analysis was restricted to women and men aged 70-79 years at examination (mean 73.9 ±2.5 years). The majority of the participants (86%) also had measured height and weight collected in a nationwide tuberculosis screening program during 1963-75 at mean age 44.6 ±3.6 years, enabling the calculation of height loss during a mean period of 29.3 ±2.9 years. They were followed with respect to incident hip fracture from the last examination throughout 2008. We estimated hazard ratios (HR) for hip fracture according to height loss (between the two examinations) and BMI (from the last examination) by Cox proportional hazards regression, adjusting for age and initial height.

During follow-up, 844 of 7,398 women and 461 of 8,611 men suffered a hip fracture. Height loss was positively and BMI inversely related to the risk of hip fracture. Independent of BMI, women with a height loss of 5 cm or more (13%) had HR = 1.95 (95% CI 1.57-2.42) for hip fracture compared to those with a height loss of less than 2 cm. The corresponding figure in men with ⩾5 cm height loss (7.6%) was HR = 2.45 (95% CI 1.82-3.30).

The highest risk of hip fracture was found in those who had both the greatest height loss (⩾5 cm) and the lowest BMI (< 24 kg/m^2) [HR 4.24 (95% CI 2.94-6.11) in women and 3.96 (95% CI 2-36-6.64) in men] compared to those with height loss < 2 cm combined with BMI ⩾ 27 kg/m^2. The probability of hip fracture in women is shown in the figure. For example, after five years of follow up it was ~9% in women with a BMI < 24 kg/m^2 and a height loss ⩾5 cm, and less than 2% in women with a BMI ⩾ 27 kg/m^2 and a height loss < 2 cm. Those with intermediate levels of the risk factors had an intermediate risk (data not shown).

In conclusion, both height loss and a low BMI were strong and independent predictors of hip fracture in elderly women and men. Those with both risk factors had a four-fold risk of hip fracture compared to those with neither risk factor. Including height loss in addition to BMI or weight has the potential to enhance fracture risk prediction in a clinical setting

Vitamin D Insufficiency Sustained Over 5 Years Contributes to Increased 10-year Fracture Risk in Elderly Women. David Buchebner*[1], Fiona McGuigan[2], Paul Gerdhem[3], Kaisa Ivaska[4], Martin Ridderstråle[5], Kristina Akesson[6]. [1]Halmstad Hospital, Sweden, [2]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [3]Karolinska Institutet, Sweden, [4]University of Turku, Finland, [5]University of Lund, Sweden, [6]Skåne University Hospital, Malmö, Sweden

BACKGROUND: Vitamin D insufficiency among the elderly is common and has been shown to contribute to increased risk of osteoporotic fractures through increased bone turnover, bone loss and mineralization defects as well as non-skeletal effects. Previous studies have used single Vitamin D measurements to investigate effects on bone. However, in elderly women, relatively little is known about the effects of long-term hypovitaminosis D on bone health. In this study we investigated sequential assessment of serum vitamin D to determine if sustained hypovitaminosis D leads to increased 10-year fracture incidence in elderly women.

METHODS: Study participants were Swedish women from the population based OPRA cohort. 1044 women, all aged 75 attended at baseline (BL), 715 attended at 5 year follow-up. Serum 25-hydroxy vitamin D (25OHD) levels (nmol/l) were classified as Low (<50), Intermediate (50-75) and High (>75) and were available for 987 (BL), and 640 (5y) women. Women with values in the same 25OHD category at both samplings were considered to have consistently low, intermediate or high levels. Fracture data was followed for 10 years through X-rays at the Radiology Department.

RESULTS: The incidence of hip fractures within 10 years was significantly lower in those women who were 25OHD sufficient (⩾50nmol/l) at baseline and maintained this level at 5 years (6.9% (H) and 9.9% (Int) vs 20.6% (L); p=0.005 and 0.031).

The proportion of women sustaining FRAX fractures was 26.2% and 30% in the consistently high and intermediate 25OHD groups compared to 45.6% in the consistently low group. (p=0.004 and 0.022). The incidence of shoulder, radius and vertebral fractures was not associated with 25OHD status in our study. The majority of fractures occurred between 5 and 10 years after baseline (hip 77%; FRAX 64%) however the time to first fracture (hip and FRAX) did not significantly differ between the 3 categories of 25OHD using either a single or serial measurement.

CONCLUSIONS: In this population sample of elderly women, 25OHD insufficiency sustained over 5-years was associated with increased 10-year risk of osteoporotic fracture.

FR0363

Decrease in Bone Strength Due to Reduced Total Density and Content is Not Completely Compensated by Increase in Bone Area: Prospective pQCT Evidence from Distal Radius and Tibia in Postmenopausal Women. Saija Kontulainen*, Chantal Kawalilak, Andrew Frank, Wojciech Olszynski, James Johnston. University of Saskatchewan, Canada

Introduction: Prospective evidence from studies using 2 dimensional (2D) measurement techniques has provided conflicting evidence regarding whether bone mineral loss at the distal radius is compensated by an increase in bone width (an estimate of periosteal expansion) in postmenopausal women; a population prone to osteoporotic wrist fractures (Ahlborg et al. NEJM 2003, Szulc et al. JBMR 2006). In addition, cross-sectional evidence has indicated that intracortical remodelling and related trabecularization of the cortex could be the main source of bone loss in older women (Zebaze et al. Lancet 2010). Our objective was to characterize 3D-changes in estimated bone strength, density, content and area in the distal radii and tibiae of postmenopausal women. We tested three hypotheses: 1) bone strength would decrease; 2) the increase in bone area would compensate for bone mineral loss; and 2) increase in trabecular area would provide evidence of cortical trabecularization.

Methods: Participants (N=114) were from a randomized sample of community dwelling postmenopausal women (Saskatoon cohort of the Canadian Multicentre Osteoporosis Study, CaMos) with a mean age of 74.3 (SD7.7) years at baseline. We obtained bone scans from the distal radius and tibia using peripheral quantitative computed tomography (pQCT) at baseline and 1-year follow-up. We assessed changes in total and trabecular densities (ToA, TrD, mg/cm3), contents (ToC, TrC, mg/cm) and areas (ToA, TrA, mm2), respectively. We estimated bone strength in compression (BSIc, mg2/mm4) by multiplying ToA with squared ToD. We used paired t-test to assess bone changes. We report mean percent and absolute changes with 95% confidence intervals and p-values (significance set $p<0.05$).

Results: At the distal radius, bone strength decreased 4.6%, and decreases in ToD (-3.4%) and ToC (-1.5%) were accompanied by increases in ToA (2%) and TrA (3.5%) (Table 1). Changes in tibia were similar but seemed less in magnitude (Table 1).

Discussion: These unique prospective changes indicated that a 1-year decrease in bone strength, observed with a concomitant decrease in total density and content, was partially compensated by periosteal bone formation (increase in bone area) in postmenopausal women supporting previous longitudinal 2D evidence (Ahlborg et al. NEJM 2003). Increased trabecular area suggests trabecularization of the cortex which agrees with earlier cross-sectional evidence (Zebaze et al. Lancet 2010).

FR0364

Differences in Cortical and Trabecular Microstructure in Chinese and Caucasian Females originate during Peripubertal Growth. Xiao-Fang Wang*[1], Ali Ghasem-Zadeh[2], Qingju Wang[2], Jia Wei Teo[2], Sandra Iuliano-Burns[2], Yohann Bala[3], Roger Zebaze[2], Ego Seeman[2]. [1]University of Melbourne, Austin Health, Australia, [2]Austin Health, University of Melbourne, Australia, [3]University of Melbourne, Dept. of Medicine, Australia

Chinese women have fewer hip and forearm fracture rates despite having more slender bones. As remodelling is surface dependent, and the endocortical surface (lining the medullary canal) and the intracortical surface (formed by osteonal Haversian and Volkmann canals) are contiguous, we speculated that Chinese have lower resorptive remodelling and excavate a smaller medullary canal producing relatively the thicker cortex, and excavate fewer or smaller intracortical canals producing less porous cortices, than in Caucasians.

Distal radius images acquired using high-resolution peripheral quantitative computed tomography (HR-pQCT, XTreme CT, Scanco) were quantified for 34 healthy Chinese and 81 Caucasian females aged 7 to 46 years using Strax 1.0, a non-threshold based image analysis algorithm that segments the mineralized matrix and void volumes of the compact-appearing cortex, the transitional and trabecular regions. The proportion of void (porosity) was quantified as the average of void spaces in each voxel. The 1st CT slice commenced at the 4% of the radius length in children (under 18 years old) to adjust for any effects of bone length on scan region.

There was no detectable structural difference between races before puberty. After puberty, in Chinese, medullary area was lower, though to significantly so (97.4 vs.110.8 mm^2) while porosity of the compact-appearing cortex, outer and inner transitional zones were lower than Caucasians, respectively (35.9 vs. 45.6%; 45.0 vs. 53.1%; 74.5 vs. 78.8%. all $p<0.05$). Correspondingly, in pre-menopausal women, medullary area (101.2 vs. 130.6 mm^2, $p<0.001$), porosity of the compact-appearing cortex and outer transitional zone was lower than in Caucasians (21.2 vs. 23.3%; 31.6 vs. 33.6%. both $p<0.05$) but the racial differences appeared attenuated compared to postpubertal girls. The porosity of the inner transitional zone was similar between races (77.0 vs. 77.9%, NS).

Modelling and remodelling assemble a more robust skeleton in Chinese than Caucasian women. The smaller bone has a relatively thicker and less porous cortex perhaps attributed to excavation of a smaller medullary canal and fewer osteons. These morphological features may contribute to the lower fracture risk in Chinese women.

Hip Cortical Porosity Predicts Fragility Fractures in Postmenopausal Women with Normal Hip Bone Mineral Density and Osteopenia. Luai A Ahmed*[1], Rajesh Shigdel[1], Ragnar Joakimsen[1], Petter Eldevik[2], Erik Fink Eriksen[3], Roger Zebaze[4], Ashild Bjornerem[1]. [1]University of Tromsø, Norway, [2]University Hospital North Norway, Norway, [3]Oslo University Hospital, Norway, [4]Austin Health, University of Melbourne, Australia

The majority of women with fractures exhibit normal areal bone mineral density (aBMD) or osteopenia. Thus, current methods based mainly on bone densitometry do not identify women at risk for fracture with high sensitivity and specificity. We hypothesized that women with fractures are better distinguished from controls by measures of microarchitecture, particular cortical porosity, or the combination of cortical porosity and aBMD, than either risk factors alone.

Using a nested case-control design we quantified microarchitecture using StrAx 1.0 software in computed tomography images of the subtrochanteric femoral site in 180 postmenopausal women aged 54-94 years with fractures (hip, humerus and forearm) and 209 age-matched controls, from the Tromsø Study, Norway. Total hip aBMD was measured using densitometry. The fracture risk was assessed using logistic regression analyses adjusted for age, height and weight, and prediction of fracture was assessed using the area under receiver operator curve (AUC).

In women with fractures, 61 (34%) had normal aBMD, 97 (54%) had osteopenia and 22 (12%) had osteoporosis. While in controls, 129 (62%) had normal aBMD, 73 (35%) had osteopenia and 7 (3%) had osteoporosis. Women with fractures exhibited 3.5% higher cortical porosity and 0.08 g/cm^2 lower aBMD than controls (both $p < 0.001$). Porosity predicted fracture independently of aBMD, in the whole cohort, in women with normal aBMD, as well as in women with osteopenia. In the whole cohort, each standard deviation (SD) higher porosity increased the risk of fracture (Odds ratio (OR) 2.13 (95% CI 1.64-2.76)), while each SD higher aBMD protected against fracture (OR 0.47 (95% CI 0.37-0.61)) both $p < 0.001$. AUC was 0.69 for porosity alone, 0.69 for aBMD alone and increased to 0.76 for the combination of porosity and aBMD. So after inclusion of cortical porosity there was an increase in AUC of 0.07 (95% CI 0.03-0.11) $p < 0.001$. In women with normal aBMD, each SD higher porosity increased fracture risk (OR 2.20 (95% CI 1.49-3.26), $p < 0.001$). In women with osteopenia, each SD higher porosity also increased fracture risk (OR 2.04 (95% CI 1.40-2.96) $p < 0.001$), while each SD higher aBMD protected against fracture (OR 0.30 (95% CI 0.12-0.76) $p = 0.01$).

In this general population, cortical porosity predicted fracture risk in women with normal aBMD and osteopenia independently of aBMD, improving the diagnostic sensitivity.

Muscle Power and Force may Contribute to Cortical Bone Strength Through Distinct Mechanisms: Findings from a Cross-sectional Study of High Bone Mass Cases and Controls. Sarah Hardcastle*[1], Celia Gregson[1], Joern Rittweger[2], Kate Ward[3], Jon H Tobias[4]. [1]University of Bristol, United Kingdom, [2]Institute of Aerospace Medicine, German Aerospace Center, Cologne, Germany, [3]MRC Human Nutrition Research, United Kingdom, [4]Musculoskeletal Research Unit, School of Clinical Sciences, University of Bristol, United Kingdom

Background: Relationships between muscle function and bone have been examined using a range of techniques, with conflicting results. We aimed to determine these associations within an adult population comprising individuals with high bone mass and family controls.

Methods: Recruitment was from 3 UK sites within the High Bone Mass (HBM) study; cases and unaffected family controls were pooled. Peak ground reaction force and peak power, during a multiple one-leg jump and single two-leg jump respectively, were recorded using a Leonardo Mechanography Ground Reaction Force Platform. Total hip BMD was determined by DXA scanning. In addition, a subgroup had mid-tibial pQCT performed (Stratec XCT2000L). Linear regression analysis adjusted for age, gender, height and weight. Force and power were log transformed.

Results: Matching jump plate and hip DXA data was available in 189 participants comprising 70 males (mean age 58y) and 119 females (mean age 56y). Median jump power was 2.25 kW (IQR 1.78,2.93) and force 1.95 kN (1.68,2.39). Jump power was positively related to hip BMD (standardised β [95% CI] 0.29 [0.07,0.51], p=0.01), but jump force was not (0.03 [-0.16,0.22], p=0.74). In 113 participants with force and pQCT data, power was positively associated with tibial SSI (0.26 [0.09,0.44], p<0.01) and with cortical thickness (0.33 [0.06,0.60], p=0.02) but not with total bone area (0.10 [-0.10,0.30], p=0.33). Force was also positively associated with SSI (0.24 [0.07,0.42], p=0.01), but in contrast to power was associated with total bone area (0.22 [0.03,0.42], p=0.02) but not with cortical thickness (0.05 [-0.22,0.32], p=0.72).

Conclusion: Muscle power and force are both positively associated with cortical bone strength. However, distinct mechanisms appear to be involved, since power was primarily associated with reduced endosteal expansion (reflected by cortical thickness and hip BMD), whereas force was associated with increased periosteal expansion (reflected by total bone area). Based on these findings, the greatest increases in cortical bone strength may be achieved by interventions targeting both muscle force and power.

Bone Remodeling and Structure in the Proximal Femur. Felicia Cosman*[1], David Dempster[2], Jeri Nieves[3], Hua Zhou[1], Catherine Roimisher[1], Yvonne Houle[4], Robert Lindsay[1], Mathias Bostrom[4]. [1]Helen Hayes Hospital, USA, [2]Columbia University, USA, [3]Columbia University & Helen Hayes Hospital, USA, [4]Hospital for Special Surger, USA

Little is known about bone remodeling in the proximal femur. We designed a double blind placebo controlled trial to evaluate histomorphometry of the femur in patients scheduled for total hip replacement (THR) for severe osteoarthritis. To date, 19 samples have been fully analyzed (13 postmenopausal women, mean age 72; 6 men, mean age 70). Participants were randomized to receive teriparatide (TPTD) or Placebo by daily injection for 6 weeks. After 3 weeks, tetracycline label was administered following a standard protocol. During the THR, specimens of the femoral neck (FN) and trochanter (Troch) were procured and subsequently sectioned with division of the FN into superior, inferior, anterior and posterior regions (Figure). The Troch sample consisted of cancellous bone with a superior cortex. Investigators remain blinded to treatment and results are not separated by group. In the FN (Table), mineralized surface (MS/BS) and bone formation rate (BFR/BS) varied across bone envelopes, with a broad range of values among subjects (up to 60 fold). MS/BS and BFR/BS were overall highest in the periosteum. There was substantial variability across FN regions within each bone envelope, with overall lower MS/BS and BFR/BS in the inferior FN in all but the periosteal envelope. MAR varied to a much lesser degree (<3 fold), was consistent across the FN regions within each envelope, and highest in the periosteum. In Troch, MS/BS and BFR/BS in all 4 envelopes were consistently lower than in the FN, but varied broadly. Cortical width was similar in the superior, anterior and posterior FN and Troch (means 612-802 um), but higher in the inferior FN (mean 1246 um). Cancellous bone volume was also highest in the inferior FN (20.8% of total volume) and 3.8-18.3% in other regions. Osteophytes were seen in 15/19 subjects and woven bone was seen in 18/19 subjects, though it varied widely in extent and distribution. We conclude that histomorphometric examination of the proximal femur is feasible in patients who have received tetracycline label before THR. MS/BS and BFR vary broadly among subjects in different bone envelopes of the FN and Troch regions after TPTD or Placebo. Notably, the highest BFR was seen in the periosteum. Structural indices also vary by FN region. This study might provide the first evidence of where and to what extent TPTD stimulates bone formation in the proximal femur. Comparative Effects of Teriparatide, Denosumab, and Combination Therapy on Peripheral Compartmental Bone Density and Microarchitecture: the DATA-HRpQCT Study. Joy Tsai*[1], Alexander Uihlein[1], Yuli Zhu[1], Katelyn Foley[1], Nicholas Derrico[1], Hang Lee[1], Sherri-Ann Burnett-Bowie[1], Robert Neer[1], Mary Bouxsein[2], Benjamin Leder[3]. [1]Massachusetts General Hospital, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Massachusetts General Hospital Harvard Medical School, USA

Background: In postmenopausal women, 12 months of combination therapy with denosumab (DMAB) and teriparatide (TPTD) increased bone mineral density at the spine and hip more than either drug alone. The effect of combined DMAB and TPTD therapy on peripheral compartmental bone density and microarchitecture, however, is unknown.

Methods: We randomized 100 postmenopausal women ages 51-91 at high fracture risk to 1 of 3 treatments: TPTD 20-ug SC QD, DMAB 60-mg SC Q6 months, or both (COMBO) for 12 months. Women were excluded if they had ever used parenteral bisphosphonates (BPs) or oral BPs in the past 6 months. Total, trabecular, and cortical density (DTot, DTrab, DCort); trabecular thickness, spacing, and number (Tb.Th, Tb.Sp, Tb.N); and cortical thickness and porosity (Ct.Th, Ct.Po) were measured by high-resolution peripheral quantitative CT (HR-pQCT) of the distal radius and tibia. Subjects completing at least 1 post-baseline visit were included in our longitudinal mixed-effects model analysis of between-group differences.

Results: As shown in the table, at both sites, DTot, DTrab, DCort and Ct.Th increased in the DMAB and COMBO groups but not the TPTD group. Ct.Po in the TPTD group increased at the radius but not the tibia. DTot increased more at the tibia in the COMBO group (3.1 ± 2.1%) than both the TPTD (0.0 ± 2.3%, P<0.0001) and DMAB groups (2.2 ± 2.0%, P=0.011) whereas radius DTot increased more in the COMBO group than the TPTD group only. DCort increased more in the

COMBO group than the TPTD group at both the radius and the tibia (P<0.001). At the tibia, Ct.Th increased significantly more in the COMBO group (5.4 ± 3.8%) than both other groups whereas at the radius, Ct.Th increased more in the COMBO group than the TPTD group only. At the tibia, cortical porosity increased more with TPTD (5.6 ± 10.3%) than both other treatments (DMAB -2.0 ± 10.6%, COMBO -1.0 ± 10.0%). At the radius, cortical porosity also increased more with TPTD (18.0 ± 36.4%) than both other treatments (DMAB 2.9 ± 18.8%, COMBO 3.0 ± 18.7%). but the TPTD vs. COMBO comparison was not significant (P=0.069). No between-group differences in trabecular microarchitecture were observed.

Conclusions: DTot and Ct.Th of the tibia increased more with combined therapy than with DMAB or TPTD alone. Moreover, the TPTD-induced changes in DCort and Ct.Po were prevented by DMAB co-administration. Combined DMAB-TPTD therapy appears to result in the most favorable changes in cortical bone parameters.

Cortical Thickness and Density Changes Over the Proximal Femur Resulting From Switching To or Combining With Teriparatide After Prior Treatment With Raloxifene or Alendronate. Tristan Whitmarsh*, Graham Treece, Andrew Gee, Kenneth Poole. University of Cambridge, United Kingdom

For osteoporotic women undergoing treatment with an antiresorptive drug, such as Raloxifene (RLX) or Alendronate (ALN), a following treatment of Teriparatide (TPT) is sometimes recommended. In this case, a decision has to be made to either switch to or add TPT to the current treatment. The effects of adding versus switching to TPT have been previously studied by examining aBMD changes from DXA (Cosman, J Clin Endocrinol Metab 2009) and vBMD changes from QCT (Cosman, JBMR 2012.). These indicated a significant increase in density for all treatment groups, which was of greater magnitude when adding than when switching in that trial. However, previous studies have not separated cortical mass and thickness effects, nor assessed the distribution and extent of more localised changes.

In previous work, a method was presented to map the cortical thickness and mass from clinical CT over the surface of the proximal femur, accurate down to a thickness of 0.3mm (Treece, Med Image Anal 2010, 2012). We use this technique to analyse changes in cortical mass and thickness from QCT scans acquired 18 months after switching to TPT after 12 months prior treatment with RLX (25 women aged 69±9 years) or ALN (40 women aged 69±8 years) and 18 months after combining a previous treatment of RLX (28 women aged 67±8 years) and ALN (41 women aged 67±10 years) with TPT. Fig. 1 shows the mean thickness and mass changes compared to baseline, and the significance of such changes, for each of the four treatment groups.

Averaging these results over the entire proximal femur reveals global mass increases for the add group (2.8% RLX, 1.6% ALN) which are significantly (p<0.001) greater than for the switch group (0.7% RLX, -0.8% ALN). For cortical thickness, the increases for the add group (3.7% RLX, 1.9% ALN) are not significantly different from the switch group (1.7% RLX, 3.0% ALN).

These results are broadly in agreement with previously published work, though we here reveal significant mass increases for the add compared to the switch groups, which are primarily located at the posterior side of the trochanter. Hence this study provides new insights into the effects of switching versus adding Teriparatide on the cortical thickness and mass changes.

Once-weekly Teriparatide Reduces Vertebral Fracture Risk – Subgroup Analysis from the Teriparatide Once Weekly Efficacy Research (TOWER) Trial. Toshitsugu Sugimoto*[1], Masataka Shiraki[2], Tetsuo Nakano[3], Hideaki Kishimoto[4], Masako Ito[5], Masao Fukunaga[6], Hiroshi Hagino[7], Teruki Sone[6], Toshitaka Nakamura[8]. [1]Shimane University School of Medicine, Japan, [2]Research Institute & Practice for Involutional Diseases, Japan, [3]Tamana Central Hospital, Japan, [4]Nojima Hospital, Japan, [5]Nagasaki University Hospital, Japan, [6]Kawasaki Medical School, Japan, [7]Tottori University, Japan, [8]University of Occupational & Environmental Health, Japan

Introduction: We analyzed the effects of once-weekly teriparatide (human parathyroid hormone 1-34) injection on incident vertebral fracture in various subgroups using data from the TOWER trial (2012 JCEM).

Methods: Anti-fracture efficacy with weekly 56.5 μg teriparatide injection was examined in a randomized, double-blind, placebo-controlled trial of 542 Japanese patients with osteoporosis (65-95 years). Patients were divided by baseline age, number or deformity grade of prevalent vertebral fractures, BMD level, bone turnover marker levels (osteocalcin; N-terminal propeptides of type 1 procollagen; N-terminal crosslinking telopeptides of type 1 collagen; deoxypyridinoline), and level of renal function using estimated glomerular filtration rate (eGFR). Relative risk (RR) was calculated using Cox regression analysis.

Results: Incident vertebral fracture occurred in 2.7% (7/261) subjects in the teriparatide group and 13.2% of subjects (37/281) in the placebo group. The RR for incident vertebral fracture in teriparatide group was 0.20 (p<0.001), compared to placebo group. Significant fracture risk reductions were observed in the subgroup of subjects <75 years (RR, 0.06; p=0.007) and ⩾75 years (RR, 0.32; p=0.015). For prevalence of vertebral fractures, a significant risk reduction was observed in the subgroup with 1 vertebral fracture (RR, 0.08; p=0.015) and in those with ⩾2 vertebral fractures (RR, 0.29; p=0.009). In the subgroup based on deformity of vertebral fracture, a significant risk reduction was observed in subjects with grade 3 deformity

(RR, 0.26; p=0.003). Significant risk reduction was observed in the subgroup with lumbar BMD <-2.5SD (RR, 0.25; p=0.035). No incident vertebral fracture was observed in the subgroups with no prevalent vertebral fractures, with vertebral deformity grade 0 to 2, and with lumbar BMD ⩾-2.5 SD in the teriparatide group. Significant risk reductions were observed in the subgroups over/under the median value for each bone turnover marker. The subgroups over/under the eGFR levels: 70 ml/min/1.73m^2 showed a significant reduction in fracture risk (RR, 0.13, p=0.001; RR, 0.31; p=0.004, respectively).

Conclusion: Once-weekly injection of 56.5 μg teriparatide reduced vertebral fracture risk in subgroups divided by age, number and deformity of vertebral fractures, bone turnover levels, and eGFR levels. These results indicate a consistent anti-fracture efficacy of teriparatide in patients with various degrees of fracture risk.

Teriparatide Delivered Orally with Novel Drug Delivery Technology - First in Humans Results. Hillel Galitzer*[1], Naifang Wang[2], Gregory Burshtien[3], Phillip Schwartz[1], Yoseph Caraco[4], Ehud Arbit[5]. [1]Entera Bio, Israel, [2]Entera Bio & Align Bioscience, USA, [3]Entera Bio Ltd., Israel, [4]Hadassah Hospital Jerusalem, Israel, [5]Entera Bio & NYU-Poly, USA

Teriparatide (PTH_{1-34}) is currently the only marketed anabolic agent for the treatment of osteoporosis. Its effect is mediated by an increase in osteoblast number and activity, leading to increased bone formation, bone mass and, as a consequence, substantial reduction in the risk for vertebral and non-vertebral fractures. A major obstacle to the broader adoption of teriparatide, as first line therapy in the treatment of osteoporosis, is its route of administration by s.c. (subcuatneous) injection. An oral dosage form will likely result in broader clinical use and foster compliance and adherence. In previous preclinical studies (Galitzer et. al. ASBMR 2012), we have demonstrated the utility of our proprietary drug delivery technology for delivering teriparatide orally. Here we present data from our first- in-human studies focusing on safety, tolerability and the absorption dynamics of oral teriparatide.

Methods: 12 healthy volunteers were given a single dose of s.c. teriparatide (20ug), as a comparator. One week following the s.c. dose a 200ug dose of Entera Bio's oral teriparatide was given to the same subjects. A full panel of safety parameters were measured following drug administration. Blood samples were taken at predetermined intervals and analyzed for PTH_{1-34} and a full set of standard of safety parameters.

Concentration of Human PTH_{1-34} in blood plasma was analyzed using a high sensitivity chemiluminescent immunoassay. Values were checked and normalized to known teriparatide standards.

Results: Oral PTH_{1-34} was well tolerated with no abnormal laboratory values or incidence of adverse events observed.

The absorption pattern was similar to that observed in SC injections and known to be therapeutically effective. The PTH_{1-34} increased rapidly followed by a slightly less rapid decrease.

[Graph attached]

Conclusion: This first in human study has demonstrated potential therapeutically relevant PTH_{1-34} systemic exposure after administration of Entera's proprietary oral PTH_{1-34} . These preliminary clinical studies have shown that volunteers manifest a pharmacokinetic profile similar to that observed with the SC injection. With additional research and development Entera's oral formulation of teriparatide may have the potential to serve as a viable alternative to currently used injectable forms of PTH.

Calcium plus Vitamin D supplementation: a Meta-analysis of Risk and Benefit. Steven Frost*[1], Nguyen Nguyen[2], Jacqueline Center[2], John Eisman[2], Tuan Nguyen[2]. [1]University of Western Sydney, Australia, [2]Garvan Institute of Medical Research, Australia

Background and Aim — Supplements of calcium and vitamin D have been suggested to be associated with an increased risk of cardiovascular disease (CVD) and stroke. However, calcium and vitamin D have also been suggested to reduce fracture risk. In this study, we sought to simultaneously examine the risk and benefit of calcium and vitamin D (CaD) supplementation.

Methods — This study is a meta-analysis of randomized controlled trials (RCTs). We identified 9 primary RCTs on the efficacy of CaD on fracture risk, and 3 post-hoc analyses of RCT on the association between CaD and CVD outcomes. The data were synthesized by both traditional and Bayesian random-effects meta-analysis, in which the risk of an outcome in individuals on CaD was compared with those on placebo. In addition, we used the Bayesian approach with non-informative priors to estimate the probability that CaD supplements increase or decrease the risk of an outcome by more than 10% - a level of difference usually deemed to be clinically meaningful. A meta-regression analysis was also conducted to identify the level of risk that is associated with the outcomes.

Results — CaD supplements reduced the risk of fragility fracture by 11% (RR 0.89; 95%CI 0.80-0.97), and the reduction was observed in nonvertebral fractures (RR 0.90; 0.79-0.99) and clinical vertebral fracture (RR 0.86; 0.75-0.99), but not in hip fracture (RR 0.88; 0.71-1.06). There was 48% chance that CaD supplements reduced fracture risk by at least 10%. Meta-regression analysis suggested that the anti-fracture benefit of CaD supplements was more likely observed in individuals with 2% and greater risk of fracture per year. CaD supplements were not significantly associated with any CVD outcome: myocardial infarction (RR 1.18; 0.73-1.74), stroke (RR 1.17; 0.75-1.70), myocardial infarction or stroke (RR 1.14; 0.74-1.64), and death (RR 1.01; 0.67-1.58). The probability that CaD supplements increase the risk of CVD outcomes by more than 10% was 0.34. The number needed to treat to reduce a fracture was 85, and the number needed to incur a CVD event was 170. Thus, the ratio of benefit over potential risk was 2.

Conclusions — These results confirm that CaD supplements reduce the risk of fracture, but the effect size is likely modest. The results also indicate that there is likely to be no significantly increased risk of CVD outcomes associated with CaD supplements.

Risk ratio of fracture and CVD outcomes associated with CaD supplements

Outcome	Relative Risk (RR) and 95% CI	Probability of RR<0.90 (for fracture) or RR>1.10 (for CVD outcomes)
All fractures	0.89 (0.80 – 0.97)	0.48
Vertebral fracture	0.86 (0.75 – 0.99)	0.59
Non-vertebral fractures	0.90 (0.79 – 0.99)	0.46
Hip fracture	0.88 (0.71 – 1.06)	0.47
Myocardial infarction (MI)	1.18 (0.73 – 1.74)	0.63
Stroke	1.17 (0.75 – 1.70)	0.62
MI or stroke	1.14 (0.74 – 1.64)	0.59
Death	1.01 (0.67 – 1.58)	0.30

Table

Bisphosphonates, Glucocorticoids, and Suffering from Collagen Diseases were Risk Factors for Developing Atypical Femoral Fractures in Japan. Yoshitomo Saita*, Muneaki Ishijima, Masashi Nagao, Kazuo Kaneko. Department of Orthopaedics, Juntendo University School of Medicine, Japan

Purpose: The long-term treatment of osteoporosis with anti-resorptive drugs may be associated with an increase in atypical femoral fractures (AFFs). However, the risk factors for Asian populations have not been fully elucidated.

Methods: In this retrospective observational cohort study, the clinical characteristics of patients with AFFs and typical femoral fractures (TFFs) treated from 2005 to 2010 in our hospitals were analyzed. A fracture location-, age- and gender-matched (1:3) case-control study was conducted to examine the risks for developing AFFs. The odds ratios of taking BPs, GCs, vitamin D analogues and proton pump inhibitors, and for suffering from collagen diseases and diabetes, were analyzed. The significance of the differences in the data was evaluated using the Mann-Whitney U-test. Odds ratios (ORs) and their 95% confidence intervals (CIs) between the patients with TFFs and those with AFFs in terms of several parameters, including BP exposure and comorbid conditions, were estimated by the Chi-square test. A p value < 0.05 was considered to be statistically significant. These analyses were performed using the SPSS ver.17 statistical software package (SPSS Inc., Chicago, IL).

Results: Fourteen AFFs were found in ten patients (four bilateral fractures) among all 2,238 hip and femoral shaft fractures, as we previously reported in annual meeting of ASBMR in 2011. The patients with AFFs (66.0 years) were significantly

younger than those with TFFs (78.8 years, p<0.0001). Nine (90%) and six (60%) of the ten patients with AFFs were using bisphosphonates and glucocorticoids (GCs), while 9.4% and 4.8%, respectively, of the patient with TFFs were using these agents. The case-control study showed that a high proportion of patients with AFFs used BPs and GCs and were suffering from collagen diseases (CDs)(odds ratios; 36.0, 13.0 and 9.0, respectively). On the other hand, no significant differences in the frequencies of using PPIs, vitamin D analogues, and suffering from diabetes were observed between the patients with AFFs and those with TFFs.

Conclusion: The prevalence of AFFs in the Japanese population was similar to that of Western countries. BPs, GCs, and suffering from CDs were the major risk factors for developing AFFs. To the best of our knowledge, this is the first report describing the case-control study of AFFs in East Asian countries.

FR0388

Microdamage analysis of the cortical bone of fracture site in the patient with atypical femoral fracture. Ken Iwata*[1], Tasuku Mashiba[2], Takeshi Manabe[3], Toshiaki Hitora[1], Yoshiki Yamagami[1], Tetsuji Yamamoto[1]. [1]Kagawa University School of medicine, Japan, [2]Kagawa University Faculty of Medicine, Japan, [3]Kinashi Ohbayashi Hospital, Japan

In recent years, case reports of atypical femoral fracture (AFF) caused by minor trauma in patients receiving long-term bisphosphonate therapy have been makledly increased. Little is known regarding their etiology and mechanism. While report of a task force of the ASBMR suggests the possibility that microdamage accumulation due to severely suppressed bone turnover by long-term bisphosphonate treatment could cause AFF, few microdamage evaluations have been done in the fracture site. We report a case of AFF receiving long-term intravenous bisphosphonate therapy and the result of microdamage analysis in the cortical bone of fracture site.

A 56-year-old Japanese woman was admitted with non-traumatic subtrochanteric fracture of right femur. She was diagnosed with right breast cancer and taken radical mastectomy at the age of 35. Because multiple rib metastases were found 12 years after surgery, she was put under intervenous incadronic acid for 3 years, pamidonic acid for 1 year, then zoledronic acid for 3 years. At the age of 52, she suffered from spontaneous left subtrochanteric femoral fracture and treated with an intramedullary nail. However, because it was recognized as pathological fracture due to bone metastasis at that time, she had continued zoledoronic acid therapy for 3 years further. This time, she was diagnosed with right AFF (Fig 1.) and the fracture was osteosynthesised also using an intramedullary nail. Because there were no evidences of bone metastasis in her whole skeleton at the time of surgery, zoledronic acid was stopped after the surgery and complete radiological fracture healing was obtained 6 months after surgery.

At the surgery, a bone biopsy was performed at the thickened cortical bone of fracture site for bone histology and microdamage measurement. For microdamage analysis, bone sample was bulk stained with 1% basic fuchsin. There were no histological evidences of metastatic cancer, however, tremendous amount of microcracks were observed in the thickened cortical bone of fracture site (Fig. 2, Table 1). Although there is a limitation that microdamage can be overestimated due to the bone biopsy site adjacent to fracture, this is the first report demonstrated that marked accumulation of bone microdamage was clearly observed in the hypertrophic cortical bone of atypical femoral fracture site.

Adherence to Oral Bisphosphonate Therapy in a Fracture Liaison Service: A Randomised Controlled Trial. Kirtan Ganda*[1], Markus Seibel[2], Andrea Schaffer[3], Sallie Pearson[3]. [1]Concord Hospital, Australia, [2]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, [3]Pharmcoepidemiology & Pharmaceutical Policy Ressearch Group, Faculty of Pharmacy, School of Public Healht, Sydney Medical School, The University of Sydney, Australia

Background: Fracture Liaison Services (FLS) are known to increase the proportion of patients initiated on osteoporosis medication following a minimal trauma fracture. However, little is known about long-term therapeutic adherence in patients managed by such fracture prevention programs.

Methods: This 2-year randomised controlled trial included 102 patients, all of whom had suffered an incident osteoporotic fracture prior to attending the FLS. After initiation of oral weekly bisphosphonate treatment, patients were randomised to either six-monthly follow-up visits with the FLS (Group A) or referral to their primary care physician with a single follow-up visit at the FLS after 24-months only (Group B). All patients received treatment subsidised through the Australian Pharmaceutical Benefits Scheme (PBS). Adherence was measured using pharmaceutical claims data extracted from the PBS database. Subjects with missing PBS data were excluded from the analysis (n=4 in each group). Patients with complete PBS data who attended at least one clinic appointment were included in the intention-to-treat (ITT) analysis (n=94). Subjects who attended all appointments were included in the per protocol (PP) analysis (n=74). Compliance (medication possession ratio, MPR) and persistence as well as predictors of adherence were analysed and compared between Group A and B. Associations between adherence and changes in bone mineral density (BMD) or bone turnover were determined at 24-months.

Results: Baseline characteristics were well matched across groups in both the ITT and PP populations. In the ITT analysis, median MPR over 24 months was 0.78 (IQR 0.50-0.93) and 0.79 (IQR 0.48-0.96) in Group A and B, resp. (p=0.68). Persistence at 24-months was 64% and 61% in Group A and Group B, resp. (p=0.75). After adjusting for confounders, patients in Group A were not more likely to be compliant (OR 1.06, 95%CI 0.46-2.47, p=0.89) or persistent (HR 0.83, 95%CI 0.27-1.67, p=0.61) than those in Group B. Results were nearly identical in the PP analysis. Ethnicity was a significant predictor of adherence. Neither compliance nor persistence were associated with changes in bone turnover markers or BMD over 24-months.

Conclusion: Once treatment has been initiated within the setting of a dedicated FLS, patient adherence to oral bisphosphonate therapy over 24 months remains high, independent of whether follow-up occurs through the primary care physician or the specialist service.

Does Calcitonin-Salmon Cause Cancer?. George Wells[1], David Krause*[2], Jonathan Chernoff[3], James Gilligan[4]. [1]Universtiy of Ottawa, Canada, [2]Tarsa Therapeutics Inc., USA, [3]Fox Chase Cancer Center, USA, [4]Tarsa Therapeutics, USA

BACKGROUND: Calcitonin-salmon (sCT) is a 32 AA peptide hormone in birds, fish and mammals. Its mechanism of action is mediated via coupling to G protein-coupled receptors. sCT is a more potent antiresorptive agent than human calcitonin,

and has been used for > 30 yrs for the treatment of postmenopausal osteoporosis. Recently sCT was withdrawn from the market in EU because of a putative association with prostate cancer identified in an interim analysis of a large trial of oral sCT in osteoarthritis in adults. Subsequently a metanalysis of 17 clinical trials of intranasal (IN) sCT was reported to confirm an increased risk of any cancer, although final data from the OA trial did not ultimately reveal an increased risk of prostate cancer. This association would not have been predicted by previously performed carcinogenicity and mutagenicity studies or sCT's mechanism of action, and no signal was apparent in postmarketing surveillance data. METHODS: Data from 17 controlled IN studies and 3 large studies of an investigational orally administered sCT (Novartis) were obtained from publically available information, and combined with data from a different oral sCT product (Tarsa). An additional 2 studies of IN CT were obtained from the literature. Only data from female subjects were included. In IN studies the dose ranged from 8.3 mcg to 66.6 mcg/day, and the duration from 0.5 to 5 years. In oral studies the dose ranged from 200 mcg/day to 800 mcg BID, and the duration from 1 to 3 years. Adverse events (AEs) were recorded at periodic intervals. In all studies cancer was recorded as an AE; no study included prospective case definitions or blinded adjudication of cases. RESULTS: Almost 11,000 women were exposed to oral or nasal CT, or placebo. No AEs of malignancy were recorded in 4 trials, and results were heavily influenced by one trial (CT320). More than 20 types of malignancy were represented. Using the Mantel-Haenszel method with adjusted continuity correction for those trials with no cases, the, the odds ratio (OR) for the reporting of any malignancy, calcitonin: placebo, was 1.16 (95% CI: 0.925, 1.458). The Fig. shows the point estimate of OR and 95% CI for each trial. CONCLUSIONS: There is little biological plausibility to the thesis that sCT causes cancer or is tumor promoting. A meta-analysis of all available trials of IN and oral sCT trials in women yielded a narrow OR close to unity. sCT does not appear to cause cancer.

Characteristics, Treatments, and Quality Of Life of Patients In a Swedish Osteoporosis Patient Registry. Dan Mellstrom[1], Arun Krishna*[2], Zhiyi Li[3], Chun-Po Steve Fan[4], Stina Salomonsson[5]. [1]Sahlgrenska University Hospital, Sweden, [2]Merck, USA, [3]AsclepiusJT LLC, USA, [4]AsclpeiusJT LLC, Canada, [5]MSD, Sweden

Objective: To describe patient characteristics, use of drug treatments, and quality of life on subjects in a Swedish patient registry database.

Methods: A descriptive analysis using a Swedish patient registry collected in an outpatient clinic in the region of Göteborg from 1991 to 2009 (study period). Included subjects were referred to the clinic for DXA scan for bone mineral density (BMD) measurement and osteoporosis (OP) diagnosis. Subjects were invited for a follow-up DXA scan every 2 years if the prior scan showed low BMD/OP diagnosis. This study analyzed subjects' current and previous OP treatments, fracture risk related to characteristics at enrollment, and Quality of life (QoL). QoL was collected post-2004 and measured by EQ-5D-3L covering dimensions of mobility, self-care, usual activities, pain/discomfort and anxiety/depression. Current and previous OP treatments were reported among subjects diagnosed with OP at the first visit. Means and standard deviations (SD) were reported for continuous measures; percentages were reported for categorical measures.

Results: 9,312 subjects were enrolled in the registry. 91% were female, with average age of 64.1 [SD=11.8] years. Average weight and height were 66.1 [SD=20.6] kg and 161.4 [SD=22.3] cm, respectively. 23% of subjects reported fractures at age >40, 35% had family history of fractures, 28% had back pain, and 33% were currently smokers. At the first visit, 3,292 (35%) subjects had a T-score (either hip or lumbar spine) ≤ -2.5 and 3,897 (42%) between -1 and -2.5. 3,587 (38.5%) were diagnosed with OP and 4,031 (43%) with osteopenia. EQ-5D was available for 1,570 subjects whose first visit was post-2004. The average scores were as follow: mobility: 1.37 [SD=0.49], self-care: 1.11 [SD=0.35], usual activities: 1.34 [SD=0.56], pain/discomfort: 1.91 [SD=0.60], and anxiety/depression: 1.52 [SD=0.57]. Among 2,101 diagnosed with OP at first visit and having ⩾1 follow-up visit, 1,146 (55%) received bisphosphonates (BIS) (alendronate, optinate, and etidronate), 259 (12%) received non-BIS (raloxifene and teriparatide), 1,651 (79%) received calcium+vitamin D, and 542 (26%) received estrogen.

Conclusion: This analysis provided an overview of the characteristics in a Swedish registry. In this Swedish population, more than 1/3 of subjects receiving DXA scan were diagnosed with OP or having T-score≤ -2.5; however, approximately one-third received no OP drug treatment (BIS or non-BIS) despite OP diagnosis.

FR0407

CaMKK2 Inhibition as a Novel Bone Anabolic Strategy in the Prevention of Post-Menopausal and Therapy-Induced Osteoporosis. Zachary Pritchard*[1], Rachel Cary[2], Deborah Novack[3], Michael Voor[4], Uma Sankar[1]. [1]Department of Pharmacology & Toxicology, University of Louisville, USA, [2]University of Louisville, USA, [3]Washington University in St. Louis School of Medicine, USA, [4]Department of Orthopedic Surgery, University of Louisville, USA

Osteoporosis is often detected only after the patient has sustained significant bone loss or a fracture, revealing acritical clinical need for anabolic bone therapies. We recently identified Ca^{2+}/calmodulin (CaM)-dependent protein kinase kinase 2 (CaMKK2) as a novel bone anabolic target in anti-osteoporosis therapy, as it plays key roles in both the anabolic and catabolic pathways of bone remodeling. Genetic ablation of CaMKK2 or its inhibition using the highly selective and cell permeable inhibitor STO-609 enhances osteoblast differentiation and bone growth while suppressing osteoclast differentiation, in vivo and in vitro. In vivo administration of STO-609 in ovariectomized (OVX) mice confers significant protection from osteoporosis.

Bilateral orchiectomy (ORX) or surgical castration triggers hypogonadism in male mice, resulting in bone loss similar to that following androgen-deprivation therapy (ADT) in men undergoing treatment for prostate cancer. To test whether pharmacological inhibition of CaMKK2 will protect against ADT-induced bone loss, we performed ORX in male WT mice with half of the mice receiving tri-weekly i.p. injections of STO-609 (10 μmol/kg body weight) or saline for 6 weeks post-surgery. STO-609 treatment conferred significant protection from ORX-induced bone loss as indicated by the significantly higher % of trabecular bone volume (BV/TV) and lower % of trabecular separation (Tr. Sp.), compared to saline treated controls. Subsequent studies have explored the utility of using STO-609 as a bone strengthening therapy and assessed the toxicity involved with the use of the drug in normal WT mice. Following a six-week regimen of STO-609 administration, long bones isolated from younger (6 week-old) and older (6 month-old) male and female mice indicate enhanced trabecular bone formation that translates into increased strength. Further, no differences were observed in weight,complete blood countprofile, serum inflammatory cytokine profile or hepatic biochemistry following drug administration. Furthermore, pharmacokinetic analyses did not detect the presence of the inhibitor in the brain homogenates from treated mice, indicating that STO-609 does not cross the blood-brain barrier. Taken together, our findings highlight the potential for therapeutic inhibition of CaMKK2 as a highly efficacious and safe bone anabolic strategy that also inhibits osteoclast differentiation in the treatment of age- and therapy-induced osteoporosis.

Long Term effect of BA058, a Novel Human PTHrP Analog, Restores Bone Mass in the Aged Osteopenic Ovariectomized Cynomolgus Monkey. Nancy Doyle*[1], Aurore Varela[1], Susan Y. Smith[1], Gary Hattersley[2]. [1]Charles River Laboratories, Canada, [2]Radius, USA

BA058 is an analog of hPTHrP (1-34) undergoing clinical development for the treatment of osteoporosis. The purpose of this study was to evaluate the effects of BA058 for 16 months on bone markers and bone mineral density (BMD) measured by DXA and pQCT in the aged osteopenic, ovariectomized cynomolgus monkey. Female cynomolgus monkeys, ⩾9 years of age, were randomly assigned to 5 groups based on whole body bone mineral content. Four groups of 16 animals were ovariectomized (OVX) and an additional group underwent Sham surgery. Treatment commenced after a 9-month bone depletion (BD) period. Animals received daily subcutaneously injection of either vehicle (Sham and OVX controls), or BA058 at 0.2, 1 or 5 μg/kg for 16 months. Blood and urine samples were analyzed for NTx, CTx, BAP and P1NP. DXA and pQCT were performed prior to surgery, at the end of the BD period, and after 4, 6, 12 and 16 months of treatment. DXA scans were obtained for the lumbar and thoracic spine, and proximal femur. Peripheral QCT scans were obtained at the proximal tibia metaphysis and diaphysis. At the end of the BD period, increases in bone markers and decreases in BMD by DXA/pQCT were observed for OVX controls compared to pre-OVX or Sham controls, consistent with estrogen deprivation. Daily administration of BA058 for 16 months resulted in marked bone anabolic effects at all dose levels, with complete reversal of the OVX-induced osteopenia with 1 and 5 μg/kg/day after only 4 months. This was associated with increases in P1NP, without changes in resorption markers. DXA values were comparable to or above pre-surgery levels at the spine and femoral neck, by 4 months of treatment, with 4 to 9% increases after 12

months of treatment, which were sustained at 16 months, relative to changes in OVX controls. Total tibia metaphysis BMD (pQCT) increased at all doses, 3 to 6% from end of BD at 4 months, 8 to 11% after 12 months of treatment, and was sustained after 16 months of treatment. Daily administration of BA058 for 16 months resulted in marked bone anabolic effects with complete reversal of OVX-induced osteopenia at all sites evaluated by DXA and pQCT, at all doses. Serum calcium levels remained within physiological ranges. BA058 potentially offers important advantages as a new treatment for post-menopausal osteoporosis, including the ability to rapidly build new bone and sustain gains over time.

Role of paraoxonase-1 in bone anabolic effects of parathyroid hormone in hyperlipidemic mice. Jinxiu Lu[1], Henry Cheng[2], Elisa Atti[1], Diana Shih[1], Linda Demer[3], Yin Tintut*[4]. [1]UCLA, USA, [2]Johns Hopkins, USA, [3]David Geffen School of Medicine At University of California Los Angeles, USA, [4]University of California, Los Angeles, USA

Hyperlipidemia blunts anabolic effects of intermittent parathyroid hormone (PTH) on cortical bone, and the responsiveness to PTH are restored in part by oral administration of the antioxidant ApoA-I mimetic peptide, D-4F. To evaluate the mechanism of this rescue, mice overexpressing the high-density lipoprotein-associated antioxidant enzyme, paraoxonase 1 (Ldlr-/-PON1tg) were generated, and daily PTH injections were administered to Ldlr-/-PON1tg and to littermate Ldlr-/- mice. Expression of bone regulatory genes was determined by realtime RT-qPCR, and cortical bone parameters of the femoral bones by micro-computed tomographic analyses. PTH-treated Ldlr-/-PON1tg mice had significantly greater expression of PTH receptor (PTH1R), activating transcription factor (ATF4), and osteoprotegerin (OPG) in femoral cortical bone, as well as significantly greater bone mineral content, thickness, and area in femoral diaphyses compared with untreated Ldlr-/-PON1tg mice. In contrast, in control mice (Ldlr-/-) without PON1 overexpression, PTH treatment did not induce these markers. Calvarial bone of PTH-treated Ldlr-/-PON1tg mice also had significantly greater expression of osteoblastic differentiation marker genes as well as BMP-2-target and Wnt-target genes. Untreated Ldlr-/-PON1tg mice had significantly greater expression of PTH1R than untreated Ldlr-/- mice, whereas sclerostin expression was reduced. In femoral cortical bones, expression levels of transcriptional factors, Fox1 and ATF4, were also elevated in Ldlr-/-PON1tg mice, suggesting enhancement of cellular protection against oxidants. These findings suggest that PON1 restores responsiveness to PTH through effects on oxidant stress, PTH receptor expression, and/or Wnt signaling.

Effects of the Novel Cathepsin K Inhibitor, SCI-629, on Bone Resorption in in vitro and in vivo Assays. Yoshitaka TANAKA*, Toshiaki Fujii. SEIKAGAKU CORPORATION, Japan

SCI-629 is a next generation analog newly designed and synthesized based on SI-591, a unique peptidomimetic compound. It is orally bioavailable and inhibits the lysosomal cysteine protease cathepsin K involved in bone loss processes.

In an enzyme inhibition assay, SCI-629 inhibited human cathepsin K with an IC50 value of 0.61 nM, and its inhibitory effect was 18- to 7900-fold more selective for cathepsin K than other members of the human cathepsins. SCI-629 inhibited human osteoclast-mediated bone resorption with an IC50 value of 39 nM.

To study the preventive effects of SCI-629 on the ovariectomized (OVX) rat as a model of postmenopausal osteoporosis, adult female F344 rats underwent OVX surgery and were treated with a vehicle or SCI-629 (0.8-100 mg/kg p.o., s.i.d. or 0.4-50 mg/kg, b.i.d.) for 4 weeks. In either case, SCI-629 dose-dependently inhibited the urinary C-terminal cross-linking telopeptide of Type I collagen (CTX-I) release and prevented bone mineral density (BMD) loss in the lumber vertebrae. To further investigate the preventive effect of SCI-629 on OVX, cynomolgus monkeys (aged 9-10 years) underwent OVX surgery and were treated with a vehicle or SCI-629 (0.9-8 mg/kg p.o., s.i.d.) for 4 weeks. The OVX resulted in increases in both urine N-terminal cross-linking telopeptide of type I collagen (NTX) levels and serum bone gla protein (BGP) levels, when compared with pre-OVX values. Although no significant changes were noted in either parameter up to 2.7 mg/kg, SCI-629 at 8 mg/kg continuously suppressed the OVX-induced increase in urinary NTX levels during the 4-week dosing period. SCI-629 up to 8 mg/kg did not have any significant effects on serum BGP levels.

In addition, to evaluate the safety of SCI-629, the effects on the cellular accumulation of cathepsin B were evaluated. SCI-629 did not increase the cellular protein levels of cathepsin B in HepG2 cells even at a concentration of 10 μM. This result suggests that SCI-629 is a non-lysosomotropic molecule and potentially has a lesser risk of producing the adverse effects associated with the inhibition of the off-target cathepsins.

In summary, these results suggest that SCI-629 is a novel, safe and orally bioavailable inhibitor of cathepsin K. We decided to develop this compound as a preclinical candidate for postmenopausal osteoporosis.

Transplantation of Hemopoietic Cells Engineered to Constitutively Produce Wnt10b Leads to Massive Bone Anabolism – A New Potential Strategy for Bone Regeneration and Fracture Repair. Jau-Yi Li*, Jonathan Adams, M. Neale Weitzmann, Roberto Pacifici. Emory University School of Medicine, USA

Wnt10b is a potent osteogenic Wnt ligand produced by bone cells and hemopoietic cells. Wnt10b activates Wnt signaling in stromal cells (SCs) and osteoblasts (OBs) leading to increased osteoblastogenesis and decreased adipogenesis. In addition, production of Wnt10b by bone marrow (BM) T cells is required for intermittent PTH treatment to increase bone formation and exert its bone anabolic activity. We generated retroviral transgenic mice (also known as retrogenic mice) that express a constitutively active (ca) form of Wnt10b by hemopoietic and immune cells to determine whether Wnt10b might be used as a bone anabolic agent either alone or in combination with iPTH. BM cells from caWnt10b retrogenic mice produced levels of Wnt10b ~ 10 fold higher than controls. BM cells were then harvested from the retrogenic mice and transplantation into additional lethally irradiated WT mice. Changes in indices of bone volume and structure were followed by in vivo μCT scanning. Eight weeks after transplantation of caWnt10b BM cells, recipient mice exhibited a ~3 fold increase in trabecular metaphyseal bone volume and a dramatic development of new trabecular bone in the shaft of the femoral diaphysis, a region lacking trabecular bone in control mice. Serum levels of P1NP (a marker of bone formation) were higher in caWnt10b retrogenic mice than in controls, while levels of CTX (a marker of bone resorption) were similar in the two groups. In a second experiment, caWnt10b T cells were purified from the spleen of caWnt10b retrogenic mice and adoptively transferred into T cell deficient mice. μCT analysis revealed that 8 weeks after the T cell transfer mice reconstituted with caWnt10b T cells had a metaphyseal BV/TV 1.7 fold higher than mice reconstituted with control T cells. However, adoptive transfer of caWnt10b T cells induced no new trabecular bone formation in the diaphysis. These findings demonstrate that the production of large amounts of Wnt10b by all hemopoietic cells has a potent bone anabolic effect and leads to "de novo" formation of trabecular bone in the femoral diaphysis. By contrast, over production of Wnt10b by T cells only induce a more modest increase in trabecular BV/TV without de novo diaphyseal bone growth. Delivery of Wnt10b by transduced BM cells may thus represent a novel therapeutic approach for bone regeneration and fracture repair.

A Randomized Controlled Trial of Exercise to Prevent Bone Loss and Adverse Cardiovascular changes in Premenopausal Women with Breast Cancer. Deborah Sellmeyer*[1], Susan Stewart[2], Joan Bloom[3]. [1]The Johns Hopkins Bayview Medical Center, USA, [2]University of California, Davis, USA, [3]University of California, Berkeley, USA

Increasing numbers of premenopausal women diagnosed with breast cancer are becoming long-term survivors, creating challenges regarding the long term consequences of successful breast cancer therapy such as bone loss and cardiovascular changes. In this randomized, controlled trial, we recruited 206 women age < 55 years at diagnosis who were within two years of receiving adjuvant chemotherapy. Complete data are available for 184 women. Women were randomized, stratified by tamoxifen use, to a 12 month exercise program with resistance training and cardiovascular activities implemented by a YMCA based personal coach. Women in the control group received a monthly health newsletter. Bone mineral density (BMD) and body composition were measured by dual energy x-ray absorptiometry at baseline and after one year of exercise; blood was drawn for skeletal and cardiovascular markers. The change in each parameter from baseline to end of study was compared within and between treatment groups using t-tests. Overall, lumbar spine BMD declined in both treatment groups with no significant difference between treatment groups (-0.008 g/cm^2 + 0.003 g/cm^2 treatment group vs. -0.014 g/cm^2 + 0.003 g/cm^2 control group, p=0.24). However, among the women who did not lose lean mass during the study (n=100, 54 control, 46 exercise), the exercise intervention was effective in preventing lumbar spine bone loss (0.001 g/cm^2 + 0.005 g/cm^2 treatment group vs. -0.014 g/cm^2 + 0.005 g/cm^2 control group, p=0.03). Bone turnover markers decreased significantly in both groups with no significant differences between groups. Among the metabolic parameters, HOMA-IR increased in both groups, but fructosamine increased only in the control group (p=0.06). Additionally, cholesterol/HDL ratio increased in the control group (p=0.03), but was unchanged in the exercise group. In summary, premenopausal women with breast cancer continue to lose bone density more than two years after diagnosis and treatment. Among women who maintained lean mass, our exercise intervention prevented ongoing bone loss; however, our intervention did not prevent bone loss among women who lost muscle mass. Adverse changes in metabolic parameters such as increased fructosamine and cholesterol/HDL ratio were also prevented by the exercise regimen. Additional investigation into exercise regimens that can prevent both bone and muscle loss may help prevent long term consequences of premenopausal breast cancer treatment.

Bone loss and microarchitectural deterioration continue despite cessation of weight loss after bariatric surgery. Emily Stein*[1], Polly Young[2], Mariana Bucovsky[2], Chiyuan Zhang[2], Angela Carrelli[3], Marcella Walker[2], Elizabeth Shane[1], Shonni Silverberg[2]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA, [3]Columbia University Medical Center, USA

The long-term effects of bariatric surgery on bone are unknown, as few studies have evaluated changes beyond one year and none have used any modality other than DXA. We evaluated annual changes in cortical (Ct) and trabecular (Tb) volumetric BMD (vBMD) and microarchitecture using high resolution peripheral computed tomography (HRpQCT) in addition to areal BMD by DXA [lumbar spine (LS), total hip (TH), femoral neck (FN), 1/3 (1/3R) and ultra distal radius (UDR)]. We previously reported that aBMD at the TH and FN declined in association with weight loss 1 year after surgery. HRpQCT showed significant cortical bone loss at the tibia but no change at the radius. We now report on changes in the 2nd year following Roux-en-Y gastric bypass. Ten women (mean baseline age 45 ± 10 yrs, BMI 45 ± 7kg/m^2, 20% Caucasian, 70% Latina) have been followed for 2 years. In year 2, there were no further declines in weight (Yr1:-28%; Yr2:-1%) or aBMD at the TH and FN (Yr1:-7-8%; Yr2:-1%). LS and 1/3R BMD did not change. At the UDR, a decline in BMD that began in Yr 1 (-2.9%) became significant in Yr 2 (-4.5%;$p<0.05$). HRpQCT indices changed significantly in year 2 (Table). At the radius, Ct area declined and Tb area increased. Total, Ct and Tb vBMD declined. Tb BMD declined in both the sub-cortical and inner Tb compartments. Tb heterogeneity increased. At the tibia, the declines in Ct bone observed in year 1 continued, with further loss of Ct area, density, and thickness. Total density declined, and new changes in Tb bone were observed: Tb area increased, Tb density decreased in both the inner and sub-cortical compartments and there was a trend toward increased Tb separation. Thus, in the 2nd year following bariatric surgery, weight loss plateaus as do the associated declines in hip BMD. Meanwhile, cortical bone deterioration progresses, with declines in Ct density and thickness. The decrease in Ct area and increase in Tb area suggests endocortical resorption. Tb bone loss also becomes prominent in the 2nd year after surgery. UDR BMD declines, as does Tb density, while Tb separation and network heterogeneity increase. Total vBMD declines. In summary, prominent cortical and trabecular deterioration occur in the 2nd year after surgery. While the association of these findings with skeletal fragility and fracture is unknown, these preliminary data raise concern that bariatric surgery may have significant long-term detrimental effects on the skeleton even after cessation of weight loss.

Denosumab for Elderly Men with Osteoporosis: A Cost-effectiveness Analysis from the US Payer Perspective. Anju Parthan[1], Morgan Kruse[1], Irene Agodoa*[2], Stuart Silverman[3], Eric Orwoll[4]. [1]OptumInsight, USA, [2]Amgen, USA, [3]Cedars-Sinai/UCLA, USA, [4]Oregon Health & Science University, USA

Purpose: To evaluate cost-effectiveness of denosumab (Dmab) versus other osteoporotic treatments (txt) in male osteoporosis (MOP) patients ⩾75 years (yrs) from a US 3rd party payer perspective.

Methods: A lifetime cohort Markov model previously developed for post-menopausal osteoporosis (PMO) was used for the study. During each 6-month cycle, patients could experience a hip, vertebral or other osteoporotic fracture (fx), remain in a non-fx state, remain in a post fx state or die (Figure 1). Background fx risks, mortality rates, persistence rates, health utilities, medical and drug costs were derived from published sources. Bone mineral density (BMD) improvements have shown to be similar between MOP and PMO populations. A recent fx trial showed zoledronate (Zol) to have effects in men similar to those reported previously in women; therefore fx efficacy data from PMO were used. Lifetime expected costs and quality-adjusted life-yrs (QALYs) were estimated for Dmab, generic alendronate (Alen), risedronate, ibandronate, teriparatide, and Zol. Rates of non-persistence for oral and injectable drugs were taken from published reports. Patients in the model were 78 yrs-old, with BMD T-score≤-2.12 and prevalent vertebral fx of 23%, based on the ⩾75 yr-old sub-group population in the ADAMO trial comparing 1 yr of Dmab vs. placebo.

In the base-case, model assumed patients received txt effects up to 2 yrs after discontinuing (offset time). Costs and QALYs were discounted 3% annually. One-way and probabilistic sensitivity analyses were conducted.

Results: Total lifetime costs and QALYs for all txts are shown in Table 1. Dmab had an incremental cost-effectiveness ratio (ICER) of $16,888 compared to Alen and dominated all other txts. Results were most sensitive to changes in drug costs of Dmab and relative risks of hip fx. The probability of Dmab being cost-effective compared to other txts was 75% at a threshold of $50K/QALY and 88% at a threshold of $100K/QALY.

In a sensitivity analysis using offset time of 5 yrs for all txts except Dmab (2 yrs) and teriparatide (2.5 yrs), Dmab had an ICER of $21,963 compared to Alen and dominated all other txts. Anticipating the availability of generic Zol, when the price was reduced by 35% and 65% of the brand price (to $705 and $379 annually, respectively), Dmab remained dominant compared to Zol.

Conclusion: Dmab is cost-effective compared to other osteoporotic txts in the US elderly male osteoporosis population.

Keywords: male osteoporosis, denosumab, cost-effectiveness analysis, elderly

Discrepant Areal and Volumetric BMD of the Spine and Hip in HIV-infected Postmenopausal Women. Polly Young*[1], Michael Yin[1], Ivelisse Colon[2], Mariana Bucovsky[1], Chiyuan Zhang[1], Susan Olender[1], Thomas Lang[3], Isra Saeed[3], David Ferris[4], Cosmina Zeana[5], Donald McMahon[6], Elizabeth Shane[6]. [1]Columbia University, USA, [2]Columbia University Medical Center, USA, [3]University of California, San Francisco, USA, [4]St Lukes Hospital Center, USA, [5]Bronx Lebanon Hospital Center, USA, [6]Columbia University College of Physicians & Surgeons, USA

HIV infection and antiretroviral therapy have been associated with low areal bone mineral density (aBMD) by dual energy xray absorptiometry (DXA). Some investigators have argued that BMD differences between HIV-infected and controls are largely attributable to group differences in weight. Previously, we reported that while aBMD by DXA was lower at the forearm in HIV-infected versus uninfected postmenopausal women, volumetric (vBMD) by High Resolution peripheral Quantitative CT (QCT) did not differ. We therefore assessed aBMD by DXA and

central QCT at the spine and hip to determine whether these measures were also discrepant at the central skeleton in 39 HIV-infected and 55 uninfected postmenopausal African American and Hispanic women from an established HIV cohort study of bone metabolism. HIV-infected women were of comparable age (58±5 vs 59±7, p=0.45) and height (158±8 vs157±8 cm, p=0.56) to uninfected women, but had lower weight (69±16 vs 79±21 kg, p=0.01), BMI (27.6±5 versus 32±7, p=0.001), %Total Body Fat (35.5±8 vs 42.8±6 p<.0001) and % Trunk Fat 34.9±8 vs 41.6±7, p<.0001). aBMD by DXA was lower at all sites in HIV-infected women (Table). In contrast, integral and trabecular vBMD and compressive strength did not differ at the spine (Table) or total hip (not shown). At the FN, cortical vBMD was higher and trabecular vBMD lower in the HIV-infected women, with no difference in Integral vBMD or compressive strength. In summary, although aBMD by DXA was lower in HIV-infected than uninfected postmenopausal women, true volumetric BMD by cQCT and compressive strength did not differ. We conclude that the lower areal BMD we previously observed in HIV-infected postmenopausal women could be an artifact of differences in body fat between HIV-infected and uninfected women. The lack of detectable differences in vBMD and microarchitecture is surprising given emerging data on increased fracture risk in older HIV-infected individuals.

Table	HIV+ (n=39)	HIV- (n=55)	p value
Areal BMD by DXA (g/cm2)			
Lumbar spine	0.87±0.13	0.93±0.17	0.03
Total Hip	0.85±0.15	0.92±0.14	0.02
Femoral Neck	0.72±0.12	0.81±0.17	0.006
Volumetric BMD by QCT (g/cm3) and Estimated Strength			
Lumbar spine Integral	0.21 ± 0.03	0.22 ± 0.03	0.11
Lumbar spine Avg Trab L1L2	0.21 ± 0.03	0.22 ± 0.03	0.06

FRAX Predicts Fracture Risk in Kidney Transplant Recipients. Kyla Naylor*[1], William Leslie[2], Anthony Hodsman[1], David Rush[3], Amit Garg[4]. [1]Western University, Canada, [2]University of Manitoba, Canada, [3]Department of Medicine, University of Manitoba, Canada, [4]Division of Nephrology, Western University, Canada

Purpose: The WHO Fracture Risk Assessment Tool (FRAX) estimates the 10-year probability of fracture and has been validated in the general population. However, the utility of FRAX in the kidney transplant population is unknown. We assessed the prognostic value of FRAX in kidney transplant recipients (KTR).

Methods: We identified all adult KTRs from 1996 to 2011 undergoing baseline dual energy X-ray absorptiometry (DXA) examinations within 5 years of transplantation (median 5 months) in a large clinical database for the Province of Manitoba, Canada. FRAX probabilities were calculated from baseline information (age; sex; clinical risk factors; bone mineral density [BMD]). Incident fractures were determined through linkage with a population-based data repository. Change in BMD was examined as a secondary outcome (N=806 follow up DXA scans with 328 2nd DXA, 198 3rd DXA, 129 4th DXA, 80 5th DXA).

Results: Of 458 KTRs, 64% were men with an average age of 45 years. Mean BMD at baseline was only slightly below expected (mean Z-scores: lumbar spine -0.3; femoral neck -0.7; total hip -0.7). Based on National Osteoporosis Foundation criteria, only 19.0% of KTRs would be designated high risk (16.0% osteoporotic T-score; 2.2% prior spine/hip fracture; 1.5% high major osteoporotic fracture [MOF] probability [>20%]; 6.5% high hip fracture probability [≥3%]). Twenty-one (4.6%) recipients experienced a MOF over a mean follow-up of 6 years. The 10-year FRAX MOF probability was higher in fracture compared with non-fracture KTRs (8.3% versus 5.5%, $\rho<0.01$ FRAX with BMD; 6.8% versus 4.9%, $\rho<0.05$ FRAX without BMD). Mean total hip T-score was significantly lower in fracture compared with non-fracture KTRs (-"1.2±0.9 versus -0.6±1.3, $\rho<0.05$). Area under the curve (AUC) for incident MOF discrimination was similar to the general population (AUC: FRAX without BMD 0.62 [95% CI: 0.49-0.75]; FRAX with BMD 0.62 [95% CI: 0.50-0.74]; total hip T-score 0.64 [95% CI: 0.53-0.75]). The observed 10-year MOF fracture risk of 6.3% (95% CI: 3.4-9.2%) was concordant with FRAX predictions (5.0% with BMD, 5.6% without BMD). Mean BMD measurements at all sites increased over time (lumbar spine) or remained stable (femoral neck and total hip).

Conclusions: FRAX scores categorized most KTRs as a low risk group for fracture, and the low observed fracture rates were consistent with the ten-year fracture predictions. The WHO FRAX tool may serve as a useful prognostic aid for treatment decision-making in KTRs.

FR0439

Clinical outcome with long-term bisphosphonate therapy in Paget's disease of Bone: The PRISM-EZ study. Kirsteen Goodman[1], Graeme MacLennan[2], Peter Selby[3], William Fraser[4], Stuart Ralston*[1]. [1]University of Edinburgh, United Kingdom, [2]University of Aberdeen, United Kingdom, [3]Manchester University, United Kingdom, [4]University of East Anglia, United Kingdom

Paget's disease of bone (PDB) is a common metabolic bone disease characterised by increased and disorganised bone remodelling. Bisphosphonates are highly effective at suppressing bone turnover in PDB are considered to be the treatment of choice. While aminobisphosphonates can normalise bone turnover in a high proportion of patients, it remains unclear whether this prevent complications. In the PRISM study we previously reported that bone pain, quality of life and complications of PDB were similar in patients randomised to ''intensive'' treatment in which the aim was to normalise alkaline phosphatase (ALP) versus ''symptomatic'' treatment in which treatment was given only if symptoms were present. Here we report upon the results of a three year extension to PRISM (PRISM-EZ) in which zoledronic acid was used as the bisphosphonate of choice in the ''intensive'' arm. The study group comprised 502 patients; 270 continued with intensive treatment and 232 with symptomatic treatment. The average total duration of follow up was about 6 years. The treatment groups were well matched at entry to PRISM-EZ for age, previous fracture, previous orthopaedic surgery, bone deformity and quality of life scores, but those in the intensive group had lower ALP levels (mean ± sem, 0.85±0.04 *vs.* 1.04± 0.06, p=0.012, where 1.0 is the upper limit of normal). During PRISM-EZ, ALP values decreased further in the intensive group and were consistently lower than in the symptomatic group throughout follow up (0.71±0.04 *vs.* 1.01± 0.06, p<0.0001). Despite the lower ALP, no differences were observed between the groups in quality of life scores or bone pain. Fractures were more common during follow up within the intensive group (8.2% *vs.* 4.7%; OR = 1.80 [0.87-3.71] but the difference between groups was not significant (p = 0.11). Fractures through Pagetic bone were also more common in the intensive group (1.4% *vs.* 0.8%), one of which was a subtrochanteric fracture occurring at the site of a pseudofracture in affected bone. We conclude that long term suppression of ALP with bisphosphonates including zoledronic acid did not improve clinical outcome in this group of patients with PDB and there was a slight increase in the risk of fracture.

IGF1 Contributes to the Increased Bone Formation Induced by Measles Virus Nucleocapsid Protein Expressed by Osteoclasts in Paget's Bone Disease. Noriyoshi Kurihara*[1], Jumpei Teramachi[2], Yukiko Kitagawa[1], Jolene Windle[3], G. David Roodman[1]. [1]Indiana University, USA, [2]The University of Tokushima, USA, [3]Virginia Commonwealth University, USA

We reported that 70% of patients with Paget's bone disease (PD) expressed Measles Virus Nucleocapsid Protein (MVNP) in their osteoclasts (OCLs) and that MVNP is not expressed in their osteoblasts (OBs). Further transgenic mice with targeted expression of MVNP to cells in the OCL lineage form pagetic-like bone lesions and display both increased bone resorption and rapid new bone formation. In contrast, mice with knock-in of the p62P394L mutation (p62-KI) linked to PD have increased bone resorption but do not have increased bone formation in vivo. EphrinB2 and EphB4 were identified as key coupling factors for OCL and OB. Since EphrinB2 is produced by OCL and dramatically enhances OB function and bone formation through specific interactions with EphB4 on OB, we determined if EphrinB2/EphB4 play a role in the effects of MVNP on bone formation. Therefore, we tested for expression of ephrins and Ephs in OCLs, OBs and total bone from 8 months old WT, MVNP and p62-KI mice. MVNP induced expression of both ephrinB2 and EphB4 in total bone lysates. Increased EphrinB2/EphB4 expression was only detectable in older MVNP mice (8-12 months), consistent with our previously findings that pagetic lesions are not detectable in these mice until 8-12 months of age. In contrast, total bone lysates from p62-KI mice did not express increased levels of EphrinB2 or EphB4. Only OCL derived from CD11b+ cells of MVNP or MVNP/p62-KI but not WT or p62-KI expressed increased EphrinB2. The enhanced EphB4 expression correlated with increased Runx2 expression in OBs from MVNP mice. Another coupling factor Semaphorin 3A had similar levels of expression between WT and MVNP. These results demonstrate that MVNP induces expression of EpherinB2/EphB4 coupling factors known to enhance OB activity. We then determined if other factors induced by MVNP enhanced EphrinB2/EphB4's coupling activity using gene-expressing profiling studies of highly purified OCLs derived from MVNP, p62-KI, p62-knockout and WT mice. IGF1 gene expression was significantly enhanced in MVNP expressing OCL precursors compared to other three genotypes. IGF1 expression by OCL from MVNP was confirmed at the protein level. These results suggest that EphrinB2/EphB4 enhances bone formation in vitro and in vivo in MVNP mice and IGF1 contributes to increased bone formation induced by MVNP by enhancing EphrinB2 expression.

ERα Expression in Non-Hematopoietic Cells is Required for the Protective Effects of Estrogen on Bone. Petra Henning[1], Cecilia Engdahl[2], Helen Farman[1], Andree Krust[3], Pierre Chambon[3], Hans Carlsten[4], Sara Windahl[2], Claes Ohlsson[5], Marie Lagerquist*[6]. [1]Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [2]Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, [3]Institut de Génétique et de Biologie Moléculaire et Cellulaire (CNRS, INSERM, UdS, Collège de France), Illkirch, Strasbourg, France, [4]Centre for Bone & Arthritis Research, Department of Rheumatology & Inflammation Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [5]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [6]Centre for Bone & Arthritis Research, USA

Estrogen has positive effects on both trabecular and cortical bone, but the exact mechanism behind this anti-osteoporotic effect is still not fully understood. To determine the relative importance of ERα expression in hematopoietic and non-hematopoietic cells, we have created chimeric mice with selective inactivation of ERα in hematopoietic (donor) or non-hematopoietic (recipient) cells using bone marrow (bm) transplantation.

12-week-old ovariectomized wild-type (wt) or ERα knock-out ($ER\alpha^{-/-}$) mice were lethally irradiated and reconstituted with hematopoietic stem cell (hsc)-enriched bm from wt or $ER\alpha^{-/-}$ females and, after two weeks, implanted with a 17β-estradiol (E2; 167ng/day) or placebo pellet. Four weeks after start of treatment, the mice were terminated and the bones were analyzed using computed tomography. Successful bm transplantations were verified by real-time PCR measurements of ERα gene expression, demonstrating significantly reduced ERα expression in wt/$ER\alpha^{-/-}$ mice (defined as recipient/donor) in blood, bm and spleen (-96%, -93% and -82%, respectively, $p<0.05$), while normal ERα expression was seen in $ER\alpha^{-/-}$/wt mice compared to wt/wt mice.

E2 treatment increased trabecular bone mineral density (BMD) in wt/wt mice ($507\pm36\%$, $p<0.001$) and wt/$ER\alpha^{-/-}$ mice ($370\pm39\%$, $p<0.001$), while no significant E2 effect was seen in $ER\alpha^{-/-}$/wt ($7\pm11\%$) or $ER\alpha^{-/-}$/$ER\alpha^{-/-}$ ($6\pm7\%$) mice compared to placebo treatment. E2 increased cortical thickness in wt/wt mice ($91\pm14\%$, $p<0.001$) and wt/$ER\alpha^{-/-}$ mice ($42\pm9\%$, $p<0.001$), while no cortical E2 effects were detected in $ER\alpha^{-/-}$/wt ($0\pm1\%$) or $ER\alpha^{-/-}$/$ER\alpha^{-/-}$ ($1\pm1\%$) mice. These data demonstrate the requirement of ERα expression in non-hematopoietic cells for the positive effects of E2 on bone mass. The E2 effects on trabecular BMD and cortical thickness were slightly, but significantly, reduced in wt/$ER\alpha^{-/-}$ mice compared to wt/wt mice (-27%, $p<0.05$ and -54%, $p<0.01$, respectively), suggesting that ERα expression in hematopoietic cells is involved in the estrogenic regulation of bone mass.

In conclusion, ERα expression in non-hematopoietic cells, but not in hematopoietic cells, is required for the protective effects of estrogen on both trabecular and cortical bone. However, our results indicate that ERα expression in hematopoietic cells may enhance the positive effect of E2 on bone in the presence of ERα expression in non-hematopoietic cells.

Estrogen Receptor α36 Mediates the Anti-apoptotic Effect of Estradiol *in vitro* and Associates with Clinical Outcome *in vivo*. Reyhaan Chaudhri*[1], Agreen Hadadi[2], Barbara Boyan[3], Zvi Schwartz[1]. [1]Georgia Institute of Technology, USA, [2]School of Biology, Georgia Institute of Technology, USA, [3]Virginia Commonwealth University, USA

In breast cancer cells, 17β-estradiol (E_2) rapidly increases protein kinase C activity, which is associated with increased breast tumorigenicity, and promotes cancer cell survival, metastatic potential, and osteolytic activity by acting through the ERα variant, ERα36. The aims of this study were to elucidate the mechanism by which ERα36 promotes cancer cell survival and determine if ERα36 is associated with clinical outcome. Using signaling inhibitors and activators, we evaluated the role of specific proteins on the protective effect of E_2 against taxol-induced apoptosis. In order to evaluate these effects, we used MTT to measure cell viability, TUNEL to measure cell death, and caspase-3 activity to measure apoptotic phenotype. Inhibition of phosphatidyl-choline specific phospholipase D (PC-PLD) with wortmannin, lysophosphatidic acid signaling with VPC32183S, and phosphoinositide-3-kinase (PI3K) with LY294002, blocked the inhibitory effect of E_2 against taxol-induced caspase-3 activity, while activation of LPA signaling with exogenous LPA and PI3K signaling with 740 Y-P, inhibited the apoptotic effect of taxol. To determine if ERα36 may be a potential target in cancer, a tissue microarray containing tumors from 40 breast cancer patients were assayed for presence of ERα36 and vascular endothelial growth factor (VEGF) by immunohistochemistry (IHC) and blindly scored by three independent observers to quantify number of positive cells, intensity, and subcellular localization. We used fisher's exact test to determine correlations of several variables with ERα36 or VEGF, and found that ERα36 intensity was positively associated with age ($p=.0450$) and VEGF ($p=.0226$). We also performed Kaplan-Meier survival analysis and the log-rank test to evaluate the significance of variables associated with mortality. When all patients were evaluated, we found HER2 status, tumor stage, and lymph node metastasis were associated with mortality. However, when we stratified our analysis to patients with high ERα36 levels and cytosolic ERα36, we found that progesterone receptor status and tumor size were also associated with mortality. Our results indicate ERα36 mediates the anti-apoptotic effect of E_2. These effects were mediated by activation of PC-PLD, LPA and PI3K. Our TMA results suggest ERα36 as a predictor of outcome *in vivo*. These data suggest that ERα36 may be a potential target for diagnosis or treatment in breast cancer.

Mice Lacking Estrogen Receptor α in Hypothalamic Pro-opiomelanocortin (POMC) Neurons Display Enhanced Estrogenic Response on Bone Mass. Helen Farman*[1], Sara Windahl[2], Deborah Clegg[3], Shang Kui Xie[3], John-Olov Jansson[4], Lisa Hahner[3], Jordan Zehr[3], Marie Lagerquist[5], Claes Ohlsson[6]. [1]University of Gothenburg, Sweden, [2]Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, [3]Department of Internal Medicine, UT Southwestern, Dallas, USA, USA, [4]Department of Internal Medicine, UT Southwestern, Dallas, USA, Sweden, [5]Centre for Bone & Arthritis Research, USA, [6]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

Estrogen is an important endocrine regulator of bone and exerts its physiological effect on bone mainly via estrogen receptor α (ERα). The CNS is also a major target for estrogen and ERα is widely distributed in the brain with a high expression in some hypothalamic nuclei including the arcuate nucleus (ARC) and the ventral medial nucleus (VMN). In a previous study, we demonstrated that loss of central ERα expression results in increased bone mass, indicating an inhibitory role of central ERα signaling on bone mass. However, the primary ERα expressing target cell type that mediates the central negative effect of estrogen on bone mass has not yet been identified. We here tested the hypothesis that ERα in hypothalamic Pro-opiomelanocortin (POMC) neurons, located in ARC, is involved in the central effects of estrogen on bone mass.

POMC-Cre mice were crossed with ERαlox/lox mice to generate mice lacking ERα expression specifically in POMC neurons (ERαlox/loxPOMC-Cre). Six-month-old female ERαlox/loxPOMC-Cre and littermate wild type mice were ovariectomized (ovx) and treated with either vehicle or estradiol (E2; 0.5μg/day) for six weeks. Cortical and trabecular bone parameters were analyzed by quantitative computed tomography.

As expected, E2-treatment increased the trabecular volumetric BMD (vBMD) in the distal metaphyseal region of the femur and several cortical bone parameters (cortical bone mineral content, cortical bone area and cortical thickness) in the mid-diaphyseal region of the tibia in ovx wild type mice ($p<0.01$). Importantly, the estrogenic responses were substantially increased in ovx ERαlox/loxPOMC-Cre mice compared with the estrogenic responses in ovx wild type mice on trabecular vBMD ($+42\pm9\%$, $p<0.01$), cortical bone mineral content ($+127\pm27\%$, $p<0.01$), cortical bone area ($+158\pm34\%$, $p<0.01$) and cortical bone thickness ($+233\pm53\%$, $p<0.01$).

In conclusion, mice lacking ERα in POMC neurons display enhanced estrogenic response on bone mass. This finding supports the notion that central ERα expression has an inhibitory effect on bone mass. In addition, it demonstrates that ERα in POMC neurons regulates bone mass. We propose that the balance between inhibitory effects of central ERα activity in POMC neurons in ARC and stimulatory peripheral ERα-mediated effects directly in bone determines bone homeostasis and, thereby, bone mass.

FR0446

Unlike the estrogen receptor α, the androgen receptor in osteoblast progenitors is dispensable for optimal cortical bone accrual. Semahat Serra Ucer*[1], Aaron Warren[2], Shoshana Bartell[3], Srividhya Iyer[3], Li Han[3], Julie Crawford[1], Charles O'Brien[3], Maria Jose Almeida[3], Stavros Manolagas[3]. [1]University of Arkansas for Medical Sciences, USA, [2]Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Androgens are required for optimal cancellous and cortical bone acquisition and maintenance in males. However, whereas the androgen receptor (AR) in mature osteoblasts and osteocytes is required for cancellous bone mass accrual, it is dispensable for the effects of androgens on cortical bone. On the other hand, signaling via the osteoblast progenitor estrogen receptor (ER) α is needed for optimal bone apposition at the periosteum of male mice during puberty. Here, we have explored the possibility that the AR expressed in osteoblast progenitors contributes to the well-documented anabolic effects of androgens on periosteal bone apposition and cortical bone mass. To do this, we generated mice with conditional deletion of an AR allele in pluripotent mesenchymal progenitor cells expressing Prx1 (AR flox;Prx1-Cre). AR mRNA in osteoblasts from the AR flox;Prx1-Cre mice was decreased by 80%, but unaffected in osteoclasts, seminal vesicles, soleus, and kidneys. There was no difference in seminal vesicle and total body weight among wild-type controls, AR flox,

Prx1-Cre, and AR flox;Prx1-Cre mice, confirming the specificity of the deletion in cells of the osteoblast lineage. AR flox;Prx1-Cre male mice exhibited a decrease in trabecular bone volume (30%), volumetric BMD (25%), trabecular number (37%) and connectivity (60%), whereas trabecular thickness was unaltered. Periosteal perimeter, endosteal perimeter, and cortical thickness at the femoral midshaft were unaffected by the AR deletion. The differentiation of progenitors from AR flox;Prx1-Cre mice to the osteoblast lineage was also unaltered as measured by Alizarin red staining of mineralized bone marrow cell cultures. Female AR flox;Prx1-Cre mice had no changes in bone mass. These results demonstrate that the anabolic effects of androgens on periosteal bone formation and cortical bone mass are not mediated via activation of the AR in cells of the osteoblast lineage. Instead, they are mediated via estrogens acting on the ERα present in osteoblast progenitors and perhaps indirect effects of androgens resulting from their stimulatory effects on growth factor production and/or muscle size, which in turn can increase mechanical strains on bone. On the other hand, the identical phenotype of mice with AR deletion in Prx1 cells or mature osteoblasts and osteocytes establishes that AR signaling in the latter cell types is responsible for the effect of androgens on cancellous bone.

FR0447

1, 25 dihydroxyvitamin D Regulates Tumor Growth through NF Kappa B in a Mouse Model of Breast Cancer Progression. Jiarong Li*[1], Aimee-Lee Luco[1], Ben Ochietietti[1], Rene St-Arnaud[2], Timothy Reinhardt[3], Anne Camirand[1], William Muller[1], Richard Kremer[4]. [1]McGill University, Canada, [2]Shriners Hospital for Children & McGill University, Canada, [3]National Animal Disease Center, USDA, ARS, USA, [4]McGill University, Royal Victoria Hospital, Canada

The transgenic PyVMT mouse model reproduces the various phases of human breast cancer from hyperplasia to adenocarcinoma in 100% of animals. We disrupted CYP27B1, the enzyme responsible for the conversion of 25 hydroxyvitamin D to 1, 25-dihdroxyvitamin D (1, 25(OH) 2D) in the mammary epithelium of female PyVMT mice using the Cre/LoxP recombination system. The lack of local production of 1, 25(OH) 2D resulted in accelerated mammary tumor growth. *In vitro* isolated PyVMT-CYP27B1$^{flox/flox}$-Cre^{-} cells treated with 25OHD showed dose dependent(10^{-9} -10^{-6}) growth inhibition but 25OHD had no effect on cell growth in isolated PyVMT-CYP27B1$^{flox/flox}$-Cre^{+} cells. Tumors and isolated tumor cells from control (PyVMT-CYP27B1$^{flox/flox}$-Cre^{-}) and homozygous (PyVMT-CYP27B1$^{flox/flox}$-Cre^{+}) animals were analyzed by real time quantitative PCR expression arrays (Qiagen), confocal microscopy and Western Blots. Tissue concentrations of 1, 25(OH)2D were reduced by over 80% in homozygous ablated tumors compared to tumors from control animals. Comparative analysis revealed that key components of NFKappa B signaling were upregulated in tumors from CYP27B1 ablated animals compared to controls($p<0.05$).In contrast isolated breast tumor cells from PyVMT-CYP27B1$^{flox/flox}$-Cre^{-} animals treated with 1, 25(OH)2D were characterized by downregulation of NFKappa B signaling at the gene and protein levels.Furthermore,confocal microscopy analysis of the VDR and NFKappa B regulatory protein p65 revealed that treatment of isolated cells with 1, 25(OH)2D induced retention of p65 in the cytoplasmic compartment and its co-localization with the VDR preventing activation of NFKappa B.Western Blot analysis of cytoplasmic and nuclear extracts confirmed the retention of p65 in the cytoplasmic compartment following 1, 25(OH)2D treatment.siRNA knockdown of p65 significantly reduced the growth inhibitory effect of 1, 25(OH)2D on isolated PyVMT-CYP27B1$^{flox/flox}$-Cre^{-} cells further supporting the role of NFKappa B signaling in 1, 25(OH)2D mediated growth inhibition. In summary our data demonstrate that local production of 1, 25(OH)2D by breast tumor cells plays an important role on breast tumor growth and that its effect is mediated at least in part through critical components of the NFKappa complex.

Appropriately Directed Expression of a Human Ligand Binding-Defective Vitamin D Receptor Rescues Hair Cycling Defects But Not Mineral Homeostasis in Humanized VDR-Null Mice. Seong Min Lee*[1], Erin Riley[1], Charles O'Brien[2], J. Pike[1]. [1]University of Wisconsin-Madison, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

The identification of specific VDR mutations in hereditary 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) resistant rickets (HVDRR) together with studies of directed expression of the VDR in the VDR-null mouse model have shown that VDR-mediated mineral homeostasis requires activation by $1,25(OH)_2D_3$, whereas VDR-mediated hair cycle regulation is hormone independent. A signature mutation that supports this premise is the L233S VDR mutation that abrogates $1,25(OH)_2D_3$ binding activity. Patients with this mutation do not, however, exhibit alopecia. Indeed, directed expression of the human L233S VDR mutant to the skin rescues the alopecic phenotype in the VDR null mouse. However, effect of the mutation on mineral homeostasis *in vivo* has not been elucidated. We have recently generated a humanized transgenic mouse strain with a modified wildtype hVDR BAC minigene that contained both the natural regulatory components of the gene and the VDR transcription unit as well. VDR expression from this transgene recapitulated endogenous VDR expression in the mouse, restored normal gene expression patterns and fully rescued the biological phenotype of the VDR null mouse. In the present study, we recreated the L233S-mutation in the hVDR BAC clone, introduced it as a transgene into mice and then crossed this strain into the VDR null mouse to assess whether the mutant could rescue the aberrant mineral homeostasis, the alopecia, or both. Like the wildtype transgene, the mutated transgene recapitulated the tissue-specific expression pattern of the endogenous mouse VDR. To test the transcriptional activity of the L233S mutation *in vivo*, we administered an IP injection of 10 ng $1,25(OH)_2D_3$/g body weight, collected tissues after 6 hr and evaluated the RNA for target gene expression by RT-PCR. While the wildtype transgene induced both *Trpv6* and *S100g* in the intestine, the mutant transgene was inactive. The L233S mutant also failed to upregulate *Cyp24a1* and to downregulate *Cyp27b1* in the kidney; it was similarly unable to modulate *Cyp24a1*, *Tnfsf11*, *Spp1* and *Fgf23* expression in the calvaria. Thus, the mutant L233S hVDR failed to rescue the aberrant mineral homeostasis characteristic of the VDR null mouse. Importantly, however, alopecia was not observed in these humanized L233S mutant mice. This study confirms that loss of ligand-binding activity of the VDR compromises regulation of mineral homeostasis but not of the hair cycle *in vivo*.

FR0450

Deletion of vitamin D receptor in mature osteoblasts and osteocytes, but not osteoclasts, impairs bone turnover in growing mice. Howard Morris*[1], Paul Anderson[2], Yolandi Starczak[3], Jackson Ryan[3], Helen Tsangari[3], Rebecca Sawyer[4], Kate Barratt[3], Andrew Turner[3], Gerald Atkins[5], Rachel Davey[6]. [1]SA Pathology, Australia, [2]Musculoskeletal Biology Research, University of South Australia, Australia, [3]School of Pharmacy & Medical Sciences, University of South Australia, Australia, [4]Chemical Pathology Directorate, SA Pathology, Australia, [5]University of Adelaide, Australia, [6]University of Melbourne, Australia

Direct activities of vitamin D through $1,25(OH)_2D_3$, on the skeleton have previously been reported to include catabolic, anabolic and inhibitory actions. These varied findings suggest multiple, complex roles for VDR mediated within the bone micro-environment. We have previously shown that vitamin D activity within mature osteoblasts and osteocytes enhances bone formation. In addition, vitamin D activity within osteoclasts modulates resorptive activity. It is unclear however as to the dominant activity of VDR in osteoblasts and osteoclasts in the *in vivo* setting. To address this question, we crossed the floxed-VDR (VDR-loxP) mouse with osteocalcin-Cre mice to inactivate VDR in osteoblasts and osteocytes (ObVDRKO). In addition, we crossed VDR-loxP mice with cathepsin K-Cre mice to inactivate VDR in osteoclasts (OcVDRKO). At 6 weeks of age, both male and female ObVDRKO mice demonstrated significant increases in both cortical bone volume and metaphyseal BV/TV% (Male ObVDRKO, 21% increase, $p<0.05$; Female ObVDRKO, 23% increase, $p<0.05$) when compared to VDR-loxP control littermates. The increase in bone volume in young ObVDRKO mice was associated with a marked decrease in RANKL mRNA expression, decreased metaphyseal osteoclast surface and serum Crosslaps. In addition, metaphyseal osteoblast surface and bone formation rate were both modestly reduced associated with marked reductions of mRNA for several key osteoblastic genes such as *Alkaline phosphatase*, *Osteocalcin* and *Sost*. At 6 weeks of age, both male and female OcVDRKO mice however exhibit unaltered bone volume. At 12 weeks of age, cortical bone volume in ObVDRKO mice was no longer different from levels in control mice. Metaphyseal BV/TV% was attenuated in male mice (6% increase, $p<0.05$) but remained significantly greater in female ObVDRKO mice (28% increase, $p<0.05$). By 26 weeks of age, metaphyseal BV/TV% in female ObVDRKO mice was no longer significantly different from bone levels in control mice. These data suggest that while VDR in osteoclasts appears to have no major role in regulating bone resorption in young mice, VDR in mature osteoblast and osteocytes promotes RANKL-mediated osteoclast activity, at least when RANKL is up-regulated during periods of growth.

The Vitamin D Receptor Promotes Human Breast Cancer Cell Growth via a Ligand Independent Cytoplasmic Function. Trupti Trivedi*[1], Yu Zheng[1], Pierrick Fournier[2], Colin Dunstan[3], Khalid Mohammad[2], Hong Zhou[1], Markus Seibel[1], Theresa Guise[2]. [1]Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, [2]Indiana University, USA, [3]University of Sydney, Australia

Previous reports show that vitamin D deficiency promotes human breast cancer growth in bone. In the current study we aimed to define the role of the vitamin D receptor (VDR) in breast cancer cell growth. We hypothesized that VDR knockdown enhances human breast cancer cell growth.

In vitro: Using stable shRNA expression and single cell clonal selection, VDR expression was knocked down by ~85% in MCF-7 cells (MCF-7$^{VDR-/-}$). Compared to parental (PA) and non-target (NT) controls, induction of CYP24 mRNA expression

by $1,25(OH)_2D_3$ was completely abrogated in MCF-$7^{VDR-/-}$ clones, confirming effective disruption of VDR signaling.

Treatment of PA & NT cells with $1,25(OH)_2D_3$ reduced cell growth by 32% compared to untreated cells ($p< 0.001$). In ligand-free culture, surprisingly, the growth of MCF-$7^{VDR-/-}$ clones was reduced by up to 34%, with a 6-fold increase in cell apoptosis compared to controls ($p< 0.001$), suggesting that VDR might have a ligand-independent effect in promoting cell growth. Treatment of MCF-$7^{VDR-/-}$ clones with $1,25(OH)_2D_3$ had no additional effect on cell growth and apoptosis.

In vivo: To investigate the putative effect of VDR on tumor growth *in vivo*, MCF-$7^{VDR-/-}$ and NT cells were xenografted orthotopically into the mammary fat pad of nude mice. VDR knockdown resulted in reduced tumor growth from day 18 to 51 ($p<0.001$). Intra-tibial implantation of NT cells into nude mice resulted in significant osteosclerosis as assessed by microCT (trabecular bone volume:+38%; trabecular number: +500%; compared to sham-injected tibia; $p<0.001$). Tumor-induced osteoblastic bone lesions were significantly less pronounced ($p< 0.001$ compared to NT cells) following implantation of MCF-$7^{VDR-/-}$ clones (trabecular volume: +9%; trabecular number: +30% compared to sham-injected tibia), indicating that VDR knockdown is associated with significantly retarded tumor growth.

Overexpression of a mutant VDR deficient in the nuclear localization signal (mVDR) in NT and MCF-$7^{VDR-/-}$ cells restored cell growth in MCF-$7^{VDR-/-}$ cells to the same level as seen in controls. This was associated with cytoplasmic accumulation of mVDR.Conclusion: The VDR has ligand-independent functions promoting breast cancer cell growth which contrast with its ligand-dependent, anti-proliferative effects.

FR0455

Vitamin D Is a Regulator of Endothelial Nitric Oxide Synthase and Arterial Stiffness in Mice. OLENA ANDRUKHOVA*[1], Svetlana Slavic[2], Ute Zeitz[2], Sabine Riesen[3], Tamas Ambrisko[3], Mato Markovic[3], Wolfgang Kuebler[4], Reinhold Erben[5]. [1]INST. OF PHYSIOLOGY, PATHOPHYSIOLOGY & BIOPHYSICS, Austria, [2]Department of Biomedical Research, University of Veterinary Medicine, Austria, [3]Department for Companion Animals & Horses, University of Veterinary Medicine, Austria, [4]Institute of Physiology, Charité, Germany, [5]University of Veterinary Medicine, Austria

Epidemiological data in humans have shown that vitamin D insufficiency is associated with hypertension, left ventricular hypertrophy, and increased arterial stiffness. However, the pathophysiological mechanisms underlying the association between vitamin D insufficiency and cardiovascular diseases remain largely unexplained. To elucidate further the role of vitamin D in the regulation of cardiovascular function we examined male 3-and 9-month-old mice with a nonfunctioning vitamin D receptor ($VDR^{\Delta/\Delta}$). To normalize mineral homeostasis, the mice were kept on a rescue diet enriched with calcium, phosphate, and lactose. Elderly but not young $VDR^{\Delta/\Delta}$ mice showed increased heart/body weight ratio and left ventricular muscle mass. Mean arterial pressure as well as renal renin expression and serum aldosterone were unchanged in young and older $VDR^{\Delta/\Delta}$ mice on rescue diet. However, arterial catheterization revealed profoundly increased arterial pulse pressure together with increased arterial stiffness, increased aortic impedance, structural remodeling of the aorta, and impaired systolic and diastolic heart function in elderly, but not in young $VDR^{\Delta/\Delta}$ mice. Furthermore, young and older $VDR^{\Delta/\Delta}$ mice were characterized by lower bioavailability of the vasodilator nitric oxide (NO), and showed decreased aortic expression of endothelial NO synthase (NOS3), the main regulator of vascular NO levels. Conversely, incubation of mouse aortic rings with $1,25(OH)_2D_3$ increased *NOS3* mRNA abundance *in vitro.* Treatment of $VDR^{\Delta/\Delta}$ mice with the NO donor sodium nitroprusside acutely reduced the elevated arterial stiffness to levels similar to those observed in wild-type controls. To analyze the direct effects of vitamin D signaling on *NOS3* transcriptional activity, we double transfected HEK cells with human *VDR* and *NOS3* plasmids. Stimulation of transfected cells with $1,25(OH)_2D_3$ significantly increased NOS3 expression in a VDR dependent manner. These results suggest that VDR signaling regulates NO production by enhancing the transcription of its main endothelial synthetizing enzyme, NOS3. Our data demonstrate the importance of intact VDR signaling in the preservation of vascular function, and may provide a mechanistic explanation for epidemiological data in humans showing that vitamin D insufficiency is associated with hypertension and endothelial dysfunction.

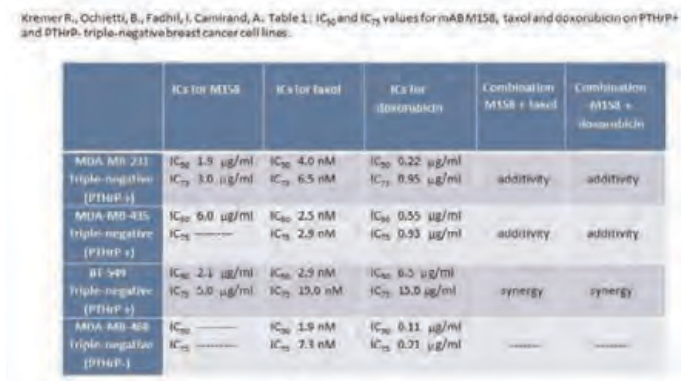
FR0456

Anti-PTHrP monoclonal antibodies are potent proliferation inhibitors in triple negative human breast cancer cells and potentiate the effects of taxol and doxorubicin. Richard Kremer*[1], Benoit Ochietti[2], Ibtihal Fadhil[2], Anne Camirand[2]. [1]McGill University, Royal Victoria Hospital, Canada, [2]McGill University, Canada

Approximately 15% of breast cancer cases present tumors that lack progesterone, estrogen and Her2/neu receptors. The majority of these triple-negative breast cancer types (TNBC) progress rapidly due to lack of effective drugs and resistance to chemotherapy. In this study, we targeted parathyroid hormone-related protein (PTHrP) using the blocking monoclonal antibody (mAb) M158 (directed against its N-terminus) to determine its effects on *in vitro* proliferation as a single agent, and in combination with standard chemotherapeutic agents taxol (Tax) and doxorubicin (Dox). TNBC cell lines MDA-MB-468, BT 549, MDA-MB-231 and MDA-MB-435 were treated with increasing concentrations of Dox, Tax, and the anti-PTHrP mAb M158 as single agents or in combination, and cell survival assayed with Presto-Blue (InVitrogen/Life Technologies). As a single agent, the anti-PTHrP M158 mAb significantly inhibited proliferation in a dose-dependent fashion in all cell lines (see table), as compared to control IgG, except in MDA-MB-468 cells which are PTHrP-negative. Tax and Dox as single agents caused dose-dependent growth inhibition in all lines tested compared to vehicle (see table). Importantly, in PTHrP-positive TNBC cells, M158 mAb enhanced the growth inhibition of Tax and Dox in additive (for MDA-MB-231 and -435) or synergistic fashion (for BT-549). In summary, all PTHrP-positive TNBC cells were significantly inhibited by the blocking mAb as a single agent, and M158 also enhanced the anti-proliferative effect of chemotherapeutic agents, suggesting that the use of an anti-PTHrP mAb in combination therapy could be beneficial to TNBC patients.



Kremer R., Ochietti, B., Fadhil, I. Camirand, A. Table 1 : IC_{50} and IC_{75} values for mAB M158, taxol and doxorubicin on PTHrP+ and PTHrP- triple-negative breast cancer cell lines.

	IC$_x$ for M158	IC$_x$ for taxol	IC$_x$ for doxorubicin	Combination M158 + taxol	Combination M158 + doxorubicin

Biological characterization of PTHrP(12-48): Novel biomarker of breast cancer bone metastasis or new active peptide?. Larry Suva[1], Archana Kamalakar*[1], Dana Gaddy[1], Charity Washam[2], Frances Swain[2], Bethany Allen[2], Nisreen Akel[1], Kim Leitzel[3], Alan Lipton[3]. [1]University of Arkansas for Medical Sciences, USA, [2]UAMS Orth Surgery, USA, [3]Penn State Hershey Cancer Institute, USA

Bone metastasis (BM) is a common occurrence in breast cancer. Approximately 20% of adjuvant breast cancer patients will relapse and die from distant metastasis; of these over 75% will develop BM. Despite intensive research in both the metastatic and early breast cancer setting, there is currently no clinically-approved biomarker that can identify or predict the development of BM. Our discovery of PTHrP(12-48) as a circulating biomarker significantly correlated with BM has the potential to change this paradigm and become the basis for a predictive BM assay that will personalize therapy for adjuvant breast cancer BM prevention. Although PTHrP(12-48) circulates at detectable concentrations ($\sim 103 \pm 46$ng/mL) in breast cancer patients with BM compared with 53 ± 23ng/mL in patients without BM (n=42), there is no evidence for any specific biologic activity. To address this question, we utilized *in silico*, biochemical and immunohistochemical approaches. First, a *de novo* structural model of PTHrP(12-48) was derived and compared to all known PTHrP (and PTH) structures. The model predicted PTHrP(12-48) to be an alpha helix followed by an unstructured region after residue 42. Structural alignments suggested that PTHrP(12-48) is unlikely to have any biological interactions with the PTH1 receptor. PTHrP(12-48) was synthesized for use as an immunogen and for biologic characterization. Supporting the model prediction, PTHrP(12-48) did not induce cAMP accumulation or phosphorylate PKC in hPTH1 receptor-expressing SaOs2 cells. Nor was any biologic function of PTHrP(12-48) detected, such as stimulation of ALP in osteoblasts or the enhancement of RANKL-induced osteoclastogenesis. Interestingly, using a polyclonal PTHrP(12-48)Ab, negatively selected against PTHrP(1-15) and PTH(1-34), we observed tissue- and breast cancer–specific immunostaining of PTHrP(12-48). The polyclonal Ab detected PTHrP(12-48), PTHrP(1-139) but not PTHrP(1-37) or PTH. Classic N-terminal PTHrP target tissues (breast, placenta, cartilage) were positive for PTHrP(1-15) as expected, but negative for PTHrP(12-48). We next examined 15 archival paired primary human breast cancer and BM specimens. Interestingly, 11/15 primary cancers that were PTHrP(1-15) negative were PTHrP(12-48) positive. Of the 15 BM examined, 10 were PTHrP(12-48) positive. These data suggest that PTHrP(12-48) not only circulates at detectable levels in breast cancer patients, but may be commonly expressed by both primary breast tumors and BM

Function of ERRa in Mediating Mixed Metastatic Bone Lesion from Prostate Cancer Cells: Implication of Endothelin 1 and Wnt/periostin pathway. Anais Fradet[1], Akeila Bellahcene[2], Vincent Castronovo[2], Philippe A.R. Clezardin[1], Edith Bonnelye*[3]. [1]INSERM & University of Lyon, France, [2]University of Liège, GIGA-CANCER, Belgium, [3]Faculte de Medecine RTH Laennec, France

Up to 80% of patients dying from prostate carcinoma have developed bone metastases that are incurable. We had shown that the orphan nuclear receptor ERRa (Estrogen receptor related receptor alpha) is involved in skeletal development and in bone metastases from breast cancer cells. Because we found ERRa also expressed in bone metastases from prostate cancer patients, we decide to modulate its expression in PC3 cells and investigate its role in the development of bone metastases from prostate cancer cells. We show that human PC3 cells over-expressing wild-type ERRa (PC3-ERRaWT) induced osteolytic bone lesions in SCID mice (n=10) that were increased (51,5 ± 6,7* for Bone volume (BV/TV)(%) and 18,5 ± 5,4** for skeletal tumor burden (TB/STV)(%)) compared to that observed with PC3-CT cells (59,5 ± 2,75 (BV/TV) and 2 ± 0,73 (TB/STV)). Surprisingly bone destruction was combined with new bone formation, as 70% of the metastatic limbs that were bearing PC3-ERRaWT cells had mixed lesions compared with CT-PC3 that only developed osteolytic lesions. Osteoclasts were not directly affected *in vivo* and *in vitro*. On the other hand, a statistical stimulation of bone nodules number (calvaria culture) was observed when cells were treated with conditioned medium extracted from PC3-ERRaWT compared with PC3-CT which was combined with the up-regulation of BSP, OCN expression and a decrease of RANKL in MC3T3 cells. Interestingly, microenvironment was impacted by PC3-ERRaWT cells, as mouse periostin (POSTN), that is known to contribute to the metastatic niche, is over-expressed *in vivo* suggesting the implication of the stroma in the tumor progression in bone mediated by ERRa. Finally, PC3-ERRaWT cells stimulated tumor growth after subcutaneous injection. Pro-osteolytic factors such as TGFβ1, MMP1, Runx2 and Cathepsin K were found to be up-regulated in PC3-ERRaWT compared with CT-PC3 tumors. The expression of pro-osteoblastic factors Wnt3a, 5a, 10b, 11 and ET1 was also stimulated *in vivo* which may explain the occurrence of bone formation in these skeletal lesions. The direct regulation of Wnt3a and 5a, ET1, OPG, MCP1, CK and Runx2 was confirmed by using the inverse agonist XCT790 (10^{-6}M) on PC3 cells during 24h. In conclusion, our data suggest that ERRa can promote both osteolysis and osteosclerosis in animal models of prostate cancer bone metastases and suggest an implication of ERRa in cancer stem cells maintenance and metastatic niche via the POSTN/ Wnt signaling.

PGE2 receptor EP4 regulates breast cancer metastasis and bone resorption through osteoblastic RANKL production. Satoshi Yokoyama[1], Kenta Watanabe[1], Michiko Hirata[1], Chiho Matsumoto[1], Takayuki Maruyama[2], Chisato Miyaura[1], Masaki Inada*[1]. [1]Tokyo University of Agriculture & Technology, Japan, [2]Ono Pharmaceutical Co., Ltd., Japan

Bone metastasis of breast cancer is accompanied by severe bone destruction. We identified that prostaglandin E2 (PGE2)-induced osteoclast formation was mediated by RANKL production in osteoblasts, and that EP4 is the most effective PGE receptor rather than the other EP subtypes (EP1, EP2, EP3). Here, we examined the effects of EP4 antagonist in the model of *in vivo* inoculation of breast cancer into bone. First, we have identified the expression profiles of EPs in mouse breast cancer cell 4T1, and found the expression of EP1 and EP4 in 4T1 cells. PGE2-induced 4T1 proliferation was suppressed by both EP1 and EP4 antagonist in the cells, suggesting the 4T1 has a diversity to respond multiple PGE2 signaling channels for the proliferation. To examine the mechanism of 4T1 induced-bone resorption, 4T1 cells were co-cultured with bone marrow cells and osteoblasts to evaluate the supporting capacities of osteoclast formation. We newly employed the experimental system to evaluate cell-cell interaction by the contact adhesion, co-cultured bone cells on fixated cancer cell with cell membrane. Contact with fixed-4T1 cell strongly induced RANKL expression and PGE2 production in osteoblasts. Osteoclast formation was induced in the co-culture of osteoblasts and bone marrow cells on fixed-4T1 cells, and only EP4 antagonist completely inhibited the osteoclast formation. When 4T1 cells were co-cultured with mouse calvaria to evaluate bone resorbing activities, 4T1 cells attachment to bone surface markedly induced the number of osteoclast and following bone resorption. In the organ culture, adding EP4 antagonist attenuated 4T1-induced bone resorption. By 3D-micro CT analyses, the resorbing trail was detected on calvarial bone surface and suppressed by the treatment of EP4. Finally, *in vivo* experiments using the tibial inoculation model of 4T1 cells, the oral administration of EP4 antagonist clearly protected the 4T1-induced bone destruction in both cancerous and cortical bone of tibia. These results suggest that the EP4 specifically regulates RANKL production in osteoblast that leads osteoclast differentiation and following osteolysis. EP4 antagonist is a candidate for the therapy of breast cancer with bone metastases.

Presence of Giant Osteoclasts in Zoledronic Acid Treated Prostate Cancer Bone Metastasis. Martine P Roudier*[1], Colm Morrissey[1], Alexander Dowell[2], Eva Corey[1], Celestia HIGANO[3], Lawrence TRUE[3], Robert Vessella[3]. [1]University of Washington, USA, [2]University of Alabama at Birmingham, USA, [3]UW, USA

Zoledronic acid (ZOL), a new generation bisphosphonate, reduces skeletal-related events in patients with prostate cancer (PCa) bone metastases. We have shown previously that bisphosphonates significantly increased bone volume in PCa bone metastases with no apparent reduction in osteoclast numbers. In the present study we aimed to characterize responses of osteoclasts in PCa bone metastases to ZOL treatment. We measured number of osteoclasts/13.55 mm2 in bone biopsies obtained from 27 ZOL-treated and 10 ZOL-untreated patients with PCa bone metastases (total of 357 TRAP stained plastic sections). We found no difference in osteoclast numbers between ZOL-treated (n=257) versus ZOL-untreated (n=100) PCa bone metastases per surface area (average 7.2 ± 8.6 vs 6.2 ± 9, p=0.143). To compare the morphology of osteoclasts in ZOL-treated and ZOL-untreated patient biopsies, we selected biopsies which had more than two TRAP-positive osteoclasts/bone surface (n=37), and counted the number of osteoclasts per section (total area 95 mm2). We did not detect differences between ZOL-treated and ZOL-untreated biopsies: no ZOL (n=10), 36.7 ± 61; ZOL-treated (n=27), 44.3 ± 49, (p=0.143). In the biopsies from patients treated with ZOL for less than 1 year and more than 3 years, we found an average of two giant osteoclasts with > 20 nuclei per section. No giant osteoclasts were observed in sections from untreated patients. In all ZOL-treated biopsies we found an average of three osteoclasts with >13 nuclei per section, none in untreated sections, and a global average of 45 osteoclasts with up to 12 nuclei per section in all metastatic biopsies that were included in the analysis. In corresponding H&E on paraffin embedded biopsies, we counted osteoclast number/section, selected the sections with more than two osteoclasts/section and performed a TUNEL assay. In 41 ZOL-treated and 65 ZOL-untreated sections, we found averages of 11 ± 9.7 and 10 ± 12.5 osteoclasts/section respectively, averages of 40 and 33 nuclei/section, and averages of 7 and 6 TUNEL-positive nuclei/section. None of these parameters were significantly different between the groups (p=0.405). In summary, our results show that osteoclasts are present in high numbers in PCa bone metastases, and the ZOL treatment does not reduce their numbers. Our results also did not reveal any differences in apoptosis of osteoclast associated with ZOL treatment in patients with advanced PCa bone metastases. However, our results indicate that ZOL treatment results in development of giant osteoclasts. Biological significance of this finding for PCa metastases and effects of ZOL on bone will require further detailed analyses.

Integrin-beta 3 is required for breast tumor cell response to bone rigidity. Jonathan Page*[1], Nazanin Ruppender[1], Shellese Cannonier[1], Ushashi Dadwal[1], Alyssa Merkel[1], Scott Guelcher[1], Julie Sterling[2]. [1]Vanderbilt University, USA, [2]Department of Veterans Affairs (TVHS)/Vanderbilt University Medical Center, USA

The importance of the bone microenvironment in the regulation of tumor cell behavior is increasingly recognized. While many aspects of this environment have been explored, we have demonstrated that the physical rigidity of bone can regulate *Pthrp* and *Gli2* expression in bone metastatic cells. This response was dependent on Rho-associated protein kinase (ROCK), as ROCK shRNA or a dominant negative ROCK construct blocked the rigidity-mediated increase in *Pthrp* expression, while a dominant active construct increased *Pthrp* expression. Since studies in soft tissue tumors have demonstrated that $\alpha_v\beta_3$ integrin mediates tumor response to rigidity, we hypothesized that the tumor response to bone rigidity was also integrin-dependent. LM609, a $\alpha_v\beta_3$ inhibitory antibody, reduced the expression of *Pthrp* and *Gli2* by 2.8 and 10-fold respectively ($p \leq 0.01$), and reduced *Pthrp* expression in the ROCK dominant active cells by 9-fold ($p \leq 0.005$) in MDA-MB-231 cells grown on rigid polyurethane (PUR) films. To further determine the importance of integrin β_3, we stably transfected MDA-MB-231 cells with β_3 shRNA (90%), and measured the cells' ability to respond to mechanical cues using PUR films with tunable rigidity. Integrin β_3 knock-down reduced *Pthrp* expression by 54-fold in cells grown on rigid PUR films ($p \leq 0.001$), but not on compliant films. Since we have previously shown that TGF-β Receptor type II (RII) is required for the mechanotransduction response of MDA-MB-231 cells, we investigated whether integrin and RII interacted. Using immuno-precipitation, we found that integrin β_3 and RII co-localized as a function of increasing rigidity, suggesting pathway cross-talk. Finally, since p38 MAPK is known to play an important role in mechanotransduction and the MAPK inhibitor SB202190 reduced *Pthrp* expression on rigid films by 4-fold ($p \leq 0.01$), we investigated whether rigidity alone, in the absence of exogenous TGF-β, could upregulate p38 MAPK phosphorylation. Phosphorylation of p38 MAPK was increased on rigid films compared to compliant films by Western blot, while no changes were observed in the expression of non-phosphorylated p38 MAPK. Additionally, no increase in p38 MAPK phosphorylation was observed in the ROCK dominant negative cells. Taken together these data indicate that integrin β_3, via a pathway involving RII, ROCK and p38, is required for tumor cells to sense the rigidity of the bone microenvironment.

Combined TGF-β and Proteasome Inhibition Improves Bone Architecture and Reduces Tumor Burden in Myeloma Bone Disease. Jeffry Nyman*[1], Alyssa Merkel[1], Barbara Rowland[2], Alexander Makowski[3], Julie Sterling[4]. [1]Vanderbilt University Medical Center, USA, [2]Department of Veterans Affairs (TVHS), USA, [3]Department of Veterans Affairs, Vanderbilt University, USA, [4]Department of Veterans Affairs (TVHS)/Vanderbilt University Medical Center, USA

Myeloma patients often develop tumor-induced bone destruction where bone volume is reduced as tumor cells expand. While there are available therapies to treat the bone disease, none eliminate the tumor or fully reverse the bone loss. Previous studies indicate that TGF-β inhibition improves bone volume and reduces tumor growth in several solid tumor models. Since elevated TGF-β signaling could also be involved in myeloma-related bone loss, we hypothesized that TGF-β inhibition would reduce tumor growth and improve bone architecture in myeloma-bearing mice. First, 5TGM1 myeloma cells were inoculated into the immune compromised, Rag 2-/- (Taconic), mice. Mice were treated with 10 mg/kg, 3x/week, of the anti-TGF-β antibody (1D11, Genzyme, n=12) or the control antibody (13C4, n=12) beginning at the time of tumor injection for 4 weeks. Surprisingly, 8 out of 12 Rag 2 -/- mice treated with 1D11 developed plasmacytomas, compared to 1 in the 13C4 group. Furthermore, 1D11 treatments did not alter IgG2bκ or spleen weights (tumor burden) in the myeloma-bearing Rag2 -/- mice, indicating no effect on tumor burden. However, 1D11 had a beneficial effect on bone architecture in that it increased trabecular BV/TV, connectivity density, and tissue mineral density ($p \leq .001$) as determined by μCT analysis of the femur metaphysis. In addition, 1D11 reduced the resorption-related increase in cortical porosity of the metaphysis. In order to determine if combining an anti-myeloma drug with 1D11 could both reduce tumor burden and improve bone architecture, we performed co-treatments with Velcade (.5 mg/kg, 3xs a week). For this study, we used the immune competent KaLwRij model inoculated with 5TGM1 cells ($n \geq 8$ per group) to avoid confounding interactions with immune deficiency. In this study, we found that Velcade + 1D11-treated mice, but not 1D11-alone, reduced spleen weight (49%, $p \leq .001$) and reduced IgG2bκ (40%, $p \leq .05$) compared to the vehicle treated mice. Furthermore, this combined therapy group displayed a reduction in μCT-derived cortical porosity (66%, $p \leq .05$) and an increase in trabecular BV/TV (50%, $p \leq .001$), whereas Velcade alone did not affect bone architecture. While 1D11 did not inhibit tumor growth and promoted plasmacytomas in immune compromised mice, combination therapy with proteasome and TGF-β inhibition improved bone architecture and inhibited tumor growth, and thus, it may be a promising strategy for treating patients with myeloma-induced bone disease.

Hypoxia upregulates calpain-6 expression in osteosarcoma cells: implication in cancer stem cells. Imene Kaci[1], Rafik MANSOURI[2], Pierre Marie[3], Dominique Modrowski*[4]. [1]Unité 606 INSERM, France, [2]INSERM, France, [3]Inserm Unit 606 & University Paris Diderot, France, [4]INSERM U606, France

We previously showed that calpain-6 overexpression in osteosarcoma cells is involved in chemoresistance. Here we characterized the mechanisms driving the abnormal expression of calpain-6 in bone tumours. Human primary bone tumours express higher calpain-6 mRNA levels compared to cultured osteosarcoma cells, suggesting a role of the microenvironment. Immunohistochemistry showed that within the tumours, calpain-6 was strongly expressed in hypoxic areas labelled by a hypoxia marker (pimonidazole). Calpain-6 promoter sequence displays functional hypoxia response elements (HRE) and consensus sites for NFkB, as assessed by ChIP analysis. Culturing human osteosarcoma cell lines in hypoxic conditions (3% O2) increased calpain-6 mRNA and protein levels, and this effect was strongly reduced when HIF-1a was silenced using siRNA. Hypoxia also activated NFkB, as shown by reporter assays, and promoted the endothelin-1/NFkB pathway by increasing endothelin-1 receptor expression. In addition to HRE, the regulatory sequence of calpain-6 displays functional sites for Oct4, Nanog and Sox2 stem cell transcription factors which were up-regulated by hypoxia. Silencing Oct4, Nanog or Sox2 strongly reduced the increase of calpain-6 induced by hypoxia, suggesting a relationship between calpain-6 and the stem cell phenotype. To test this hypothesis, we prepared stem-like cells performing sphere forming assays. Different osteosarcoma cell lines showed a various potential to form floating spherical colony-like structures that grew in anchorage-independent conditions in serum-free medium and resisted to enzymatic dispersion. The number of spheres increased when the cells were cultured under hypoxic conditions, indicating that hypoxia promotes the stem cell phenotype. Interestingly, the spheres expressed higher levels of Oct4, Nanog, Sox2 and calpain-6 than parental cells. Calpain-6 overexpression using a lentiviral vector in U2OS osteosarcoma cells did not change sphere number but increased cell survival upon cell passages, indicating that calpain-6 plays a role in stem cell renewal. Altogether, our results demonstrate that hypoxia controls calpain-6 expression in osteosarcoma cells through direct and indirect pathways involving HIF-1a and NFkB effectors. Moreover, the induction of calpain-6 by hypoxia depends on stem cell factors, suggesting a particular regulation of calpain-6 in the tumour inducing cells that may be related to its role in chemoresistance.

Potent induction of bone formation in myeloma bone lesions by the cathepsin K inhibitor KK1-300-01 in combination with the proteasome inhibitor bortezomib. Keiichiro Watanabe*[1], Masahiro Abe[2], Hiroshi Mori[3], Ryota Amachi[4], Masahiro Hiasa[5], Takeshi Harada[6], Shiro Fujii[6], Shingen Nakamura[6], Hirokazu Miki[6], Kumiko Kagawa[6], Itsuro Endo[7], Eiji Tanaka[4], Toshio Matsumoto[7]. [1]Tokushima University Hospital, Japan, [2]University of Tokushima, Japan, [3]Ono Pharmaceutical Co., Ltd., Japan, [4]Department of Orthodontics & Dentofacial Orthopedics, The University of Tokushima Graduate School, Japan, [5]University of Tokushima Graduate School, Japan, [6]Department of Medicine & Bioregulatory Sciences, The University of Tokushima Graduate School, Japan, [7]University of Tokushima Graduate School of Medical Sciences, Japan

Multiple myeloma (MM) enhances osteoclastogenesis while suppressing osteoblastogensis to develop devastating bone destruction. Restoration of bone in osteolytic lesions in MM still remains an important clinical issue in the present therapeutic strategies. Unlike other anti-bone resorptive agents, cathepsin K inhibitors potently suppress bone resorption while sparing cytotoxic damage in osteoclasts (OCs). In the present study, we explored the effects of cathepsin K inhibition on bone destruction in MM. The cathepsin K inhibitor KK1-300-01 (KK1) potently suppressed pit formation enhanced in the cocultures of rabbit bone cells with MM cells. However, KK1 did not affect the viability of OCs and osteoclastogenesis, and allowed OCs to facilitate in vitro mineralized nodule formation by MC3T3-E1 cells, suggesting the preservation of OC-driven osteoblastogenesis by KK1. We next examined the in vivo effects of KK1 using human INA6 MM-bearing SCID-rab models, which exhibit tumor progression with osteolytic lesions in implanted rabbit bones. Oral dosing of KK1 prevented bone destruction with marked increase in bone trabecular size and BMD in the rabbit bones and tumor reduction within their bone marrow cavity. Histological analyses showed increased bone volume/total volume with a marginal change in OC numbers in the treated mice. Of note, combinatory treatment with KK1 and bortezomib sq at 0.5 mg/kg twice a week almost completely eradicated MM cells and resumed bone formation achieving the highest BMD, while bortezomib alone showed only partial suppression of tumor growth and bone destruction. Given OC-derived ''coupling'', KK1 is suggested to spare the damage in OCs to retain the ''coupling'' for bone formation while inhibiting bone resorption, leading to robust bone formation and thereby MM contraction in bone. It can be envisaged that KK1 effectively induces bone restoration and tumor reduction in combination with anti-MM proteasome inhibitors with anabolic actions.

***In Vitro* Bone to Muscle Cell Signaling is Negatively Affected by Aging and Common Non-steroidal Anti-inflammatory Drugs (NSAIDs).** Asmaa Alsousi*[1], Marco Brotto[1], Chenglin Mo[1], Mostafa Badr[1], Lori Wetmore[2], Lynda Bonewald[1], Julian Vallejo[1]. [1]University of Missouri - Kansas City, USA, [2]William Jewell College, USA

Myogenic differentiation is not only critical during development, but also during adult life, since it allows muscle repair and regeneration. Previously, we demonstrated that conditioned media (CM) from the osteocyte-like MLO-Y4 osteocytes (MLO-Y4) accelerated myogenic differentiation of murine C2C12 myoblasts. We have now expanded these studies to test the effects of CM from murine primary osteocytes (MPO) on C2C12 myoblasts. Our morphological studies indicated that a low concentration of 1% CM from MPO is able to accelerate myogenic differentiation of C2C12 myoblasts. To refine our quantification and data fidelity we have used flow cytometry (FC) to more objectively quantify the effects of bone cell CM on muscle cells. C2C12 cells were cultured in growth medium (CGM: Dulbecco's modified Eagle's medium with 10% fetal bovine serum, 70% confluence). In order to arrest cell cycle differentiation, cells were synchronized with 1% FBS CGM. Medium was switched to DMEM with 2% horse serum (Differentiation medium DM). At day 5-7 of treatment, cells were trypsinized, fixed with ethanol and then treated with propidium iodide (1mg/ml) for FC analyses. In myoblasts treated with CM from young mice, cells percentage that entered the G0/G1 phase decreased by 10% in comparison with the control, which indicated an acceleration of myogenesis. This effect correlated with a significant decrease of approximately 8% in the subG population. Osteoporosis is an aging-related condition, and osteocytes from aged mice might secrete less or different factors when compared to young mice. FC revealed that CM from aged mice increased the percentage of cells entering the G0/G1 phase by 5% compared to young CM. Thus, a higher percentage of cells become arrested after treatment with aged CM, suggesting that effects of primary osteocytes CM are influenced by aging. Last, since our group has previously shown that PGE2 treatment partially mimics the acceleration of myogenesis effects of MLO-Y4 CM effects in C2C12 myoblasts, we have begun studying the effects of commonly used non-steroidal anti-inflammatory drugs (NSAIDs), Acetylsalicylic acid (Aspirin) and Acetaminophen on C2C12 myogenesis. We observed an increase of 10-15% in cells that entered the G0/G1 phase, suggesting potentially detrimental effects on myogenesis. We are currently focusing on deciphering the cellular mechanisms underlying the effects of aging and NSAIDs on myogenesis.

Age-associated Changes in MicroRNA Expression Affects Differentiation Potential in Human Mesenchymal Stem Cells. Sudharsan Periyasamy-Thandavan*[1], Sergi Mas[2], Sadanand Fulzele[3], Xingming Shi[3], Norman Chutkan[3], Randy Ruark[3], John Hinson[3], Monte Hunter[3], Raymond Corpe[3], Hongyan Xu[3], Carlos Isales[3], Mark Hamrick[4], William Hill[1]. [1]Georgia Regents University & Charlie Norwood VAMC, USA, [2]Universitat de Barcelona, Spain, [3]Georgia Regents University, USA, [4]Georgia Health Sciences University, USA

Age-associated osteoporosis is largely accepted as an emerging stem cell disease in recent times. Maintenance of the local bone marrow (BM) microenvironment extracellular matrix and signaling factors is critical in regulation of proliferation, and differentiation, of the multipotent BM mesenchymal stromal/stem cell (MSC) population with age. Recently, the role of microRNAs (miRNAs) in modulating the BM microenvironment along with the proliferation and differentiation of MSCs has been recognized. Here, we examined the role of miRNAs with age-associated changes in MSC osteogenic potential. To avoid artifacts introduced with standard MSC isolation and cell culturing techniques, we directly isolated CD271+ MSCs (that are CD90, 105, 73+ and CD14, 20, 34, 45-) from human surgical bone marrow aspirates of patients, isolated the total RNA and performed a microarray analysis (Affymetrix GeneChip® miRNA 2.0 Array) of young vs old CD271+ MSCs using the Partek Genomics Suite and Functional Hierarchical Clustering. The miRNAs identified as differentially expressed with age were validated by qRT-PCR. The predicted targets were clusters of genes associated with bone formation, extracellular matrix components, as well as osteogenic signaling pathways. The overexpressed miRNAs were predicted to target multiple osteogenic genes, including SDF-1 and BMP2; while targets of the underexpressed miRNAs included adipogenenic genes such as PPAR-gamma, and AP2-alpha. Specific miRNA mimics and inhibitors of miRNAs that were differentially expressed with age were transfected in cultured CD271+ MSCs from young patients. ELISA, quantitative Real-Time PCR (qRT-PCR), migration assay and differentiation assays were performed. Mimics of the overexpressed miRNAs significantly downregulated the mRNA expression of SDF-1-CXCR4 axis and osteogenic genes; while silencing the underexpressed miRNAs significantly upregulated PPAR-gamma mRNA expression. Similarly, ELISA analysis demonstrated the significant reduction of SDF-1 protein secretion in the cell culture medium. In addition, migration assay confirmed the reduced migration of MSCs towards the respective cell culture medium. Differentiation assays showed transfection of these miRNA mimics and inhibitors in the MSCs, reduced osteogenesis and increased adipogenic markers. Overall, these findings confirm that differential expression of miRNA shift the differentiation potential of MSCs from an osteogenic to an age-associated adipogenic lineage.

Swedish mutant APP suppresses osteoblast differentiation and causes osteoporotic deficit, which are ameliorated by n-acetyl-l-cysteine. Wen-Cheng Xiong*, Wen-Fang Xia, Jiung Jung, Shun Cui, Shan Xiong, Lei Xiong. Georgia Regents University, USA

Reduced bone mineral density and hip fracture are frequently observed in patients of Alzheimer's disease (AD). However, mechanisms underlying their association remain poorly understood. Amyloid precursor protein (APP) is a transmembrane protein that is ubiquitously expressed, including bone marrow stromal cells (BMSCs), osteoblasts (OBs), macrophages (BMMs), and osteoclasts (OCs). Mutations in APP gene identified in early-onset AD patients are believed to cause AD. But, little is known about APP's role in bone remodeling. Here, we present evidence for Swedish mutant APP (APPswe) in suppression of OB differentiation and function in culture and in mouse. APP expression in BMSCs increases during ageing. Ubiquitous expression of APPswe in young adult Tg2576 (under the control of prion promoter) recaptured skeletal "ageing-like" deficits, including decreased OB genesis and bone formation, increased adipogenesis and bone marrow fat, enhanced OC genesis and bone resorption. Remarkably, selective expression of APPswe in mature OB-lineage cells in TgAPPswe-Ocn mice [under the control of osteocalcin (Ocn) promoter driven Cre] also decreased OB genesis and increased OC formation, resulting in a trabecular bone loss. These results thus suggest a cell autonomous role for APPswe in suppressing OB formation and function, but a non-autonomous effect on OC genesis. Notably, increased adipogenesis and elevated bone marrow fat were detected in young adult Tg2576, but not TgAPPswe-Ocn, mice, implicating that APPswe in BMSCs and/or multi-cell types in bone marrow promotes bone marrow adipogenesis. Intriguingly, the skeletal ageing-like deficits in young adult Tg2576 mice were prevented by treatment with NAC (n-acetyl-l-cysteine), an anti-oxidant, suggesting that reactive oxygen species (ROS) may underlie APPswe-induced osteoporotic deficits. Taken together, these results demonstrate a role for APPswe in suppressing OB differentiation and bone formation, implicate APPswe as a detrimental factor for AD associated osteoporotic deficit, and reveal a potential clinical value of NAC in the treatment of osteoporotic deficits.

Testosterone Modulates Inflammation-Induced Periodontal Bone Loss. Luis Carlos Spolidorio*[1], Leila Santana Coimbra[2], Carlos Rossa Jr[2], Alpdogan Kantarci[3], Thomas E Van Dyke[3], João Paulo Steffens[4]. [1]Campus of Araraquara, Brazil, [2]Department of Physiology & Pathology*, Dental School of Araraquara, State University of São Paulo (UNESP), Araraquara, São Paulo, Brazil, Brazil, [3]The Forsyth Institute, Department of Applied Oral Sciences, USA, [4]Department of Physiology & Pathology*, Dental School of Araraquara, State University of São Paulo (UNESP), Brazil

Abnormal testosterone levels result from several physiological, pathological and pharmacological conditions. Periodontitis is an inflammatory condition that leads to alveolar bone loss. The purpose of this study was (i) to evaluate the impact of sub- and supraphysiologic doses of testosterone (T) on experimental periodontitis, and (ii) to assess the actions of T on osteoclastogenesis in vitro. Forty male Holtzman rats were subjected to orchiectomy to suppress T production (Ocx). Twenty of the rats received 250mg/kg T. An additional twenty rats served as sham-operated controls. Experimental periodontitis was induced in ten animals in each group by ligature placement around the lower first molar teeth 30 days post-surgery and maintained for 15 days. The remaining animals served as controls. Changes in alveolar bone height were radiographically quantified. Serum levels of cytokines and chemokines were measured. In vitro, RAW 264.7 cells were used as osteoclast (OC) precursors and OC RANKL-mediated differentiation and activity were evaluated in the presence of 1nM-1μM doses of testosterone. Flutamide (100nM) was used as a specific blocker to assess the role of androgen receptors. In the absence of periodontitis, there was significant bone loss in the T group (0.74 ± 0.04 mm) when compared to Ocx (0.49 ± 0.07) or Sham (0.55 ± 0.05; $p<0.05$). Ocx alone increased serum IL-2 levels (+90%) and T increased IL-1β (+174%), IL-2 (+200%) and IFN-γ (+73%). Periodontitis resulted in significantly higher bone loss in the Ocx group (1.69 ± 0.14) compared to Sham controls (1.32 ± 0.09; $p<0.05$), and also led to a significant reduction in IL-10 (-44 and -47%) in Ocx and T groups, respectively. A decrease in IL-4 (-52%) and an increase in IL-1β (+173%) accompanied these changes in the T group. In vitro, T dose-dependently inhibited OC numbers and area ($p<0.05$), although the highest dose resulted in an increase in OC formation. The addition of flutamide rescued the 100nM T inhibition restoring the number of OC. In conclusion, sub- and supraphysiologic T levels predispose to inflammatory changes with a significantly higher periodontal destruction in rats. These clinical observations are accompanied by

cytokine/chemokine and ALP modulation. T presents an optimal range (10/100nM) to reduce OC formation and activity in vitro, which is mediated, at least in part, via the androgen receptor.

The Role of Inflammation in Senescence of Human MSCs. Julie Glowacki*, Shuanhu Zhou. Brigham & Women's Hospital, USA

Skeletal aging is characterized as a gradual loss of bone mass to the point of osteopenia or osteoporosis, and eventually bone fracture. We reported that human marrow-derived stromal cells (hMSCs), with potential to differentiate to osteoblasts, show reproducible declines in proliferative and osteoblast potential with the age of the subject from whom the cells were obtained. They also show an age-related increase in biomarkers of cell senescence, including the % Senescence-Associated-β-galactosidase (SA-β-gal)-positive cells and expression of p53 and its target p21; furthermore there is an age-related increase in their constitutive secretion of pro-inflammatory interleukins. Our previous unsupervised miRNA cluster comparison showed NF-κB dysregulation in cells from elders; Westerm immunoblotting showed increased phosphorylated NF-κB/p65 in cells from elders. These observations raise the possibility that inflammation can be a mechanism of cell senescence in hMSCs. Tumor necrosis factor-α (TNF-α) is a key inflammatory mediator implicated in the onset of several diseases. TNF-α interacts with two receptors (TNFR1 and TNFR2) that are differentially expressed on cells and tissues and initiate both distinct and overlapping signal transduction pathways. In this study, we tested the mechanistic hypothesis that TNF-α induces senescence of human MSCs.

We examined the effects of TNF-α on hMSCs from a 17-year-old man. There was a dose-dependent increase in phosphorylation of NF-κB/p65 and on sensecence markers. TNF-α (10 ng/mL) increased the number of SA-β-gal-positive cells by 11-fold and decreased proliferation to 29% of control; there was a dose-dependent decrease in osteoblast differentiation, assessed by Alkaline phosphatase (ALP) activity after 7 days in osteoblastogenic medium (Figure). We used groups of hMSCs from 4 young (*Y*; <45 y) and 4 older (*O*; >65 y) subjects to evaluate constitutive expression of TNF receptors; expression of TNFR2 in *O*-hMSCs was 21% of that in *Y*-hMSCs (p=0.03), with no difference in TNFR1.

These studies show that TNF-α induced a senescent phenotype in hMSCs from a 17-year old man: increased SA-β-gal and decreased proliferation and osteoblast differentiation. Age effects on TNF receptors do not appear to account for senescence of hMSCs. In sum, these observations add evidence that intrinsic age-associated inflammatory processes can contribute to decreased osteoblast differentiation and skeletal aging.

Baseline serum markers of adiposity driven immune/endocrine perturbations are not significantly correlated with longitudinal changes in lean mass in postmenopausal women. Andriene Grant[1], Jennifer H Stern[2], Cynthia A Thomson[3], Robert Kaplan[4], Todd Manini[5], Charles Eaton[6], Lesley Tinker[7], Erin LeBlanc[8], Scott Going[1], Oleg Zaslavsky[9], Zhao Chen*[1]. [1]The University of Arizona, USA, [2]University of Arizona Cancer Center, USA, [3]University of Arizona College of Public Health, USA, [4]Albert Einstein College of Medicine, USA, [5]University of Florida Aging Rehabilitation Research Center, USA, [6]Division of Biology & Medicine, Brown University, USA, [7]Fred Hutchinson Cancer Research Center, USA, [8]The Center for Health Research, Kaiser Permanente, USA, [9]Faculty of Health Science & Social Welfare, University of Haifa, Israel

Background: Sarcopenic obesity, a combination of obesity and low muscle mass, has recently been defined as an epidemic. While it is possible that these pathophysiological states may simply coexist, there is a causal link between obesity and sarcopenia that has yet to be fully understood. Total body fat is associated with higher circulating pro-inflammatory cytokines, decreased growth hormone (GH) production, and altered circulating levels of adiponectin and leptin. These hormonal and inflammatory perturbations have been implicated as determinants of sarcopenia. This study investigates the association between adiposity driven immune/endocrine biomarkers and the trajectory of change in lean mass (ΔLM), with special consideration to the trajectory of change in fat mass (ΔFM) in postmenopausal women (PMW).

Methods: Utilizing a cohort of PMW from the Women's Health Initiative, we investigated the relationship between baseline circulating levels of inflammatory cytokines (CRP, IL-6, IL-1, TNF-α), GH, adiponectin, and leptin with longitudinal changes in DXA-derived total body lean mass (LM) and fat mass (FM). ΔLM and ΔFM were determined from measures collected at baseline, y3 and y6 of the study. Fasting blood samples were collected to assess baseline circulating biomarker concentrations. Multiple linear regression analysis was used to determine the association between the slope of ΔLM and biomarkers.

Results: Mean LM declined from 36.61±4.99 kg at baseline to 36.26±4.97kg at year 6 ($p<0.05$), while mean FM and body weight (BW) increased with time (FM: 29.55±10.78kg at baseline to 30.10±10.49kg at year 6, BW: 69.67±15.05kg at baseline to 70.23±14.91kg at year 6, $p<0.05$ for FM and BW). Although GH (p=0.024), leptin (p=0.041) and the leptin to adiponectin ratio (LAR) (p=0.024) were crudely associated with ΔLM in linear regression models, when the ΔFM was added to the model as a covariate, this was no longer statistically significant (p=0.05, 0.088, and 0.121 for GH, leptin, and LAR, respectively).

Conclusion: After controlling for longitudinal changes in fat mass, baseline circulating markers of adiposity driven hormonal and inflammatory perturbations were not associated with longitudinal changes in lean mass in this population of postmenopausal women. The association of growth hormone, leptin and LAR with ΔLM observed in this study may be mediated by ΔFM and thus, these biomarkers may not be reliable predictors of longitudinal changes in lean mass in PMW.

Components of sarcopenia and the risk of co-morbidity among postmenopausal women – 10 year follow-up of the OSTPRE study. Juha Suuronen*[1], Samu Sjöblom[1], Toni Rikkonen[1], Marjo Tuppurainen[2], Risto Honkanen[1], Heikki Kröger[3], Joonas Sirola[4]. [1]University of Eastern-Finland, Finland, [2]Kuopio University Hospital, Finland, [3]Kuopio University Hospital, UEF, Finland, [4]University of Eastern Finland / Kuopio, Finland

Introduction: Muscle strength and physical performance level are measures of sarcopenia. The aim of the present study was to investigate the effects of grip strength and physical capability on postmenopausal co-morbidity.

Methods: 2735 Finnish Caucasian women from the OSTPRE cohort were measured with grip strength (GS) dynamometer at baseline (1994) and at 10-year follow-up (2004) and categorized into quartiles. Physical capability (PC) was assessed with questionnaires and categorized into: 1) Full PC (n=1487) 2) Able to walk over 1 km but not to run (n=1000) and 3) Able to walk less than 1 km (n=248). Osteoporosis was defined as 10-year follow-up FN or LS T-score under -2.5 SD or under -2.0 SD + low trauma energy follow-up fracture. Information on co-morbidities was based on self-reports. Effects of Grip strength and physical capability on prediction for morbidities were analyzed disease specifically during 10-year follow-up. At baseline, women with end-point morbidity were excluded from the analysis. The risk of co-morbidity related to sarcopenia at 10-year the follow-up was estimated with multivariate logistic regression, adjusting for age, BMI, HT use, alcohol intake and smoking.

Results: The prevalence of co-morbidities at the end of follow-up were: hypertension (HT) 25.7 %, cardiac insufficiency (CI) 6.2 %, coronary artery disease (CAD) 10.3 %, stroke (ST) 5.0 %, diabetes mellitus (DM) 7.3 %, osteoarthritis (OA) 22.3 %, breast cancer (BC) 2.8 %, depression 2.8 %, osteoporosis (OP) 8.2 %, chronic back pain (BP) 17.1 % and poor self-rated health (SRH) 4.3 %. Women within the lowest grip strength quartile had lower risk of HT (OR 0.74, $p<0.05$), higher risk of ST (OR 1.74, $p<0.05$) and OA (OR 1.45, $p<0.02$) in comparison to women within the highest GS quartile in multivariable model. Women with the poorest PC had a higher risk of CI (OR 2.56, $p<0.01$), CAD (OR 2.19, $p<0.001$) and OP (OR 2.51, $p<0.001$).

Conclusions: Grip strength and Physical capability predict different co-morbidities among postmenopausal women. Physical capability is a better predictor of clinical osteoporosis than GS in multivariable model. These findings support the concept of including different measures of sarcopenia in its diagnostics. The role of muscle mass and quality to predict the morbidity remains unclear.

SA0008

Dairy intake is not associated with quadriceps muscle strength in adults: The Framingham Offspring Study. Shivani Sahni*[1], Kelsey Mangano[2], Robert McLean[1], Douglas Kiel[3], Xiaochun Zhang[4], Marian Hannan[5]. [1]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [2]Institute for Aging Research, Hebrew SeniorLifeHarvard Medical School, USA, [3]Hebrew SeniorLife, USA, [4]Institute for Aging Research, Hebrew SeniorLife, USA, [5]HSL Institute for Aging Research & Harvard Medical School, USA

Rationale: Previous studies have shown that dairy intake can aid in weight loss while retaining lean muscle mass, possibly because dairy foods are high in protein, which has been linked with muscle mass and strength. Furthermore, dairy foods provide other nutrients beneficial for muscle health such as vitamin D. Thus health effects of dairy foods on muscle may be due to more than a single nutrient. Yet, it's unclear if dairy food groups may play a direct role in muscle strength.

Objective: To determine the cross-sectional association of dairy food group with quadriceps muscle strength among Framingham Offspring participants. We further examined if these associations vary by BMI levels considering the role of dairy foods in weight loss.

Methods: 2,548 men & women completed a food frequency questionnaire to determine dairy food groups (milk, yogurt, cheese, cream, total dairy in servings/week) and had isometric quadriceps strength measured by a hand-held dynamometer (kg, max of 2 trials, 1995-98). We used linear regression to calculate beta estimates and *P* values (for dairy food groups in servings/week) as well least squares adjusted means for dairy food groups (in categories) adjusting for age, sex, height, BMI, physical activity, menopause status, and total energy intake (kcal/d). These associations were further examined by BMI levels [$<$ 25 (normal), $\geqslant$25-30, $\geqslant$30 kg/m^2 (obese)].

Results: Mean age was 59.6$\pm$9.3y (range 26-85). Mean intakes (servings/week) were 5.7$\pm$6.2 (milk), 1.0$\pm$2.0 (yogurt), 2.7$\pm$3.1 (cheese); 4.0$\pm$6.2 (cream) and mean quadriceps strength was 20.1$\pm$6.4kg. No significant association was observed between number of servings and quadriceps muscle strength for any dairy food group (*P* range: 0.26-0.96). Upon stratification by BMI groups, cream intake was inversely associated with muscle strength in normal BMI group (β: -0.054$\pm$0.03, P=0.10) while milk intake was positively associated with muscle strength in obese group (β: -0.071$\pm$0.04, P=0.08). Though these associations were not statistically significant. No significant associations were observed for any other dairy food group (P range for BMI $<$25: 0.26-0.96, BMI $\geqslant$25-30: 0.22-0.93; BMI $\geqslant$30 kg/m^2: 0.32-0.90). Similar non-significant associations were observed when dairy food groups were analyzed in categories.

Conclusions: Dairy food intake may not be associated with quadriceps strength in this cohort of adult men and women. Possible reasons for null associations may include insufficient power or other factors in the pathway may contribute more to the muscle stength.

SA0009

Genetic variants in *CAPN3* and *ACVR2B* are associated with lean body mass in postmenopausal women. Yann Klimentidis*[1], Patricia Thompson[2], Walter Klimecki[3], Chengcheng Hu[1], Guanglin Wu[4], Jennifer Bea[5], J. Skye Nicholas[6], CHARGE Consortium Musculoskeletal Working Group[7], David Allison[8], Zhao Chen[9]. [1]University of Arizona Mel & Enid Zuckerman College of Public Health Epidemiology & Biostatistics, USA, [2]University of Arizona Cellular & Molecular Medicine, USA, [3]University of Arizona Pharmacology & Toxicology, USA, [4]University of Arizona, USA, [5]University of Arizona College of Medicine, USA, [6]University of Arizona Mel & Enid Zuckerman College of Public Health, USA, [7]USA, [8]University of Alabama at Birmingham, USA, [9]University of Arizona College of Public Health, USA

Background: Loss of lean body mass is a major cause of disability and diminished quality of life. Twin and family studies have demonstrated that lean body mass is a heritable trait. However, relatively few specific genetic factors have been identified as potentially influencing this trait.

Methods: In this study, we selected 1,493 single-nucleotide polymorphisms (SNPs) in 155 candidate genes and examined their association with lean body mass in a sample of 2,406 non-Hispanic and Hispanic white postmenopausal women from the Women's Health Initiative (WHI) Observational Study. Lean body mass was assessed using dual energy x-ray absorptiometry.

Results: We identified 43 SNPs with evidence for a significant association (consistently by subgroup and by anatomical site for $p<0.05$) to lean mass in the WHI cohort. To assess the reproducibility of our findings, we replicated our findings using data from the CHARGE Consortium Musculoskeletal Working Group that performed a genome wide association study of lean mass in twenty cohorts. Considering the results from both the discovery and replication stages, genetic variation in the calpain 3 (*CAPN3)* at SNP rs12439003 and the activin A receptor, type IIB (*ACVR2B) at* SNP rs2276541 were significantly associated with lean body mass ($p<1 \times 10^{-4}$). Calpain 3 is a muscle-specific member of the family for which mutations have previously been associated with a form of muscular dystrophy. ACVR2B is known to be involved in the regulation of myostatin signaling and has previously been identified in a candidate gene study as a determinant of skeletal muscle mass in men but not women.

Conclusion: Our findings support a previously proposed role of ACVR2B allelic variation as a determinant of muscle mass and extend prior findings in men to women. To our knowledge, this is the first observation for a role of allelic variation in CAPN3 as a determinant of lean body mass. Additional large-scale studies will be needed to confirm our findings, including analyses to assess their association in different populations.

Low protein intake is one of the correctable risk factors of sarcopenia in Korean men(KNHANES IV, 2008-2009). JO EUN KIM*[1], Kwang Joon Kim[2], Sihoon Lee[3], Yumie Rhee[4], Sung-Kil Lim[5]. [1]Yonsei University Health System, South Korea, [2]Severance Hospital, South Korea, [3]Gachon University School of Medicine, Rok, [4]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea, [5]Yonsei University College of Medicine, South Korea

Sarcopenia is a syndrome characterized by the progressive loss of skeletal muscle mass and strengths and associated with increased risk of falls and fractures, loss of independence and increased risk of death. However, there are few studies about curable or non curable identification of the country specific risk factors for sarcopenia. The aim of this study is to determine the correctable risk factors for sarcopenia in Korean elderly.

We analyzed 940 men and 1,324 women aged 65 years and older who completed the analysis of body composition using a dual energy X-ray absoprtiometry (DXA) in Fourth Korean National Health and Nutrition Examination Surveys IV (2008-2009). Sarcopenia was defined as the apendicular muscle mass divided by height square of less than one standard deviation below the sex-specific normal mean for the young reference group.

In univariate analysis, age, BMI, HOMA-IR, limitation of day-to-day activities, regular exercise, frequency of high risk drinking, family income, femur neck BMD, total hip BMD, lumbar spine BMD, total energy intake and protein intake were associated with sarcopenia in men (*p* value$<$0.05, respectively), and age, BMI, limitation of day-to-day activities, regular exercise, occupation, total hip BMD and total energy intake were associated with sarcopenia in women (*p* value$<$0.05, respectively). In multiple logistic regression analysis of subgroup, sarcopenia was strongly associated with osteoporosis of femur neck (OR = 9.45, 95% CI = 1.26-70.60) and negatively associated with highest quartile of protein intake (OR = 0.003, 95% CI = 0.00004-0.32) in men.

In conclusion, osteoporosis of femur neck and low protein intake are independent risk factors for low muscle mass in Korean. Correction of common etiology related to sarcopenia and osteoporosis with encouraging sufficient protein intake might be one of good approaches to prevent sarcopenia in Korean elderly men.

Sarcopenia and health-related quality of life over five years in community-dwelling older adults. David Scott*[1], Kerrie Sanders[2], Laura Laslett[3], Alan Hayes[4], Peter Ebeling[1], Graeme Jones[5]. [1]The University of Melbourne, Australia, [2]NorthWest Academic Centre, The University of Melbourne, Western Health, Australia, [3]Menzies Research Institute, University of Tasmania, Australia, [4]Institute of Sport, Exercise & Active Living, College of Health & Biomedicine, Victoria University, Australia, [5]Menzies Research Institute, Australia

Purpose: Sarcopenia may be diagnosed according to operational definitions based on low muscle mass or function. It is unclear whether differing associations exist for sarcopenia with health-related quality of life (HRQOL) according to the definition applied. The aim of this study was to examine effects of low muscle mass and strength on HRQOL over five years in community-dwelling older adults.

Methods: 1028 community-dwelling volunteers (62.9$\pm$7.5 [mean$\pm$SD] years; 50% female) completed baseline assessments and 832 and 731 participants completed follow-up assessments 2.6$\pm$0.4 and 5.1$\pm$0.5 years later. The validated Assessment of Quality of Life (AQoL-4D) was completed at all time-points and health utility scores were calculated on a scale where 0 = death and 1 = full health. Quality-adjusted life years (QALYs) were calculated as mean utility scores multiplied by time between each measurement. Low muscle mass and strength at baseline were categorised according to the lowest sex-specific tertiles of height-adjusted lean mass (assessed by dual-energy X-ray absorptiometry) and lower-limb strength (assessed by dynamometer). Linear mixed model regression analyses adjusting for age, sex and comorbidity examined associations of sarcopenia at baseline with HRQOL over five years.

Results: Utility scores were significantly poorer for sarcopenic compared with non-sarcopenic participants at baseline, according to both muscle mass (median [Interquartile Range] 0.79 [0.69, 0.89] vs 0.82 [0.71, 0.91]; $P = 0.026$) and strength (0.71 [0.58, 0.84] vs 0.79 [0.72, 0.91]; $P < 0.001$) definitions. Non-sarcopenic participants according to muscle strength accumulated more QALYs over five years than sarcopenic individuals (4.03 [3.60, 4.58] vs 3.62 [3.09, 4.23]; $P < 0.001$), and this difference was significant after adjustment for age, but no significant differences were observed according to muscle mass. Similarly, sarcopenia according to muscle strength was a significant independent predictor of reduced utility after 2.6 years (β [95% CI] -0.05 [-0.07, -0.04]) and 5.1 years -0.05 [-0.07, -0.02]), but no associations were observed for sarcopenia according to muscle mass.

Conclusions: Low muscle strength, but not low muscle mass, is associated with a biologically meaningful reduction in HRQOL over five years in community-dwelling older adults. These findings suggest that clinical sarcopenia assessments and interventions should preferentially target muscle strength rather than mass alone.

The Frequency of Hypothyroidism in Older Patients Presenting with Acute Thoracic and Lumbar Spine Fractures. Alison Dittmer*[1], Osa Emohare[1], David Wright[2], Charles Ledonio[1], Robert Morgan[1], David Polly[1], Julie Switzer[3]. [1]University of Minnesota, USA, [2]Regions Hospital, USA, [3]University of Minnesota Physicians, USA

Introduction: Thyroid function is intertwined with bone metabolism, and both hyperthyroidism and hypothyroidism can increase the risk of fracture. The most recent study evaluating baseline levels in patients age 65 and over found 15% had subclinical and 1.6% had overt hypothyroidism. One of the characteristic spine features in older patients can be the presence of compression fractures at levels of significant axial loading; axial loading of impaired bone can predispose to fractures. This study aims to assess both the frequency of concomitant hypothyroidism in patients with thoracic and lumbar spine fractures, and the impact of advancing age on this specific complication.

Methods: Following Institutional Review Board approval, patients who presented to our facility with acute fractures of the thoracic and lumbar spine were reviewed and stratified by age (younger than 65 vs. 65 and older). Patients presenting with spine injuries that did not include an acute fracture were excluded. Electronic medical records were reviewed for clinical evidence of hypothyroidism and for previous diagnosis and treatment with levothyroxine.

Results: A total of 169 patients were included in this study. Eighty-three were younger than 65 with a mean age of 41.7 (range 18-64), and 86 were 65 or older with a mean age of 78.6 (range 65-96). In the younger cohort, a minority of 24 patients (29%) were female; this increased to a majority of 52 (60%) in the older cohort. In those $<$ 65, 2 patients (2%) were either hypothyroid or being treated for hypothyroidism; in patients $\geqslant$ 65, this increased to 22 (26%) ($p<0.001$). A further comparison was performed between the hypothyroidism rate in our older cohort of fracture patients with historical data outlining the rate in US patients over 65 ($p=0.006$).

Discussion: These results showed a tenfold difference in the proportion of hypothyroid patients when a comparison was made between those under age 65 and those age 65 and over. The magnitude of this difference suggests that impaired thyroid function critically impacts the maintenance of appropriate bone function, especially in older patients. A further comparison with US population level data showed a significantly higher incidence for both subclinical and overt hypothyroidism in our fracture cohort. This study indicates that hypothyroidism is significantly associated with agerelated impairment in bone quality and thus impacts the management of fracture risk in older patients.

Atsttrin Primer, an Engineering Protein Derived from Progranulin Growth Factor, Binds to TNF-α Receptors and is Therapeutic Against Inflammatory Arthritis. Qingyun Tian*[1], Yunpeng Liu[2], Chuanju Liu[2]. [1]NYU Hospital for Joint Diseases, USA, [2]New York University, USA

Progranulin (PGRN) is a multifunctional growth factor which is composed of seven-and-a-half repeats of a cysteine-rich motif in the order P-G-F-B-A-C-D-E. We previously reported that PGRN directly bound to TNF-α receptors (TNFR), and inhibited TNF-α activity (Tang, W, et al, Science. 2011). Atsttrin, an engineered protein composed of three PGRN fragments (1/2F-1/2A-1/2C), exhibited selective TNFR binding, and potently prevented inflammation in multiple arthritis mouse models (Tang, W, et al, Science. 2011). It is well established that TNF family ligands bind to receptors in a heterohexameric 3:3 complex. We created a novel engineering protein, Atsttrin primer, which comprised the same fragments as Atsttrin but in a different sequence (1/2A-1/2C-1/2F). The purpose of this study is to determine (1) whether the three fragments of Atsttrin (i.e. 1/2A, 1/2C and 1/2F) act independently for interacting with TNFR; and if so, (2) whether Atsttrin primer is able to block the binding of TNF-α to TNFR, and has therapeutic effect in inflammatory arthritis, as does Atsttrin. Molecular mechanistic studies through Yeast-two hybrid screening and Solid-phase binding assay revealed that Atsttrin primer had stronger binding affinity to TNFR compared with Atsttrin, and effectively inhibited TNF-α from binding to TNFRs. To define the role of Atsttrin primer in inflammatory arthritis, we induced collagen-induced-arthritis (CIA) model in DBA-1 mice. Clinical arthritis score showed that Atsttrin primer treatment delayed CIA development and ameliorated arthritis severity. Furthermore, micro-CT showed that Atsttrin primer protected against bone erosion in CIA model. In addition, Safranin O staining showed that Atsttrin primer protected loss of cartilage matrix. Besides, we used spontaneous inflammatory arthritis model in TNF-α transgenic (TNF-Tg) mice, and treatment of Atsttrin primer significantly attenuated arthritis severity in this model. Taken together, these data indicate that as a novel engineering protein derived from PGRN, Atsttrin primer has high affinity to bind TNFR and antagonize TNF-α action, and plays a protective role in murine inflammatory arthritis models. This study not only testified that the three fragments which comprise Atsttrin and Atsttrin primer function independently for binding to TNFR and antagonizing TNF-α action, but may also provide us with additional interventions for treating inflammatory musculoskeletal diseasess clinically in the future.

Bone Mass and Cartilage Traits among Asymptomatic Postmenopausal Women and those with Mild Knee Osteoarthritis. Juhani Multanen*[1], Miika Nieminen[2], Arja Häkkinen[3], Urho Kujala[4], Hannu Kautiainen[5], Eveliina Lammentausta[6], Ilkka Kiviranta[7], Ari Heinonen[4]. [1]University of Jyväskylä, Finland, [2]Department of Diagnostic Radiology, Oulu University Hospital & Department of Radiology, University of Oulu, Finland, [3]Department of Health Sciences, University of Jyväskylä, & Department of Physical Medicine & Rehabilitation, Central Finland Central Hospital, Finland, [4]Department of Health Sciences, University of Jyväskylä, Finland, [5]Unit of Family Practice, Central Finland Central Hospital, & Unit of Primary Health Care, Kuopio University Hospital, Finland, [6]Department of Diagnostic Radiology, Oulu University Hospital, Finland, [7]Department of Orthopaedics & Traumatology, University of Helsinki, & Helsinki University of Central Hospital, Finland

The purpose of this study was to determine the association of the degree of osteoarthritis (OA) to (i) femoral neck BMC and (ii) knee cartilage biochemical composition in a sample of asymptomatic postmenopausal women and those with mild knee OA.

78 postmenopausal women (mean age: 58 (SD 4) yrs, height: 163 (6) cm, weight: 71 (11) kg) with early knee OA were examined. Women with Kellgren–Lawrence (K/L) radiographic grading of knee OA 1 (n=25) and 2 (n=53) were included for a related intervention study (ISRCTN58314639). In addition, age adjusted convenience sample of 12 radiographically confirmed asymptomatic voluntary women (mean age: 58 (SD 3) yrs, height: 161 (6) cm, weight: 67 (11) kg) were included. The femoral neck BMC was measured by DXA from the higher K/L grade knee side. In asymptomatic subjects the average BMC value of both femoral neck sites was calculated for the analysis. Biochemical composition of cartilage was evaluated using delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) sensitive to cartilage glycosaminoglycan (GAG) content. Perceived knee pain, stiffness, and self-rated physical functioning were assessed with the Western Ontario and McMaster Universities Arthritis Index (WOMAC). As risk factors of falling maximal isometric knee extension and flexion forces were measured with a dynamometer. The statistical significance for linearity between K/L grades was calculated by using linear regression analysis.

The results are presented in Table 1. In femoral neck there was a significant linearity showing that BMC adjusted for age, weight and height increased with higher OA grades of the knee joint. There were no linear relationships in knee cartilage indices at any anatomical sites, or in muscle force according the K/L grades. In WOMAC subscales there were linear trends showing that the higher the OA grade was, the more the subjects experienced knee pain, stiffness and physical disability.

Our bone results show that there is an inverse relationship between BMC and mild knee OA. However, the anomalous findings of dGEMRIC indices at different radiographic OA stages suggest that a more complex pattern of GAG behavior may occur at early stages of disease.

Table 1. Bone and cartilage traits and clinical outcomes according the Kellgren-Lawrence (K/L) grades.

	K/L 0 (n=12)	K/L 1 (n=25)	K/L 2 (n=53)	P for linearity

Deficiency of epidermal growth factor receptor (EGFR) signaling enhances cartilage destruction in mouse experimental osteoarthritis. Xianrong Zhang[1], Ji Zhu[1], Yumei Li[2], Abhishek Chandra[3], Frank Beier[4], Motomi Enomoto-Iwamoto[5], Ling Qin*[3]. [1]University of Pennsylvania, School of Medicine, USA, [2]Shanghai Municipal Hospital of Traditional Chinese Medicine, Shanghai University of Traditional Chinese Medicine, China, [3]University of Pennsylvania, USA, [4]University of Western Ontario, Canada, [5]Children's Hospital of Philadelphia, USA

Osteoarthritis (OA) is a progressive joint degenerative disease characterized by destruction of articular cartilage. We have previously demonstrated a critical role of EGFR signaling in growth plate development during endochondral ossification. However, its role in the pathogenesis of OA is largely unknown. In this study, we induced experimental OA in two mouse models with deficient EGFR activity at 12 weeks of age by destabilization of the medial meniscus (DMM) of the right knees. In the first model, wild type 129/SvEv (n=17) received gefitinib (100 mg/kg/dose) every other day following DMM to specifically inhibit EGFR activity. The second model uses a genetically modified mice with a dominant-negative mutant of EGFR (Wa5/+, n=19). Twelve weeks post surgery, knee joints were isolated for histological analysis. Scoring of cartilage destruction by Mankin's method indicated that both OARSI scores for medial tibial plateau and medial femoral condyle were significantly increased in gefitinib-treated mice and Wa5/+ mice compared to their respective controls, indicating that decreased EGFR activity leads to more severe cartilage destruction after DMM. TUNEL assay revealed that chondrocyte apoptosis increased by more than 60% in the articular cartilage of gefitinib-treated mice and Wa5/+ mice, suggesting that EGFR signaling protects chondrocytes from destabilization-induced apoptosis. Furthermore, immunohistochemistry showed that aggrecan degradation products, along with their cleavage enzymes, MMP13 and Adamts5, were strongly elevated in the articular cartilage of EGFR-deficient mice after DMM. Interestingly, while Adamts5 amount was similarly increased in the sham-operated left knees of EGFR-deficient mice, MMP13 amount was significantly decreased in these knees, which is consistent with our previous report that EGFR signaling stimulates MMP13 expression in primary chondrocytes from neonatal animals. Further studies revealed that the amount of HIF-2a, a transcription factor for MMP13 in chondrocytes, was also stimulated in the cartilage of EGFR-deficient mice after DMM. Activation of EGFR by TGFa in primary chondrocytes inhibited the expression of Adamts5 and HIF-2a. Taken together, our studies demonstrate that EGFR signaling plays a significant role in OA development by stimulating chondrocyte survival and preventing articular cartilage degradation and our data also implicate this signaling pathway as a potential therapeutic target for OA treatment.

Femoral Neck Structural Traits among Asymptomatic Postmenopausal Women and Those with Mild Knee Osteoarthritis. Ari Heinonen*[1], Juhani Multanen[2], Miika Nieminen[3], Arja Häkkinen[4], Urho Kujala[1], Hannu Kautiainen[5], Eveliina Lammentausta[6], Ilkka Kiviranta[7]. [1]Department of Health Sciences, University of Jyväskylä, Finland, [2]University of Jyväskylä, Finland, [3]Department of Diagnostic Radiology, Oulu University Hospital & Department of Radiology, University of Oulu, Finland, [4]Department of Health Sciences, University of Jyväskylä, & Department of Physical Medicine & Rehabilitation, Central Finland Central Hospital, Finland, [5]Unit of Family Practice, Central Finland Central Hospital & Unit of Primary Health Care, Kuopio University Hospital, Finland, [6]Department of Diagnostic Radiology, Oulu University Hospital, Finland, [7]Department of Orthopaedics & Traumatology, University of Helsinki, & Helsinki University Central Hospital, Finland

Many studies have found increased BMD in patients with osteoarthritis (OA). However there are sparse information of the relationship between bone structural traits and OA. The purpose of this study was to examine the relationship between radiographic knee OA and femoral neck structural traits in a sample of asymptomatic postmenopausal women and those with mild knee OA.

78 postmenopausal voluntary women (mean age: 58 (SD 4) yrs, height: 163 (6) cm, weight: 71 (11) kg) with early knee OA were recruited via newspaper advertisement. Women with Kellgren–Lawrence (K/L) radiographic grading of knee OA 1 (n=25) and 2 (n=53) were included for a related intervention study (ISRCTN58314639). In addition, age adjusted convenience sample of 12 radiographically confirmed asymptomatic women (mean age: 58 (SD 3) yrs, height: 161 (6) cm, weight: 67 (11) kg) were included. Proximal femur was scanned with DXA at the narrowest femoral neck section from the higher K/L grade knee side in the subjects with mild knee OA. Femoral neck cross-sectional area (CSA, [mm^2], the surface area of bone in the cross-section after excluding all trabecular and soft tissue space) the section modulus (Z, [mm^3], an index of bending strength), and subperiosteal width (W, [mm]) were calculated with advanced hip structural analysis (AHA). In asymptomatic subjects the average bone traits values of both femoral neck sites was calculated for the analysis. Perceived knee pain, stiffness, and self-rated physical functioning were assessed with the Western Ontario and McMaster Universities Arthritis Index (WOMAC). The statistical significance for linearity between K/L grades (0-2) was calculated by using linear regression analysis.

The results are presented in Table 1. In femoral neck there was a significant linear association showing that bone structural traits adjusted for age, weight and height increased significantly with higher OA grades of the knee joint. Also, in WOMAC subscales there were significant linear trend showing that the higher the OA grade was, the more the subjects experienced knee pain, stiffness and physical disability. Our results show that there was an inverse relationship between femoral structural traits and mild radiographic knee OA.

Table 1. Bone structural traits and clinical outcomes according the Kellgren-Lawrence (K/L) grades.

	K/L 0 (n=12)	K/L 1 (n=25)	K/L 2 (n=53)	P for linearity
Bone structure				
Section modulus (Z), mm^3	543 (98)	611 (170)	628 (101)	0.033
Cross sectional area (CSA), mm^2	135 (22)	142 (28)	150 (19)	0.019

NELL-1 Protects Articular Cartilage from the Effects of IL-1β Induced Arthritis. Jie Jiang*[1], Felipe Ituarte[1], Dahae Shim[1], Varsha Gupta[1], Dang Tran[1], Frank Petrigliano[1], Benjamin Bengs[2], Kang Ting[1], Chia Soo[1]. [1]University of California, Los Angeles, USA, [2]UCLA, USA

Introduction: Arthritis is the leading cause of disability in the United States. Existing clinical options are limited to either symptomatic relief or total joint replacement. Both of these options have considerable limitations and have thus prompted significant interest in biological agents which may serve as treatment for arthritis. NELL-1 is a potent, stage-specific factor that enhances anabolic activity while inhibiting catabolic activity in articular cartilage. Nell-1 is normally expressed in articular cartilage, and its loss results in abnormal cartilage development. We have recently demonstrated the utility of NELL-1 protein for cartilage regeneration in both *in vitro* and *in vivo* models. The purpose of this study was to evaluate the therapeutic benefit of NELL-1 in the treatment of arthritic cartilage. We *hypothesized* that NELL-1 would reduce the inflammatory and catabolic response of IL-1β stimulation in articular chondrocytes.

Methods: To examine the beneficial effect of NELL-1, we used a well-established IL-1β induced arthritis model. Specifically, chondrocytes (ATDC5 and primary rabbit articular chondrocytes) were grown to confluence in 24 well plates. Prior to treatment, the cells were serum starved for 24 hours. Cells were then treated with NELL-1 for 2 hours prior to the addition of IL-1β. After 24 hours, cells were harvested and the effects of NELL-1 were examined using qPCR and immunohistochemistry.

Results: IL-1β treatment significantly increased inflammation and catabolic activity of both ATDC5 and articular chondrocytes. The addition of NELL-1 diminished the inflammatory effect of IL-1β stimulation. Specifically, in ATDC5 cells, NELL-1 treatment down-regulated inflammation (IL-6) expression after IL-1β stimulation while it had no effect in catabolic gene expression (Mmp13, Adamts4). In primary rabbit articular chondrocytes, NELL-1 significantly down regulated both IL-6 and catabolic gene expression. Additionally, NELL-1 was also able to up-regulate anabolic gene expression in articular chondrocytes (Col2a1, Agg).

Conclusion: Our data shows that NELL-1 holds potential for the treatment of arthritis. In this study, NELL-1 down-regulated both inflammation and catabolic genes, and up-regulated anabolic activity in articular chondrocytes. Future studies will focus on the effects of NELL-1 using articular cartilage explants and *in vivo* effects of NELL-1 in arthritic animal models.

Raman spectroscopy reveals evidence for early bone changes in osteoarthritis. Jemma Kerns*[1], Panagiotis Gikas[2], Kevin Buckley[3], Helen Birch[4], Ian McCarthy[4], Jonathan Miles[5], Tim Briggs[5], Richard Keen[5], Anthony Parker[3], Pavel Matousek[3], Allen Goodship[4]. [1]UCL, United Kingdom, [2]UCL, Institute of Orthopaedics, United Kingdom, [3]Central Laser Facility, STFC Rutherford Appleton Laboratory, United Kingdom, [4]UCL Institute of Orthopaedics & Musculoskeletal Science, Royal National Orthopaedic Hospital, United Kingdom, [5]Royal National Orthopaedic Hospital, United Kingdom

Osteoarthritis (OA) is a common, debilitating disease of joints involving degeneration of cartilage and bone. There are two competing theories for bone as the primary site for initiation of osteoarthritis. Firstly, increased load on the joint leads to increased subchondral bone stiffness1. Secondly, composition of the subchondral bone changing towards homotrimeric collagen2.

The aim of the study is to explore the hypothesis: there are chemical differences in the bone matrix of OA subchondral bone compared to matched individuals unaffected by OA. Samples were acquired (with ethical approval) from human tibial plateaus with established medial compartment osteoarthritis (n=10), non-OA from amputees (n=5) and non-OA aged-matched cadaveric tissue (n=5). Subchondral bone samples were analysed with Raman spectroscopy (830nm excitation wavelength, Renishaw, UK)3,4, peripheral quantitative computed tomography (pQCT; for bone mineral density) and chemical analysis (collagen alpha chain ratios). Mineralisation ratios were calculated from spectra and multivariate analysis performed to assess variance across the spectral range (750–1800 cm-1)5.

Results showed that medial subchondral bone of the OA samples had a greater vBMD (p=0.05) and was thicker than the lateral side. The non-OA specimens had the same thickness on both sides of the tibial plateau with some differences in density. The Raman results showed no spectral differences between medial and lateral areas of the plateau in OA or in the non-OA samples (Figure 1). However, regardless of compartment, there were significant differences in Raman spectra between the OA and non-OA samples (p=0.02), and differences in type I collagen chemistry with medial OA samples exhibiting higher than normal levels of homotrimeric collagen.

These results support the theory that there is a biochemical difference between OA and non-OA subchondral bone. Future efforts will assess Raman spectroscopy for both characterising and detecting osteoarthritis during its early subclinical phase.

The results suggest that Raman spectroscopy could be further developed as a screening tool for early detection of joint degeneration based on detecting molecular modifications in the subchondral bone.

Subchondral Bone Turnover and Osteophyte Formation Are Key aspects in the Progression of Osteoarthritis (OA) and May Be Assessed and Predicted by α-CTX. Morten Karsdal*[1], Janet Huebner[2], Virginia Kraus[2], Diana Leeming[3], R Edward Coleman[2], Gary McDaniel[2], Kim Huffman[2], Anne-Christine Bay-Jensen[4], Kim Henriksen[1]. [1]Nordic Bioscience A/S, Denmark, [2]Department of Medicine, Duke University, USA, [3]Nordic Bioscience & University of Copenhagen, Denmark, [4]Nordic Bioscience, Denmark

Osteoarthritis (OA) is the most common form of arthritic disease. It is characterized by pathological changes in both bone and cartilage turnover as well as structure in which subchondral bone remodeling is speculated to be both an initiator and driver of OA.

The aim of the current study was to evaluate a biomarker of high localized bone resorption, a-CTX, previously used for bone metastasis. OA patients were characterized by; radiographic knee OA, severity, progression and localized knee bone turnover as assessed by bone scintigraphy, a dynamic and sensitive indicator of symptomatic knee OA.

Methods: A total of 149 participants (111 women, 38 men) were included who met ACR criteria for symptomatic OA and had the presence of Kellgren Lawrence (K/L) grade 1-4 radiographic OA in at least one knee. Late-phase bone scan images of both knees were obtained 2 hours after administration of ^{99m}Tc-MDP. The intensity of uptake was scored semi-quantitatively and summed for each joint site. Radiographic knee OA severity, based on the summed scoring of osteophytes (OST) and joint space narrowing (JSN) was assessed using the standardized OARSI radiographic atlas. Progression status was determined by calculating the sum of the change score in either JSN or OST between baseline and the 3-year follow-up assessment. The concentrations of urinary αCTX and CTX-II were determined by ELISA and normalized to creatinine concentration.

Results: a-CTX was related to OST formation independent of the effects of age, gender, BMI, and HRT (p=0.009). α-CTX did not correlate with severity of knee OA based on OST and JSN, but did correlate with bone turnover assessed by intensity of ^{99m}Tc-MDP uptake in the medial knee compartment. Concentrations of urinary CTX-II were strongly associated with knee OA severity based on osteophyte, intensity of total knee ^{99m}Tc-MDP uptake, and joint space narrowing.

Discussion: αCTX was associated with subchondral bone turnover, and osteophyte formation, both central features of the pathogenesis of OA. CTX-II was correlated to JSN, and burden of disease as previously reported. The significant and strong association of αCTX to bone turnover in the subchondral region suggests that this marker may be a non-invasive surrogate for active bone turnover in knee OA. Such markers may assist in the identification patients whom may benefit from strong anti-resorptives which inhibit bone and subchondral bone turnover.

α5 Integrin Deficiency Attenuates Osteoarthritic Changes in Mouse Knee Joints. Maria Elena candela*[1], Leslie Cantley[1], Motomi Enomoto-Iwamoto[1], Arjan van der Flier[2], Richard O. Hynes[2]. [1]Children's Hospital of Philadelphia, USA, [2]Howard Hughes Medical Institute, USA

α5 integrin is a major fibronectin receptor. Previous studies have demonstrated that α5 integrin is involved in regulation of synovial joint development and chondrocyte survival and matrix degradation in articular cartilage. Expression of α5 integrin was high in the superficial layer and down-regulated in the deeper zones of articular cartilage. It remains unclear whether control of α5 integrin expression is important for articular cartilage development and whether α5 integrin mediates protective or harmful actions in articular chondrocytes for maintenance of articular cartilage. To ask these questions, we generated compound mice (GDF5Cre;α5fl/-) lacking α5 integrin expression specifically in synovial joints.

The GDF5Cre;α5fl/-mice, α5 conditional knock out (α5 CKO), lacked alpha5 expression in articular cartilage and mice were born normally and had an overall appearance similar to the control (α5fl/fl or α5fl/-) mice. Histological analysis of the knee joints of the α5 CKO mice did not show significant abnormalities in the structure of synovial joints including articular cartilage. Next we compared the osteoarthritic changes between α5 CKO and the control mice after hemisectomy of the medial meniscus in the knee joint. Interestingly, we observed significantly milder histological osteoarthritic changes in the tibial medial plateaus of the α5 CKO mice than those in the control mice as determined by Mankin's score and OARSI score methods. The α5 CKO group contained a smaller number of TUNEL-positive cells as the control group, while the expression levels of MMP13 were similar between these two groups. The epiphyseal chondrocytes were isolated from the wild type mice and sorted by FACS to divide them into two groups that showed high levels of α5 integrin expression (high α5 group) and low or undetectable levels of α5 integrin expression (low α5 group). Chondrocytes in the low α5 group maintained polygonal cell morphology even at a low density in culture whereas chondrocytes in the high α5 group readily became fibroblastic and contained a much lower amount of highly sulfated proteoglycans than the low α5 group culture. These findings indicate that α5 integrin may not be essential for synovial joint development and articular cartilage organization, but participates in induction of cell apoptosis and osteoarthritic changes in articular cartilage and that down-regulation of α5 integrin could be important for stabilization of chondrocyte phenotype.

An Examination of the Dose Response of Bone Consolidation to Docosahexaenoic Acid (DHA) in Young Female Sprague-Dawley Rats. Marie Freundorfer*[1], Hope Weiler[2]. [1]McGill University, Canada, [2]McGill University, USA

Recent animal studies have shown that DHA helps maintain bone mineral density (BMD) during aging, however little is known of the effects of DHA on growing bone. Since optimizing bone mass accumulation during growth can help prevent osteoporosis later in life, there is value to examining the effects of DHA on the development of peak bone mass. The purpose of this study was to determine the effects of increasing doses of DHA on consolidation of bone in young female rats during and after sexual maturation. Sixty female Sprague-Dawley rats (7wk at baseline) were randomized into the control (AIN93-M with 6% fat) or 1 of 4 experimental diets (n=12/diet) fed over 10 wk. The experimental diets contained increasing doses of DHASCO (0.1%, 0.4%, 0.8% and 1.2% DHA as % total diet), mixed with soybean oil to provide 6% fat in all diet groups. Blood was collected (unfed-am-state) at baseline, mid-way and end of study to measure biomarkers. Bone mineral content (BMC), bone area (BA), areal BMD and volumetric BMD were measured at baseline, mid-way and endpoint using dual-energy x-ray absorptiometry (DXA) and microcomputed tomography (μCT). Groups were not different at baseline for weight, length, BMC or BMD. Weight, length, and calcium homeostasis were not altered by the diets. Preliminary results for DXA and μCT regional lumbar spine scans show a significant increase in aBMD for 0.1% and 0.4% DHA groups, and a significant increase in vBMD for the 0.4% and 1.2% DHA groups (Table 1). Whole femur regional scans aBMD and vBMD were not different among the groups (Table 1). Whole body scans showed a significant increase in aBMD for the 0.4% and 1.2% DHA groups ($p<0.05$), however no significant differences in vBMD between the diet groups (data not shown). Further research including blood biochemistry, higher resolution μCT scanning and biomechanical testing is planned to clarify these preliminary results.

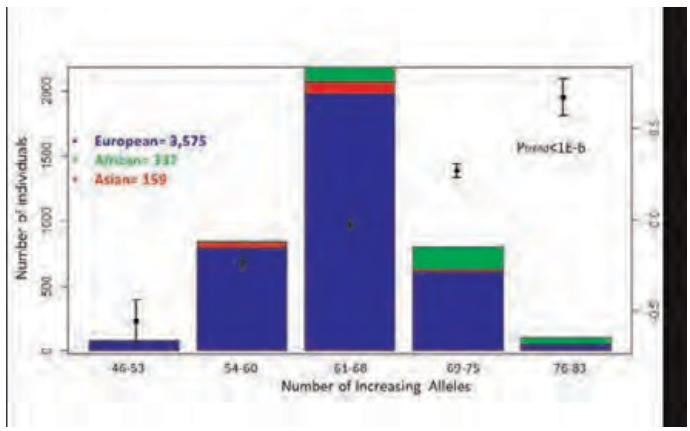
Bone Mineral Density Variation In Children Across Different Ethnic Backgrounds Is Partially Explained By Genetic Profiling. The Generation R Study. Carolina Medina-Gomez*[1], Denise H.M. Heppe[2], Karol Estrada[3], Ling Oei[4], Claudia J. Kruithof[2], Albert Hofman[5], Vincent V.W. Jaddoe[2], Andre Uitterlinden[6], Fernando Rivadeneira[4]. [1]Erasmus Medical Center, The Netherlands, [2]The Generation R Study Group, Erasmus Medical Center, Netherlands, [3]Analytic & Translational Genetics Unit, Massachusetts General Hospital, USA, [4]Erasmus University Medical Center, The Netherlands, [5]Department of Epidemiology, Erasmus Medical Center, Netherlands, [6]Rm Ee 575, Genetic Laboratory, The Netherlands

Aim: Ethnic differences in BMD variation are documented. To study genetically-determined differences in BMD in children across ethnicities, we compared total body BMD (TB-BMD) and examined the behavior of a genetic risk score (GRS), constructed from variants from 56 loci associated with BMD in adults, predicting total body BMD (TB-BMD) across children from multiple ethnic background.

Methods: We included 4,009 children from The Generation R study, a single center prospective birth cohort in Rotterdam, The Netherlands, with GWAS data and TB-BMD measured by DXA at a mean age of 6.2 years. The children come from a wide spectrum of ethnic origins including blends between continental groups. Clustering based on genetic data (using ADMIXTURE) was employed assigning children to one of three transcontinental ancestral groups: predominantly European (n=3,513), Asian (n=159) and African (n=337). Differences in TB-BMD were assessed by least-squares means using European population as reference and adjusting for age, sex, fat mass, lean mass and height. GRS consisted of the sum of BMD-increasing alleles (0,1,2) in each of the 63 genetic variants reported and analyzed across quintiles.

Results: As compared to Europeans (0.552 g/cm^2) age and sex corrected TB-BMD was higher in Africans (0.585 g/cm^2; P<1E-6) and lower in Asians (0.54 g/cm^2; P=0.002). Further adjustment for height, fat and lean mass resulted in children of both African (0.575 g/cm^2; P<1E-6) and Asian (0.559 g/cm^2;P=0.03) descent having higher BMD than Europeans (0.552 g/cm^2). Overall the GRS explained 5.2% of the variance (P<1E-6). As compared to children in the middle quintile (54% of the population; n=2,179), individuals in the highest quintile (2.6% of the population; n=106) had 0.69 SDs higher BMD (P<1E-6), while those in the lowest quintile (1.9% of the population; n=77) had 0.53 SDs (P=4E-6) lower BMD. Overrepresentation (65%) of the children of African descent was present in the two highest quintiles.

Conclusions: Ethnic differences in BMD are already evident at childhood. Apparent lower BMD in Asians is consequence of smaller skeletal frame size and adaptation to loading; correction for height, fat and lean mass results in relatively higher BMD in Asian children as compared to Europeans. Children of African descent have a higher frequency of BMD-increasing alleles. Ethnic differences in bone accrual are thus partially explained by allele frequency differences in variants from known BMD loci.



Combined effect of BMD-increasing alleles modelled in three ancestral groups

Does Insulin Initiate a Toxicity to the Bone Marrow Microenvironment Eliminating the Developmental Benefit of Bone Marrow Adipose Tissue?. Krista Casazza*[1], Lynae Hanks[2], Anna Newton[1], Stephenie Wallace[1]. [1]UAB, USA, [2]University of Alabama at Birmingham, USA

There is growing interest in understanding the physiology and function of adipose tissue within the bone marrow. Bone marrow adipose tissue (BMAT) is a metabolically distinct tissue from other peripheral fat depots, hypothesized to locally contribute to bone metabolism and hematopoiesis, and has been inversely associated with measures of bone strength and structure. Primarily in the long bones, BMAT replaces hematopoietic/osteogenic marrow at a rapid yet predictable and progressive rate during puberty, a well-established critical period for long-term bone health. Though a specific cue has not been elucidated, this conversion is thought to respond to hormonal trigger(s). Perturbed hormonal milieu as described in the obese state may accelerate normative conversion altering marrow composition properties, and may potentially provoke long-term consequences. The objective of this study was to evaluate the relationship between glucose and lipid metabolism and femoral BMAT in forty-six early pubertal girls ages seven to eleven years. Femoral BMAT was assessed by MRI, bone and fat mass by DXA and glucose, insulin and lipid profile by venipuncture while fasted. We observed a positive relationship between BMAT and body fat ($p=0.05$), bone mass ($p<0.001$) and fasting insulin ($p<0.05$). When the sample was stratified by adiposity using 30% body fat or BMI greater than 85th percentile as a cut-point, the relationship of BMAT with bone ($p<0.05$) and insulin ($p=0.06$) was only apparent in obese girls. Insulin, a known potent growth factor responsible for glucose handling commonly dysregulated in the obese state, may initiate toxicity within the bone marrow microenvironment eliminating the developmental benefit, provoking the pathogenesis attributed to BMAT in adulthood. While animal and human data demonstrate an inverse association between BMAT and measures of bone health, understanding the functional significance and role in skeletal maturation will be critical to better understanding pathophysiology of bone.

Implications of Mild vs Moderate Trauma Childhood Distal Forearm Fractures for Peak Bone Mass Acquisition: The Two Faces of Growth.
Joshua Farr*[1], Sundeep Khosla[2], L. Joseph Melton[1], Elizabeth Atkinson[1], Salman Kirmani[1], Louise McCready[1], Shreyasee Amin[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic College of Medicine, USA

Growth is the most opportune period to modify bone structure. We recently found that children who sustain a distal forearm fracture (DFF) due to mild, but not moderate, trauma have cortical thinning and deficits in bone microarchitecture at the radius and tibia. However, whether these skeletal deficits track into adulthood is unknown. Therefore, we used HRpQCT to examine cortical and trabecular bone parameters at the distal radius and tibia in 150 subjects (75 women; 75 men), age 20–40 yrs, who had a childhood (<18 yrs) DFF and 150 sex- and age-matched non-fracture controls. None used medications, or had diseases, affecting bone metabolism. We used the Landin classification (Acta Orthop Scand 202:1, 1983) to assign trauma levels, blind to the bone imaging results. None had a severe trauma DFF (e.g., traffic accident).

Adult women (Fig. A) and men (Fig. B) with a mild trauma (e.g., fall from standing height) DFF in childhood had significant deficits in cortical area (–10.2% and –9.2%, respectively; P<0.05) at the radius as compared to controls. Women with a mild trauma DFF in childhood also had significantly lower cortical volumetric BMD (vBMD, –1.7%; P=0.002), whereas men with a mild trauma DFF in childhood had significantly lower trabecular bone volume fraction (BV/TV, –9.0%; P=0.008) compared to controls. By contrast, adult women and men with a moderate trauma (e.g., sport-related collision) DFF in childhood both had higher radial cortical areas as compared to controls, although only the difference in men was statistically significant (+8.6%; P=0.041). Importantly, skeletal deficits in the mild trauma DFF cases were generalized, as these subjects tended to have similar changes at the tibia, as well as significantly lower DXA-derived areal BMD at the radius, lumbar spine, hip and total body regions as compared to their controls (all P<0.05).

In conclusion, a mild trauma DFF during childhood presages deficits in bone structure and density in adulthood. By contrast, as hypothesized by Parfitt ("The Two Faces of Growth: Benefits and Risks to Bone Integrity", Osteoporos Int 4:382, 1994), children who suffer a moderate trauma DFF may be paying the price of risk-taking behaviors (e.g., sports) in childhood that optimize cortical bone structure during growth. Therefore, children with a mild trauma DFF should be identified and targeted for lifestyle interventions that encourage achievement of their full skeletal genetic potential.

Influence of Age and Gender on Spine Bone Density and TBS Microarchitectural Texture Parameters in Infants.
Renaud Winzenrieth*[1], Catherine Cormier[2], Silvana DiGregorio[3], Luis Del Rio[4]. [1]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [2]AP-HP Groupe Hospitalier Cochin, France, [3]Cetir Grup Mèdic, Spain, [4]Cetir Centre Medical, Spain

Children bone knowledge is relatively sparse. This is especially true for infant and for bone microarchitecture data. We have investigated, in this study, the age-related modifications of spine microarchitectural texture, as assessed by TBS, on male and female infants during their two first years of life.

The study group was composed of 143 and 109 healthy female and male infants aged between 0 and 2 years. Height and weight Z-scores were normal for age (-0.61 and -0.65 for female; -0.62 and -0.77 for male) relative to The WHO Child Growth Standards. The areal BMD (aBMD) was assessed at spine L1-L4 using a prodigy densitometer (GE-LUNAR, USA). TBS was evaluated using TBS iNsight v2.0 (Medimaps, France). The LMS statistical method proposed by Cole and Green (Stat Med, 1992) was used to construct aBMD and TBS age-related curves for each gender using R software (v2.15.3).

Female and male infant shave the same mean age, height and weight Z-score and TBS (p>0.3) whereas female infants have higher aBMD than male (p=0.01). Before and after 12 months of age, TBS and aBMD correlations in both female and male infants were low (r^2<0.20).We have observed a first TBS decreasefrom birth to 12-15 months (for female and male infants respectively) followed by a TBS increasing without reaching the mean birth TBS value. In parallel, the aBMD always increases (see figure 1).

To date, our study is the first which has evaluated the modification of spine microarchitectural texture occurring in infants. Results obtained showed similar aBMD and TBS evolution shapes for both male and female infants. Surprisingly, TBS evolution exhibits a decreasing/increasing pattern. We can hypothesis that this pattern correspond to the infants bed-rest phase (no weight loads on the spine-> trabecular structure adaptation using minimum energy adaptation rule-> TBS decreasing) and the stand/walking phase (weight loads on spine->mechanical stress increasing -> trabecular structure positive adaptation -> TBS increasing). Further studies have to be conduct to confirm these first findings.

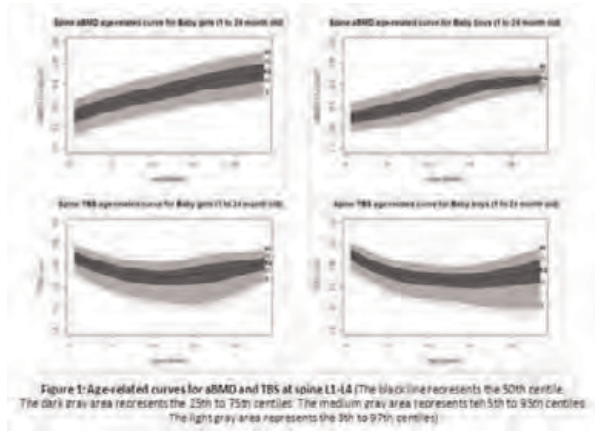

Figure 1

[1]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [2]Institute of Developmental Sciences, University of Southampton, United Kingdom, [3]Singapore Institute for Clinical Sciences, Singapore, [4]Liggins Institute, University of Auckland, & Singapore Institute for Clinical Sciences, Singapore, New Zealand, [5]MRC Lifecourse Epidemiology Unit, University of Southampton, & NIHR Southampton Biomedical Research Centre, University of Southampton & University Hospital Southampton NHS Foundation Trust, United Kingdom

We used a population-based mother-offspring cohort to investigate relationships between methylation status of the CDKN2A gene locus in umbilical cords at birth, and bone size, mineralisation and density measured by DXA in childhood.

Based on differentially methylated sites identified as having strong associations with offspring bone mass from a MeDIP-CHIP methylation array (Agilent) in 19 subjects, we used pyrosequencing to perform in-depth analysis of the methylation status of 9 CpGs within a region of CDKN2A in umbilical cords of 292 children assessed by DXA (Hologic Discovery) at 4 and 6 years old from the Southampton Women's Survey. Appropriate institutional ethics committee approval and participants' informed consent were obtained.

There was a wide variation in percentage methylation. After adjustment for age and sex, there were inverse associations between CDKN2A methylation at 5 of 9 CpG sites and bone measures in childhood (all p<0.05). At one of these sites, consistently strong inverse associations between percentage methylation and offspring whole body BA, BMC and BMD at both 4 and 6 years were observed. Thus BMC decreased by 1.0g at age 4 years and 1.8g at age 6 years (p=0.005 and 0.008 respectively) for each 1 percentage point increase in CpG methylation. Inclusion of percentage methylation at RXRA promoter sites, maternal parity, and maternal smoking, triceps skinfolds and physical activity in late pregnancy (all previously associated with offspring bone mass) in the models did not alter these relationships.

In this study, perinatal methylation status of CpG dinucleotides within the CDKN2A gene locus was inversely associated with bone size, mineral content and areal density in childhood. If replicated in other cohorts, these findings might suggest a specific role for CDKN2A in skeletal development and the potential for its use as a novel biomarker for later osteoporosis risk.

Soluble Corn Fiber Increases Calcium Absorption in Free Living Adolescent Girls. Claire Macdonald-Clarke*[1], Berdine Martin[1], Corrie Whisner[2], George McCabe[1], Linda McCabe[1], Kimberly Ziarko[1], Claire Murphy[1], Connie Weaver[3]. [1]Purdue University, USA, [2]Cornell University, USA, [3]Purdue University, Dept of Nutrition Science, USA

Prebiotics have the potential to improve calcium nutrition through increasing calcium absorption which can benefit bone health. Previously, we demonstrated efficacy of Soluble Corn Fiber (SCF) in adolescent boys and girls with a 12% increase in calcium absorption after consuming 12 g fiber via SCF for 21 days compared to a control period in a crossover design using a controlled feeding metabolic balance approach (Whisner *et al* 2012). The objectives of the current study were to evaluate the dose response of 0, 10 and 20 g fiber/d via SCF supplementation on calcium absorption and biochemical bone properties in free-living adolescents. Twenty six females aged 11-14 y with habitual calcium intakes ≤ 800 mg/d and BMI <90th percentile for age, were randomized into this 3-phase, double blind, crossover study. For 4 weeks participants consumed a daily muffin and beverage containing a total of 0, 10 or 20 g fiber from PROMITOR® SCF (Tate & Lyle) followed by a 3-day clinical visit and 3-week washout phase. During the clinical visit, participants consumed a controlled basal diet containing 800 mg/d calcium, 15 g/d fiber and adequate nutrients and calories using the Harris-Benedict equation. Fractional calcium absorption was measured using a dual stable isotope method from pooled urinary Ca excretion at 12, 24, 36, and 48 hours following the test meal. Isotope enrichment was measured by ICP-MS. To determine the effects of SCF on calcium absorption over time, a mixed model was used based on sequence, ID nested within sequence, and treatment, at each 12 hour time point. Calcium absorption increased significantly, with dose ($p=0.016$) and with time ($p<0.001$), consistent with lower gut absorption. In summary, fermentable, non-digestible oligosaccharide carbohydrate SCF, given in snack products, can increase calcium absorption in free-living adolescent females. Food supplementation with SCF is well tolerated and an effective method to increase calcium absorption and bone health in populations where calcium intake is low. This study was sponsored by Tate & Lyle Health & Nutrition Sciences.

The Relationship Between Intramuscular Fat and Cortical Bone Development from Age 11 to 19 Years. Natalie Glass*, Kathleen Janz, Elena Letuchy, James Torner, Trudy Burns, Julie Eichenberger Gilmore, Steven Levy. University of Iowa, USA

Purpose: Limited cross-sectional data suggest a relationship between intramuscular fat and cortical bone development. However, the direction of that relationship has varied among studies. The purpose of this study was to evaluate the longitudinal association between intramuscular fat and cortical bone development at the tibia throughout adolescence.

Methods: Iowa Bone Development Study participants who attended at least two measurement visits were included. Visits took place every 2 years from age 11 to 19 years. Cortical bone mineral density, mineral mass (BMC, mg) and area, periosteal and endosteal circumference, cortical thickness, strength-strain index (SSI, mm^3), muscle density (mg/cm^3) and muscle cross-sectional area were measured by peripheral quantitative computed tomography (Stratec XCT 2000/3000, Pforzheim, Germany) at the 66% site of the tibia. Muscle density was used to estimate intramuscular (IM) fat. Lower muscle density indicates greater IM fat. Anthropometric measurements were taken and maturity offset (years from peak height velocity) was estimated. The relationship between muscle density and cortical bone parameters was modeled using sex-specific multilevel regression models adjusted for age, limb length, muscle cross-sectional area and maturity status (pre/post peak height velocity).

Results: 249 girls and 243 boys attended at least two measurement visits. In multilevel linear regression models adjusted for covariates, muscle density was positively associated with cortical bone parameters but only reached statistical significance for BMC and SSI in girls (regression coefficient beta=15.3 ± 4.6 mm^3, $p=0.001$) and SSI in boys (beta=12.1 ± 4.9 mm^3, $p<0.05$). At age 13, this represented, for an individual with an average SSI, 3% greater SSI in girls and 2.3% greater SSI in boys in the 90th compared with the 10th percentile of muscle density. There was also a statistically significant interaction effect between muscle density and age ($p<0.001$) as well as maturity status ($p<0.01$) for BMC in girls.

Conclusions: Cortical bone strength generally increased as the amount of intramuscular fat within adjacent skeletal muscle decreased independent of muscle cross-sectional area and this relationship was sustained throughout adolescence. Because analyses controlled for differences in muscle size, these results suggest that greater fat content within muscle may not be beneficial to weight-bearing cortical bone during adolescence.

Tracking of Bone Mass from Age 8 to 15 Years and Factors Associated with Tracking Deviations. Elena Letuchy, Julie Eichenberger Gilmore*, Kathleen Janz, Trudy Burns, James Torner, Steven Levy. University of Iowa, USA

Purpose: The purpose of this research is to determine the effects of body composition (whole body lean mass [LM] and fat mass [FM]), physical activity and health (asthma, medication use and bone fractures) on consistently high and increasing, or consistently low and decreasing hip and spine bone profiles.

Methods: DXA scans were obtained (Hologic 2000 and Hologic 4500) for 200 girls and 189 boys at baseline (age 8) and again at age 15. Measurements included bone mineral content (BMC) and density (BMD) for hip and spine, LM and FM. Translational equations were applied to account for machine differences. Minutes of daily moderate to vigorous intensity physical activity (MVPA) was measured using accelerometry (ActiGraph). Gender-specific tracking of bone outcomes was determined by correlation of residuals from models adjusted for height, weight, and scan age. Further analysis concentrated on tracking (remaining in the upper [lower] tertile) or deviation from tracking (moving to a higher [lower] tertile) for participants with consistently high [low] or increasing [decreasing] BMC/BMD, respectively. Body composition and MVPA changes were investigated as determinants of the tracking deviations. Associations with asthma, corticosteroid use and bone fractures were also explored to investigate the interrelation of health status and BMC/BMD tracking. Gender-specific logistic regression modeling was conducted for all association analyses.

Results: Residuals for all four bone outcomes demonstrated high levels of tracking during adolescence; r=0.73-0.79 for girls and 0.68-0.74 for boys in correlation analysis. Larger increases in LM and consistently high physical activity levels over time were associated with consistently high or movement to a higher tertile of BMC/BMD in both girls and boys. For example, for hip BMC OR 1.4, 95% CI (1.3, 1.6) and 1.3, 95% CI (1.2, 1.4) per 1 kg of LM increase, respectively. Greater FM increase had the opposite effect. For girls, low or relatively decreasing spine BMC was associated with bone fracture. For boys, corticosteroid use was associated with low or a relative decrease in hip and spine BMC/BMD.

Conclusion: Greater lean mass [fat mass] increase is a strong determinant of high [low] or movement to higher [lower] BMC/BMD. Physical activity and other environmental factors are also associated with the tracking of bone measures.

Disruption of Shp2 in Osteoblasts Causes Skeletal Abnormality in Mice Resembling of Human Noonan Syndrome. Jun Zheng*[1], Jay Cao[2], Kehong Ding[1], Nianlan Yang[3], Thomas Clemens[4], Mark Hamrick[1], Carlos Isales[3], Xing-Ming Shi[1]. [1]Georgia Health Sciences University, USA, [2]USDA ARS, USA, [3]Georgia Regents University, USA, [4]Johns Hopkins University, USA

Noonan syndrome (NS), characterized by skeletal malformations such as kyphosis and scoliosis, is a relatively common autosomal dominant disorder occurring between 1 in 1,000 and 1 in 2,500 children worldwide. 50% of all cases of NS are caused by mutations in the PTPN11 gene. PTPN11 encodes Src homology-2 domain-containing tyrosine phosphatase 2 (Shp2), a protein expressed ubiquitously in mammalian tissues. Shp2 gene KO is embryonic lethal, the role of Shp2 in skeletal development is not clear. We generated conditional Shp2 KO mice using Ocn2.3-Cre and we show here, for the first time, that disruption of Shp2 in osteoblasts is sufficient to cause skeleton abnormalities in mice resembling that of human NS (Fig. 1). All Shp2 cKO mice develop kyphosis and scoliosis, and a rapid reduction of body weight (-17%, $p<0.05$), at about 2.5mo of age. This phenotype manifests at 3mo of age and becomes worse thereafter. u-CT analysis of 3-mo-old femurs showed that the BV/TV, Cort. Th and Tb. N are all decreased dramatically (-50%, -44% and -29%, respectively), but the Tb.Sp is increased significantly (+46%) in Shp2 KO mice. DXA analysis of 3-mo-old femurs showed that while the BMD is decreased (-8.0%, $p<0.01$), the BMC is increased significantly (+14%, $p<0.05$) in Shp2 KO mice due to the increase in femoral size (length +8%, $p<0.01$; width +37%, $p<0.001$). Histological studies show that at 3 months of age, the growth plate of the cKO mice is markedly enlarged (distal femur: +114%; L5 vertebrae: +190%; and T5/6: +296%). While the BrdU labeling experiment showed no difference in cell proliferation between cKO and WT mice, TUNEL assays revealed a remarkable increase of apoptosis in both cortical and trabecular bones (femur, lumbar and thoracic vertebrae) in cKO mice. In line with the increased apoptosis, in vitro cell culture studies showed a significantly decreased osteogenic differentiation capacity of primary bone marrow cells from Shp2 cKO mice. To gain insight into the underlying molecular mechanisms by which Shp2 in osteoblasts regulates skeletal development, we examined the signaling pathways controlled by Shp2 and found that the level of pERK and pSTAT3 are reduced significantly in Shp2 KO osteoblasts. Together, our results have demonstrated that disruption of Shp2 signaling in osteoblasts is sufficient to cause NS, suggesting that targeting Shp2 signaling in osteoblasts is a potential therapeutic approach for correcting the skeletal abnormalities of children with NS.

The Role of the Systemic Micro-Environment in DMD Bone Abnormalities. Nicholas Greco*[1], Johnny Huard[2], Hongshuai Li[2], Bing Wang[2], Ying Tang[2]. [1]University of Pittsburgh, USA, [2]Orthopaedic Surgery, USA

Introduction: Duchenne muscular dystrophy (DMD) is a genetic disorder causing skeletal muscle deterioration in affected children; however, there are also disturbances of osseous structure and function that have a significant impact on patient mobility and quality of life. In this study we determined whether providing a DMD animal model with a systemic milieu from a young, healthy animal through the technique of parabiosis could improve their osseous phenotype.

Methods: previous parabiotic method [1] was applied in a dystrophin/utrophin knockout (dKO) murine model of DMD [2]. In the first experiment, the parabiosis groups consisted of an old dKO-heterozygous mouse (dys-/-, utr-/+; age 12-14 mo) paired with a young mdx mouse (age 3-5 mo), while the control was a pair of old dKO-hetero mice. Bone quality was then evaluated via microCT (morphometric) and histomorphometic analysis after 5 months. In the second experiment, the groups consisted of a dKO-homozygote (dys-/-, utr-/-) mouse paired with a wild type mouse, while the control was a pair of dKO-homo mice. Two weeks after parabiosis, a tibial defect was created. The healing dynamics of the bone defect were evaluated via microCT and the content of bone marrow and hematopoietic stem cells were also compared between groups.

Results: After pairing with young mdx mice, Herovici staining and micro-CT analysis showed significantly less bone loss and greater trabeculae in the lumbar vertebrae and proximal tibia of the old dKO-hetero mice. Likewise, after pairing with wild type mice, there was a significantly increased rate of bone healing during the second and third weeks after the bone defect procedure in the dKO-homo mice (Figure 1). Furthermore, hematopoietic stem cell quantity was significantly increased with no significant difference in the bone marrow-derived stem cells in dKO-homo mice paired with wild type mice.

Discussion: Sharing of the vascular supply between an animal model with severe DMD pathology and one without disease burden as well as sharing between an aged DMD model with a young DMD model improved the osseous DMD phenotype. Furthermore, there was an increase in the hematopoietic stem cell population. This data implicates factors within the systemic milieu in the regulation of bone homeostasis, thus presenting a novel avenue to explore and improve osseous deficiencies in DMD patients.

A Randomized, Double-blind, Placebo-controlled Trial of Alendronate Treatment for Fibrous Dysplasia of Bone. Alison Boyce*[1], Marilyn Kelly[2], Beth Brillante[2], Harvey Kushner[3], Shlomo Wientroub[4], Mara Riminucci[5], Paolo Bianco[5], Pamela Robey[6], Michael Collins[7]. [1]Children's National Medical Center, USA, [2]Clinical Skeletal Diseases Branch, National Institute of Dental & Craniofacial Research, National Institutes of Health, USA, [3]BioMedical Computer Research Institute, USA, [4]Dana Children's Hospital, Israel, [5]University La Sapienza, Italy, [6]National Institute of Dental & Craniofacial Research, USA, [7]National Institutes of Health, USA

Fibrous dysplasia (FD) is a benign skeletal disease caused by somatic activating mutations of $G_s\alpha$. These mutations lead to formation of abnormal and mechanically unsound bone and fibrotic tissue. Clinical sequelae include deformity, fracture, and pain. Studies in bisphosphonates have shown improvement in bone pain and inconsistent effects on FD mineralization; however interpretation has been limited by a lack of controlled trials. Objective: To determine the efficacy of oral alendronate for treatment of FD. Methods: Forty subjects with FD (15 children, median age 10, range 6-16, and 23 adults, median age 40, range 20-57) were enrolled in a randomized, double-blind placebo-controlled trial of alendronate (1 subject in each group withdrew prior to treatment). The co-primary efficacy endpoints were the change from baseline in N-telopeptide and osteocalcin at 18 months. Secondary endpoints included effects on pain, and bone mineral density at FD and non-FD sites. Subjects received drug or placebo for 6 months, followed by 6 months off, 6 months on, and 6 months off. Dosing was stratified as follows: 40 mg/day for subjects >50 kg, 20 mg for 30-50 kg, and 10 mg for 20-30 kg. Results: Compared to placebo at baseline, at 18 months alendronate use was associated with a decrease in the resorption marker N-telopeptide (p=0.001), with no significant effect on the formation marker osteocalcin (p=0.7). Subjects in the alendronate group did not show significant changes in pain as compared to placebo. At FD sites there was no significant change in bone mineral density at affected femora or humeri. At non-FD sites there was a significant increase in bone mineral density (p=0.003). Three subjects in the placebo and three in the alendronate group sustained fractures during the study period. One alendronate-treated subject with an undisclosed history of reflux developed an esophageal stricture. Conclusions: Alendronate at four times the osteoporosis dose decreased bone resorption markers, but did not improve FD mineralization or bone pain. These data support findings from previous open-label studies which demonstrated a lack of effect of bisphosphonates on FD mineralization, and suggest that oral bisphosphonates may be ineffective for FD-related bone pain.

Exome Sequencing Reveals a Novel Nonsense Mutation in *MMP13* as a New Cause of Autosomal Recessive Metaphyseal Anadysplasia Type 1. David Weber*[1], Dong Li[1], Matthew Deardorff[1], Hakon Hakonarson[1], Michael Levine[2]. [1]The Children's Hospital of Philadelphia, University of Pennsylvania, USA, [2]Children's Hospital of Philadelphia, USA

Background: Metaphyseal anadsyplasia (MAD) is an uncommon chondrodysplasia characterized by early onset short stature, bowing of the legs, and abnormal growth plates. Because the metaphyseal dysplasia improves with age, the diagnosis of MAD is usually made retrospectively. MAD is caused by mutations in the genes encoding matrix metalloproteinase (MMP) 9 and 13. Type 1 MAD shows more severe skeletal defects and has been associated with dominant negative mutations, while the milder type 2 form is due to autosomal recessive (AR) missense mutations. Here we describe the molecular characterization of skeletal dysplasia in two brothers of Albanian descent who presented with marked short stature, metaphyseal dysplasia, and musculo-skeletal complaints. Heights of mother (-1.7 SD) and father (-1 SD) were below average; there was no history of consanguinity.

Methods: Peripheral blood mononuclear cell genomic DNA from the affected brothers was subjected to whole exome sequencing (WES) and identity by descent (IBD) analysis. The exome variant profile was considered under the assumption of an AR model based on family history. Variants with minor allele frequency>1%, found in our in-house database, or not present in the IBD regions were excluded. Validation was performed by Sanger sequencing in all family members.

Results: WES identified a homozygous C>T transition mutation in exon 2 of *MMP13* (c.325C>T) on chromosome 11q22.2 resulting in a premature stop codon (p.R109X) that is predicted to result in a markedly truncated protein. Sanger sequencing confirmed that the affected brothers were homozygous, while the parents were heterozygous. IBD analysis identified a 2.22 Mb homozygosity block around the *MMP13* gene in the affected brothers supporting a founder effect from a common ancestor.

Conclusions: We report a novel c.325C>T nonsense mutation in *MMP13* leading to an AR form of MAD type 1. The phenotype of our patients is more severe than was reported in the previous case of AR MAD type 2 due to a c.722C>A (p.H213N) missense mutation in exon 5 of *MMP13*. The mutation is in the catalytic region of MMP13 and results in a stable secreted protein; by contrast, the R109X mutation we identified occurs just after the pro-domain and is unlikely to result in a functional secreted protein. Given the mild short stature in the heterozygous parents of our patients, we hypothesize that there is a unique *MMP13* gene dosage effect on the growth plate that affects final adult height.

Serum Vitamin D Level can Affect the Treatment Outcome of Whole-body Vibration (WBV) for Osteopenia in Girls with Adolescent Idiopathic Scoliosis (AIS). Tsz Ping Lam*[1], Franco Tsz Fung Cheung[1], Queenie Wah Yan Mak[1], Fiona Wai Ping Yu[1], Kwong Man Lee[2], Bobby Kin Wah Ng[1], Ling Qin[3], Jack Chun Yiu Cheng[1]. [1]Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Hong Kong, [2]Lee Hysan Clinical Research Laboratories, The Chinese University of Hong Kong, China, [3]Chinese University of Hong Kong, Hong Kong

INTRODUCTION: AIS was associated with systemic osteopenia which, apart from being an important health issue that could persist into adulthood, was also found to be a significant prognostic factor for curve progression in AIS. Our group has conducted a randomized controlled trial on WBV and reported its effect on increasing femoral neck areal bone mineral density(aBMD) mainly at the dominant leg. The objective of this study was to evaluate the role of Vit-D in moderating and enhancing the anabolic bone effect of WBV.

METHODS: This was a study nested within the randomized, controlled trial just mentioned, with enrolment of 122 skeletally mature (15-25 years old) girls with AIS and all with BMD Z-scores < -1. They were randomly allocated to the Treatment or Control group. In the Treatment group, subjects were treated by standing on a low-magnitude high-frequency WBV platform 20 mins/day, 5 days/week (acceleration 0.3g, frequency 35 Hz). Subjects in the Control group received observation alone. The study period was one year. aBMD at both femoral necks was measured with Dual-Energy X-ray Absorptiometry at baseline and at 12-month. Serum 25(OH)Vit-D level by liquid chromatography tandem mass spectrometry (LCTMS) was measured at 6-month within the treatment period.

RESULTS: The mean age was 17.8 (SD=1.5) years old and mean Cobb angle was 29.4 (SD=8.8) degrees. Subgroup analysis for those with serum 25(OH)Vit-D>40nmol/L revealed not only the positive effects of WBV were greater at both sides, treatment effects were explicitly also noted at the non-dominant leg (Table 1). In addition, the positive correlation between serum 25(OH)Vit-D and percentage increase in femoral neck aBMD that was not present in the control group was explicitly detectable in the WBV-treated group at the non-dominant leg (p=0.004) (Fig 1a and 1b).

CONCLUSIONS AND DISCUSSION: The results strongly suggested the treatment effect of WBV could be enhanced through its synergistic factor interaction with Vit-D. The study carried significant clinical implication in that Vit-D insufficiency could affect negatively the treatment outcome of WBV for osteopenia in girls with AIS.

Table 1: Percentage change in femoral neck aBMD from baseline to 12-month follow up for the Treatment and Control group

	Percentage change				
	Treatment group		Control group		
	Mean	SD	Mean	SD	p
All cases n=61(Treatment group), n=61 (Control group)					
Dominant femoral neck aBMD (g/cm^2)	2.15	4.32	0.14	3.67	0.007*
Non-dominant femoral neck aBMD (g/cm^2)	2.11	3.95	1.97	3.29	0.835
For those with serum 25(OH)Vit-D level <= 40 n=46 (Treatment group), n=42 (Control group)					
Dominant femoral neck aBMD (g/cm^2)	1.50	4.11	-0.17	3.37	0.039*
Non-dominant femoral neck aBMD (g/cm^2)	1.40	3.36	2.26	3.39	0.238
For those with serum 25(OH)Vit-D level > 40 n=15 (Treatment group), n=19 (Control group)					
Dominant femoral neck aBMD (g/cm^2)	4.14	4.48	0.83	4.28	0.035*
Non-dominant femoral neck aBMD (g/cm^2)	4.27	4.01	1.33	3.04	0.040*

Accuracy of QCT-Based Finite Element Models of the Vertebra. Amira Hussein*[1], Ginu Unnikrishnan[1], Glenn Barest[2], Elise Morgan[1]. [1]Boston University, USA, [2]Boston University Medical Center, USA

Introduction: Patient-specific quantitative computed tomography (QCT)-based finite element (FE) models of vertebrae have tremendous promise for non-invasive prediction of bone strength. However, these models have not yet been fully validated. Differences between FE-computed and experimentally measured values of vertebral strength can differ by more than two-fold, and few studies have assessed how well these models predict the deformation of the vertebra. Experimental measurements of deformation throughout the vertebral body are possible with digital volume correlation (DVC). The goal of this study was to evaluate the accuracy of QCT-based FE models generated using two common modeling approaches: voxel-based and geometry-based.

Methods: Fresh-frozen, human, L1 functional spine units (age: 80 ± 10, 2 female, 3 male) were scanned via QCT (0.3125x0.3125x0.625 mm/voxel) and then compressed axially in stepwise fashion to failure (1 mm/step applied at 0.25mm/sec). A micro-computed tomography (μCT) scan was performed at each step (37 μm/voxel). A validated DVC technique was applied to the μCT images to quantify displacements and strains throughout the vertebral body. Voxel-based FE models were generated from coarsened QCT images (hexahedral elements ~1.25mm in side length). Geometry-based FE models were created by meshing a solid geometric representation of the vertebral body (created from the QCT images) with tetrahedral elements. Linear, orthotropic elastic properties estimated from the local value of bone mineral density. Axial compression was simulated by applying displacements across the endplates that corresponded to the DVC-measured values at the yield point.

Results: Good agreement was found between the experimental and FE results in terms of the locations of large displacements and large strains (Figure 1). Greater spatial variations in strain were observed in the FE vs. experimental results.Conclusions: The two FE approaches yielded reliable and comparable results. Differences between FE and experimental strain distributions may be due to the relatively low spatial resolution of the experimental displacement fields. The non-uniformity in endplate displacements observed in the experiments suggests that FE models may benefit from accounting from factors such as intervertebral disc health that affect the load distribution across the endplate. This modification may provide even greater fidelity of QCT-based FE analyses for predicting vertebral failure.

Advanced Glycation End Product Accumulation in Cortical and Cancellous Bone Predicts Vertebral Load Share and Vertebral Fracture Behavior. Catalina Bravo*, Robert Hoy, Deepak Vashishth. Rensselaer Polytechnic Institute, USA

Vertebral fractures disproportionately affect the elderly and osteoporotic poulations. Computational models show the complexity of vertebral fracture and predictload sharing between cortical and cancellous bone[1]. Matrix modifications of bone collagen by Non enzymatic Glycation (NEG) vary with age in cortical and cancellous bone[2]. However, the differential accumulation of advanced glycation end products (AGEs) in vertebral cortical vs cancellous bone and its role in load sharing and eventual vertebral fracture is unknown. Using a mouse model, we conducted experimental biomechanical and biochemical analysis of whole vertebrae. Our results show for the first time that load sharing between vertebral cortical and cancellous bone varies with AGE accumulation and AGE accumulation in cortical and cancellous bone is associated with different aspects of vertebral fracture.

L1 to L3 vertebrae from 6 month old WT mice were randomly divided into three groups. Group 1 was separated into cortical and trabecular samples for biochemical analysis. AGE content was measured via fluorometric assay. Group 2 (intact) was compression tested to failure at a crosshead speed of .02 mm/s using an ELF 3200 and custom made self-aligning compression plates. Using established procedures [3], a cut was made on the cortical shell of vertebrae in Group 3 (cored) and the cancellous bone was extracted. Similar to intact, the cored vertebrae were loaded to failure. Load values at yield were compared to estimate the extent of load sharing between cortical and cancellous bone.

Our results show the load bearing by cancellous bone at yield decreased with an increase in the AGE content for cancellous bone (r= -0.94; p=0.02). In contrast, load bearing by cortical bone in vertebrae at yield increased with an increase in cortical AGE content (r=0.81; p=0.09). AGE accumulation in cortical and cancellous bone was not different (p=0.90) but was associated with different aspects of vertebral fracture. Cancellous bone AGEs predicted stiffness and yield vertebral properties ($r > 0.80$, $p < .05$). Cortical bone AGEs predicted energy to fracture (r=0.70, p=.07) (Fig 1). These finding suggest that the relative accumulation of AGEs in cortical and cancellous bone determines extent of load sharing and fracture of whole vertebrae.

To identify new genes controlling bone density, structure, and strength, we undertook a series of large-scale mouse F2 crosses. The purpose is to report bone geometric and mechanical strength in femurs from young adults (age 20 weeks) of three of these F2 mouse crosses; 1) B6129 [C57BL/6Jx129S1vImJ] [N=427], 2) B6A [C57BL/6JxA/J] [N=472], and 3) B6D2 [C57BL/6JxDBA/2J] [N=282].

The distal metaphysis volume of interest (VOI) was 0.5mm inside the endocortical surface and 1.5-3.0mm proximal to the growth cartilage-metaphyseal junction. The diaphysis VOI was the central 1.5mm of the femur. Both were scanned @12µm pixel resolution (MicroCT, ScanCo40). Distal femur [df] bone volume (df.BVTV), trabecular number (df.TbN) and thickness (df.TbTh), apparent volumetric bone mineral density (df.vABMD), central femur [cf] cortical area (cf.CtAr.), and moment of inertia (cf.MOI) were determined. After MicroCT, a three point bending test of the mid-shaft (3mm/min displacement rate) was done (Instron 5534). Ultimate load (cf.ULd) was derived from the load deformation curve. Ultimate stress (cf.UStr) was calculated from cf.MOI. Data were analyzed by Kruskal-Wallis ANOVA with PLSD post-hoc testing. Multiple regression analysis was done for ULd vs. cortical geometric properties by gender and cross.

Gender differences exist within all crosses for each endpoint. df.BVTV and df.vBMD were similar in B6129 and B6A female mice, but lower in B6D2 mice. dfTbN, cf.CtAr, cf.MOI, and cf.ULd were lower in B6A and B6D2 than in B6129 mice. The strongest determinant of cf.ULd was cf.CtAr (R^2=~0.66), with occasional contribution by cf.MOI.

Significant variation exists among the crosses in bone microarchitecture and strength, as a function of mouse strain. Female B6129 mice, the basis of many genetically-altered mice, have rather low trabecular bone volume, making evaluation of further bone loss difficult. Cross-related microarchitectural differences are related to trabecular number, rather than thickness. Geometric properties are important determinants of cortical bone strength, confirming the ability of quantitative CT to improve bone strength prediction, when added to bone mass.

Variable	B6129 (223)	B6A (236)	B6D2 (140)
df.BV/TV	0.081±0.040	0.084±0.040	0.056±0.031[ab]
df.vABMD (mg/cm^3)	137.3±41.5	134.4±40.0	108.5±37.1[ab]
df.TbN (#/mm)	3.07±0.57	2.80±0.58[a]	2.54±0.5[ab]
df.TbTh (mm)	0.058±0.007	0.060±0.006	0.058±0.005
cf.ULd (N)	25.22±3.25	24.05±3.34[a]	21.71±2.83[ab]

Characterization of Bone Mineralization in a Rat Model of Chronic Kidney Disease. Hiromi Kimura-Suda*[1], Kyosuke Kanazawa[1], Sachio Kobayashi[2], Mieko Kuwahara[3], Teppei Ito[1], Naoya Sakamoto[2], Makoto Kajiwara[4], Hideyuki Yamato[3], Kuniharu Ijiro[5], Hisayoshi Yurimoto[6]. [1]Chitose Institute of Science & Technology, Japan, [2]CRIS, Hokkaido University, Japan, [3]Kureha Corporation, Japan, [4]Kureha Special Laboratory, Japan, [5]RIES, Hokkaido University, Japan, [6]Department of Natural History Science, Hokkaido University, Japan

One of the most important functions of the kidneys is to maintain calcium and phosphorus homeostasis in a body. Therefore, chronic kidney disease (CKD), which is characterized by an irreversible deterioration of kidney functions, causes bone and mineral disorder (MBD). CKD-MBD patients are characterized to reduce bone strength due to abnormal bone turnover. We have previously characterized bone quality of femur in rat 5/6 nephrectomy (5/6-Nx) model of CKD by Fourier transform infrared (FTIR) imaging, Raman spectroscopy and SEM with EDX. We have succeeded in showing that both cortical and trabecular bone in the femur of rat 5/6-Nx model of CKD was reduced, and also found that mineral/collagen matrix ratio in trabecular bone is lower than that in the cortical bone, and the center of cortical bone is calcified rather than the each side of cortical bone, namely, the endosteum side and the periosteum side. In this work, we characterize bone mineralization in CKD rat by FTIR imaging, Raman spectroscopy and isotope imaging. Thirteen-week male rats induced 4/5-nephrectomy (4/5-Nx) and sham-operated rats (Sham) were kept for 15 weeks to produce a rat model of CKD and a control, and then the CKD and the control rats were fed a diet containing at least one of stable calcium isotope (40Ca, 42Ca or 44Ca) for a week, and after that each femur in the rats was extirpated and embedded by poly (methyl methacrylate) (PMMA) to make longitudinal sections for each measurement. FTIR images of distribution of phosphate show that both cortical and trabecular bone in femur of rat 4/5-Nx model of CKD is also reduced; however, mineral/collagen matrix ratio of rat 4/5-Nx model of CKD is slightly higher than that of rat 5/6-Nx model of CKD. In isotope imaging, the stable calcium isotopes, 40Ca, 42Ca and 44Ca, were observed in both trabecular and cortical bone in the femur of the control rat and the rat of 4/5-Nx model of CKD. The stable calcium isotopes were observed in the area of low mineral to matrix ratios such as the endosteum side and the periosteum side.

Characterization of Cancellous and Cortical Bone Strain in the Mouse Tibia During Axial Compression Loading Using Micro-CT Finite Element Analysis: A Sensitivity Study. Haisheng Yang*[1], Kent Butz[2], Daniel Duffy[3], Glen Niebur[4], Eric Nauman[2], Russell Main[1]. [1]Purdue University, USA, [2]School of Mechanical Engineering, Purdue University, USA, [3]Weldon School of Biomedical Engineering, Purdue University, USA, [4]The University of Notre Dame, USA

Characterization of the load-induced strain environment is critical to understanding the mechanobiological response of bone tissue to mechanical loading. Increasing use of the mouse tibial loading model in skeletal mechanobiological studies has produced a growing dataset of empirical strain measures and finite element analyses (FEA) for the tibia during compression loading. Despite this wealth of data, the strain distribution and factors affecting accurate strain assessment in cancellous tissues remain poorly understood. The objective of this study was to quantify tissue-level strain using micro-CT FEA, while considering the influence of multiple model parameters on the resulting analyses.

FE models of one representative 16wk old female C57Bl/6 tibia were created from micro-CT scans and loaded in simulated axial compression at -7N to mimic the *in vivo* tibial loading configuration. Strains in the proximal metaphyseal cancellous and midshaft cortical bone were calculated. A sensitivity analysis was performed according to Cotter's Method to evaluate the importance of 7 model parameters on the outcome strain measures: scan resolution, cancellous bone threshold, bone tissue heterogeneity, mesh refinement, element type, inclusion of the fibula, and horizontal constraint of the proximal tibia. This required 16 FE simulations for specified combinations of the lower and upper levels of each model parameter.Across all FE simulations, the range for the average longitudinal strain modeled on the medial midshaft surface exhibited good agreement with experimental strain gauge measures from the same bone (857-1998με vs. 1340με). The cut-offs for the upper 95th percentile of the minimum principal strain in the cancellous and cortical bone ranged from -2249με to -785με and -4959με to -1712με, respectively. Bone tissue heterogeneity had a strong influence on cancellous strain while cortical strain was mainly affected by the presence of the fibula and the proximal boundary conditions (Figs.1 & 2). Our results suggest that using a finer scan resolution, a cancellous-based threshold for cancellous tissues, density-based heterogeneous material properties, and inclusion of the fibula could improve the accuracy of FEA for addressing cancellous tissue-level strain environments in the mouse tibia. The validated model will be critical for relating detailed strain distributions in cancellous and cortical bone tissue in the tibia to the biological response to mechanical load.

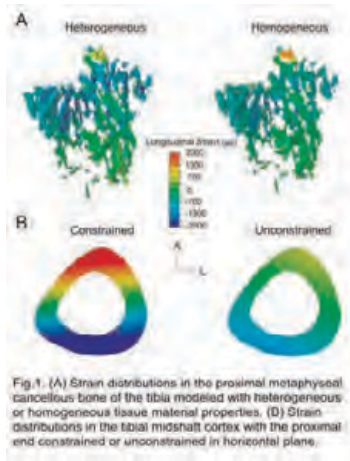

Fig.1. (A) Strain distributions in the proximal metaphyseal cancellous bone of the tibia modeled with heterogeneous or homogeneous tissue material properties. (B) Strain distributions in the tibial midshaft cortex with the proximal end constrained or unconstrained in horizontal plane.

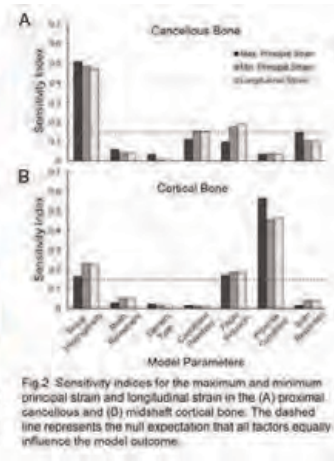

Fig.2. Sensitivity indices for the maximum and minimum principal strain and longitudinal strain in the (A) proximal cancellous and (B) midshaft cortical bone. The dashed line represents the null expectation that all factors equally influence the model outcome.

Combined effects of botulinum toxin injection and hindlimb unloading on bone and muscle. Rachel Ellman*[1], Daniel Grasso[1], Miranda Van Vliet[1], Daniel Brooks[1], Jordan Spatz[2], Christine Conlon[1], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, USA, [2]Harvard-MIT Division of Health Sciences & Technology (HST), USA

Bone receives mechanical stimulation from two primary sources, muscle contractions and external gravitational loading, but the relative contribution of each to bone maintenance is not well studied. Thus, we investigated the relative effects of paralysis and unloading on changes in muscle mass, bone mass and microarchitecture.

Adult female C57Bl/6J mice (12 wks old) underwent one of the following (n=10/group): botulinum toxin A (BTX) injection, hindlimb unloading (HLU), both HLU and BTX (HLU+BTX), or no intervention. BTX-treated groups received a unilateral IM injection to the quadriceps and calf muscle groups (2U/100g total dose) three days before HLU; all mice were sacrificed after 21 days.

HLU, BTX and HLU+BTX all led to significant loss of leg muscle mass, hindlimb BMD and bone microarchitecture relative to controls, while generally the combined HLU+BTX intervention had the most detrimental changes in bone and muscle. As an example, controls gained BMD (+4.6%, $p<0.001$ vs. baseline, Figure) while HLU mice lost BMD (-4.9%, $p<0.01$). BTX-treated mice lost even more BMD in their injected leg (-19.1%, $p<0.001$), and the most severely affected were the HLU+BTX group with a -30.2% loss of BMD in their injected leg ($p<0.001$) – or 6-fold more than with HLU alone. Unexpectedly, we found a strong systemic effect of BTX affecting the uninjected (contralateral) leg that led to large BMD losses (-5.2% and -17.8% for BTX and HLU+BTX, respectively, $p<0.05$) and significant deficits relative to untreated controls in muscle mass (-25.2% BTX vs. control; -30.3% HLU+BTX vs. HLU) and trabecular bone volume (-24.0% BTX vs. control; -52.8% HLU+BTX vs. HLU). The magnitude of this indirect effect was comparable to the direct effects of BTX treatment and HLU alone. This confounding factor hinders our ability to conclude whether muscle forces or external gravitational forces contribute more to bone maintenance, but it appears that BTX-induced muscle paralysis was more detrimental to muscle and bone than hindlimb unloading. In light of this, untreated controls should be included in future BTX studies to gauge the presence of indirect effects on the uninjected leg that would otherwise go undetected. Our data indicate that BTX may affect bone through mechanisms other than direct loading.

Comparative Study on the Effects of PTH(1-84) and Strontium Ranelate on Bone Biomechanics in Orquidectomized Rats. David Guede*[1], María Permuy[2], Marta Martín-Fernández[3], Mónica López-Peña[2], Concepción de la Piedra[3], Antonio González-Cantalapiedra[2], José R. Caeiro[4]. [1]Trabeculae, S.L., Spain, [2]Departamento de Ciencias Clínicas Veterinarias, Universidade de Santiago de Compostela, Spain, [3]Bioquímica Investigación, Instituto de Investigación Sanitaria Fundación Jiménez Díaz, Spain, [4]Servicio de Cirugía Ortopédica y Traumatología, Complexo Hospitalario Universitario de Santiago de Compostela, Spain

INTRODUCTION: Strontium ranelate (SrR) and PTH(1-84) have demonstrated their efficacy in the treatment of postmenopausal osteoporosis in experimental studies and clinical trials, being able to improve BMD and microarchitecture, significantly reducing the risk of fracture. The effects of these treatments on male osteoporosis are less well studied.

OBJECTIVES: To evaluate the effects of PTH(1-84) and SrR on bone strength in an experimental model of male osteoporosis (orchidectomized rats).

MATERIAL AND METHODS: Sixty 6-month-old male Sprague-Dawley rats were divided into 6 groups: SHAM (simulated operation); OQX (orchidectomized); OQX+PTH50 (OQX treated with PTH 50 µg/kg/day VO); OQX+PTH10 (OQX treated with PTH 10 µg/kg/day VO); OQX+SrR600 (OQX treated with strontium ranelate 600 mg/kg/day SC); and OQX+SrR250 (OQX treated with strontium ranelate 250 mg/kg/day SC). Treatments lasted 3 months (starting 6 months after orchiectomy). After sacrifice, the right femora were subjected to three-point bending mechanical testing while L5 vertebrae to compression assays.

RESULTS: In the vertebrae, orchiectomy caused a general worsening of the intrinsic and extrinsic mechanical properties, particularly noticeable in the values of work to failure and toughness. In the femurs, however, the variable showing the greatest decrease in the OQX group versus SHAM group is extrinsic stiffness.

SrR treated groups showed similar values to OQX group in all determined mechanical parameters, not being able to improve the biomechanical strength in compression or bending. The lower dose of PTH has not been able to cause remarkable changes in mechanical properties compared to OQX group. However, the dose of 50 µg of PTH increased the values of many mechanical parameters even significantly exceeding the values of SHAM group in work to failure and toughness of the lumbar vertebrae ($p<0.05$).

CONCLUSIONS: None of the tested doses of SrR neither the lower dose of PTH were able to significantly modify the negative effects of orchiectomy on mechanical properties in this model of male osteoporosis. However, the group treated with the highest dose of PTH have demonstrated the ability to considerably improve femoral and lumbar mechanical properties, reaching values even higher than SHAM group.

Crack Accumulation and Strength Loss in Fatigue-damaged Bone Increase when Osteoclasts Are Stimulated and Decrease when Osteoclasts Are Inhibited. Nicolas Bonnet*[1], Maude Gerbaix[2], Paul Kostenuik[3], Mike Ominsky[4], Serge Ferrari[5]. [1]University Geneva Hospital-Department of Internal Medecine Specialities, Switzerland, [2]Service of Bone Diseases, Hôpitaux Universitaires, Switzerland, [3]Amgen Inc., USA, [4]Metabolic disorders, Amgen Inc., Switzerland, [5]Geneva University Hospital & Faculty of Medicine, Switzerland

Antiresorptives consistently improve bone mass and structural strength in normally- and under-loaded bones, but concerns have been raised regarding potential effects on skeletal adaptation to fatigue loading, including damage accumulation and atypical fractures. We thus inhibited or activated osteoclasts with OPG-Fc or RANKL, respectively, and evaluated bone damage and strength after fatigue. Adult male mice were treated with RANKL (2mg/kg/d), OPG-Fc (5mg/kg 2/wk) or PBS (Veh) for 35 days. At day 28 of treatment, one tibia was fatigue loaded for 20 min by in vivo axial compression (14N, 4Hz), with animals sacrificed one week later. In another study, axial compression was applied 2 days after initiating OPG-Fc or RANKL, with treatments continuing for 28 more days (n=6 per group). We assessed cortical damage, bone mass, microarchitecture, and axial compressive strength. In mice treated 28 days before fatigue, tibial aBMD, trabecular and cortical parameters were all significantly higher with OPG-Fc and lower with RANKL, compared to Veh. One week post-fatigue, crack number per bone area (CrN/BA) was higher with RANKL ($368\pm48/mm^2$) compared to Veh ($205\pm29/mm^2$) or OPG-Fc ($233\pm47/mm^2$), both $p<0.05$. CrN/BA and total aBMD were respectively negatively and positively associated with peak load ($r^2=0.13$, $p<0.05$; $r^2=0.73$, $p<0.0001$). Tibial ultimate force was significantly higher with OPG-Fc ($29.8\pm0.8N$) and lower with RANKL ($16.9\pm1.0N$) compared to Veh ($25.8\pm1.9N$, both $p<0.05$). When fatigue was induced 2 days after initiating treatment, i.e., prior to changes in bone mass, CrN/BA at 28 days post-fatigue was higher with RANKL ($265\pm26/mm^2$) and lower with OPG-Fc ($78\pm17/mm^2$, $p<0.05$) vs Veh ($158\pm19/mm^2$; $p<0.01$). Reactive callus size was greater with 28 days of post-fatigue OPG-Fc administration ($0.098\pm0.009mm^3$) than with vehicle ($0.045\pm0.005mm^3$, $p<0.05$), and was unaffected by RANKL ($0.043\pm0.002mm^3$). Post-fatigue OPG-Fc administration led to the greatest bone strength, followed by vehicle and RANKL groups. In summary, bone mass exerted a dominant positive influence on the strength of post-fatigued bone, while cracks had a modest negative influence. OPG-Fc decreased cracks, likely due to increased bone volume and improved strength, whether or not bone mass had improved at the time of fatigue. RANKL had the opposite effects. We provide evidence that osteoclasts can weaken bone in the pre- and post-fatigue settings, possibly by compromising structure and predisposing to new cracks.

CrN/BA (1/mm²)	Veh	OPG-Fc	RANKL
28days treatments + 7days post-fatigue	205 ± 29	233 ± 47	368 ± 48
2days treatments + 7days post-fatigue	114 ± 7	119 ± 11	160 ± 12
2days treatments + 28days post-fatigue	158±19	78±17	265±26

Effects of OPG-Fc and RANKL on crack number per bone area in response to fatigue loading

Fetal Exposure to Selective Serotonin Reuptake Inhibitors has Long-Term Adverse Effect on Bone Properties in Rats. Maryam Badv*, Zahra Hosseini, Nicole De Long, Alison Holloway, Gregory Wohl. McMaster University, Canada

Introduction: Selective Serotonin Reuptake Inhibitors (SSRIs) are a class of antidepressant drugs that are commonly prescribed to treat depression during pregnancy. SSRI use during pregnancy has been associated with shorter birth length and congenital deformities including anencephaly. However, the effects of maternal SSRI use on the development of the appendicular skeleton in the offspring have not been investigated. The purpose of this study was to assess, in rats, the effects of fetal exposure to an SSRI (sertraline, Zoloft®) on postnatal bone properties.

Methods: Nulliparous female Wistar rats (200-250g) were randomly assigned to receive either SSRI (10 mg/kg/day; N=8) or vehicle (N= 5) from the confirmation of mating until parturition. Tissues were collected at necropsy from one male and one female pup per litter at 3, 7 and 26 weeks of age. Left femurs were scanned by microCT (23 µm resolution) and then loaded in three-point bending. Cross-sectional area properties were determined from microCT scans. Structural properties (maximal load, stiffness) were determined from mechanical tests. Maximal stress was calculated using areal properties. Groups were compared by two-way ANOVA with sex and treatment as the independent variables ($\alpha=0.05$).

Results: At 3 weeks of age, femurs of SSRI exposed female rats had larger cross-sectional area than controls (Fig 1). At 3 and 7 weeks of age, femurs of SSRI exposed animals had significantly lower maximal load (Fig 2), and at 7 weeks of age lower stiffness (Fig 3) compared to controls. At 3 weeks of age, femurs of SSRI exposed rats had significantly lower maximal stress (Fig 4) but there was no difference in older ages. At 26 weeks of age there was no main effect of either sex or SSRI exposure, However there was a significant interaction between sex and treatment; while femurs in the female rats from SSRI dams tended to be stronger than the controls, the femurs from males SSRI rats tended to be weaker.

Discussion: The bones of offspring born to SSRI-exposed dams are weaker compared to controls until 7 weeks of age (i.e., the peripubertal period). The fact that SSRI-exposed female offspring regain bone strength by 26 weeks of age an effect not seen in males, suggests that male bones are more susceptible to persistent effects of fetal SSRI exposure. Taken together these data indicate that fetal exposure to an SSRI antidepressant has long-term adverse effects on the development of the appendicular skeleton.

High Resolution Imaging of Reference Point Indentations in Control and Type II Diabetic Bone. Connor Randall*, Kevin Hoffseth, Daniel Bridges, Henry Yang, Paul Hansma. University of California, Santa Barbara, USA

Individuals with type 2 diabetes (T2D) have an increased risk of bone fracture; however, bone mineral density is typically normal in these patients, suggesting the desirability of measuring bone fracturability directly. Reference Point Indentation has this capability. Though only a clinical study could determine if it is indeed useful for this application, we were able to obtain tibia from two 83 year old female cadavers, one with and one without T2D, to investigate with Reference Point Indentation, conventional four-point bending tests, and high resolution imaging of the induced micro-fractures.

Reference Point Indentation works by creating micro-indentations in the bone and measures the bone's ability to resist deformation. Recently Reference Point Indentation has been shown clinically to distinguish patients with and without fracture (JBMR 25: 1877, 2010). This technique does not require excised bone specimens and destructive sample preparation. Here, however, we do use excised bone specimens and destructive sample preparation to investigate microscopic mechanisms behind differences in the Bone Material Strength (BMS), a normalized measure of a bone's resistance to micro-indentations deep enough to cause microscopic fractures (Rev. Sci. Instrum. 83: 044301, 2012). BMS was measured with a new hand-held Reference Point Indentation instrument, the Osteoprobe®. The BMS of the healthy sample was 99.4 ± 4.3 (N=5), while the T2D sample had a BMS of 83.6 ± 2.2 (N=9). High resolution Scanning Electron Microscopy revealed dense collagen-fibril bridging across the microscopic fractures created by the Reference Point Indentations for the healthy bone, but not for the T2D bone. This is a toughening mechanism (Phys. Today 62: 41, 2009) that could be compromised by T2D. Four-point bending test confirmed that the toughness of the T2D sample, 3.1 mJ/mm^3, was indeed lower than the healthy sample, 5.0 mJ/mm^3. This is in qualitative agreement with a recent Reference Point Indentation study with animal models (Bone 53: 301, 2013)

The conclusion suggested from this case study is based on specimens from only two cadavers. It would, of course, be premature to conclude that this is a general characteristic of human T2D compared to control bone without further research.

Inhalant Lung Injury following Complex Organic Dust Extracts Results in Systemic Bone Loss and Disease in Mice. Anand Dusad*[1], Geoffery M. Thiele[2], Lynell W. Klassen[2], Angela M. Gleason[2], Christopher Bauer[2], Ted R. Mikuls[2], Michael J. Duryee[2], William W. West[2], Debra J. Romberger[2], Jill A. Poole[2]. [1]University of Nebraska Medical Center, USA, [2]UNMC, USA

Purpose. Skeletal health consequences associated with chronic inflammatory respiratory diseases, particularly chronic obstructive pulmonary disease (COPD), contribute to overall disease morbidity. Agriculture environmental exposures induce significant airway diseases including COPD. However, animal models to understand inhalant exposures-induced lung injury and bone disease have not been described.

Methods. Male C57BL/6 mice (6-8week old) were exposed to repetitive intranasal inhalation of sterile saline (PBS), complex organic dust extracts (ODE, 12.5%), lipopolysaccharide (LPS, 100 ng) and peptidoglycan (PGN, 100µg). Mice were treated daily for 3 weeks and euthanized 24 hours following the final exposure. Right hind limbs were collected for micro-CT and histology to analyze bone quantity and quality parameters. Analysis was focused on the trabecular bone of distal calcaneus. Whole lungs were also excised, inflated to preserve architecture and semi-quantitatively assessed for the degree of inflammation, as per published scoring system.

Results. As shown in Table 1, three weeks of repetitive ODE, LPS and PGN inhalation exposure lead to a significant loss of bone mineral density and trabecular bone volume fraction along with deteriorating microarchitecture changes in the trabecular bone as compared to saline control animals (Figure 1). Torsional resistance was also significantly reduced in these groups as compared to saline. Findings were not secondary to animal distress, and not entirely dependent upon the degree of induced lung parenchymal inflammation. Repetitive ODE and PGN treatment resulted in significant increases, while LPS treatment showed subtle but non-significant increase in all inflammatory parameters, compared to saline treated animals (Figure 2).

Conclusions. Overall this information suggests that inhalation of varying microbial motifs might be impacting lung (localized) versus systemic consequences differently. This animal model might substantially contribute to understanding mechanisms and evaluate therapeutics associated with adverse skeletal health consequences following chronic airway injury and can also be expanded to include other environmental exposure agents that might affect skeletal health. Future lines of epidemiologic research might be needed to determine links between occupational exposures and bone loss or fractures.

Life-long Western Style Diet has Greater Adverse Affects on Cancellous Bone in Adult Female Wistar Rats Compared to Male Rats. Cheryl Druchok*, Alison Holloway, Andrew Don-Wauchope, Gregory Wohl. McMaster University, Canada

Introduction: A high-fat diet has been shown to adversely affect bone properties in rats, but most of these dietary interventions have been short-term. Generally, in humans, poor dietary habits occur over a period of time, they are not short-term insults. The purpose of this study was to examine cortical and cancellous bone properties in rats fed a life-long Western style diet (HF) or normal control (NC) diet.

Methods: At weaning (3 weeks of age), male and female Wistar rats were randomly assigned to receive a NC diet (NC–17% fat; N=8 male, 11 female) or HF diet (HF–41% fat; N=10 male, 9 female) until termination (39 weeks of age). Post-mortem, femoral cross-sectional area properties were determined by microCT. Femurs were loaded in three-point bending, to failure, to determine mechanical properties. L6 vertebrae were scanned by micro-CT to determine trabecular bone volume (BV/TV), trabecular number (Tb.N), thickness (Tb.Th) and spacing (Tb.Sp.).

Results: Body mass was significantly greater in HF males beginning at 14 weeks and females at 4 weeks compared to NC ($p < 0.05$) (Fig. 1). Cross-sectional area properties (bone area, moment of inertia) of the femoral mid-diaphysis were significantly greater in HF femurs vs. NC, for both sexes ($p < 0.05$). The HF diet did not adversely affect cortical bone mechanical properties (maximal load, bending stiffness, deformation and energy) ($p > 0.05$) in males. The only difference in females was significantly greater bending stiffness in HF femurs vs. NC ($p < 0.05$). Elastic modulus, calculated from deformation data, did not differ between HF and NC femurs ($p > 0.05$) for either sex. Female HF L6 vertebrae had a significantly lower BV/TV and Tb.N compared to NC ($p < 0.05$). There were no differences between male HF and NC vertebrae ($p > 0.05$).

Conclusions: Based on these data, a life-long Western style diet does not appear to adversely affect cortical bone mechanical properties in male or female rats, but it does diminish cancellous bone properties in females. It is not surprising that the HF diet affects cancellous bone, as it is more responsive to diet interventions than cortical bone. These results suggest that female rats are more sensitive to a HF diet than male rats over a life-long exposure and further work is required to elucidate the mechanisms that are involved.

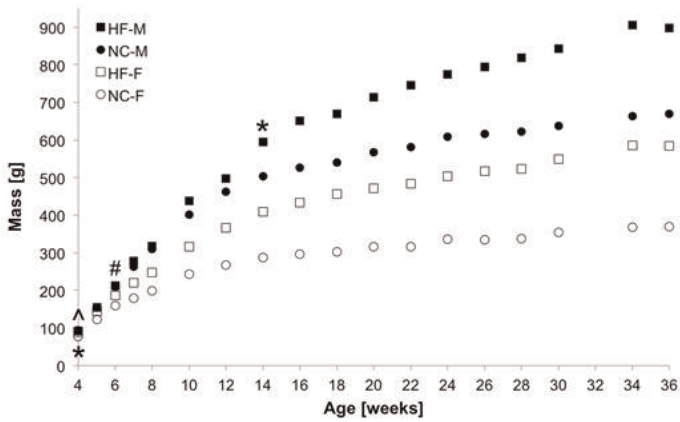

Figure 1. Body mass (g) over 36 weeks. Body mass was significantly greater in HF males beginning at 14 weeks (*p = 0.004) and females at 4 weeks (*p = 0.029) compared to NC. The males had significantly greater body masses than the females beginning at 4 weeks for NC (^p = 0.027) and at 6 weeks for HF (#p = 0.036).

Reference Point Indentation Detects Changes in Rat Bone Induced by In Vitro Sodium Fluoride Incubation. Lamya Karim*, Mamadou Diallo, Mary Bouxsein. Beth Israel Deaconess Medical Center, USA

The mechanical behavior of whole bone is determined by its mass, geometry, and tissue mechanical properties. Assessment of cortical bone tissue mechanical properties is now possible by in vivo and ex vivo reference point indentation (RPI), which measures cortical bone indentation properties resulting from cyclic loading. Our goal was to determine the ability of RPI and whole bone testing to detect changes in rat cortical bone tissue mechanical properties induced by in vitro sodium fluoride (NaF) incubation, which alters the physico-chemical structure of bone mineral.

Forty-two ulnae from adult rats were randomly divided into 5 groups (vehicle, 0.05M NaF, 0.25M NaF, 0.75M NaF, 1.5M NaF). Bones were washed in a detergent solution to remove organic barriers to ion exchange and incubated in respective treatment solutions (12hrs, 23℃). Cortical tissue mineral density (TMD) and geometry at the mid-diaphysis were determined by microCT. RPI was performed on the posterior surface of the distal diaphysis (9N, 2Hz, 10 cycles), and then bones were tested in 3-point bending until failure to assess stiffness and failure load. MicroCT data were used to compute apparent elastic modulus.

NaF-treated bones had significantly greater creep indentation distance (CID) and total indentation distance (TID) than vehicle treated bones ($p<0.05$). Specifically, TID increased with NaF dose until a plateau at 0.75M (Fig 1). Whole bone apparent elastic modulus, stiffness, and maximum load were also lower in NaF treated bones than in vehicle treated bones ($p<0.05$), with values decreasing with increasing NaF dose until a plateau at 0.75M (Fig 1). CID and TID were negatively correlated ($p<0.01$) with apparent elastic modulus (r= -0.68 and r= -0.73), stiffness (r= -0.50 and r= -0.61), and maximum load (r= -0.57 and r= -0.65), respectively. TID was independent of cortical TMD, but CID was negatively correlated with TMD (r=-0.27, p=0.09).

In conclusion, in vitro exposure to NaF dose-dependently led to reduced whole bone and tissue-level mechanical properties, as seen by higher indentation distances. Indentation distances correlated moderately with several whole bone mechanical properties. These results suggest that RPI can detect physico-chemical changes in cortical bone tissue that have a deleterious effect on mechanical behavior and that are independent of bone remodeling status.

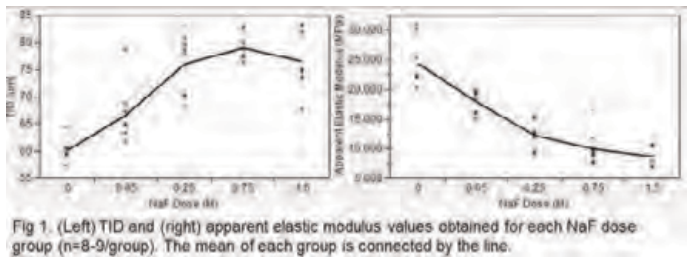

Fig 1. (Left) TID and (right) apparent elastic modulus values obtained for each NaF dose group (n=8-9/group). The mean of each group is connected by the line.

Relationships between Cortical Bone Quality and Serum FGF23 in Growing Mice Challenged by Low Calcium and High Fructose in the Diet. Edek Williams*[1], Veronique Douard[1], Devendra Bajaj[2], Yves Sabbagh[3], Ronaldo Ferraris[1], JC Fritton[1]. [1]Rutgers/NJMS, USA, [2]NJMS, USA, [3]Genzyme, A Sanofi Company, USA

Serum levels of calcium, phosphate and $1,25(OH)_2$ Vitamin D_3 ($1,25(OH)_2D_3$) have long been known to affect fracture risk. More recently, fibroblast growth factor 23 (FGF23), produced primarily by osteoblasts and osteocytes, has demonstrated potent regulation of phosphate and $1,25(OH)_2D_3$ homeostasis [1]. The intake of these minerals and synthesis of these hormones have changed along with the Western diet. Fructose intake, in particular, has increased 10 fold over the past 30 years. Few studies have investigated the effects of fructose on bone growth [2]. To study these effects, thirty-six, 3-week-old C57BL/6 mice (n=9/group) were fed a combination of normal-calcium (0.5%) / low-calcium (0.02%) and glucose (43%) / fructose (43%) diets for 5 weeks. Humerii were tested in 3-point bending (Bose ElectroForce LM1 TestBench) and femurs were scanned for bone mineral density (Skyscan 1172 μCT), sectioned (Buehler 5000) and imaged for histomorphometry (Nikon A1 Confocal). Measured whole bone and calculated tissue-level mechanical properties were reduced with the calcium-deficient diet (ultimate strength: -40%, elastic modulus: -50%, $p<0.01$). FGF23 was positively correlated with stiffness for both glucose-fed and fructose-fed ($R^2=0.44$) groups. However, the positive correlation between FGF23 and bone tissue mineral density in glucose-fed mice ($R^2=0.52$; $p<0.05$) was not observed in the fructose-fed mice ($R^2=0.12$; ns). Several pathological conditions involving disruption of bone mineralization may be related to inappropriate, fructose-induced increases of FGF23 that reduce synthesis of $1,25(OH)_2D_3$, eventually decreasing intestinal calcium uptake [3]. Our next steps will determine if the dietary effects of fructose and calcium on FGF23 during bone growth are direct and regulated at the individual cell level or influenced by osteocyte density. By challenging mice with a calcium-deficient, fructose-excessive diet, we uncovered surprising relationships between serum levels of

FGF23, and the mineral quality of cortical bone. Following up on this work may lead to better serum readouts for bone quality during growth that include FGF23.

Running decreases marrow adipose tissue in chow and high fat fed mice. Maya Styner*[1], Sanjay Kadari[1], Kornelia Galior[2], Gunes Uzer[3], William Thompson[3], Natasha Case[1], Zhihui Xie[3], Buer Sen[4], Andrew Romaine[5], Martin Styner[5], Gabriel Pagnotti[6], Clinton Rubin[7], Mark Horowitz[8], Janet Rubin[1]. [1]University of North Carolina, Chapel Hill, School of Medicine, USA, [2]UNC-CH School of Medicine, USA, [3]University of North Carolina, USA, [4]University of North Carolina At Chapel Hill, USA, [5]University of North Carolina, departments of computer science & psychiatry, USA, [6]Stony Brook University, USA, [7]State University of New York at Stony Brook, USA, [8]Yale University School of Medicine, USA

The contribution of marrow adipose tissue (MAT) to states of low (osteoporosis, anorexia) and high bone mass (obesity) is unknown. A challenge in understanding the MAT: Bone relationship has been the quantification of marrow fat. We sought to measure volumetric MAT in both chow-fed and high fat diet (HFD)-fed mice treated with an exercise intervention. We hypothesized that MAT would increase with HFD and would decrease with running. 8-wk old female C57BL/6 mice were chow or HFD fed and divided into ± exercise groups consisting of voluntary access to running wheels (n= 5/group). Femoral MAT was quantified after infusing the lipid binder osmium tetroxide to assess osmium mm^3/bone volume by μCT with a volumetric semi-automated approach; the method employed rigid co-alignment, regional bone masks and normalization for total bone volume. Perigonadal fat pad weight was normalized to body weight. Bone quantity was assessed via tibial μCT. After 6 wk, weights of HFD and chow fed mice were similar, but perigonadal fat pads were 30% larger in HFD (p=0.005). Chow and HFD mice ran equivalent distances and times/day (11 km/320min). Running did not alter perigonadal fat within diet groups. In chow-runners compared with non-runners, distal femoral MAT was 118% less (p=0.036, quantified as % osmium, see Figure 1). In HFD, MAT was 62% greater than in chow fed (p=0.002, see Figure 1). Despite the significantly increased MAT due to HFD, running was associated with 122% less MAT as compared with HFD non-runners (p=0.018, see Figure 1). Triglyceride/femur protein correlated with volumetric osmium data for MAT. Bone quantity inversely correlated to MAT: Trabecular BV/TV and Ct.Th were higher in chow-run compared with nonrunners (27% and 13%, p=0.01 for both). HFD had lower trabecular BV/TV (p=ns) and showed reduction in Ct.Th of 8% compared to chow fed mice (p=0.004). HFD-runners had trabecular BV/TV that was 32% greater than HFD-nonrunners (p=0.01). There was a trend for greater cortical bone in HFD runners compared with nonrunners. In conclusion, applying a novel method for quantification of MAT that used osmium labeling along with volumetric μCT image analysis, we find that MAT is meaningfully increased in the setting of HFD, prior to onset of obesity. Distinct from white adipose tissue, MAT is highly sensitive to 6wk of running exercise in both chow and HFD-fed mice. As such, running exercise enhances the reciprocal relationship between MAT and bone quantity.

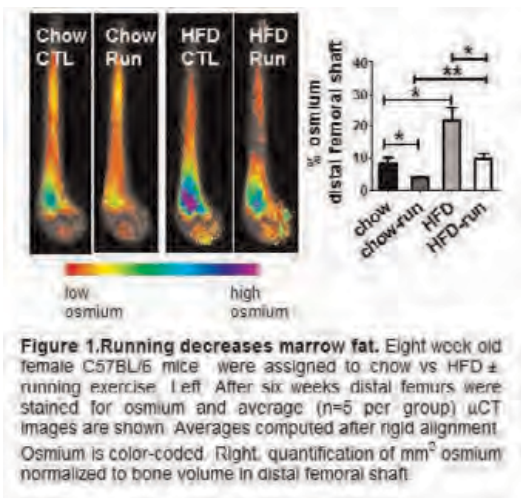

Figure 1.Running decreases marrow fat. Eight week old female C57BL/6 mice were assigned to chow vs HFD ± running exercise. Left: After six weeks distal femurs were stained for osmium and average (n=5 per group) μCT images are shown. Averages computed after rigid alignment. Osmium is color-coded. Right: quantification of mm^3 osmium normalized to bone volume in distal femoral shaft.

Small-angle X-ray Scattering Analysis of Bone Mineral in a Type 2 Diabetes Mouse Model. Silvia Pabisch*[1], Tsuguno Yamaguchi[2], Yasushi Koike[2], Shoko Tanaka[2], Shinsuke Kataoka[2], Wolfgang Wagermaier[3], Richard Weinkamer[3], Michiaki Murakoshi[2], Peter Fratzl[4]. [1]Max Planck Institute of Colloids & Interfaces, Potsdam, Germany, [2]Life Science Research Laboratories, LION Corporation, Japan, [3]Max Planck Institute of Colloids & Interfaces, Department of Biomaterials, Germany, [4]Max Planck Institute of Colloids & Interfaces, Germany

Metabolic diseases may influence bone formation and resorption processes, thereby reducing the mechanical performance of the material, which is known to crucially depend on the amount, size and distribution of mineral particles in the organic matrix. In this study, we investigate thickness (T-parameter) and degree of alignment (rho-parameter) of mineral particles in bone of a mouse model for type 2 diabetes mellitus (T2DM) using small-angle scattering of x-rays and synchrotron radiation. Resin-embedded bone sections from femur of 5, 15 and 22 weeks old animals as well as mandible (22 weeks old animals) were obtained from obese diabetes KKAy mice, as well as from C57BL/6 controls. Mineral particles were characterized at multiple sites within the femur and the mandible. For the latter, scans with 30 μm resolution (beam- and stepsize) were made to study the dependence of alveolar bone mineral on the distance from tooth cementum. Both T and rho were found to increase with age in the femoral cortex with a tendency for a lower rho in the KKAy mice. There was also a variation of T inside the cortex, with generally larger values on the periosteal side. In alveolar bone, there was an interesting gradient in mineral characteristics, where T decreases from both the medial and the lateral sides towards the tooth. Close to cementum, the mineral particles in alveolar bone were generally much thinner than in dentin. This could probably be related to the high turnover rate in alveolar bone, as compared to dentin which is not remodeled. Indeed, T is known to increase with time, once the mineralized tissue is laid down, so that younger bone packets have generally smaller T-values. In conclusion we find that mineral characteristics vary strongly between bone sites in both KKAy mice and controls, with a tendency for less well aligned tissue in the cortices of the KKAy mouse bones.

Studying bone as a complex adaptive system may help identify QTLs that regulate strength. Lauren M Smith*[1], Erin M.R. Bigelow[1], Bonnie T Nolan[1], Meghan Faillace[2], Joseph H Nadeau[3], Karl Jepsen[1]. [1]University of Michigan, USA, [2]GE Inspection Technologies, USA, [3]Pacific Northwest Diabetes Reasearch Institute, USA

Identifying fracture susceptibility genes is important for the early diagnosis of at-risk individuals and for identifying novel treatment pathways. The complex adaptive nature of bone poses a significant challenge to identifying QTLs regulating bone strength, because genetic perturbations affecting one trait often lead to coordinated changes in other traits. If the coordination is adequate then strength is maintained despite altered bone traits. In contrast, QTLs or genetic perturbations that alter the system's ability to compensate are postulated to lead to reduced bone strength. Our goal is to identify these QTLs that impact bone strength by acting through the functional adaptation process. We phenotyped 16 week old male C57BL6/J – $Chr^{A/J}$ / NaJ, chromosome substitution strains (CSS), which is a panel of inbred strains where each B6 chromosome was replaced by an intact A/J chromosome. We examined 20 strains; 19 autosomal and the X substitutions (n>10/strain). Our prior work established a predictable pattern in the way cortical area (Ct.Ar) and tissue-mineral density (TMD) functionally covary relative to the natural variation in bone robustness (total area/bone length). Total area (Tt.Ar), Ct.Ar and TMD were analyzed for each strain using nanoCT (8μm). Whole bone stiffness, max load and post-yield deflection were assessed from 4-point bending tests. We identified 7 strains that showed no effect on strength, morphology or TMD (CSS-7, 9, 11, 13, 14, 16 and X); 6 strains with significantly ($p<0.05$ per GLM ANOVA, body size as a covariate) altered morphology and/or TMD but not altered strength (CSS-4, 5, 8, 17, 18 and 19); 5 strains with significantly altered morphology and/or TMD but with decreased strength (CSS-1, 2, 10, 12 and 15); and 2 stains with decreased strength but not altered morphology or TMD (CSS-3 and 6). The magnitude of the CSS with functional changes was significant, showing decreases in stiffness ranging from 14.1-26.6% and decreases in max load ranging from 9.9-16.9% compared to the B6 control. This systems analysis identified multiple biomechanical pathways linking genetic perturbations with altered bone strength. Thus, knowledge of how bone traits functionally interact may improve our ability to identify fracture susceptibility genes. These results caution against the indiscriminate use of single traits in GWAS, as genetic perturbations affecting one trait are often associated with coordinated changes in other traits to maintain strength.

The Effects of Age, Weight and Femoral Shape on Cortical Thickness and Mass of the Hip. Graham Treece*, Andrew Gee, Tom Turmezei, Kenneth Poole. University of Cambridge, United Kingdom

Several studies have linked local properties of the cortex, particularly thickness, to fracture risk (Johannesdottir, Bone 2011; Yang, JBMR 2012). It is also clear that bone strengthening drugs have localised effects on the femur (Poole, PLoS1 2011). Recent developments in image processing allow accurate estimates of cortical thickness down to 0.3mm (Treece, Med Image Anal 2010, 2012). However, interpretation of the resulting data requires an improved understanding of the effects of other covariates on such data.

In this study, we determine how a priori selected covariates are predictive of cortical thickness and mass. We have previously investigated the effect of age, weight and osteophytes (Turmezei, Insights Imaging 2013): here, the explanatory variables we examine are subject age and weight, and femur size and shape. We analysed QCT data from 268 women, aged 53 to 98 years and weight 40 to 103 kg, from two studies conducted at two sites. Combining studies in this manner increases the significance of the results, provided we allow for site as a confounding variable. After spatially aligning the cortical data onto a canonical model, we use statistical parametric mapping as implemented in the SurfStat package (Worsley, NeuroImage 2009) to analyse the results. The generalized linear model for cortical thickness or mass is 1 + age + weight + site + s1 + s2 + s3 + s4 + s5, where s1-s5 are the first five modes of shape variation derived from a statistical analysis of a much larger population. The results for age, weight and shape modes 1 (size) and 3 (head-neck angle) are shown in Figure 1.

Age (approx -1% per year) and weight (approx +0.5% per kg) are predictive of cortical properties over significant areas of the femur. There are also more localised effects associated with the shape modes. Observe how larger bones (mode 1) have thinner and lighter cortices: this might explain some of the process of causation by which taller people with larger femurs are more likely to fracture (Carballido-Gamio, JBMR 2013; Whitmarsh, Bone 2012). The results for modes 2–5 (not all shown) need interpreting with greater caution: they might not be caused by thickness and mass differences, but by misregistration in the spatial alignment, since such errors depend systematically on the individual's shape. The effects for mode 3 (head-neck angle) are more widespread and perhaps indicate a genuine reduction in the cortex with increasing head-neck angle.

The Effects of Disuse and Low Steroid Hormone Level due to Hindlimb Unloading on Mouse Femora and Muscle Quality. Young Jeong*[1], Andries Ferreira[2], Marybeth Brown[2], Charlotte Phillips[3]. [1]University of Missouri, USA, [2]Biomedical Sciences & Physical Therapy Program, USA, [3]University of Missouri-Columbia, USA

Low sex hormone levels due to trauma are hypothesized to contribute to the loss of muscle and bone mass and strength, which is further exacerbated by loss of activity with bed rest. Bone is inherently mechanosensitive, and muscles typically exert the largest physiological loads that bones experience; with bone strength being directly proportional to muscle mass and load. Recent meta-analyses demonstrated significant differences in muscle mass and strength between intact mice and mice that were ovarectomized (Ovx). To investigate the role of simulated bed rest [hindlimb unloading (HLU)] on bone and muscle strength, and sex hormone levels, we analyzed the impact of 4 weeks of HLU and 3 days re-ambulation on hindlimb muscle masses and strength, uterine weight, and bone geometry and strength in intact and Ovx+HLU mice and in Ovx mice with normal cage activity. Female mice were assigned randomly to 6 groups: age-matched normal cage activity (control), HLU, HLU+3days of re-ambulation, Ovx, Ovx+HLU, and Ovx+HLU+3days of re-ambulation. For each group, the mice were anesthetized and peak tetanic contraction of the hindlimb muscles (gastrocnemius, soleus, plantaris, and tibialis anterior) was determined prior to sacrifice, and the muscles were then excised and weighed. Right femora were then excised, cleaned of the remaining soft tissue, and femoral geometry analyzed by μCT prior to the evaluation of bone biomechanical and material properties by torsional loading to failure testing. In contrast to the Sham Ovx mice, the gastrocnemius, tibialis anterior, plantaris, and soleus muscles in Ovx mice exhibited atrophy and failed to recover after 3 days of re-ambulation following HLU. By μCT analyses the femora from HLU mice demonstrated decreased cortical bone width, and biomechanically they exhibited reduced whole bone ultimate breaking strength and energy to failure as compared to control mice. Ovx+HLU femurs exhibit similar femoral geometry as HLU alone with the further diminishment of bone biomechanical properties. In addition, HLU mice had decreased uterine weights suggesting decreased estrogen levels. Our findings suggest that 4 weeks of HLU causes loss of muscle mass, bone material and biomechanical integrity, due to inactivity and disuse, as well as the result of decreased estrogen (E2) levels. Decreased E2 levels negatively impacts bone quality and when combined with inactivity the loss of bone material and strength is further exasperated.

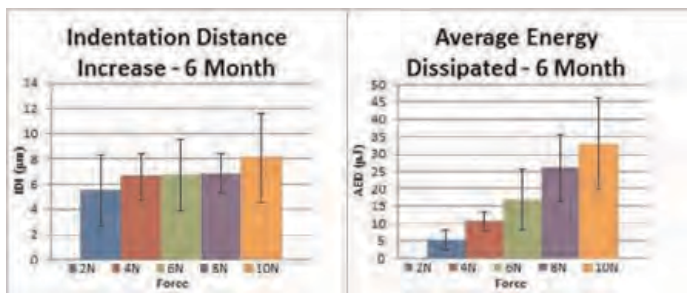
Towards Standardized Protocols for the Reference Point Indentation Method. Alexander Setters*[1], Iwona Jasiuk[2]. [1]University of Illinois, USA, [2]University of Illinois at Urbana-Champaign, USA

Reliable bone strength prediction is still an outstanding medical challenge. The novel reference point indentation (RPI) technique has a potential to directly measure bone properties in patients. In this work, we address several issues regarding sample preparation and testing parameters using 6 month swine femurs. We investigated the effect of radiation, polishing and force magnitude on indentation distance increase (IDI) and average energy dissipated (AED). To determine radiation's effect, we tested bone samples using a 6N force before and after being exposed to Micro-CT radiation. Eighteen indents were done for each quadrant with 10 of these on the transverse surface and 8 on the longitudinal surface. The difference between IDI and AED before and after being irradiated by Micro-CT was found to not be statistically significant ($p<0.05$). The effect of polishing was much more prevalent. The bone was indented in the same manner as for the radiation tests, but indentation was done on the longitudinal surface before and after polishing. The sample was cut in half after polishing the longitudinal surface to expose mating transverse surfaces. Measurements were also done on these surfaces and they were only tested polished, as this is the standard for nanoindentation. The effect of polishing on the longitudinal surface was found to be statistically significant ($p<0.05$). The values of IDI and AED were 2-3 times greater for the unpolished samples compared to the polished samples. The difference between the polished longitudinal surface and polished transverse surface was found to not be statistically significant ($p<0.05$). In force magnitude variation, we tested the bone with 2N, 4N, 6N, 8N and 10N forces. Ten indents were done per force on the unpolished longitudinal surface. The changes due to a linear increase of the force resulted in a linear increase in the AED. IDI showed large increases from 2N to 4N and from 8N to 10N, but was relatively constant between 4N and 8N (Figure 1). In summary, through these tests we aimed to standardize the testing procedure for this novel RPI technique. Further studies on the effects of different testing parameters and sample preparations are needed to provide a more standardized testing procedure that can be used for a wide range of bone ages, types and locations. Such analysis will facilitate basic research on this method, required before this technique's use in clinical settings.



Efect of force magnitude on IDI and AED

Trabecular bone Adaptation declined Asymmetrically with Aging: a 3D Dynamic *in vivo* Morphometry Study. Annette Birkhold*[1], Hajar Razi[1], Richard Weinkamer[2], Sara Checa[1], Georg Duda[1], Bettina Willie[3]. [1]Julius Wolff Institute, Charité Universitätsmedizin Berlin, Germany, [3]Max-Planck Institute of Colloids & Interfaces, Department of Biomaterials, Germany, [3]Charité-Universitätsmedizin Berlin, Germany

Bone adaptation to physical stimuli occurs by a balance between formation and resorption. It is known that mechanical loading shifts this balance towards increased bone formation. What is not known is how this response to loading changes with age. We hypothesized loading would increase formation and decrease resorption, but that this mechano-responsiveness would diminish with aging.

We measured structural adaptive changes of trabecular bone inside the tibia of living 10, 26, and 78 wk old female C57Bl/6J mice. Mice underwent 2 wks of in vivo cyclic loading (216 cycles/day; f = 4 Hz; εmax = 1200 με, right tibia as internal control) and *in vivo* microCT (10.5μm) at day 0, 5, 10, 15. The scan region began 50 μm below the growth plate (10% of tibia). Images were aligned using a registration algorithm. Differences between two consecutive microCT scans indicate where bone was resorbed or deposited in the time between the scans. Formation and resorption were then quantified by volume (fBV/tBV, rBV/tBV), surface area (fSA/tSA, rSA/tSA) and thickness/depth (fTh, rTh). Bone (re)modeling rates (3D-BFR, 3D-BRR, 3D-MAR, and 3D-MRR) were determined. An ANOVA assessed effects of loading, age, and interactions.

Mice of all ages had an anabolic response to loading. At day 15 the loaded limbs had (10wk: 145%, 26wk: 114%, 78wk: 67%) more fBV/tBV than control limbs and the rBV/tBV was reduced (10wk: 12%, 26wk: 21%, 78wk: 5%). Age influenced the bone formation response to loading, with differences in some parameters at day 5 (fBV/tBV, fSA/tSA, fTh; $p \leq 0.03$) and all parameters by day 15. Age influenced the bone resorption response to loading at day 5 (rBV/tBV, rSA/tSA, rTh $p < 0.007$), but no significant differences were measured at later time points, with only rBV/tBV ($p = 0.079$) and rSA/tSA ($p = 0.075$) approaching significance at day 15.Our study demonstrated that the adaptive capacity diminished with age, and that the time between loading and response became longer. While this is probably not unexpected, strikingly, adaptation was asymmetric. The bone formation response showed decreased surface area and thickness, while the bone resorptive response showed a trend of decreased surface area with aging, but a limited change in depth with aging. These structural data suggest reductions in adaptive capacity with age may be due to a lack of osteoblasts and osteoclasts and a reduced formation capacity, while resorptive capacity remains almost constant. This asymmetry further shifts the (re)modeling balance towards a net bone loss with age.

Validation of Mechanical Response Tissue Analysis by Quasistatic Mechanical Testing of Artificial Human Ulnas. Patricia Arnold*, Emily Ellerbrock, Lyn Bowman, Anne Loucks. Ohio University, USA

Osteoporosis is defined by NIH as a skeletal disorder characterized by compromised bone strength leading to increased risk of fracture, but no medical device measures bone strength directly *in vivo.* Bone stiffness is strongly associated with bone fracture load ($r \geqslant 0.95$), but no clinical method measures bone stiffness *in vivo,* either. Quasistatic Mechanical Testing (QMT) is the reference gold standard method for directly measuring the stiffness and strength of bones, but it can only be employed on excised bones and bone samples. Mechanical Response Tissue Analysis (MRTA) is a minimal-risk, non-invasive, radiation-free technique for directly measuring the bending stiffness of long bones *in vivo*. MRTA has been used for research purposes, but limited information about its measurement accuracy has been published. To begin to gather such information, this study quantified the precision, repeatability, and accuracy of MRTA measurements of bending stiffness in artificial human ulnas.

Standard and custom artificial human ulnas (N = 39) with -10% to +10% excess glass fill in the glass-epoxy composite emulating cortical bone were acquired from Pacific Research Laboratories/Sawbones, Vashon, WA. Ulna bending stiffness (K_b) was measured by MRTA and QMT in 3-point antero-posterior bending with proximal support by an articulating vertical Sawbones® humerus and distal support by the anterior distal radio-ulnar articular surface on a steel block. The load was applied at the mid-point of the posterior border. Precision and repeatability, respectively, were calculated without and with removal of ulnas from the humerus between repeated measures.

MRTA precision ($1.0 \pm 1.0\%$) and repeatability ($3.1 \pm 3.1\%$) were not as high as those of QMT ($0.2 \pm 0.2\%$ and $1.3 + 1.7\%$, both $p < 10^{-4}$), but regression analysis (Figure 1) found MRTA = 1.001 QMT ($R^2 = 0.999$). Bland-Altman analysis (Figure 2) showed that MRTA was unbiased (mean difference = $0.2 \pm 0.8\%$, $p = 0.67$) with respect to QMT, and individual MRTA and QMT measurements were interchangeable within limits of agreement of $\pm 5\%$.

In our hands, MRTA measurements of K_b in artificial human ulnas would be sufficiently precise, repeatable, and accurate for clinical purposes. If ongoing research finds that MRTA also achieves sufficient measurement performance in cadaveric human arms and ulnas, then MRTA may eventually prove useful for assessing, measuring bone stiffness, estimating peripheral bone strength and predicting fracture risk.

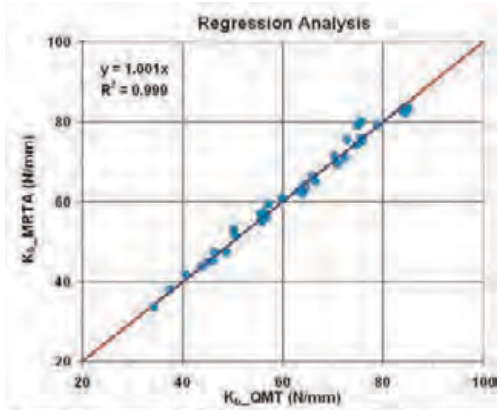

Figure 1. Regression of ulna transverse bending stiffness (K_b) measured by MRTA on paired measurements by QMT (N = 39). Red line = identity, Blue line = regression line y = 1.001x.

Figure 1– Regression Analysis

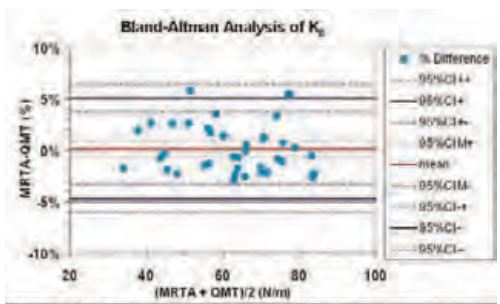

Figure 2. Bland-Altman analysis of paired measurements of K_b by MRTA and QMT in the same ulnas (N=39). CIM = confidence interval of the mean difference. CI = confidence interval of individual paired differences.

Intermittent PTH and Mechanical Loading Increase the Quality, Quantity and Mechanical Integrity of a Porous Titanium Implant-Bone Interface. Hayden-William Courtland*[1], Matthew Grosso[1], James Sutherland[1], Kirsten Stoner[1], BIN HU[2], Joseph Nguyen[1], Anna Fahlgren[1], F. Patrick Ross[1], Timothy Bromage[2], Marjolein Van Der Meulen[3], Mathias Bostrom[1]. [1]Hospital for Special Surgery, USA, [2]New York University College of Dentistry, USA, [3]Cornell University, USA

A strong bone-implant interface is essential for successful joint replacement surgery. This study investigated the differences in bone surrounding and within a porous titanium implant after single or combined treatment with two anabolic bone therapies: intermittent parathyroid hormone (teriparatide) and mechanical loading. Porous titanium implants were inserted bilaterally on the distal lateral femurs of rabbits. The right implant was loaded daily (1 MPa, 50 cycles/day) while the left implant was not. Rabbits received daily PTH injections (20 ug/kg) or saline vehicle. Periprosthetic cancellous bone 0.5, 1.0, and 2.0 mm below the implant surface, bone at the 0.25 mm bone-implant interface and total bone within each implant were examined using tissue-level analyses (quantitative backscattered electron microscopy), cellular analyses (immunohistochemistry staining of osteoblasts with procollagen-1 and TRAP staining of osteoclasts), and shear testing (implant-bone interface). Statistical significance was determined using GEE models ($p<0.05$). For tissue located 0.5 mm below the implant, significant increases in bone area per total area (BA/TA) were observed with PTH treatment (56%) and with loading (27%). Further, an 18% increase in mineralization density with PTH treatment and a 20% increase in mineralization density with loading was found. Loading effects were not present beyond the 0.5 mm periprosthetic region, but PTH significantly increased BA/TA 2.0 mm below the implant and mineralization density 1.0 mm below the implant. Tissue-level changes were supported by increases in osteoblast activity 0.5 mm below the implant with PTH (79%) and loading (34%), as well as by minimal osteoclast changes. At the 0.25 mm implant-bone interface PTH and loading increased BA/TA (16% and 23%, respectively), but only loading increased mineralization density (7%). Further, total integrated bone area was increased 35% with PTH. Both PTH and loading enhanced the mechanical integrity of the implant-bone; shear strength increased 34% and 60%, respectively. Although combined treatment was not synergistic, both PTH and loading individually enhanced the amount and mineralization density of bone at the implant interface and immediately below the interface, thereby increasing the mechanical strength of the metal-bone interface. This research suggests that modulation of both quantity and quality of peri-implant bone may be viable options to improve implant fixation and patient outcomes.

Mechanical Loading And Big Endothelin-1 In Trabecular Bone Cores. Diane Cullen*[1], Gwendolin Alvarez[1], Luisa Meyer[2], Michael Johnson[3], Juan Vivanco[3], Robert Blank[3], Heidi-Lynn Ploeg[3], Everett Smith[3]. [1]Creighton University, USA, [2]University of Wisconsin - Madison, USA, [3]University of Wisconsin, USA

Mechanical loads are anabolic stimuli for bone, increasing formation and strength in adaptation to the stresses. Endothelin-1 (ET1), a ubiquitous autocrine/paracrine signaling molecule promotes osteogenesis associated with breast and prostate cancer. In this ex vivo study we combined both anabolic stimuli and hypothesized that bone formation would increase synergistically. Bovine sternal trabecular bone cores (5x10mm) were maintained in individual polycarbonate chambers with media changed daily over 23 days. Cores were placed into four groups blocked by stiffness and treated daily with compressive loading (-2000 με, 120 cyc, 2 Hz) and/or big ET-1 (25 ng/mL). Bone formation was labeled in culture with calcein on days 9 and 19. Bone stiffness and prostaglandin production was measured throughout the experiment. After collection cores were embedded in methylmethacrylate and sectioned for histomorphometric measurement of bone area, surface, label length, and label width. Differences among groups were analyzed by 2-way ANOVA for the effects of Load x Endothelin. There was no difference among groups in bone volume (BV/TV) of the cores. Due to the long labeling interval, single label predominated over double. Load cores had 50% more single label bone surface (sLS/BS) than NoLoad cores. Mineral apposition rate (MAR) showed a stair step pattern with a positive Load impact ($P=0.007$) and ET-1 showing a positive trend ($P=0.16$). Bone formation rate (BFR), a product of label length and MAR, was twofold greater in Load than NoLoad ($P=0.009$), but not altered by ET-1 although the same pattern was observed. There was no significant interaction between Load and ET-1. The bone formation response to Load and ET-1 correlate with the change in stiffness across the experiment. In conclusion, ex vivo mechanical loads increased bone formation and stiffness of the cores. ET-1 response in this study was less than predicted from previous work. The combined effects tended to be additive rather than synergistic.

Mechanical Stimulation Induces the Production of Soluble RANKL to Modulate Osteogenesis of Mesenchymal Stromal Cells. Chun-Yi Chiu[1], Tsung-Lin Tsai[1], Ray Vanderby[1], Gino Bradica[2], Shyh-Liang Lou[3], Wan-Ju Li*[1]. [1]University of Wisconsin-Madison, USA, [2]Kenseynash, USA, [3]Chung-Yuan Christian University, Taiwan

Introduction: During bone formation or remodeling, mesenchymal stromal cells (MSCs) receive mechanical signals along with chemical cues to differentiate into osteoblasts and produce bone matrix. However, the biological mechanism underlying mechanically-induced osteogenesis is not clear. In addition, it has not been reported that whether sequential compressive stimulation (CS) and ultrasonic stimulation (US) can enhance MSC osteogenesis compared to CS or US alone. In this study, we aimed to compare osteogenesis of MSCs stimulated by CS and/or US, and hypothesized that soluble receptor activator of nuclear factor kappa-B ligand (RANKL) and/or osteoprotegerin (OPG) secreted from MSCs by mechanical stimulation regulate osteogenesis of MSCs.

Materials and Methods: Human MSCs (hMSCs) cultured in β-tracalcium phosphate/polylactide scaffolds were treated with optimized CS for 60 minutes and/or US for 20 minutes daily for 16 days (Fig. 1A). The mRNA expression of bone-related markers, alkaline phosphate (ALP) activity, calcium deposition of specimens were analyzed to determine osteogenic differentiation. ELISA was used to detect soluble RANKL and OPG in culture. The activity of soluble RANKL or OPG was attenuated by neutralizing antibody during mechanically-stimulated osteogenesis to determine their regulatory roles. One-way ANOVA with Holm-Sidak post hoc was performed to determine statistical significance among the experimental groups.

Results: Real-time PCR results showed that the mRNA levels of bone-related markers, including core-binding factor subunit alpha1 (CBFA1), activating transcription factor4, ALP (Fig. 1B), osteocalcium, RANKL, and OPG, of hMSCs stimulated by US were the highest among all the experimental groups. In addition, hMSCs receiving mechanical stimulation produced significantly more soluble RANKL than those in the control culture without mechanical stimulation (Fig. 1C). On the other hand, hMSCs produced comparable levels of soluble OPG in culture among the groups with and without mechanical stimulation. Attenuating the activity of soluble RANKL in the culture treated with US during osteogenesis significantly down-regulated the mRNA expression of CBFA1, osterix, ALP (Fig. 1D), and OPG, suggesting that US modulates hMSC osteogenesis through the activity of soluble RANKL.

Conclusions: US is potent mechanical stimulation for enhancing hMSC osteogenesis. Soluble RANKL induced by US modulates osteogenesis of hMSCs.

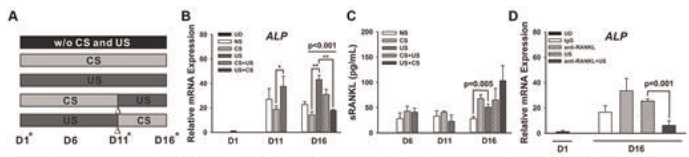

Figure 1. (A) Experimental setup of mechanical stimulations. (B) mRNA expression of ALP of hMSCs receving different mechancial stimuation during osteogenesis. (C) Production of soluble RANKL in culture treated with different mechanical stimulations. NS: no stimulation. (D) mRNA expression of ALP of hMSCs treated with or without US and with or without RANKL neturalizing antibody during osteogenesis. UD: undifferetiated.

Mechanosensitivity with cyclic loading is maintained with age at a localand global level in murine caudal vertebrae. Floor Lambers*[1], Gisela Kuhn[2], Claudia Weigt[2], Kathleen Koch[2], Friederike Schulte[2], Ralph Müller[2]. [1]Cornell University, USA, [2]Institute for Biomechanics, ETH Zurich, Switzerland

Mechanosensitivity can be described as the ability of bone to respond to mechanical signals. While an increase in bone mass and bone strength with *in vivo* mechanical loading in animals has often been reported at a global level, little is known about the local bone remodeling response at the bone surface. The aim of this study was to determine the local and global mechanosensitivity of the sixth caudal vertebra after cyclic loading in mice aged 15, 52, and 82 weeks.

The sixth caudal vertebra was cyclically loaded by a force of 8N (10 Hz, 3000 cycles, three times per week for six weeks) through pins in the adjacent vertebrae for the loaded groups. Control mice were anesthetized, but no loading was applied. The bone microstructure was monitored longitudinally with *in vivo* micro-computed tomography (10.5 μm voxel size). By overlaying time-lapsed scans, three-dimensional bone remodeling rates were determined (Fig. 1a), as validated previously [1]. Scans were converted to micro-finite-element models to determine bone stiffness and the mechanical environment at surfaces where bone formation, bone resorption, or no bone remodeling followed (Fig. 1b), using strain energy density (SED) as the mechanical signal assumed to be a stimulus for bone adaptation.

Mechanical loading had beneficial effects at the global bone level in all age groups. The increase in bone volume fraction was 20% and 18% greater ($p<0.05$) in loaded than control group in 15- and 82-week-old mice, respectively. In 52-week-old mice, the greatest effect of loading on the bone microstructure was observed in the cortical bone, in which the cortical thickness decreased for the control group ($p<0.05$), but not for the loaded group. Mineralizing surface was on average 13% greater ($p<0.05$) in loaded than control groups in 15- and 82-week-old mice. Mechanical loading had a beneficial effect on bone stiffness in 52- and 82-week-old mice ($p<0.05$). SED predicted the change in bone volume fraction for loaded groups (R = 0.83-0.92), but not control groups (Fig. 2). At the local level, SED was 14%-20% greater at sites of bone formation, and 15%-20% lower at sites of bone resorption than at quiescent bone surfaces for all age groups, indicating that SED was a stimulus for bone adaptation (Fig. 3). Taken together, these results support that mechanosensitivity is maintained with age in caudal vertebrae of mice at a local and global level.

Wnt16 Is an Important Regulator of Bone Size and the Periosteal Bone Formation Response to Mechanical Loading. Chandrasekhar Kesavan*[1], Subburaman Mohan[1], Robert Brommage[2], Jon Wergedal[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]Lexicon Pharmaceuticals, USA

Compromised bone strength leads to increased risk of fracture with bone size and BMD key determinants of bone strength. Human GWAS studies in several populations identifying a chromosomal locus containing the Wnt16 gene contributing to BMD variations and the finding that mice with targeted Wnt16 gene disruption have reduced bone strength both suggest that Wnt16 is an important regulator of bone strength. Reduced bone strength in Wnt16 knockout (KO) mice is caused by a 30% reduction in femur cross-sectional area and 24% reduction in cortical thickness compared to littermate wild type (WT) mice. Histomorphometric studies revealed that periosteal bone formation (BFR) and mineral apposition (MAR) rates were reduced ($P<0.05$) by 55% and 32%, respectively, in Wnt16 KO vs WT mice at 12 weeks of age. In contrast, TRAP labeled surface at the periosteum was not different between the two genotypes. *In vitro* studies using periosteal cells derived from Wnt16 KO and WT mice revealed reduced proliferation potential is the cause for reduced BF and bone size in Wnt16 KO mice. To determine the mechanism for Wnt16 effects, RNA was extracted from periosteal tissue of Wnt16 KO and WT mice at 5 weeks of age for measurement of expression levels of canonical and non-canonical Wnt signaling genes by RT-PCR. Significant 30-60% reductions in the expression levels of canonical (β-catenin, Axin2, c-myc) but not non-canonical (Nfatc1, Tnnt2) signaling genes were seen in the KO mice compared to WT mice. Since mechanical strain is an important physiological regulator of periosteal BF, we next tested if mechanical loading-induced periosteal BF is compromised in Wnt16 KO mice. Application of 9N and 6N forces producing 4800 με strain to the right tibia using a four-point bending loading method for 2 weeks (6 days/week) at 2 Hz frequency, for 36 cycles per day produced significant increases ($P<0.05$, n=6) in total volume (11%), BV/TV (6%) and cortical thickness (12%) of loaded compared to externally unloaded left tibia bones in the WT but not in KO mice (<1.2% change vs unloaded tibia). Histomorphometric analyses revealed increases in periosteal BFR and MAR in the loaded bones of WT but not KO mice. In conclusion, 1) Wnt16 is a major regulator of long bone cross sectional size by affecting periosteal BF and not resorption. 2) Wnt16 acts through the canonical Wnt signaling pathway. 3) Wnt16 is critical for translating the mechanical loading signal into an anabolic response at the periosteum.

Atypical Femoral Fractures were Estimated Dependent on Deterioration of Bone Quality and Curvature of Femoral Shaft. SATOSHI IKEDA*[1], Akinori Sakai[2], Hidetoshi Tanaka[1], Hideo Ohnishi[2], Yoshinori Takeuchi[2], Mitsuru Saito[3], Masako Ito[4], Toshitaka Nakamura[2]. [1]Ken-Ai Memorial Hospital, Japan, [2]University of Occupational & Environmental Health, Japan, [3]Jikei University School of Medicine, Japan, [4]Nagasaki University Hospital, Japan

Introduction: Atypical femoral fracture focused on relation of bisphosphonate use, frequently. However, the mechanism of atypical femoral fracture was not yet clarified. Atypical femoral fractures have been kept femoral shaft cortical thickness and BMD, practically. We hypothesized that atypical femoral fractures were dependent on impaired bone quality and curvature of femoral shaft.

Material & Methods: We experienced four atypical femoral fractures. One was subtrochanteric and three were shaft fracture. Two cases received bisphosphonate therapy for 3-5 years. BMD, bone metabolic markers, and bone quality markers values were obtained. Histomorphometry and collagen cross-link analysis were performed. Curvature of femoral shaft and 3-D finite element analysis in one incomplete fracture case were assessed.

RESULTS: BMD values were either maintained or not severe decreased. Deterioration of bone quality were verified that result of histomorphometry, collagen cross-link analysis, and bone quality maker. Especially, homocystine values, such as one of bone quality markers, were increased all cases. All atypical femoral shaft fractures showed outward curvature of femoral bone. One incomplete atypical femoral shaft fracture, stress was concentrated at the fracture region by 3-D finite element analysis.

CONCLUSIONS: The results of this study suggest that atypical femoral fractures were estimated dependent on deterioration of bone quality and curvature of femoral shaft.

BMI Has a Positive Non-Linear Association with Femoral Neck BMD and Structure But a Negative Linear Association with Strength Index in a Large Canadian Cohort. Jian Shen*[1], Carrie Nielson[1], Eric Orwoll[1], Sumit Majumdar[2], William Leslie[3]. [1]Oregon Health & Science University, USA, [2]University of Alberta, Canada, [3]University of Manitoba, Canada

Emerging evidence indicates that fractures in obese individuals are of public health importance and that the relationship between obesity and fracture is complex and poorly understood. We previously reported that the relationship of BMI with hip structural and densitometric measures was non-linear in older US men. We sought to confirm these findings and extend them to women.

Using data from the Manitoba Bone Density Program, we conducted cross-sectional analyses of baseline BMI and DXA-derived measures of femoral density and structure in all women and men age ⩾ 50 y referred for DXA scan. Advanced Hip Analysis software (enCore version 13.6, GE Healthcare) was used to derive hip structural parameters including cross-sectional moment of inertia (CSMI) and cross-sectional area (CSA). Femoral strength index (SI) was calculated as the ratio of the compressive yield strength of the femoral neck to the expected compressive stress of a fall on the greater trochanter. We used both ANCOVA and generalized additive models (cubic splines with 4 df) to identify nonlinearity in the associations between BMI and hip structural parameters after adjustment for osteoporosis treatments and other relevant covariates.

Hip DXA scans were analyzed in 41,919 women (mean age: 66 y, 24.9% obese) and 4085 men (mean age: 69y, 22.4% obese). In both women and men, higher BMI was independently correlated with greater areal BMD, CSMI and CSA at the femoral neck. However, these relationships were non-linear (all P for nonlinearity <0.0001). Among individuals with BMI < 30 kg/m^2, increasing BMI was associated with progressive increases in BMD, CSMI and CSA (Table). However, the relationship appeared to reach a plateau at BMIs of 30 kg/m^2, with little additional increment in the structural parameters with further increases in BMI (all P for interaction <0.0001, obese versus non-obese). Furthermore, increasing BMI was associated with decreases in SI, and the association was linear in men and near-linear in women.

In this large Canadian cohort we confirmed that the relationships of BMI with femoral BMD and structure are nonlinear in men and we have now extended this finding to women. The positive association of BMI on hip BMD and structure is not sustained as BMI increases in the obese. Moreover, femoral strength index declines in linear fashion as BMI increases in both sexes. These results provide some mechanistic insight into fracture risk in the obese.

Table. The association between BMI and femoral neck structural measures stratified by obesity status and adjusted for relevant covariates

	BMI< 30 kg/m^2		BMI >=30 kg/m^2		Obese vs Non-obese

Bone Shock Absorbance (BSA) and Trabecular Bone Score (TBS) in Patients With Osteoporosis, With and Without Vertebral Fracture. Nelson Watts*[1], Didier Hans[2], Cyndy Cox[3], Ben House[3], Rakesh Shukla[3], Alok Dwivedi[4], Amit Bhattacharya[3]. [1]Mercy Health Osteoporosis & Bone Health Services, USA, [2]Lausanne University Hospital, Switzerland, [3]University of Cincinnati, USA, [4]Texas Tech University Health Sciences Center, USA

Purpose: To evaluate the performance of trabecular bone score (TBS) compared with bone shock absorbance (BSA) and dual-energy x-ray absorptiometry (DXA) in determining the presence of vertebral fractures in postmenopausal women with osteoporosis.

Background: Bone shock absorbance (BSA) and trabecular bone score (TBS) are noninvasive and novel tests of "bone quality." We previously showed that BSA was a better discriminator of the presence of vertebral fracture than DXA in a cohort of 67 postmenopausal women with osteoporosis (28 with vertebral fracture) (Bhattacharya et al, J Clin Densitom 2010). BSA is a dynamic, non-invasive measure of bone damping capacity using skin-mounted accelerometers at load-bearing skeletal sites. TBS is a gray-level texture measurement that is applicable to DXA.

Methods: We recruited women ages 65-86 who had T-scores of -2.5 or below in the hip or spine. Presence or absence of vertebral fracture was determined by lateral spine radiographs or Vertebral Fracture assessment using DXA. BSA was measured using previously reported methods. TBS was determined from spine DXA parameters.

Results: We studied 67 women, age 71 ± 4.2, height 162 ± 6.6 cm, weight 74 ± 16.0 kg, BMI 28 ± 5.1. Spine BMD was 0.989 ± 0.218 g/cm2 (T-score -0.5); 28 had vertebral fractures and 39 had no vertebral fractures. BSA damping value was significantly lower in patients with vertebral fractures compared with those without fracture (median -44$, range -35% to -72%). TBS was 1.281 ± 0.877. There was no significant correlation between TBS and spine BMD. Further analyses comparing TBS and BSA are ongoing and will be presented.

Conclusions: Both BSA and TBS provide additional information, over and above that obtained with DXA, to distinguish patients with vertebral fractures from those without. Further investigation is warranted to see how these measures, alone or in combination provide useful clinical information for assessment of future fracture risk.

Physical Activity Related to Cortical but Not Trabecular Architecture in Young Women. Joseph Kindler*[1], Hannah Goff[1], Emma Laing[1], Christopher Modlesky[2], Norman Pollock[3], Clifton Baile[1], Richard Lewis[1]. [1]The University of Georgia, USA, [2]University of Delaware, USA, [3]Georgia Regents University, USA

The purpose of this study was to determine relationships between three physical activity questionnaires and both magnetic resonance imaging (MRI)-derived measures of trabecular and cortical bone and dual energy X-ray absorptiometry (DXA)-derived areal bone mineral density (aBMD) in 18-19 year old white females (N=24). Participants completed three physical activity questionnaires at one testing visit; two bone-specific (the bone loading history questionnaire [BLHQ] and the bone-specific physical activity questionnaire [BPAQ]) and one non-bone-specific (the 7-day physical activity recall questionnaire [7-day PAR]). Bone loading scores were calculated through completion of the BLHQ and BPAQ, and energy expenditure was calculated through completion of the 7-day PAR. Trabecular and cortical bone were measured via MRI at the non-dominant tibia and radius, and aBMD of the total body, lumbar spine, femur, femoral neck, trochanter, and radius via DXA. Hip BLHQ and past BPAQ scores were positively associated with cortical volume at the mid-tibia (r=0.43 and 0.62, respectively; p<.05). Past BPAQ scores correlated positively with mid-tibia polar moment of inertia (J), section modulus (Z), and cross sectional moment of inertia (CSMI) (r=0.56; p<.02) and aBMD (r=0.45-0.63; p<.03 for all measured sites). Energy expenditure negatively correlated with mid-radius J, Z, and CSMI (r=-0.42 to -0.43; p<.05). While previous studies report positive relationships between BLHQ and BPAQ scores with calcaneal broadband ultrasound attenuation and aBMD in adults, this was the first study to observe a relationship with MRI-derived outcomes. The greater number of associations of BPAQ scores with weight-bearing bone outcomes versus BLHQ scores or energy expenditure shows that the BPAQ is a superior tool for assessing weight-bearing physical activity in bone studies involving young adult females.

Presence Of Adrenal Incidentaloma induces Bone micro-architectural texture (TBS) impairment at Axial Skeleton in women. Giuseppe Guglielmi[1], Michelangelo Nasuto[2], Alfredo Scillitani*[3], Renaud Winzenrieth[4], Didier Hans[5]. [1]Department of Radiology, University of Foggia, Viale Luigi Pinto 1, 71100, Foggia, Italy; - Department of Radiology, Scientific Institute Hospital "Casa Sollievo della Sofferenza", Viale Cappuccini 1, 71013, San Giovanni Rotondo (FG), Italy, [2]Department of Radiology, University of Foggia, Viale Luigi Pinto 1, 71100, Foggia, Italy, [3]Casa Sollievo Della Sofferenza Scientific Institute, Italy, [4]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, [5]Lausanne University Hospital, Switzerland

RATIONAL: Adrenal Incidentaloma (AI) could induce subclinical hypercortilism (SH). This cortisol excess is associated with a bone mass alteration and a fracture risk increasing. Effects of AI and SH on bone microarchitecture in human axial skeleton have been few evaluated to date. In this study, we have evaluated the impact of AI on both bone mineral density (BMD) and bone micro-architectural texture, as assessed by TBS.

METHODS: Fourty-one caucasian italian women (mean age = 60.614.1years) with unilateral incidentaloma were recruited. Presence of hypogonadism and hypercortisolism was confirmed using at least two out of three following parameters: urinary free cortisol >70µg/die, plasma ACTH <10 pg/ml or serum cortisol >3µg/dl at 9.00 am after 1 mg dexamethasone overnight. BMD was evaluated at lumbar spine (LS) using a Hologic QDR 4500 device as well as at femur (total and neck). TBS was evaluated at lumbar spine on the same region of interest used for the LS-BMD using TBS iNsight software v1.9.2 (Med-Imaps, France).

RESULTS: Mean values of lumbar and femoral (total) T-score were -1.49 and -0.65, respectively, whereas corresponding Z-score values where normal (0.03 and 0.46, respectively). Among AI subjects, 24% were osteoporotic, 80% have hypogonadism (Hy) and 27% suffering from SH. Whatever the LS-BMD stratification, TBS is significantly lower in AI patient in comparison with Age-matched TBS reference (TBSref) values (p<0.002) while no differences were obtained for LS-BMD. Hy subjects have a significant lower LS-BMD and TBS (p<0.001). Furthermore, TBS values of these subjects was lower in comparison with TBSref values (p<.0001) whereas no differences have been obtained for LS-BMD and LS-BMD reference values (p>0.80). Finally, TBS value of SH subjects was lower in comparison with TBSref values (p<0.001).CONCLUSION: Our study showed a micro-architectural texture impairment due to AI whereas no effect has been obtained on LS-BMD. Both Hypogonadism and hypercortisolism have a negative effect on micro-architectural texture. These results suggest that the micro-architectural texture alteration at axial skeleton have to be assessed and take into account for the management of patient with adrenal incidentaloma.

Relationship between Bone Marrow Edema and Structural Parameters in Cortical and Trabecular Bone. Afrodite Zendeli*[1], Christian Muschitz[2], Lukas Fischer[3], Roland Kocijan[4], Judith Haschka[4], Wolfgang Schima[5], Fritz Lomoschitz[5], Arastoo Rahbarnia[1], Christina Marterer[1], Alexandra Kaider[6], Heinrich Resch[7]. [1]The VINFORCE Study Group - St. Vincent Hospital - Medical Department II, Austria, [2]St. Vincent's Hospital, Austria, [3]CIR LAB, Department of Radiology/Medical University Vienna Austria, Austria, [4]St. Vincent Hospital Vienna, Austria, [5]Medical Department of Radiology – St. Vincent Hospital, Vienna Austria, Austria, [6]Center for Medical Statistics, Informatics & Intelligent Systems, Section of Clinical Biometrics, Medical University of Vienna, Austria, [7]Medical University Vienna, Austria

Background:Bone marrow edema (BME) is a localised painful bone lesion, often caused by an insufficiency fracture due to moderate mechanical strain. Evidence for BME is effectively provided by MRI. We hypothesize that structural bone alterations increase the susceptibility to the development of a non-traumatic BME. The aim of this pilot study was to investigate bone micro structure, areal and volumetric bone mineral density (aBMD and vBMD), and serum BTM values in patients with non-traumatic BME of the lower limb.Methods:We consecutively investigated 26 treatment naive, otherwise healthy female and male subjects (38.4 ± 16.8 ys) with MRI diagnosed non-traumatic BME of the lower limb. We calculated structural parameters of cortical and trabecular compartments in the tibia (T) and radius (R) The data were compared to a control group consisting of 50 sex and age matched healthy individuals (HC) (39.9 ± 13.7 ys). In 3 patients BME was found in the hip, in 9 in the tibia/knee and in 14 patients in the foot/ankle region. HR-QCT and MRI showed in 6 out of 17 patients micro-fractures adjacent to the BME.HR-pQCT (Scanco Medical) analysis of the healthy contralateral distal tibia and radius as well as DXA measurements (GE Lunar iDXA) of spine and hip, and serum fasting BTM were carried out in all subjects. Results:BMD values were similar in both groups, as well as bone turnover markers, 25-OH-vit-D-levels were in all subjects above 30 ng/ml. Structural analysis by HR-pQCT revealed significant differences both for radius and tibia. BME compared to HC had decreased CtBMD [mgHA/cm^3] (R: 909.7±124.8 vs 1001.4±39.1; T: 891.9±74.7 vs 953.1±76.8) and decreased CtTMD [mgHA/cm^3] (R: 963.1±61.8 vs 1022.3±33.1; T: 975.3±46.1 vs 1014±46.1). CtPo [%] was increased in BME (R*: 4.3±0.1 vs 1.5±0.01; T: 6.7±0.04 vs 4.7±0.03), as well as CtPoV [mm^3] (R: 28.5±97.9 vs 7.1±5.7; T: 62.3±32.9 vs 40.7±22.6), EndoCtPm [mm] (R: 680.4±107.5 vs 569.5±65.5; T: 973.9±115.9 vs 836.3±85.5) and TrabArea [mm^2] (R: 277.8±92.7 vs 213.0±57.4; T: 684.3±200.7 vs 571.8±136.4) - p ≤ 0.01 for all values; * p=0.02.In the BME CtTh [mm] was significantly lower in the radius (p=0.003) and trend-wise in the tibia (p=0.06).Conclusion:Our data clearly show a ubiquitous structural alteration of cortical bone parameters and trabecular area measured by HR-pQCT. This systemic structural deficit could enhance a subject's susceptibility to suffer from a BME caused by a local insufficiency fracture due to moderate strain.

Sub-compartmental Bone Morphometry Analysis in Longitudinal HRpQCT Scans with Application to Chronic Kidney Disease. Matthew DiFranco*[1], Lukas Fischer[1], Alexander Valentinitsch[1], Franz Kainberger[1], Georg Langs[1], Janina Patsch[1], Thomas Nickolas[2]. [1]Medical University of Vienna, Austria, [2]Columbia University College of Physicians & Surgeons, USA

High resolution peripheral quantitative CT (HRpQCT, resolution 82 μm) measures true volumetric bone mineral density of the distal extremities and enables analysis of longitudinal microarchitectural changes. However, these changes may be difficult to quantify. They may be dependent on image registration and their clinical interpretation may be difficult due to disease and treatment specific effects. In order to overcome limitations of autosegmentation, we determined whether HRpQCT can detect sub-compartmental volumetric changes in mineralized bone in patients with known loss of cortical bone. We imaged 8 chronic kidney disease (CKD) patients at baseline and 1-year and applied a spatio-temporal morphometry (STM) method to longitudinal HRpQCT scans. We hypothesized that STM would detect mineralization changes specific to bone loss in CKD patients.

Baseline and follow-up scans were rigidly registered using adaptive stochastic gradient descent on a sum of squared voxel differences cost function. Optical flow was then applied to produce a deformation vector at each voxel to represent local volumetric changes of mineralized bone between the two scans. Per-voxel volume change was then quantified as the determinant, J(x), of the Jacobian matrix of a local deformation field centered on the target voxel (x). Values of $J(x) > 1$ indicate local expansion, values of $J(x) < 1$ indicate local shrinkage, and $J(x) = 1$ indicates no volume change. Using the distance of each voxel from the periosteum in conjunction with the values of J(x) at each voxel, we calculated the mean J(x) of mineralized bone within incremental and cumulative distance ranges measured from the periosteum and plotted the results against distance.

Between baseline and follow-up, mean±SD% loss in cortical density was 4.1±4.5% and thickness was 4.1±4.5%. There were no changes in trabecular density and microarchitecture. Our method detected volume loss concentrated in regions between 10% and 20% distance from the periosteum, corresponding to the endocortex. Inner trabecular results suggested negligible to slight expansion of trabecular structures.

In summary, we demonstrated a novel method for calculating sub-compartmental volumetric changes in longitudinal HRpQCT scans that may assess disease-specific mineralization changes. Larger studies are needed in patients with different disorders of bone metabolism to determine disease specific changes to sub-compartmental volume alterations.

Towards Hip Fracture Prediction using Finite Element analysis and Machine Learning. Samy Missoum*[1], Peng Jiang[2], Chengcheng Hu[3], Pei-Shan Hsieh[4], Zhao Chen[5]. [1]University of Arizona Aerospace-Mechanical Engineering, USA, [2]University of Arizona Mechanical Engineering, USA, [3]University of Arizona Mel & Enid Zuckerman College of Public Health Epidemiology & Biostatistics, USA, [4]University of Arizona, USA, [5]University of Arizona College of Public Health, USA

Background: Almost 50% of US women aged 50 or older experience a hip fracture in their remaining life. Therefore, the prediction of hip fracture has become of prime importance. Different statistical models based on clinical data are currently available. However, the number of factors and the complexity of the phenomenon require further research to refine the prediction of these models.

Methods: This study proposes to use the modeling of femoral hip fractures using finite element analysis for the construction of a hip fracture model. The computational data would come as a complement to existing clinical data. The finite element model, which is fully parameterized, enables the creation of a large number of cases representative of a large cohort of patients. In order to extract a risk model from the data, a machine learning technique, known as support vector machine (SVM), is used. SVM can capture highly nonlinear relation between the factors involved in hip fracture. The risk model based on SVM is compared to the traditional logistic model. We performed the study based on computational data only, thus allowing us to obtain reference metrics since the ''true'' model is known.

Conclusions: The fully parameterized model and the use of SVM have the potential to markedly contribute to the refinement of hip fracture models. In addition, the use of a mechanically oriented model provides an essential insight into the importance of the geometric characteristics of the femur.

Comparison of US and French TBS normative data. Christine Simonelli*[1], Edward Leib[2], E Mossman[3], Remy Dufour[4], Alain Heraud[5], Renaud Winzenrieth[6], Michael McClung[3], Didier Hans[7]. [1]HealthEast Osteoporosis Care, USA, [2]University of Vermont, USA, [3]Oregon Osteoporosis Center, USA, [4]Institut Sainte Catherine, France, [5]Rhumatologie, Centre hospitalier Robert Boulin, France, [6]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [7]Lausanne University Hospital, Switzerland

Introduction: The Trabecular Bone Score (TBS, Med-Imaps, France) is an index of the trabecular bone texture, computed on antero-posterior lumbar spine DXA scans. To use TBS in clinical routine, we need to know the age-related evolution of the lumbar vertebrae trabecular texture. We have studied these trabecular texture changes at spine L1-L4 lumbar vertebrae of two cohorts of US and French Caucasian women.

Methods: Subjects were US and French white women aged 45 and older. All data have been obtained from Prodigy DXA devices (GE-Lunar, Madison, WI, USA). In US, three geographically spread off centers were used whereas two centers were used in France. Cross-calibrations between centers, for each country, were performed for both TBS and BMD. BMD and TBS were evaluated at spine L1-L4 and for others vertebrae combinations. Validation of the two cohorts was done by comparing BMD normative data of our cohorts with US or French Caucasian Lunar data provided by the manufacturer. Creation of these cohorts was done using two different approaches: a classical approach using 'healthy' subjects for the US curve and an all comers approach for the French curve.

Results: The two cohorts were composed of512 'healthy' and 5942 'all-comers' Caucasian women for the US and French curve respectively. BMD normative data obtained from these cohort were not statistically different from the US or French Caucasian Lunar normative data ($p>0.15$). In both cohorts, poor correlations have been obtained between L1-L4 TBS and BMI ($r=-0.17$) or weight ($-0.14<r<=-0.16$) while no correlation has been obtained with height. TBS values decreased significantly with age in both cohorts. There was a piecewise linear decline of -2.53 and -2.58 TBS T-score between 45 and 90 years of age (vs.-2.38 and -2.32 for BMD T-score) for the US and the French cohort respectively at L1-L4. In both cohorts, trabecular texture loss rate are exactly similar. After the age of 65 years, loss was accelerated (-0.004 to -0.006 per year) at L1-L4. Both cohorts are similar ($r^2>0.99$).

Conclusion: L1-L4 TBS, which reflects trabecular texture of the lumbar spine, decreases with age. Both the overall decline and rate per year are similar in the US and French cohorts. These results suggest that age-related changes in trabecular bone texture, as evaluated by TBS, are similar for Caucasian women, independently of the country.

Strontium Ranelate Treatment Improves Bone Material Level Properties and Microarchitecture of Human Transiliac Bone Biopsy Specimens. Patrick Ammann*[1], Rene Rizzoli[2]. [1]Division of Bone Diseases, Che, [2]Geneva University Hospitals & Faculty of Medicine, Switzerland

Bone strength, hence fracture risk, is dependent on bone geometry, microstructure and bone material level properties. We previously reported that microstructure and material level properties contribute independently to the increase in bone strength of rats treated with strontium ranelate for 2 years, as evaluated by μCT-based Finite Element analysis. We investigated the effects of strontium ranelate (SrRan) treatment on bone material level properties of transiliac bone biopsy and on bone microarchitecture from postmenopausal osteoporotic patients in three studies. In a longitudinal study, 84 paired biopsies were obtained at baseline, and after 6 or 12 months of treatment with 2 g/day SrRan. In SOTI/TROPOS studies 3 paired biopsies were obtained at baseline and after 36 months of treatment. Elastic Modulus, Hardness and Working Energy were blindly analyzed by nanoindentation at the level of the interstitial bone of the cortex and of trabecular nodes under humid conditions. Parameters of microarchitecture were evaluated by microCt (Scanco Medical).

Effects on bone material level properties were observed by 6, 12 and 36 months of treatment. Bone microarchitecture was significantly influenced after more than 12 months. Overall, these results detected in 90 human biopsies indicates an early improvement of bone material level properties followed by later changes on bone microarchitecture in bone specimens collected in patients treated with strontium ranelate. Both effects could contribute to increase of bone strength and to fracture risk reduction. These results suggest different kinetics of SrRan action on bone microarchitecture and bone material level properties.

Bone quality in osteopenic post-menopausal women is not improved during 12 months of whole body vibration training. Anna-Maria Liphardt*[1], Michelle Kan[2], John D. Schipilow[2], Anna Steinhoff[3], Anne Bauer[4], David Hanley[2], Steven Boyd[2]. [1]German Sport University Cologne (DSHS Köln), Germany, [2]University of Calgary, Canada, [3]University Aachen, Germany, [4]German Sport University Cologne, Germany

Whole body vibration training (WBVT) has been suggested as a preventive measure against bone loss. However, results of previous studies are contradicting, which may be in part due to insufficiently sensitive outcome measures to detect relevant bone changes, as most studies have been based on areal bone mineral density (aBMD) measurements by DXA. WBVT might possibly improve bone quality through structural adaptations without increasing BMD. We hypothesized that 12 months of WBVT will improve or maintain bone micro-architecture and bone strength in osteopenic post-menopausal women between the ages of 50 – 65 yr.

A 12-month trial recruited 22 women who received supervised WBVT (Vibraflex, Galileo, Novotec, Pfortzheim, Germany; 20Hz, 3-4mm, 20 min, 2-3 sessions/wk) and 20 controls. All women had T-scores between -1.3 and -2.2 (osteopenic) and BMI between 20 and 28. Tibia bone outcomes were measured by high-resolution peripheral quantitative CT (HR-pQCT, XtremeCT, Scanco Medical) for bone macro- and microarchitecture and finite element estimated bone strength. DXA provided aBMD at LS and FN. Balance and jump performance and maximum voluntary contraction (MVC) of knee flexor and extensor muscles were recorded. All measurements were taken at baseline, 4-, 8-, and 12 months. WBVT and control group comparisons used a mixed model repeated measures ANOVA with group and time as factors. Level of significance was $p<0.05$.

31 women completed the study with approximately 90% compliance (WBVT: n=17, control N=14). No participants dropped out due to adverse affects related to WBVT. Both groups had similar characteristics and dependent variables at the onset of the study (Table 1). Tt.BMD ($p<0.001$), Ct.Ar*($p=0.004$), Ct.Th. ($p=0.011$) and Ct.Po ($p=0.024$) all significantly decreased over time in both groups; WBVT did not affect the response. Areal BMD by DXA was not affected by time or WBVT at FN (time: $p=0.332$, time*group: $p=0.843$) and LS (time: $p=0.783$, time*group: $p=0.103$). Load carried by the cortex at the distal site decreased from baseline to 4 months in the vibration group but not in the control subjects ($p=0.002$). All other bone outcomes were not affected by WBVT or time. No differences in balance, jump and MVC due to WBVT were detected.In our relatively small cohort, WBVT did not lead to improved bone quality in postmenopausal osteopenic women after 12 months of training compared to controls, and there were no detected benefits for balance and muscle strength outcomes.

Variation in Bone Turnover Markers in Professional Sport Players During Training is Mediated by Changes in Sclerostin Levels. Ranuccio Nuti*[1], Daniela Merlotti[1], Michele Bisogni[2], Beatrice Franci[2], Barbara Lucani[2], Stella Campagna[2], Laura Cresti[2], Matteo Beltrami[2], Konstantinos Stolakis[2], Stefano Rotatori[2], Andrea Causarano[3], Luigi Gennari[1]. [1]University of Siena, Italy, [2]Dept. Medicine Surgery & Neurosciences University of Siena, Italy, [3]Medical Staff Siena Football Club, Italy

It is well known that bone turnover changes in response to exercise and that this effect is in part mediated by osteocytes through the release of mediators which affect osteoclast and osteoblast activity. However the variation of bone turnover and of markers of osteocyte activity following a rapid change in exercise level has not been investigated in detail. The aim of the study was to assess changes in bone turnover in 25 professional soccer players (27.8±4.3 yrs) at 3 different times: before pre-season training, at the end of the pre-season training and during the soccer season. Four different groups of males of the same age (G1, n=30), middle age (G2, n=76), elderly (G3, n=44) or long-term immobilized subjects (G4, n=20) were selected as reference. Bone alkaline phosphatase (BALP) and osteocalcin (OC) were assessed as markers of bone formation while carboxy-terminal telopeptide of type I collagen (CTX) was measured to assess bone resorption. In professional soccer players CTX levels were significantly higher before training than at the end of post training or during mid-season (1.48±0.4 vs. 0.91±0.5 vs. 1.01±0.4 ng/ml; $p<0.001$) while an opposite trend was observed for BALP (13.1±5.4 vs. 17.5±6.0 vs. 15.8±5.0 mcg/l; $p<0.01$). A parallel increase in OC was observed, which became significant at mid-season (6.1±1.7 vs. 7.1±1.5 ng/ml; $p<0.01$). Of interest, CTX levels of soccer players at the beginning of training were significantly higher than those observed in control groups of different ages but also with respect to those observed during long-term immobilization. Conversely, before exercise bone formation markers were higher than those observed in older reference groups (G3, G4) while did not significantly differ from age-matched controls (G1). After training and during soccer season either OC or BALP levels were significantly higher than correspondent levels of all the reference groups. At the beginning of pre-season, circulating sclerostin did not differ from controls of different ages but significantly decreased during pre-season training (30.6± 9 vs. 26.0±7 pmol/l; $p<0.05$). This decrease was significantly correlated with the increase in bone formation markers. These results suggest that in professional players bone adapts to the high impact exercise with an increase in bone remodeling. However, during post-season a rapid unbalance between bone resorption and bone formation occurs which appears at least in part mediated by variation in sclerostin levels.

Masticatory muscle tendon-aponeurosis hyperplasia exhibits heterotopic calcification in temporal tendon. Tsuyoshi Sato*[1], YUICHIRO ENOKI[1], Shoichiro Kokabu[2], Masahiko Okubo[1], Tetsuya Yoda[1]. [1]Saitama Medical University, Japan, [2]Harvard School of Dental Medicine, USA

Masticatory muscle tendon-aponeurosis hyperplasia (MMTAH), which was recently established in Japan, is a new disease associated with limited mouth opening. The condition of this disease advances very slowly from adolescence and both mandibular angles exhibit hyperplasia, resulting in a characteristic square mandible. MMTAH is diagnosed by a palpable dense band at the anterior border of the masseter muscle upon maximum mouth opening and square mandible configuration. A lack of recognition of this disease among general practitioners results in misdiagnosis of the temporomandibular disorders, and patients have often been treated with irreversible operations. To date, no clinical reports are available on this disease from other countries. Almost clinicians may fail to notice this disease. Previously, we have demonstrated that good long-term recovery has been reliably obtained in patients with MMTAH via resection of the hyperplastic masseter muscle aponeurosis with coronoidectomy for separation of the temporal muscle from the coronoid process. Chiba et al. mentioned that both tendon and aponeurosis in MMTAH exhibit normal tendon structure because of a lack of inflammation. These observations suggest that tendon tissues in MMTAH represent hyperplasia. In MMTAH, although tendon tissues have been analyzed light-microscopically, the microstructure of muscles and tendons remains still unclear. We thus performed microstructural analysis of muscles and tendons in MMTAH by using electron microscopic technique and energy dispersive X-ray analysis to identify the elemental composition. We assessed the structure of the muscle and tendon tissues by using both TEM and SEM. In muscle tissues, TEM showed the narrowing of vascular lumen, contraction bands and areas of myofibrillar degeneration in MMTAH compared to FD (facial deformity). In tendon tissues, the irregular particles whose diameter was between 10-100 micrometers were observed on the surface of tendon tissues under SEM. Mineralized nodules were observed in tendon tissues of MMTAH compared to FD. Element mapping of tendon tissues revealed that Ca and P were detected on the region of calcification whereas Si was detected on tendon which was not calcified around Ca and P. In summary, we have found that MMTAH exhibited heterotopic calcification of tendon tissues by using electron microscopic techniques. We would like to discuss the diseases that ectopic calcification occurs in tendon tissues.

Microstructure of Narwhal Tusk Studied by Synchrotron Radiation Nano-Tomography. Mie Birkbak[1], Karl Anker Jørgensen[2], Henrik Birkedal*[3]. [1]iNANO & Department of Chemistry, Aarhus University, Denmark, [2]Department of Chemistry, Aarhus University, Denmark, [3]Aarhus University, Denmark

We investigate narwhal tusk microstructure using synchrotron radiation nano-CT to reveal a very complex hierarchical pore structure. Narwhals whose impressive tusks have inspired unicorn myth are one of the few animals that display such impressive external dentitions.

Narwhal tusk is most often a single tooth with a spiral surface composed of a central pulp chamber surrounded by primary dentine which again is surrounded by a thick layer of cementum replete with cementocytes as evidenced by very abundant cementocyte lacunae [1]. This is in opposition to normal teeth that have cementum on the interior interface between bone and tooth rather than on the outside. Narwhal dentine has roughly the same calcium content as narwhal cementum, but has a markedly higher Youngs modulus [2]. While there is some knowledge of Narwhal tusk microstructure and mechanics, the full tusk structure is far from understood. Herein we use synchrotron radiation nano-CT with 325 nm voxel size to reveal a very complex hierarchical pore structure.

The interior dentine part that dominates the tooth is dominated of mineralized bundles of about 15 µm diameter giving rise to an appearance resembling fleecy clouds in cross sectional nano-CT images. The dentine is tubular with tubule diameters of the order of 1 µm. The tubules are not perfectly straight but span long distances in a continuous manner. The tubules appear to be arranged in ribbons perpendicular to the axis of the tooth. The cementum/dentine junction is characterized by an abrupt change of microstructure. The junction itself is characterized by a microporous structure that is much less ordered than the tubular structure in the dentine layer. In the cementum layer two distinct morphologies are found. The first is replete with small pores seemingly randomly dispersed in the mineralized tissue. The other type is much more compact and only few micropores are present. However, both cementum types show cementocyte lacunae that are known to be abundant in tusk cementum [1].The biological function of the Narwhal tusk remains debated and the detailed functional implications of the present investigations will be the subject of future work

Pericapillary Bone Formation by Mural Osteoblasts during Endochondral Ossification. Ichiro Takada*[1], Nobuhito Nango[2], Yoshihiro Takeda[3], Atsushi Momose[4], Yoshiaki Kubota[1], Sho Kanzaki[1], Kouji Shimoda[1], Yasunari Takada[1], Latifa Bakiri[5], Erwin Wagner[5], Koichi Matsuo[1]. [1]School of Medicine, Keio University, Japan, [2]Ratoc System Engineering Co., Ltd., Japan, [3]Rigaku Corporation, Japan, [4]Tohoku University, Japan, [5]CNIO, Spain

Blood vessel invasion of cartilage is crucial for endochondral ossification. However, spatio-temporal relationships among capillary endothelial cells, chondro/osteoclasts and osteoblasts are still under investigation. To understand potential contribution of blood vessels to cellular processes underlying replacement of cartilage by bone, we analyzed transgenic mice overexpressing the transcription factor Fra-1 (Fra-1 mice), which show enhanced bone formation. Preliminary experiments suggested that adult Fra-1 mice showed increased number and size of blood capillaries in cortical bones. Transgenic mice exhibited abundant blood capillaries even in the malleal processus brevis (mPB), a hemispherical protrusion 300 μm in diameter, from which capillaries gradually disappear during postnatal endochondral ossification in wild-type mice. The observation that capillary volume remained high until adulthood in Fra-1mice suggests persistent capillary survival within bone. Synchrotron X-ray phase-sensitive microscopy demonstrated a roughly concentric, cylindrical arrangement of osteocytic lacunae along the capillary in the wild-type mPB indicative of pericapillary bone formation. Calcein double-labeling analysis showed that osteoblasts surrounding the capillary secreted bone matrix away from the capillary, thereby reducing the circumference of the capillary lumen. We conclude that hyperactivity of "osteogenic capillaries" could underlie the previously reported enhanced bone formation seen in Fra-1 transgenic mice. These data support the view that ''osteogenic capillaries'' directly interact with and polarize mural osteoblasts, thereby determining the location and direction of bone formation within ossifying cartilage during endochondral ossification.

Complete Suppression of PTHrP Signaling in Chondrocytes in the Histone Deacetylase 4 and 5 Double Knockout Mouse. Shigeki Nishimori*[1], Forest Lai[1], Marc Wein[1], Elena Kozhemyakina[2], Eric Olson[3], Andrew Lassar[2], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]Harvard Medical School, USA, [3]UT Southwestern Medical Center at Dallas, USA

Both parathyroid hormone-related protein (PTHrP) and Histone Deacetylase (HDAC) 4 suppress chondrocyte hypertrophy. We confirmed that HDAC4 is a mediator of the PTHrP signaling pathway by knocking out the HDAC4 gene in the PTHrP transgenic mouse. The similarities between the HDAC4 KO mouse and the PTHrP KO mouse also support this hypothesis. However, the delayed onset in the HDAC4 KO mouse suggests the existence of other mediators. Here we identified HDAC5 as a mediator of the PTHrP signaling pathway using mouse genetics.

The PTHrP KO mouse dies just after birth due to respiratory failure caused by ectopic chondrocyte hypertrophy and ossification in the rib cartilage (Karaplis, Genes Dev. 1994). The HDAC4 KO mouse exhibits normal rib cartilage at birth (P0), but dies around 10 days after birth (P10) with progressive chondrocyte hypertrophy and ossification in the rib cartilage (Vega, Cell. 2004). Accelerated chondrocyte hypertrophy in the PTHrP KO mouse leads to a very short proliferating region in the growth plate (30% of the wild type (WT) at P0). We found the similar short proliferating region in the HDAC4 KO mouse (60% of the WT at P0, 40% of the WT at P8).

We focused on HDAC5 as a possible mediator, because we found HDAC4 and HDAC5 show similar mRNA expression levels in the growth plate. As another Class IIa HDAC, HDAC5 might complement functions of HDAC4.

The HDAC4 KO; HDAC5 heterozygotes mouse (HET) mouse died just after birth with a rib phenotype like that of the PTHrP KO mouse, but the growth plate phenotype in the proliferating region was milder than that of the PTHrP KO mouse (50% of the WT at P0). The HDAC 4 and 5 double KO mouse died at birth with a phenotype similar to that of the PTHrP KO mouse both in the rib cartilage and the growth plates. These results suggest that HDAC5 mediates PTHrP signaling when HDAC4 is missing. HDAC5 is not essential when HDAC4 is working, judged by the normal phenotype of the HDAC5 KO mouse and the HDAC5 KO; HDAC4 HET mouse.

In the growth plate of the HDAC4 KO mouse, HDAC5 mRNA was expressed at normal level by RT-qPCR analysis. In contrast, the HDAC5 protein level was upregulated in the proliferating chondrocytes of the HDAC4 KO mouse by immunohistological analysis using confocal fluorescent microscopy. These results are consistent with the idea that HDAC5 compensates for the loss of HDAC4 as a mediator of the PTHrP signaling pathway.

Long bone phenotypes of the PTHrP KO mouse and the HDAC related KO mice

Gene Expression Profiling Reveals Similarities between the Spatial Architectures of Articular and Growth Plate Cartilage. Michael Chau*[1], Julian Lui[1], Stephan Spath[2], Jeffrey Baron[1], Ola Nilsson[1]. [1]NICHD, USA, [2]NIH, USA

Background: In the embryo, articular cartilage is initially continuous with growth plate cartilage. Subsequently, a secondary ossification center forms within the epiphyseal cartilage, dividing it into future articular cartilage peripherally and growth plate cartilage more centrally. Articular and growth plate cartilage both consist of three distinct zones of chondrocytes.

Objective: To test the hypothesis that gene expression profiles of superficial, intermediate, and deep zones of articular cartilage are spatially similar to those of resting, proliferative, and hypertrophic zones of growth plate cartilage, respectively.

Methods: Rat articular cartilage was microdissected into superficial and intermediate/deep regions manually, mouse articular cartilage into superficial, intermediate, and deep zones by laser capture, and rat growth plate into resting, proliferative, and hypertrophic zones manually. Gene expression was analyzed by microarray (Affymetrix). A gene was considered to be spatially regulated if its expression in two adjacent zones differed by ⩾2-fold and false discovery rate <0.01.

Results: In rat, many genes that were spatially upregulated in the intermediate/deep region of articular cartilage were also upregulated in resting zone of growth plate cartilage (overlap greater than expected by chance, $P<0.001$, chi-square test). Interestingly, superficial zone of articular cartilage showed an expression profile with similarities to both proliferative and hypertrophic zones of growth plate cartilage ($P<0.001$ each). Additionally, known proliferative zone markers Gdf10, Prelp, and Olfml3 were significantly upregulated in superficial zone ($P<0.01$ each), whereas resting zone markers Sfrp5, Efemp1, and Pcp4 were upregulated in the deep/intermediate region ($P<0.01$ each). In mouse articular cartilage, we similarly found that intermediate and deep zones resembled resting zone ($P<0.001$ each), while superficial zone resembled proliferative and hypertrophic zones ($P<0.001$ each).

Conclusion: Contrary to our hypothesis, we found that intermediate-deep zones of articular cartilage were similar in gene expression profile to resting zone of growth plate cartilage and that superficial zone resembled proliferative and hypertrophic zones. Since proliferative and hypertrophic chondrocytes derive from resting zone chondrocytes, these findings raise the possibility that superficial zone chondrocytes analogously differentiate from intermediate-deep zone chondrocytes.

Histone Deacetylase 3 Controls Extracellular Matrix Degradation, Vascularization, and Secondary Ossification Formation during Endochondral Ossification. Lomeli Carpio*, Elizabeth Bradley, Meghan McGee-Lawrence, Jennifer Westendorf. Mayo Clinic, USA

Histone deacetylases (Hdacs) epigenetically regulate many cellular processes by modulating chromatin structure and repressing gene expression. Endochondral ossification is a tightly regulated and complex process and several Hdacs are involved at each stage. We previously showed that conditional deletion of Hdac3 in osterix-expressing osteo/chondroprogenitor cells resulted in severe osteopenia and growth retardation due to reduced numbers of osteoblasts and abnormal maturation of chondrocytes in the growth plate. Hdac3-deficient chondrocytes entered hypertrophy more quickly and secreted less extracellular matrix due to reduced Akt signaling than wildtype cells. In this study, we further defined the cell-autonomous role of Hdac3 in chondrocyte maturation by crossing $Hdac3^{fl/fl}$ mice with animals expressing chondrocyte-specific, tamoxifen-inducible type II collagen-Cre. Tamoxifen was

administered at postnatal day 5 and the animals were studied at 4 or 8 weeks of age by histology, microCT, and EPIC imaging. At 8 weeks of age, the Hdac3 CKO mice had increased cortical bone and trabecular bone thickness; however, trabecular number was reduced, trabecular spacing was increased and trabecular bone volume fraction was decreased. This phenotype is likely compensatory in response to disrupted growth plate development. Indeed, at 4 weeks of age, the growth plate was thicker in the Hdac3 CKO mice and associated with an expansion of hypertrophic zone chondrocytes. Secondary ossification center formation was delayed in these animals. Additionally, immunohistochemistry showed decreased expression of the angiogenic marker, platelet/epithelial cell adhesion molecule (Pecam)-1, in the secondary ossification center of the Hdac3 CKO mice compared to control animals. These data indicate Hdac3 deletion negatively impacts vascularization and chondrocyte hypertrophy. In vitro gene expression analysis of immature mouse articular chondrocyte micromass cultures demonstrated decreased expression of vascular endothelial growth factor (Vegf) and increased expression of tissue inhibitors of matrix metalloproteinase (Timps) in Hdac3-deficient chondrocytes. Together these data demonstrate Hdac3 regulates extracellular matrix degradation and subsequent vascularization in chondrocyte maturation during endochondral ossification.

Identification of chondrocyte-binding peptides by phage display. Sao Fong Cheung*[1], Julian Chun Kin Lui[2], Jeffrey Baron[2]. [1]National Insitutes of Health, USA, [2]NIH, USA

Numerous genetic and environmental disorders disturb cartilage generation and maintenance in growth plate or articular cartilage, causing a wide variety of disorders. As a first step toward novel experimental and therapeutic approaches to these diseases, we sought to identify peptides that bind cartilage tissue using phage display.

An M13 phage library exhibiting random 12-amino acid peptides on the viral surface was iteratively selected for affinity to cultured murine chondrocytes by repetitive binding and amplification. From the resulting enriched phage pool, 23 clones were picked and assessed for their binding characteristics by ELISA. Of these clones, 8 showed at least a 2-fold increase in binding to cultured chondrocytes, compared to a phage lacking the inserted peptide. Phage clones C1 and C19, which display peptide sequences RLDPTSYLRTFW and HDSQLEALIKFM respectively, possessed the greatest binding to cultured chondrocytes. Using ELISA, these two phage were also demonstrated to have substantially less affinity to fibroblasts, myocytes, osteoblasts and hepatocytes, compared to chondrocytes, suggesting an interaction that was moderately tissue-specific. Immunohistochemical staining revealed that phage C1 and C19 bound to cultured chondrocytes and extracellular matrix. To determine whether the binding to chondrocytes and matrix was attributable to the affinity of the inserted peptide independent of the phage coat proteins, free peptides, conjugated with the fluorescent probe FITC, were synthesized and incubated with cultured chondrocytes. Peptides C1 and C19, but not a random peptide, bound to both cultured chondrocytes and extracellular matrix, confirming that binding involved the peptides per se. In conclusion, using phage display, we successfully identified peptide sequences that are capable of targeting chondrocytes. Further studies may be needed to determine if such cartilage-binding peptides have potential applications for treating cartilage disorders.

Identifying Sox9 regulatory programs in mammalian skeletogenesis. Xinjun He*[1], Andrew McMahon[1], Shinsuke Ohba[2]. [1]University of Southern California, USA, [2]The University of Tokyo, Japan

Sox9, an HMG-box containing transcriptional regulator, is essential for chondrocyte development. Ectopic expression of Sox9 is sufficient to reprogram several cell types to a chondrocyte state. The evidence indicates Sox9 is a key determinant of many aspects of chondrogenesis. Here, we explored the direct mechanisms of Sox9 action through a comprehensive analysis of Sox9 binding sites in mammalian, neonatal rib chondrocytes. Sox9 chromatin immunoprecipitation and next generation sequencing (ChIP-seq) identified 27,656 Sox9-associated regions in the genome. Broadly, these fall into two categories: Class I, within 500 base-pairs (bp) of a transcriptional start site (TSS) accounting for 25% of the data, and Class II where binding lies outside this local TSS domain, in some cases many hundreds of kilobases (kb) from the likely gene target. Analysis of Class I sites in conjunction with a number of measures of chromatin organization (histone acetylation and methylation) and transcriptional activity (histone methylation, RNA polymerase II and p300 association) suggest a mechanism where Sox9 associates at the TSS through protein-protein interactions rather than direct DNA-binding. Here, the level of binding reflects transcriptional activity of the target and targets encode general regulators of cell activity, not cartilage specific programs. In contrast, Class II sites correlate with active enhancer signatures, verified in transgenic studies, through direct binding of DNA target sites. Bioinformatic analysis reveals a striking chondrocyte signature with over 795 direct target genes. Motif recovery, and biochemical and transgenic studies analyzing recovered motifs, suggest that Sox9 regulates targets through sub-optimal dimeric binding sites where robust, high-level expression is achieved through the use of multiple enhancer elements. Further, these studies predict Sox9 acts in conjunction with the Ap1 family of transcriptional regulators; ChIP-seq analysis of c-Jun confirmed this prediction. These data are an important first step in identifying the gene regulatory networks regulating chondrocyte and osteoblast development.

Longitudinal Overgrowth Following Circumferential Periosteal Division of Femur of Developing Rat. Shinjiro Takata*. Tokushima National Hospital,National Hospital Organization, Japan

Circumferential periosteal division (CPD) of rat tibia produces an increase in its growth rate and in the activity of both the proliferative and hypertrophic zones (Taylor FJ et al. J Anat 151:221-231,1987). The purpose of this study was to show mechanisms of longitudinal overgrowth following CPD of femur of developing rat.Twelve male Wistar rats aged 8 weeks were used for this study. Periosteum of diaphysis of the right femur was divided circumferentially (CPD group), and the left femur was control (Control group). Rats were sacrificed 4 weeks after CPD. The longitudinal length of femur (n=6) and rate of longitudinal growth and bone turnover by bone histmorphometry were compared between CPD group and Control group 4 weeks after CPD (n=6).Longitudinal length of rat femur of CPD group and Control group were 39.4 ± 1.2 mm and 38.5 ± 0.8mm, respectively (p=0.0086), showing that CPD for 4 weeks produced an approximately 2.5% increase of rat femur compared with Control group.Bone histomorphometry shows that the rate of longitudinal growth of femur of CPD group and Control group 4 weeks after CPD was 92.3 ± 5.3 and 54.4 ± 4.6 μm/day, respectively ($p<0.0001$). Mineral apposition rate of femora of CPD group and Control group 4 weeks after CPD was 3.90 ± 0.38 and 3.07 ± 0.25 μm/day, respectively (p=0.0004). Osteoclast surface/bone surface of CPD group and Control group 4 weeks after CPD was 13.1 ± 1.0 and 9.1 ± 1.8%, respectively ($p<0.0001$).Histological analysis of distal growth plate of rat femur showed an increased number of hypertrophic chondrocytes and width of hypertrophic zone of the distal growth plate of rat femur of CPD group compared with Control group. The major finding of this study was that CPD of diaphysis of rat femur stimulates endochondral ossification to produce longitudinal overgrowth. The results suggest that periosteum of tubular bone plays an important role in endochondral ossification of growth plate.

Modulating *Sost* Expression Influences the Progression and Severity of Post Traumatic Osteoarthritis in Mice. Jiun Chiun Chang*[1], Blaine A. Christiansen[2], Cynthia B. Thomas[3], Nicole M. Collette[3], Craig Blanchette[4], Gabriela Loots[5]. [1]University of California, Merced, USA, [2]UC Davis Medical Center, Department of Orthopaedic Surgery, USA, [3]Lawrence Livermore National Laboratories, Physical & Life Sciences Directorate, USA, [4]Lawrence Livermore National Laboratories, USA, [5]Lawrence Livermore National Laboratory, UC Merced, USA

Sclerostin (Sost), a Wnt antagonist known to play important roles in bone development, metabolism and fracture repair has also been implicated in regulating chondrocyte function. Recently it has been shown that Sost is expressed in articular cartilage and its levels increase in focal areas of osteoarthritis (OA) damage in surgical models of OA. Using a recently described noninvasive mouse model of post traumatic osteoarthritis (PTOA) in which the anterior cruciate ligament ruptures in response to a single tibial compression overload, we compared OA progression and cartilage damage severity in mice lacking Sost (KO) or overexpressing SOST (TG) to C57BL/6 (WT) control mice. Injured joints were examined histologically at 3, 6, 12, and 16 weeks post injury. At 6 weeks post injury WTs and TGs demonstrated minimal cartilage loss whereas the KOs showed mild OA. At 12 weeks post injury, the WTs displayed moderate OA, while the KOs had more severe cartilage loss. In contrast, TGs maintained mild OA, showing a delay in the disease progression, and a phenotype significantly less severe than the WT controls, consistent with the previous hypothesis that Sost overexpression may have a protective role in OA. We also quantified subchondral trabecular bone loss at the femoral epiphysis and ectopic bone formation by micro-computed tomography. We found significantly greater osteophyte formation in KOs than in WTs and TGs. Consistent with Sost's role in stimulating bone formation KOs sustained no significant subchondral bone loss from 10 days to 16 weeks post injury while WT femurs lost 24 ± 9%. To determine if Sost interferes with initial inflammatory response, we quantified matrix metalloproteinases (MMP) activity post injury. Fluorescent MMP-Sense substrate was administered intravenously immediately post injury, and MMP activity was quantified based on *in vivo* fluorescence levels 3 days post injury. Whereas WT and KO injured joints showed similar MMP activity levels, TG injured joints displayed 2-fold less MMP activity than WT and KO injured joints, suggesting that SOST overexpression inhibits initial inflammation and the activity of proteolytic enzymes known to degrade articular cartilage matrix. By utilizing a clinically relevant PTOA model, by 16 weeks post injury, Sost KO mice developed severe OA while Sost TG showed moderate signs of cartilage damage. Collectively, these findings support the hypothesis that Sost has a protective role in PTOA.

Phosphate regulates signaling molecules and apoptotic proteins in hypertrophic chondrocytes. Eva Liu*[1], Francesca Gori[2], Marie Demay[3]. [1]Brigham & Women's Hospital & Massachusetts General Hospital, USA, [2]Harvard School of Dental MedicineMassachusetts General Hospital, USA, [3]Massachusetts General Hospital & Harvard Medical School, USA

Phosphate plays an essential role in growth plate maturation. Hypophosphatemia impairs hypertrophic chondrocyte apoptosis, resulting in rickets, characterized by expansion of the hypertrophic chondrocyte layer of the growth plate. Phosphate-mediated activation of the mitochondrial apoptotic pathway in hypertrophic chondrocytes requires induction of Erk1/2 phosphorylation. Phosphate induction of Erk1/2 phosphorylation in murine hypertrophic chondrocytes, is seen in response to 3mM, 5mM and 7mM phosphate with peak levels observed 15 minutes post-treatment. Phosphate has been shown to regulate levels of pro- and anti-apoptotic factors in hypertrophic ATDC5 chondrocytes treated with 20 mM phosphate. However, it is not known whether phosphate leads to acute subcellular redistribution of factors that regulate the mitochondrial apoptotic pathway. Therefore, studies were performed to determine the time course of change in signaling and apoptotic proteins following treatment of hypertrophic chondrocytes with phosphate.

Murine costal chondrocytes were cultured under conditions that promote hypertrophic differentiation. Hypertrophic chondrocytes were treated with 7 mM phosphate and subjected to subcellular fractionation. Within 15 minutes of exposure to 7 mM phosphate, C-raf and Erk1/2 phosphorylation are observed in both the cytosol and mitochondria of hypertrophic chondrocytes. After one hour exposure to 7 mM phosphate, increases in the cytosolic and mitochondrial levels of total and phosphorylated Erk1/2 are observed. Cytosolic levels of the anti-apoptotic protein Bcl-2 and of the pro-apoptotic protein Bax increased in hypertrophic chondrocytes treated with phosphate, returning to baseline by 2 hours post-treatment. Pro-apoptotic phospho- p-53 localized predominantly to the mitochondria of hypertrophic chondrocytes and did not change with phosphate treatment. Phosphate treatment of hypertrophic chondrocytes leads to changes in levels of signaling molecules and apoptotic factors in both the cytosol and mitochondria. The increase in mitochondrial pErk1/2 in response to phosphate suggests phosphate-induced pErk1/2 may play a direct role in activating the mitochondrial apoptotic pathway in hypertrophic chondrocytes.

Potential roles of neurotrophin-3 in growth plate cartilage bony repair and skeletal cell formation. Yu-Wen Su[1], Rosa Chung[1], Cristina Vincent[1], Shek Man Chim[2], Fiona Zhou[1], Alice Lee[1], Chia-Ming Fan[1], Jiake Xu[2], Xin-Fu Zhou[3], Cory Xian*[1]. [1]University of South Australia, Australia, [2]University of Western Australia, Australia, [3]University of South Australia, Azerbaijan

Injury to the growth plate cartilage often results in undesirable bony repair at the injury site causing bone growth defects in children, for which the underlying mechanisms remain unclear. Neurotrophic factors (NTs) have been shown to be involved in bone fracture healing; this study investigated potential functions of NTs in the bony repair of injured tibial growth plate in rats and during skeletal cell formation in vitro. Firstly, up-regulated expression of NGF, BDNF, NT-3, and NT-4 (with NT-3 showing the highest induction) and receptors (TrkA, TrkB and TrkC) by RT-PCR was observed at the injury site at different time points after injury. NTs were found to be immunolocalized in mesenchymal cells, chondrocytes, osteoblasts, and osteocytes at the injury site. Secondly, differentially regulated expression of NTs and receptors was detected during in vitro chondrogenesis, osteoblastogenesis, mineralization and osteoclastogenesis in rat bone marrow cells and murine progenitor cell-line cells. Thirdly, in vitro assays showed that addition of NT-3 protein decreased chondrocyte formation and expression of chondrogenesis-related genes, but enhanced expression of osteogenesis related genes (Runx2, osterix, osteocalcin and BMP-2), as well as osteoclastogenesis-related molecules (RANK and OSCAR) and osteoclast formation. Conversely, anti-NT-3 antibody treatment had the opposite effects. Neither anti-NT-3 nor NT-3 treatment affected activation of transcription factor NF-κB in osteoclast precursor RAW264.7 cells. Lastly, micro-CT and histology analyses of injured rats treated with NT3 or anti-NT-3 antibody indicated that anti-NT-3 treatment attenuated bone formation at the injury site at day 28. RT-PCR analysis with injury site samples found that anti-NT-3 treatment alleviated the injury-induced down-regulation of cartilage markers while inhibited expression of osteocalcin and osteoclast receptor gene RANK. Conversely, NT-3 treatment had a trend of suppressing levels of chondrogenesis markers (Sox9, collagen-2&10) but significantly enhanced those for both osteogenesis (Runx2, osterix and osteocalcin) and osteoclastogenesis (RANK and OSCAR). It is concluded that neurotrophic factor signaling is involved in the bony repair process at the injured growth plate and the associated skeletal cell formation; in particular, NT-3 may attenuate chondrogenesis but enhance osteogenesis and osteoclastogenesis during growth plate repair and in vitro skeletal cell formation.

RBPjκ-dependent Notch Signaling Regulates the Initiation of Chondrocyte Hypertophy via SOX9. Anat Kohn*[1], Timothy Rutkowski[2], Anthony Mirando[2], Alana Osinski[2], Yufeng Dong[1], Michael Zuscik[2], Regis O'Keefe[1], Matthew Hilton[3]. [1]UNIVERSITY OF ROCHESTER, USA, [2]University of Rochester School of Medicine & Dentistry, USA, [3]University of Rochester Medical Center, USA

We have recently identified RBPjκ-dependent Notch signaling as an important regulator of chondrogenesis and chondrocyte maturation during cartilage development. Specifically, we demonstrated that loss of RBPjκ-dependent Notch signaling results in the delayed onset of chondrocyte hypertrophy, as well as, delayed progression to terminal chondrocyte maturation *in vivo* and *in vitro*. These data have also implicated Notch signaling in the suppression of the transcription factor SOX9, indicating a possible mechanism by which Notch signaling promotes chondrocyte maturation or hypertrophy. To identify whether *Sox9* is a down-stream target of Notch signaling during chondrocyte maturation, we first analyzed RBPjκ loss-of-function (LOF) (*Prx1Cre;Rbpjκ$^{f/f}$*) and RBPjκ LOF Sox9 haploinsufficient (*Prx1Cre;Rbpjκ$^{f/f}$;Sox9$^{f/+}$*) mutant embryos at E14.5 and E18.5. Hind limbs and fore limbs from embryos at E14.5 and E18.5 were analyzed using histology, histomorphometric measurements, and *in situ* hybridization for markers of chondrocyte maturation (*Ihh, Col10a1* and *Mmp13*). At E14.5, analyses revealed that delays in the onset of chondrocyte hypertrophy seen in RBPjκ LOF embryos are rescued by Sox9 haploinsufficiency. However, analyses of E18.5 RBPjκ LOF Sox9 haploinsufficient growth plates revealed no rescue in the delayed terminal chondrocyte maturation observed in RBPjκ LOF mutant growth plates. Furthermore, our in vitro studies revealed that over-expression of the Notch Intra-Cellular Domain (NICD1 or NICD2) in chondrogenic cells leads to a significant reduction in *Sox9* expression. Similarly, over-expression of NICD1 or NICD2 suppressed luciferase expression driven by a 1kb fragment of the *Sox9* promoter. Interestingly, the 1kb fragment of the *Sox9* promoter does not contain any direct RBPjκ binding sites, but does contain N-box and E-box DNA motifs. HES/HEY factors, transcriptional repressors classically activated by RBPjκ-dependent Notch signaling, specifically bind N-box and some E-box sequences. Based on these findings we performed ChIP analyses of the *Sox9* promoter and demonstrated that several HES/HEY factors are capable of binding the N-box/E-box region of the *Sox9* promoter and may be required for Notch-mediated inhibition of *Sox9* expression. Collectively, these data suggest that RBPjκ-dependent Notch signaling promotes the initiation of hypertrophy via HES/HEY mediated suppression of *Sox9*.

Runx1 Increased Expression in Superficial Zone Chondrocytes in Response to Mechanical Loading and in Chondrocyte Clones of Osteoarthritic Tissue: Functional Implications. Paul Fanning*[1], Kimberly LeBlanc[2], Marie Walcott[3], Tripti Guar[4], Shannon O'Connell[3], Kirti Basil[3], April Mason-Savas[3], Jason Silva[3], Andre Van Wijnen[5], Janet Stein[6], Gary Stein[7], David Ayers[8], Jane Lian[6]. [1]University of Massachusetts Medical School, USA, [2]Dept. of Cell Biology & Cancer Center, University of Massachusetts Medical School, USA, [3]Dept. of Orthopedics & Physical Rehabilitation, University of Massachusetts Medical School, USA, [4]Dept. of Cell Biology & Cancer Center, University of Massachusetts, USA, [5]Mayo Clinic, USA, [6]University of Vermont, USA, [7]University of Vermont, College of Medicine, USA, [8]UMass Memorial Medical Center, USA

Runx1 is a hematopoietic lineage transcription factor, but is present in perichondrium and chondrocytes. To address functions in supporting chondrogenesis, we determined Runx1 expression patterns in the epiphysis and articular cartilage zones in response to mechanical loading of bovine articular cartilage and during progression of osteoarthritis (OA) in a mouse model, as well as in human OA tissue. By immunohistochemistry, spared and diseased compartments in knees of OA patients were dissected for examination of Runx factors, proliferation and differentiation markers. Experimental OA in mouse was induced by surgical destabilization of the medial meniscus (DMM). We find in normal articular cartilage of normal bovine, mouse, and the lateral spared compartment of human bone, that Runx1 is enriched in superficial chondrocytes. Under loading conditions, Runx1 expression is elevated and positively correlates with increasing loading conditions. In human and mouse OA tissue, Runx1 becomes highly expressed in the superficial zone chondrocytes at the periphery of mouse OA lesions and in human OA chondrocyte 'clones'. Further characterization of these high Runx1 expressing cells identified Runx1 co-localization with VCAM-1, the mesenchymal progenitor cell marker and PRG-4, a cartilage chondroprotective protein. These OA induced cells represent a proliferative population marked by Ki-67 and PCNA staining. In complementary studies, Runx1 depletion in chondroprogenitor cells results in decreased proliferation, supporting Runx1 contribution to cell expansion. Together these data indicate that Runx1 functions in the unique phenotype of articular chondrocytes, reflected by enriched levels in superficial zone chondrocytes and upregulation under conditions of compression. We propose that co-expression of Runx1 with VCAM-1 and PRG4 in murine cell clusters and human 'clones' of OA cartilage, suggests Runx1 participates in a cooperative compensatory mechanism and anabolic function.

Transient,but not Sustained, NOTCH1 Signaling Promotes Articular Cartilage Maintenance. Zhaoyang Liu*[1], Anthony Mirando[2], Regis O'Keefe[3], Michael Zuscik[4], Matthew Hilton[1]. [1]University of Rochester Medical Center, USA, [2]University of Rochester Medical Center, Center for Musculoskeletal Research, USA, [3]University of Rochester Medical Center, Department of Orthopaedics & Rehabilitation, Center for Musculoskeletal Research, USA, [4]University of Rochester School of Medicine & Dentistry, USA

Recently, we have identified the Notch signaling pathway as a critical regulator of articular cartilage and joint maintenance and implicated Notch signaling in osteoarthritis (OA). Specifically, genetic ablation of Notch signaling in joint precursor cells (*Prx1Cre;Rbpjκ$^{f/f}$*) or in joint cartilages (*Col2Cre^{ERT2};Rbpjκ$^{f/f}$*) resulted in a loss of anabolic gene expression and extracellular matrix (ECM) molecules resulting in a progressive OA-like pathology in mouse. Based on these findings, we set out to determine whether Notch activation within joint cartilage could promote ECM synthesis and joint maintenance. We first developed two sustained cartilage-specific Notch gain-of-function models: *Agc1Cre^{ERT2};Rosa-NICD1* and *Col2Cre;Rosa-rtTA$^{f/+}$;tetON-NICD1* (tGOF NICD1) with high dose and frequency of doxycycline. Interestingly, both models exhibited severe joint degenerative phenotypes, including articular cartilage fibrosis, synovial tissue expansion, and growth plate collapse. IHC analyses demonstrated a significant increase in the expression of both fibrosis markers COL1A1 and COL3A1, coupled with decreases in COL2A1 in the joints of sustained Notch gain-of-function mutants. Since both loss- and sustained gain-of-function models develop OA-like phenotypes, we generated a transient Notch activation model to mimic levels and durations of physiological Notch signaling. We injected 1-month old tGOF NICD1 mutants and controls with low doses of doxycycline (1ug dox/g body weight, once/week for four weeks), and harvested knee joints at 2 and 4 months. ABH/OG staining and histomorphometric analyses of tGOF NICD1 mutant knee sections demonstrate a dramatic increase in articular cartilage area and thickness in both 2- and 4-month old mice. The mutant mice also exhibited significant increases in COL2A1 expression in all zones of the articular cartilage, with a mild enhancement of COL10A1 in the deep zone. No significant change was observed in COL1A1 or COL3A1 expression in the mutant mice. Real-time RT-PCR revealed that transient Notch signaling promoted the expression of anabolic genes such as *Sox9*, *Col2a1* and *Agc1* at both 2 and 4 months. The expression level of *Mmp13* was elevated at 2-months, although by 4-months of age was reduced by ~60%. Collectively, these data indicate that transient activation of Notch signaling enhances articular cartilage ECM synthesis, promotes joint cartilage maintenance, and implicates the Notch pathway as a novel therapeutic target for OA.

***Mustn1* Spatiotemporal Protein Expression During Skeletal Development and Regeneration.** Michael Hadjiargyrou*[1], Amanda Zigomalis[2], Affan Haleem[3], David Komatsu[4]. [1]New York Institute of Technology, USA, [2]Stony Brook University, Department of Biomedical Engineering, USA, [3]Stony Brook University, School of Medicine, USA, [4]Stony Brook University, Dept. of Orthopaedics, USA

Since the discovery of *Mustn1*, a gene encoding a small nuclear protein, much has been learned about its mRNA expression and function in developing and regenerating musculoskeletal tissues. However, almost all studies to date have evaluated *Mustn1* expression at the transcriptional level and very little is known about the expression of *Mustn1* protein. Therefore, using a newly developed *Mustn1* antibody, we conducted a series of experiments to evaluate the spatiotemporal expression of *Mustn1* protein during embryonic skeletal development and adult skeletal regeneration. Immunostaining transverse sections from embryonic day (E) 16 and 18 mouse embryos revealed *Mustn1* protein expression in skeletal muscles, mesenchymal condensations of ribs and limb buds, and chondrocytes of the vertebrae at both time-points analyzed. Using coronal sections from post-fracture day (PFD) 1, 3, 5, 7, 10, 14, and 21 rat femoral fracture calluses, *Mustn1* expression was observed in osteocytes near the fracture line, as well as the nearby activated periosteum on PDF 1. On PFD 3 and 5 osteocytic and periosteal *Mustn1* expression progressed proximally and distally from the fracture. By PFD 7, strong *Mustn1* expression was also seen in hypertrophic chondrocytes, as well as throughout regions of fibrocartilage. This continued into days 10 and 14, when *Mustn1* expression was seen in osteoblasts lining regions of woven bone. Finally, by PFD 21, *Mustn1* expression was reduced, with moderate staining seen in osteocytes near the fracture line and osteoblasts lining regions of woven bone. These data are consistent with prior *in situ* hybridizations and additionally reveal strong expression of *Mustn1* protein in osteocytes early in bone regeneration. The expression of *Mustn1* protein in cartilage and muscle is also consistent with prior studies demonstrating the necessity of *Mustn1* expression for chondrogenesis and myogenesis. The newly detected expression of *Mustn1* in osteocytes, as well as confirmatory evidence of *Mustn1* expression in osteoblasts, suggests that *Mustn1* may also be necessary for osteogenesis. Additional experiments to test this hypothesis, as well as quantify *Mustn1* protein levels during skeletal and muscle regeneration are ongoing. Further elucidating the expression, and ultimately the function, of *Mustn1* during the development and regeneration of musculoskeletal tissues will potentially enable the discovery of new targets for treating injuries and diseases of these tissues.

Genome-wide alterations in polycomb-regulated epigenomic modification in embryonic osteoblasts following exposure to maternal obesity in rats. Jin-Ran Chen*[1], Jian Zhang[2], Oxana P. Lazarenko[2], Michael L. Blackburn[2], Martin J. J. Ronis[2], Thomas M. Badger[2], Kartik Shankar[2]. [1]University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, [2]University of Arkansas for Medical Sciences & Arkansas Children's Nutrition Center, Little Rock, AR 72202, USA

Nutritional status during intrauterine and early postnatal life impacts the risk of chronic diseases, presumably via epigenetic mechanisms. However, evidence on the impact of gestational events on regulation of bone development is sparse. Recently we showed that bone development is inhibited in gestational day 18.5 (E18.5) embryos from rat dams made obese by feeding a high-fat diet (HFD). In these studies, female Sprague-Dawley rats were fed either a low-fat AIN-93G control diet or a HFD (45% fat calories) for 10 wk starting at 6 wk of age. Fetal rat osteogenic calvarial cells (FOCCs) from HFD-fed obese dams showed impaired osteogenic potential, decreased expression of osteogenic markers and higher levels of PPARγ relative to cells from dams fed AIN-93G. More importantly, this impairment was associated with diminished mRNA/protein expression and increased promoter methylation of the osteogenic regulator HoxA10, suggesting involvement of mechanisms regulating DNA and repressive histone methylation. DNA methylation is intricately linked to histone methyltransferase (HMT) activity; especially the repressive mark H3K27me3. Since, establishment of H3K27me3 is exclusively mediated via the polycomb (PcG) HMT, Enhancer of zeste homolog 2 (Ezh2), we examined this pathway. Recent studies have also shown that suppression of Ezh2 via CDK1 promotes osteogenesis. FOCCs from obese rat dams showed significantly increased mRNA and protein expression of Ezh2. Conversely, CDK1 expression and phosphorylation of Ezh2 (an inactivation event) were significantly lower in FOCCs from obese rat dams. In line with these results, H3K27me3 abundance in FOCCs from embryos of obese dams was significantly higher compared to cells from control dams. Analysis of genome-wide localization of the repressive histone mark, H3K27me3 via ChIP-seq identified 338 genes with at least 2-fold increase in H3K27me3 in FOCCs from obese dams. Enrichment of GO terms for these genes revealed that appendage morphogenesis and bone development biological processes were signficantly enriched. Transcriptional regulation of these genes was confirmed using real-time PCR. Of these genes, H3K27me3 of IGF1 promoter was found to be increased, and H3K27me3 of BMP4 promoter was decreased, suggesting altered differentiation potential toward either osteoblasts or adipocytes. These results suggest that maternal obesity may affect fetal skeletal development through epigenetic regulation of polycomb-regulated genes, which may contribute to low bone mass in the offspring later in life. *Supported in part by ARS CRIS* #6251-51000-005-03S.

Matrix Vesicle-Bound Bone Alkaline Phosphatase for the Assessment of Peripheral Blood Admixture of Human Bone Marrow Aspirates. Evelien Nollet[1], Emeline Van Craenenbroeck[2], Wim Martinet[1], Inez Rodrigus[3], Christiaan Vrints[2], Viviane Conraads[2], Viviane Van Hoof*[4]. [1]University of Antwerp, Belgium, [2]University of Antwerp / Antwerp University Hospital, Belgium, [3]Antwerp University Hospital, Belgium, [4]University Hospital Antwerp, Belgium

Quality assessment of bone marrow (BM) aspirates is important to circumvent the problem of unreliable cytokinetic results in BM serum as a consequence of peripheral blood (PB) admixture. Quality of BM is previously determined by flow cytometric quantification of specific BM cell populations. However, since this technique is critically dependent on the presence of normal BM, its use in pathophysiological conditions in which the BM is affected, is hampered. In search for an alternative stable marker, bone alkaline phosphatase (ALP), produced by osteoblasts residing in BM, was studied as a potential marker for the assessment of PB admixture of BM aspirates.

14 patients undergoing elective cardiac surgery were included. Renal failure, abnormal bone turnover and BM disorders served as exclusion criteria. Bone marrow aspirates were taken by sternal puncture prior to sternotomy. Venous PB was sampled simultaneously. After centrifugation (15min 1500g) total ALP activity was spectrophotometrically quantified (Dimension Vista System) in BM and PB serum. Agarose gel electrophoresis allowed differentiation between ALP isoenzymes (bone, liver,

intestinal ALP). Furthermore, native PAGE experiments were performed to identify the present molecular mass (Mr) ALP isoforms.

Overall, total ALP activity was significantly higher in BM serum (130 ± 95U/L) compared to PB serum (59 ± 9U/L; p=0.002). The agarose electrophoretic pattern also showed a marked difference between both matrices: BM contained a fraction of bone origin (41 ± 17%) that was absent in PB. This fraction was retained at the origin on native PAGE, indicating its high-Mr nature. Upon butanol extraction, the high-Mr fraction was converted to tetrameric bone ALP. Based on these observations, this BM-unique fraction was identified as membrane-bound bone ALP, most likely originating from bone matrix vesicles. Future electron microscopic studies could confirm this presumption. We called this unique fraction High-Mr Bone (HMB) ALP. Based on addition experiments with different percentages of PB serum to BM serum, good quality BM aspirates were defined by a ratio of total ALP activity in PB versus BM < 0.59 and a HMB ALP fraction > 40%. Using these criteria, 5 of 14 BM samples did not meet the quality requirements.

In conclusion, total ALP activity and ALP isoenzyme patterns are different in BM as compared to PB serum and therefore could serve as markers to assess admixture of PB in BM samples.

***Prx1* and *Col1a1* promoters target distinct bone cell populations in transgenic mice.** Zhufeng Ouyang, Zhijun Chen*, Masakazu Ishikawa, Xiuzhen Yue, Edward Greenfield, Shunichi Murakami. Case Western Reserve University, USA

Background: We previously generated *Prx1CreER-GFP* transgenic mice that express CreER and GFP under the control of a 2.4 kb *Prx1* promoter. The *Prx1CreER-GFP* transgene marks osteochondro progenitor cells in the periosteum of long bones. Because a 3.2 kb *Col1a1* promoter directs transgene expression in immature osteoblasts, we hypothesized that the *Prx1*-driven transgenes and *Col1a1*-driven transgenes are expressed in distinct but overlapping domains in the bone.

Methods: To compare *Col1a1* and *Prx1*-driven transgenes, we generated *Col1a1CreER-DsRed* transgenic mice that express, in osteoblasts, CreER and DsRed under the control of a 3.2 kb *Col1a1* promoter. The expression domains of *Col1a1CreER-DsRed* and *Prx1CreER-GFP* transgenes were analyzed in *Prx1CreER-GFP; Col1a1CreER-DsRed* double transgenic mice by histological analysis. We further isolated *Col1a1CreER-DsRed* and *Prx1CreER-GFP*-expressing cells by flow cytometry, and chondrogenic and osteogenic potential was analyzed.

Results: Our histological and flow cytometric analyses demonstrated that *Col1a1CreER-DsRed* and *Prx1CreER-GFP* transgenes are expressed in distinct cell populations in the long bones and calvariae. In the periosteum of long bones, *Col1a1CreER-DsRed* is expressed in the innermost layer directly lining the bone surface, while *Prx1CreER-GFP*-expressing cells are localized immediately outside of the *Col1a1CreER-DsRed*-expressing osteoblasts. In the calvaria, *Prx1CreER-GFP*-expressing cells are also localized in the cranial suture mesenchyme, while the *Col1a1CreER-DsRed* transgene is expressed in bone lining osteoblasts. Our in vitro experiments indicated that *Col1a1CreER-DsRed*-expressing cells are committed osteoblasts lacking chondrogenic potential, while the *Prx1CreER-GFP*-expressing cells show both chondrogenic and osteogenic potential. We also showed that *Prx1CreER-GFP*-expressing cells are precursor cells for *Col1a1CreER-DsRed*-expressing osteoblasts.

Discussion: Our results demonstrate that *Prx1CreER-GFP* and *Col1a1CreER-DsRed* transgenes are expressed in distinct cell populations both in the long bones and calvariae. These transgenes will provide novel approaches for analyzing the biology of the periosteum and cranial suture mesenchyme under physiologic and pathologic conditions.

Advanced Glycation End Products Inhibit the Mineralization of Mouse Stromal ST2 Cells by Binding the Receptor for AGEs and Increasing TGF-β Expression and Secretion. Masakazu Notsu*[1], Toru Yamaguchi[2], Kyoko Okazaki[3], Ken-ichiro Tanaka[4], Noriko Ogawa[3], Ippei Kanazawa[2], Toshitsugu Sugimoto[4]. [1]Shimane University, Japan, [2]Shimane University Faculty of Medicine, Japan, [3]Internal Medicine 1 Shimane University Faculty of Medicine, Japan, [4]Shimane University School of Medicine, Japan

We and others have recently showed that patients with type 2 diabetes mellitus (T2DM) have a higher risk for fracture, although they have normal or slightly higher bone mineral density (BMD). These findings suggest that bone fragility in T2DM, which is not defined by BMD, may contribute to fracture risk. Hyperglycemia accelerates the formation of advanced glycation end products (AGEs) and causes diabetic complications. AGEs including pentosidine are also known to cause bone fragility due to quality deterioration in diabetic patients. We found that AGEs suppressed mineralization of mouse stromal ST2 cells by inhibiting their differentiation with reduced expressions of osteocalcin (OCN) and osterix (OSX) mRNA in the cells. Recent studies have shown that AGEs increased TGF-β expression and activated Smad signals in mesangial and nerve cells, indicating that AGEs cause diabetic complications in kidneys and nerves by activating TGF-β. It is known that TGF-β is especially abundant in bone, and that enhancement of its signals deteriorates bone quality in animal experiments. However, it is still unclear whether or not TGF-β signal is involved in the AGEs-induced suppression of osteoblastic bone formation. In this study, we made AGE3 by incubating BSA with glycolaldehyde, and examined the roles of TGF-β in the suppression of mineralization of ST2 cells induced by AGE3. Treatments of the cells with AGE3 (200μg/mL) significantly inhibited mineralization by 71.2% on experimental day 21 ($P<0.001$). Simultaneously, AGE3 significantly increased the mRNA expression and protein level of TGF-β by real-time PCR and ELISA of whole cell lysates, respectively, on days 3, 5, and 7 ($P<0.001$). Transfection of siRNA of the receptor for AGEs (RAGE) significantly inhibited the AGE3-induced increase in TGF-β protein level ($P<0.001$), and recovered mineralization in the cells ($P<0.05$). Moreover, treatments with TGF-β type I receptor kinase inhibitors (2.5uM SD208) significantly antagonized the AGE3-induced suppression of OCN and OSX mRNA expressions ($P<0.05$), and recovered mineralization completely ($P<0.001$). These findings indicate that the AGEs-RAGE pathway inhibits the mineralization of ST2 cells by increasing TGF-β expression and secretion, suggesting that TGF-β action stimulated by AGEs adversely affects not only kidney or nerve but also bone in the process of diabetic complications.

Blocking β-adrenergic signaling attenuates reductions in trabecular bone mass, marrow adiposity and marrow leptin expression in high calorie diet fed but not low calorie diet fed growing mice. Kyunghwa Baek*[1], Hyo Rin Hwang[2], Hyun-Jung Park[2], Arang Kwon[2], Abdul Qadir[2], Jeong-Hwa Baek[3]. [1]Gangneung-Wonju national university, School of dentistry, South Korea, [2]Seoul National University, South Korea, [3]Seoul National University, School of Dentistry, South Korea

We sought to compare the effects of high calorie or low calorie diet on the skeletal integrity and elucidate whether β-adrenergic blockade attenuates dietary calorie alteration induced bone loss and whether such an effect is associated with leptin. Male 6-week-old C57BL/6 mice were randomly assigned into 3 groups (20 mice each): ad-lib fed control diet group (CON; 10 kcal% fat), high calorie diet group (HIGH; 60 kcal% fat), and low calorie diet group (LOW; 30% kcal restriction *vs*. CON diet). In each diet group, 10 mice were treated with vehicle (VEH) and the other 10 mice were treated with propranolol, a b-adrenergic receptor antagonist (BB; 0.5g/L in drinking water). Over 12 weeks, HIGHVEH had higher while LOWVEH had lower body weight/fat mass *vs*. CONVEH. β-blockade mitigated high calorie diet induced body weight and fat mass increase. Femoral trabecular bone mineral density (BMD) was declined in both HIGHVEH and LOWVEH but the magnitude of decline was greater in LOWVEH mice. This femoral trabecular BMD decrement was attenuated only in HIGHBB. Adipocyte number in HIGHVEH and LOWVEH was higher vs. CONVEH, but this increment was abolished in both HIGHBB and LOWBB. Reduction in marrow leptin expression was observed in HIGHVEH and LOWVEH and this decrement was abolished only in HIGHBB. In summary, the magnitude of low calorie diet induced bone loss was greater than that of high calorie diet in growing mice. β-adrenergic blockade mitigated metaphyseal bone loss and reductions in marrow adiposity and marrow leptin expression seen with high calorie diet. These data suggest an important role for β-adrenoreceptor signaling pathway in bone and marrow fat response to dietary calorie alteration.

Bmi-1 Is A Critical Molecule for Activation of the Sonic Hedgehog Signal Pathway. Jun Wu*[1], Wen Sun[2], Rong Wang[1], David Goltzman[3], Dengshun Miao[4]. [1]Nanjing Medical University, China, [2]Nanjing Medical University, The Research Center for Bone & Stem Cells, Peoples Republic of China, [3]McGill University, Canada, [4]Nunjing Medical University, Peoples Republic of China

Our previous study demonstrated that Bmi1 deficiency resulted in skeletal growth retardation and premature osteoporosis with up-regulation of p27 in bone marrow mesenchymal stem cells (BM-MSCs). In this study, we confirmed this up-regulation of p27 at both mRNA and protein levels in bone tissue from Bmi-1 deficient mice. To determine whether p27 acts downstream of Bmi1 to regulate skeletal growth and development in vivo, we generated $Bmi1^{-/-}p27^{-/-}$ double knockout mice and compared them with $p27^{-/-}$, $Bmi1^{-/-}$, and wild-type littermates. Body size, body weight, bone mineral density, trabecular bone volume, osteoblast numbers, ALP and type I collagen positive areas were increased significantly in $p27^{-/-}$ mice, but decreased significantly in $Bmi1^{-/-}$ mice compared to wild-type mice. The double mutant $Bmi1^{-/-}p27^{-/-}$ mice however closely resembled the phenotype of the $Bmi1^{-/-}$ mice, including growth retardation and premature osteoporosis. Consequently, we asked whether the signaling pathway activated by p27 deletion and leading to increased skeletal size could be blocked by the deletion of Bmi-1. To examine this question, microarray analyses of differential gene expression profiles were performed in long bone extracts from $p27^{-/-}$ mice and their wild-type littermates. Results revealed that the expression levels of molecules in the sonic hedgehog (Shh) signaling pathway, including Shh, Smoothened (Smo), Gli1/2/3 and Bmi1 were up-regulated, whereas

suppressor of fused (Sufu), a negative regulator of this pathway was down-regulated in $p27^{-/-}$ mice. Their up-regulation or down-regulation at mRNA and protein levels was confirmed by real-time RT-PCR and Western blots. We then employed Shh-N and the Shh antagonist KAAD-Cyclopamine to treat BM-MSCs derived from wild-type, $p27^{-/-}$, $Bmi1^{-/-}$ or $Bmi1^{-/-}p27^{-/-}$ mice, respectively. Results showed that cell proliferation was accelerated in a dose dependent manner in Shh-N-treated BM-MSCs derived from wild-type or $p27^{-/-}$mice, but not in those derived from $Bmi1^{-/-}$ or $Bmi1^{-/-}p27^{-/-}$ mice. In contrast, cell proliferation was inhibited in a dose dependent manner in KAAD-Cyclopamine-treated BM-MSCs derived from wild-type or $p27^{-/-}$ mice, but not in those derived from $Bmi1^{-/-}$ or $Bmi1^{-/-}p27^{-/-}$ mice. Our results demonstrated that deletion of Bmi-1 can blocks effects of p27 deficiency induced activation of Shh signal pathway. Bmi-1 therefore is a critical effective molecule for the activation of Shh signal pathway.

Contribution of Hematopoietic Stem Cells to Dental Tissues. Amanda LaRue[1], Beneta Parthiban[2], Jasper L Cumbee IV[2], James Borke[3], Makio Ogawa[2], Meenal Mehrotra*[4]. [1]Ralph H. Johnson VAMCMedical University of South Carolina, USA, [2]MUSC, USA, [3]Western University of health Sciences, USA, [4]Medical University of South Carolina & Research Services, Ralph H Johnson VAMC, USA

While the complex structural composition of the teeth provides hardness and durability, structures like dentin and periodontal ligament (PDL) are vulnerable to damage and require constant maintenance. It is generally believed that the regeneration of both odontoblasts and PDL cells is provided by local stem cells, i.e., stem cells in the dental pulp and those residing in PDL. Recent studies have shown that bone marrow (BM) mesenchymal stem cells (MSC) can differentiate into odontoblast and regenerate the PDL and alveolar bone. BM is thought to contain two types of stem cells, MSCs and hematopoietic stem cells (HSCs). Using a single HSC transplantation model, we have previously shown that adipocytes, osteoblasts, osteocytes and fibroblasts/myofibroblasts in multiple tissues are derived from HSCs. Studies from other groups have suggested that HSCs may participate in dental tissues too. Indeed, the presence of $CD45^+$ cells has been demonstrated in reparative dentin in mice. c-kit enriched BM cells give rise to odontoblast and $CD34^+$ cells have been demonstrated in the human gingiva. Thus, we hypothesize that HSCs can differentiate into odontoblasts and cells in the PDL. Transplantation of un-manipulated BM cells harvested from enhanced green fluorescent protein (EGFP) mice into lethally irradiated recipients generated $EGFP^+$ runt-related transcription factor-2^+ ($Runx2^+$) and $EGFP^+$ Dentin Matrix Protein-1^+ ($DMP\text{-}1^+$) odontoblasts/pulp cells and $EGFP^+$ Alpha Smooth Muscle $Actin^+$ ($\alpha\text{-}SMA^+$) and $EGFP^+$ $Osteocalcin^+$ (OCN^+) cells in the PDL. Furthermore, we identified $CD45^+$ cells in the pulp and PDL, indicating their origin from the HSCs. To confirm the HSC origin of these cells, mice were lethally irradiated, transplanted with a clonal population of cells derived from a single $EGFP^+$ HSC and multilineage engraftment confirmed. Analysis of paraffin sections from the molar crown showed numerous $EGFP^+$ cells within the pulp region and the PDL attached to the tooth. Analysis of pulp showed $EGFP^+$ cells which also expressed DMP-1 and Runx-2, markers for odontoblasts/pulp cells. Immunohistochemical analysis of PDL showed $EGFP^+$ cells that expressed α-SMA and OCN, markers for fibroblasts and osteogenic cells respectively. Thus, our studies confirm that HSCs can give rise to these dental cells and may open new avenues of therapy for a number of dental diseases and injuries through the use of this novel source.

Impact of RARγ- BMP Signaling Cross-talk on Endochondral Bone Formation. Kenta Uchibe*, Jiyeon Son, Maurizio Pacifici, Masahiro Iwamoto. Children's Hospital of Philadelphia, USA

The nuclear retinoic acid receptors—RARα, β and γ—play key roles in the skeletal pattern formation and development. We previously showed that RARγ is a major regulator of chondrogenesis, which is the initial step of endochondral ossification. Pharmacological activation of RARγ effectively blocked ectopic bone formation (heterotopic ossification; HO) in several HO model mice. A series of biochemical analysis revealed that at least part of the anti-HO action of RARγ is mediated by the inhibition of the canonical BMP signaling pathway. RARγ could regulate cellular function by activating its target gene expression (genomic action) and/or indirectly modulate the function of other transcription factors by competing co-factors (trans-repression). In the present study, we further characterized the relationship between RARγ and BMP signaling pathways and evaluated its importance in endochondral ossification.

In the first experiment, we created bone defects in wild type and RARγ null mice, and compared their repair process. By day 14 after injury, mutant mice showed remarkably faster repair compared to wild type mice. Histological analysis revealed that pSmad expression is enhanced in the healing area of mutant mice. Interestingly, in mutant mice, pSmad proteins were ectopically detected at the hypertrophic zone of the growth plate where RARγ is usually expressed. To test the effect of RARγ inhibition on canonical BMP signaling, ATDC5 cells were treated with selective RARγ antagonists, and Smad phosphorylation and Id1-luc reporter activity were analyzed. Increases in pSmad1, 5 and 8 and Id1-luc reporter activity, both of which indicate BMP signaling activity, were significantly enhanced by RARγ inhibition. Lastly, to quantify the effect of RARγ inhibition on endochondral bone formation *in vivo*, we injected Matrigel/BMP-2 subcutaneously in wild type mice, treated them with RARγ antagonist or vehicle by oral administration, and examined bone formation with micro CT. We found that ectopic bone formation (BV/TV) was dramatically enhanced in RARγ antagonist-treated compared to the vehicle-treated mice.In sum, our data indicate that interference with RARγ function stimulates bone formation and does so at least in part by stimulation of the canonical BMP signaling pathway. This strategy could represent a promising new means by which the endochondral bone formation process could be stimulated in the context of various orthopaedic needs and applications.

Increased Dietary Advanced Glycation End Products Induces Early Degenerative Spinal Structural Changes. Young Lu*[1], Svenja Illien-Junger[2], Sheeraz Qureshi[2], Weijing Cai[2], Helen Vlassara[2], Gary Striker[2], James Iatridis[2]. [1]Mount Sinai Medical Center, USA, [2]Icahn School of Medicine at Mount Sinai, USA

Introduction: Intervertebral disc degeneration and spinal degenerative changes are major causes of back pain and other lumbar spine pathologies in obese and diabetic individuals. The modern diet includes thermally processed foods that contain high levels of inflammatory advanced glycation end products (AGEs), known contributors to diabetes and aging complications. We previously showed that diabetes-related intervertebral disc degeneration in mice is associated with AGE accumulation. This study investigates the role of AGEs on the intervertebral discs and spine independent of hyperglycemia.

Materials and Methods: C57BL6 mice were pair-fed isocaloric diets with either high amount of AGEs, eg. methylglyoxal-derivatives (AGE/MG+: 1.8x104 nmoles/day; n = 9) or reduced AGEs (AGE/MG-: 0.65x104 nmoles/day; n = 11; $p<.01$) for 5 generations. Mice (F5) were sacrificed at 18 months. AGE/MG+, but not AGE/MG- mice, were insulin resistant but not hyperglycemic and had higher serum MG (1.59 ± 0.2 vs. 0.83 ± 0.2 nmole/ml $p<.05$), and weights (35.1 ± 1.8 vs. 29 ± 0.52g $p<.05$). Lumbar spines were analyzed using μCT and immunohistochemistry (anti-MG).

Results and Discussion: Vertebral cortical thickness and surface area were higher in AGE/MG+ compared to AGE/MG- mice ($p=0.029$ and $p=0.047$ respectively) (Table 1, Figure 1). The superior vertebral endplates of AGE/MG+ mice had significantly higher bone mineral density ($p=0.016$) but lower connectivity density ($p=0.0062$) compared to that for AGE/MG- mice (Table 1). Histological staining showed reduced proteoglycan content and an overall thinner glycosaminoglycan rich region in AGE/MG+ compared to AGE/MG- mice (Figure 2). Immunohistochemistry revealed greater MG accumulation in the vertebral endplates of AGE/MG+ mice.

Conclusions: Chronic exposure to oral AGEs promote early degenerative changes to the vertebrae, vertebral endplates, and intervertebral disc in parallel with insulin resistance, independent of hyperglycemia. Therefore, these effects were largely attributable to exogenous AGEs . Further studies are needed to mechanistically establish the role of AGEs on spinal structures relative to metabolic syndrome and diabetes.

Internal Ribosome Entry Site (IRES) Mediates theTranslation of Nuclear DMP1 (nuDMP1). Suzhen Wang, Chunlin Qin, Rena D'Souza, Yongbo Lu*. Texas A&M University Baylor College of Dentistry, USA

Dentin matrix protein 1 (DMP1) is highly expressed in tooth and bone. Several lines of evidence suggest that there are two forms of DMP1, a secretory form and a nuclear form (nuDMP1). The purpose of this study was to determine the nature and function of nuDMP1. Site-directed mutagenesis and PCR were employed to generate various DMP1-expressing constructs: a construct expressing full-length DMP1 with the endoplasmic reticulum (ER)-entry signal peptide deleted (SPdel-DMP1), a construct expressing a putative nuDMP1 (nuDMP1), four constructs carrying full-length DMP1 cDNA with a two-nucleotide deletion in the N-terminal 37 kDa fragment coding region and/or substitution mutations at the two putative alternative in-frame start codons and a construct in which DMP1 cDNA was fused downstream to the C-terminal end of Twist1 cDNA (Twist1-nuDMP1). Western immunoblotting and immunofluorescent staining analyses were performed to determine the expression and subcellular localization of DMP1 produced by these constructs in Cos-7 and C310T1/2 mesenchymal cells. Promoter-luciferase assays were used to analyze the effects of the various DMP1 constructs on the activity of a 5.7 kb Dspp promoter fragment. When the SPdel-DMP1 construct was transfected into Cos-7 cells, Western immunoblotting analysis showed that the SPdel-DMP1 construct produced two proteins, a full-length SPdel-DMP1 and a putative nuDMP1. Although a DMP1 construct carried a two-nucleotide deletion, which led to a premature stop codon in the N-terminal region, it still expressed the putative nuDMP1. However, the production of nuDMP1 was completely lost when the two potential downstream in-frame start codons were substituted with isoleucine. Furthermore, when the Twist1-nuDMP1 construct was transfected into Cos-7 cells, it produced both Twist1 as well as nuDMP1. In addition, when the nuDMP1 construct was transfected into C3H10T1/2 cells, immunofluorescent staining revealed the nuclear localization of the nuDMP1. Consistently, the nuDMP1 was more potent in stimulating the 5.7kb Dspp promoter activity than the full-length DMP1 with or without the ER-entry signal peptide. These data suggest that the nuDMP1 is translated from an alternative downstream in-frame start codon(s) via an internal ribosome entry site (IRES)-mediated mechanism, and that it functions as a transcription factor or co-transcription factor.

Postnatal Ablation of Ext1 in Cartilage Induces Ectopic Hypertrophy of Articular Chondrocytes and Loss of Bone Volume in Primary Spongiosa. Federica Sgariglia*[1], Maria Elena Candela[2], Julianne Huegel[2], Olena Jacenko[3], Eiki Koyama[1], Yu Yamaguchi[4], Maurizio Pacifici[1], Motomi Enomoto-Iwamoto[1]. [1]Children's Hospital of Philadelphia, USA, [2]Translational Research Program in Pediatric Orthopaedics, Division of Orthopedic Surgery, Department of Surgery, Children's Hospital of Philadelphia, USA, [3]University of Pennsylvania, School of Veterinary Medicine, USA, [4]Sanford Children's Health Research Center, Sanford-Burnham Medical Research Institute, USA

EXT1 encodes a Golgi-associated glycosyltransferase primarily responsible for heparan sulfate (HS) synthesis, and genetic mutations in *Ext1* cause severe skeletal and craniofacial phenotypes in developing and postnatal mice. To determine whether long bone epiphyseal development and endochondral ossification continuously require heparan sulfate, we conditionally ablated *Ext1* in cartilage at postnatal stages in compound *Ext1flf;Col2CreER* transgenic mice by tamoxifen injection at postnatal day 5. qPCR analysis revealed that efficiency of floxed Ext1 ablation in chondrocytes was about 80%. Mutant mice displayed growth retardation, scoliosis and limb deformities starting by 2 weeks post injection. They also displayed formation of excess cartilage that extended away from the growth plate toward perichondrium and resembled exostoses seen in Hereditary Multiple Exostoses that is caused by EXT mutations. Closer histological inspection revealed that the chondrocytes were misaligned in the mutant growth plates and the typical columnar structure was disrupted. Moreover, the hypertrophic zone was reduced, as confirmed by a decrease in collagen 10-expressing chondrocytes. We also found a major decrease in bone volume in the primary spongiosa accompanied by a significant increase in osteoclast number at the chondro-osseus junction, clearly detectable at 4 weeks after tamoxifen injection. Very interestingly, a preponderance of articular chondrocytes had undergone hypertrophy in the mutants and displayed an enlarged cell size and ectopic expression of the hypertrophic markers collagen 10 and MMP13. Furthermore, immunostaining revealed that the hypertrophic articular chondrocytes had accumulated a large amount of Perlecan pericellularly, indicating that a deficiency of heparan sulfate may have affected Perlecan homeostasis or distribution. Taken together, the data indicate that Ext1 and heparan sulfate proteoglycans are essential regulators of postnatal epiphyseal cartilage development and skeletal growth. The results point to roles of Ext1 and heparan sulfate in maintaining long-term interactions between cartilage and bone and preserving chondrocyte organization and trabecular bone.

Bone Shaft Revascularization after Marrow Ablation is Dramatically Accelerated in BSP-/- mice, along with Faster Haematopoietic Recolonization. Wafa Bouleftour*[1], Renata Neves Granito[1], Arnaud Vanden Bossche[1], Odile Sabido[2], Bernard Roche[1], Mireille Thomas[1], Marie-Thérèse Linossier[1], Jane Aubin[3], Marie-Helene Lafage-Proust[4], Laurence Vico[5], Luc Malaval[6]. [1]LBTO/INSERM U1059 - Université de Lyon, France, [2]Flow Cytometry Facility - Université de Lyon, France, [3]University of Toronto Faculty of Medicine, Canada, [4]INSERM Unit 890, France, [5]University of St-Etienne, France, [6]INSERM U1059-Université de Lyon-Université Jean Monnet, Saint-Etienne, France

The bone organ integrates the activity of bone tissue, bone marrow and blood vessels and the factors ensuring this coordination remain ill defined. Bone sialoprotein (BSP) is with osteopontin (OPN) a member of the Small Integrin Binding Ligand N-Linked Glycoprotein (SIBLING) family, involved in bone formation, hematopoiesis and angiogenesis. In rodents, bone marrow ablation induces a rapid formation of medullary bone which peaks by ~8 days (d8) and is blunted in BSP-/- mice (Bone, 50:1064, 2012). We investigated the coordinate hematopoietic and vascular recolonization of the bone shaft after marrow ablation of 2 month old BSP+/+ and BSP-/- mice (N=5/group).

Bone marrow was aspirated through the right femur epiphysis. Hematopoietic recolonization was analyzed by flow cytometry after labeling with specific antibodies. The bone vascular network was contrasted by barium sulfate infusion. Bone and vascular volume and density were measured on frontal sections. RT-PCR was performed on tri-reagent flushed bone marrow.

At d3, the ablated area in BSP-/- femurs showed higher vessel density (99.2 ± 4.9 vs $23.2 \pm 8.5/mm^2$, $p<0.05$, MWU) and vascular volume (x7) than BSP+/+ (Figure), along with higher VEGF (x1.95) and OPN (x1.8) expression. Interestingly, unablated BSP-/- femur marrow also contains more blood vessels than BSP+/+ (74.2 ± 8.4 vs $58.0 \pm 7.6/mm^2$, N=6, p=0.01, MWU). Vessel numbers in the shaft of ablated BSP+/+ mice reached BSP-/- values only by d8, but with a vascular volume which was twice the value in BSP-/-, reflecting smaller vessel size in mutants. At d6, a much higher number of Lin^- (x3) as well as LSK (Lin^- IL-7Rα^- Sca-1^{hi} c-Kit^{hi}, x2) and hematopoietic stem cells (HSC: $Flt3^-$ LSK, x2) were counted in BSP-/- marrow, indicating a faster recolonization. However, the proportion of LSK and HSC within the Lin^- was lower in BSP-/- and more differentiated stages were more abundant, as

also observed in unablated bone (Granito et al., submitted), suggesting that hematopoietic differentiation is favored in the absence of BSP.

In conclusion, bone marrow ablation in BSP-/- mice is followed by a faster vascular and hematopoietic recolonization, along with lower medullary bone formation. Thus, lack of BSP affects the interplay between hematopoiesis, angiogenesis and osteogenesis. The higher expression of the angiogenic SIBLING, OPN concomitant with massive revascularization in BSP-/- mice suggests a functional role, presently investigated with siRNA targeting OPN.

Defective Mineralization in Craniofacial Bone and Cementum in *Bsp* Null Mice. Brian Foster*[1], Yohannes Soenjaya[2], Francisco Nociti, Jr.[3], Erik Holm[4], Kamila Kantovitz[3], Helen Wimer[5], Patricia Zerfas[6], Jane Aubin[7], Graeme Hunter[8], Harvey Goldberg[9], Martha Somerman[3]. [1]National Institute of Arthritis & Musculoskeltal & Skin Diseases (NIAMS), USA, [2]Biomedical Engineering Program, Schulich School of Medicine & Dentistry, University of Western Ontario, Canada, [3]National Institute of Arthritis & Musculoskeletal & Skin Diseases (NIAMS), National Institutes of Health (NIH), USA, [4]Department of Biochemistry, Schulich School of Medicine & Dentistry, University of Western Ontario, Canada, [5]Department of Vertebrate Zoology, National Museum of Natural History, Smithsonian Institution, USA, [6]Department of Research Services, Division of Veterinary Resources, National Institutes of Health (NIH), USA, [7]University of Toronto Faculty of Medicine, Canada, [8]School of Dentistry, Schulich School of Medicine & Dentistry, University of Western Ontario, Canada, [9]The University of Western Ontario, Canada

Purpose: Bone sialoprotein (BSP) is a multifunctional extracellular matrix protein found in mineralized tissues, including bone, cartilage, tooth root cementum (both acellular and cellular types), with lesser amounts in tooth dentin. In order to understand the functional significance of BSP in biomineralization of these tissues, we analyzed intramembranous and endochondral osteogenesis, cementogenesis, and dentinogenesis, in *Bsp* null mice.

Methods: Craniofacial/dental development was analyzed in *Bsp*$^{-/-}$ and wild-type (WT) controls over a developmental time-course (1-60 days post natal; dpn) by histology, immunohistochemistry, undecalcified histochemistry, microCT, SEM, and TEM. Serum biochemistry was analyzed at 2-8 weeks.

Results: Regions of both endochondral (e.g. synchondroses) and intramembranous (e.g. calvaria, mandible, alveolar bone) ossification presented delayed mineralization, assessed by von Kossa and Goldner's trichrome stains at 1 and 14 dpn. Early osteoblast markers, osterix and alkaline phosphatase, were unchanged in *Bsp* null osteoblasts compared to WT. Cellular cementum in *Bsp* null mice featured hypomineralization parallel to that found in bone, corrected by 60 dpn. More dramatically, *Bsp* null mouse molars featured a significant reduction in acellular cementum formation (20% of WT at 60 dpn), with a lack of mineralized ultrastructure by SEM and TEM. Loss of functional acellular cementum caused periodontal breakdown, including periodontal ligament (PDL) detachment and disorganization, and extensive alveolar bone and tooth root resorption, associated with increased RANKL immunostaining and osteoclast presence. Conversely, dentin formation was unperturbed in *Bsp* null mouse molars, with no delay in mineralization, no alteration in dentin dimensions (at 1, 14, and 26 dpn), and no differences in odontoblast markers osterix, alkaline phosphatase, osteocalcin, and dentin sialoprotein. Serum calcium, phosphate, and alkaline phosphatase were undiminished in *Bsp* null mice, supporting local, tissue-specific roles for BSP that would account for different phenotypes in bone, cementum, and dentin.

Conclusions: These analyses confirm an important role for BSP in bone and cellular cementum mineralization, a critical and non-redundant function in acellular cementum formation, and lack of perceived role in molar dentin formation. Additionally, owing to its importance to cementum, BSP is essential for tooth attachment and periodontal function.

The Calcitonin hormone regulates the Osteocye. Stephen Henry*[1], Su-Chen E Huang[2], Michael Starbuck[1], Ana Hoff[3], Gilbert Cote[4], Robert Gagel[4]. [1]University of Texas MD Anderson, USA, [2]mdanderson, USA, [3]ICESPUniversity of São Paulo, Brazil, [4]University of Texas M.D. Anderson Cancer Center, USA

Calcitonin (CT) is a peptide hormone secreted predominately by the C-cells or parafollicular cells of the thyroid gland that lowers blood calcium levels. Clinically, calcitonin is used diagnostically as a tumor marker for medullary thyroid cancer (MTC), and therapeutically to transiently lower blood calcium, treat osteoporosis (e.g., a weak antiresorptive drug), and alleviate bone pain. Calcitonin is widely known for its action upon the calcitonin receptor localized to the osteoclast, and its role in mitigating bone resorption. Recently, we have discovered that a mouse model of calcitonin deficiency exhibits not only the expected increase in osteoclastic bone resorption, but also a profound increase in bone remodeling and formation. Microcomputer tomography (micro CT) images of bones from CT-null mice and control mice, as well as other histomorphometric and kinetic parameters (double-calcein labeling) illustrate that increased bone formation occurred in the trabecular region of the calvaria and long bones in CT-null mice. Furthermore, the analysis of the differential gene expression between the RNA harvested from the bones of CT-null and control mice shows a downregulation of several osteocyte-specific genes such as SOST, Dkk1, Mepe, and DMP-1 in the CT-null mice. Interestingly, the calcitonin G-coupled receptor was upregulated 10-fold in the CT-null mice. A reciprocal experiment was performed in which exogenous, recombinant calcitonin hormone was injected subcutaneously above the calvarial bones of CT-null mice, and these same osteocyte-specific genes were upregulated, thus further substantiating that the calcitonin hormone may regulate osteocytes. We hypothesize that calcitonin regulates bone resorption positively and formation negatively; a corollary is that a calcitonin antagonist would lead to increased bone resorption and increased formation. Currently, we are intrigued with the possibility that a calcitonin antagonist may serve as a potential osteoanabolic agent that stimulates *de novo* bone formation.

SA0115

Extracellular Ca^{2+} and the calcium-sensing receptor, CaSR, are important regulators of fetal lung development. Sarah Brennan*[1], William Wilkinson[1], Hsiu-Er Tseng[1], Bethan Monk[1], Holly Dibble[1], Samantha Quilliam[1], Rebecca Wadey[1], David Warburton[2], Luis Galietta[3], Paul Kemp[1], Daniela Riccardi[1]. [1]Cardiff University, United Kingdom, [2]University of Southern California, USA, [3]University of Genoa, Italy

Immature development of the lungs continues to be one of the major complications with preterm birth. Optimal postnatal lung function depends on the co-ordinated development of lung branching morphogenesis, vasculogenesis and fluid secretion. These processes start during the *pseudoglandular* stage (weeks 9 – 17 post-conception in humans, and embryonic day (E)11.5 – 16.5 in the mouse) and our group has demonstrated that the relatively hypercalcemic environment of the fetus (~1.7 mM v ~1.2 mM for a normocalcemic adult) regulates all of these processes. Previously, we have shown that this relative hypercalcemia suppresses lung branching morphogenesis through activation of the calcium-sensing receptor (CaSR) [1].

In addition, we have also shown that fetal hypercalcemia stimulates fluid secretion in the developing mouse lung, and that this process is partly controlled by the CaSR. Fluid secretion in the developing lung lumen is driven by, and proportional to, active Cl^- transport, which results in a negative transepithelial potential difference (PD), that can be measured electrophysiologically. Using this approach, here we show that, in pseudoglandular human and mouse fetal lung explants, approximately 50% of this fluid secretion is sensitive to bumetanide, and correlates with basolateral entry of Cl^- into the lumen epithelium via the Na^+-K^+-$2Cl^-$ cotransporter, NKCC2. The remaining 50% is $Ca^{2+}{}_o$-sensitive and dependent on activation of the CaSR, since the CaSR pharmacological activator NPS-R568 could also evoke fluid secretion in the presence of lower $Ca^{2+}{}_o$ concentrations (1.05 mM $Ca^{2+}{}_o$).

Immunohistochemistry shows that a number of apical chloride channels, including bestrophin, TMEM16, and the cystic fibrosis transmembrane conductance regulator (CFTR), are expressed in human fetal lung epithelium. Inhibition of CFTR using Inhibitor-172 halved Cl^--driven fluid secretion, but only in CaSR-activating conditions (by either mimicking fetal hypercalcemia or through the use of NPS-R568), suggesting an hitherto unknown interaction between the CaSR and CFTR that is currently undergoing further investigation.

In conclusion, this study indicates that fetal hypercalcemia is an important extrinsic factor in the normal development of the human lung. Furthermore, the CaSR plays an essential role in lung development through control of lung growth and fluid secretion through activation of CFTR.

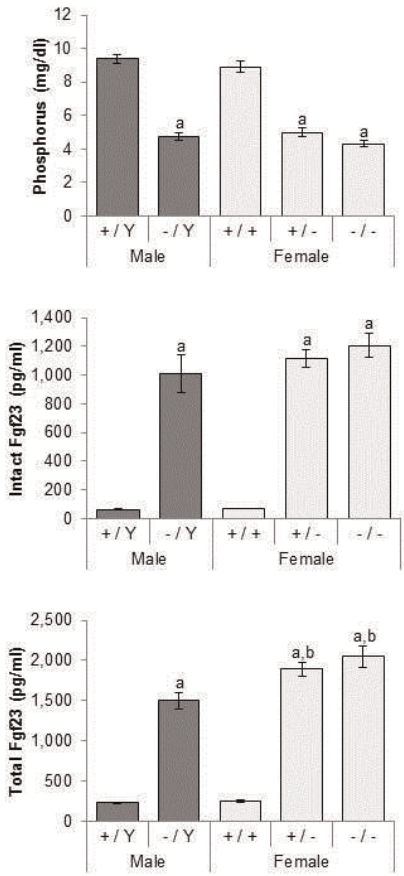
Dosage Effect of a *Phex* Mutation in a Murine Model of X-linked Hypophosphatemia. Shoji Ichikawa*, Amie Gray, Emmanuel Bikorimana, Michael Econs. Indiana University School of Medicine, USA

X-linked hypophosphatemia (XLH) is caused by mutations in the *PHEX* gene, which increase circulating levels of the phosphaturic hormone, fibroblast growth factor 23 (FGF23). Since XLH is a dominant disease, one mutant allele is sufficient for manifestation of the disease. However, dosage effect of a *PHEX* mutation in XLH is not completely understood. To examine the effect of *Phex* genotypes, we compared serum biochemistries and skeletal measures between all five possible genotypes of a new murine model of XLH ($Phex^{K496X}$ or $Phex^{Jrt}$). Compared to sex-matched littermate controls, all *Phex* mutant mice had hypophosphatemia, mild hypocalcemia, and increased parathyroid hormone and alkaline phosphatase levels. Furthermore, mutant mice had markedly elevated serum Fgf23 levels due to increased *Fgf23* expression and reduced cleavage of Fgf23. Although females with a homozygous *Phex* mutation were slightly more hypocalcemic and hypophosphatemic than heterozygous females, the two groups had comparable intact Fgf23 levels. Similarly, there was no difference in intact Fgf23 or phosphorus concentrations between hemizygous males and heterozygous females. Compared to heterozygous females, homozygous counterparts were significantly smaller and had shorter femurs with reduced bone mineral density, suggesting the existence of dosage effect in the skeletal phenotype of XLH. Howevever, overall phenotypic trends in regards to mineral ion homeostasis were mostly unaffected by the presence of one or two mutant *Phex* allele(s). The lack of gene dosage effect on circulating Fgf23 (and thus, phosphorus) levels suggests that a *Phex* mutation may create the lower set point for extracellular phosphate concentrations.



Effects of *Phex* genotypes on serum biochemistries. Total Fgf23 represents intact Fgf23 protein and C-terminal fragments of Fgf23 measured by C-terminal ELISA. Dark gray bars, males; light gray, females. Number of animals = 11-13 per group. Significant difference to same-sex littermates (+/Y vs. -/Y and +/+ vs. +/- or +/+)[a], comparable male genotypes (+/Y vs. +/+ and -/Y vs. +/- or -/-)[b], and heterozygous females (+/- vs. -/-)[c] by unpaired t-test (p-value < 0.05). All values are presented as mean ± SEM.

Crosstalk Between Parathyroid Hormone Related Proteins And Minor Fibrillar Collagens. Minoti Hiremath*, Neda Shefa, Julia Oxford. Boise State University, USA

The aim of our study is to determine if PTHrP regulates bone growth during endochondral ossification by regulating the expression of minor fibrillar collagens. Based on abundance, collagens are classified as major collagens, including type 1 and 2, and minor collagens including type 5 and 11. Minor collagens regulate the formation of major collagen fibrils and dictate the quality of the ECM that is synthesized. In humans, heterozygous mutations in the COL11A1 gene cause chondrodysplasia with eye and ear defects designated as Stickler syndrome type II or Marshall syndrome. Collagen 11 is expressed at the periphery of the cartilage underlying the bone collar, distal to the hypertrophic zone. Based on the human diseases caused by mutations of COL11A1 and the expression profile, Collagen XI appears regulate bone growth.Parathyroid hormone related protein (PTHrP) also regulates bone growth by binding to its cognate G-protein coupled receptor, PTHR1. PTHrP maintains columns of proliferating chondrocyte and delays their differentiation into prehypertrophic chondrocytes, preventing premature ossification. Loss of PTHrP results in Bloomstrand's osteo-chondrodystrophy characterized by short bones, small ribcage and domed skulls, and is phenocopied by $PTHrP^{-/-}$ mice.

We hypothesized that one of the mechanisms by which PTHrP regulates endochondral ossification is by regulating expression of minor fibrillar collagens or their isoforms. We used C2C12 cells treated with Bmp2, as a model of osteoblasts. After 5 days of Bmp2 treatment, PTHrP was added for 24 hours and control plates were left untreated. Using semi-quantitative RT-PCR, we observed that PTHrP regulates expression of *COL11* isoforms V1b and V1bV2 in C2C12 cells. This result is intriguing because we found that V1b isoforms of *COL11* were expressed adjacent to the bony collar and distal to the hypertrophic zone. Moreover, these isoforms decrease mineralization in MC3T3-E1 and in Bmp2-treated C2C12 osteoblasts. We also tested regulation of minor collagens *COL5A1, COL5A3* and *COL11A2* by PTHrP, in C2C12 cells, using RT-PCR. Our results indicate that PTHrP reduces *COL5A1* and *COL11A2* and increases *COL5A3* expression in C2C12 cells. Thus, we demonstrate that PTHrP regulates minor collagens in myogenic and osteoblastic cell lines. We are currently examining the expression of minor collagens to determine if they are absent or mislocalized in the developing long bones $PTHrP^{-/-}$ mice.

Parathyroid Hormone Agonists Linked to a Collagen Binding Domain Increase Anagen Hair Follicles and Reduce Hair Loss in Mice with Alopecia Areata. Ranjitha Katikaneni*[1], Rohan Gulati[2], Daniel Suh[1], Joshua Sakon[3], Andrew Seymour[4], Tulasi Ponnapakkam[5], Robert Gensure[6]. [1]Childrens Hospital at Montefiore/Albert Einstein College of Medicine, USA, [2]Children's Hospital at Montefiore, USA, [3]University of Arkansas, USA, [4]Pathology, Montefiore Medical Center, USA, [5]Childrens Hospital at Montefiore, New York/Albert Einstein College of Medicine, USA, [6]Children's Hospital at Montefiore, Albert Einstein College of Medicine, USA

Parathyroid hormone can stimulate the hair cycle by activating Wnt signaling and increasing production of beta-catenin and LEF-1 in keratinocytes, which causes hair follicles to transition to the anagen (growth) phase. Alopecia areata is a common form of hair loss affecting 1.7% of population, in which autoimmune-mediated destruction of anagen phase hair follicles leads to patchy hair loss; currently there is no adequate therapy. PTH-CBD is a fusion protein of PTH(1-33) linked to a bacterial collagen binding domain which targets delivery to collagen-containing tissues, including skin. We tested if PTH-CBD would promote hair growth in the mouse model of alopecia areata. 40 Female C3H/HeJ engrafted mice were obtained from Jackson Laboratories (Bar Harbor, ME). After 8 weeks (partial hair loss), mice were treated with either Vehicle, Low Dose PTH-CBD (320 mcg/kg), High Dose PTH-CBD (1000 mcg/kg), Weekly Dose PTH-CBD (1000 mcg/kg), or PTH(7-33)-CBD (antagonist - 320 mcg/kg), and monitored for 2 months. There were visible effects of treatment within the first few days, and overall improvements in hair growth pattern remained evident over the 2 month period. At the end of the study, hair regrowth or maintenance (within 40% of baseline using gray scale analysis) was observed in 17/21 (81%) total PTH-CBD treated mice vs. 3/10 (30%) vehicle control mice ($p<0.01$, Chi Square test). Animals receiving higher doses or more frequent doses of PTH-CBD appeared to have a greater response, although this was more difficult to quantify. Histological examination revealed marked increase in anagen VI follicles in PTH-CBD treated animals relative to vehicle controls (Figure 1), regardless of the dose or dose frequency. There was evidence of an ongoing immune response in most treated animals, as expected. These histological

changes were also present in the 4 treated animals with ongoing hair loss, suggesting that combined immunosuppressant treatment may result in more consistent responses. The antagonist compound appeared to have little effect on hair growth, follicle number, or immune response. Overall, PTH-CBD administration resulted in increased hair growth and a marked increase in number of growing hair follicles despite an ongoing immune reaction in C3H/HeJ engrafted mice. PTH-CBD shows promise as a therapy for alopecia areata, particularly in conjunction with a mild immune suppressant such as hydrocortisone cream.

SA0122

Subclinical PTH resistance in a patient with a novel heterozygous GNAS mutation: Gαs haploinsufficiency as a plausible cause. Serap Turan*[1], Susanne Thiele[2], Bettina Brix[2], Zeynep Atay[3], Saygin Abali[3], Murat Bastepe[4]. [1]Marmara University Istanbul-Turkey, Turkey, [2]Division of Experimental Paediatric Endocrinology & Diabetes, University of Luebeck, Germany, [3]Pediatric Endocrinology, Marmara University, Turkey, [4]Massachusetts General Hospital, Harvard Medical School, USA

Pseudohypoparathyroidism (PHP) is characterized by hypocalcemia and hyperphosphatemia due to renal proximal tubular resistance to parathyroid hormone (PTH). PHP-Ia, which is associated with Albright's hereditary osteodystrophy (AHO) and resistance to some other hormones, results from mutations within *GNAS* that lead to loss of Gαs activity. Paternal Gαs allele is normally silenced in the renal proximal tubule, and therefore, PTH resistance develops only when these *GNAS* mutations occur on the maternal allele. The same *GNAS* mutations do not lead to PTH resistance but cause AHO alone when located on the paternal allele, i.e. pseudopseudohypoparathyroidism (PPHP). Here, we describe a patient with persistent PTH elevation without hypocalcemia (Table), who plausibly carries a paternal inactivating *GNAS* mutation. The patient is a female who presented at the age of 13.5 years with multiple AHO features, including short stature, shortening of the third and fourth metacarpals, and subcutaneous calcification. The patient was not obese (BMI=19 kg/m^2) and did not have cognitive impairment. She was born from a healthy mother, with a birth weight of 1 kg at term. There was no family history of AHO features or hormone resistance. Biochemical analysis showed no evidence for resistance to TSH or gonadotropins. Serum calcium, phosphorus, and vitamin D values were within the normal range (Table). Erythrocyte Gαs activity of the patient was reduced (46.7%). Accordingly, nucleotide analysis of leukocyte DNA revealed a novel heterozygous *GNAS* mutation (c.328 G>C; p.A109P) in the patient, which affects the C-terminal end of the Gαs alpha-helical domain. The mutation is not detected in her mother and DNA from the father was not available for genetic analyses, making it difficult to determine whether the mutation occurred de novo (maternal or paternal) or inherited from the father. However, it is possible that this mutation is located on the paternal allele, given that others and we have previously observed elevated serum PTH without hypocalcemia in mice with paternal *Gnas* disruption. Furthermore, our patient exhibited AHO features and evidence of PTH resistance but none of the PHP-Ia features associated with inactivating maternal *GNAS* mutations, such as obesity, cognitive impairment, and resistance to other hormones. We are currently performing additional investigations to determine whether this novel mutation is indeed paternal. If verified, this finding would indicate the presence of subclinical PTH resistance in PPHP and suggest the existence of Gαs haploinsufficiency in a PTH responsive tissue in which Gαs is biallelically expressed, such as bone.

Table. Serum biochemistries of the patient.

βAdrenergic Receptor agonist suppresses BMP-induced osteoblastic differentiation in MC3T3E-1 cells while epinephrine modulates it differently. Takayuki Yamada*[1], Tadayoshi Hayata[2], Takuya Notomi[3], Yoichi Ezura[4], Kiyoshi Harada[5], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [3]GCOE, Tokyo Medical & Dental University, Japan, [4]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [5]Department of Maxillofacial Surgery, Maxillofacial & Neck Reconstruction, Graduate School of Medical & Dental Sciences, Tokyo Medical & Dental University, Japan

Currently, about 10% of the total population suffers from osteoporosis and the number of patients is still increasing. Parathyroid hormone (PTH) is currently the only bone anabolic drug. However, PTH is expensive and its use is limited to less than 2 years. Therefore the first choice treatment of osteoporosis is bisphosphonate (BPs). They are efficacious in reduction of risks of pathological fractures in patients with osteoporosis, while side effect, such as bisphosphonate-related osteonecrosis of the jaw (BRONJ) have be described BRONJ could occur after surgical dental treatments such as tooth extraction. As a possible solution for this situation is to develop a drug that may enhance bone formation. The presence of ß2 adrenergic receptor (ß2AR) is essential for PTH-induced anabolic action on bone. This suggests that downstream of adrenergic pathway may modulate PTH action. Therefore, we tried to identify new ways that could increase bone formation. Specifically, we examine genes targeted by adrenergic signaling in osteoblasts. MC3T3E-1 cells were stimulated by isoproterenol or by epinephrine using cyclic treatments (every three minutes), and were then cultured for additional 3 days in the presence of low dosage of BMP. ALP activity was measured using PNPP and the obtained data were normalized against the protein. Epinephrine treatment tended to increase ALP activity in the presence of BMP, whereas, PTH did not enhance ALP activity even in the presence of BMP. We also examined ß2 adrenergic receptor agonist, isoproterenol. We found that isoproterenol inhibited ALP activity by opposing BMP action, suggesting that isoproterenol action is different from that of epinephrine. These data suggest individual effects of GPCR agonists on the expression of osteoblastic genes.

A Genetic Test to Predict Patient Response to rhBMP-2 for Lumbar Spinal Arthrodesis. Travis Burgers*[1], Jianfeng Xu[2], Martin Hoffmann[3], Debra Sietsema[4], Victoria Zismann[5], Berry Button[5], Paula Davidson[1], Sha Tao[6], Waibhav Tembe[5], Jeffrey Kiefer[5], James Mason[1], Bart Williams[7], Jeffrey Trent[8], Clifford Jones[4]. [1]Van Andel Institute, USA, [2]Translational Genomics Research Institute; Center for Cancer Genomics, USA, [3]Grand Rapids Medical Education Partners, USA, [4]Orthopaedic Associates of Michigan; Michigan State University, USA, [5]Translational Genomics Research Institute, USA, [6]Center for Cancer Genomics, USA, [7]Van Andel Research Institute, USA, [8]Translational Genomics Research Institute, USA

INTRODUCTION: The use of rhBMP-2 (Medtronic, Memphis, TN) in spinal arthrodesis remains controversial due to off-label use, cost, and reported complications despite high fusion rates. Up to 4.6% of rhBMP-2 posterolateral lumbar arthrodeses have a complication of postoperative painful seroma formation requiring secondary surgery. The biological attributes underlying these responses to rhBMP-2 have not been fully elucidated. This study aims to identify genetic variants that will predict a patient's risk of complications associated with rhBMP-2.

METHODS: Our previous analysis described the exome sequencing-based search for risk-predictive genetic markers in eight patient samples, consisting of six hyperresponders (required operative dural decompression due to seroma accumulation) and two non-hyperresponders. In the current study, we selected 200 SNPs from the exome sequencing results based on prevalence in hyperresponders and a ranking scheme using molecular associations. We then genotyped these SNPs in 108 Caucasian patients treated with rhBMP-2. Standard statistical analyses of genetic association were performed to identify SNPs that correlate with hyperresponse to rhBMP-2.

RESULTS: An allelic test comparing frequency of each SNP between hyperresponders and non-hyperresponders confirmed an association for 5 SNPs ($p<0.05$); these consisted of nonsynonymous changes or splice variants in *NID1*, *SENP7*, *FARP1*, *PRGRI*, and *CDH3*. The performance of each mutation for discriminating hyperresponders from non-hyperresponders, measured by area under the receiver

operating characteristic curves (AUC), ranged from 0.65 to 0.68. The combined AUC of these 5 variants was 0.75 (p=0.0003). Among patients with 7 or more hyperresponsive alleles, 78% were hyperresponders; in comparison, only 10% were hyperresponders among patients with 6 or fewer hyperresponsive alleles. Importantly, differentiation between the two groups is highly significant (p=0.00002).

CONCLUSION: Our results are the first to suggest that a combination of multiple genetic variants associated with pathological response to rhBMP-2 can be used to identify those at greatest risk to be hyperresponders. Studies are underway to validate the predictive power of our current panel of SNPs in independent cohorts of rhBMP-2 treated patients. This study provides the foundation to support pre-operative genetic screening to guide rhBMP-2 use in spinal arthrodesis patients.

A Mouse Model to Study the Function of *RECQL4* on Skeletogenesis. Linchao Lu*[1], Karine Harutyunyan[2], Weidong Jin[1], Tao Yang[3], Yuqing Chen[4], Jianhong Wu[1], Brian Dawson[4], Ming-Ming Jiang[4], Kyu-Sang Joeng[1], Brendan Lee[4], Lisa Wang[1]. [1]Baylor College of Medicine, USA, [2]MD Anderson Cancer Center, USA, [3]Van Andel Research Institute, USA, [4]Baylor College of Medicine, Howard Hughes Medical Institute, USA

Background: *RECQL4* is a member of ATP-dependent DNA helicase superfamily II, and has been shown to play a role in DNA replication, homologous recombination and DNA damage repair. Deleterious mutations in *RECQL4* are responsible for several human genetic disorders, including Rothmund-Thomson syndrome (RTS), RAPADILINO syndrome, and Baller-Gerold syndrome. Skeletal abnormalities are common among these three disorders, including radial ray/thumb defects, radio-ulnar and radio-humeral synostoses, foreshortened limbs, brachymesophalangy, absent patellae, osteopenia, and craniosynostosis. Furthermore, RTS patients with *RECQL4* mutations have a significant risk of developing bone cancer (osteosarcoma). However, the molecular mechanisms underlying these findings remain to be elucidated.

Methods: To study the function of *RECQL4* on skeletogenesis *in vivo*, a mouse *Recql4* conditional allele with two loxp sites flanking exons 5 and 8 was generated by gene targeting. Transgenic mice expressing Prx1-Cre were crossed with these floxed *Recql4* mice to inactive *Recql4* in mesenchymal progenitors of developing limbs.

Results: $Recql4^{fl/fl}$;Prx1-Cre^{+} mice (Prx1-CKO) were born with a normal Mendelian ratio. However, these mice had short forelimbs and smaller hindlimbs, missing digits, and displayed severe growth retardation and increased postnatal lethality before weaning age. Dissection of different stages of embryonic development showed that Prx1-CKO embryos started to exhibit abnormal forelimb formation at E12.5. Furthermore, micro-CT analysis of skulls of 3 week old Prx1-CKO mice demonstrated bilateral synostosis of coronal and squamosal sutures. Using *Rosa26-lacZ* reporter mice, Prx1-Cre was shown to be strongly expressed in the coronal and squamosal sutures at P1 age. H&E staining of coronal suture in these Prx1-CKO mice showed that the suture was already fused at day E16.5.

Conclusions: The skeletal findings in these $Recql4^{fl/fl}$;Prx1-Cre^{+} mice recapitulate the major skeletal findings in the *RECQL4* spectrum of disorders, and suggest that *Recql4* is required for normal limb and cranial suture development. This Prx1-CKO mouse model will be used to further study the molecular mechanisms underlying the skeletal abnormalities in *RECQL4* associated diseases.

Cinacalcet as adjunct therapy in familial hypophosphatemic rickets: 18 months experience. Uri Alon*. Children's Mercy Hospital, USA

Objective: based on preliminary findings, indicating a potential for Cinacalcet, due to its suppression of PTH (CJASN 2008;3:658), to allow the use of lower doses of oral phosphate (OP) and calcitriol in treating XLH, the objective of this study was to examine its long-term effect as adjunct treatment in children with XLH.

Methods: Eight children (F5), ages 7.8-20.9y (median 13.9), who were already treated by OP and calcitriol were enrolled in the study. Cinacalcet was added at 30mg once daily to those weighing <= 30kg and 60mg to those >30kg. Clinic visits were done every 3m; dose of medications adjusted to maintain serum P similar to baseline, PTH within its normal range and Ca^{++} >1.00 mmol/l. In case of hypercalciuria (>4mg/kg/24h) thiazide/amiloride was added. Blood was checked for creatinine, Ca^{++}, P, ALP, PTH and FGF23; urine for TP/GFR and Ca excretion. Radiographs of lower joints were done every 6 months, renal ultrasound annually.

Results: Follow-up lasted 21.2 ± 5.3m (median 18). Rickets stayed healed in all. In one child nephrocalcinosis grade 1, present at baseline did not change and in another developed after 2 years into the study. At the end of the study, 7 children were receiving Cinacalcet 30mg, and the oldest 60mg. 3 children had their growth plates closed at the beginning of the study, Height SDS improved in 2 patients, were unchanged in 2 and decreased in 1. One child was on thiazide/amiloride at baseline and in 3 it was added during the study. No side effects were observed and none of the patients discontinued the study.

Conclusions: The addition of the calcimimetic: (1) resulted in significant decreases in PTH and FGF23 and increase in TP/GFR enabling significant decreases in calcitriol and OP doses (2) requires careful attention to serum and urine calcium. Further studies are warranted exploring the beneficial effects of calcimimetics in the treatment of children with XLH.

Delayed Fracture Healing in a Mouse Model for Craniometaphyseal Dysplasia. Yusuke Hagiwara, Xi Jiang, Zhifang Hao, Ernst Reichenberger, I-Ping Chen*. University of Connecticut Health Center, USA

Homozygous knock-in mice ($Ank^{KI/KI}$) carrying a Phe377del mutation in ANK replicate many features of human craniometaphyseal dysplasia (CMD), a rare genetic bone disorder characterized by hyperostosis of craniofacial bones and metaphyseal flaring of long bones with undertrabeculation of metaphyses and increased trabeculation of diaphyses. Serum TRAP5b levels are increased in $Ank^{KI/KI}$ mice whereas *in vitro* osteoclast (OC) formation and function are decreased.

We studied $Ank^{KI/KI}$ OC activity in a tibia fracture healing model where the fracture callus is actively remodeled within a 2- to 3-week period. 3-month-old male $Ank^{+/+}$ and $Ank^{KI/KI}$ mice were subjected to transverse diaphyseal fracture of the left tibia. Radiographs were taken at days 0, 7, 14 and 21 to monitor the healing progress. Mice were sacrificed at day 14 or 21 post-fracture. For the 21 day group, an intraperitoneal injection of calcein and demeclocycline was administered two weeks and one day prior to sacrifice, respectively. The fractured tibia was fixed and frozen sections were stained for TRAP using the fluorescent substrate ELF-97.

Qualitative histological analyses together with radiographs, showed significant callus remodeling in $Ank^{+/+}$ mice but less decrease in callus size in $Ank^{KI/KI}$ mice between 14 to 21 days after fracture. More calcein label was retained and larger amounts of cartilaginous callus remained in $Ank^{KI/KI}$ mice compared to $Ank^{+/+}$ mice 21 days after fracture. Trabeculae in the remodeled $Ank^{KI/KI}$ callus were reduced, both in thickness and number. Alternatively to TRAP staining, we used CD11c as a reporter to visualize OC activity during fracture healing *in vivo*. Dendritic cells (DC) were reported to be recruited to sites of inflammation to mediate bone resorption. We sorted cells positive for CD11c, a marker for DC, from bone marrow of CD11c-mCherry reporter mice. Multinucleated cells formed after treatment with M-CSF and RANKL and the majority of cells coexpressed TRAP and CD11c. Our preliminary data using the CMD mouse model expressing CD11c-driven mCherry reporter showed that CD11c-mCherry cells were located on the bone surface inside the callus and stained positive for TRAP.

Tibia fracture is a useful tool for evaluating the ability of mice to initiate bone formation followed by remodeling. Our results suggest that the decrease in new bone formation and osteoclast remodeling may account for reduced metaphyseal and increased diaphyseal trabeculation in $Ank^{KI/KI}$ mice.

Discoidin Receptor 2 Control of Skeletal Osteogenesis and Adipogenesis. Chunxi Ge*[1], Zhengyan Wang[2], Jinhui Liao[3], Guisheng Zhao[3], Binbin Li[3], Renny Franceschi[2]. [1]Pom Univ of Michigan School of Dentistry, USA, [2]University of Michigan, USA, [3]University of Michigan School of Dentistry, USA

Human mutations in discoidin receptor 2 (*Ddr2*) cause spondylo-meta-epiphyseal dysplasia (SMED), resulting in shortened digits and limbs and craniofacial abnormalities. DDR2, a collagen receptor tyrosine kinase, stimulates ERK1/2 and p38 MAP kinase pathways, which, in other systems, activate osteoblast differentiation and suppress adipogenesis via selective phosphorylation of RUNX2 and PPARg transcription factors. In this study, we examine effects of *Ddr2* deletion on bone structure, marrow adipogenesis and mesenchymal stem cell (MSCs) differentiation to osteoblasts or adipocytes.Bone and marrow fat was analyzed in 5 month-old *smallie* (*slie*) mice harboring a spontaneous 150 kb deletion in *Ddr2* ($Ddr2^{slie/slie}$ mice) using microCT and osmium staining. Mice were also used as a source of calvarial osteoblasts, marrow stromal cells (MSCs) or ear mesenchymal stem cells (EMSCs). Runx2 and PPARg phosphorylation was measured using antibodies specific to MAPK phosphorylation sites (RUNX2, S319; PPARg, S112). RUNX2 and PPARg transcriptional activity were measured using 6OSE2-Luc and ARE-luc reporters.

$Ddr2^{slie/slie}$ mice had multiple skeletal defects. Skulls had widened calvarial sutures and increased mandibular porosity. A progressive decrease in tibial trabecular BV/TV was observed when wild type, $Ddr2^{+/slie}$ and $Ddr2^{slie/slie}$ mice were compared. These changes were accompanied by drops in trabecular number and thickness and increased trabecular spacing in both males and females. Interestingly, cortical

thickness was not affected in males, but was lower in Ddr2$^{slie/slie}$ females. In addition, marrow fat volume was increased in Ddr2$^{slie/slie}$ mice. To examine the role of DDR2 signaling in cell differentiation, we prepared calvarial osteoblasts, BMSCs and EMSCs from the 3 genotypes and grew cells under osteogenic and adipogenic conditions. Regardless of cell source, Ddr2$^{slie/slie}$ cells exhibited defective osteoblast differentiation and accelerated adipogenesis. Furthermore, both RUNX2-S319 phosphorylation and PPARg-S112 phosphorylation were decreased in Ddr2$^{slie/slie}$ cells, resulting in decreased RUNX2 and increased PPARg transcriptional activity.

Conclusion: Ddr2 is necessary for normal bone development and MSC differentiation to osteoblasts and is able to suppress adipocyte differentiation. This regulation requires MAPK-dependent phosphorylation of RUNX2 and PPARg transcription factors.

ER stress response to procollagen misfolding leads to osteoblast malfunction in the Amish mouse model of OI. Lynn Mirigian, Elena Makareeva, Sergey Leikin*. National Institutes of Health, USA

Mutations that disrupt procollagen folding are responsible for most cases of severe osteogenesis imperfecta (OI). Such mutations include not only those that cause structural defects in type I procollagen but also deficiencies in proteins that chaperone procollagen folding in the Endoplasmic Reticulum (ER), e.g. deficiencies in HSP47 or in any of the P3H1/CRTAP/CYPB protein complex components. Several studies suggest that ER stress response to procollagen misfolding might disrupt differentiation and function of osteoblasts, contributing to bone pathology in OI. Yet, molecular mechanisms of this ER stress response and its role in OI pathophysiology are still poorly characterized. To address these questions, we investigated procollagen misfolding in a mouse model mimicking the α2(I)-Gly610Cys substitution in OI patients from the Old Order Amish community in Lancaster County, PA. We found at least a twofold delay in procollagen folding in osteoblasts from heterozygous animals compared to wild type littermates, resulting in excessive accumulation of misfolded molecules in the ER. At the same time, we observed no upregulation of BIP or other markers of conventional unfolded protein response, in agreement with previous studies of fibroblasts from OI patients or murine models of Gly substitutions. Consistent with this observation, inhibition of ER-associated proteosomal degradation did not cause accumulation of misfolded molecules in the cell. In contrast, increased expression of LC3B in cells from heterozygous mice and intracellular accumulation of procollagen in these cells in response to autophagy inhibitors indicated that degradation of misfolded molecules occurs via autophagy and proteolysis in lysosomes. Overall, the ER stress response was reminiscent of the ER-overload in serpinopathies. It likely underlies abnormal differentiation of osteoblasts revealed by quantitative, real-time PCR comparison of bone sialoprotein, osteocalcin and dentin matrix acidic phosphoprotein transcription in cells from heterozygous animals and their wild type littermates. Based on these observations, we are currently testing a simple dietary approach to enhancing autophagy and reducing the misfolded protein load in osteoblasts in mutant animals. However, additional studies of pathways involved in the ER response to procollagen misfolding and effects of this response on osteoblast differentiation and function are needed for identifying other treatment strategies.

High-Throughput DEXA and MicroCT Screening in Gene Knockout Mice Identifies Bone Mass Phenotypes. Robert Brommage*, Jeff Liu, Laura Kirkpatrick, Gwenn Hansen, David Powell, Peter Vogel. Lexicon Pharmaceuticals, USA

Screening gene function *in vivo* is a powerful approach to discover novel drug targets in the human genome (Nature Reviews Drug Discovery 2:38-51; 2003). We present data for 3779 distinct gene knockout (KO) mouse lines with viable adult homozygous mice generated using both gene-trap (1369 KOs) and homologous recombination (2410 KOs) technologies. Embryonic/neonatal/juvenile lethality or reduced viability was observed in an additional >970 KO lines. KO strategies are available for 4,077 lines at http://www.taconic.com/wmspage.cfm?parm1=2522. Bone mass was determined from PIXImus DEXA scans of male and female mice at 14 weeks of age and by microCT analyses of bones from male mice at 16 weeks of age. Wild-type (WT) littermates/cagemates were examined for each gene KO. For most lines DEXA scans were performed on 4 KO and 2 WT mice of each gender. Body BMC, aBMD, vBMD, and BMC/LBM ratio, femur BMD and spine BMD were monitored. Bone parameters were normally distributed. Volumetric BMD in KOs (N = 3632) averaged 99.5% of WT values with a SD of 3.7%. Using a Scanco Medical μCT40, trabecular bone parameters in LV5 were analyzed in 3386 lines and midfemur cortical thickness (CT) in 3350 lines (generally 4 KO and 2 WT). Specially designed plastic inserts held 48 LV5s (scanned overnight with 4 LV5s scanned simultaneously) and 18 femurs (scanned in 30 minutes with 6 femurs scanned simultaneously). LV5 trabecular BV/TV in KOs averaged 16.2% (SD = 3.9%). Femoral CT averaged 245 μm (SD = 16 μm). Since primary high-throughput screens (HTS) are susceptible to false positive findings, additional cohorts of mice from KO lines with intriguing HTS bone data were examined. Aging, ovariectomy, histomorphometry and bone strength studies were performed on lines identifying potentially novel osteoporosis drug targets, and possible non-skeletal phenotypes were explored. Together, these screens identified previously reported (Lrp5, Sost, Wnt10b, Sfrp4, myostatin, Klotho, c-Src, Ostm1, Dcstamp and Crtap) as well as novel (Wnt16 – reduced cortical bone, Lrrk1 - osteopetrosis, Fam20c – hypophosphatemic rickets, sphingosine-1P-lyase – osteopetrosis, and Cldn18 - enhanced osteoclast activity) genes regulating bone mass.

Neurofibromin regulates pyrophosphate homeostasis and bone matrix mineralization. Jean De La Croix Ndong*[1], Koichiro Ono[2], Alexander Makowski[3], Daniel Perrien[4], Jeffry Nyman[4], Florent Elefteriou[1]. [1]Vanderbilt University, USA, [2]Center for Bone Biology, USA, [3]Department of Veterans AffairsVanderbilt University, USA, [4]Vanderbilt University Medical Center, USA

Neurofibromatosis is caused by mutations in NF1, a gene encoding the RAS-GTPase neurofibromin. Patients with NF1 can present with a number of skeletal maladies, including tibia bowing and pseudoarthrosis (PA). Despite substantial advances in our understanding of the role of neurofibromin in bone cells, the etiology of NF1 PA remains unclear and its treatment still require multiple and invasive surgeries. Based on the existence of non-mineralized matrix in NF1 PA biopsies and the skeleton of multiple NF1 bone mouse models, we investigated whether Nf1 loss-of-function impairs the maturation and mineralization potential of Nf1-/- osteoprecursor cells. Using bone marrow stromal cells (BMSCs) isolated from Nf1col2-/- cKO mice (characterized by Nf1 deficiency in osteochondroprogenitors), we found that compared to WT BMSCs, Nf1-/- BMSCs formed a reduced number of alkaline phosphatase-positive (cfu-AP) colonies and mineralized alizarin red-positive (cfu-Ob) colonies, which was suggestive of impaired differentiation and/or mineralization. Further investigations revealed that levels of extracellular inorganic pyrophosphate (ePPi), a potent inhibitor of hydroxyapatite formation and propagation, were elevated in the conditioned medium from Nf1-/- BMSCs compared to WT BMSCs. The expression of Ank, a transporter of ePPi, Enpp1, an enzyme generating PPi, and Opn, an inhibitor of mineral nucleation was significantly increased in immature Nf1-/- BMSCs compared to WT controls, whereas the expression of Tnsalp, whose activity is to cleave PPi, was reduced. BMP2 treatment was unable to correct the differentiation and mineralization defects of Nf1-/- BMSCs, and further promoted the expression of Ank and Enpp1. These results thus indicate that the impaired bone mineralization observed in NF1 mouse models and possibly in NF1 PA is caused by accumulation of ePPI. Importantly, treatment of Nf1-/- BMSCs with a recombinant form of human TNSALP (used as a mean to catabolize ePPi) rescued their matrix mineralization defect in vitro, and daily administration of rhTNSALP in growing Nf1col2-/- mice for 18 days significantly promoted their growth, cortical thickness, mineral-to-collagen ratio and crystallinity. There results identify what we believe is an important molecular defect underlying the development of tibia bowing, fragility and PA in NF1 children, and suggest that the successful treatment of NF1 PA will require not only bone anabolic agents but also inhibitors of ePPi.

Osteoblast CFTR Regulates Bone Formation and Osteoprotegerin Expression in Cystic Fibrosis-Related Bone Disease. Michael Stalvey, Katrina Clines, Viktoria Havasi, W. Joon Chung, Gregory Clines*. University of Alabama at Birmingham, USA

Low bone mass and increased fracture risk are recognized complications of cystic fibrosis (CF). CF-related bone disease is characterized by uncoupled bone turnover—impaired osteoblastic bone formation and enhanced osteoclastic bone resorption. Intestinal malabsorption, vitamin D deficiency and inflammatory cytokines contribute to CF-related bone disease, but epidemiological investigations and animal models now support a direct causal link between inactivation of bone cystic fibrosis transmembrane regulator (CFTR), the gene that when mutated causes CF, and CF-related bone disease. The objective of this study was to examine the direct actions of CFTR inactivation on bone. Expression analyses revealed that CFTR mRNA and protein were expressed in osteoblasts, but not in osteoclasts. Functional studies were then performed to investigate the direct actions of CFTR on the osteoblast utilizing a CFTR knockout (Cftr-/-) mouse model. In the murine calvarial organ culture assay, Cftr-/- calvariae displayed significantly less bone formation (6430 μm2 vs. 16440 μm2, p=0.0023) and osteoblast numbers than calvariae harvested from wildtype (Cftr+/+) littermates. CFTR inactivation also reduced alkaline phosphatase expression in cultured calvarial osteoblasts. Although CFTR was not expressed in murine osteoclasts, significantly more osteoclasts formed in Cftr-/- compared to Cftr+/+ bone marrow cultures. This result suggested that other cell types in bone that regulate osteoclastogenesis are influenced by CFTR. The consequence of osteoblast CFTR inactivation on RANKL and OPG expression to indirectly control osteoclastogenesis was next examined. Although no difference in Rankl mRNA was detected, significantly less Opg was expressed in Cftr-/- compared to Cftr+/+ osteoblasts. Together, the Rankl:Opg ratio was significantly higher in Cftr-/- calvarial osteoblasts contributing to a higher osteoclastogenesis potential. The combined findings of reduced osteoblast differentiation and lower Opg expression suggested a possible

defect in canonical Wnt signaling. In fact, Wnt3a and PTH-stimulated canonical Wnt signaling was defective in Cftr-/- calvarial osteoblasts. These results support that genetic inactivation of CFTR in osteoblasts contributes to low bone mass and that targeting the osteoblast may represent an effective strategy to treat CF-related bone disease.

Trabecular and Not Cortical Bone Is Affected in Different Forms of Osteogenesis Imperfecta. Roland Kocijan*[1], Christian Muschitz[2], Didier Hans[3], Judith Haschka[1], Janina Patsch[4], Georg Schett[5], Matthias Englbrecht[5], Afrodite Zendeli[6], Daniela Süß[6], Heinrich Resch[4]. [1]St. Vincent Hospital Vienna, Austria, [2]St. Vincent's Hospital, Austria, [3]Lausanne University Hospital, Switzerland, [4]Medical University of Vienna, Austria, [5]Friedrich-Alexander University Medical School, Germany, [6]The VINFORCE Study Group - St. Vincent Hospital - Medical Department II, Austria

Purpose: Areal bone mineral density (aBMD) by DXA as the standard measuring tool has several limitations in osteogenesis imperfecta (OI) due to partly high bone mineralization as well as vertebral fractures and scoliosis in severe cases. Therefore, the aim of this study was to evaluate alternative radiological tools at different sites in adult patients with different types of OI.

Methods: We investigated 23 patients with OI (11 female, 12 male, mean age 45.7 $\pm$ 16.4 years). OI was divided into the mild OI-I and the moderate-severe OI-III-IV group. Bone microarchitecture and volumetric BMD (vBMD) were determined by high resolution peripheral quantitative computed tomography (HR-pQCT, SCANCO Medical) at the radius and tibia. HR-pQCT data were compared to 23 healthy, age and gender matched controls (CO, mean age 42.5 $\pm$ 9.9 years). Moreover, trabecular bone score (TBS) at the lumbar spine (LS) and aBMD by DXA at the LS and hip as well as by DXL (Calscan, dual X-ray and laser) at the calcaneus were carried out in OI.

Results: At both, radius and tibia, trabecular but not cortical vBMD was significantly lower in OI-I ($p<0.05$) and OI-III-IV ($p<0.001$) compared to CO. Significantly decreased bone volume fraction (BV/TV) and trabecular number (Tb.N), as well as an increased inhomogeneity of the network and trabecular separation (Tb.Sp) were found in OI-I ($p<0.05$-0.001) and OI-III-IV ($p<0.001$ for all) compared to CO. BV/TV, Tb.N, Tb.Sp and inhomogeneity were significantly worse in OI-III-IV compared to OI-I. No differences were found regarding cortical porosity at tibia and radius.

TBS was significantly lower in moderate-severe OI-III-IV compared to mild OI-I ($p<0.05$). Correlations were found between TBS and BV/TV (r=0.460), Tb.N (r=0.518), inhomogeneity (r=-0.484), trabecular density (r=0.461) and aBMD of LS (r=0.495) and hip (r=0.720, $p<0.05$ for all). Differences in aBMD between OI-I and OI-III-IV were higher at the calcaneus ($p<0.001$), as a mainly trabecular bone, than the hip ($p<0.05$).

Conclusions: Especially trabecular and not cortical BMD and microstructure are severely affected in OI-I and even more in OI-III-IV. HR-pQCT and TBS are helpful tools to quantify microstructure in OI. Moderate correlations approve TBS for microstructure analysis. The trabecular deterioration is even reflected by simple applicable tools like TBS and DXL of the calcaneus. The latter might be optimal for BMD measurement in severe OI with vertebral fractures or scoliosis.

SA0137

Whole Exome Sequencing is a Sensitive and Cost-Effective Means of Detecting Mutations in Patients with Marfan Syndrome and Osteogenesis Imperfecta. Emma Duncan*[1], Aideen McInerney-Leo[2], Paul Leo[2], Brooke Gardiner[2], Mhairi Marshall[2], Paul Coucke[3], Bart Loeys[4], Malcolm West[5], Jennifer west[5], Paul Wordsworth[6], Andreas Zankl[2], Matthew Brown[7], Lut van Laer[8]. [1]Royal Brisbane & Women's Hospital, Australia, [2]University of Queensland Diamantina Institute, Australia, [3]University of Ghent, Belgium, [4]Antwerp University, Belgium, [5]Prince Charles Hospital, Australia, [6]University of Oxford, United Kingdom, [7]Diamantina Institute of Cancer, Immunology & Metabolic Medicine, Australia, [8]University of Antwerp, Belgium

Marfan syndrome and Osteogenesis Imperfecta (OI) are amongst the most common Mendelian disorders. These conditions are normally diagnosed clinically without genetic testing, as the large gene sizes and diversity of mutation location and type make conventional sequencing prohibitively expensive (A$1500 for *FBN1*; $1850 for *COL1A1*/*COL1A2*). Efficient gene testing would greatly benefit at-risk family members, individuals with borderline clinical features, and genetic counselling; and allow critical differential diagnoses (e.g. non-accidental injury).Methods: We performed exome capture and massive parallel sequencing on genomic DNA from 11 patients with Marfan syndrome and 13 patients with OI in whom mutations had been previously identified conventionally. Exome capture was performed using liquid phase hybridisation and Illumina/TruSeq Exome Enrichment Kit v2.0; massive parallel sequencing was performed on Illumina HiSeq 2000 (6 multiplexed samples/flow cell lane; 100 base pair (bp) paired-end reads).CASAVA 1.8.2 was used for de-multiplexing and initial base calling. Sequence data was aligned to the current human genome build (hg19); SNPs and small indels were called using Genome Analysis Toolkit GATK (v2.4-9) and annotated using ANNOVAR. CREST and exomeCopy were used to search for large deletions. We compared our sequencing results with the previous data.

Results: We detected 13/13 mutations in OI patients and 10/11 mutations in Marfan patients, including non-synonymous SNPs and small indels (up to 10bp) in each patient group. The remaining Marfan sample was reported to carry a large deletion of both exons 1 and 2. This was not detected with either CREST or exomeCopy. CREST uses alignment discrepancy to identify mutations; as the start and stop sites of this deletion are intronic, and the sample was exome-sequenced, no such discrepancy was present. ExomeCopy relies on relative sequencing depth; however, exons 1 and 2 of *FBN1* are always poorly captured due to their high GC content. Although deletions occur in 30% of Marfan syndrome patients, most are small (<10bp); only 2% are large insertions/deletions. Our costs for exome sequencing were lower than current commercial conventional sequencing services.

Conclusions: Exome sequencing is both sensitive and cost-effective for detecting mutations in patients with either OI or Marfan syndrome, with high sensitivity (>95%) for both disorders. Providing a genetic diagnosis in these conditions provides diagnostic certainty and enables effective screening.

SA0138

A Functional Amino Acid Substitution in the Glucose-dependent Insulinotropic Polypeptide-Receptor (GIPR) Gene is Associated with Bone Mineral Density, Bone Loss, and Osteoporotic Fractures: The Danish Osteoporosis Prevention Study. Torben Harsloef*[1], Signe S Torekov[2], Torben Hansen[2], Jens J Holst[2], Oluf Pedersen[2], Lars Rejnmark[3], Bente Langdahl[3]. [1]Aarhus University Hospital, Aarhus Sygehus, Denmark, [2]Department of Biomedical sciences & Novo Nordic Center for Basic Metabolic Research, Faculty of Health Sciences, University of Copenhagen, Denmark, [3]Aarhus University Hospital, Denmark

Food ingestion decreases bone resorption. Glucose-dependent insulinotropic polypeptide (GIP) may mediate this effect. GIP is produced in the duodenum and in the presence of glucose stimulates production of insulin. A functional GIP receptor (GIPR) has been demonstrated on both osteoblasts and osteoclasts: Mice overexpressing GIP have increased osteoblast activity and are rescued from age-related bone loss. The rare allele of *GIPR* rs1800437 promotes a substitution of glutamate to glutamine. This variant decreases insulin secretion and increases 2-hour blood glucose in an oral glucose tolerance test in non-diabetic individuals. This suggests that the variant decreases the effect of GIP. We therefore investigated the relationship between the *GIPR* polymorphism rs1800437 and bone mineral density (BMD), changes therein, and risk of osteoporotic fractures in a cohort of Danish perimenopausal women.

A total of 2016 women with last menstrual bleeding within 3 months to 2 years were included. Exclusion criteria were drugs and diseases affecting BMD. Hormone therapy or placebo were initiated at baseline and continued for 10 years. DXA scans were performed at baseline and after 10 years. Incident fractures were recorded at scheduled visits during the 10 years of follow up. Vertebral fractures were documented with spinal x-rays and information on incident fractures between inclusion and June 2008 were obtained from the Danish National Patient Registry.

After 10 years women homozygous of the common G-allele of rs1800437 had significantly higher BMD at both the femoral neck (0.766 ± 0.004g/cm2 (mean $\pm$ SEM) vs. 0.747 ± 0.005 and 0.755 ± 0.015g/cm2 in women heterozygous and homozygous for the variant allele, respectively, p=0.008) and total hip (0.906 ± 0.004g/cm2 vs. 0.884 ± 0.005 and 0.881 ± 0.016 g/cm2 in women heterozygous and homozygous for the variant allele, respectively, p=0.002). Accordingly, women homozygous of the variant C-allele had a tendency towards a greater 10-year loss of BMD (p=0.07). Finally, women homozygous for the variant C-allele had an increased risk (HR 1.57 (CI: 1.0 – 2.45) p=0.05) of non-vertebral osteoporotic fractures.This is the first study associating a functional *GIPR* polymorphism (rs1800437) with BMD and fracture. Thus, it seems that the *GIPR* rs1800437, which promotes an amino acid substitution, have effects both on blood glucose regulation and on bone quality. These finding further establish GIP as involved in regulation of bone density.

Association of Vitamin D Binding Protein Polymorphisms, Serum 25-hydroxyvitamin D and Serum Parathyroid Hormone Concentrations in 37-47 Year Old Caucasian Women and Men in Finland. Elisa Saarnio*[1], Minna Pekkinen[2], Suvi Itkonen[1], Virpi Kemi[1], Heini Karp[1], Merja Karkkainen[1], Outi Makitie[3], Christel Lamberg-Allardt[1]. [1]University of Helsinki, Finland, [2]Folkhälsan Institute of Genetics, University of Helsinki, Finland, [3]Children's Hospital, Helsinki University Central Hospital, Finland

Vitamin D and its metabolites are bound to vitamin D binding protein (DBP) also known as group- specific component (GC) in the circulation. It is the primary protein involved in the transport of vitamin D. DBP has a high affinity to serum 25-hydroxyvitamin D (S-25OHD). DBP is a polymorphic protein and variants of it can be associated with circulating S-25OHD concentrations.

In this study we investigated the associations between the GC gene variants and S-25OHD and serum parathyroid hormone (S-PTH) concentrations in middle-aged Caucasians in Finland.

We examined 617 healthy 37-47 year old Caucasian women and men in a cross-sectional study. Fasting blood samples were collected, as well as dietary intake of vitamin D and calcium (Ca) by a validated food frequency questionnaire (FFQ). Concentrations of S-25OHD and S-PTH were determined. Background data including sunlight exposure and the amount of vitamin D and Ca supplements were collected. DNA was isolated from blood and genotyped with Taqman method. Three SNPs were genotyped based on polymorphisms in the GC gene: rs4588, rs7041 and rs705124. SNPs 4588 and 7041 combine to form six GC diplotypes.

The GC diplotype distribution was: 1S/1S (46% of the subjects), 1S/2 (25%), 1F/1F (2%), 1F/2 (6%), 1F/1S (16%) and 2/2 (4%). The distribution of the third SNP rs 705124 was: genotype 1 60%, genotype 2 34 % and genotype 3 5%. There was a difference among the GC diplotypes in S-25OHD concentrations (ANCOVA, p=0.015) when adjusted with covariates: S-PTH, vitamin D intake (including supplements), sunlight exposure and body mass index (BMI).When pairwise comparisons were made, a difference in S-25OHD concentrations was between 1S/2 (51.6 nmol/L) and 1F/1S (58.7 nmol/L) (p=0.026). Furthermore S-PTH concentrations differed between the diplotypes (ANCOVA, p=0.013) when adjusted for S-25OHD and Ca intake. No differences in S-25OHD concentrations were found among the SNP rs705124. However, there was a difference among SNP in S-PTH concentrations (p=0.018), adjusted for S-25OHD and Ca intake. When pairwise comparisons were made, there was a difference between S-PTH concentrations between the genotype 1 and 2 (p=0.016).

In conclusion, we found significant associations in S-25OHD concentrations among the GC diplotypes. In addition, there were differences in PTH concentrations among the diplotypes and among SNP 705124.

Keywords: Vitamin D binding protein (GC), S-25OHD, PTH, Single Nucleotide Polymorphism (SNP).

We conducted a GWAS meta-analysis to search for genetic risk factors associated with fracture risk and work is now underway to determine the function of the underlying genes. We identified 3 loci at the genome-wide significant level ($P<5x10^{-8}$) and 5 loci at the highly suggestive level ($P<1x10^{-6}$). For 3 of these loci, the peak signal was either in or next to a gene with a known function in bone biology. The closest gene to the peak SNP has not been well studied in bone for the remaining loci, which included: *RNMT, SLC25A13, RASSF4*, *CPED1* and *SPTBN1*. For these, we examined gene expression patterns across osteoblastogenesis to determine if these genes function in this cell type. Specifically, RNA-seq was used to assess gene expression profiles across osteoblastogenesis in cells obtained from mouse calvaria and co-expression network analysis was used to identify clusters of genes with expression profiles across osteoblastogenesis that were similar to our signal genes. Then we applied gene-annotation enrichment analysis (DAVID, v6.7) to each cluster of correlated to genes to characterize its putative biologic function. As a follow-up we examined correlation between gene expression from whole bone tissue and BMD obtained from iliac crest biopsies in postmenopausal women. We found that genes correlated in expression with *Slc25a13* were enriched for cell cycle genes (fold enrichment=4.8, $P=6.8^{-61}$), but found no correlation between gene expression and BMD in humans. Genes with correlated expression to *Cped1* were enriched for extracellular matrix genes and increased with osteoblastogenesis (fold enrichment=2.8, $P=1.8^{-13}$). Expression was negatively correlated with hip and spine BMD T-score. Genes correlated in expression to *Sptbn1* were cell junction proteins (fold enrichment=6.5, $P=4.7^{-3}$), and expression showed a mixed association with hip and spine BMD. Expression of *RASSF4* was negatively correlated with hip and spine T-score and gene expression databases suggest that this gene is expressed in osteoclasts (biogps.org). Expression of *Rassf4* increased with osteoblastogenesis but expression correlated with too few genes to conduct meaningful annotation enrichment. Expression of *RNMT* was positively corrected with whole body BMD T-score in patient samples, but its expression in osteoblasts was very low. The work to characterize the function(s) of these genes is on going, including development of mouse models to better assess the whole organismal function of these genes.

Haplotype Analysis Supports a "Founder" for the Balkan OPG Mutation Causing Juvenile Paget's Disease. Steven Mumm*[1], Kristin Geczi[2], Margaret Huskey[2], Dorit Naot[3], Stergios Polyzos[4], Tim Cundy[3], Wim Van Hul[5], Panagiotis Singhellakis[6], Michael Whyte[7]. [1]Washington University School of Medicine, USA, [2]Washington University, USA, [3]University of Auckland, New Zealand, [4]Aristotle University of Thessaliniki, Greece, [5]University of Antwerp, Belgium, [6]Athens University, Greece, [7]Shriners Hospital for Children, USA

Juvenile Paget's disease (JPD), a rare autosomal recessive disorder, features extremely rapid bone turnover causing skeletal pain, fracture, and deformity in early childhood. Deafness and retinopathy leading to blindness can follow. Most JPD is due to homozygous loss-of-function mutations in the *TNFRSF11B* gene encoding osteoprotegerin (OPG) – the decoy receptor that prevents RANKL binding to its cognate receptor RANK, a major stimulus element for osteoclastogenesis. A variety of mutations in *TNFRSF11B*, typically transmitted by apparent "founders" in various geographic locations worldwide, cause JPD. The severity of "OPG deficiency JPD" seems to vary depending on mutation type and how much of the OPG coding region is disrupted. In two Greek men and another Croatian man who are seemingly unrelated and manifest the mildest form of JPD, a unique homozygous deletion/insertion mutation (966_969delTGACinsCTT) has been reported. This frame-shift deletes 79 carboxy terminal amino acids from the OPG monomer, including a cysteine necessary for homodimerization. When recently referred 2 additional unrelated Greek JPD

patients homozygous for this "Balkan mutation", we studied the likelihood that all of these patients are in fact related by a distant "founder" in whom the mutation arose many generations ago. To test this hypothesis, we performed haplotype analysis of the 5 Balkan JPD patients and 2 control JPD patients from other geographic regions using SNPs within and surrounding *TNFRSF11B*. We developed primer sets for 13 informative SNPs, and then PCR-amplified and sequenced these SNPs using leukocyte-derived genomic DNA from each patient. All 5 individuals shared a homozygous common core haplotype of 4 SNPs, whereas each of the "control" JPD patients had a unique haplotype. Two of the four Greek patients shared a common haplotype of 10 homozygous SNPs, indicating closest kinship. A different Greek patient shared only 5 of these SNPs suggesting more distant relationship. The Croatian JPD patient shared only 4 common markers suggesting he is the most remotely related and consistent with his geographic distance. Hence, all Balkan JPD patients share the common OPG mutation (966_969delTGACinsCTT) and common haplotypes indicating relationship to a genetic founder. Further analysis can determine how many generations ago this founder mutation arose.

Systematic integration of functional and computational genomics suggests that the indel rs79240969 in the *DNM3* gene influences both bone- and obesity-related traits. Melina Claussnitzer*[1], Xing Chen[2], David Karasik[3], L Adrienne Cupples[4], Douglas Kiel[5], Yi-Hsiang Hsu[6]. [1]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [2]Harvard University, USA, [3]Hebrew SeniorLife; Bar Ilan University, USA, [4]Boston University, USA, [5]Hebrew SeniorLife, USA, [6]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

Recent studies suggest shared etiologies of bone and adiposity phenotypes. Previously, we conducted a multivariate genome-wide association study (GWAS) of bone mineral density (BMD) at different skeletal sites and metabolic syndrome risk factors, and identified 31 bivariate genome-wide significant ($p<5 \times 10^{-8}$, p(bivariate) < p(univariate)/10). However, signals emerging from GWAS are merely markers for large genomic regions in linkage disequilibrium (LD), potentially harboring the disease-causing variant. Identifying the shared causal variants is central to elucidate the molecular mechanisms underlying the genetic correlation between bone and fat.

Specifically, we applied an integrative bioinformatics approach leveraging tissue-specific functional genomics and sequence data to narrow-down the potential causal variants. We identified all reported sequence variants (from the 1000 Genomes Project) within the identified bivariate GWAS loci (physical boundaries LD r2>0.7). We merged data on sequence variants with bone- and adipose-specific genome-wide epigenomic profiling data, reported from the ENCODE project, that allow for chromatin state-dependent analyses of regulatory variation. Within predicted regulatory regions, we discovered *cis*-regulatory modules (CRMs) by analyzing conserved patterns of transcription factor binding sites (TFBS) across 16 vertebrate species (923 motifs). Using our approach, we identified potential causal variants within the bivariate association loci that may be responsible for the association with BMD and obesity traits. One example is the bivariate signal at *DNM3*, 1q24.3 (GWAS SNP rs10489290, bivariate association test $p=8.4 \times 10^{-11}$ for femur neck BMD with waist-to-hip ratio). We pinpointed an intronic insertion/deletion variant rs79240969 (-/TCA, MAF=0.296, LD $r^2=1.0$), specifically mapping within predicted osteoblast and adipocyte gene regulatory regions. The cell-type specific TFBS pattern analysis revealed rs79240969 localizing within a cross-species conserved CRM relevant to bone and fat. The rs79240969 insertion allele creates a perfect binding site for the zinc-finger protein Zfp521 which has been previously shown to control bone mass.

Our bioinformatics analysis may represent a useful step toward pinpointing causal variants from potentially pleiotropic loci for direct laboratory validation and ultimately for improving therapeutic strategies addressing shared etiological mechanisms of BMD and obesity-related phenotypes.

CK2.3, a mimetic peptide of the Bone Morphogenetic Protein receptor Ia, increases endochondral bone formation *in vivo*. Kristine Olli*[1], Jeremy Bonor[1], Hemanth Akkiraju[1], Christopher Bowen[1], Beth Bragdon[2], Randall Duncan[1], Anja Nohe[1]. [1]University of Delaware, USA, [2]Boston University School of Medicine Department of Orthopaedics, USA

The goal of this study was to determine whether a novel petide CK2.3 can induce bone formation by increasing osteogenesis and decreasing osteoclastogenesis. Osteoporosis is a disease that results in a harsh loss of bone mass and affects approximately 4.5 million women and 800,000 men in America. The current treatment options are either antiresorptive or anabolic. However these options come with a myriad of negative side effects. Bone Morphogenetic Protein 2 (BMP2) is a potent inducer of bone formation. Unfortunately, it also is known to induce osteoclast activity, therefore leading to a higher rate of bone turnover in the long term. We recently developed a novel peptide, CK2.3, that acts downstream of Bone Morphogenetic Protein type Ia receptor (BMPRIa) in the BMP2 signaling pathway signaling. Systemic injection of CK2.3 into 8 week old mice led to an increase of ALP and Osteocalcin serum levels. In sharp contrast to BMP2, it decreased TRAC5b levels, a marker for bone turnover. Osteoblasts isolated from the femur of these mice showed increased mineralization ability compared to control injected mice. Additionally, bone mineral density and mineral apposition rate were enhanced. Micro CT analysis revealed increased number of trabeculi and decreased trabecular spacing. Additionally, injection of CK2.3 caused a significantly decreased number of osteoclasts and reduced osteoclast activity when compared to both the control and BMP2. Furthermore, we determined the mechanism of CK2.3 signaling in osteoclasts. Our data demonstrate that CK2.3 signals through BMPRIa in osteoclasts. Therefore CK2.3 may be the first peptide based on BMP2 signaling to reduce osteoclastogenesis and increase osteogenesis making it a potential treatment for osteoporosis.

L51P, a BMP-2 Antagonist Inhibitor, Enhances the Osteoiduction of BMP-2 by a Negative Feedback Regulation. Hany Khattab*[1], Mitsu ONO[2], Wataru Sonoyama[3], Yasutaka OIDA[2], Shigehiko SHINKAWA[2], Kenji MAEKAWA[2], Kazushige SUGAMA[4], Walter SEBALD[5], Takuo KUBOKI[2]. [1]Okayama University Graduate School of Medicine, Japan, [2]Department of Oral Rehabilitation & Regenerative Medicine, Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, [3]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci, Japan, [4]Osteopharma Inc., Japan, [5]Physiological Chemistry II, Theodor-Boveri-Institute for Biocenter of Würzburg University, Germany

Bone morphogenetic proteins (BMPs) are cytokines with promising potential for clinical bone repair. Since large amounts of BMPs are required to induce bone formation as a result of BMP antagonists, targeting these antagonists provide an attractive strategy to enhance BMP's osteogenic activity. Our group generated the BMP mutant (L51P) lacking the BMP receptor binding site. Although previous reports have shown that L51P can bind to noggin and interfere with its binding to BMP, the functions of L51P are yet not fully understood. In this study, we investigated the biological functions of L51P *in vitro* and *in vivo*. A rat critical-sized calvarial defect model was performed to examine the effect of L51P on bone formation. L51P did not possess similar osteoinductive activity like BMP-2. However, the combination of BMP-2 and L51P enhanced bone regeneration four weeks post-injury, compared to BMP-2 alone. To confirm the function of L51P *in vitro*, MC3T3E1 cells were first stimulated with BMP-2 and L51P simultaneously. While BMP-2 enhanced SMAD signaling and luciferase activity of BMP-responsive Id1 promoter, L51P did not enhance the effect of BMP-2. On the other hand, when MC3T3E1 cells were pre-treated with BMP-2 for 3 days, there was an increase in the mRNA expression levels of *noggin;* and under this condition, L51P dramatically enhanced SMAD signaling and luciferase activity. These findings support the concept of L51P as a promising down regulator of BMP negative feedback, which can be expected to renovate the future of BMP-based regenerative therapy for bone repair.

SDF-1/CXCL12 is Critical for Bone Regeneration: SDF-1β Promotes BMP-2 Function. Samuel Herberg*[1], Manuel Pelaez[1], Nicole Howie[1], Mohammed Elsalanty[2], Mark Hamrick[2], Carlos Isales[1], Ulf Wikesjö[1], Cristiano Susin[1], William Hill[3]. [1]Georgia Regents University, USA, [2]Georgia Health Science University, USA, [3]Georgia Regents University & Charlie Norwood VAMC, USA

Purpose: Bone morphogenetic protein-2 (BMP-2) has widely been used clinically, albeit at high doses linked to adverse effects. Increasing evidence suggests that stromal cell-derived factor-1 (SDF-1/CXCL12) is involved in bone formation; however, underlying molecular mechanisms remain largely unknown. Recently, we showed that SDF-1β, the less abundant but more potent splice variant vs. SDF-1α, enhances osteogenesis through regulating BMP-2 signaling *in vitro*. Here we investigated local bone formation in a critical-size rat calvarial defect model 1) using increasing doses of BMP-2 delivered in an absorbable collagen sponge (ACS) carrier to define optimal and suboptimal BMP-2 doses, and 2) following co-delivery of suboptimal BMP-2 and SDF-1β in an ACS carrier. We tested the hypotheses that SDF-1β potentiates BMP-2 osteoinduction and that blocking SDF-1 signaling reduces the osteogenic potential of BMP-2.

Materials: Critical-size calvarial defects were created in 172 adult male Sprague-Dawley rats. Experimental defects received: 1) increasing doses of BMP-2 (0.1-20 μg), and 2) suboptimal BMP-2 (0.5 μg) ± increasing doses of SDF-1β (1-60 μg), benchmark BMP-2 (5 μg), BMP-2+AMD3100, or controls in an ACS carrier. A titanium mesh was fitted over the defects to prevent soft tissue collapse. Surgical staples were used to evert the wound margins to ensure wound closure for primary intention healing. Radiographic, μCT, and histometric analysis was performed after 4 weeks.

Results: Radiographic analysis revealed a dose-dependent increase in BMP-2 osteoinduction ($p<0.0001$) with an ED_{50} of 1.2 μg/ACS. Furthermore, radiographic

and μCT analyses showed a dose-dependent increase in SDF-1β-potentiated suboptimal BMP-2 osteoinduction ($p<0.01$), reaching comparable levels to the benchmark 10-fold greater BMP-2 dose. Co-delivery of the specific SDF-1 receptor (CXCR4) antagonist AMD3100 and BMP-2 attenuated the osteoinductive potential ($p<0.0001$), suggesting that SDF-1 signaling is pivotal for BMP-2-induced bone formation. Histometric analysis revealed a greater fraction lamellar/woven bone in SDF-1β co-delivered groups, similar to the benchmark BMP-2 dose, indicating accelerated bone maturation.

Conclusion: Our data suggest that SDF-1β provides new opportunities to broaden the clinical utility of BMP-2 by decreasing the dose, potentially reducing undesirable effects, and allowing expanded regenerative medicine approaches to treat acute/chronic bone injuries.

A novel oxysteol, Oxy133, promotes cranial bone regeneration through Hedgehog signaling pathway. Akishige Hokugo*[1], Andrew Li[1], Farhad Parhami[2], Reza Jarrahy[1]. [1]David Geffen School of Medicine at UCLA, USA, [2]University of California, Los Angeles, USA

Current reconstructive techniques for complex craniofacial osseous defects are associated with significant morbidity profiles. Tissue engineering solutions offer an alternative to these techniques. Bone morphogenetic protein (BMP) is an effective osteoinductive growth factor, but its clinical application is limited by exorbitant cost and undesirable side effects. Oxysterols are naturally occurring cholesterol oxidation products some of which are capable of inducing osteogenic differentiation. In this study, we investigated the effect of a novel semi-synthetic oxysterol, Oxy133, a structural analogue of the naturally occurring osteogenic oxysterol, 20(*S*)-hydroxycholesterol, in inducing in vitro osteogenesis and in vivo bone regeneration. Rabbit bone marrow stromal cells (BMSCs) were incubated with 1 μM of Oxy133 or 50 ng/ml of BMP-2. Alkaline phosphatase (ALP) activity, expression of markers of osteogenic differentiation Runx2, Collagen I and Osterix, and in vitro calcification were examined. For in vivo evaluation, Oxy133 (1 and 10 mg) or BMP-2 (45 μg) absorbed onto collagen sponge were implanted in 6 mm diameter cranial defects in 3.5-4 kg 5 months old rabbits. Six weeks after implantation, bone regeneration was assessed by microCT and histology. To determine the mechanism of action of Oxy133, rabbit BMSC were pre-treated with the Hedgehog (Hh) pathway inhibitor, cyclopamine, prior to treatment with Oxy133, and ALP activity was measured. In vivo, the role of Hh pathway was assessed by the inclusion of cyclopamine (2 mg) with Oxy133 when implanted and its effect on Oxy133-induced bone regeneration was evaluated. In vitro, ALP activity in rabbit BMSCs treated with 1 μM of Oxy133 was induced after 4 days and was significantly higher than in control cells or in cells treated with BMP-2. Expression of osteogenic markers in BMSCs treated with 1 μM of Oxy133 was significantly higher than in control group. In vivo, complete bone regeneration occurred when cranial defects were treated with Oxy133. Addition of cyclopamine inhibited the stimulatory effects of Oxy133 on ALP activity in vitro and on bone regeneration in vivo. Collectively, these results demonstrate that Oxy133 has the ability to induce osteogenic differentiation in rabbit BMSCs with an efficacy comparable to that of BMP-2, and to promote robust bone regeneration in rabbit cranial defects. Therefore Oxy133 may be a viable novel agent in bone tissue engineering.

EGF suppresses BMP-induced osteogenic differentiation through the up-regulation of Smurf1 expression. Jeong-Hwa Baek*, Hye-Lim Lee, Hyun-Mo Ryoo, Kyung Mi Woo. Seoul National University, School of Dentistry, South Korea

Although EGF has been known to inhibit osteoblast differentiation, its molecular mechanism has not been clearly elucidated. Smurf1 acts as a negative regulator of BMP signaling by inducing ubiquitination and proteasomal degradation of BMP type I receptor and R-Smads. In this study, we investigated the effect of EGF on the expression of Smurf1 and the role of Smurf1 in EGF-induced inhibition of BMP2-induced osteogenesis. EGF increased Smurf1 expression which was blocked by treatment with a specific inhibitor of EGFR tyrosine kinase, JNK or ERK. Reporter assay using the constructs containing the Smurf1 promoter sequence, demonstrated that AP-1 and Runx2 are the transcription factors activated by JNK and ERK, respectively. EGF treatment or Smurf1 overexpression suppressed BMP2-induced expression of osteogenic marker genes, whereas knockdown of Smurf1 partially rescued the expression of these genes in EGF-treated cells. Taken together, these results suggest that the JNK-c-Jun and the ERK-Runx2 signaling pathways play an important role in the regulation of Smurf1 expression by EGF and that Smurf1 partially mediates the inhibitory effect of EGF on osteogenic differentiation.

Enhanced Bone Regeneration Utilizing Non-Viral Nanoplex Activated Collagen Scaffolds. Satheesh Elangovan*[1], Sheetal D'Mello[2], Liu Hong[3], Ryan Ross[4], Clark Stanford[1], Georgia Johnson[3], Rick Sumner[5], Aliasger Salem[2]. [1]University of Iowa, USA, [2]University of Iowa College of Pharmacy, USA, [3]University of Iowa College of Dentistry, USA, [4]Rush University Medical Center, USA, [5]Rush University Medical College, USA

Purpose: To develop and test a non-viral gene delivery system for bone regeneration that utilizes collagen scaffold to deliver polyethylenimine (PEI) – pDNA [encoding platelet derived growth factor (PDGF)] nanoplexes.

Methods used: PEI – pDNA (PDGF) nanoplexes were synthesized and characterized for size and surface charge using Malvern Zetasizer Nano ZS and the collagen scaffold was characterized using scanning electron microscopy. The in vitro cytotoxicity and transfection efficacy of the synthesized nanoplexes were evaluated in bone marrow stem cells (BMSCs) using the MTS assay and by quantifying the amount of secreted PDGF-B in cell culture supernatants using ELISA. Heparin was used to prevent the retention of PDGF-B on the cell surface. In addition, the influence of the nanoplex-loaded scaffold on cellular proliferation was evaluated in vitro using confocal microscopy. The in vivo regenerative capacity of the gene delivery system was assessed in critical-sized calvarial defects in Fisher 344 rats with microCT.

Results: The PEI-pDNA nanoplexes were approximately 150 nm in size with a small polydispersity index (<0.3), indicating a narrow size distribution. At the concentrations used for transfection, the nanoplexes displayed low toxicity as assessed by the MTS assay. At an N/P ratio of 10, PEI-pDNA nanoplexes exhibited the maximum transfection efficiency with acceptable cytotoxicity in BMSCs. Highest PDGF protein expression levels (86.42 pg/ml) were obtained by treating the cells with 1 μg of the pDNA for 4 hours, followed by further incubation for 44 hours. Heparin, added to the cells 4 hours prior to the analysis, resulted in an increased detection in the protein levels of PDGF-B (132 pg/ml). Confocal microscopy revealed significantly higher proliferation of BMSCs on collagen scaffolds loaded with the nanoplexes, compared to empty scaffolds. In vivo studies showed a five-fold higher new bone volume in the test group after 4 weeks of implantation, compared to empty defect or the empty scaffold groups.

Conclusions: Non-viral nanoplex activated collagen scaffolds are an effective gene delivery and bone regeneration system with significant potential for clinical translation.

Inhibition of Hedgehog But Not Trpv1 Signaling Sustainably Attenuates Heterotopic Ossification Induced by Midpoint Achilles Tenotomy. Ina Kramer*[1], Charles Gerard Moes[1], Annabelle Heier[1], Janet Dawson[1], Francesco Galimi[2], Mark Nash[1], Ursula Schramm[1], Michaela Kneissel[1], Sabine Guth-Gundel[1]. [1]Novartis Institutes for Biomedical Research, Switzerland, [2]Genomics Institute of the Novartis Research Foundation, USA

Heterotopic ossification (HO) of soft tissue following severe traumatic injury or complicated joint surgery represents a frequent clinical complication with unmet medical need. The heterotopic bone forms through endochondral ossification via an intermediate cartilage template and is thought to be triggered by trauma-induced release of high levels of growth factors including members of the bone morphogenetic protein (BMP) family. In addition to acting as direct osteo-inducers, BMPs can also enhance local release of neuroinflammatory molecules from peripheral nociceptive neurons. Moreover, BMP2-induced HO is suppressed in *transient receptor potential cation channel V1/Trpv1* deficient mice suggesting that neuroinflammation contributes to HO development.

Here, we tested two pharmacological principles based either on inhibition of Trpv1 activity, a key nociceptive ion channel, or chondrogenesis as an early or intermediate step of the HO process, respectively, for their therapeutic potential to prevent HO in a rat model of trauma-induced nonhereditary HO following Achilles midpoint tenotomy. 7-week-old male Sprague Dawley rats underwent unilateral Achilles tenotomy and prophylactic 10-week oral treatment with either vehicle, a selective Trpv1 antagonist or two doses of a selective Smoothened (Smo) inhibitor blocking hedgehog signaling required for normal chondrogenesis, respectively. We followed HO development by radiography at 5 and 7 weeks post-tenotomy and quantified the amount of heterotopic bone by longitudinal micro-computed tomography at 6 and 9 weeks post-injury. Neither treatment regime was able to prevent HO development, as all rats displayed heterotopic bone formation at 5 weeks post-surgery. Interestingly, at 6 weeks post-tenotomy rats treated with either pharmacologic principle had about 60% reduced heterotopic bone volume compared to vehicle-treated animals. As HO progressed, HO remained significantly lower by about 45% in rats treated with the higher dose of the Smo antagonist, whereas HO was non-significantly decreased by about 30% in rats receiving the Trpv1 inhibitor relative to vehicle-treated rats. However, in contrast to Trpv1 inhibition, at the effective dose Smo antagonism was associated with significant treatment-related side effects. Together, these findings suggest that trauma-induced HO can be reduced when interfering with critical early or intermediate steps of the heterotopic ossification process.

Novel Hedgehog Agonists Regulate Dental Epithelial Cell Proliferation and Differentiation. Masahiro Naruse*, Tomoko Ikeuchi, Yuta Chiba, Mariko Ono, Satoshi Fukumoto, Takashi Nakamura. Tohoku UniversityGraduate School of Dentistry, Japan

Aim: The reciprocal interactions between dental epithelium and mesenchyme preciously control tooth development to form the tooth crown and root with optimized shapes and size. Growth and differentiation of dental epithelium and mesenchyme are regulated by secreted proteins such as Sonic hedgehog (Shh). The Shh signaling pathway plays a number of roles during tooth development including the early tooth morphogenesis, cusp formation, ameloblast differentiation, and root formation.

In this study, we demonstrate that HH-Ag 1.3 and HH-Ag 1.7, novel synthetic non-peptidyl shh agonists, regulate differentiation of dental epithelium cell line and murine tooth germ.

Design: To analyze action of HH-Ag 1.3 and HH-Ag 1.7 on growth and differentiation in dental epithelial cell, we cultured the rat dental epithelial cell line HAT-7 and murine tooth germs from murine embryos at E14. We investigated cell proliferation activities and mRNA expressions of ameloblast marker genes in the presence or absence of the compounds at the different concentrations in those culture systems.

Results: Both HH-Ag 1.3 and HH-Ag 1.7 promote expression of Gli1, a hedgehog signaling target gene, in HAT-7 and cultured murine tooth germ, suggesting activation of shh signaling. Interestingly, HH-Ag 1.3 and HH-Ag 1.7 act distinct roles on cell proliferation and gene expression in HAT-7. HH-Ag 1.3 promoted cell proliferation activity, while no action was observed in cell differentiation. In contrast, HH-Ag 1.7 greatly enhanced gene expression of ameloblastin and amelogenin, ameloblast marker genes, suggesting that HH-Ag 1.7 promotes dental epithelial cell differentiation.On the other hand, HH-Ag 1.3 and HH-Ag 1.7 act positive regulators in dental epithelial cell differentiation into ameloblast in organ cultured murine tooth germ. HH-Ag 1.3 and HH-Ag 1.7 slightly enhanced expression of ameloblastin and amelogenin.

Conclusion: Our results suggest that HH-Ag 1.3 and HH-Ag 1.7 regulate cell proliferation and/or differentiation of dental epithelium. The combination of them could mimic in vivo Shh function perfectly in dental epithelial proliferation and differentiation. For therapeutics approach, small molecules are focused on the regenerative medicine due to their advantages of low biological risk. We would like to uncover the detail molecular mechanism of HH-Ag 1.3 and HH-Ag 1.7 in the regulation of proliferation and differentiation in dental epithelium cells.

Oncostatin M Promotes Osteoblastic Differentiation of Human Vascular Smooth Muscle Cells. Yoshinori Kakutani*[1], Atsushi Shioi[2], Tetsuo Shoji[3], Hirokazu Okazaki[4], Hidenori Koyama[4], Masanori Emoto[1], Masaaki Inaba[1]. [1]Department of Metabolism, Endocrinology, & Molecular Medicine, Osaka City University Graduate School of Medicine, Japan, [2]Osaka City University Graduate School of Medicine, Japan, [3]Department of Geriatrics & Vascular Medicine, Osaka City University Graduate School of Medicine, Japan, [4]Department of Internal Medicine, Division of Endocrinology & Metabolism, Hyogo College of Medicine, Japan

Vascular calcification is a common feature of atherosclerotic lesions, especially in advanced stages of plaque formation and is an independent risk factor for cardiovascular disease. Macrophages may play a key role in the development of atherosclerotic calcification. By using a coculture model, we have identified oncostatin M (OSM) and tumor necrosis factor-α (TNF-α) as major cytokines derived from macrophages responsible for induction of calcifying phenotype in human vascular smooth muscle cells (HVSMC) in the presence of interferon-γ and 1α,25-dihydroxyvitamin D_3. Recently, it has been demonstrated that OSM derived from activated macrophages induces osteogenesis in bone marrow-derived mesenchymal stem cells. Therefore, OSM may also facilitate osteoblastic differentiation of HVSMC. In this study, we investigated the stimulatory effects of OSM on osteoblastic differentiation of HVSMC derived from various arteries including umbilical, aortic, and coronary arteries. Osteoblastic differentiation was induced by exposure of HVSMC to osteogenic differentiation medium (ODM) (10% fetal bovine serum, 0.1 μM dexamethasone, 10 mM β-glycerophosphate and 50 μg/ml ascorbic acid 2-phosphate in DMEM). OSM significantly increased alkaline phosphate (ALP) activity and expression of osteoblast marker genes such as Runx2 and ALP in HVSMC from all sources. Matrix mineralization was also stimulated by OSM treatment in HVSMC derived from umbilical and coronary arteries. OSM treatment induced activation of STAT3 in HVSMC from umbilical artery as evidenced by immunoblot analysis. Moreover, a JAK3 inhibitor, WHI-P154 inhibited the OSM-induced osteogenic differentiation including induction of ALP activity and its gene expression and matrix mineralization. Finally, we examined the expression of OSM in macrophages infiltrated in atherosclerotic plaque lesions of apoE-deficient mice by immunohistochemistry. OSM-positive macrophages were detected in plaque lesions. These data suggest that OSM derived from macrophages may play an important role in the development of atherosclerotic calcification by promoting osteoblastic differentiation of vascular smooth muscle cells through JAK3-STAT3 pathway.

Remote Remodeling Does Not Contribute to Systemic Differences in Biomarkers Following Local Skeletal Insult. Ryan Ross*[1], Amarjit Virdi[1], Shou Liu[2], Kotaro Sena[3], D. Rick Sumner[1]. [1]Rush University Medical Center, USA, [2]University of Maryland, USA, [3]Kagoshima University, Japan

We recently showed that particle-induced peri-implant osteolysis in a rat model was caused by locally elevated bone resorption and suppressed bone formation. Correspondingly, CTX-1 levels increased and osteocalcin decreased in the serum. The goal of the current study was to determine if systemic remodeling contributes to changes in biomarkers levels by investigating bone remodeling at local, contiguous and remote sites following particle-induced osteolysis.

Two groups of adult male rats underwent bilateral femoral implant placement through a knee joint arthrotomy in a previously reported study. Rats received weekly intra-articular injections of vehicle or LPS-doped polyethylene (PE) particles. 12 weeks after implant surgery the animals were sacrificed and bones and blood were harvested. Bone remodeling within the femur (local), tibia (contiguous) and humerus (remote) were evaluated using dynamic and static histomorphometry. Serum concentrations of the soluble biomarkers osteocalcin, PINP, CTX-1, TRAP 5b, RANKL, OPG and SOST were measured by ELISA.

As reported previously, PE particle administration led to increased ES/BS ($p<0.001$) and decreased BFR/BS ($p=0.016$) in the peri-implant trabecular bone of the distal femur. We now show that BFR/BS was suppressed on the periosteal surface of the tibial diaphysis ($p=0.004$), but remodeling in the humerus was unaffected by PE administration in the knee joint. Following particle administration, serum osteocalcin was decreased ($p<0.001$), while PINP ($p<0.001$), CTX-1 ($p<0.001$), and OPG ($p<0.001$) were increased. Serum levels of RANKL, TRAP 5b, and SOST were not affected by particle administration. Local (peri-implant) trabecular bone BFR/BS was positively correlated with osteocalcin and negatively correlated with OPG, while ES/BS was negatively correlated with osteocalcin and positively correlated with OPG, PINP, and CTX-1. No correlations existed between humeral remodeling and the biomarker concentrations.

In addition to affecting peri-implant remodeling in the distal femur, the PE particles also affected remodeling in the tibia, presumably because the particles were administered via the knee joint. This local stimulus, however, did not alter remote remodeling as measured in the humerus. Therefore, systemic changes in the concentration of bone biomarkers were found to reflect local remodeling changes and may have potential as a means for clinical diagnosis of peri-prosthetic osteolysis and prediction of implant loosening.

Tissue-type Plasminogen Activator Is Involved in Bone Repair. Naoyuki Kawao*[1], Yukinori Tamura[1], Katsumi Okumoto[2], Masato Yano[1], Kiyotaka Okada[1], Osamu Matsuo[1], Hiroshi Kaji[1]. [1]Kinki University Faculty of Medicine, Japan, [2]Life Science Research Institute, Kinki University, Japan

The clarification of bone regeneration mechanism is important for the treatment of bone defects. We recently reported that plasminogen, a critical component of the tissue fibrinolytic system, plays a crucial role in bone repair through enhancement of macrophage accumulation and subsequent angiogenesis. However, the roles of plasminogen activator (PA) in the tissue fibrinolytic system in bone repair still remain unknown. We therefore investigated the role of tissue-type PA (t-PA) during bone repair using t-PA-deficient ($t\text{-}PA^{-/-}$) mice and their wild-type ($t\text{-}PA^{+/+}$) mice.

A hole was drilled in the femur of the 7-9 weeks old mice for the bone repair model. The process of bone repair was analyzed by *in vivo* quantitative computed tomography (qCT) and immunohistochemistry. The mRNA levels of osteogenic and chondrogenic markers in primary osteoblasts and chondrocytes were analyzed by real time-PCR.

The bone repair was delayed in $t\text{-}PA^{-/-}$ mice as compared with $t\text{-}PA^{+/+}$ mice, as assessed by *in vivo* qCT. Number of alkaline phosphatase-positive cells in $t\text{-}PA^{-/-}$ mice was significantly decreased as compared with $t\text{-}PA^{+/+}$ mice at the damaged site on day 7 after a femoral bone defect. The mRNA levels for Runx2, Osterix, and type I collagen in primary calvarial osteoblasts from $t\text{-}PA^{-/-}$ mice were decreased as compared with those from $t\text{-}PA^{+/+}$ mice. In alcian and toluidine blue stains, the area of cartilage matrix was comparable between $t\text{-}PA^{+/+}$ and $t\text{-}PA^{-/-}$ mice on day 7 after a femoral bone defect. In addition, the mRNA levels for type II and X collagens as well as aggrecan in primary articular chondrocytes were not significantly different between $t\text{-}PA^{+/+}$ and $t\text{-}PA^{-/-}$ mice. The accumulation of macrophages was comparable between $t\text{-}PA^{+/+}$ and $t\text{-}PA^{-/-}$ mice on day 4 at the damaged site, suggesting that the plasminogen-related macrophage accumulation during bone repair might be independent of t-PA.

In conclusion, the present study indicates that t-PA plays a key role during bone repair. Osteoblastic bone formation, but not chondrogenesis and macrophage accumulation during bone repair, seems to be involved in the process of t-PA-related bone repair. The modulation of the tissue fibrinolytic system might be a new strategy for the enhancement of bone repair and the development of bone regeneration.

Osteoblast-Specic Loss of IGF-1R Results in Impaired Callus Formation during Tibial Fracture Healing. Tao Wang*[1], Yongmei Wang[2], Muriel Babey[3], Frankie Fong[2], Candice GT Tahimic[4], Alicia Menendez[2], Zhiqiang Cheng[1], Daniel Bikle[4]. [1]University of California, San Francisco, USA, [2]University of California, San Francisco, California, USA, [3]UCSF, Division of Endocrinology, USA, [4]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA

The specific role of endogenous Insulin-like Growth Factor I (IGF-1) signaling in osteoblasts in fracture healing was investigated by generation and analysis of osteoblast-specific IGF-1 receptor (IGF-1R) conditional knockout (CKO) mice. A unilateral closed tibial fracture was induced in female IGF-IR $^{flox/flox}$ / 2.3-kb α1(I)-collagen-Cre (CKO) and IGF-IR $^{flox/flox}$ (CON) mice aged 12 weeks. Bone fracture callus samples were collected and analyzed by micro-CT, histology, and gene expression assays 10, 15, 21, and 28d after fracture. The results demonstrated that the lack of IGF-1R expression in osteoblasts leads to smaller callus size, decreased mineralization and bone formation, and delayed cartilage maturation/ossification. These findings indicate that endogenous IGF-1 signaling in osteoblasts plays an essential role in chondrocyte maturation and bone formation during fracture healing. Therefore, enhancing IGF-I signaling may provide a means to stimulate bone formation in the callus resulting in improved fracture healing.

Differential regulation of osteoblast function by toll-like receptor 2 and 4. Wareeratn Chengprapakorn*[1], Alejandro Garcia[1], Rene Chun[2], Ichiro Nishimura[1], Martin Hewison[1]. [1]University of California Los Angeles, USA, [2]UCLA/Orthopedic Hospital Research Center, USA

Toll-like receptors (TLRs) play a critical role in promoting innate immune responses to infection by recognizing pathogen associated molecular patterns (PAMPs) such as bacterial and viral particles. Osteoblasts express TLR2 and TLR4 and can therefore recognize Gram+ve and Gram-ve bacteria respectively, but the skeletal function of this response is unclear. MC3T3-E1 cells and primary mouse calvaria were used to evaluate osteoblast responses following PAMP-stimulation of TLR2 (Pam3CysK, 1 μg/ml), or TLR4 (LPS, 1 ng/ml) at different stages of differentiation (5, 14, or 21 days in osteogenic culture medium). Western blot and RT-PCR analyses confirmed expression of TLR2, TLR4 and the TLR4-specific signaling factor TRIF at all stages of osteoblast differentiation. Further RT-PCR analyses showed that Pam3CysK and LPS stimulated osteoblast expression of the inflammatory cytokine IL-6 at each differentiation time point, confirming functionality of TLR2 and TLR4. In a similar fashion, both the TLR2 and TLR4 ligands stimulated expression of osteoclastogenesis markers such as RANKL and OPG. By contrast, at day 14 and 21, LPS (TLR4) stimulated expression of the osteoblast differentiation markers alkaline phosphatase and osteocalcin, whilst Pam2CysK (TLR2) suppressed these markers. TLR2 and TLR4 share an MyD88 signaling pathway to induce inflammation and osteoclastogenesis, but only TLR4 can signal via the intracellular TRIF/TRAM pathway. Further analysis of day 14 osteoblasts showed that pro-osteoblastic differentiation effects of LPS were associated with induction of TLR4, and TRIF and TRAM. In immune cells, TLR ligands also stimulate intracrine metabolism and signaling by vitamin D. In day 14 osteoblasts LPS stimulated expression of the vitamin D receptor (VDR), the vitamin D-activating enzme CYP27B1 and the vitamin D catabolic enzyme CYP24A1, suggesting an enhanced vitamin D intracrine system. By contrast, Pam3CysK suppressed CYP27B1 and VDR, indicating decreased intracrine vitamin D activity. These data show that TLR2 and TLR4 are potent modulators of osteoblast function. However, although both Pam3CysK (TLR2) and LPS (TLR4) can promote inflammatory, pro-osteoclastogenic activity, only the TLR4 ligand LPS can promote pro-osteoblastic activity. Thus, Gram+ve (TLR2) and Gram-ve (TLR4) bacteria may exert opposing effects on bone turnover. In addition, this response may involve TLR-mediated effects on localized metabolism and function of vitamin D.

The Molecular Mechanism of Macrophage Polarization Epigenetically Regulated by Adiponectin in Obesity. Dong Ying Xuan*, Qisheng Tu, Jake Jinkun Chen. Tufts University School of Dental Medicine, USA

The macrophage phenotype is crucial to determine wound fate, however, the molecular events in this complex system remains unknown. In particular, obesity induces a phenotypic switch in adipose tissue macrophage polarization. Adiponectin, an adipocyte-derived secreted factor that is down-regulated in the obese state, functions to switch the macrophage polarization from pro-inflammatory states to anti-inflammatory phenotypes, thereby attenuating chronic inflammation. In our experiment, the possible epigenetic mechanism of macrophage polarization was analyzed in obese mice by injection of adiponectin. The results showed that adiponectin reduced macrophage infiltration in obese adipose tissue, and abolished the up-regulation of Jmjd3, a histone 3 Lys27 (H3K27) demethylase, in peritoneal macrophages collected from diet-induced obese mice when challenged with *Porphyromonas gingivalis* lipopolysaccharide (*Pg* LPS). Jmjd3 has been implicated in the activation of macrophages, and up-regulated in the early macrophage phase *in vitro* when challenged with *Pg* LPS, however, Jmjd3 was significantly down-regulated in macrophages from obese mice. Our results showed that adiponectin regulated the Jmjd3-IRF4 axis, which regulated anti-inflammation macrophage polarization. In future studies, we will use the adiponectin knockout mouse model to explore how adiponectin affects macrophage polarization and determine the epigenetic status change. It is crucial for understanding macrophage polarization in the obese state.

Chronic Kidney Disease Induces a Microarchitectural Alteration at the Spine as Evaluated by TBS. Edward Leib*[1], Renaud Winzenrieth[2], Didier Hans[3]. [1]University of Vermont, USA, [2]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [3]Lausanne University Hospital, Switzerland

Chronic kidney disease (CKD) has a negative effect on bone leading to an increased risk of fracture. It has been shown, on Iliac crest biopsy, that CKD patients have a microarchitectural impairment. HoweverCKD effects at the axial skeleton are not clear. In this study, we have evaluated microarchitectural texture impairment in patients with CKD at the lumbar spine using Trabecular Bone Score(TBS).

This mono-centric study involves US white women who underwent bone density testing. Control subjects were excluded if they had a historical fracture or past or present treatment or illness that could influence bone metabolism. Each CKD subject was matched for age ($\pm$3 years) and BMI ($\pm$2 kg/m^2) with two controls.Forty-seven women with CKD were age and BMI-matched with 94 healthy women (age=55.9$\pm$13.3 years, BMI=26.4$\pm$4.7 kg/m^2). 21% of subjects with CKD had an exposure to glucocorticoids, 3.4% had a thyroid disease and 17% had at least one low energy fracture. The majority of women were postmenopausal (73%). Correlations between spine TBS and BMD and TBS and BMI were 0.48 ($p<0.01$) and 0.08 ($p=0.4$) respectively. Spine TBS was significantly lower in subjects with CKD ($p<0.01$) whereas site-matched BMD was borderline non-significant ($p=0.054$). Of the subjects with CKD those with fracture had a significantly lower TBS ($p=0.034$) whereas no difference was seen for BMD ($p=0.46$). TBS was associated with fracture (OR = 2.5[1.02-6.15]; AUC = 0.756[0.609-0.870]) in the CKD group. In multivariate analysis, CKD was associated with TBS ($p=0.019$) and maternal history of hip fracture ($p=0.012$) whereas BMD, steroids, smoking and family history of osteoporosis were not kept in the model. After adjustment for maternal history of hip fracture, the odds ratio for fracture by TBS was 4.67[1.29-16.85].CKD has a negative effect on spine microarchitectural texture, as evaluated by TBS, whereas no such effect was seen withBMD. This is the first time that impairment of axial trabecular microarchitectural texture as measured by TBS has been observed in CKD subjects. TBS seems to be a reliable tool for CKD patient management.

Serum Sclerostin Predicts Bone Loss more Strongly than Age in Patients with CKD-5D. Hartmut Malluche*[1], Daniel Davenport[2], Gustav Blomquist[3], Marie-Claude Faugere[1]. [1]University of Kentucky Medical Center, USA, [2]University of Kentucky, Department of Surgery, USA, [3]University of Kentucky, Department of Radiology, USA

Introduction: Virtually all patients with CKD-5D have renal osteodystrophy and low bone volume is an integral part of this disease. This prospective study was performed to identify serum markers of bone loss in CKD-5D patients.

Patients and Methods: In patients with CKD-5D, BMD was measured by QCT of the hip and spine at baseline and at one year. Biochemical markers (including intact parathyroid hormone (iPTH), bone specific alkaline phosphatase (BSAP), C-terminal telopeptides type I collagen (CTX), Dickkopf 1 (DKK1) and sclerostin) were also measured and recorded at the same time along with demographic and clinical information. Correlation and group differences were measured using Spearman's Rho and Mann-Whitney U rank tests. Significant correlates were regressed versus bone loss for their predictive value. Significance was set at $P<.05$.

Results: Sixty-four patients (mean age 56 years $\pm$ 14 SD; 46% female; 50% black, 49% white and 1% other race) completed one-year follow-up. Mean baseline body mass index was 32.6 kg/m2 $\pm$ 7.9 SD and dialysis vintage was 59 months $\pm$ 7.9 SD. Among patients: 55% were diabetic, 21% had coronary artery disease, 24% smoked within the last 2 years, 79% were treated with vitamin D analogs and 91% with phosphate binders.

At baseline, age correlated with BMD, blacks had greater BMD of both hip and spine and patients who received treatment with vitamin D analogs had lower BMD of both hip and spine (Mann-Whitney U test $p<.05$).

After one year, median change in BMD of the spine was +2.4 mg/cm^3 (interquartile range [IR] from -11.4 to +15.2 mg/cm^3) and median change in BMD of the hip was -6.6 mg/cm3 (IR from -15.6 to +3.8 mg/cm^3). iPTH, BSAP, CTX and DKK1 did not correlate with BMD changes at any site. Sclerostin and age did not correlate with BMD changes at the spine but correlated inversely with BMD changes at the hip (rho = -.464, $p<.001$ and rho = -.274, $p<.05$ respectively). In multivariable regression, sclerostin predicted bone loss after adjustment for age (Table).

Conclusion: Serum levels of sclerostin predict bone loss at the hip but not the spine. This is likely due to the predominant production of sclerostin in cortical bone, the major component of hip bone. These patient findings support the experimental findings in animals of a negative effect of sclerostin on bone formation and demonstrate a linear relationship between blood levels of sclerostin and changes in bone mass.

Table: Independent Predictors of Change in BMD at One Year.

	Multivariable Regression Results Δ QCT of the Hip at 1 Year	
	Regression Coefficient (95% CI)	Standardized Coefficient
Sclerostin, ng/mL	12.5*** (-19.5 to -5.5)	.401
Age, y	-0.435** (-0.758 to -0.111)	-.322

The CKD-MBD is Established in Early CKD by Stimulation of Vascular Calcification, Modulation of Osteocyte Function and an Osteodystrophy While Ca, Pi, VitD and PTH are Normal. Keith Hruska*[1], Yifu Fang[2], Toshifumi Sugatani[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

We tested the hypothesis that the chronic kidney disease – mineral bone disorder (CKD-MBD) causes vascular calcification (VC) in early kidney failure. We developed a model of early CKD in the background of atherosclerosis stimulated vascular calcification. The animal model was in the *ldlr-/-* mouse fed high fat diet. CKD equivalent in glomerular filtration reduction to human stage 2 CKD stimulated early VC and inhibited the expression of α-klotho in the aorta. In addition, osteoblastic transition in the aorta was stimulated by early CKD as shown by the expression of the critical transcription factor, RUNX2. The ligand associated with the α-klotho-fibroblast growth factor receptor (FGFR) complex, FGF23, was found expressed in the vascular media of sham operated mice and decreased in the early CKD mice. Increased circulating levels of osteocyte secreted proteins, FGF23, and sclerostin may have been related to circulating klotho levels. A low turnover osteodystrophy including reduction in bone formation rates, cortical porosity and decreased size was found in the skeleton. In summary, the CKD-MBD, characterized by the cardiovascular risk factor, vascular calcification, circulating klotho, FGF23 and sclerostin secretion, and a renal osteodystrophy, was established in early CKD. Early CKD caused a reduction of vascular klotho, stimulated vascular osteoblastic transition, stimulated osteocytic secreted proteins and inhibited skeletal modeling.

Localization Of The Gene For X-linked Calvarial Hyperostosis To Xq27.3-Xqter. Vere Borra*[1], Ellen Steenackers[1], Els Van Hul[2], Ian Glass[3], Wim Van Hul[1]. [1]University of Antwerp, Belgium, [2]University & University Hospital Antwerp, Belgium, [3]University of Washington, Seattle Children's Hospital, USA

X-linked calvarial hyperostosis is a rare disorder characterized by isolated calvarial thickening. Symptoms are prominent frontoparietal bones, a flat nasal root and short upturned nose, a high forehead with ridging of the metopic and saggital sutures, and lateral frontal prominences. The mandible is normal, as are the clavicles, pelvis and long bones. The thickened bone in the skull appeared to be softer than normal bone. Despite calvarial hyperostosis, increased intracranial pressure and cranial nerve entrapment did not occur. The major disability seems to be cosmetic. The disease segregates with an X-linked recessive mode of inheritance. Female carriers do not show any clinical symptoms.To date, only one family has been described with X-linked calvarial hyperostosis including three affected individuals. In order to localize the disease causing gene, 31 polymorphic microsatellite markers spread across the X-chromosome were analyzed. Genotypes were combined in haplotypes to delineate the region. A chromosomal region spanning from Xq27.3 to Xqter cosegregates with the disorder. This region encompasses 23,53 cM or 7,92 Mb according to the DECODE map and contains 163 genes. Exome sequencing was performed on a male patient in this family. However, this did not reveal any putative mutation. CNV-analysis did not show small duplications or deletions in this region. These results indicate that a non-coding regulatory sequence might be involved in the pathogenesis of this disorder.

[1]Yale University School of Medicine, USA, [2]University of Texas, M. D. Anderson Cancer Center, USA, [3]Memorial Sloan-Kettering Cancer Center & Weill Cornell Medical College, USA, [4]Institut Gustave Roussy, France, [5]Montefiore Medical Center-Bronx, USA, [6]Endocrinology Department, Medical Center for Postgraduate Education, Poland, [7]Peninsula Regional Medical Center, USA, [8]Centre Val d'Aurelle Paul Lamarque, France, [9]California Cancer Associates for Research & Excellence, USA, [10]Centre Hospitalier Universitaire de Limoges - Hôpital Dupuytren, France, [11]Policlinico Universitario Campus Biomedico, Italy, [12]Amgen Inc., USA

Background. HCM, caused primarily by tumor-induced bone resorption, is commonly treated with intravenous (IV) bisphosphonates: HCM may persist or relapse despite such therapy. Denosumab binds to RANK ligand (RANKL) to inhibit osteoclast-mediated bone resorption.

Methods: In this single-arm, open-label study, patients with HCM (corrected serum calcium [CSC] >12.5 mg/dL) despite IV bisphosphonate treatment ≥7 and ≤30 days before screening received subcutaneous denosumab 120 mg on days 1, 8, 15, and 28, then every 4 weeks. The primary endpoint was the proportion of patients with CSC ≤11.5 mg/dL within 10 days of denosumab initiation.

Results: The study enrolled 33 patients; key baseline characteristics are shown in Table 1. By day 10, 21 patients (64%) reached CSC ≤11.5 mg/dL, including 7 of 13 patients (54%) with bone metastases and 14 of 20 (70%) without bone metastases. Over the course of the study, 23 patients (70%) reached CSC ≤11.5 mg/dL. A complete response (CSC ≤10.8 mg/dL) occurred in 12 patients (36%) by day 10 and in 21 patients (64%) over the course of the study. In patients who reached CSC ≤11.5 mg/dL, the estimated median duration of response was 104 days. By day 10, mean percentage reduction from baseline of urinary-n telopeptide (corrected for urinary creatinine) (uNTx/uCr) was 53% (standard deviation 36%). Of the 17 patients whose uNTx/uCr was ≥50 nmol/mmol at baseline, 14 (82%) reached CSC ≤11.5 mg/dL by day 10, including 8 of the 9 patients (89%) whose uNTx/Cr was reduced to <50 nmol/mmol. Reductions at day 10 in uNTx/uCr and CSC were associated (Spearman rank correlation coefficient 0.6216, P<0.01). The most frequently reported serious adverse events were hypercalcemia (5 patients, 15%) and dyspnea (3 patients, 9%). Two patients had isolated episodes of CSC levels ≤8.0 mg/dL; no patients had CSC <7.0 mg/dL. No osteonecrosis of the jaw was reported.

Conclusions: In this study of patients with persistent or relapsed HCM despite recent IV bisphosphonate treatment, 64% of patients responded to denosumab within 10 days. The sustained duration of response observed in this study is a clinically favorable outcome in this population. Consistent with the known mechanism of action of denosumab, reduction of bone turnover was associated with reduction of CSC from baseline. No unexpected safety findings were identified. Denosumab may offer a new treatment option for HCM.

Table 1. Baseline patient characteristics

Characteristic	Denosumab treatment group (N = 33)
Men, n (%)	21 (64)
Age, mean (SD)	60 (15)
Median (Q1, Q3) time from last bisphosphonate treatment to enrollment, days	17 (13, 22)
ECOG performance status 2-4	25 (76)
CSC, mg/dL, median (Q1, Q3),	13.7 (13.2, 14.2)
uNTx/uCr, nmol/mmol, median (Q1, Q3)	76.9 (26.0, 148.2)
Proportion of patients with uNTx/uCr ≥50 nmol/mmol, n (%)	17 (52)

SD: standard deviation

CSC: corrected serum calcium, calculated as {total serum calcium in mg/dL + [0.8 x (4–serum albumin in g/dL)]}

uNTx/uCr: urinary n-telopeptide corrected for urinary creatinine

A New Class of Osteoblast Ion Transport Defects Causing Delayed Mineralization. Li Liu*[1], Deborah Nelson[2], Paul Schlesinger[3], Lisa Robinson[1], Peter Friedman[4], Harry Blair[1]. [1]University of Pittsburgh, USA, [2]University of Chicago, USA, [3]Washington University, USA, [4]University of Pittsburgh School of Medicine, USA

We examined ion transport in membrane vesicles made from mineralizing nontransformed osteoblasts; using acridine orange uptake, we found H+ uptake consistent with high capacity, low gradient, acid uptake. This suggested support for mineral nucleation and phosphate deposition by facilitated removal of H+ that is evolved when phosphate salts, hydroxyapatite, precipitate in a membrane-delimited space, i.e., the osteon. Examination of H+-transport in living osteoblast cultures by monitoring intracellular pH while modifying extracellular solution composition revealed that osteoblasts have high-capacity Na+/H+ exchange polarized to the basolateral surfaces of active bone formation sites. This involves both NHE1 and NHE6; the redundant transporters likely minimize the impact of defects in either transporter. On the other hand, the Na+-H+ exchanger regulatory protein 1, which is coordinates several regulatory and transport activities in the osteoblast, when knocked out resulted in a disorder of delayed mineral deposition consistent with idiopathic osteomalacia not related to vitamin D, PTH, collagen, or phosphate defects, when a high phosphate diet was used to avoid low phosphate due to renal NHERF1 absence. If regulated Na+/H+ removal from the basolateral surface of a bone forming unit does facilitate rapid vectorial mineral deposition, then there must also be a H+ uptake mechanism at or very close to the mineralizing front. Returning to analysis of osteoblast membrane vesicle acid uptake, we eliminated active transport mechanisms, and, by varying external and internal ion composition concluded that a CLC-class cation-gradient, probably K+, driven H+/Cl- exchange mechanism might mediate H+ uptake. This would be an analog of the CLC7-dependent mechanism in the osteoclast that balances electrogenic H+ secretion by exchanging half of the H+ for Cl-. Examination of all CLC transporters expressed in murine osteoblasts showed that CLC3 and CLC5 are expressed at high levels, with 80% of CLC mRNA transcripts being CLC3. Antibody to CLC3 labeled the apical surfaces and canalicular processes of osteoblasts in mouse bone. The CLC3-/- mouse displayed delayed mineralization and reduced bone mass, in keeping with a role of this transporter in supporting vectorial H+ transport out of the osteon to allow crystal nucleation and ordered mineral deposition. This work points to a new class of cation transporters that are required to maintain normal rates of mineral deposition.

The Effects of Loss of Function *PHEX*/*Phex* Mutations in X-Linked Hypophosphatemia are Mediated by Up-Regulation of the MicroRNA335 Family. Baozhi Yuan*[1], Abigail Radcliff[2], Michael Johnson[1], Robert Blank[1], Marc Drezner[1]. [1]University of Wisconsin, USA, [2]University of Wisconsin-Madison, USA

Hyp-mice manifest renal phosphate wasting, hypophosphatemia and severe rickets/osteomalacia due to a loss of function *Phex* mutation. Although our previous studies have established that mutated *Phex* results in decreased production of *Sgne1* (7B2) mRNA, the mechanism underlying PHEX effects on this pivotal biochemical alteration, which is the fulcrum for the cascade of events resulting in the *HYP* phenotype, remains unknown. However, recent studies indicate that microRNAs (miRNAs) decrease the expression level of target genes by suppressing translation or reducing mRNA abundance. Thus, in the present study, we examined the possible role of a miRNA(s) in mediating Phex effects on 7B2 gene expression. Initially, screening of a microarray with 88 known miRNAs revealed up-regulation of 7 miRNAs in bones from *hyp*-mice compared to normal mice. TargetScan software indicated that the 3' untranslated region (UTR) of the 7B2 gene has an 8mer match with miRNA335-3p and a 3' compensatory match with miRNA335-5p, suggesting that this miRNA family, with the greatest up-regulation in *hyp*-mouse bone, may target 7B2. In support of this possibility, we found a significant decrease in *Sgne1* (7B2) mRNA in h-Tert-osteoblasts, incubated with 25μM miRNA335-3p mimic (0.19 ± 0.04 vs 1.0 ± 0.04 fold; $p<0.001$) or miRNA335-5p mimic (0.23 ± 0.02 vs 1.0 ± 0.04 fold; $p<0.001$). Since miRNAs bind to the 3'UTR of a gene to regulate expression, we used a 7B2-3'UTR luciferase construct to confirm that the 7B2 gene is directly responsive to the miRNA335 family. We observed significant inhibition of 7B2-3'UTR luciferase activity in h-Tert-osteoblasts, cotransfected with the 7B2-3'UTR luciferase reporter and the miRNA335-3p mimic (0.55 ± 0.08 vs 1.0 ± 0.06 fold; $p<0.05$) or the miRNA335-5p mimic (0.69 ± 0.07 vs 1.0 ± 0.06 fold; $p<0.05$). These data indicate that the miRNA335 family directly targets the 7B2-3'UTR to regulate 7B2 gene transcription. To assure that the increment in miRNA335 is dependent upon decreased bioactive Phex, we transfected h-Tert-osteoblasts with *Phex* siRNA (5μM) and after 48 hours evaluated effects on miRNA335 expression. RT-PCR revealed a dramatic increase in the expression of miRNA335-3p (3.12 ± 0.45 vs 1.06 ± 0.20 fold; $p<0.01$) and miRNA335-5p (3.96 ± 0.51 vs 1.06 ± 0.20 fold; $p<0.01$). In concert with our previous studies, these data indicate that the *HYP* phenotype, resulting from loss of function *PHEX*/*Phex* mutations in humans and mice, is mediated by elevated miRNA335 levels.

Bone-Related Complications Reported Among Patients With Hypoparathyroidism: Patients' Attitudes and Reponses About HypoparathyroiDism TOleration EXplored (PARADOX Study). Bart Clarke*[1], James Sanders[2], Hjalmar Lagast[3]. [1]Mayo Clinic College of Medicine, USA, [2]Hypoparathyroidism Association, Inc., USA, [3]NPS Pharmaceuticals, Inc., USA

Hypoparathyroidism is a rare endocrine disorder due to absent or inappropriately low levels of parathyroid hormone. This results in low bone remodeling that leads to high bone mineral density. There are limited reports of the disease-related burden of illness. The PARADOX study assessed the clinical, personal, and social impact of hypoparathyroidism in patients (pts) aged ≥18 y and diagnosed ≥6 mo ago. Members of the Hypoparathyroidism Association, Inc., were invited to complete an institutional review board–approved, self-reported questionnaire online. This report focuses on bone-related symptoms and comorbidities experienced by pts despite being on standard symptomatic management (eg, calcium and active vitamin D).

The web-based survey received 1294 initial hits and 442 pts completed the screening portion. Of 387 pts who completed the questionnaire, 13 were excluded because they did not meet the inclusion criteria.

The study population (N=374) included mostly women (85%); with a mean age of 49 y, mean disease duration of 13 y, and moderate-severe disease condition (79%). A total of 251 pts (67%) reported symptoms of joint or bone pain in the last 12 mo, with most reporting their overall disease condition as moderate (32 mild, 129 moderate, 90 severe). Bone fractures were experienced by 7 pts in the last 12 mo (4 moderate, 3 severe) and by 41 pts in their lifetime since diagnosis (6 mild, 17 moderate, 18 severe). The reported effects on BMD were variable; 24 pts reported decreased BMD (4 mild, 10 moderate, 10 severe), and 30 pts reported elevated BMD (3 mild, 13 moderate, 14 severe) in the last 12 mo. Since diagnosis, 53 pts reported decreased BMD (13 mild, 18 moderate, 22 severe; 31 >51 y of age), and 58 pts reported elevated BMD (7 mild, 28 moderate, 23 severe; 31 >51 y of age). In the same period, 42 pts reported soft tissue calcifications (5 mild, 16 moderate, 21 severe). Other complications possibly resulting from the underlying mineral homeostasis disruption were reported: brittle nails (44%), dental problems (29%), and hypercalcemia (18%).

Pts with hypoparathyroidism have substantial burden of illness in the skeleton and joints. The unexplained large number of BMD decreases needs further study, but suggests that bone loss in postmenopausal women with hypoparathyroidism is similar to other postmenopausal women. Bone-related comorbidities afflict pts despite being on standard symptom management therapy that includes calcium and active vitamin D.

Effects of Long Term PTH(1-84) Replacement Therapy in Hypoparathyroidism and the Consequence of Termination of Therapy. Tanja Sikjaer*[1], Lars Rolighed[2], Emil Moser[3], Leif Mosekilde[3], Lars Rejnmark[2]. [1]Department of Medicine & Endocrinology, MEA Aarhus University Hospital, Denmark, [2]Aarhus University Hospital, Denmark, [3]Department of Endocrinology & Internal Medicine, MEA, Aarhus University Hospital, Denmark

The aim of the study is to investigate the long-term effect of PTH(1-84) treatment in hypoparathyroidism (hypoPT). We have previously reported results on 62 patients with hypoPT randomized to 6 months of treatment with either PTH(1-84) 100 µg/d s.c. or similar placebo, administrated as an add-on therapy (1). We followed 42 of these patients for an extension of 2 yrs. 17 patients treated with placebo continued as a control group, 9 patients continued treatment with PTH(1-84) 100 µg/d and 15 discontinued PTH(1-84) treatment and returned to only calcium and active vitamin D analogs.

The 42 participants have had hypoPT for a mean of 12 (range: 4;32)yrs. Only 1 subject had idiopathic hypoPT whereas 41 had acquired hypoPT following surgery. Mean age of subjects was 54±12 yrs and 90% were females. There were no significant differences in plasma levels of calcium, phosphate, creatinine, eGFR or renal calcium excretion between groups.

As previously reported, 6 months of treatment with PTH(1-84) decreased BMD at the hip, spine and whole body (WB) (1). This effect was reversed during the 2 years follow up period by both discontinuation and continuously PTH(1-84) treatment. BMD increased significantly in the discontinued group at the hip by 4.7±1.5%, the lumbar spine by 7.8±2.1% and WB by 2.3±1.0 compared to the control group. In the continuously treated group, BMD increased significantly at the spine by 7.2±2.4% compared to the control group. Compared with controls, there were no differences in BMD at the hip and WB in the PTH(1-84) group. There were no differences between groups at the forearm.

Bone turnover, as assessed by levels of biochemical markers, such as bone formation: P1NP, Osteocalcin, bone-specific alkaline phosphatase and bone resorption: urinary-NTX, serum-CTX, was previously shown too increase gradually during the 6 months of treatment. After 2 years of discontinuation of PTH(1-84) the levels of bone turn over markers returned to baseline levels. Compared with the other groups, the bone markers remained significantly higher in the PTH(1-84) treated patients.

In conclusion, the previously shown reduction in BMD at the hip, spine and WB in PTH(1-84) substitution therapy is neutralized if treatment is continued for 2.5 years and even increases BMD at the spine. If the treatment is discontinued, bone turn over markers returns to baseline and BMD increases at the hip, spine and WB.

Methylation of cytosine-guanine dinucleotide (CpG) islands of vitamin D receptor (VDR) and calcium sensing receptor (CaSR) genes in parathyroid adenomas. Sanjay Bhadada*[1], Shweta Varshney[2], Naresh Sachdeva[3], Uma Nahar Saikia[4], Ashutosh Arya[2], Arunanshu Behera[5], Sudhaker D. Rao[6]. [1]PGIMER, Chandigarh, India, [2]Department of Endocrinology, PGIMER, India, [3]Department of Endocrinology, India, [4]Department of Histopathology, PGIMER, India, [5]Department of General Surgery, India, [6]Henry Ford Hospital, USA

Aim: Exact mechanism(s) for decreased expressions of vitamin D and calcium sensing receptors (VDR & CaSR) in sporadic parathyroid adenomas is not known. However, methylation of promoter regions (so-called gene silencing) is often detected during epigenetic down regulation of gene expression. We investigated whether such epigenetic silencing is involved in the decreased expression of VDR and CaSR.

Experimental Design: Real-time PCR and immunohistochemistry were used to confirm the down regulation of VDR and CaSR genes at transcriptional and translational levels. Bisulfite-converted DNA samples from parathyroid adenomas with control samples were analyzed for methylation in the promoter region of VDR and CaSR genes.

Results: As reported by us and others, immunohistochemistry revealed significant reductions in VDR and CaSR expressions, and a significant increases in CD1 and PTH expressions in adenomatous compared to normal parathyroid tissue. Consistent with immunohistochemistry findings, both VDR and CaSR mRNAs were reduced by 0.36 and 0.45 fold change ($p<0.001$), and CD1 and PTH mRNAs were increased by 9.4 and 17.4 fold change respectively ($p<0.001$) in adenomatous parathyroid tissue. PTH mRNA correlated with plasma PTH ($r=0.864$; $p<0.001$), but not with adenoma weight, while CD1 mRNA correlated with adenoma weight ($r=0.715$; $p<0.001$). There was no relationship either between the decreases in VDR and CaSR mRNA expressions or the increases in PTH and CD1 mRNA expressions.

Most importantly, there was no significant methylation in the promoter regions of VDR or CaSR genes in the parathyroid adenomatous tissues.

Conclusions: we confirmed reductions in VDR and CaSR expressions both at the protein and mRNA levels. However, methylation-mediated silencing of VDR and CaSR promoter does not appear to be associated with these reduced expressions. This suggests involvement of other factors in the specific suppression of VDR and CaSR gene expressions in parathyroid adenomas.

Normocalcemic Primary Hyperparathyroidism: BMD gain at the individual patient level after parathyroidectomy. Eugenie Koumakis*[1], Jean-Claude Souberbielle[2], Emile Sarfati[3], Didier Borderie[4], Andre Kahan[5], Catherine Cormier[6]. [1]Hôpital Cochin, France, [2]Explorations Fonctionnelles, Hôpital Necker Enfants Malades, France, [3]Chirurgie Générale et Endocrinienne, Hôpital Saint-Louis, Paris, France, [4]Laboratoire de Biochimie Générale et Spécialisée, Hôpital Cochin, Paris, France, [5]Rheumatology Department A, Cochin Hospital, France, [6]AP-HP Groupe Hospitalier Cochin, France

In primary hyperparathyroidism (PHPT), it is unclear whether parathyroidectomy (PTX) may be beneficial in patients with a mild phenotype, in particular in normocalcemic PHPT. Our aims were to assess BMD gain after PTX at the individual level in normocalcemic PHPT patients, and to investigate the predictive factors of individual BMD gain.

Patients and Methods: longitudinal cohort study of 60 PHPT patients (aged 64.0±10.1 years) referred for low bone mass and mild abnormalities of calcium/phosphorus metabolism, and successfully treated by PTX. BMD was assessed at the spine, hip and forearm before and 1 year after PTX using QDR 4500 (Hologic). To determine the impact of PTX on BMD at the individual level, the mean difference between pre and post-PTX BMD values was calculated (g/cm^2). The least significant change (LSC) was chosen as threshold for individual BMD gain, and calculated using the ISCD recommendations: $LSC=2\sqrt{2}xSD$, with a SD of $0.01 g/cm^2$. BMD gain was considered significant if ≥ 0.030 g/cm^2 at one site or more, without any equivalent BMD loss at another site. A logistic regression analysis was performed to determine whether baseline characteristics were predictive of individual BMD gain.

Results: Two groups of patients were individualized according to baseline serum total (albumin-corrected) calcium (tCa): 39 normocalcemic patients, and 21 hypercalcemic patients. An individual gain was observed at 1 yr in 73.7% of hypercalcemic patients, and 44.4% of normocalcemic patients (p=0.05). In univariate analysis, patients with a significant BMD gain were more likely to have lower baseline eGFR (72.8±18.6 vs 79.9±13.4 ml/min/1.73m^2, p= 0.02), tended to have higher baseline serum tCa (2.56±0.14 vs 2.51±0.12 mmol/l, p=0.07) and higher ALP (79.1±30.7 vs 65.1±23.1 UI/l, p=0.06) than patients who did not. In logistic regression analysis, baseline ALP in the upper median range (67-161 UI/L) was the only variable identified as an independent predictor for BMD gain (OR=4.8, 95% CI 1.3-17.6). Similarly, baseline ALP in the upper median range was also predictive of BMD gain in the normocalcemic group (OR=8.4, 95% CI 1.4 to 56.6). No association was identified with any other baseline characteristic.

Conclusion. These results highlight that successful PTX is followed at 1 year by an increase in BMD at the individual level, in nearly 50% of patients with normocalcemic PHPT. This suggests that PTX may have a positive impact in normocalcemic PHPT patients with osteoporosis.

Parathyroidectomy eliminates arrhythmic risk in primary hyperparathyroidism, as evaluated by exercise test. Jessica Pepe*, Mario Curione, Marisa Varrenti, Mirella Cilli, Sara Piemonte, Cristiana Cipriani, Claudio Savoriti, Orlando Raimo, Federica De Lucia, Carolina Clementelli, Elisabetta Romagnoli, Salvatore Minisola. "Sapienza", Univeristy of Rome, Italy, Italy

Objective: to investigate if parathyroidectomy (PTx) reverses risk factors for arrhythmias, related to the QT dynamic changes evaluated during bicycle ergometry exercise test (ET).

Methods: twenty four postmenopausal women with primary hyperparathyroidism (PHPT) (mean age 60.0±8.4 years) and 30, sex and age-matched, controls underwent ET, echocardiographic and biochemical evaluation. The following stages were considered during ET: rest, peak exercise, recovery (early recovery, 2 minutes, and 10 minutes after peak exercise). The patients were randomized into two groups: 12 patients underwent PTx (Group A) and 12 were followed-up conservatively (Group B). After 6 months the patients were again studied.

Results: there was no significant difference between PHPT patients (Group A and Group B) compared to controls, apart from the expected significantly mean higher levels of total, ionized calcium and PTH and significantly mean lower levels of phosphorus in PHPT patients (total calcium A:2.7±0.1, B:2.7±0.1 vs controls 2.30±0.14 mmol/l; ionized calcium A:1.45±0.16, B:1.39±0.03 vs controls 1.22±0.04 mmol/L; phosphorus A:0.89±0.11, B:0.92±0.12 vs controls 1.25±0.15 mmol/L; parathyroid hormone A:80.3±23.5, B:83.4±23.1 vs controls 34.2±10.3 ng/L, all p≤0.01). Group A and B, showed no differences in mean baseline biochemical values, echocardiographic parameters and QTc interval. PHPT patients, showed an increased occurrence of ventricular premature beats (VPBs) during ET compared with controls (37% vs 6.6%, p=0.03). Serum total calcium level was a predictor of VPBs (p=0.05). Mean value of QTc was in the normal range at baseline (A: 401.0±16.9; B: 402.25±13.5 msec), but significantly shorter than controls (417.8±25.1 msec, p<0.01); a negative correlation was found between QTc and total calcium values (p=0.03). Physiological reduction of QTc interval from rest to peak exercise was not observed in PHPT patients before surgery. After PTx, Group A had a significant reduction in VPBs compared to baseline (at baseline, 5 out of 12 vs none out of 12 patients after PTx, p=0.03) and a restored normal QT adaptation during ET. Group B showed no significant changes after a six month period.

Conclusions: PTx reduces the occurrence of VPBs and restored the QTc adaptation during ET.

Figure 1: QTc interval during exercise test in Group A and controls.

Figure 2: QTc interval during exercise test in Group B and controls.

*p≤0.01 baseline vs controls, p≤0.01 baseline vs after 6 months.

Predictors of Bone Mass Recovery Following Cure of Primary Hyperparathyroidism: 1-Year Follow-Up of 49 cases. Bruno Ferraz-de-Souza*[1], Regina M Martin[1], Manuela GM Rocha-Braz[1], Adriana M Fernandes[1], Pedro Henrique Correa[2]. [1]Univ of Sao Paulo School of Medicine (FMUSP), Brazil, [2]University of Sao Paulo School of Medicine, Brazil

Introduction: Primary hyperparathyroidism (PHPT) leads to increased bone remodeling and reduced bone mass. In PHPT patients with evident bone involvement, bone mass can be greatly recovered following surgical treatment, and hungry bone syndrome might ensue during the immediate postoperative period. Currently, most PHPT patients do not have symptoms of bone disease at diagnosis and identifiable factors predicting bone mass gain following treatment are not well established.

Objectives: To identify predictors of bone mass recovery at lumbar spine following cure of PHPT.

Methods: Retrospective analysis of PHPT cases cured by surgery followed in our center with pre- and postoperative register of: bone mineral density (BMD) and T-/Z-scores at lumbar spine (LS), total hip and forearm as determined by DXA; serum determinations of total calcium (Ca), ionized Ca, phosphorus, PTH, creatinine, 25OHD, alkaline phosphatase (ALP), P1NP, osteocalcin and CTX; 24-hour calciuria; and bone scintigraphy. Pearson's correlation coefficient and statistical significance were calculated using PAWS17.

Results: Forty-nine patients (8M, 41F) between 20 and 82 yrs of age (median 63.3) were identified. Median interval between surgery and postoperative DXA was 12.3 mo, and the adjusted 1-yr delta BMD at LS ranged from -13.4% to +47.2%. 71% of patients had delta BMD >3% and 47% had >6% gain in LS BMD in 1 yr. Delta LS BMD was significantly correlated (p<0.001) with basal serum PTH (r=0.77), ALP (r=0.72), P1NP (r=0.71) and osteocalcin (r=0.66), amongst others. No correlation was seen between delta BMD and age at surgery, basal serum Ca, CTX, 25OHD or 24-h calciuria. After the removal of delta LS BMD outliers, correlation was no longer significant for the aforementioned variables, indicating that the observed association was driven by extreme cases of PHPT with severe bone disease at diagnosis.Conclusion: Recovery of BMD in LS one year after surgical cure of PHPT was observed in a large proportion of patients, suggesting frequent bone involvement. Basal serum determinations of PTH and bone formation markers seem to best predict BMD recovery after surgery but this correlation is determined by the inclusion of severe cases. In more mild PHPT cases, routine investigation does not seem to provide predictive factors of BMD recovery. Extrapolation of these findings can have important implications for the indication of surgical treatment for asymptomatic PHPT.

SA0182

Standard Definition of Vitamin D Deficiency Does Not Identify Bone Mineral Density Differences in Mild Primary Hyperparathyroidism. Elaine Cong*[1], Marcella Walker[2], Chiyuan Zhang[2], Shonni Silverberg[2]. [1]Columbia Presbyterian Medical Center, USA, [2]Columbia University, USA

Vitamin D deficiency and primary hyperparathyroidism (PHPT) have independent skeletal effects, and vitamin D deficiency is known to exacerbate hyperparathyroidism in PHPT. In 2009, the 3rd International Workshop on the Management of Asymptomatic PHPT recommended a goal 25-hydroxyvitamin D (25OHD) level > 20 ng/dl in PHPT. However, data on PHPT patients using this cut-point for vitamin D are lacking. Although controversy remains regarding definitions of vitamin D deficiency, we sought to compare PHPT patients who are clearly vitamin D deficient (D-deficient: 25OHD < 20 ng/dl) and those who are clearly vitamin D replete (D-replete: 25OHD > 30 ng/dl). We retrospectively analyzed baseline data from our longitudinal natural history study of mild PHPT, including the 103 of 137 subjects with complete vitamin D and BMD data. Serum calcium (10.5 vs 10.6 mg/dl) and

PTH (127 vs 126 pg/ml) levels were similar to the overall cohort. D-deficiency was common (n=47, 46%; 25OHD 15±4 ng/ml) while only 18% were D-replete (25OHD 38±8 ng/ml). Deficient and replete groups did not differ by gender, menopausal status, or ethnicity. D-deficient subjects were older (57±1.6 vs 50±3.5 years, p=0.04) and had higher BMI (26±1 vs 22±1 kg/m^2, p=0.02). D-deficient subjects had higher PTH levels (148±11 vs 104±11 pg/ml, p=0.008) and tended to have lower 1,25$(OH)_2$-vitamin D levels (54±2 vs 67±6 pg/ml, p = 0.058), while serum calcium (10.6±0.1 vs 10.6±0.1 mg/dl) and alkaline phosphatase (108±7 vs 95±9 U/L, p=0.2) did not differ. D-deficient and D-replete groups also had similar and BMI adjusted BMD (lumbar spine: 0.95±0.03 vs 0.90±0.05 g/cm^2, p=0.38; femoral neck: 0.68±0.02 vs 0.67±0.02 g/cm^2, p =0.73; 1/3 radius: 0.59±0.01 vs 0.56±0.02 g/cm^2, p=0.29).

In summary, using the 25OHD cut-point of 20 ng/ml, D-deficient PHPT patients were older and heavier, as expected in any D-deficient population. With regard to PHPT disease activity, D-deficient patients had PTH levels 42% higher than those who were D-replete but other indices did not differ. Although prior analyses in this cohort demonstrated lower 1/3 radius BMD when an older definition of D-deficiency was used (25OHD < 9 ng/ml vs > 9 ng/ml: 0.48 vs 0.58 g/cm^2, p=0.05), we did not find lower BMD when stratifying subjects using the more current descriptions of vitamin D status as suggested in the 2009 Guidelines. Despite much higher PTH levels, these data do not support an important impact on BMD using a 25OHD cut-point of 20 ng/ml in mild PHPT.

SA0183

Carotid Calcification and Osteoporosis in Postmenopausal Women – OSTPRE BBA – Study. Miika Värri*[1], Tomi-Pekka Tuomainen[2], Risto Honkanen[3], Heikki Kroger[4], Marjo Tuppurainen[4]. [1]Bone & Cartilage Research Unit, University of Eastern Finland, Finland, [2]Institute of Public Health & Clinical Nutrition, University of Eastern Finland, Finland, [3]University of Eastern Finland, Finland, [4]Kuopio University Hospital, Finland

Atherosclerosis (AS) and osteoporosis (OP) are common diseases in elderly people. Several metabolic connections as well as same risk factors have been suggested for both carotid calcification and OP. The aim of this cross-sectional study was to explore the association between carotid artery intima- media thickness (IMT), carotid artery calcification and bone mineral density (BMD) in postmenopausal women. In addition, the association of postmenopausal hormone therapy (HT) with IMT and carotid calcification was studied.

Study population was drawn from the Kuopio OSTPRE- BBA (Bone-Brain and Atherosclerosis) study. In all, 346 women (mean age 73.6 years) were randomly selected for carotid IMT measurements with B-mode ultrasound; femoral neck, lumbar spine (L2-L4) and total body BMD were measured with DXA (Dual-energy X-ray absorptiometry).

In 63.6 % of cases, atherosclerotic plaques were observed at carotid arteries bifurcations. Increased right carotid maximum IMT was significantly associated with low femoral neck T-score. In the osteoporotic group (T-score < -2.5, n=20) the maximum IMT was 2.66 mm ± 1.19 SD and in non-osteoporotic group (T-score > -1, n=122) 1.95 mm ± 0.73 SD, respectively (P<0.001). The presence of carotid artery calcifications was more prevalent in the osteoporotic group than in the normal T-score group (OR = 4.6, P=0.002). IMT values were not associated with lumbar spine T-score. Maximum values of common carotid IMT were smaller in HT users (1.26 mm ± 0.16 SD) than in non-users (1.31mm ± 0.23 SD) (P=0.010). There were no associations between HT and carotid calcifications.

The results of our population-based study suggest that OP is related to AS changes in carotid arteries, and indirectly support the hypothesis of partially shared pathophysiological mechanisms in the two disorders. In addition, follow-up of carotid arteries of osteoporotic women might be useful for assessment of preventive and treatment.

Ectopic mineralization of spinal tissues in mice lacking equilibrative nucleoside transporter 1: Age-dependent alterations in the expression of genes regulating biomineralization. Hisataka Ii*[1], Sumeeta Warraich[1], Diana Quinonez[1], James R. Hammond[2], S. Jeffrey Dixon[1], Cheryle A. Séguin[1]. [1]The University of Western Ontario, Canada, [2]University of Alberta, Canada

The equilibrative nucleoside transporter 1 (ENT1) transfers adenosine across plasma membranes. We reported recently that mice lacking ENT1 (KO) exhibit progressive ectopic mineralization of spinal tissues, resembling diffuse idiopathic skeletal hyperostosis (DISH) in humans. Pathological calcification was first noted in the paraspinal ligaments of the cervical-thoracic region at 2 months of age. Lesions extended to the lumbar and caudal regions with advancing age, and eventually involved the entheses, intervertebral discs and sternocostal articulations. Moreover, plasma levels of inorganic pyrophosphate (PPi, an inhibitor of biomineralization) were greater in KO mice than in wild-type (WT) at 2 months of age. The purpose of the current study was to investigate the mechanisms underlying ectopic mineralization in KO mice. Accordingly, we quantified the expression of genes known to regulate biomineralization. Intervertebral discs (IVDs) were isolated by microdissection from KO mice and WT littermate controls at 2 months of age (when lesions were not detectable in IVDs by micro-CT) and at 6 months of age (when there was extensive involvement of the IVDs). RNA was extracted and transcripts were quantified by real-time RT-PCR. Compared to tissues from WT mice, IVDs from 2-month-old KO mice exhibited greater expression of alkaline phosphatase (*Alpl*, enzyme responsible for the hydrolysis of PPi to Pi, which promotes mineralization) and ectonucleotide pyrophosphatase/phosphodiesterase 1 (*Enpp1*, enzyme responsible for the production of PPi). On the other hand, there was no significant difference in the expression of progressive ankylosis protein (*Ank*, a putative PPi transporter). These findings are in striking contrast to the pattern of gene expression in IVDs from KO and WT mice at 6 months of age. In these older mice, expression of *Alpl*, *Enpp1* and *Ank* was significantly less in KO mice than in WT. It is possible that upregulated expression of alkaline phosphatase in the IVDs of KO mice at 2 months of age leads to the eventual mineralization of these structures seen in older mice; whereas, in older mice, there may be compensatory changes in gene expression as mineralized lesions extend into the IVDs. KO mice may be a useful model to investigate the etiology of and therapies for DISH and related disorders of mineralization in humans.

Effects of Irisin on Bone Metabolism and its Signal Mechanism. Jin Zhang*, Jessica Cheng, Qisheng Tu, Jake Jinkun Chen. Tufts University School of Dental Medicine, USA

Irisin, a newly discovered myokine induced in exercise, has potential effects in stimulating adipose tissue browning, and fighting obesity and diabetes. This study investigates the effects of irisin on bone metabolism and its signal mechanism.

Cultured pre-osteogenic MC3T3-E1 cells were treated with ascorbic acid (AA) and irisin. The mRNA expressions of osteogenic factors Runx2, Osterix, and Satb2 were increased several fold after irisin treatment. Bone sialoprotein (BSP), type I collagen, and osteocalcin (OCN) were considerably upregulated in the late osteogenic stage. We screened a variety of osteogenic signaling pathways and found that irisin promoted the translocation of β-catenin into the nucleus of MC3T3-E1 cells at 3, 6, and 12h. Irisin increased total b-catenin protein levels at 6h following AA induction; BMP pathway inhibitor LDN193189 further increased β-catenin protein levels. Irisin also increased phosphorylation of Smad1/5/8, which was inhibited by LDN193189, indicating that irisin affects osteoblastogenesis via the Wnt/β-catenin pathway downstream of the BMP receptor signal. Additionally, irisin increased Erk1/2, JNK, P38, AKT1, and calcineurin phosphorylation, which were all increased by β-catenin inhibitor XAV939.

We found that irisin inhibited RANKL-induced RAW264.7 cell osteoclastogenesis through NFATc1 suppression in a time and dose-dependent manner. Irisin reduced expressions of osteoclast differentiation markers TRAP and cathepsin K, and reduced numbers of TRAP+ osteoclasts. Irisin also inhibited expressions of MITF, PU1, and AKT1 and reduced AKT1 protein phosphorylation. However, expressions of p-B, p-Erk/c-Fos, p-JNK, and c-Myc, were increased. As NFATc1 was down-regulated, irisin might specifically inhibit osteoclast differentiation through calcineurin/NFATc1 and AKT1/MITF/PU1-NFATc1 pathways.

In vivo, irisin protein or FNDC5-lentivirus injections increased bone volume/total volume, trabecular thickness, and cortical thickness compared to control mice (*p<0.05), as well as BSP and OCN expressions compared to scramble-virus control. Irisin positive osteoblasts were found on the edge of the growth plate.

In conclusion, we demonstrated that irisin promoted osteoblast differentiation through the Wnt/β-catenin pathway and inhibited osteoclast differentiation by suppressing the RANKL/NFATc1 pathway. Hence, exercise-induced irisin has initially proven to be a potent factor in strengthening bone by regulating bone metabolism.

Interdependence of Muscle and Bone Loss Induced by Disuse and Aging. Shane Lloyd*, Yue Zhang, Emmanuel Paul, Lacee Laufenberg, Charles Lang, Henry Donahue. The Pennsylvania State University College of Medicine, USA

Mechanical unloading induces muscle atrophy and bone loss, but the relative time course and interdependence of these deleterious effects is unknown. To address this issue we subjected 4-month-old C57BL/6J mice to hindlimb suspension (HLS) or normal loading for 3 weeks. We sacrificed 12-16 mice per condition on day (d) 0, 7, 14, and 21.

^{1}H-NMR revealed a maximal 7% decrease in lean mass with HLS by d7 (Fig1A; p<0.05). The gastrocnemius (gast) was affected earliest (-8% by d7), with mass being reduced 16% by d14 (p<0.05). Quadriceps (quad) mass was unchanged at d7, but decreased 14% by d14 (p<0.05). Muscle mass did not change with age. Atrogin-1 and MuRF1 are muscle-specific ubiquitin ligases involved in protein degradation. At d7,

atrogin-1 mRNA was increased 122% and 99% in quad (Fig1B) and gast, respectively ($p<0.05$). MuRF1 mRNA was increased 88% and 44% in the quad and gast, respectively, at d7 ($p<0.05$). The mRNA content for both returned to baseline thereafter. Protein syntheses decreased by 30% in quad and gast at d7 ($p<0.05$), returning to baseline by d21 (Fig1C). The phosphorylation of S6K1 (T389) and S6 (S240/244), surrogate markers of mTOR kinase activity, was reduced in gast after 7-21 d of HLS.

Skeletal effects were not apparent until d14. There was a 4% decrease in femur cortical thickness at d14 (Fig1D; $p<0.05$) and similar response in the tibia. Distal femur trabecular parameters were not different at d7. By d14, HLS mice had a reduction in bone volume fraction (22%), trabecular thickness (15%), and tissue mineral density (16%; Fig1E; $p<0.05$); however, the effect of HLS was often eliminated by d21 due to age-related decline in trabecular microstructure in controls. Trabecular response at the proximal tibia was similar.

There was a 13% decrease in femur force to failure and bending rigidity by d14, and 17% decrease by d21 (Fig1F; $p<0.05$). Surprisingly, there was no effect of unloading on tibia strength.Our results suggest muscle atrophy, and thus reduced mechanical force, precedes bone loss during unloading and may compound unloading-induced bone loss. Countermeasures that preserve muscle may prevent or delay the deleterious skeletal effects of unloading. Furthermore, age-related trabecular bone loss in mice, similar to that which occurs in mature astronauts, is superimposed on unloading. Preservation of muscle mass, cortical structure, and bone strength with age suggests muscle may have a greater effect on cortical than trabecular bone.

SA0188

Muscle, Physical Activity and Sedentary Time are Independent Predictors of Bone Strength in Post-Menarcheal Girls. Vina Tan*[1], Lindsay Nettlefold[2], Heather Macdonald[1], SoJung Kim[3], Douglas Race[2], Joan Wharf-Higgins[4], Patti-Jean Naylor[4], Heather McKay[1]. [1]University of British Columbia, Canada, [2]Centre for Hip Health & Mobility, Canada, [3]University of British Columbia, South Korea, [4]University of Victoria, Canada

Muscle contractions impose a dynamic force on bone during physical activity (PA). However, the interaction between PA, muscle and bone in pubertal girls is not well described. Therefore, we assessed the association between muscle, PA and sedentary time on estimated bone strength, structure and density in post-menarcheal girls.

Methods: We measured the tibia bone (left, 8% and 50% sites) using pQCT (XCT3000, Stratec) in 102 post-menarcheal girls (15.3 ± 0.4 yrs). We assessed PA by accelerometer (GT1M, ActiGraph) that girls wore for 7 consecutive days during waking hours. We included participants with at least 3 valid days (wear time $\geq$600 min/day, non-wear time defined as 60min zeros with 2min non-zero allowance block). We used age-specific cut-points to classify activity as sedentary (<1.5 metabolic equivalents (METs)), moderate-to-vigorous PA $\geq$ 4METs (MVPA) and vigorous PA $\geq$7 METs (VPA). At the distal tibia, we assessed bone strength index (BSI, mg^2/mm^4), bone area (Ar, mm^2) and density (BMD, mg/cm^3) for total (Tt) and trabecular (Tb) bone. At the midshaft, we assessed polar strength-strain index (SSI_p, mm^3), periosteal (Peri) and endosteal (Endo) circumference (mm), cortical bone area, density and thickness (Ct.Ar (mm^2), Ct.BMD (mg/cm^3), Ct.Th (mm)) and muscle cross-sectional area (MCSA, mm^2). Age at menarche was self-reported. We fit multivariable regression models to evaluate the influence of MCSA and PA levels on bone outcomes (adjusted for tibia length, ethnicity and maturity). In PA models, we also controlled for MCSA and accelerometer wear time.

Results: MCSA strongly predicted 26.5% and 31.7% of the variance in BSI and SSI_p, respectively ($p<0.001$) after controlling for covariates. MCSA explained 3.6-29.9% of variance in Tt.BMD, Tt.Ar, Tb.BMD, Tb.Ar and Ct.Ar ($p<0.05$). After additional covariates, MVPA explained 14.0% of the variance in BSI and 5.0% in SSI_p ($p<0.05$). MVPA explained 5.4-11.3% of the variance in Ct.Ar, Tt.BMD and Tb.BMD ($p<0.05$). Sedentary time was a negative predictor of SSI_p (4.8%) and Tt.BMD (5.6%) ($p<0.05$). MVPA and VPA were negative predictors of Ct.Th and Endo ($p<0.05$), accounting for 6.8-18.9% of the variance, respectively.

Conclusion: MCSA, PA levels and sedentary time have a unique influence on estimated bone strength, structure and density at the weight-bearing tibia in post-menarcheal girls. Increased PA and decreased sedentary time are modifiable factors that should be addressed to promote bone health during growth.

Table 1. Descriptive characteristics for post-menarcheal girls (n=102).

	Mean	SD
Age (years)	15.3	0.4
Height (cm)	162.8	6.4
Weight (kg)	59.0	10.0
Years post menarche	2.9	1.2
Ethnicity (Caucasian/ Others)	55/47	-
MCSA (mm^2)	3782.9	643.8
BSI (mg^2/mm^4)	8516.8	1883.2
SSI_p (mm^3)	1543.2	289.9
Accelerometer data (n=60)		
Number of valid days (3/4/5/6/7)	11/22/17/6/4	-
Total wear time (min/valid day)	791.5	57.2
Sedentary <1.5METs (min/day)	646.6	62.4
MVPA ≥4METs (min/day)	33.6	17.8
VPA ≥7METs (min/day)	4.9	4.9

Table 1

Table 2: Multivariable regression models for bone outcomes at the a) 8% tibia and b) 50% tibia ($p<0.05$), adjusted for tibia length, years post menarche and ethnicity. Models developed to predict PA outcomes also adjusted for MCSA and accelerometer wear time.

Bone outcome	MCSA		Sed		MVPA		VPA

17ß-Estradiol and Testosterone Exert Antiapoptotic Effects in Skeletal Muscle Cells Involving AR, ER, ERK, MnSOD and COXIV. Anabela La Colla, Lucia Pronsato, Ana Carolina Ronda, Lorena Milanesi, Andrea Vasconsuelo, Ricardo Boland*. Universidad Nacional del Sur, Argentina

17b-Estradiol (E2) and Testosterone (T) have effects in several tissues including skeletal muscle. In aged skeletal muscle both a deficit of sex hormones and prominent apoptosis are observed contributing to the pathogenesis of sarcopenia. We previously showed that E2 and T inhibit H_2O_2 - induced apoptosis in C2C12 muscle cells. Here we demonstrate that E2 has a relevant role in muscle mitochondria, up-regulating the expression and activity of manganese superoxide dismutase (MnSOD) and increasing the activity of cytochrome c oxidase IV (COXIV), through ERK signaling. Pharmacological and immunological assays employing the estrogen receptor (ER) antagonist fulvestrant indicate that ER mediates these events. In addition, MnSOD expression and COXIV activity decrease when cells are treated with H_2O_2, effects that are reversed with E2 pretreatment. Experiments with the androgen receptor (AR) antagonist flutamide involved the AR in the antiapoptotic action of T. Competitive binding assays, immunocytochemistry and Western blots supported a non-classical localization of the AR in C2C12 cells. Thus, AR was detected by immunoblots using specific antibodies after subcellular fractionation, not only in nucleus and cytosol, but also in mitochondria and microsomes. [^{3}H] T binding characteristics were established in total homogenates and subcellular fractions. Specific and saturable [^{3}H] T binding sites were detected in mitochondria and microsomes. Immunolocalization of the non-classical AR was also confirmed using confocal microscopy. Sucrose gradient fractionation demonstrated the presence of the AR in lipid rafts and caveolae. These results point to an active role of the AR during the antiapoptotic effect of T at different levels: nuclear (in the genomic response), mitochondrial (in the intrinsic pathway) and microsomal (in the response mediated by membrane proteins). Besides, coimmunoprecipitation assays indicated that the AR physically interacts with caveolin-1, association which was lost after T treatment at the same time that a decrease of AR expression was observed in the microsomal fraction, suggesting

translocation of the membrane AR to inner cellular compartments. Our studies contribute to elucidate the mechanism by which these hormones regulate signaling cascades throwing light on the molecular basis of myopathies associated with deregulation of apoptosis by sex hormone deficiency states

Clinical Definitions of Sarcopenia and Risk of Falls and Hip Fractures in Older Men: The Osteoporotic Fractures in Men (MrOS) Study. Peggy Cawthon*[1], Terri Blackwell[2], Jane Cauley[3], Christine Lee[4], Deborah Kado[5], Elizabeth Barrett-Connor[5], Andy Hoffman[6], Marcia Stefanick[6], Michael Nevitt[7], Nancy Lane[8], Kristine Ensrud[9], Steven Cummings[10], Eric Orwoll[4]. [1]California Pacific Medical Center Research Institute, USA, [2]CPMCRI, USA, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]Oregon Health & Science University, USA, [5]University of California, San Diego, USA, [6]Stanford, USA, [7]UCSF, USA, [8]University of California, Davis Medical Center, USA, [9]Minneapolis VA Medical Center / University of Minnesota, USA, [10]San Francisco Coordinating Center, USA

We examined whether two consensus definitions of sarcopenia (and their components) were associated with incident falls and hip fractures in men aged ⩾65 yrs in MrOS (N=5934).

We assessed appendicular lean mass (ALM) by whole-body Hologic 4500 DXA; grip strength by dynamometry; and walking speed over 6 meters. Fractures were centrally adjudicated over 9.8 years. Falls were by self-report 3x/year with recurrent falls defined as ⩾2 in the year after baseline. The International Working Group (IWG) sarcopenia definition included slowness (walking speed<1.0 m/s) and low lean mass (ALM/ht^2≤7.23 kg/m^2); both must be present for ''sarcopenia''. The European Working Group on Sarcopenia in Older Persons (EWGSOP) definition included: 1) slowness (gait speed≤0.8 m/s); 2) weakness (grip strength<30 kg); and 3) low lean mass (ALM/ht^2≤7.23 kg/m^2). ''Sarcopenia'' was defined as low lean mass plus either slowness or weakness, and ''severe sarcopenia'' as all three; severe sarcopenia was rare, so ''sarcopenia/severe sarcopenia'' were analyzed together. We used logistic regression to estimate odds ratios (OR) for recurrent falls (N=694, 11.9%), and proportional hazards to estimate hazard ratios (HR) for hip fractures (N=207, 3.5%).

By the IWG, men with sarcopenia (N=277, 4.7%) were more likely have recurrent falls (OR: 2.2, 95%CI: 1.7, 3.0) and fracture a hip (HR: 2.2, 95%CI: 1.7, 3.0) than men without sarcopenia. For IWG definition components, slowness independently predicted recurrent falls and hip fractures, whereas low lean mass predicted hip fractures but not recurrent falls (Table 1).

By the EWGSOP, men with sarcopenia/severe sarcopenia were more likely have recurrent falls (OR: 2.4, 95%CI: 1.8, 3.2), and had a borderline increased risk of hip fracture than men without sarcopenia (HR: 1.7, 95%CI: 0.99, 2.7). For EWGSOP definition components, slowness predicted recurrent falls and hip fractures (Table 2), whereas weakness only predicted falls and low lean mass only predicted hip fracture.In summary, the IWG definition predicted both falls and hip fractures, whereas the EWGSOP definition was only significantly associated with falls. The component of slowness by either definition predicted falls and hip fractures, while low lean mass and weakness were not consistently associated with these outcomes. Further research with other outcomes such as disability and mortality is needed for full evaluation these consensus definitions for sarcopenia.

Table 1. Likelihood of recurrent falls & risk of hip fractures by components of IWG sarcopenia definition

Model predictors	Slowness N=1034 (17.4%)	Low lean N=1239 (20.9%)
	Falls: OR (95% CI)	
Age, slowness	2.4 (2.0, 2.9)	--
Age, low lean	--	1.1 (0.9, 1.3)
Age, slowness & low lean	2.4 (2.0, 2.9)	1.1 (0.9, 1.3)
	Hip Fractures: HR (95% CI)	
Age, slowness	1.7 (1.3, 2.4)	--
Age, low lean	--	1.5 (1.1, 2.0)
Age, slowness & low lean	1.7 (1.3, 2.4)	1.5 (1.1, 2.0)

Table 1

Table 2. Likelihood of recurrent falls & risk of hip fractures by components of EWGSOP sarcopenia definition

Model predictors	Slowness N=262 (4.4%)	Low lean N=1239 (20.9%)	Weakness N=474 (8.0%)
	Falls: OR (95% CI)		
Age, slowness	3.0 (1.9, 4.7)	--	--
Age, low lean	--	1.5 (1.1, 2.0)	--
Age, weakness	--	--	1.4 (0.9, 2.1)
Age, slowness, weakness & low lean	2.8 (1.8, 4.4)	1.4 (1.1, 1.9)	1.2 (0.8, 1.9)
	Hip Fractures: HR (95% CI)		
Age, slowness	3.6 (2.7, 4.7)	--	--
Age, low lean	--	1.1 (0.9, 1.3)	--
Age, weakness	--	--	2.0 (1.6, 2.5)
Age, slowness, weakness & low lean	3.3 (2.5, 4.4)	1.0 (0.8, 1.3)	1.8 (1.4, 2.3)

The relationship between HRpQCT derived muscle parameters and DXA derived lean tissue mass. Marta Erlandson*[1], Eva Szabo[1], Miranda Boggild[2], Nicolas Vilayphiou[3], Robert Josse[4], Angela M. Cheung[5]. [1]University Health Network, Canada, [2]University of Toronto, Canada, [3]INSERM UMR1033, Université de Lyon & Hospices Civils de Lyon, France, [4]St. Michael's Hospital, University of Toronto, Canada, [5]University Health Network-University of Toronto, Canada

Purpose: To determine the relationship between HRpQCT-derived muscle measures obtained at the distal tibia using an experimental algorithm and DXA derived total body and lower limb lean tissue mass.

Methods: A total body DXA scan using Hologic Discovery A densitometer was performed on 67 men and women from the Toronto cohort of the Canadian Multicenter Osteoporosis Study (CaMos). Total body lean tissue mass (TBLM) and lower limb lean tissue mass (LLLM) were obtained from the scans using standard analysis protocols. Standard HRpQCT scans using Scanco Xtreme CT were acquired at the distal tibia. HRpQCT-derived muscle density (MD), muscle volume (MV) and muscle cross-sectional area (MCSA) were then calculated using a newly developed algorithm in which tight thresholding limits for muscle (34.22-194.32mgHA/cm^3) and fat (-238.6 - -84.9mgHA/cm^3) were used to identify muscle seed volumes which were then iteratively expanded. In areas where the muscle and fat volume boundaries met or overlapped after expansion iteration, a short grayscale border was added between the volumes before the next iteration. After the final iteration, any remaining grayscale areas were segmented with a threshold mid-way between the upper fat and lower muscle seeding thresholds (-25.34mgHA/cm^3). Independent sample T-tests were used to examine sex differences and Pearson correlation coefficients were calculated to assess the relationship between DXA and HRpQCT measurements.

Results: Women (n=45, mean age=68.5±9.3) had a mean TBLM (38.0±6.5kg) and LLLM (18.1±3.6kg) that was significantly lower than those of men (n=22, mean age=67.4±8.5) (55.2±7.1kg, 22.7±3.6kg; respectively) (p<0.05). However, there was no difference between men and women in HRpQCT-derived MD, MV and MCSA (13.2±3.3 vs 12.9±2.5mgHA/cm^3, 13223.8±3343.3 vs 13404.9±3497.9mm^3 and 1521.4±384.6 vs 1553.1±418.1mm^2; respectively) (p>0.05). There was no relationship between HRpQCT-derived MD, MV and MSCA and DXA TBLM and LLLM (r=-0.047 to 0.031, p=0.7-0.9).

Conclusion: These preliminarily findings suggest that MD, MV and MCSA obtained from HRpQCT may not be predictive of DXA TBLM and LLLM. There were no sex differences in HRpQCT-derived muscle parameters, perhaps because it was volumetric MD and we expect smaller absolute differences at more distal sites. Moving forward it will be important to measure muscle function and determine if functional measures are related to HRpQCT muscle parameters.

SA0196

Apoptosis Induced by Bilirubin and Lithocholic Acid in Human Osteoblasts Is Decreased by Ursodeoxycholic Acid. Silvia Ruiz-Gaspa*[1], Marta Dubreuil[1], Andres Combalia[2], Pilar Peris[3], Ana Monegal[2], Albert Pares[4], Nuria Guanabens[5]. [1]Centro de Investigación Biomédica en Red en Enfermedades Hepáticas y Digestivas (CIBERehd), Spain, [2]Metabolic Bone Diseases Unit, Department of Rheumatology &, Spain, [3]Hospital Clínic of Barcelona, Spain, [4]Liver Unit, Digestive Diseases Institute, Hospital Clínic, IDIBAPS, University of Barcelona, Spain, [5]Universitat De Barcelona, Spain

Introduction: Low bone turnover osteoporosis is common in patients with chronic cholestasis. Ursodeoxycholic acid (UDCA) counteracts the damaging effects of bilirubin or lithocholic acid (LCA) on osteoblast viability, proliferation and mineralization. Likewise, UDCA is anti-apoptotic in a number of cell lines, but this effect has not been investigated in bone cells. Therefore, the consequences of bilirubin and LCA on apoptosis, and if UDCA has antiapoptotic effects have been assessed on osteoblastic cells. Material and Methods: The experiments were performed in primary human osteoblasts (hOB), human osteosarcoma cell line (Saos-2) and hepatocarcinoma cell line (HepG2). Cells were treated at different times and concentrations of camptothecin as proapoptotic agent, and UDCA, LCA and bilirubin. Apoptosis was determined by DNA fragmentation, flow cytometry (annexin V-FITC labeling), caspase-3 activity, and gene expression of Bcl-2–associated X protein (*BAX*) as antiapoptotic, and *BCL2* and BCL2-like 1 protein (*BCL2L*) as proapoptotic genes, respectively. Results: LCA (10 μM) and bilirubin (50 μM) significantly induced cell apoptosis as indicated by DNA fragmentation (4.7 and 3.7 fold vs control, respectively, $p<0.01$), with parallel results by flow cytometry and caspase-3 activity in Saos-2 and hOB. UDCA (100 μM) alone had no consequences on apoptosis. However, UDCA not only significantly reduced the apoptotic effects of camptothecin (0.5 μM) by 69%, ($p<0.001$), but counteracted the apoptotic effects of LCA and bilirubin as observed by DNA fragmentation (51% and 68%, respectively, $p<0.01$), cytometry and caspase-3 activity in Saos-2 cells. The counteracting effects of UDCA were lower in hOB. UDCA had no effects on *BAX* expression, but upregulated *BCL2L* gene expression (3.5 fold versus control, $p=0.002$). Moreover, UDCA neutralized the effects of LCA and bilirubin on the up-regulated *BAX* by 52% and 68%, respectively ($p<0.01$), and on the down-regulated *BCL2L* gene expression by 550% and 146%, respectively ($p<0.05$). Conclusions: Bilirubin and lithocholic acid induce apoptosis in osteoblastic cells. Ursodeoxycholic acid has clear antiapoptotic effects counteracting the consequences of these two substances increased in cholestasis. These results suggest that ursodeoxycholic acid may have further benefitial effects on neutralizing the decreased bone formation in patients with cholestasis.

A *Gja1* Oculodentodigital Dysplasia Mutant Discloses Complex Functions of Connexin43 (Cx43) in Bone Modeling and Homeostasis. Marcus Watkins*[1], Susan Grimston[1], Jin Yi Norris[2], Roberto Civitelli[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University in Saint Louis, USA

Oculodentodigital dysplasia (ODDD) is an autosomal dominant disorder linked to mutations of the Cx43 gene (*Gja1*), characterized by craniofacial and dental defects, type III syndactyly, and eye abnormalities. We have previously reported that mice in which one allele of *Gja1* is replaced by the $Gja1^{G138R}$ mutant in osteo-chondroprogenitors, using the *Dermo1 (DM1)-Cre* (DM1;cOD), have a larger cortical total tissue ($54\pm6\%$) and marrow area ($30\pm6\%$) while cortical thickness and cortical BMD is significantly decreased ($-20\pm7\%$ and $-4\pm2\%$), respectively, compared to wild type (WT) littermates. These features, linked to increased osteoclastogenic support by mutant osteoblastic cells, phenocopy mice with conditional deletion of *Gja1*, confirming that the $Gja1^{G138R}$ mutant is dominant negative for Cx43. To further determine the biologic effect of the mutant connexin, we generated mice in which gene replacement occurs later in osteoblast differentiation using the *Osterix/SP7-Cre* (Sp7;cOD), and also introduced the $Gja1^{G138R}$ allele in a *Gja1* null background ($Sp7;Gja1^{G138R/-}$). Sp7;cOD mice exhibit a similar but less pronounced phenotype relative to DM1;cOD mice, with increased total tissue ($13\pm6\%$) and marrow area ($36\pm12\%$), and decreased cortical thickness ($-23\pm12\%$) compared to WT. Cortical BMD is not altered. This phenotype is more severe in $Sp7;Gja1^{G138R/-}$ littermates, with tissue and marrow area being larger than WT littermates ($47\pm12\%$ and $108\pm20\%$, respectively). In $Sp7;Gja1^{G138R/-}$, cortical thickness and mineral density are also decreased relative to WT ($-24\pm6\%$ and $-16\pm4\%$, respectively); and endocortical osteoclast number is increased, similar to DM1;cOD mice. However, unlike other models of *Gja1* deletion/mutation, compared to WT littermates, $Sp7;Gja1^{G138R/-}$ mice have significantly reduced trabecular bone volume/tissue volume ($-49\pm16\%$), decreased trabecular number ($-31\pm9\%$) and increased trabecular separation ($39\pm18\%$), as assessed by in vivo μCT. Thus, disruption of Cx43 function by the $Gja1^{G138R}$ mutant in differentiated osteoblasts and osteocytes is sufficient to cause cortical modeling defects. Since the ODDD mutant disrupts gap junction function but not cell permeability to ATP or other large molecules, these results do not support a role of Cx43 hemichannels in cortical modeling. Finally, the more severe phenotype of $Sp7;Gja1^{G138R/-}$ mice suggests the $Gja1^{G138R}$ mutant may interfere with other connexins or with other, non-gap junction related functions of Cx43.

ATF4 Regulates Bone Angiogenesis by Promoting VEGF Expression And Release in the Bone Environment. Ke Zhu*[1], Hongli Jiao[2], Shuai Li[1], Huiling Cao[3], Deborah Galson[3], Zhongfang Zhao[1], Xi Zhao[1], Yumei Lai[2], Jie Fan[4], Hee-Jeong Im[5], Di Chen[6], Guozhi Xiao[6]. [1]College of Life Sciences, Nankai University, China, [2]Department of Biochemistry, Rush University Medical Center, USA, [3]University of Pittsburgh School of Medicine, USA, [4]Department of Surgery, University of Pittsburgh, USA, [5]Department of Biochemistry, Rush University Medical Center, Chicago, Illinois 60612, USA, USA, [6]Rush University Medical Center, USA

Transcription activation factor 4 (ATF4) is critical for bone remodeling during skeletal development and throughout life; however, its role in bone angiogenesis is unclear. We performed contrast-enhanced μCT imaging in Microfil-perfused femurs and showed that ATF4 deficiency strikingly reduced vessel volume and vessel number in femurs. Results from immunohistochemical staining of tibial sections using a specific antibody against CD31 revealed that both the size and density of vessels within the metaphyseal periosteum and diaphyseal endosteum from $Atf4^{-/-}$ tibiae were dramatically decreased compared to those of WT tibiae. In vitro angiogenesis assay showed that ablation of ATF4 prevented endothelial sprouting from metatarsals, which was rescued by treatment with a recombinant VEGF. Adenoviral overexpression of ATF4 increased HIF-1α and VEGF expression levels in osteoblasts in a hypoxia-dependent manner. Mechanistically, loss of ATF4 increased HIF-1α ubiquitination and decreased HIF-1α protein stability without affecting its mRNA stability and protein translation. In addition, loss of ATF4 increased the binding of HIF-1α to prolyl hydroxylases, the enzymes that hydroxylate HIF-1α protein and promote its proteasomal degradation via the pVHL pathway. Interestingly, parathyroid hormone-related protein and receptor activator of NF-κB ligand, both well-known activators of osteoclasts, increased release of VEGF from the bone matrix and promoted angiogenesis through the protein kinase C- and ATF4-dependent activation of osteoclast differentiation and bone resorption. Finally, our in vivo studies revealed that hypoxia/reoxygenation induction of HIF-1α and VEGF expression leading to bone angiogenesis, a key adaptive response to hypoxic conditions, was severely compromised in mice lacking the *Atf4* gene. Taken together, our studies demonstrate that ATF4 is a new key regulator of the HIF/VEGF axis in osteoblasts in response to hypoxia and of VEGF release from bone matrix, two critical steps for bone angiogenesis.

c-Abl broadcasts BMP-2 function to Osterix and CSF-1 for concerted osteogenesis via PI 3 kinase/Akt. Nandini Ghosh-Choudhury*. University of Texas Health Science Center at San Antonio, USA

Receptor and non-receptor tyrosine kinases play important roles in osteoblast differentiation. c-Abl is a non-receptor tyrosine kinase, inhibition of which in experimental rat model and in human chronic myeloid leukemia patients, resulted in compromised bone remodeling due to impaired osteoblast and osteoclast activities. We have shown that BMP-2 plays a significant role in bone formation and resorption by contributing to the formation of mature osteoblasts and osteoclasts. Identification of the role of c-Abl in BMP-2-induced bone remodeling and characterization of the underlying mechanisms are the focus of this study. We used a pharmacological inhibitor (Imatinib mesylate) and a dominant negative mutant of c-Abl to block its activity in osteoblast cells. Inactivation of c-Abl significantly blocked BMP-2-induced osteoblast differentiation as evidenced by inhibition of alkaline phosphatase activity and formation of mineralized bone nodules. Formation of multinucleated osteoclasts in response to BMP-2 was severely impaired in the absence of c-Abl activation. Using primary calvarial osteoblasts prepared from c-Abl null mouse we show an absolute requirement of this tyrosine kinase in maturation of osteoblasts and osteoclasts. We have reported an essential requirement of PI 3 kinase/Akt signaling in BMP-2-induced osteoblast and osteoclast differentiation. Remarkably, inhibition of c-Abl significantly suppressed BMP-2-stimulated PI 3 kinase activity and its downstream Akt phosphorylation. We have shown that BMP-2 regulates CSF-1 expression and thus activates osteoclast differentiation. We find that c-Abl activation is critical for BMP-2-induced osteoclastogenic CSF-1 expression. Importantly, we identified requirement of c-Abl in BMP-2 gene autoregulation and osterix expression necessary for osteoblast differentiation. Smad-dependent transcription of CSF-1, osterix and BMP-2 essentially was found to require c-Abl activation. Finally, we show that c-Abl regulated Smad phosphorylation in response to BMP-2. We propose that activation of c-Abl is an important step in integrating the noncanonical PI 3 kinase and the canonical Smad signaling pathway to control BMP-2-induced osteogenesis.

Diabetes Inhibits Bone Formation via Regulation of Histone Acetylation by HDAC2. Qianqian Han*, Liming Yu, Dong Ying Xuan, Lan Zhang, Qisheng Tu, Jake Jinkun Chen. Tufts University School of Dental Medicine, USA

Diabetes is closely related with bone disorders, and histone deacetylase, HDAC, was recently found to be involved in the renal damages caused by diabetes. Other studies demonstrated that the activity of HDAC is altered during osteogenic differentiation. HDAC2 is one of class I HDACs and has been proven to play an important role in diabetes. In this study, we hypothesized that diabetes inhibits bone regeneration via increasing the HDAC2 expression, which converts bone markers chromatin into a transcriptionally inactive conformation.

Bone marrows of wild-type mice and pre-diabetic mice were collected and RNAs were extracted. Real time PCR was used to detect the HDAC and bone marker mRNA expressions. Our results showed that HDAC2 expression was much higher while the bone marker expressions Col I, ALP, OCN, Runx2, and Satb2 were lower in bone marrow diabetic mice than in wild-type mice. These results indicated that HDAC2 might play an important role in bone disorders caused by diabetes.

MC3T3 cells, a mouse pre-osteoblast cell line and primary cultures of mouse bone marrow stem cells were cultured in a-MEM with 10% FBS, 0.1mg/ml streptomycin, and 100U/ml penicillin. After confluence, cells were treated with D-glucose at the concentrations of 5, 10, 15, or 25 mM, respectively and cells treated with 25mM mannitol were used as the negative control. After 7 days of treatment, RNAs were extracted and real time PCR was performed to detect the expression of HDAC2 and bone markers including OCN, COL I, Runx2, and OSX.When BMSCs and MC3T3-E1 cells were treated with D-glucose at the concentrations of 15 mM or 25mM for 7 days, the mRNA expression of HDAC2 was up-regulated and the expression of bone markers was down-regulated. Taken together, our results suggest, for the first time, that diabetes inhibits osteogenic differentiation via regulating the bone marker expression pattern by modulating histone acetylation states.

Hypoxia-Inducible Factor-1α-Induced Bone Anabolism Requires Heightened Glycolysis. Jenna Regan*[1], Kyu Sang Joeng[2], Emel Esen[1], Fanxin Long[3]. [1]Washington University St. Louis, USA, [2]Baylor College of Medicine, USA, [3]Washington University School of Medicine, USA

The cancellous bone surface in contact with the bone marrow is considered among the most hypoxic regions in the bone marrow. In response to low oxygen levels, the hypoxia-inducible factor alpha (HIFα) proteins are stabilized and upregulate genes involved in a wide variety of processes, including cell metabolism and angiogenesis. We have confirmed that osteoblasts experience low-oxygen (<10 mm Hg) conditions *in vivo*. Thus the purpose of this study was to investigate how events downstream of HIF stabilization impact osteoblast-lineage cells in a cell-autonomous manner. When a stabilized form of HIF1α (HIF1-PPN) is expressed in SP7-positive cells in postnatal mice, bone volume increases nearly 6-fold within 15 days. The increased bone is a direct effect of significantly increased osteoblast numbers. In this model, the bone volume is not dependent upon an increase in cancellous vascularity, as normalization of the vascular density (through concomitant deletion of VEGF) did not impact the bone accrual. Another well-recognized set of HIF1α target genes encode components of the glycolytic metabolism pathway. Direct HIF1α targets such as PDK1 and LDHA are upregulated in SP7;HIF1-PPN bones, indicating that HIF1α stabilization is inducing a shift to glycolytic metabolism in the SP7-positive cells. To test whether glycolysis plays an important role in the increased bone mass in SP7;HIF1-PPN mice, we treated the mice with dichloroacetate (DCA) to block PDK1 activity. Strikingly, administration of DCA during the 15-day period of HIF1α stabilization completely blocked the increase in bone mass and normalized osteoblast numbers. Our results indicate that HIF1α stabilization in osteoblast-lineage cells rapidly and significantly increases osteoblast numbers and bone volume and that a shift to glycolytic metabolism is required for these effects.

Isolation and Characterization of Human Osteoblasts From Needle Biopsies Without *In Vitro* Culture. Koji Fujita*[1], Matthew Roforth[1], James Peterson[1], Salman Kirmani[1], Matthew Drake[2], Louise McCready[1], David Monroe[3], Sundeep Khosla[4]. [1]Mayo Clinic, USA, [2]College of Medicine, Mayo Clinic, USA, [3]Mayo Foundation, USA, [4]Mayo Clinic College of Medicine, USA

There is currently no data regarding the expression of specific genes or pathways in purified human osteoblasts that have not been subjected to extensive *in vitro* culture. Since the latter is likely to alter the RNA expression profile of these cells, we have developed methods to obtain progressively enriched human osteoblast populations within 2-4 hr of obtaining a small needle biopsy (1-2 mm x 1 cm) and coupled this to high-throughput RNA sequencing (RNAseq) and focused QPCR analyses.

Needle biopsies were obtained from the posterior iliac crest of 8 human male subjects and subjected to serial collagenase digests. Because the 1st 30 minute digest (~100 million cells) contained surface hematopoietic and loosely adherent cells, we used the 2nd 60 minute digest (~10 million cells), which contained mineralizing cells and was highly enriched for osteoblast marker genes (*col1α1*, 5-fold; osteocalcin [*ocn*], 8-fold; *bsp*, 11-fold; osteopontin [*opn*], 10-fold). The 2nd fraction was then stained with an AP antibody and the AP+ cells (~1 million cells) were rapidly isolated (within ~2 hr from biopsy) using magnetic activated cell sorting. Relative to AP- cells, the AP+ cells contained all of the mineralizing cells and were further enriched for osteoblast marker genes (*AP*, 10-fold; *col1α1*, 1000-fold; *ocn*, 300-fold; *bsp*, 300-fold; *opn*, 50-fold). We then further purified the AP+ cells by depletion of cells expressing CD45, CD34, or CD31 by FACS to obtain AP+/CD45/34/31- (AP+/—) cells (within ~4 hr from biopsy), which represented a highly enriched human osteoblast preparation devoid of hematopoietic/endothelial cells. In addition to *in vitro* mineralization, AP+/— cells expressed very low to undetectable levels of osteocyte marker genes, including *E11, dmp-1, phex, fgf23,* and *sost.*

Finally, we used high-throughput RNAseq analysis to compare the transcriptome of the AP+/— cells (n = 6) to human fibroblasts (n = 3). By Ingenuity Pathway Analysis, we identified a set of unique pathways reflecting genes expressed only in human osteoblasts (AP+/— cells) *in vivo* but not in fibroblasts, including (all $P < 0.05$) Osteoblast Related, VDR/RXR Activation, LXR/RXR Activation, NF-kB Signaling, CXCR4 Signaling, and GPCR Signaling.

In summary, we describe a novel approach to isolate and interrogate highly enriched human osteoblast populations without *in vitro* culture which should be broadly applicable to studying the pathogenesis of osteoporosis and other metabolic bone diseases.

Microvesicles released from stromal/osteoblast facilitate ostoclast formation via RANK/RANKLOPG pathway. Lili Deng*[1], Ying Peng[1], Yu Wu[1], Yuedi Ding[1], Meilin Yang[1], Qiang Fu[2]. [1]Jiangsu Institute of Nuclear Medicine, China, [2]Institute of Nuclear Medicine, Peoples Republic of China

Microvesicles, including shedding microvesicles (100-1000nm) and exosomes (50-100nm), are membrane-bound vesicular particles that are released into the extracellular environment by almost all cell types. Microvesicles contain receptor proteins, proteolytic enzymes, miRNAs, and mRNAs, which are transferred into the target cell, in turn affect cell functions. Previous research had shown that osteocytes shed microvesicles containing bone regulatory proteins and this may represent a novel mechanism for cell-cell communication in bone. However, the detail mechanisms of microvesicles regulation in bone are not well defined. Here we demonstrated that UAMS32, the stormal/osteoblastic cell line, release microvesicles into the culture medium. Western blotting displayed that the cells with PTH treatment increase the level of RANKL, the essential cytokine for osteoclast formation, in microvesicles and decrease the level of OPG. Immune electron microscopic study revealed that the RANKL protein is located in the surface of microvesicles released from UAMS32 cells. To test the function of RANKL protein which existed in microvesicles, the microvesicles, which were collected from UAMS32 cells after treated with/without PTH for 12hrs, were co-cultured with Raw264.7 cells, the macrophage cell line that can differentiate to osteoclast after RANKL stimulation. TRAP staining has shown that osteoblast-derived microvesicles from PTH treated cells stimulate osteoclast formation, and this effect of microvesicles can be blocked by adding RANKL antibody or OPG to the culture medium. Our data demonstrated that microvesicles released from stromal/osteoblast regulate bone remodeling via RANK/RANKL/OPG pathway.

New therapeutic approach for the induction of bone formation by muramyl dipeptide. Ok-Jin Park*[1], Cheol-Heui Yun[2], Seung Hyun Han[1]. [1]School of Dentistry, Seoul National University, South Korea, [2]Department of Agricultural Biotechnology & Research Institute for Agriculture & Life Sciences, Seoul National University, South Korea

Microbiota and its molecular patterns are engaged in the regulation of immune responses and bone metabolism. Muramyl dipeptide (MDP) is the shared structural unit of peptidoglycans from both Gram-positive and Gram-negative bacteria. In the present study, we investigated the effect of MDP on the bone metabolism. When mouse osteoblast cell-line MC4 and primary osteoblasts derived from mouse calvaria were stimulated with MDP, there was a substantial increase in alkaline phosphatase (ALP) and alizaline red S staining. Moreover, MDP augmented the expression of bone sialoprotein and osteocalcin. Confocal microscopy and transient transfection followed by reporter gene assay demonstrated that MDP enhanced the nuclear translocation of Runx2 and its transcriptional activity, respectively, in MC4 cells. In addition, MDP increased the expression of nucleotide oligomerization domain 2 (NOD2), which is a MDP receptor. However, osteoblast differentiation and activation induced by MDP were not observed in the osteoblasts derived from NOD2-deficient mouse calvaria. MDP increased phosphorylation of MAP kinases (MAPK) and transcriptional activity of Runx2 and ALP staining were attenuated by inhibitors blocking MAPK. Mice intraperitoneally administrated with MDP showed an increase in the trabecular bone volume. Remarkably, not only pretreatment but also post-treatment in mice with MDP alleviated the bone loss induced by RANKL. Conclusively, these results suggest that MDP could increase the bone formation by enhancing osteoblast differentiation and activation through NOD2/MAPK/Runx2 signaling pathway and it could be potentially a new therapeutic against osteoporosis.

Osteoblast GH actions promote bone mass and strength through mechanisms that are independent of local IGF-I production: Lessons from the SOCS2 knockout mouse. Ross Dobie*[1], Vicky MacRae[2], Carmen Huesa[2], Rob van't Hof[2], S. Faisal Ahmed[3], Colin Farquharson[4]. [1]Edinburgh University, United Kingdom, [2]University of Edinburgh, United Kingdom, [3]Royal Hospital for Sick Children, United Kingdom, [4]Roslin Institute, University of Edinburgh, United Kingdom

Suppressor of cytokine signalling (SOCS) -2 is an important regulator of the anabolic actions of growth hormone (GH) on bone. The SOCS2 knockout (KO) mouse has increased bone mass despite normal systemic insulin like growth factor -1 (IGF-1) and GH levels. In this study we have exploited this mouse model to unravel the anabolic mechanisms of GH on the skeleton.

In keeping with the known anabolic effects of GH, micro-CT analysis of juvenile (6 wks) and adult (17wks), male and female SOCS2 KO mice highlighted increased trabecular thickness and BV/TV compared to age and sex matched wild-type (WT) controls ($p<0.05$). Analysis of the tibial cortex revealed a sex specific difference with only male SOCS2 KO mice having increased cortical thickness (6wks, WT $246 \pm 7.96\mu m$, KO $281 \pm 11.1\mu m$; $p<0.05$; 17wks, WT $270 \pm 3.37\mu m$, KO $282 \pm 2.79\mu m$; $p<0.05$). Increased cortical parameters resulted in increased breaking strength ($p<0.05$) as determined by 3-point bending. Transcript analysis of liver samples revealed no alteration in *Igf1* levels in SOCS2 KO mice although a modest 2.21-fold increase in *Igfbp3* levels in 6wk male SOCS2 KO mice was noted ($p<0.05$). The increased bone mass of SOCS2 KO mice was not associated with increased *Igf1* or *Igfbp3* transcript levels in bone supporting a local, IGF-1 independent, mechanism for bone growth. *In vitro* mechanistic studies revealed that in WT osteoblasts, GH induced a 7.09-fold increase in *Socs2* expression levels ($p<0.001$) (but not *Socs1* or *Socs3*). This was verified at the protein level. GH also promoted enhanced STATs 1, 3 and 5 phosphorylation in SOCS2 KO calvarial osteoblasts in comparison to WT cells. This was confirmed by immunocytochemistry which revealed increased STAT5 activation within the nucleus of cultured osteoblasts. Conversely, overexpression of SOCS2 in MC3T3 osteoblast-like cells resulted in decreased STAT 5 activation following GH challenge. Furthermore, no regulatory role for SOCS2 in GH induced Akt or ERK1/2 signalling was found. As expected, GH mediated increased STAT signalling in SOCS2 KO cells resulted in elevated *Igf1* mRNA expression (1.60 fold; $P<0.05$), however the magnitude of increase was similar to that noted in WT cells (1.43 fold; $p<0.05$).

These data corroborate our in vivo observations and emphasise the critical role for SOCS2 in controlling GH anabolic bone effects. They also confirm the functional contribution to bone mass of osteoblast GH actions that are independent of local IGF-I production.

Osteoblastic and T Cell-derived RANKL in Bone Remodeling and Modeling. Toshio Fumoto[1], Sunao Takeshita[1], Masako Ito[2], Kyoji Ikeda*[1]. [1]National Center for Geriatrics & Gerontology, Japan, [2]Nagasaki University Hospital, Japan

RANKL is a pleiotropic cytokine and is essential for osteoclast development in bone; however, the key cellular source(s) of RANKL that generates osteoclasts under various pathophysiologic conditions remains elusive. In the present study we show that inactivation of the RANKL gene in osteoblast lineage cells (ΔOb) using osterix-cre results in typical osteopetrosis in the trabecular compartment of tibia, while the phenotype is progressively less marked in femur and vertebra in this order. In contrast to the trabecular bone, the femoral cortex of ΔOb mice was thin with suppressed bone formation in modeling process. Deletion of RANKL form T cells (ΔT) using CD4-cre resulted in a modest but significant increase in tibial trabecular bone. ΔOb, but not ΔT, mice were protected from bone loss caused by ovariectomy and partially from joint destruction associated with serum-induced arthritis. Finally, inducible deletion of RANKL preferentially in osteoblasts, with doxycycline discontinuation for 6 weeks starting at 6 weeks of age, resulted in an increased bone mass with reduced bone resorption and formation, suggesting that in addition to osteocyte-derived RANKL, RANKL produced by osteoblasts also contributes to osteoclast development in vivo.

Osteogenic Differentation and Mineralization of Adult Mesenchymal Stem Cells Isolated from Human Periodontal Ligament. Cecilia Romagnoli*[1], Niccolò Nuti[1], Roberto Zonefrati[1], Francesco Saverio Martelli[2], Marialaura Martelli[2], Elena Fanti[2], Marco Duvina[1], Paolo Tonelli[1], Luisella Cianferotti[3], Annalisa Tanini[1], Maria Luisa Brandi[1]. [1]University of Florence, Italy, [2]I.R.F. in Microdentistry, Italy, [3]University of Florence, Florence, Italy, Italy

Periodontal ligament (PDL) is a dynamic connective tissue embedded between the cementum and the alveolar bone. The role of PDL is to anchor and support the tooth root within the jaw, cushioning mechanical load that precede from mastication. Periodontal diseases are the major cause of tooth loss in adults leading to the destruction of periodontal tissues, including PDL, cementum and bone. Since mesenchymal stem cells have been isolated from PDL, this might be an ideal cell source for repairing bone defects and they are supposed to have a greatpotential in regenerative dentistry.

The aim of the present study was to isolate mesenchymal stem cells from PDL (PDLSCs) and to evaluate their osteogenic potential analyzing the expression of markers of osteoblast differentiation such as alkaline phosphatase (ALP) activity and the mineralization process.

Two primary culture of PDLSCs, LP8 and LP9, obtained from the extracted healthy third molar of patients of eighteen and twenty years old, respectively, were induced into the adipocyte lineage phenotype using the adipogenic medium (AM) composed by Ham's F12 Coon's modification medium supplemented with 10% FBS, 1 μM dexamethasone, 1 μM bovine insulin, 0.5 mM isobutylmethylxanthine and 1% antibiotics. The osteoblastic phenotype was induced using the osteogenic medium (OM) composed by Ham's F12 Coon's modification medium supplemented with 10% FBS, 10nM dexamethasone, 10mM β-glycerophosphate, 50 μg/ml L-ascorbic acid 2-phosphate and 1% antibiotics. Adipogenic and osteogenic phenotypes were assessed from 4 to 21 days in culture by appropriate cytochemical staining (Oil Red O and Fast Blue BB/naphthol AS-MX) and microscopic observations. The ALP activity and hydroxyapatite production were quantified by fluorometric assay.

Under adipogenic differentiation, accumulations of intracellular lipid-filled droplets after 21 days were observed in more than 5% of cells. Under osteogenic induction, significant increments (+86%) of ALP activity at 7 days vs not inducted control ($p<0.005$) were observed, and then ALP decreases, while mineralization increases at 14 and 21 days (+74% and +814% respectively), as demonstrated by a great deposition of hydroxyapatite vs not inducted control ($p<0.005$).

Our preliminary data suggest that PDL represents an optimal source of stem cells that can be used for bone tissue regeneration in dentistry. Studies are in progress to evaluate the effect of bioactive factors that could facilitate the process.

Repair of Nonunion with Percutaneous Autogenous Iliac Crest Bone Marrow Aspirate; Demineralised Bone Matrix and Bone Morphogenic Protein. Pingal Desai*, Joseph Lane, Parth Vyas. Hospital for special surgery, USA

Background: Bone is the second most common transplanted tissue after blood.[1] Bone marrow aspirated from iliac crest after concentration is more useful for healing of nonunion and concentrated cells increase the callus formation and reduce time to healing of nonunion.[2,3]Bone marrow aspirate contains osteoprogenitor cells which under the influence of bone inducing growth factors can differentiate into

osteoblasts.[4,5] The study evaluated the addition of bone marrow concentrate with BMP vs. demineralized bone matrix in nonunions and atypical femoral fractures.

Materials and methods: We did prospective age and sex matched study of concentrated autologous iliac crest bone marrow stem cells with DBM or BMPin nonunion and AFF pts. Gap in the fracture was measured with pre-operative radiograph. We hypothesized that Modified Hernigou technique is useful for the healing of fracture, useful in bones other than tibia, effective when the gap in fracture is more than 5 mm and useful in atypical fractures, and that DBM and BMP are comparable.

Results: We had total 49 patients enrolled in our study. All the patients were available for final follow up. The overall healing of fracture in our group was 79.6%. Average healing time in our study was 5.4 months.Rate of healing for fracture nonunion for femur was 73.6%, tibia was 86.9% and humerus was 71.4%. (p=0.481). The healing rate was 93% when intervention was done within 6 months while healing rate was 57.9% when intervention was done after 6 months. (p=0.008). The rate of healing in atypical fracture was 63.6% while in other fracture was 84.2% (p=0.201). The rate of healing was 80.7% when gap was less than 5 mm and 78.3% when gap was more than 5mm. (p=0.828).There was also no statistically significant difference in the rate of healing related to open fracture, communition of fracture, fixation procedure used and use of adjuvants.

Conclusion: Our modified Hernigou technique is minimally invasive procedure for treatment of fracture nonunion regardless of gap size or bone involved. The rate of healing is higher when this technique is performed within 6 months of injury. DBM is equally effective as BMP when used with concentrated autogenous iliac crest stem cells. The union rate was same for atypical fracture compared to other fractures.

TRAPPC9 modulates osteoblast proliferation and differentiation through NIK – IKK signaling. Thomas Mbimba*[1], Kabrina Monton[2], Kevin Crowford[3], Roshanak Razmpour[3], Samir Abdelmagid[4], Safadi Fayez[5]. [1]Kent State University, USA, [2]Central State University, USA, [3]Temple University, USA, [4]Northeast Ohio Medical University, USA, [5]NEOMED, Temple University, USA

Intellectual disability (ID) is a serious disorder of the central nervous system with a prevalence of 1-3% in the general population. Recent studies identified different nonsense mutations in the trafficking protein particle complex (TRAPPC9) gene in consanguineous and non-consanguineous families of ID patients. Patients with ID also present skeletal abnormalities such as short stature, misaligned limbs and loose teeth. TRAPPC9 is one of the largest subunits of the transport protein particle II (TTRAPPII), an important membrane tethering complex for coated vesicles during intra-Golgi and early endosome to late Golgi traffic. TRAPPC9 also binds and regulates NIK and IKK signaling upstream of NF-κB, thus regulating both the canonical and non-canonical NF-κB pathways. Recent studies have identified NFkB as a major negative regulator of osteoblast proliferation and differentiation. We first examined the expression and localization of TRAPPC9 in bone. qPCR, Western blot and immunohistochemical analyses showed that TRAPPC9 is expressed in bone and the expression levels increase during osteoblast differentiation and matrix mineralization. Co-immunoprecipitation studies confirmed binding of TRAPPC9 to both NIK and IKKβ in osteoblasts. To study the role of TRAPPC9 in osteoblast differentiation and function, we performed a loss-of-function experiment using TRAPPC9 specific shRNA in MC3T3-E1 osteoblast-like cell line. TRAPPC9 shRNA-transfected cells showed decreased NIK, IKKβ and NF-κB activation, while osteoblast proliferation was increased compared to controls. Osteoblast differentiation, determined by alkaline phosphatase (ALP) staining and activity, as well as matrix mineralization, determined by Von Kossa staining revealed increased osteoblast differentiation and function in TRAPPC9 shRNA-transfected cells. qPCR analysis showed increased expression of osteoblast differentiation markers (ALP, Runx2, collagen type I, and osteocalcin) in TRAPPC9 shRNA-transfected cells. Taken together, these data suggest that TRAPPC9 is a major regulator of osteoblast proliferation, differentiation and function. These data might explain, at least in part, the increased bone mass in patients with TRAPPC9 mutations. In addition, regulation of TRAPPC9 may help to promote bone formation for the treatment of osteoporosis and other metabolic bone diseases.

Aminobisphosphonates promote osteoblastic differentiation and function in association with upregulation of Cx43 in vitro. Dong Jin Chung*, Jin Ook Chung, Dong Hyeok Cho, Min Young Chung. Chonnam National University Medical School, South Korea

Aminobisphosphonates are potent antiresorptive drugs which have antifracture efficacy by reducing bone turnover rate and increasing bone mineral density. In addition to inhibiting osteoclast function, bisphosphonates have been reported to also promote survival of osteocyte and osteoblast via an anti-apoptotic effect, mediated by opening of hemi-gap junction channels formed by connexin43 (Cx43). In this study, we investigated the effect of various aminobisphosphonates such as risedronate,

alendronate, ibandronate, and zoledronate on osteoblast differentiation and Cx43 expression using the cell line C2C12. All the aminobisphosphonates increased the activity of OSE, OC and BSP-luciferase in a dose-dependent manner. They also increased ALP activity dose-dependently, and further induced enhanced alkaline phosphatase (ALP) staining in the presence of BMP-2 (5 ng/mL), indicating positive action on osteoblast differentiation. Connexin 43 promoter activity was upregulated by co-transfection of increasing concentrations of a Runx2-expressing construct. A similar effect was obtained with an Osterix and Dlx5 constructs. All the aminobisphosphonates also increased Cx43 promoter activity. As the concentration of aminobisphosphonates was increased, Cx43-promoter activity was increased by 2.5~3 fold. Furthermore, the combination of Runx2 (0.5 μg) and each aminobisphosphonate up-regulated Cx43 promoter activity to a far larger extent than did either Runx2 or each aminobisphosphonate alone, suggesting an interaction between the aminobisphosphonate and Runx2 in activating the Cx43 promoter. A similar interaction was observed between Dlx5 (0.5 μg) and each aminobisphosphonate. Western blot analysis confirmed that each aminobisphosphonate increased protein expression of Cx43, Runx2, Osterix, and Dlx5. The effective concentrations and peak responses were somewhat different among aminobisphosphonates. These results suggest that aminobisphosphonates promote osteoblastic differentiation and positively regulates Cx43 gene transcription.

Epigenetic Plasticity of MSC Trans-Differentiation and Selective Distal Enhancers for Mmp13. Mark Meyer*[1], Nancy Benkusky[1], Amber Mael[1], Janet Rubin[2], J. Pike[1]. [1]University of Wisconsin-Madison, USA, [2]University of North Carolina, Chapel Hill, School of Medicine, USA

Marrow derived multipotential mesenchymal stem cells (mdMSC) have the ability to become different cell types given the appropriate chemical stimulus *in vitro*. However, trans-differentiation of the osteoblast to the adipocyte can occur even 7 days post differentiation, after substantial matrix deposition. Conversely, differentiated adipocytes (7 days) will trans-differentiate to mineralize matrix and express osteogenic genes/proteins in osteogenic media. In our studies, we demonstrate plasticity in the epigenetics of the mdMSC through ChIP-seq investigation of chromatin modifying marks H3K4me1, H3K4me2, H3K4me3, H3K9Ac, H4K5Ac, H3K36me3 and H4K20me1. Dynamic and local chromatin modifications allow trans-differentiation to occur in these cells without permanent global changes. We found the epigenetic marks are accurate in predicting gene expression by RNA-seq and identifying unique enhancers for transcription factors important to differentiation such as C/EBPβ, C/EBPα, PPARγ, RUNX2, SP7, CREB, RXR and VDR. We identified adipogenic specific enhancers unique for C/EBPα and C/EBPβ near the mouse *Pparγ* gene at +64 and +150kb. More interestingly, we found unique osteogenic enhancers within the genomic loci of many osteogenic genes, such as the mouse *Mmp13* gene. Matrix Metalloproteinase 13 (*Mmp13*, collagenase-3) has an essential role in the developing osteoblast that leads to improved bone quality and bone fracture resistance. It is known to be stimulated by compounds such as BMP-2, PTH and $1\alpha,25(OH)_2D_3$ and through transcription factors RUNX2, C/EBPβ, OSX, VDR and others. Through unbiased ChIP-seq methodology, we have discovered that there is transcriptional regulation in regions more distal to the *Mmp13* promoter. There is RUNX2 and C/EBPβ binding at -30kb upstream, C/EBPβ binding only at -20kb upstream and finally a VDR bound region at -10kb. These regions were accompanied by strong histone marks clearly denoting the enhancers. A pair of VDREs (approx. 450bp apart) that controls *Mmp13* gene expression by $1\alpha,25(OH)_2D_3$ is located at -10kb as assayed by traditional mutagenesis, large BAC luciferase reporters and even direct genome-editing using CRISPR, focused on the enhancers. Through these studies we learn that the epigenetic plasticity of mdMSC cells allows their differentiation and trans-differentiation from osteogenic and adipogenic lineages, and helps facilitate induction of many genes, including *Mmp13* stimulated by $1\alpha,25(OH)_2D_3$ from unique distal enhancers.

Global Epigenetic Changes in Histone Post-translational Modifications Establish the Osteoblast Lineage. Jonathan Gordon*[1], Hai Wu[2], Troy Whitfield[3], Phillip Tai[4], Andre Van Wijnen[5], Janet Stein[1], Gary Stein[6], Jane Lian[2]. [1]University of Vermont, Department of Biochemistry, USA, [2]University of Vermont, USA, [3]University of Massachusetts Medical School, Department of Cellular & Developmental Biology, USA, [4]University of VermontCollege of MedicineDepartment of Biochemistry, USA, [5]Mayo Clinic, USA, [6]University of VermontCollege of Medicine, USA

Bone marrow stromal cells (BMSCs) undergo stochastic epigenetic changes initiating commitment to the osteoblast phenotype that define lineage-specific gene expression. To determine which histone modifications are indicative of osteoblast differentiation and gene expression, we generated high quality, multi-replicate data sets for histone methylations and acetylations that are markers for epigenetic regulation. These markers include H3K4me1, H3K4me3, H3K9me3, H3K9acetyl, H3K27me3, H3K27acetyl and H3K36me3). Using supervised pattern discovery models, these histone marks were segmented across the mouse genome in order to discover genomic segments associated with known and novel regulatory regions. These data sets were merged with gene expression profiles at defined stages of BMSC differentiation. These analyses have identified on a genome-wide basis have identified novel features of epigenetic regulation of differentially expressed genes. For example, we have discovered that the osteoblast-related osteocalcin (bglap2) gene locus (chr3:88181512-88182731) is not significantly associated with H3K4me3 signal, a marker generally linked to genes poised for expression. However, the bglap2 gene locus is initially enriched with H3K4me1 upon commitment and progressively accumulates H3K9acetyl and H3K27acetyl signals. This finding indicates that osteocalcin is 1) poised for expression by H3K4me1 and 2) strongly regulated by acetylation of histones within the gene body when the gene is actively expressed. These data provide a global map of epigenetic changes in genes that are classified into functional pathways during lineage commitment. The epigenetic signature generated by this study for normal events of the BMSC can be used as a platform to determine modifications in histone marks contributing to skeletal disorders.

Lactoferrin activates Osx gene expression through the mitogen-activated protein kinase p38 pathway in osteoblasts. Chi Zhang*[1], Yang Li[2], Harry Kim[3]. [1]Bone Research Laboratory, Texas Scottish Rite Hospital, USA, [2]Texas Scottish Rite Hospital for Children, USA, [3]Scottish Rite Hospital for Children, USA

Lactoferrin (LF) is an iron-binding glycoprotein that belongs to the transferrin family of proteins. While diverse physiological functions have been proposed for LF, including the regulation of intestinal iron uptake, antimicrobial activity, regulation of cell growth and differentiation, anti-inflammatory activity, the precise mechanism of action of LF in many of these processes remains poorly known. LF found in human and bovine milk may have a place in osteopenia or osteoporosis remedies because it has been found to be effective in promoting bone growth. A study by Blais et al. showed that a dietary LF supplementation for 27 weeks to ovariectomized mice improved their bone mineral density. However, molecular mechanisms of LF activity on bone formation are not well understood. In this study, immunohistochemistry staining demonstrated LF expression in osteoblasts. We found that LF activated Osx expression in a dose-dependent manner and a time-dependent manner. LF also further activated expression of osteoblast marker BSP. Interestingly, a specific mitogen-activated protein kinase p38 inhibitor SP203580, but not JNK kinase inhibitor SP600125, abrogated LF activation of Osx gene expression. LF-induced increase in Osx protein level was in parallel with the phosphorylation of p38 in osteoblasts. To further investigate the effect of LF on osteoblasts in vivo, calvaria organ culture from newborn mice was performed. We showed that Osx expression level in calvaria organ increased after stimulation by LF. Taken together, we provide the first evidence to demonstrate that LF activates Osx expression through the mitogen-activated protein kinase p38 pathway in osteoblasts, suggesting a novel mechanisms by which LF promotes bone formation.

SA0216

Lysyl Oxidase is a BMP Target Gene Regulated by Smad4 and Runx2 in Osteoblasts. Valerie Salazar*[1], Gabriel Mbalaviele[2], Vicki Rosen[1], Roberto Civitelli[2]. [1]Harvard School of Dental Medicine, USA, [2]Washington University in St. Louis School of Medicine, USA

Collagen abnormalities can be an underlying cause of brittle bones and fractures in humans. Collagen biosynthesis is a complex process involving many collagen-modifying enzymes, and the signaling pathways that regulate collagen biosynthetic enzymes in the skeleton are still unknown. Whereas brittle bones and spontaneous fracture are not reported in mice with genetic manipulation of the TGF-β pathway, we previously reported these as key features in mice with genetic ablation of *BMP2* or *Smad4* in endochondral lineages of the skeleton, $Bmp2^{flox/flox}$*; Prx1-Cre* ($Bmp2^{Prx1\Delta/\Delta}$) and $Smad4^{flox/flox}$*; Osx1-Cre* ($Smad4^{Osx1\Delta/\Delta}$). We find that expression of lysyl oxidase (*Lox*), a key enzyme mediating covalent crosslinking of collagen fibrils, is reduced by >30% in $Bmp2^{Prx1\Delta/\Delta}$ and >75% in $Smad4^{Osx1\Delta/\Delta}$ bones relative to littermate controls, while mature osteoblast markers, including *Col1α1*, are expressed normally. Accordingly, picrosirius red staining and polarized light microscopy of $Bmp2^{Prx1\Delta/\Delta}$ and $Smad4^{Osx1\Delta/\Delta}$ long bones reveal reduced lamellar organization and diminished birefringence of cortical collagen. In MC3T3 cells, *Lox* mRNA is upregulated by BMP2 but not TGF-β. Upregulation of *Lox* is enhanced by Jnk inhibition, which boosts Smad-dependent transcriptional activity; and it is blocked by PI3K inhibition, *Akt* siRNA, or *Smad4* siRNA, all of which effectively prevent Smad-dependent transcriptional responses to BMP2. Interestingly however, upregulation of *Lox* is also abrogated by inhibition of p38, but this is not associated with decreased Smad-dependent transcriptional activity. These results suggest that a BMP2-responsive, p38-dependent transcription factor cooperates with Smad4 to regulate *Lox*. Indeed, ChIP analysis reveals that both Smad4 and Runx2 are recruited to the *Lox* promoter in response to BMP2; and recruitment of Runx2, but not Smad4, is fully dependent on p38. Consistently, BMP2-dependent induction of *Lox* is reduced >80% by *Runx2* siRNA and

>90% by *Runx2* siRNA plus p38 inhibition. In summary, we identify the collagen–crosslinking enzyme, *Lox*, as a novel BMP2 target gene in osteoblasts, providing initial evidence of cooperative interactions between BMP/Smad4 and p38/Runx2 signaling in regulation of *Lox* expression, and therefore in skeletal collagen processing.

MicroRNA-99a is a Novel Regulator of KDM6B-Mediated Osteogenic Differentiation. Yin Tang*, Lan Zhang, Qianqian Han, Dana Murray, Qisheng Tu, Jake Jinkun Chen. Tufts University School of Dental Medicine, USA

Currently little is known about the epigenetic regulation of the commitment of multipotent progenitor cells to bone tissue. One of the central epigenetic chromatin modifications is histone lysine methylation. It has been identified that histone demethylase KDM6B plays an important role in promoting osteogenic differentiation of bone marrow stem cells (BMSCs). In this study, we found that miR-99a is potentially involved in regulating the KDM6B protein level during osteogenic differentiation.

First, we selected two well-studied osteoblast cell lines, MC3T3-E1 osteoblast-like cells and MLO-A5 preosteocyte-like cells, representing two key developmental stages of the osteoblast for miRNA profiling. Both cells exhibit unique miRNA expression profiles after osteogenic induction. Statistically significant differences in the expression of 38 miRNAs between MLO-A5 and MC3T3-E1 cells also were observed. miR-99a was selected for further investigation, as its expression changed most dramatically among these 38 miRNAs, and it was significantly downregulated in MLO-A5 cells. miRNA target prediction was carried out using a combination of the following computational algorithms: targetscan, Sloan-Kettering Cancer Center Human MicroRNA Targets Data-base, and miRBase Targets. KDM6B is predicted to be a potential target of miR-99a during ostegenic differentiation.

Microarray results validated by real-time RT-PCR analysis showed that miR-99a was significantly down regulated in preosteoblast MC3T3-E1 cells compared to multipotent C3H10T-1/2 cells, and was further down regulated in preosteocyte MLO-A5 cells.

KDM6B mRNA levels decreased significantly in MC3T3-E1 cells compared to C3H10T-1/2 cells, and was further down regulated in MLO-A5 cells. However, western blot analysis revealed that KDM6B protein increased more than 2-fold in MC3T3-E1 cells compared to C3H10T-1/2 cells. We also performed experiments using primary BMSCs and similar results were obtained.These studies indicate that there is post-transcriptional regulation of KDM6B protein levels during osteogenic differentiation, and miR-99a may be involved in this regulation. Currently, we are performing luciferase assays and gain- and loss-of-function analyses to further determine the specific function of miR-99a in control of KDM6B expression in a cell- and stage-specific manner.

Oxygen-Dependent Mineralization Differences with High Intrinsic Aerobic Capacity are Associated with Osteoblast Extracellular Matrix Gene Expression. Jacqueline Cole*[1], Kristin Graf[1], Parth Patel[1], Lauren Koch[1], Steven Britton[1], Andrea Alford[1], Ronald Zernicke[1], Kenneth Kozloff[2]. [1]University of Michigan, USA, [2]University of Michigan Department of Orthopaedic Surgery, USA

Dysfunctional aerobic metabolism is associated with various age-related diseases, including cardiac arrhythmias and metabolic syndrome. We hypothesize that variation in the capacity for oxygen metabolism is a driving factor in complex disease development and that this mechanism is important for bone health. Our objective was to examine the role of aerobic capacity in the response of osteoblast lineage cells to varying oxygen tension. Female rats selected for high (HCR) and low (LCR) aerobic capacity were age- and body mass-matched (10 wk; 173 g). Aerobic capacity was 8-fold greater in HCR than LCR, measured by a run to exhaustion. For *in vitro* analyses (n=3 per group), marrow stromal cells were harvested from femora/tibiae and differentiated at 1% or 20% oxygen for 14 days using osteogenic medium. Gene expression was assessed with real-time PCR arrays. Cycle threshold data were normalized and compared across line (HCR, LCR) and oxygen level. For *in vivo* bone formation (n=15 per group), calcein and alizarin were injected at 10 and 3 days before sacrifice, respectively. Femora were fixed, embedded in PMMA, and sectioned at the mid-diaphysis and distal metaphysis for dynamic histomorphometry.

In general, differences emerged for genes regulating the osteoblast extracellular matrix (ECM). Regardless of oxygen tension, aerobic capacity affected gene expression. Compared with LCR, HCR showed a time-dependent reduction in *Col1a1* (ECM formation), *Ibsp* (ECM maturation), and *Dmp1* (ECM mineralization) (Fig. 1). Oxygen tension also impacted gene expression; cells cultured at 1% oxygen had decreased *Col1a1*, *Ibsp*, and *Dmp1* and increased *Sost* (Wnt antagonist) (Fig. 2).

At the femoral mid-diaphysis, endosteal bone formation rate and mineral apposition rate did not differ between HCR and LCR, although bone surface was 5-10% lower in HCR (Fig. 3). Analysis of dynamic cancellous bone formation is ongoing.Rats genetically divergent for aerobic capacity exhibit different osteoblast phenotypes. We previously reported that HCR mineralize less per cell than LCR, perhaps explained by the differences in ECM gene expression seen here. HCR consistently have greater tissue mineral density, likely due to greater osteoblast number. Oxygen-dependent differences in osteoblast number suggest cellular differences in oxygen utilization and metabolism, which may drive ECM regulation. Oxygen availability is important for osteoblast function, particularly in rats with high aerobic capacity.

P2X7 Nucleotide Receptor Signaling Potentiates the Wnt/β-catenin Pathway in Osteoblasts: Implications for Mechanotransduction in Bone. Matthew Grol*, Patricia Brooks, Alexey Pereverzev, Stephen Sims, S. Jeffrey Dixon. The University of Western Ontario, Canada

Nucleotides are released from cells in response to mechanical stimuli and signal through cell-surface P2 receptors. The P2X7 and Wnt/β-catenin pathways regulate osteoblast differentiation and are critical for anabolic responses of bone to mechanical loading. However, whether these pathways interact to control bone formation is unknown. The purpose of this study was to investigate effects of P2X7 activation on Wnt/β-catenin signaling in osteoblasts. We first determined whether P2X7 couples to inhibition of GSK3β, a negative regulator of Wnt/β-catenin signaling. The phosphorylation status of GSK3β in MC3T3-E1 cells was assessed by immunoblot analysis. The P2X7 receptor agonist BzATP significantly increased inhibitory phosphorylation of GSK3β, an effect that was blocked by the P2X7 antagonist A 438079. We next monitored β-catenin nuclear localization using immunofluorescence and confocal microscopy. Canonical Wnt3a elicited a gradual increase in β-catenin nuclear localization that peaked at 3 h and slowly returned to baseline by 24 h. In contrast, BzATP caused transient nuclear localization only at 0.5 h post-treatment. Notably, Wnt3a and BzATP together elicited dramatically sustained β-catenin nuclear localization compared to Wnt3a alone. To monitor changes in β-catenin transcriptional activity, cells were transfected with a β-catenin luciferase reporter. In MC3T3-E1 cells, BzATP alone did not increase β-catenin transcriptional activity. On the other hand, Wnt3a induced a dramatic increase in β-catenin transcriptional activity that was potentiated by treatment with BzATP. Consistent with involvement of the P2X7 receptor, a high ATP concentration (1 mM, which activates many P2 receptors including P2X7) potentiated β-catenin transcriptional activity elicited by Wnt3a, whereas low concentrations of ATP, ADP or UTP (10 μM, which activate P2 receptors other than P2X7) failed to elicit a response. Moreover, BzATP-induced potentiation of Wnt3a-induced β-catenin transcriptional activity was blocked by A 438079. Finally, responses to Wnt3a in calvarial cells from *P2rx7* knockout mice were significantly less than in cells from wildtype controls. Taken together, we demonstrate for the first time that P2X7 activation prolongs and potentiates β-catenin transcriptional activity elicited by canonical Wnt signaling. Thus, crosstalk between the P2X7 and Wnt/β-catenin pathways may modulate osteoblast activity in response to mechanically-induced ATP release in bone.

Prx-1 Coverts MAPK Regulation of Osterix Transcription from Stimulation to Inhibition. Linda Gilbert[1], Mark Nanes*[2]. [1]VA Medical Center, USA, [2]VA Medical Center & Emory University, USA

The homeobox-like protein Prx-1 (MHox, Prrx-1) is a required inducer of the limb bud during embryogenesis, normally silenced at E10. We previously showed that Prx-1 is reactivated in adult tissues by the inflammatory cytokine TNF. TNF inhibition of Osx and osteoblast differentiation is abrogated by silencing Prx-1 using shRNA and also by inhibitors of MAPK including DN-MKK1, DN-ERK1, and PD 98059, suggesting possible interaction of Prx-1 and MAPK in the regulation of Osx transcription (Lu et al J Biol Chem 281:6297 2006, Lu et al J Bone Min Res 26:209 2011). To determine how Prx-1 and MAPK regulate Osx, we used a -1269/+91 murine Osx reporter in C3H10T1/2 mesenchymal cells and tested the effects of constitutive activation of Prx-1 and/or MAPK. Surprisingly, constitutive expression of Prx-1b or activation of MAPK (CA-Prx1b or CA-MKK1) alone dose dependently stimulated, rather than inhibited, transcription of Osx. Co-expression of both CA-Prx1b and CA-MKK1 reestablished the inhibitory effect on Osx transcription in a Prx-1 dose-dependent manner. Prx-1 binds the Osx promoter at a unique TNF inhibitory response element (-512/-496) and also upstream at a homologous homeobox (HBox) consensus sequence that is contiguous with a RUNX2 binding site (-720/-705). Deletion constructs that included or excluded the TNF/Prx or HBox/Prx sites were used to localize the independent vs. interactive effects of the two stimuli. Prx-1 and MAPK stimulation of Osx transcription were mediated by upstream regions of the promoter independent of the downstream TNF or HBox binding sites, but the combined Prx-1/MAPK inhibitory effect was a function of the more proximal promoter regulatory regions containing the inhibitory TNF/Prx response element, though some combinatorial inhibitory effect was still observed upstream. CA-Prx1b and CA-MKK1 mediated independent inhibitory actions when the upstream promoter was deleted (-665/+91 or -770/+91). Our results suggest that Prx-1 converts the stimulatory effect of MAPK on Osx expression and osteoblast differentiation to an inhibitory one. This may explain the discrepancy between reports showing an overall stimulatory effect of MAPK on osteoblast differentiation with studies showing that TNF inhibition of osteoblast differentiation is mediated by MAPK. Inflammation stimulated Prx-1 may have a role in the inhibition of osteoblast differentiation.

Role of Sirtuin 1 in the Function of PTH in Osteoblasts. Yurong Fei*, Emi Shimizu, Teruyo Nakatani, Nicola Partridge. New York University College of Dentistry, USA

Sirtuin 1 (Sirt1), an NAD-dependent deacetylase, participates in a variety of human diseases. The function of Sirt1 in bone is not well defined. More than 40 million Americans are threatened by osteoporosis. Currently, the only anabolic agent for treating osteoporosis in the US is parathyroid hormone (PTH). One downstream target of PTH in bone is collagenase 3 (MMP13). PTH significantly induces expression of MMP13 in bone. Collagenases are required for bone resorption stimulated by PTH *and* MMP13 is required for endochondral bone formation. The goal of this study is to determine the role of Sirt1 in the action of PTH in osteoblasts. Osteoblastic UMR 106-01 cells and Sirt1 knockout mice were utilized. Gene expression was analyzed by qPCR, protein interaction by immunoprecipitation, protein-DNA interaction by the chromatin immunoprecipitation assay, and promoter activity by luciferase assay. We observed that *Mmp13* mRNA expression in bone from Sirt1 knockout mice was increased significantly (five fold stimulation) compared to wild type mice. The Sirt1 activator, resveratrol, profoundly blocked *Mmp13* mRNA expression induced by PTH in UMR 106-01 cells. In contrast, the Sirt1 inhibitor, EX527, significantly enhanced *Mmp13* mRNA expression induced by PTH. Additionally, PTH after two hours of treatment enhanced Sirt1 binding to JUN, a component of the transcription factor complex, activator protein 1 (AP-1), but not to FOS. Furthermore, PTH treatment for two hours promoted Sirt1 binding to the AP-1 sites of the *Mmp13* promoter and this binding was further increased by resveratrol, implicating Sirt1 as a feedback inhibitor regulating *Mmp13* transcription. The AP-1 site of the *Mmp13* promoter is required for PTH stimulation of *Mmp13* transcription activity. When the AP-1 site was mutated, resveratrol was unable to inhibit PTH stimulated *Mmp13* promoter activity, indicating a role for the AP-1 site in Sirt1 inhibition. These data indicate that Sirt1 is a negative regulator of MMP13, Sirt1 activation inhibits PTH stimulation of *Mmp13* and this regulation is mediated by Sirt1 binding to AP-1.

Stepwise Differentiation of Pluripotent Stem Cells into Osteoblasts with Four Small Molecules under a Serum-free Condition. Kosuke Kanke*[1], Taku Saito[2], Hironori Hojo[3], Alexander Lichtler[4], Ung-Il Chung[5], Shinsuke Ohba[1]. [1]The University of Tokyo, Japan, [2]University of Tokyo, Graduate School of Medicine, Japan, [3]The Center for Disease Biology & Integrative Medicine, USA, [4]University of Connecticut Health Center, USA, [5]University of Tokyo Schools of Engineering & Medicine, Japan

The limited number of specific cell populations obtained from animals hampers the study of protein interactions, transcriptional networks, and epigenetics in osteoblast development. Embryonic stem cell (ESC)-based osteogenic differentiation may be an attractive model for such studies, given its pluripotency and capacity for self-renewal. Here, we developed an efficient, mass-producible, and reproducible culture protocol directing mouse ESCs (mESCs) toward osteoblasts under a serum-free condition, then applying the protocol to human induced pluripotent stem cells (h-iPSCs). The protocol is composed of four phases: mESC maintenance in serum-free 2i culture (Nature 453:519, 2008), mesoderm induction (5 days), osteogenic induction (14 days), and maturation of osteoblasts (4 days). Mesoderm induction was achieved in serum-free media by inhibiting neural differentiation with the Hh signaling inhibitor cyclopamine and by inducing mesoderm differentiation with the GSK-3 inhibitor CHIR99021. Cells were then cultured with the Hh signaling activator SAG and the helioxanthin-derivative TH (Biochem Biophys Res Commun 357:854, 2007) in serum-free osteogenic media for 14 days; the cells spontaneously differentiated into mature osteoblasts without any inducers in the next maturation phase. Mesoderm markers, *T* and *Mixl1*, were transiently up-regulated by the mesoderm induction. Subsequent osteogenic induction induced GFP expression in mESCs engineered to express GFP under the control of a rat 2.3-kb *Col1a1* promoter (Col1a1-GFP). Consistent with this, osteoblast-related genes including *Runx2*, *Sp7*, *Col1a1*, *Ibsp*, and *Bglap* were strongly up-regulated by the induction ($p<0.05$ vs. control). Other lineage markers did not alter with pluripotency genes being down-regulated. Immunocytochemistry revealed that high percentages of the cells expressed Runx2 (78 $\pm$ 12%), Sp7 (66 $\pm$ 11%), and Col1a1-GFP (45 $\pm$ 6%) at the end of the osteogenic induction. When we applied our protocol to h-iPSCs, *RUNX2*, *SP7*, *COL1A1*, *IBSP* and *BGLAP* were up-regulated during the induction, and RUNX2 and SP7 proteins were highly expressed in the periphery of the cell clusters. Thus, we achieved the direct differentiation of pluripotent stem cells into osteoblasts using four small molecules under serum-free conditions. This system will be useful for in vitro mechanistic studies of osteoblast development in near in vivo settings and may be applied to stem cell-based therapies for massive bone defects.

The Transcriptional Coregulator αNAC is a PKA Substrate Downstream of PTH Signaling. Martin Pellicelli*[1], Julie Miller[1], Claude Gauthier[1], Rene St-Arnaud[2]. [1]Shriners Hospitals for Children - Canada, Canada, [2]Shriners Hospital for Children & McGill University, Canada

In the nucleus of differentiated osteoblasts, the DNA-binding αNAC protein acts as a transcriptional coactivator of the *Osteocalcin* (*Ocn*) gene. The activity of αNAC is extensively modulated by post-translational modifications (PTMs). To further examine potential PTMs of αNAC, we performed *in silico* analysis which identified residue serine 99 as a potential PKA phosphoacceptor site. To evaluate if αNAC is a *bona fide* PKA substrate we performed an *in vitro* kinase assay using recombinant αNAC and PKA proteins. Our results show that wild type αNAC is phosphorylated by PKA at residue serine 99. Mutation of this amino acid to an alanine (S99A) abrogated phosphorylation. In osteoblasts, one of the main signals that lead to PKA activation is the PTH-Gsα signaling pathway. To assess whether this pathway can lead to S99 phosphorylation in living cells, we developed a specific phospho-S99-αNAC antibody. Immunoblotting revealed an accumulation of phospho-S99-αNAC in osteoblasts exposed to PTH(1-34) or 6-Bnz-cAMP, a PKA-selective activator. The same treatment also induced the nuclear translocation of αNAC. Nuclear accumulation was abrogated by the S99A mutation but enhanced when serine 99 was mutated to a phosphomimetic residue (S99D). Moreover, ChIP analysis showed that PTH(1-34) or 6-Bnz-cAMP treatment leads to accumulation of wild-type αNAC (but not S99A mutated αNAC) at the *Ocn* promoter. Finally, to validate the signaling cascade between PTH, PKA and αNAC, we have altered gene dosage for Gsα and αNAC in compound heterozygous mice. Compound Gsα;αNAC heterozygotes have a reduced bone mass phenotype and show increased numbers of osteocytes per surface area, as well as enhanced expression of osteocytic differentiation markers. Taken together, our results support that αNAC is a substrate of PKA following PTH signaling. This phosphorylation enhances αNAC translocation to the nucleus and leads to its accumulation at the *Ocn* promoter.

TIEG enhances canonical Wnt signaling in the skeleton via dual mechanisms. John Hawse*[1], Kevin Pitel[1], Anne Gingery[2], Nalini Rajamannan[3], Malayannan Subramaniam[4], Thomas Spelsberg[4]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic School of Medicine, USA, [3]Northwestern University Medical School, USA, [4]Mayo Clinic, USA

We have previously demonstrated that TGFβ Inducible Early Gene-1 (TIEG) plays important roles in mediating bone physiology as loss of TIEG expression *in vivo* results in a gender specific osteopenic phenotype which is observed only in female mice. Recently, TIEG has been identified in clinical studies as one of only a handful of genes whose altered expression levels or allelelic variations are associated with decreased bone mass and osteoporosis in humans. Our ongoing studies have now identified novel roles for TIEG in mediating Wnt signaling in bone. Here, we provide evidence that TIEG enhances canonical Wnt signaling in the skeleton via multiple mechanisms. Specifically, through the use of gene expression profiling studies on the cortical shells of long bones isolated from wild-type (WT) and TIEG KO mice, we determined that sclerostin mRNA levels were elevated approximately 12-fold in KO animals relative to WT controls. Serum sclerostin protein levels were also significantly elevated in KO mice. Since sclerostin is a potent inhibitor of Wnt signaling, we next utilized the TOPGAL reporter mouse to determine if loss of TIEG expression altered the activity of the canonical Wnt pathway in the skeleton. LacZ staining of the L5 vertebrae revealed a 3-fold decrease in Wnt pathway activity in TIEG KO mice relative to WT controls. In light of this observation, we next determined if TIEG could regulate Tcf/Lef enhancer elements through the use of the TopFlash reporter construct. TIEG expression was shown to increase TopFlash activity and to further enhance the Lef1 and β-catenin mediated induction of this reporter construct in osteoblasts. Co-immunoprecipitation studies revealed that TIEG also interacts with Lef1 and β-catenin. Since nuclear localization of β-catenin is essential for activation of the canonical pathway, we next sought to determine if TIEG played a role in mediating this process. Over-expression of TIEG in U2OS cells resulted in enhanced nuclear localization of β-catenin, an observation which was confirmed using wild-type and TIEG KO calvarial osteoblasts. Enhancement of β-catenin nuclear localization by TIEG appears to be mediated by TIEG's activation of AKT and subsequent inhibition of GSK3-β. Taken together, these data demonstrate that TIEG regulates canonical Wnt signaling through dual mechanisms which include the suppression of SOST expression and enhancement of β-catenin nuclear localization and transcriptional activity.

Transcription factor AP2 suppresses FZD1 expression and mineralization in osteoblasts. Shibing Yu*[1], Laura Yerges-Armstrong[2], Yanxia Chu[3], Joseph Zmuda[4], Yingze Zhang[5]. [1]University of Pittsburgh Medical Center, USA, [2]University of Maryland School of Medicine, USA, [3]upmc, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]University of Pittsburgh, USA

FZD1 plays a role in osteoblast differentiation and mineralization. The mechanisms underlying the transcriptional regulation of FZD1 gene expression are not well understood. The aim of this study was to characterize the potential roles of transcription factor AP2 in regulating FZD1 expression and osteoblast differentiation and mineralization. Co-transfection of an AP2 expression plasmid with a full length FZD1 promoter (726bp) luciferase reporter resulted in the repression of promoter luciferase activity. Repression of FZD1 promoter by AP2 was not affected by two single nucleotide polymorphisms (rs2232157, rs2232158) that were previously associated with bone mineral density. Bioinformatic analysis of the FZD1 promoter identified multiple putative AP2 binding sites. Mutagenesis of these sites did not abolish the repression activity of AP2 on FZD1 promoter suggesting that these were not functional AP2 binding sites. In contrast, analysis of multiple truncated FZD1 promoter constructs abolished AP2 dependent repression in one of the promoter constructs suggesting AP2 binding in the full length promoter. Consistent with these results, endogenous FZD1 mRNA and protein expression in Saos2 cells were decreased by AP2 overexpression. The specificity of AP2 repression of FZD1 promoter was further confirmed using AP4, another transcription factor belonging to the Activation Protein (AP) family as it transactivated FZD1 promoter activity in Soas2 cells. Furthermore, suppression of FZD1 by AP2 overexpression led to the reduction of osteoblast differentiation and mineralization visualized by Alizarin Red staining. Taken together, our study demonstrates that AP2 is an important repressor for FZD1 gene expression and osteoblast differentiation and mineralization.

PTH Additively Enhances The Mechanical Stress-induced Proliferation of Calvarial Osteoblasts. Jumpei Shirakawa*[1], Yoichi Ezura[2], Makiri Kawasaki[1], Takayuki Yamada[1], Shuichi Moriya[3], Takuya Notomi[4], Tadayoshi Hayata[5], Ken Omura[1], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Department of Orthopaedics, Juntendo University School of Medicine, Japan, [4]GCOE, Tokyo Medical & Dental University, Japan, [5]Medical Reserach Institute, Tokyo Medical & Dental University, Japan

Mechanical forces on skeletal system promote osteoblast proliferation and bone remodeling. Intermittent administration of parathyroid hormone (PTH) also stimulates osteoblast activity. Therefore, relationships between PTH and mechanical stimulation have been postulated. However, molecular links between these factors in osteoblast proliferation remains unclear. Here, we hypothesized that these factors could affect osteoblast proliferation through independent pathway at least in part, and thus could induce additive effects if both stimuli were applied. To test this hypothesis, calvaria derived osteoblastic cells (MC3T3E1) were subjected to flow-induced mechanical stress, using flow chambers with a push-pull pump or a reciprocal shaker as mechanical stress. In addition, some cells were exposed to PTH (100nM) or control buffer (PBS). BrdU incorporation after treatment indicated that mechanical stress and PTH increased osteoblast proliferation by either of the treatment. When these treatments were combined, a trend of further enhancement was observed in vitro. To examine in vivo effects, we intermittently injected PTH(1-34) daily for 7days into the mice that were subjected to mechanical stress at calvarial suture using expansion system based on application of dental coil spring. The initial force was around 1 N. PTH injection tended to increase cyclin D1 mRNA expression after the treatment in sham operated mouse calvarial suture. PTH futher enhanced cyclin D1 expression in the mice subjected to mechanical expansion. These results indicate that mechanical stress and PTH additively enhance bone formation via stimulation of osteoblasts proliferation.

Rho GTPases control nuclear localization of beta-catenin and TCF/LEF activity in osteoblasts under flow. Qiaoqiao Wan*[1], Eunhye Cho[2], Ping Zhang[2], Hiroki Yokota[2], Sungsoo Na[2]. [1]Purdue University, USA, [2]Indiana University-Purdue University Indianapolis, USA

Mechanical loading of bone is known to influence bone growth and remodeling. Application of physiological loading to bone accelerates bone formation and fracture healing, whereas removal of loading results in bone loss. Beta-catenin dependent TCF/LEF (T-cell factor/lymphocyte enhancing factor) is known to be mechanosensitive and an important regulator for promoting bone formation. However the mechanism by which how β-catenin signaling interacts with other mechanoresponsive signaling proteins, such as Rho family GTPases, is not clearly understood. Here we show that Rac1 and Cdc42 are critical components of β-catenin signaling in shear stress-induced osteoblasts.

FRET-based GTPase biosensors were used to monitor Rac1 and Cdc42 activities. A TCF/LEF-green fluorescent protein (GFP) reporter was used to monitor the activity of β-catenin signaling. Enhanced GFP (EGFP)-β-catenin fusion proteins were used to monitor nuclear translocation of β-catenin. MC3T3-E1 osteoblasts were used for this study. The DNA plasmids were transfected into the cells using a Neon transfection system. Oscillatory (1 Hz) shear stress (10 dynes/cm2) was applied to the cells grown in the cell culture chamber. A Nikon Ti-E inverted microscope was used for imaging experiments. FRET images for GTPases activity were generated by computing an emission ratio of YFP/CFP for individual cells. The GFP images for TCF/LEF activity and β-catenin localization were background-subtracted and the fluorescence intensity was averaged over the whole cell area or over the nucleus. Images were scaled according to the color bar.

Results show that oscillatory shear stress stimulated translocation of β-catenin to the nucleus and increased TCF/LEF activity (Fig. 1A, B). Rac1 and Cdc42 displayed distinct dynamics of activation under flow (Fig. 2A, B). The shear stress-induced TCF/LEF upregulation was blocked by the inhibition of Rac1 and Cdc42 with their dominant negative mutants (Rac1-N17 and Cdc42-N17, respectively) or GTPase-specific drugs (NSC23766 and ML141, respectively) (Fig. 3). In contrast, constitutively active Rac1 and Cdc42 mutants caused a significant enhancement of TCF/LEF activity (data not shown). Our findings suggest that Rac1 and Cdc42 GTPases may play a role in regulating TCF/LEF-mediated transcription process and consequently contribute to load-induced bone repair and remodeling.

SA0229

Tob1, a BMP repressor, is activated by parathyroid hormone in osteoblasts in vitro and in vivo and reciprocally regulates PTH signaling. Shuichi Moriya*[1], Tadayoshi Hayata[2], Jumpei Shirakawa[3], Makiri Kawasaki[3], Takuya Notomi[4], Yoichi Ezura[5], Kazuo Kaneko[1], Masaki Noda[3]. [1]Department of Orthopaedics, Juntendo University School of Medicine, Japan, [2]Medical Reserach Institute, Tokyo Medical & Dental University, Japan, [3]Tokyo medical & dental university, Japan, [4]GCOE, Tokyo Medical & Dental University, Japan, [5]Tokyo Medical & Dental University, Medical Research Insititute, Japan

PTH receptor is expressed in bone and is involved in anabolic action of bone during intermittent administration of PTH. Tob1 (transducer of erbB2) is a member of antiproliferative family proteins and regulates bone mass as a BMP repressor (Yoshida et al. Cell 2000). However, the role of Tob1 during the action of PTH in osteoblast has not been understood. The purpose of this study was to identify the effect of PTH on Tob1 in bone. PTH directly enhanced the expression of Tob1 messenger RNA (mRNA) levels in MC3T3-E1 osteoblastic cells. This was an immediate early effect with a peak at 1 h after human PTH (1-34) treatment and the

levels returned to the baseline within 3 h. The PTH effects on the expression of Tob1 mRNA levels in vitro were dose dependent with a maximal effect at 100 nM PTH. PTH also enhanced Tob1 mRNA expression in the primary calvarial osteoblasts. PTH enhancement of Tob1 mRNA expression was suppressed by the DRB, a transcription inhibitor, while it was not inhibited by the presence of cycloheximide. These data suggested that PTH directly enhances Tob1 mRNA expression in osteoblasts at least in part via transcriptional events without requirement for new protein synthesis. In addition to the in vitro effects, PTH injection also enhanced Tob1 mRNA expression in bone in vivo. The PTH effect on Tob1 mRNA in bone was peaked at 1h after the injection and the levels returned to base line within 6 h. PTH effects were first observed at 10 μg/kg body weight and the effect was peaked at 80 μg/kg. These PTH effects on Tob1 mRNA in vivo were closely paralleling those observed in vitro on osteoblasts. Intermittent administration of PTH also elevated steady-state levels of Tob1 in bone after 7days of daily injection. To analyze the mode of PTH regulation by Tob1 gene expression, CRE (cyclic AMP response element)-Luc activity (pCRE-Luc) was used. Control cells or cells transfected with si-Tob1 or expression vector for TOB were tested for their response to 100 nM PTH or transfected constitutively active PTHR variant (His223Arg, caPPR) was performed. si-RNA for Tob1 suppressed the effects of caPPR on pCRE-luc. Conversely, Tob overexpression enhanced the caPPR-induced increase of the levels of luciferase activity. These observations indicate that Tob1 is one of the early direct target genes of PTH and Tob1 inhibits PTH signaling by interaction via transcriptional events.

A Novel hESC/iPSC Differentiation Protocol Generates a Cell Population with Endochondral Bone Formation Potential. Xiaonan Xin*, Xi Jiang, Liping Wang, Mary Louise Stover, Shuning Zhan, Jianping Huang, I-Ping Chen, Ernst Reichenberger, David Rowe, Alexander Lichtler. University of Connecticut Health Center, USA

The use of hESC and induced pluripotent stem cells (iPSC) for study and treatment of bone diseases or traumatic bone injuries requires efficient protocols to differentiate hESC/iPSC into cells with osteogenic potential, and the ability to isolate differentiated osteoblasts for analysis. Utilizing zinc finger nuclease (ZFN) technology to deliver a construct containing the Col2.3 promoter driving GFPemerald to the AAVS1 site, we successfully generated hESC and iPSC with Col2.3 promotor driven GFP or RFP (H9ZnCol2.3GFP/iPSC-ZnCol2.3RFP). We observed GFP positive osteoblasts in our mouse calvarial defect model by differentiating H9ZnCol2.3GFP into mesenchymal cells using a published protocol. With this differentiation protocol, we observed that the cells appear to undergo membranous bone formation, which may not be ideal for generating hESC/iPSC derived mesenchymal stem cells (MSC) for long bone non-union segmental defect repair. In contrast, we have developed a new differentiation protocol that may provide MSC that undergo endochondral bone formation, utilizing our H9ZnCol2.3GFP cells to facilitate evaluation of the osteogenic potential of cells produced with this protocol. The procedure involves producing embryoid bodies (EBs) with H9ZnCol2.3GFP or iPSC-ZnCol2.3RFP cells in mouse embryonic fibroblast conditioned (CM) media. After 10 days, EBs were collected and re-plated on a gelatin coated plate. MSCs were allowed to migrate out from the EBs in endothelial growth media (EGM). Cells were passaged and expanded after 10 days. The MSCs were first tested with our mouse calvarial defect model. In the defect, we observed dramatic cartilage formation after 6 weeks of implantation. Giving longer implantation time, we found increased amounts of human bone formed in the defects. Formation of hypertrophic cartilage was observed, which was replaced by bone, indicating that endochondral bone formation was taking place. We also observed human endochondral bone formation in a mouse non-union segmental long bone defect model. With these results, we believe that the newly developed differentiation protocol may provide a starting point for development of a method for producing MSC with endochondral bone formation potential that can be used clinically for repair of long bone defects in patients.

Copper Coated Bone Implant Material Prevents Bacterial Growth and Stimulate Osteogenic Differentiation of Mesenchymal Stem Cells. Ines Burghardt[1], Frank Lüthen[1], Cornelia Prinz[2], Hans-Georg Neumann[2], Joachim Rychly*[1]. [1]Rostock University Medical Center, Germany, [2]DOT GmbH, Germany

To prevent infection due to bacteria, the design of anti-microbial medical implants is a great challenge in implant technology. We tested whether implant material coated with copper salts are suitable both to prevent growth of bacteria and to stimulate regeneration of bone by osteogenic differentiation of mesenchymal stem cells (MSC). Copper salts were implemented on titanium discs by galvanic deposition with an average copper load of 0.06 μg/mm^2. The anti-microbial activity of the material surface was tested with *S.aureus*. Growth of both planktonic and biofilm forming bacteria was inhibited at a Cu-concentration above 0.5 mM in the culture medium. Because of the known physiological role of copper, we studied the effect of $CuSO_4$ added to the culture medium and of Cu-ions released from the material surface on the biological responses of human MSC derived from bone marrow. We found that Cu-ions stimulated various parameters of the osteogenic differentiation of MSC. ALP activity increased due to a copper concentration of 0.1 mM in osteogenic differentiation medium after 7 days. Copper also stimulated the expression of collagen I detected by Western blot. After 28 days in Cu-containing osteogenic differentiation medium increased mineralization of MSC was detected at an optimal concentration of 0.3 mM of copper. In addition to stimulating osteogenic differentiation of MSC, proliferation of the MSC was increased at a concentration of 0.1 mM copper both in expansion and osteogenic differentiation medium.We conclude that copper containing implants are suitable to prevent bacterial infection and to promote bone regeneration by a stimulating effect on biological responses of mesenchymal stem cells. Both effects are concentration dependent. At higher concentration of Cu, i.e. immediately after implantation or directly at the implant surface, the anti-microbial action predominates, whereas in a late phase after implantation or at a greater distance from the implant surface, the implant may stimulate bone regeneration.

Effect of Type I Diabetes Mellitus in Circulating Osteoblastic Cells in Pheripheral Blood in Children and Young Adults. Merce Giner*[1], Ramón Pérez-Temprano[2], Mª Angeles Vázquez[3], Mª José Montoya[4], Cristina Miranda[5], Mª José Miranda[5], Ramón Pérez-Cano[2]. [1]Bone Metabolism Unit, "Virgen Macarena" University Hospital, Spain, [2]Bone Metabolism Unit, "Virgen Macarena" University Hospital & University of Seville, Spain, [3]Medicine Department, University of Seville, Spain, [4]University of Seville, Spain, [5]Bone Metabolism Unit, "Virgen Macarena" University Hospital of Seville, Spain

Introduction: Type 1 Diabetes Mellitus (DM1) has negative effects in various organs and systems, including bone tissue. In adults with DM1, there is an increased risk of osteoporotic fractures and lower BMD than the general population. This may be due to an imbalance in bone metabolism, either by accelerated bone resorption and/or less training in the growth stage.

Objectives: The purpose of our study was to determine if children and young adults with DM1 have decreased osteoblast lineage cells in peripheral blood and their association with bone mass values, the time course of the disease and metabolic control.

M & M: We studied four groups: A) 23 healthy children (5-12 years), B) 20 children with DM1 (5-12 years), C) 15 healthy young (22-38 years), D)15 young adults with DM1 (22-38 years). Mononuclear cell were isolated from whole blood by means of density gradients in Ficoll-Paque. For flow cytometry cells were incubated with antiosteocalcin antibody and a 2nd antibody marked with FITC.

Biochemical values we determined such as serum hemaglobin A 1c levels (HbA1c by HPLC), bone turnover markers (bone-specific alkaline phosphatase (BAP), procollagen type I N-terminal propeptide (P1NP), beta-crosslap, insulin growth factor 1 (IGF-1) and parathyroid hormone (PTH).

Bone mineral density (BMD) at the lumbar spine (L2-L4) and femur was measured (DXA).

Statistical analysis of the results was conducted using the T-student test and Pearson correlation coeficient (SPSS 20.0) and values were represented as means $\pm$ SD.

Results: The group of diabetic children has a significantly lower percentage of cells preosteoblasts (preOB) in peripheral blood (3.02% $\pm$ 1.8) than their control group (9.75% $\pm$ 7.4, p = 0.0001), and the same applies to the adult diabetic group, which has a smaller number of circulating pre-osteoblastic cells (2.2% $\pm$ 1.7) than their control group (5.9% $\pm$ 5.3, p = 0.013).

We observed a negative correlation between the number of pre-osteoblastic cells in blood and HbA1c (r = - 0.523, p = 0.0001) and serum glucose levels (r = -0.428 p = 0.001).

Conclusions: The enhanced bone fragility adults who have diabetes may be the result of a lower rate of bone formation in remodeling units influenced by glucose levels and metabolic control of the disease.

Epigenetic Landscaping using HDAC Inhibitors Primes Multi-Potent Human Adipose-Derived Mesenchymal Stem Cells for Osteogenic Lineage-Commitment. Amel Dudakovic*[1], Andre Van Wijnen[1], Gary Stein[2], Jennifer Westendorf[1], Sergii Kvasha[1], Xiaodong Li[1], Michael Yaszemski[3], Martin Montecino[4], Johannes Van Leeuwen[5], Eric Hesse[6], Simon Cool[7], Alan Dietz[1]. [1]Mayo Clinic, USA, [2]University of VermontCollege of Medicine, USA, [3]Mayo Clinic College of Medicine, USA, [4]Universidad de Concepcion, Chile, [5]Erasmus University Medical Center, The Netherlands, [6]University Medical Center Hamburg-Eppendorf, Germany, [7]Institute of Medical Biology, Singapore

Skeletal tissue engineering permits the restoration of damaged bone tissues that are apparent in aging orthopedic patients. Effective bone tissue engineering strategies critically depend on the ability to direct differentiation of mesenchymal stem cells into the osteogenic lineage. Epigenetic events that alter chromatin structure (e.g., histone acetylation and DNA methylation) alter the phenotype of skeletal progenitor cells through the concerted actions of histone code writers, readers and erasers. Histone acetyltransferases that mediate histone acetylation relax chromatin structure and induce gene expression, while histone deacetylases (Hdacs) that remove acetyl groups from histones reverse this effect. Histone deacetylase inhibitors (HDIs) such as vorinostat and valproate are clinically approved therapeutics (e.g., for cancer and epilepsy). HDIs have been shown to induce osteoblastic gene expression and promote terminal osteoblast maturation in mouse cells. Here, we examined whether HDIs can prime human adipose-derived mesenchymal stem cells (AMSCs) into the osteoblastic lineage using xenobiology-free conditions required for clinical bone tissue engineering. Expression of class I, II, and IV HDACs (HDACs 1-11) was measured in human AMSCs, primary fibroblasts, fetal osteoblasts (hFOB) and Saos2 osteosarcoma cells, as well as primary and immortalized TC28 chondrocytes using real-time quantitative PCR. Our data demonstrate that HDAC expression differs between these mesenchymal lineages and is altered during AMSC lineage commitment. Treatment of human AMSCs at confluence with vorinostat (1 μM for 24 hours) modestly enhances expression of representative mesenchymal lineage-specific transcription factors and bone-related extracellular matrix proteins. Strikingly, 72 hours after vorinostat removal we observed a more pronounced induction of expression for a subset of these same regulatory genes, including those encoding factors that play critical roles in AMSCs stemness (OCT4, NANOG), osteogenesis (RUNX2, SATB2, DLX5), chondrogenesis (SOX5 and SOX9), and myogenesis (MYOD). Thus, a single short-term dose of an HDI suffices to modify the epigenetic state of multipotent human stem cells to facilitate programming of transitions into alternative mesenchymal cell fates for skeletal tissue engineering.

Epigenetic modification enables transdifferentiation between adipocytes and osteoblasts. YOUNG DAN CHO*[1], Won Joon Yoon[1], Kyung Mi Woo[2], Jeong-Hwa Baek[2], Hyun-Mo Ryoo[2]. [1]Seoul National University, South Korea, [2]Seoul National University School of Dentistry, South Korea

Bone marrow of a young and healthy human is filled with osteoblasts or hematopoietic cells while that of older and osteoporosis patients is filled with adipocytes indicating they have a different epigenetic landscape. DNA methylation and histone acetylation are very important epigenetic modifications that control gene expression in the promoter region, and involve latent ability to switch the cells character. We present evidence that the new possibility to rescue bone marrow adiposity through transdifferentiation from adipocytes to osteoblasts by modifying their epigenetic landscape.

We found the CpG islands in the promoter of osteogenic (ALP and Runx2) and adipogenic marker genes (PPARr and C/EBPa) with in silico analysis. The trends of these gene expression levels were correlated conversely with the methylation status of the CpG islands in the osteogenesis and adipogenesis. In the 3T3-L1 pre-adipocytic cells, hypermethylated ALP promoter legion was demethylated by treatment of 5'-aza-2'-deoxycytidine (5'-aza-2'-dC) and/or Trichostatin A (TSA), which are well characterized inhibitors of DNA methylation and histone deacetylation, respectively. Furthermore, ALP staining showed that Wnt3a treatment or overexpression of bone marker genes induced transdifferentiation from adipocytes to osteoblasts in the 5'-aza-2'-dC or TSA pretreated 3T3-L1 cells.

Taken together, these results suggest that histone acetylation and DNA demethylation at the promoter regions of osteogenic and adipogenic marker genes, and then specific signaling to drive differentiation are crucial to enable transdifferentiation between adipocytes and osteoblasts.

SA0236

Intermittent PTH administration inhibits transformation of mature osteoblasts into quiescent lining cells. Mi Gyeong Jang*[1], Seung Hye Kim[1], Jae-Yeon Yang[1], Hyojung Park[1], Jung Hee Kim[2], Sun Wook Cho[3], Jung-Eun Kim[4], Chan Soo Shin[2], Sang Wan Kim[5]. [1]Seoul National University, South Korea, [2]Seoul National University College of Medicine, South Korea, [3]National Medical Center, South Korea, [4]Kyungpook National University School of Medicine, South Korea, [5]Seoul National University Boramae Hospital, South Korea

The fates of mature osteoblasts (Obs) are either of three: buried in the bone matrix as osteocytes (Ocys) or remain on the bone surface as quiescent lining cells, or undergo apoptosis. However, whether intermittent parathyroid hormone (iPTH) could modulate the fate of mature Obs *in vivo* has been little known. We conducted a lineage tracing study using an inducible gene system to understand possible effect of of iPTH on the fate of mature Obs. *Dmp1*-CreERt2 mice were crossed with ROSA26R reporter mice to render targeted mature Obs and their descendents, lining cells or Ocys, detectable by X-gal staining. ROSA26R:*Dmp1*-Cre(+) mice were injected with 0.25 mg 4-OH-tamoxifen (4-OHTam) on postnatal day 5, 7, 9, 16 and day 23. In previous study, on 22 days after the last 4-OHTam injection, most X-gal (+) cells on the periosteal surfaces of both the calvaria and tibia were inactive lining cells. Thus, on day 25, mice were challenged with a subcutaneous injection of human PTH (1–34, 80mg/kg) or vehicle daily for 10 or 20 days. The animals were sacrificed on postnatal day 25 or 36 or 46. We evaluated the number and thickness of X-gal (+) lining Obs descendents and the number of X-gal (+) or X-gal (-) Ocys in 4-6 consecutive 100 x or 200 x microscopic fields in the calvaria of these animals. PTH increased the thickness and the number of X-gal (+) Obs descendents in the calvaria compared to the vehicle (thickness; on day 23, 5.9 $\pm$ 3.4, on day 36, PTH: 2.5 $\pm$ 1.2, vehicle: 2.3 $\pm$ 0.7, on day 46, PTH: 2.6 $\pm$ 0.8, vehicle: 1.8 $\pm$ 0.5 mm, PTH versus vehicle on day 46: $p < 0.05$, number; on day 23: 45.1 $\pm$ 35.7, on day 36, PTH:11.7 $\pm$ 11.4, vehicle: 9.3 $\pm$ 12.5, on day 46, PTH: 40.7 $\pm$ 31.4, vehicle: 5.3 $\pm$ 7.5/mm, PTH vs vehicle on day 46: $p < 0.01$, n=4~6/group). PTH also increased X-gal (+) Ocy density compared to the vehicle in the calvaria (on day 23, 11.7 $\pm$ 6.0; on day 36, PTH: 11.6 $\pm$ 4.9, vehicle: 6.9 $\pm$ 3.8, on day 46, PTH: 6.6 $\pm$ 2.7, vehicle: 4.4 $\pm$ 1.9 x $10^3/mm^2$, PTH vs vehicle on day 36 and 46: $p < 0.05$; n=4~6/group). Moreover, fraction of X-gal (+) Ocy/total Ocy per area was increased after PTH administration (on day 23, 68.0 $\pm$ 13.5; on day 36, PTH: 73.9 $\pm$ 11.9, vehicle: 64.8 $\pm$ 14.7, on day 46, PTH: 67.2 $\pm$ 15.3, vehicle: 52.0 $\pm$ 19.0 %/mm^2, PTH vs vehicle on day 46: $p < 0.01$; n=4~6/group). This data suggests that PTH could inhibit transformation of mature Obs into lining cells, and PTH could modulate differentiation of mature Obs into Ocys *in vivo*.

Normoxia vs Hypoxia: Nutrient Activation of Distinct Signaling Pathways in Bone Marrow Mesenchymal Stem Cells is Dependent on Experimental Conditions. Mona El Refaey*[1], Qing Zhong[2], Xing-Ming Shi[3], Yun Su[1], Kehong Ding[3], William Hill[4], Wendy Bollag[1], Maribeth Johnson[1], Norman Chutkan[1], Mark Hamrick[3], Carlos Isales[1]. [1]Georgia Regents University, USA, [2]Medical College of Georgia, USA, [3]Georgia Health Sciences University, USA, [4]Georgia Regents University & Charlie Norwood VAMC, USA

We have previously reported that individual amino acids were potent agonists for stimulating increases in intracellular calcium and phospho c-Raf and in promoting Bone Marrow Stromal cell (BMSCs) differentiation down the osteogenic pathway. L-type amino acids bind with high specificity to GPRC6A receptors with aromatic amino acids (Tyrosine, Phenylalanine and Tryptophan) being the most potent activators of this pathway. These experiments were done in the presence of 5% CO2 and ambient air (78% N2 and 21% O2). However, physiologic oxygen pressure inside the bone marrow environment are much lower ranging from 1-7% and as high as 10-13% in the arteries, lungs and liver. We had not previously examined the effects of different levels of oxygen tension on BMSCs. Thus, we compared a normoxic (78% N2 and 21% O2) vs. a hypoxic environment (3% O2) alone or after treatment with aromatic amino acids. Reverse phase protein arrays (which test for 171 different phospho proteins) showed that Tyrosine (100 μM), under either normoxic or hypoxic conditions, upregulated protein kinase B (Akt), Forkhead box protein M1 (FOXM1) and Ribosomal protein S6 (RPS6) signaling pathways. In contrast, Tryptophan (100 μM) while activating the Akt pathway under normoxia (2-fold), under hypoxic conditions it instead increased ribosomal protein S6 kinase, 70kDa, and polypeptide 1 (RPS6KB1). Valine (100 μM), a branched-chain amino acid, downregulated RPS6 signaling under hypoxic conditions. Thus, under normoxic conditions, pathways involved in handling reactive oxygen species and promoting BMSC differentiation were activated while under hypoxic conditions, BMSC proliferative pathways were preferentially activated. These data, suggest that oxygen tension has an impact on the signaling pathways activated in BMSCs and that results under ''hypoxic'' conditions more closely resemble the normal physiologic conditions these cells are exposed to in their niches.

N-Terminus Amelogenin Peptide Induces Osteoblastic Differentiation of Stem Cells through ERK1/2. Rene Olivares-Navarrete*[1], Sharon Hyzy[2], Kathryn Vesper[3], Argelia Almaguer-Flores[4], Zvi Schwartz[1], Barbara Boyan[1]. [1]Virginia Commonwealth University, USA, [2]Georgia Tech, USA, [3]Georgia Regents University, USA, [4]Universidad Nacional Autonoma de Mexico, Mexico

Porcine enamel matrix derivative (EMD), composed mostly of amelogenin, is used as a therapeutic agent in clinical applications to regenerate bone and supportive tissue around teeth. Amelogenin is produced by ameloblasts as a full length protein or splice variants. Amelogenin also can be cleaved by enzymatic activity, resulting in a broad range of peptides. It is unclear whether the therapeutic effect of EMD is due to the full-length amelogenin protein, splice variants, proteolytic peptides, or a combination. Since EMD is known to produce bone regeneration, our hypothesis is that amelogenin peptides stimulate osteogenesis of mesenchymal stem cells. The aim of this study is to demonstrate the potential of amelogenin or N-terminal amelogenin peptide (NTAP) to promote osteogenic differentiation of mesenchymal stem cells (MSCs) and to elucidate the possible signaling pathways involved in periodontal regeneration. Human MSC cultures were treated with amelogenin or NTAP. While amelogenin induced MSC osteogenesis, increasing alkaline phosphatase specific activity, osteocalcin levels, and OSX and RUNX2 gene expression, a more robust osteogenic induction was seen after NTAP treatment. A phospho-kinase proteosome array measuring phosphorylation of 35 proteins indicated that protein kinase C (PKC), ERK1/2, and β-catenin were highly phosphorylated by NTAP. This was confirmed by measuring PKC activity and levels of phospho-ERK1/2 and β-catenin. Amelogenin and NTAP increased PKC. NTAP induced higher phosho-ERK1/2 than amelogenin. Phospho-β-catenin was higher in NTAP treated cells than in amelogenin treated cells. Inhibition of ERK1/2 with chemical compounds blocked both amelogenin and NTAP induced increases in RUNX2, ALP, OCN, COL1, and BMP2 mRNA. The results demonstrate that NTAP induces osteogenic differentiation of MSCs, mediated through activation of PKC and ERK1/2 and degradation of β-catenin, indicating that NTAP is an active amelogenin peptide. Taken together, the results suggests that NTAP can be used as an extracellular matrix product for induction of ostoeblastic induction and bone regeneration.

Pigment Epithelium Derived Factor Enhances Differentiation and Mineral deposition of Human Mesenchymal Stem Cells. Feng Li*[1], Na Song[1], Joyce Tombran-Tink[1], Christopher Niyibizi[2]. [1]Penn State College of Medicine, USA, [2]The Pennsylvania State University College of Medicine, USA

Pigment epithelium-derived factor (PEDF) is a potent anti-angiogenic factor found in a wide variety of fetal and adult tissues. Recent findings have shown that lack of PEDF leads to osteogenesis imperfecta (OI) type VI. The mechanisms by which PEDF leads to the development of OI type VI remain unknown. In the present report, we determined the effects of PEDF on human mesenchymal stem cells (hMSCs) differentiation and mineral deposition and signaling pathways through which PEDF displays its functions. Human MSCs incubated in maintenance medium in presence of PEDF induced expression of osteoblasts related genes. In addition, exposure of MSCs to PEDF induced expression of ALP activity and this activity was enhanced when the cells were incubated in osteogenic medium. hMSCs incubated in osteogenic medium in presence of PEDF significantly enhanced mineral deposition, as low as 50 ng/ml of PEDF enhanced mineral deposition in differentiating MSCs in comparison to the cells incubated in osteogenic medium alone. Expression of PEDF in MSCs was silenced using siRNA and the resulting cells were assessed for alkaline phosphatase activity and mineral deposition. The results revealed that MSCs deficient in PEDF expression exhibited decreased ALP activity and significant reduction in mineral deposition as assessed by Alizarin Red staining. Decreased ALP activity and reduction in mineral deposition were restored by supplementation with exogenous PEDF protein. PEDF activated ERK and AKT signaling pathways in MSCs to induce expression of osteoblast related genes and mineral deposition. Inhibition of ERK signaling pathway decreased expression of osteoblast related genes indicating that PEDF signals through this pathway to regulate osteoblasst related genes. These data demonstrate that PEDF plays a role in osteogenesis and that lack of its expression leads to reduction in mineral deposition as a result of reduced osteoblasts maturation. Thus, failure of osteoblasts maturation due to lack of PEDF may explain defects seen in type VI OI.

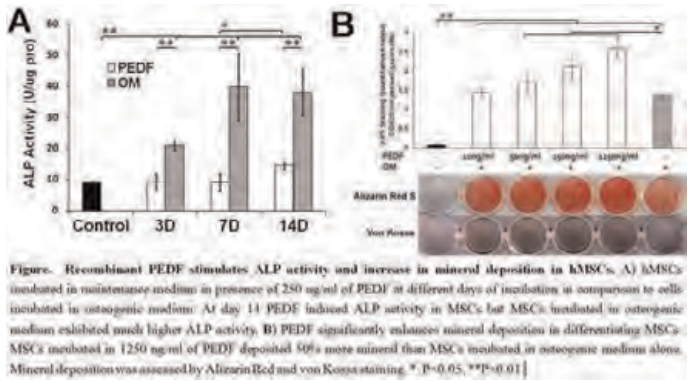

Figure. Recombinant PEDF stimulates ALP activity and increase in mineral deposition in hMSCs. A) hMSCs incubated in maintenance medium in presence of 250 ng/ml of PEDF at different days of incubation in comparison to cells incubated in osteogenic medium. At day 14 PEDF induced ALP activity in MSCs but MSCs incubated in osteogenic medium exhibited much higher ALP activity. B) PEDF significantly enhances mineral deposition in differentiating MSCs. MSCs incubated in 1250 ng/ml of PEDF deposited 50% more mineral than MSCs incubated in osteogenic medium alone. Mineral deposition was assessed by Alizarin Red and von Kossa staining. *, P<0.05, **P<0.01

Pin1 plays a critical role in Wnt3a-induced osteoblast differentiation through structural modification of β-catenin. Hea-rim SHIN*[1], Taegyung Lee[1], Young-Dan Cho[1], Won-Joon Yoon[1], Kyung Mi Woo[2], Jeong-Hwa Baek[2], Hyun-Mo Ryoo[2]. [1]Seoul National University, South Korea, [2]Seoul National University School of Dentistry, South Korea

Canonical Wnt signaling plays an important role in osteoblast differentiation, in which β-catenin is the key mediator. Pin1 (Peptidylprolyl cis/trans isomerase, NIMA-interacting 1) isomerizes only phophorylated Serine/Threonine-Proline motif. It regulates the conformational change of β-catenin, which has known to be associated with increased cancer risk, because of increased β-catenin level in nucleus. Canonical Wnt signaling also is very important in osteoblast differentiation, however, association of Pin1 in this signal transduction pathway is still unknown. The specific aim of this study was to investigate what if Pin1 is involved in the Wnt-induced osteogenesis. Inhibition of Pin1 activity by Juglone treatment repressed Wnt3a-induced osteoblast differentiation and bone marker gene expression in C2C12 cells. In contrast, overexpression of Pin1 stimulated osteoblast differentiation of C2C12 cells by Wnt3a administration. The transcriptional synergy including TOP flash and ALP promoter activity was observed with Pin1 and Wnt3a. We demonstrated that Pin1 binds to β-catenin. Its interaction was occurred by Wnt3a-induced ERK dependent phosphorylation of β-catenin and it enhanced stability of β-catenin. On the other hand, when we treated the U0126, an ERK inhibitor, the stability of β-catenin was reduced. Consequently, Pin1 increases retention of β-catenin in nucleus, which may explain the increased reporter activity. Taken together, our results reveal that Pin1 is a novel regulator that promotes osteoblast differentiation through structural modification and stabilization of β-catenin. These results provide us a great insight for the importance of Pin1 and the crosstalk between ERK MAP kinase and Wnt signaling pathway in bone development.

Toll-Like Receptor 2 Modulating Lipids of *Porphyromonas Gingivalis* Inhibit Osteoblast Differentiation and Function. Yu-Hsiung Wang*, Qiang Zhu, Jin Jiang, Jianping Huang, Robert Clark, Frank Nichols. University of Connecticut Health Center, USA

Porphyromonas gingivalis (*P. gingivalis*), a Gram(-) anaerobic organism associated with chronic periodontitis, is reported to promote periodontal bone loss through engagement of Toll-like receptor 2 (TLR2). However, the virulence factors responsible for periodontal bone loss have not been identified. We have previously shown that the total lipid extract of *P. gingivalis* inhibits osteoblast-mediated bone deposition through engagement of TLR2. Recent work has shown that an unusual serine lipid, called Lipid 654, is the primary lipid class of *P. gingivalis* that engages TLR2. The purpose of the present study was to examine the effect of Lipid 654 on osteoblast differentiation, gene expression, and mineralization in cell culture. Calvarial osteoblasts were isolated from mice transgenic for pOBCol3.6GFP. This GFP reporter is activated in the early preosteoblasts and its activity intensifies as osteoblasts differentiate. Lipid 654 was highly enriched by HPLC and purity was verified by mass spectrometry. Lipid 654 was compared with the total lipid extract of *P. gingivalis* by sonicating lipids in culture medium immediately prior to addition to cell cultures. Our results showed that the expression of pOBCol3.6GFP (examined by cell fluorescence) and mineralized nodule formation (revealed by von Kossa's staining) were substantially inhibited by *P. gingivalis* total lipids. The same effects were observed in the cultures treated with Lipid 654. Gene expression using PCR showed that the expression of osteoblastic markers of bone sialoprotein, dentin matrix protein, and osteocalcin were down-regulated in cultures treated with Lipid 654 when compared with the control cultures. In contrast to the inhibition of osteoblastic markers, ELISA of culture medium from osteoblast cells treated with Lipid 654 showed a significant increase in tumor necrosis factor alpha secretion. We also examined the role of TLR2 in lipid-induced inhibition of osteoblast differentiation using cell cultures derived from mice transgenic for pOBCol3.6GFP with deleted expression of TLR2 (*TLR2*$^{-/-}$). Both *P. gingivalis* total lipids and Lipid 654 failed to inhibit the expression of pOBCol3.6GFP and the mineral nodule formation in *TLR2*$^{-/-}$ cells. These results demonstrate that a highly enriched preparation of Lipid 654 of *P. gingivalis* significantly inhibits osteoblast differentiation and function through engagement of TLR2. Future work will evaluate the effect of Lipid 654 on osteoblast cell function in vivo.

Abnormal Mitochondrial Energetics in Osteoblasts Derived from Aromatase Deficient Male Mice. Orhan Oz*[1], Aktar Ali[2], Jianfei Guo[2]. [1]University of Texas Southwestern Medical Center, Dallas, USA, [2]UT Southwestern Medical Center at Dallas, USA

Estrogens regulate both formation and metabolism and regulate glucose and lipid metabolism. Aromatase catalyzes the formation of estrogens from androgen precursors. Aromatase deficient (ArKO) male mice develop adiposity, have low turnover osteopenia, low lGF-I levels and increased leptin levels associated with low levels of osteocalcin, a regulator of glucose homeostasis. In vitro differentiation assays bone marrow cells from 12 week old male mice develop fewer alkaline phosphatase colonies and mineralized nodules. To determine if osteoblasts derived from ArKO mice have altered mitochondrial function we studied using the XF24 analyzer. Bone marrow cells from WT and ArKO mice were allowed to differentiate for 7- 10 days under osteogenic conditions. The differentiated cells from ArKO mice did not show a significant difference in basal respiration but showed higher maximal respiration when compared to WT cells. The maximal respiratory rate was increased by 2h treat with estradiol (10-8M) or the ERalpha agonist PPT in WT with estradiol being more potent. On the other hand the response in ArKO cells varied in different experiments from either no estradiol induced enhancement or relatively suppressed enhancement. These data show that estradiol can regulate osteoblast metabolism.

From fibers to peptides: The mechanism of collagen degradation by cathepsin K. Dieter Bromme*. The University of British Columbia, Canada

Introduction: Cathepsin K (catK), a cysteine protease highly expressed in osteoclasts, is the only mammalian collagenase that effectively cleaves at multiple sites within triple-helical collagens. We have previously demonstrated that the collagenase activity of catK requires the presence of glycosaminoglycans (GAGs). Based on novel X-ray structures of catK-chondroitin sulfate complexes, we propose that the active collagenase forms either tetramers or dimers of catK molecules. These oligomers are responsible for the degradation of tropocollagen molecules and collagen fibers.

Methods: Various catK variants were expressed in *Pichia pastoris* and purified. The enzymatic activities of the variants as well as of wild type catK were tested using soluble and insoluble type I collagen, gelatin, and a fluorogenic peptide substrate. Atomic force microscopy (AFM) and circular dichroism (CD) were used to characterize the interactions between catK and collagens and scanning electron microscopy (SEM) was used to characterize the degradation of collagen fibers.

Results: The most effective degradation of collagen was achieved at molar ratios of 2:1 (catK : GAG). AFM studies indicated that the tetramer is active at soluble triple helical collagen whereas dimers are likely acting on insoluble collagen fibers. The tetramer forms a central pore that is sufficient to accommodate triple helical collagen. CD-analysis suggests that the tetrameric complex acts as a helicase by unwinding the collagen helix. Mutations within the pore, and at sites of the chondroitin sulfate-protein and protein-protein interactions of the complex significantly decreased the collagenase activity of the variant proteins without interfering with their non-collagenase activities. For the dimer, mutation at the protein-protein interaction sites specifically inhibited the degradation of insoluble collagen. AFM, SEM, and degradation studies suggest that catK releases triple-helical tropocollagen fragments from the fiber that are subsequently degraded into small peptides.

Conclusions: The collagenase activity of catK depends on specific dimer and tetramer forms of catK/GAG complexes. The inhibition of complex formation may represent a highly specific method to selectively inhibit the therapeutically relevant collagenase activity of this enzyme.

Effect of celecoxib on osteoclast differentiation. Kakei Ryu*[1], Hitoshi Amano[2], Haruka Emori[1], Takehiko Sambe[1], Katsuji Oguchi[1], Shinichi Iwai[3]. [1]Department of Pharmacology, School of Medical, Showa University, Japan, [2]Showa University School of Dentistry, Japan, [3]Department of Healthcare & Regulatory Sciences, School of Pharmacy, Showa University, Japan

Introduction: Prostaglandin E_2 (PGE_2) an inflammatory cytokine, produced by cyclooxygenase-2 (COX-2) acted on osteoclast formation not only bone resorption. The aim of this study was undertaken to investigate whether celecoxib, a selective COX-2 inhibitor, a direct effect on osteoclast differentiation.

Materials and Methods: Bone marrow cells from femur and tibia of five-weeks-old male ddY mice passed Sephadex G10. The cells were cultured with pH7.0 αMEM, which include CSF-1 (25 ng/ml) RANKL (100 ng/ml), with or without celecoxib (2.5 - 30 μM) and with or without PGE_2 (0.1 μM). RAW 264.7 cells for this experiment are the same as before, added only RANKL.

Result: Cells use abcam® Anti-COX2 / Cyclooxygenase 2 rabbit polyclonal antibody for primary antibody and immunostaining shows COX-2 protein was expressed in osteoclasts in the presence of CSF-1 and RANKL. After 6 days, both cells were differentiated to TRAP positive multinucleated osteoclasts. The number of osteoclast was suppressed completely with 30 μM celecoxib. Further additional PGE_2, the number of actin ring having osteoclast recovered in the presence of 2.5 μM and 5 μM celecoxib.After 8 days, pit formation assay showed bone-resorption was suppressed in a dose-dependent of celecoxib.

Discussion: These result showed that the activity of COX-2 inhibitor may directly inhibit the osteoclastogenesis and differentiation via inhibited PGE_2 synthesis.

Conclusion: COX-2 dependent signaling pathway might be involved in the process of osteoclast differentiation.

SA0251

EphrinB2/EphB4 control of osteoclast formation is mediated by the osteoblast lineage. Stephen Tonna*[1], Farzin Takyar[2], Blessing Crimeen-Irwin[1], Patricia Ho[3], T. John Martin[3], Natalie Sims[3]. [1]St Vincent's Institute, Australia, [2]Yale University, School of Medicine, USA, [3]St Vincent's Institute of Medical Research, Australia

Osteoblasts express both the EphB4 receptor and its ligand ephrinB2, while osteoclasts express only ephrinB2. It has been reported that ephrinB2 reverse signaling in the osteoclast lineage restrains their differentiation. In addition, pharmacological inhibition of ephrinB2/EphB4 interaction within osteoblasts promoted osteoclast formation by increasing osteoblastic RANKL production (Takyar et al., JBMR 2013). To determine whether the key pathway restraining osteoclast formation is EphB4 forward signaling within the osteoblast lineage or ephrinB2 reverse signaling in the osteoclast or the osteoblast lineages, we conditionally deleted the ephrinB2-signaling domain from both lineages using Ctsk.Cre and Osx1.Cre.

Stimulation of ephrinB2 reverse signaling with exogenous clustered EphB4-Fc in osteoclast cultures (wild-type bone marrow macrophages plus RANKL/M-CSF) had

no significant effect on osteoclast numbers. In addition, the number of osteoclasts generated with RANKL/M-CSF from Ctsk.Cre.EfnB2f/f precursors was not increased compared to Ctsk.Cre.EfnB2wt/wt controls. This indicates that ephrinB2 reverse signaling within the osteoclast lineage does not restrain osteoclast formation.

In both neonate and adult Osx1.Cre.EfnB2f/f mice, osteoclast numbers were decreased compared to Osx1.Cre.EfnB2wt/wt controls. Consistent with this, Osx1.Cre.EfnB2f/f calvarial osteoblasts showed a 50% reduction in RANKL mRNA and reduced support of osteoclast formation in co-culture with wild-type bone marrow. In contrast, inhibition of ephrinB2 interaction with EphB4 by a receptor antagonist (soluble EphB4) increased RANKL expression in both Osx1.Cre.EfnB2f/f and Osx1.Cre.EfnB2wt/wt control osteoblasts. Furthermore, soluble EphB4 increased osteoclast formation to the same extent from both Ctsk.CreEfnB2f/f and Ctsk.CreEfnB2wt/wt bone marrow precursors in co-culture with wild-type osteoblasts. This demonstrates that EphB4 forward signaling in osteoblasts restrains osteoclast formation by limiting RANKL production, and that this is not modified by ephrinB2 reverse signaling in either osteoblasts or osteoclasts.

In conclusion, this data indicates that the interaction of ephrinB2 and EphB4 within the osteoblast lineage restrains osteoclast formation by limiting RANKL availability and this is mediated through EphB4 forward signalling. A role of reverse signaling through ephrinB2 inhibiting osteoclast formation in either osteoblasts or osteoclasts was not demonstrated in this work.

Gene Expression Profiling during RANKL-Induced Osteoclastogenesis Using RNA-Sequencing and Identification of the Novel Component of NFATc1 Transcription Complex. Tomohiko Yoshida*[1], Akitoshi Nakayama[2], Hidekazu Nagano[2], Hisashi Koide[2], Yutaka Suzuki[3], Sumio Sugano[3], Ichiro Tatsuno[4], Koutaro Yokote[2], Tomoaki Tanaka[2]. [1]Chiba University Hospital, Japan, [2]Division of Endocrinology, Diabetes & Metabolism, Chiba University Graduate School of Medicine, Japan, [3]Institute of Medical Science, University of Tokyo, Japan, [4]Center for Diabetes, Metabolism & Endocrinology, Toho University Sakura Medical Center, Japan

Background: During osteoclastogenesis, osteoclast precursors undergo dramatic changes in the morphology and function, in which mononuclear preosteoclasts proliferate in bone marrow, are fused into multinuclear osteoclasts, and are activated to resorb bone. Osteoclast differentiation is characterized by the sequential expression of specific genes in response to certain signals such as RANKL and M-CSF, and the transcription factor NFATc1 plays a pivotal role in regulating downstream gene expression. However, little is known about the constituent molecules of NFATc1 transcription complex and their role in the osteoclastogenesis. The objectives of the current study were to a) analyze the transcriptome during RANKL-induced osteoclastogenesis including non-coding RNAs using RNA-sequencing, and b) identify the key constituents of NFATc1 transcription complex and their role in the epigenetic gene regulation.

Methods: To evaluate global changes in gene expression during RANKL-induced osteoclastogenesis, gene expression profiling was performed in murine pre-osteoclastic RAW264.7 cells using Illumina® genome analyzer by comparing the difference between treatment and control groups at four different time points (2, 3, 7, 14 days after treatment with RANKL). To identify the NFATc1 binding protein(s), putative NFATc1 transcription complex was isolated from the cell lysate of HEK293 cells expressing FLAG- and HA- tagged human NFATc1 protein by tandem affinity purification, and was separated by SDS-PAGE and bands of interest are cut from the gel, and the generated peptides are sequenced by LC-MS/MS.

Results: Regarding the mRNA expression of NFATc1, calcitonin receptor, cathepsin K and β3 integrin, the highest level was observed at 3 days after treatment with RANKL. The peak gene expression of TRAP and DC-STAMP was occurred at 7 days. Moreover, several novel potential osteoclastogenic genes and non-coding RNAs (e.g., miR 146a) were found to be induced after the treatment. Polycystic kidney disease protein1 (PKD1) and other novel proteins were identified as the putative component of NFATc1 transcription complex.

Conclusions: We have identified several putative constituents of NFATc1 transcription complex, and found that each NFATc1 downstream gene has a different timing of its peak expression, suggesting stage-specific regulation of the each NFATc1 target genes.

Inhibitory effects of intravenous immune globulin (IVIG) on osteoclastogenesis and bone resorption. Elisha Lim, Lionel Ivashkiv, Kyung-Hyun Park-Min*. Hospital for Special Surgery, USA

Intravenous immune globulin (IVIG) is an effective therapy in a variety of autoimmune and chronic inflammatory diseases. Investigations of the therapeutic effects of IVIG have focused on the suppression of autoantibody and immune complex-mediated pathogenic mechanisms. It is increasingly appreciated that IVIG can exert its inhibitory effects through not only inhibitory Fcγ receptors but also activating Fcγ receptors. It has been shown that IVIG protects mice from developing inflammatory arthritis via a prominent contribution of activating Fcγ receptors. Here, we investigated whether IVIG directly controls osteoclast differentiation and whether this pathway represents a potential therapeutic target for osteoclast-mediated bone destruction. Using the TNF-induced supracalvarial osteolysis model, we show that IVIG administration significantly decreased serum tartrate-resistant acid phosphatase (TRAP), a marker of in vivo osteoclastogenesis and bone resorption. Consistent with this reduction, treating human blood-derived osteoclast precursor cells (OCPs) with IVIG suppressed *in vitro* osteoclastogenesis. Previously, we showed that soluble immune complexes (sICs) in the IVIG pool play an important role in its inhibitory action. In this study, we find that cross-linking Fcγ receptors with either sICs or plate-coated IVIG could efficiently block osteoclastogenesis and the expression of osteoclast-related genes such as integrin β3 and cathepsin K in a dose-dependent manner. Mechanistically, both sICs and plate-coated IVIG suppress osteoclastogenesis by downregulating RANKL-induced expression of NFATc1, the master regulator of osteoclastogenesis. Suppression of *NFATC1* expression was mediated in part by the transcriptional suppressor Bcl6. RANKL stimulation diminished levels of Fcγ receptors, and thus RANKL-pretreated cells were refractory to the inhibition of osteoclastogenesis by IVIG, further supporting the role of Fcγ receptors in IVIG-mediated inhibition of osteoclastogenesis. Taken together, our results suggest that crosslinking of Fcγ receptors directly suppresses osteoclastogenesis and regulates bone resorption.

miRNA-29 Promotes Osteoclastogenesis Through Regulation of Osteoclast Commitment and Migration. Tiziana Franceschetti*, Catherine B. Kessler, Sun-Kyeong Lee, Anne Delany. University of Connecticut Health Center, USA

Osteoclast differentiation is complex and tightly regulated at multiple levels. microRNAs (miRNAs) are key post-transcriptional factors that control gene expression, and play a critical role in osteoclastogenesis. Although disrupted miRNA processing results in osteopetrosis, the function of specific miRNAs in osteoclasts is elusive.

We analyzed the role of the miR-29 (a/b/c) family in osteoclast differentiation, using primary cultures of mouse bone marrow-derived macrophages. Retroviral-mediated miR-29a knock-down decreased osteoclast formation and size. qRT-PCR showed that expression of the miR-29 family increased during osteoclast differentiation, in concert with mRNAs for TRAP and Cathepsin K. Similar regulation was observed in the monocytic cell line RAW264.7.

To determine the function of miR-29 in osteoclastogenesis, we used as a model stably transduced RAW264.7 cells expressing a doxycycline (DOX)-inducible miR-29 competitive inhibitor, or miR-29 ''sponge'' construct. Expression of the miR-29 sponge impaired RAW264.7 differentiation into osteoclastic cells and decreased the size of cells formed. The miR-29 sponge inhibited the chemotactic migration of RAW264.7 cells toward M-CSF, and promoted macrophage lineage commitment. However, the miR-29 sponge did not affect precursor cell replication, or the actin ring formation and apoptosis of mature osteoclasts.

To better understand how miR-29 regulates osteoclast function, we validated novel miR-29 target genes using Luciferase-3'-UTR (untranslated region) reporter assays and miR-29 inhibitors. miR-29 targeted the UTR of RNAs critical for cytoskeletal organization, including Cell Division Control protein 42 (Cdc42) and SLIT-ROBO Rho GTPase activating protein 2 (srGAP2). miR-29 also targeted the UTR of RNAs associated with the macrophage lineage, including G protein-coupled receptor 85 (GPR85), Nuclear Factor I/A (NFIA), and CD93. Additional novel miR-29 targets that promote osteoclast differentiation included the proton sensor GPR68, Calcitonin receptor (CTR), and Jun Dimerization Protein 2 (JDP2).

miR-29 is a positive regulator of osteoclast formation, promoting motility and progenitor commitment. Since miR-29 also targets RNAs that are positive regulators of osteoclast differentiation, this miRNA family may control the tempo of osteoclast maturation. An expanded understanding of how miRNAs regulate osteoclast formation and activity may lead to new therapeutics for skeletal disease.

MSK1 is a novel signaling molecule involved in RANKL-induced osteoclastogenesis. Hong-Hee Kim*[1], Hyung Joon Kim[1], Jeongim Ha[1], Hao Huang[2], Zang Hee Lee[3]. [1]Seoul National University, South Korea, [2]University of Chicago, USA, [3]Seoul National University School of Dentistry, South Korea

MSK (Mitogen- and stress-activated protein kinase) 1 is a Ser/Thr protein kinase that is activated by ERK1/2, JNK, and p38 MAPKs. This kinase has been suggested to play a role in the regulation of immune responses and mitogenic signaling. The activation of MAPK signaling pathway is one of the intracellular signaling events triggered by RANK stimulation in osteoclasts. Therefore, we explored the possibility

of MSK1 involvement in osteoclast differentiation by RANKL (receptor activator of nuclear factor kappaB lingand). We found that ERK1/2 and p38, but not JNK, could activate MSK1 upon RANKL stimulation of bone marrow-derived macrophages (BMMs) used as osteoclast progenitor cells. Inhibition of MSK1activity with a chemical reagent and suppression of MSK1 expression with a siRNA oligonucleotide resulted in a reduced formation of osteoclasts from BMMs with concomitant decrease in c-Fos and NFATc1 expression. The anti-osteoclastogenic effect of MSK1 siRNA was verified in vivo in a calvarial bone resorption model with RANKL. Our results suggest that MSK1 is an important novel signaling molecule involved in osteoclastogenesis induced by RANKL.

Mutation in SNX10 gene leads to autosomal recessive osteopetrosis and formation of osteoclasts unable to resorb bone. Petra Henning*[1], Eva-Lena Stattin[2], Per-Erik Sandström[3], Christina Stecksen-Blicks[4], Therese G. Kellgren[5], Patrik Ryden[5], Torsten Lönnerholm[6], Niklas Dahl[7], Joakim Klar[7], Ulf Lerner[8]. [1]Centre for Bone & Arthitis Research, University of Gothenburg, Sweden, [2]Department of Medical Biosciences, Medical & Clinical Genetics, Umeå University, Sweden, [3]Barnkliniken, Umeå University Hospital, Sweden, [4]Pediatric Dentistry, Department of Odontology, Faculty of Medicine, Umeå university, Sweden, [5]Department of Mathematics & Mathematical Statistics, Computational Life science Cluster (CLiC), Umeå University, Sweden, [6]Department of Radiology, Akademiska sjukhuset, Uppsala University, Sweden, [7]Department of Immunology, Genetics & Pathology, Science for Life Laboratory, Uppsala University, Sweden, [8]University of Umea, Sweden

Autosomal recessive osteopetrosis (ARO) is a rare disease having an incidence of 1 in 250,000 births. ARO can vary in severity from mild to severe and at least 10 genes leading to dysfunctional osteoclasts have been identified as causative.

We have studied eight individuals with intermediate form of ARO from the county of Västerbotten in Northern Sweden. Using Exome Sequencing, three patients were found to be homozygous for a splice site mutation in the Sorting Nexin 10 gene (SNX10) located at the donor splice site of exon 4 (c.212+1G>T). Sanger sequencing verified the mutation in all patients and their parents were found to be heterozygous. The phenotype is characterized by short stature and generalized increase in bone density with a radiological bone-within-bone appearance. All cases have experienced multiple fractures.

In vitro osteoclastogenesis using CD14+ monocytes purified from peripheral blood and cultured in M-CSF without and with RANKL was studies. There was no proliferative or morphological differences between M-CSF treated cells from controls and cells from patients. When cultured on plastic, cells from patients robustly responded to RANKL with increased formation of TRAP positive osteoclasts .

Osteoclasts formed from cells from patients were larger than osteoclasts formed from cells from controls. The increased size of osteoclasts from patients was associated with decreased number of osteoclasts. The expression of genes known to be important for osteoclastic functions such as *ACP5, CTSK, ITGB3, ITGAV*, *TCIRG1* and *DCSTAMP* were similar in cells from patients and controls. When cultured on bone, cells from patients were capable to differentiate to multinucleated TRAP positive cells. Most importantly, these cells, in contrast to osteoclasts from healthy controls, were unable to resorb bone measured as CTX release.

Splice predictor programs (SpliceSiteFinder, MaxEntScan, NNSPLICE and GeneSplicer) suggested that the SNX10 mutation would result in the absence of exon 4 in the mRNA. Using TaqMan Assays with primers spanning the exon junctions we show that exon 1-2 is expressed at similar levels in cells from patients and controls. In contrast, there was a 20-30 fold reduction of spliced exon 4-5 mRNA levels.In conclusion, we have identified a SNX10 mutation associated with ARO and showed that monocytes from the patients can be differentiated to osteoclast and that these cells are unable to resorb bone.

A novel role of farnesyl diphosphate synthase (FDPS) on the activity of Cl^- extrusion in osteoclasts. Hiroshi Kajiya*, Takashi Tsutsumi, Yoshiyuki Nagaoka, Kazuko Goto-T, Teruhisa Fukawa, Mina Sasaki, Fujio Okamoto, Koji Okabe. Fukuoka Dental College, Japan

Farnesyl diphosphate synthase (FDPS), an important enzyme in mevalonic acid metabolism catalyzes the production of geranyl pyrophosphate and farnesyl pyrophosphate, resulting in increase prenylation in small GTP proteins. Prenylated GTP proteins are located to the membrane and activated in migration, proliferation, and differentiation. In contrast, nitrogen-containing bisphosphonates (NBPs) have well known to inhibit FDPS, leading to disturbance of polymerization in cytoskeleton structure during bone resorption and promotion in apoptosis in mature osteoclasts.

However, little is known whether FDPS regulate directly the bone resorption activity, including in hydrochronic acid extrusion via specific transporters in mature osteoclasts. Using yeast two-hybrid screening method, we found that the FDPS were combined with cytoplasmic domain of ClC-7 Cl^- transporters. Therefore, the aim of this study was to investigate the expression and functional role of FDPS on the extrusion activity of ClC-7 Cl^- transporters in osteoclasts.

FDPS were expressed in osteoclast precursors and slightly upregulated by RANKL during osteoclastogenesis. Furthermore, FDPS was associated and colocalized with ClC-7 Cl^- transporters in mouse osteoclasts and HEK cells coexpressing FDPS and ClC-7 Cl^- transporters. Extracellular acidification induced outwardly rectifying Cl^- currents and decreased intracellular Cl^- concentration ($[Cl^-]_i$) associated with in ClC-7 Cl^- transporters in osteoclasts. Zoledronic acid and alendronate sodium, FDPS inhibitors suppressed acid-induced Cl^- currents and $[Cl^-]_i$ reduction in a dose-dependent manner. The tetracycline-induced FDPS silencing significantly suppressed the Cl^- currents and $[Cl^-]_i$ reduction. In contrast, the inhibitory action of zoledronic acid was rescued by addition of geranylgeranyl acid, a derivative of mevalonic acid metabolism. In transgenic mice overexpressing with FDPS under control of cathepsin K promoter (*ctsk* FDPS Tg-mice), bone mineral density significantly decreased with elevation of the number of osteoclasts, but not osteoblasts compared to WT mice. Furthermore, the activation of the acid-induced Cl^- currents dominantly augmented in osteoclasts derived from *ctsk* FDPS Tg-mice.

The results suggest that FDPS may contribute to regulate the bone resorption activity, especially the ClC-7 Cl^- transporter activity in mature osteoclasts because FDPS inhibitors NBPs, at least partially, suppressed the activity of Cl^- transporters.

Dual Modulation of Activin A on Osteoclast Differentiation, Activity and Survival. Tristan Fowler*, Archana Kamalakar, Nisreen Akel, Larry Suva, Dana Gaddy. University of Arkansas for Medical Sciences, USA

The process of bone resorption is regulated at multiple levels. Current bone-active therapies primarily target bone resorption, whereas additional targets such as the formation of osteoclasts (OC), and their motility, fusion and lifespan have been largely unexplored. We and others have shown that RANKL and Activin A (ActA) are potent stimulators of murine bone marrow osteoclastogenesis. However, ActA treatment does not induce osteoclastogenesis in purified populations of murine bone marrow macrophages (BMM), but inhibits RANKL-induced OC development. We hypothesized that these factors differentially regulate the migration of both OC precursors and mature OC. We determined the effects of ActA and RANKL on BMM motility and bone resorption using time-lapse video microscopy. BMMs were plated onto culture dishes with 25 ng/ml mCSF alone for 24hr, prior to the addition of 100 ng/mL RANKL or 50 ng/mL ActA, alone or together, for up to 4d. Other BMMs were cultured on bone slices for 5d in the presence of mCSF+RANKL to stimulate OC differentiation prior to treatment with RANKL or ActA, alone or together for an additional 1-2d. Cells were imaged at 60 images/hour and the cells maintained at 37℃ and 5% CO_2/Air. The 4hr movement of ten individual motile OC precursors were tracked and analyzed with NIH ImageJ. Parameters calculated for each individual cell track included cumulative track length, migration rate, maximum instantaneous velocity, range of velocity, and percent total displacement. BMMs migrated at a constant velocity and distance from d1-4. RANKL significantly increased motility parameters on d2 and d3, an effect that was lost by d4. In contrast, ActA treatment decreased all motility parameters on d1-4. Surprisingly, when added with RANKL, ActA treatment completely blocked all RANKL stimulated OC precursor motility on plastic, as well as mature RANKL-stimulated OC motility on bone slices. ActA treatment of mature OC (d5) also suppressed RANKL-stimulated bone resorption, measured by pit formation. The suppression appeared to be associated with a decrease in OC lifespan, since ActA increased activated Caspase 3, and caused a decrease in actin ring formation in mature OC on bone slices. Collectively these data indicate a dual modulatory function of ActA on OCs. ActA indirectly stimulates murine whole bone marrow osteoclastogenesis, but it also directly inhibits RANKL-induced murine OC differentiation, motility, and resorption and enhances OC apoptosis.

Loss of *Aim2* is Associated with Increased BMD and Decreased Bone Resorption. Kathryn Shultz*[1], Laura Reinholdt[1], Leah Rae Donahue[1], Katherine Fitzgerald[2], Leonard Shultz[1], Wesley Beamer[1], Cheryl Ackert-Bicknell[1]. [1]The Jackson Laboratory, USA, [2]Department of Medicine, University of Massachusetts Medical School, USA

Genetic association with bone mineral density (BMD) regulation have been demonstrated for human Chr 1q and at the distal end of mouse Chromosome 1 (Chr 1). The mouse locus, designated Bmd1, is in fact a series of smaller effect size loci. Consequently multiple genes in this region affect BMD. Using nested congenic mouse strains (C57BL/6J strain carrying small C3H/HeJ Chr 1 regions), we narrowed one of these loci to a 0.152 Mb segment containing the gene, Aim2 (Absent in melanoma2), and a predicted gene Gm4955. We found that at 16 weeks of age, female mice lacking the Aim2 gene have significantly increased whole body areal (a)BMD as compared to wildtype controls (Aim2-/-: 0.0538 ± 0.0007 vs Aim2+/+: 0.0508 ± 0.0007 g/cm2, p = 0.004). Further, femoral volumetric (v)BMD is also increased in Aim2-/- mice (Aim2-/-: 0.650 ± 0.009 vs Aim2+/+: 0.611 ± 0.012 mg/mm3, p = 0.006). Gene expression analyses suggested that Aim2 is expressed in both osteoblasts and osteoclasts. We cultured calvarial osteoblasts from neonatal Aim2-/- and Aim2+/+ mice. No differences were found in alkaline phosphatase activity between the Aim2-/- and Aim2+/+ cells at day 6 post differentiation or in mineralized nodule formation at day 14 post differentiation. Thus, Aim2 does not appear to affect bone formation or mineralization in culture. We cultured bone marrow cells from 6 week old female Aim2-/- mice in the presence of mCSF and RANK ligand. No differences in TRAP positive, multinucleated osteoclast cell number were observed between the Aim2-/- and Aim2+/+ cultures (Aim2-/-: 653 ± 59 vs Aim2+/+: 690 ± 89, p = 0.74). Thus, Aim2 did not affect either osteoclast precursor pools or osteoclast maturation. To explain the increased BMD in Aim2-/- mice, we hypothesize that the osteoclasts were deficient in activity. Urinary deoxypyridinoline (DPD, marker of bone resorption) was assayed in 8 week old female Aim2-/- and Aim2+/+ mice and found to be significantly lower in Aim2-/- vs controls (corrected for urinary creatinine, Aim2-/-: 4.67 ± 0.24 vs Aim2+/+: 6.60 ± 0.38, $p < 0.001$). The combined in vivo resorption marker and BMD data suggest that Aim2 has a regulatory role in osteoclast function. Aim2 is part of the interferon-inducible gene cluster, and its deficiency activates interferon signaling suggesting that this gene links the skeletal and immune systems. In summary, we show that loss of Aim2 impacts bone biology, supporting the hypothesis that this gene underlies one of the distal Chromosome 1 BMD loci.

Molecular Mechanism of the Inhibitory Effect of Oleanolic Acid on Osteoclastogenesis. Dongfeng Zhao*[1], Xu Feng[2], Yongjun Wang[3]. [1]The University of Alabama At Birmingham, USA, [2]University of Alabama at Birmingham, USA, [3]Longhua Hospital, Shanghai University of Traditional Chinese Medicine, China

Oleanolic acid (OA) is one of the major active ingredients from Chinese medicinal herb Nvzhenzi (Fructus Ligustri Lucidi), which exerts beneficial effects on various organs including the skeleton. We have recently demonstrated that OA exerts the osteoprotective effect in part by promoting bone formation via the stimulation of osteoblast differentiation. Interestingly, a number of studies showed that OA derivatives inhibit osteoclastogenesis. The objective of this study was to investigate the effect of OA on osteoclast formation and function. Primary mouse bone marrow macrophages (BMMs) were treated with M-CSF and RANKL in the presence of different doses of OA (0, 1, 2, 4, 8, 10uM) to promote osteoclastogenesis. We found that OA inhibited osteoclastogenesis dose-dependently and 10uM OA completely blocked osteoclastogenesis. Consistently, addition of OA (10uM) led to no resorption pits in bone resorption assays. Next, we pretreated BMMs with OA (10uM) for 4 days and OA-pretreated BMMs were fully capable of forming osteoclasts with M-CSF and RANKL stimulation, ruling out that this inhibitory effect of OA resulted from cytotoxicity. Notably, while lipopolysaccharide, IL-4 and IFN-γ inhibit osteoclastogenesis from fresh BMMs, they fail to do so with RANKL-primed BMMs. To determine whether OA acts similarly, we pretreated BMMs with M-CSF and RANKL for 1, 2, or 3 days prior addition of OA (10uM). Interestingly, OA is able to inhibit osteoclast formation from BMMs pretreated by RANKL as long as 3 days. These data indicate that the effects of OA on osteoclastogenesis are not affected by RANKL-mediated lineage commitment of osteoclast precursors. To elucidate the molecular mechanism underlying the inhibitory effect of OA on osteoclastogenesis, we determined whether OA affect known RANK signaling pathways. OA exerts no effect on the activation of ERK, p38, JNK and I?B pathways. However, OA impairs RANKL-induced expression of NFATc1 and four osteoclast genes (cathepsin K, matrix metalloproteinase 9, carbonic anhydrase 2 and tartrate acid resistant phosphatase) in both fresh and RANKL-pretreated BMMs. In conclusion, we have demonstrated that OA, similar to its various derivatives, exerts an inhibitory effect on osteoclastogenesis. Moreover, unlike other anti-osteoclast factors, OA can inhibit osteoclastogenesis from both fresh and RANKL-primed BMMs. Finally, OA inhibits osteoclastogenesis by suppressing the expression of NFATc1 and osteoclast genes.

Relationship between Soluble OSCAR and Disease Activity: A 12 Month Study of Newly Diagnosed RA Patients. Anak Dharmapatni[1], Roxanne Coleman[1], Michelle Lorimer[2], Andrew Zannettino[1], Helen Weedon[3], Mihir Wechalekar[3], David Haynes[1], Malcolm Smith[3], Tania Crotti*[4]. [1]School of Medical Sciences, The University of Adelaide, Australia, [2]School of Public Health, The University of Adelaide, Australia, [3]Rheumatology, Repatriation General Hospital, Australia, [4]University of Adelaide, Australia

Rheumatoid arthritis (RA) is characterized by synovitis and an increase in osteoclast number and activity, leading to bone erosions and joint destruction. Osteoclast-associated receptor (OSCAR) is a member of the leukocyte receptor complex and is involved in co-stimulating osteoclastogenesis. Studies suggest that OSCAR may contribute to the pathogenesis and severity of RA and osteoporosis (1, 2, 3, 4,). Increased levels of membrane bound OSCAR are associated with the peripheral blood monocytes (2), and synovial tissue macrophages and the vasculature in RA synovial tissues compared to healthy controls (2, 4). Conversely soluble (s) OSCAR is lower in the serum of active RA patients compared with healthy individuals (3). OSCAR-Fc has been shown to decrease osteoclast formation in pre-osteoclast: osteoblast co-cultures (5). We propose that successful treatment of RA results in increased cleavage of cell associated OSCAR resulting in increased sOSCAR levels in the joint. Thus elevated sOSCAR suppresses osteoclastic bone resorption and its elevation may be an early marker that can predict reduced joint damage and successful treatment. This study examines the changes in serum levels of sOSCAR following individual active RA patients from initial diagnosis (before treatment) through to 12 months of combination DMARD therapy.

Methods: The levels of sOSCAR in serum were measured by enzyme-linked immunosorbent assay (ELISA) of the serum from 10 RA patients at 0, 6 and 12 months (where possible). sOSCAR levels were compared at initial diagnosis and at 12 months using a paired t-test. Associations between sOSCAR and disease activity markers C-reactive protein (CRP), as well as the erythrocyte sedimentation rate (ESR), and disease activity score (DAS28), over time were also compared.

Results: Of interest sOSCAR significantly ($p = 0.04$) increased after 12 months treatment from baseline with a mean increase of 37ng/ml. No strong associations were observed between sOSCAR levels and CRP or ESR. However, in 6 of 8 patients DAS28 decreased whilst sOSCAR increased.

Conclusion: sOSCAR increases with combination DMARD therapy and sOSCAR may be inversely correlated with DAS28 in RA.

Salubrinal Inhibits Differentiation of Osteoclasts in Unloaded Mice. Ping Zhang*, Andy Chen, Hiroki Yokota. Indiana University – Purdue University Indianapolis, USA

Disuse osteoporosis is a skeletal problem induced by lack of weight bearing and imbalanced activities of osteoclasts and osteoblasts. We previously reported that salubrinal enhances healing of bone wounds. Little is known, however, about its effects on osteoclasts (OCL) in response to disuse. Herein, we addressed a question: in unloaded mice, does salubrinal suppress differentiation of OCL?

Forty C57BL/6 female mice (~14 wks) were subjected to unloading (20 for unloading controls, and 20 for salubrinal at 1 mg/kg), and 13 mice were used as age-matched controls. Changes in BMD/BMC in the lumbar spine, femur, and tibia were determined. To evaluate disuse-linked effects on OCL, bone marrow cells were harvested, and activities of OCL (formation, migration, and adhesion) as well as colony forming unit macrophage (CFU-M) were determined. Differentiation of osteoblasts was also examined using CFU assays for osteoblasts (CFU-OBL) and fibroblast-like MSCs (CFU-F).

Compared to age-matched controls, unloading induced a significant loss of BMD/BMC. Importantly, salubrinal suppressed reduction in BMD/BMC ($p<0.05$) compared to the unloading vehicle control. The cells isolated from the unloaded mice showed higher CFU-M, formation of OCL, migration of OCL progenitors, and adhesion of OCL (all $p<0.001$) compared to age-matched controls. Compared to the unloading control, salubrinal suppressed the number of CFU-M and the formation, migration and adhesion of OCL (all $p<0.001$). Salubrinal-driven reduction in the formation of OCL and CFU-M was dose-dependent. Furthermore, compared to the unloading control, salubrinal presented a significant increase in both CFU-F colonies ($p<0.01$) and CFU-OBL colonies ($p<0.001$).

This study demonstrates that unloading-reduced bone mass was significantly restored by salubrinal. The result is consistent with salubrinal's inhibitory effects on osteoclasts, as well as its stimulatory role on osteoblasts. The study provides evidence that salubrinal can be a potential therapeutic agent for preventing bone loss in disuse osteoporosis.

The Successful Design Of A Novel Highly Potent Nitrogen-Containing Bisphosphonate With Lower Bone Affinity. Frank H. Ebetino*[1], Mark Lundy[2], Aaron A. Kwaasi[1], James Dunford[3], Xuchen Duan[1], James Triffitt[4], Adam Mazur[5], Gwyn Jeans[6], Bobby L. Barnett[7], R Graham Russell[8]. [1]University of Oxford, United Kingdom, [2]Osteoresearch LLC, USA, [3]Oxford University, Headington, United Kingdom, [4]University of Oxford Nuffield Orthopaedic Centre, United Kingdom, [5]TWI Chem LLC, USA, [6]Procter & Gamble, USA, [7]University of Cincinnati, USA, [8]University of Oxford, United Kingdom

The antiresorptive mechanism of action of the current clinically used nitrogen-containing bisphosphonates (N-BPs) appears to be due to a combination of bone affinity characteristics, which target BPs to bone, and the inhibition of the farnesyl diphosphate synthase (FPPS) enzyme within osteoclasts and their precursors. Their prolonged presence in bone may be related to their high bone affinity. Bisphosphonates with lower bone affinity may provide more even skeletal distribution, shorter residence time on bone surfaces, lesser turnover reduction, and less concern about potential skeletal side effects. We have therefore sought to improve the profile of N-BPs by optimizing their inhibition of the FPPS enzyme while reducing their bone affinity. Driven by advances in structural biology, several optimized analogs were identified. When compared with the other clinically utilized N-BPs, one of these analogs, OX-14 (1-fluoro-2-(imidazo-[1,2-a]pyridin-3-yl)-ethyl-bisphosphonic acid) has the highest inhibitory potency at the enzyme and has the lowest affinity for bone mineral. This series, led by OX-14 (IC_{50}=2.5 nM), was an even more potent inhibitor of FPPS than zoledronate (IC_{50}=4.1 nM). Urinary excretion after parenteral dosing is inversely related to skeletal retention, and was greater for Ox-14 than for other N-BPs in rats, indicative of lower bone affinity. Thus, using ibandronate as a control = 1.0, the relative 24 hour urinary excretion of Aln, Zol, Ris, OX-14 was 0.53, 0.61, 1.0, 1.24 respectively. However, adequate bone affinity and excellent in vivo efficacy was demonstrated by OX-14 in the growing rat model. Thus OX-14 (D_{20}=0.0003 mg P/kg) was a very potent antiresorptive analog in vivo relative to other N-BPs (alendronate D_{20}=0.0016 mg P/kg; ibandronate D_{20}=0.0006 mg P/kg; zoledronate D_{20}=0.0001 mg P/kg) (D_{20}= the dose needed to produce a 20% increase in bone density above vehicle control). In a model of collagen induced arthritis in rats, OX-14 demonstrated efficacy similar to other potent N-BPs. In the knee, a 0.5 mg P/kg dose of OX-14 decreased bone resorption by 100%, as did zoledronate, while no dose tested of alendronate was completely antiresorptive. Since lower bone affinity BPs, at maximally effective doses, may reduce overall skeletal turnover less, these potent new FPPS inhibitors may also offer enhanced therapeutic utility in other bone related diseases including rheumatoid arthritis, osteoarthritis and certain cancers.

Periosteal Preosteoclasts Direct Cortical Bone Growth and Modeling by Secretion of PDGF. Hui Xie*[1], Zhuang Cui[2], Weizhong Chang[3], Chang-Jun Li[2], Lingling Xian[4], Bing Yu[5], Gehua Zhen[6], Janet Crane[3], Mei Wan[4], Maureen Pickarski[7], Le Thi Duong[8], Er-Yuan Liao[9], Xu Cao[3]. [1]Johns Hopkins Medical Institution, USA, [2]Department of Orthopaedic Surgery, Johns Hopkins Medical Institution, USA, [3]Johns Hopkins University, USA, [4]Johns Hopkins University School of Medicine, USA, [5]Johns Hopkins School of Medicine, USA, [6]The Johns Hopkins Hospital, USA, [7]Merck & Co., Inc., USA, [8]Merck Research Laboratories, USA, [9]Institute of Endocrinology & Metabolism, Second Xiangya Hospital of Central South University, China

Cortical bone makes up 80% of the weight of the human skeleton and provides mechanical support of the body and protection of vital organs, but little is known about factors that regulate cortical bone formation. Here we report that periosteal $Trap^+$ preosteoclasts (pOCs) secrete platelet-derived growth factor (PDGF) to induce migration of mesenchymal stem cells (MSCs) for cortical bone modeling. $Trap^+$ pOCs and osteoclasts are absent in CSF-1 knockout mice. There was a very thin cortical bone shell developed in the osteopetrotic CSF-1 knockout mice as detected by μCT and histology analysis. We hypothesized that the osteoclastic cell lineage could be essential to maintain normal cortical bone formation, and thus examined if these cells secret potential factor(s) to induce MSCs recruitment. Conditioned media from $Trap^+$ mononuclear pOCs derived from wild type (WT) mice was shown to induce migration of MSCs significantly more relative to conditioned media from $Trap^-$ monocytes. To identify the potential factor(s) secreted by pOCs, neutralizing antibodies specific for TGFβ2, TGFβ3, IGF-I, IGF-II, PDGF-AA, PDGF-BB, and noggin were evaluated with the conditioned media. The PDGF-BB antibody abolished the induced migration, though other neutralizing antibodies had no effect. Western blots confirmed that pOCs specifically secrete PDGF-BB, not PDGF-AA, and cells plated on bone slices enhanced the secretion of this growth factor. Moreover, PDGF-BB was co-localized with pOCs in the periosteum of WT mice, whereas no PDGF-BB was detectable in the periosteum of CSF-1 knockout mice. Genetic deletion of cathepsin K (CatK) in mice or pharmacological inhibition of CatK activity in ovariectomized monkeys has been shown to increase cortical thickness and periosteal bone formation. Here, the number of periosteal pOCs and the level of PDGF-BB were increased in CatK knockout mice and in WT mice treated with a CatK inhibitor. Conditioned medium of CatK-deficient pOCs or the CatK inhibitor-treated WT pOCs secreted more PDGF-BB and recruited more MSCs than conditioned medium of WT pOCs. This suggested that CatK inhibition stimulates cortical bone formation potentially via increasing pOC number and secretion of PDGF-BB. Taken together, the genetic and pharmacological evidence support the role of periosteal $Trap^+$ preosteoclasts in directing cortical bone formation by secretion of PDGF-BB.

Calcium-dependent actomyosin contractility in osteocytes. Andrew Baik*[1], Ivo Kalajzic[2], Elizabeth M.C. Hillman[1], Yingxiao Wang[3], Cheng Dong[4], X Guo[1]. [1]Columbia University, USA, [2]University of Connecticut Health Center, USA, [3]University of California, San Diego, USA, [4]Penn State University, USA

Intracellular Ca^{+2} ($[Ca^{+2}]_i$) oscillations, mediated by mechanosensitive Ca^{+2} channels and the ER Ca^{+2} store, have been observed in osteocytes in response to mechanical loading *in vitro* and *ex vivo* in our laboratory (Lu XL et al., 2012, Jing D et al., 2013). While many distant downstream gene expression pathways of $[Ca^{+2}]_i$ signaling have been studied, the immediate, temporally regulated effects of these numerous $[Ca^{+2}]_i$ oscillations in osteocytes have not been elucidated. A recent study in the gene expression of primary osteocytes has suggested high levels of muscle contraction-related proteins (Paic F et al., 2009). A hallmark of muscle is its $[Ca^{+2}]_i$-dependent actomyosin contractility. We hypothesized that osteocytes utilize $[Ca^{+2}]_i$ oscillations to activate pulsing, muscle-like contractile mechanical behavior. In this study, we used a fast 3D imaging technique to simultaneously measure the contractile behavior of the actin networks *and* $[Ca^{+2}]_i$ in single osteocytes.

$[Ca^{+2}]_i$ spikes were induced using fluid flow, ATP, or ionomycin in MLO-Y4 osteocytes (Figure 1). Contraction in the actin networks was measured immediately upon onset of $[Ca^{+2}]_i$ influx in all groups, indicated by a decrease in the strain value (Figure 1 A,B,C). Microtubule networks did not display a similar contractile response (Figure 1D). Longer imaging of contractions displayed reversible, phasic contractions in the actin networks over a period of ~180 seconds (Figure 1B).

As non-muscle and smooth muscle myosin II isoforms are regulated by myosin light chain kinase (MLCK) and skeletal and cardiac myosin II isoforms by troponins, we sought to determine the myosin responsible for the observed contraction. Under ATP stimulation, MLCK inhibition by ML-7 drastically altered the kinetics of contraction (Figure 1 E,F), but skeletal and non-muscle myosin II inhibition by blebbistatin had no effect (Figure 1E). This pointed towards a smooth muscle myosin mediated contraction. Furthermore, we verified the presence of smooth muscle myosin heavy chain (SMMHC) in primary osteocytes and MLO-Y4 osteocytes by western blot.

Here, we demonstrate a novel osteocyte mechano- and transduction behavior where $[Ca^{+2}]_i$ oscillations activate dynamic actomyosin contractions. Future studies will investigate downstream behaviors of contractility in osteocytes, such as contractility-mediated vesicle exocytosis (Wollman R et al 2012).

Cortical Bone Gene Expression is Altered by Post Obitum Isolation Treatment Prior to RNA Extraction in Adult Female Mouse Tibiae. Kimberly Atteberry*, Whitney Bullock, Russell Main. Purdue University, USA

Mouse cortical bone is commonly used in gene expression analyses of skeletal tissues to examine the effects of transgenic or experimental manipulations on osteocyte gene expression. Many methods are used to isolate osteocyte-enriched cortical samples prior to RNA isolation, including: (1) flushing the bone marrow with PBS and (2) flushing followed by collagenase digestion. When bone marrow is flushed with PBS, there likely remains a cellular layer lining the endosteum, which the collagenase treatment is designed to remove. To our knowledge, the effect of these different treatments on osteocyte gene expression and their ability to remove endosteal surface lining cells have not been systematically examined.

Female, 13 week old, C57Bl/6 mice were euthanized and both tibiae were extracted. The marrow was removed from all tibiae by repeated flushing with PBS. Following this, tibiae were either snap frozen in liquid nitrogen or subjected to one of two collagenase treatments (n=4-5/treatment). In Treatment 1, the tibial diaphysis was broken into fragments and subjected to a single-25 minute collagenase digestion. In Treatment 2, broken cortical tibial fragments were subjected to three-25 minute collagenase digestions. After each treatment, all samples were rinsed three times in αMEM, snap frozen in liquid nitrogen, and stored at -80˚C. RNA was subsequently isolated from all samples, quantified, and reverse transcribed to cDNA. Relative expression of DMP1 and Col1A1 were used to account for the proportion of osteocytes and osteoblasts in the sample. RPLP2 was used as an internal control gene and did not vary in expression between the Control group (PBS flush only) and Treatments 1 and 2. We hypothesized that expression of Col1A1 would decrease with the number of osteoblasts as the number of collagenase washes increased. DMP1 expression should not change across the treatments, as we expected osteocytes to be unaffected by the collagenase treatments.

Relative gene expression for Treatments 1 and 2 were calculated relative to the Control Treatment using the ΔΔCt method. Col1A1 expression did not change significantly following a single collagenase digestion in Treatment 1, but increased 240-fold in Treatment 2. DMP1 expression changed in a similar, yet less dramatic fashion. Overall, our results show that multiple collagenase treatments drastically alter cortical DMP1 and Col1A1 expression and should be avoided in future studies targeting these genes.

Osteocyte Lacuna Density Scales With Human Body Size. BIN HU*[1], Ingrid Murra[1], Yusuf Juwayeyi[2], John Chisi[3], Timothy Bromage[1]. [1]New York University College of Dentistry, USA, [2]Department of Anthropology, Long Island University, USA, [3]University of Malawi College of Medicine, Malawi

Aim: Comparative mammalian osteocyte densities are inversely relate to body mass. This relationship has never been tested among individuals that vary in body size within a single species. The goal of our research is to tally the number of osteocytes from human bone samples to evaluate the relationship between osteocyte density and body size.

Methods: Ten midshaft femurs obtained from sub-Saharan Africans of Bantu origin and known life history, and body mass index (BMI), were embedded in polymethylmethacrylate, sectioned and polished to 1μm finish. Montages of entire femur cross sections were obtained by backscattered electron microscopy in the scanning electron microscope (BSE-SEM) with a Zeiss EVO 50 SEM and SmartStich software. Monochrome 256 gray level images (0.978 μm/pixel) were converted to a binary, rendering lacunae to 0-level. Lacunae aspect ratios allowed them to be identified and automatically enumerated separately and measured in proportion to the detected bone area using Leica Quantimet 550 analysis software.

Results: The correlation between osteocyte lacuna density and body height was high, positive, and significant ($r = 0.78$, $R^2 = 0.54$, $p = 0.037$). When osteocyte lacuna density was evaluated in respect to an individual's BMI, the relationship improved further still ($r = -0.83$, $R^2 = 0.62$, $p = 0.022$), though it was negative. No relationship between osteocyte lacuna density was recovered in tests that included weight alone, nor were there any apparent associations with characteristics of an individual's social, economic, occupational, or medical history.

Conclusion: There is a relationship between human femoral osteocyte lacuna density and body height, though body weight interacts with body height to generate variability in bone cell density. In deference to comparative mammalian studies, the relationship between osteocyte lacuna density bore no relationship to body mass alone, but, instead, to a complex relationship with height and weight; i.e. BMI. Furthermore, while the comparative mammalian relationship between osteocyte lacuna density and body mass is negative, the relationship between lacuna density and height among humans is positive (though negative with BMI).

Sclerostin expression in bone is associated with bone mass. Nathalie Bravenboer*[1], Ruben Visser[2], Angela Oostlander[3], Eveline Sohl[3], Huib Van Essen[4], Annemieke Heijboer[5], Martin Den Heijer[6], Paul Lips[1]. [1]VU University Medical Center, The Netherlands, [2]Dept Clinical Chemistry, VU Unversity Medical Center, The Netherlands, [3]dept Endocrinology, VU University Medical Center, The Netherlands, [4]VU Medical Center, The Netherlands, [5]dept Clinical chemistry, VU University Medical Center, The Netherlands, [6]VU Medical CenterPostbus 70571007 MB Amsterdam, The Netherlands

Sclerostin is a major negative regulator of osteoblastic activity. Serum sclerostin has a weak positive association with bone mineral density (BMD), but high sclerostin levels were strongly associated with increased fracture risk. These contradictions could be explained by the fact that serum sclerostin does not reflect its action in bone. The aim of this study was to investigate whether sclerostin expression in bone is related to bone mass measured as BMD or using histomorphometry.Twenty six patients with Crohn's disease and osteopenia were included. These patients were a subgroup from a large randomized clinical trial, investigating treatment with risedronate (Crohn and Bone study registered as NTR 163 Dutch Trial Register). Sclerostin expression in bone was detected on iliac crest bone biopsies, using immunohistochemistry (mouse-human antibody, R&D systems) and measured as sclerostin positive cortical area (Scl postive area) (NIS elements, Nikon). Histomorphometry was performed according to the standardized nomenclature (Dempster et al., JBMR 2013, 28, 1: 2-17). DXA was used to obtain total hip (THP-BMD) and lumbar spine bone mineral density (LS-BMD).

Scl positive area showed a positive correlation with bone mineral density: for LS-BMD and THP-BMD, respectively.R=0.38 (95%CI 0.00-0.66) and R=0.55 (95%CI 0.27-0.75). Scl postive area was only weakly correlated with trabecular bone volume (BV/TV, R= 0.07, 95%CI -0.28-0.40) but slightly positively correlated with cortical thickness (CTh, R= 0.2, 95%CI -0.05-0.58, p= 0.08) Correlations between bone formation rate and osteoclast number were weak.

In conclusion, a positive correlation was detected between sclerostin expression in bone and BMD. This correlation was previously reported for serum as well. Correlations with histomorphometric indices indicate that cortical bone is more associated to sclerostin than trabecular bone. The impact of sclerostin expression in bone on bone quality needs further study.

A role for cementocytes in the pathogenesis of periapical bone resorption. Andiara De Rossi*[1], Raquel Silva[2], Sandra Alves[3], Lea Assed Bezerra da Silva[2], Paulo Nelson Filho[2], Marcos Antonio Rossi[4]. [1]Faculty of Dentistry of Ribeirão Preto, University of São Paulo, Bra, [2]School of Dentistry of Ribeirao Preto - University of Sao Paulo, Brazil, [3]School of Pharmaceutical Sciences of Ribeirao Preto - University of Sao Paulo, Brazil, [4]School of Medicine of Ribeirão Preto, University of São Paulo, Brazil

Periapical bone resorption occurs as consequence of polymicrobial infection of the dental pulp and root canal system, and ultimately results in destruction of periapical tissues including periodontal ligament, cementum and bone surrounding the tooth apex. Although osteocytes has been recently suggested to play role in regulation of bone diseases, the role of cementocytes in periapical bone loss has not been suggested. The aim of the present study was to evaluate the possible role of cementocytes in the regulation of periapical bone resorption at different stages of development. Inflammatory periapical bone resorption was experimentally-induced in the lower first molars of male C57BL/6 wild-type mice, aging 6 to 8 weeks, by pulp exposure to the oral environment. Intact teeth were used as controls. At 0, 7, 21 and 42 days following pulp infection, the periapical region was evaluated under conventional microscopy (morphologic analysis), fluorescence microscopy (morphometric analysis), immunohistochemistry (neutrophils, macrophages and lymphocytes), immunofluorescence (RANK, RANKL and OPG), enzymehistochemistry (osteoclasts) and RT-PCR (RNAm expression of IL-1alpha, TNF-alpha, IFN-gamma, KC, IL-17, RANK, RANK-L, OPG and catepsin K). Our results show a progressive increase in cementum and bone resorption, inflammatory cells and osteoclasts number, accompanied by enhanced mRNA levels of IL-1alpha, IFN-gamma, IL-17, RANKL, and catepsin K. The immunofluorescence showed that RANKL was expressed on cementocytes, and its expression increased with the lesion progression. Conclusion: our findings shows that cementocytes produce RANK-L in response to endodontic infection and are involved in the pathogenesis of bone resorptive periapical lesions.

Osteocytes Produce Interferon-β to Negatively Control Osteoclastogenesis. Chiyomi Hayashida, Junta Ito, Mai Nakayachi, Mari Okayasu, Yoshiyuki Hakeda, Takuya Sato*. Meikai University School of Dentistry, Japan

Interferon (IFN)-β deficiency causes osteoporosis because of an excessive osteoclastogenesis (OC-genesis), which has been widely accepted due to an incapability of RANKL-stimulated osteoclast precursors (OC-pre) to produce IFN-β as a negative feedback factor. OC-genesis during bone remodeling is controlled by osteocytic RANKL and OPG. However, other such factors have been largely unknown. Here we searched for osteocyte-derived OC-genesis regulatory factors using osteocytic MLO-Y4 cells and a newly developed culture system of primary osteocytes. First we studied the effects of MLO-Y4 cell-conditioned medium (MLO-Y4-CM) on M-CSF-induced OC-pre generation from bone marrow (BM) cells. The cells generated by M-CSF with MLO-Y4-CM showed an increased mRNA expression of double-stranded RNA-dependent protein kinase (PKR), which is known to inhibit c-Fos translation evoked by RANKL in OC-pre. Accordingly, when treated with soluble RANKL (sRANKL), the cells induced by M-CSF with MLO-Y4-CM exhibited a reduced capability of osteoclastic differentiation concomitant with decreased c-Fos translation. The addition of neutralizing anti-IFN-β antibody (αIFN-β-Ab) to MLO-Y4-CM during M-CSF-induced OC-pre generation partially abolished the increase in *PKR* mRNA expression in the generated cells. Consequently, the decreased c-Fos production and the reduced capability of osteoclastic differentiation were partially resuced. MLO-Y4 cells expressed *IFN-β* mRNA more than 400 times higher compared to OC-pre treated with sRANKL for 3 hr, a condition for OC-pre to significantly express *IFN-β* mRNA for negative feedback regulation. Next, we developed a culture system of osteocyte-enriched bone fragments (OEBFs), that osteocytes reside in lacunae of bone matrix freed from non-osteocytic cells by sequential collagenase/EDTA treatments. OEBFs expressed osteocyte marker genes, *DMP-1* and *sost* mRNAs, but not osteoblast marker gene, *keratocan.* Importantly, OEBFs produced *IFN-β* mRNA two times higher compared to intact bone fragments. When BM cells and OEBFs were cocultured without contact during M-CSF-induced OC-pre generation, OEBFs reduced the capability of the generated cells to differentiate into OCs, which was partially recovered by the addition of αIFN-β-Ab during coculture with OEBFs. OEBFs prepared from *OPG*-knockout mice had a similar effect on OC-pre generation. These data suggest that osteocytes produce IFN-β to negatively control OC-genesis.

PTH/PTHrP Receptor Signaling in Osteocytes Differentially Regulates Skeletal Homeostasis during Adulthood and Aging. Vaibhav Saini*[1], Keertik Fulzele[1], Xiaolong Liu[2], Christopher Dedic[2], Hiroaki Saito[3], Eric Hesse[3], Paola Divieti Pajevic[1]. [1]Massachusetts General Hospital; Harvard Medical School, USA, [2]Endocrine Unit, Mass General Hospital, Harvard Medical School, USA, [3]University Medical Center Hamburg-Eppendorf, Germany

Parathyroid hormone (PTH) is the only FDA approved anabolic agent to treat osteoporosis. PTH modulates bone turnover by binding to the PTH/PTH- related Peptide (PTHrP) type 1 receptor (PPR), highly expressed in bone and kidneys. Osteocytes, the most abundant cells in adult bone, also express PPR. However, physiological relevance of PPR signaling in osteocytes remains to be elucidated. Osteocytes may partially mediate the anabolic effects of PTH by suppressing SOST/Sclerostin, a Wnt signaling inhibitor. To investigate the role of PPR signaling in osteocytes, we generated mice lacking PPR in osteocytes (OcyPPRKO). Littermates with floxed PPR alleles served as controls. qPCR showed significantly decreased PPR transcripts in the osteocyte-enriched tibiae of OcyPPRKO as compared with control, demonstrating successful PPR ablation. To investigate the role of PPR signaling during adulthood and aging, we compared the skeletal phenotype of 3- and 12-month-old OcyPPRKO and control. H&E and Von Kossa staining showed increased trabecular bone in OcyPPRKO at 3 months that was absent at 12 months. Dual-energy X-ray absorptiometry (DXA) analysis showed significantly increased bone mineral density (BMD) in OcyPPRKO at 4 months ($p<0.05$, $N>10$) that was absent at 12 months ($p>0.05$, $N>5$). High resolution microcomputed tomography (microCT) analysis of L5 vertebrae and femur midshafts showed significantly increased trabecular and cortical bone parameters in OcyPPRKO at 3 months ($p<0.05$, $N>10$) that was absent at 12 months ($p>0.05$, $N>5$). Histomorphometric analysis of femurs showed significantly higher bone volume (BV/TV, $p<0.05$, $N>8$) and osteoblast parameters ($p<0.05$, $N>8$), and a trend for decreased osteoclast parameters at 4 months in OcyPPRKO than control; however these parameters appeared similar between OcyPPRKO and control at 12 months ($p>0.05$, $N>5$), yet a trend for increased number of resorption lacunae was observed in OcyPPRKO at 12 months. To understand the molecular perturbation, SOST and RANKL mRNA expression was compared in osteocyte-enriched calvariae. At 3 months, there was a significant 450% increase in SOST ($p<0.05$) and 48% decrease in RANKL mRNA expression ($p<0.05$) in OcyPPRKO as compared with control, suggesting low bone turnover resulting in higher BMD. Interestingly, at 12 months, SOST mRNA expression was similar between OcyPPRKO and control ($p>0.05$); however RANKL mRNA expression was significantly increased by 378% in OcyPPRKO ($p<0.05$). These data suggest that with age OcyPPRKO and control have similar osteoblast activity, but OcyPPRKO have a significantly higher osteoclast activity than control. Our results identify a temporal regulation of osteoblasts and osteoclasts by PPR signaling in osteocytes in adult and aging skeleton.

Assessment of Peri-lacunar and Peri-canalicular Tissue Mass Density Alterations in Human Jaw Bone after Bisphosphonate Treatment by 3D Synchrotron Phase NanoCT. Bernhard Hesse*[1], Peter Varga[2], Max Langer[3], Heikki Suhonen[1], Nils Maennicke[2], Susanne Schrof[2], Peter Cloetens[1], Peter Maurer[4], Françoise Peyrin[3], Kay Raum[2]. [1]European Synchrotron Radiation Facility, France, [2]Julius Wolff Institut, Charité - Universitätsmedizin Berlin, Germany, [3]Creatis, INSA-Lyon, CNRS, Université CB Lyon 1; European Synchrotron Radiation Facility, France, [4]Klinikum Bremerhaven, Germany

The interplay of osteocytes with their surrounding tissue is the subject of recent research [1]. The high connectivity of the lacunar-canalicular-network (LCN) and alterations of the mineral crystals close to the LCN has recently been demonstrated in an animal model [2].

The present study investigates alterations of mass density of the peri-canalicular and peri-lacunar matrix in human jaw bone after bisphosphonate (BP) treatment. 3D Synchrotron phase nanoCT (50 nm isotropic voxel size) enabling sufficient spatial resolution to resolve the LCN [3] in combination with a high sensitivity to the mass density was used to image bone samples. In total, 21 osteocyte lacunae and their surrounding tissue regions were investigated. The samples were obtained from BP-treated (N=3) donors and healthy (N=4) controls. The 3D analysis provided the mean mass density as functions of the shortest distances to canaliculi and lacunae.

We found significantly higher mean mineralized tissue mass densities for the BP treated samples ($F=18$, $p<0.001$). In average, 50 % of the mineralized tissue was found to be located within less than 1.4 µm and 14 µm away from the next canalicular and lacunar boundaries, respectively. Mass density was highest close to the LCN and showed a decreasing trend with increasing distance from both the canaliculi and the lacunae. Both of these mass density gradients were significantly lower for the BP treated group compared to the healthy controls (with respect to lacunae distance: $p=0.02$, canaliculi distance: $p=0.03$).

This is the first study that i) compared mass density of the peri-LCN bone matrix between healthy and BP treated samples using 3D phase nano-CT images at 50nm and ii) shows a higher mass density close to both canaliculi and lacunae in human bone. Our findings support the recent discussion on the ability of the osteocytes to interact with their surrounding matrix [1]. Furthermore, the differences found in the gradient of the mass density suggest that the osteocyte interaction with the mineralized tissue matrix does not only occur at the central lacunar boundary, but also at the canaliculi via the dendritic processes. Moreover, the reduced gradients in the treated group suggest an inhibition of cell-matrix crosstalk by BP treatment.

Signaling of Extracellular Inorganic Phosphate Induces the Expression of *Dmp1* in Osteoblast/Osteocyte Lineage Cells via Na^+/Pi Co-transporter and MEK/ERK Pathway. Jin Nishino*[1], Kazuaki Miyagawa[2], Masanobu Kawai[1], Miwa Yamazaki[1], Kanako Tachikawa[1], Yuko Mikuni-Takagaki[3], Mikihiko Kogo[4], Keiichi Ozono[4], Toshimi Michigami[1]. [1]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [2]Osaka University, Japan, [3]Kanagawa Dental College & Graduate School of Dentistry, Japan, [4]Osaka University Graduate School of Dentistry, Japan

Accumulating evidence has suggested that osteocyte plays a key role in phosphate homeostasis. Several molecules responsible for hypophosphatemic rickets, including FGF23, PHEX, DMP1 and FAM20C, are expressed in osteocytes. We as well as others have previously shown that an increase in extracellular inorganic phosphate (Pi) concentration exerts signal transduction to alter gene expression in some cell types. In the current study, we examined the direct effects of Pi on the gene expression in osteocytes, using primary osteocytic cells isolated from mouse long bones by sequential digestion with collagenase and decalcification with EGTA. We treated the isolated osteocytic cells with 1 mM or 10 mM Pi for 24 h, and found that the expression of *Dmp1* was markedly increased, while that of *Fgf23*, *Phex*, and *Fam20C* was not obviously changed by 24-h treatment with 10 mM Pi. The increase in *Dmp1* expression by the elevated extracellular Pi suggests that osteocytes are responsive to the alteration in extracellular Pi concentration. Since the expression of *Dmp1* is high in osteocytes while very low in osteoblasts, we next examined whether high extracellular Pi induced the expression of *Dmp1* in osteoblasts, using the murine osteoblastic cell line MC3T3-E1. We treated the cells with various concentrations (1-10 mM) of extracellular Pi for 48 h, and found that expression of *Dmp1* and phosphorylation of ERK1/2 were induced by the increased extracellular Pi in a dose-dependent manner. Then, we examined the time course of *Dmp1* up-regulation and ERK1/2 phosphorylation by harvesting the cells at 0, 0.5, 1, 6, 12, 24 and 48 h after treatment with 10 mM Pi. The phosphorylation of ERK1/2 reached the maximum at 1 h, while the marked increase in *Dmp1* expression was observed at 12 h and thereafter. Interestingly, treatment with U0126, a MEK inhibitor, abolished the up-regulation of *Dmp1* expression by the increased Pi. Treatment with phosphonoformic acid (PFA), an inhibitor of Na^+/Pi co-transporter cancelled the increase in *Dmp1* expression by the elevated Pi, either. These results suggest that signaling by extracellular Pi leads to increased expression of *Dmp1* via Na^+/Pi co-transporter and MEK/ERK pathway.

Assessing the balance between formation and resorption: An index of net bone formation. Albert Shieh*[1], Neil Binkley[2], Teresa Seeman[1], Gail Greendale[1], Dana Miller-Martinez[1], Carolyn Crandall[1], Arun Karlamangla[1]. [1]University of California, Los Angeles, USA, [2]University of Wisconsin, Madison, USA

Purpose: Markers of either bone formation or resorption do not individually reflect bone loss or gain, because formation and resorption are coupled. Both types of markers increase with high bone turnover, regardless of whether there is net bone gain or loss. Our objective was therefore to create and evaluate a bone balance index that quantifies excess formation relative to resorption. Methods: Data came from participants in the Midlife in the U.S. study (729 men and women, ages 25-74 years, not taking medications affecting bone metabolism). Bone formation [bone specific alkaline phosphatase (BSAP), procollagen type 1 N-terminal propeptide (P1NP)] and resorption [N-telopeptide (NTx)] markers were measured from fasting blood. On the same day, bone mineral density (BMD) was measured by dual energy x-ray absorptiometry. We regressed NTx on BSAP, P1NP, and body weight, and used the estimated regression coefficients to determine E(NTx), the expected value of the resorption marker NTx corresponding to measured levels of formation markers and weight. We created a bone balance index (BBI) as E(NTx)–NTx, to reflect excess formation relative to resorption. BBI values were compared across age categories in men and menopause transition status in women. BMD was regressed on BBI to assess the ability of BBI (assuming it has been stable for some time) to predict BMD. Results: Expected NTx was E(NTx) = 7.0 + 0.178*BSAP + 0.070*P1NP – 0.022*weight, with NTx, BSAP, and P1NP in nM BCE, μg/L, and U/L units respectively, and weight in kilograms. Accordingly, BBI = 7.0 + 0.178*BSAP + 0.070*P1NP – NTx – 0.022*weight. BBI trended downwards with increasing age in men and with progression along the menopause transition in women. But BBI was 0.25 standard deviations (SD) higher (more favorable) in postmenopausal women on hormone therapy (HT) than in late perimenopausal and postmenopausal women not on HT (p=0.04). Adjusted for age, sex, menopause transition stage, HT use, and study site, each SD increment in BBI was associated with a 0.07 SD increment in spine BMD (p=0.01), but was not associated with femoral neck BMD. Conclusions: A bone balance index that quantifies excess bone formation relative to resorption can be created from bone turnover markers and may be useful in assessing current bone metabolism and potentially in predicting future bone strength.

Serum Levels of Procollagen type 1 Amino-terminal Propeptide (PINP) and Risk of Hip Fracture in Elderly Women. The Hordaland Health Study. Trine Elisabeth Finnes*[1], Haakon E. Meyer[2], Cathrine Marie Lofthus[3], Erik Fink Eriksen[3], Ellen Margrethe Apalset[4], Grethe S Tell[5], Kristin Holvik[6]. [1]Sykehuset Innlandet Thrust, Norway, [2]Norwegian Institute of Public Health/University of Oslo, Norway, [3]Oslo Universtiy Hospital, Norway, [4]Department of Public Health & Primary Health Care, University of Bergen. Department of Rheumatology, Haukeland University Hospital, Norway, [5]Department of Public Health & Primary Health Care, University of Bergen, Norway, [6]Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway. Department of Global Public Health & Primary Care, University of Bergen, Bergen, Norway. Surgical Department, Diakonhjemmet Hospital, Oslo, Norway., Norway

BACKGROUND: The usefulness of bone turnover markers as determinants of fracture risk in osteoporosis needs further investigations, and IOF/IFCC recommends the bone formation marker Procollagen type 1 Amino-terminal Propeptide (P1NP) to be used in studies to clarify its utility in clinical use.

AIM: To investigate the relation between serum P1NP levels and the risk of subsequent hip fractures in elderly women with, and without bone mineral density (BMD).

MATERIALS AND METHODS: A case-cohort study was performed in a cohort of 1817 women born 1924-27 participating in a health study covering western parts of Norway from 1997-99. In a subsample of about 60% of the women, baseline total hip BMD was measured by a dual x-ray densitometer (Lunar EXPERT-XL). Information on incident hip fractures was obtained from computerized discharge diagnoses records from the hospitals serving the region. P1NP was measured in frozen serum samples obtained at baseline in all women who suffered a hip fracture, and in a randomly collected subcohort of 9% of the total cohort. P1NP was determined by Multigamma radioimmunoassay kit (Orion Diagnostica). The current analyses include women not medication known to influence on the P1NP level, and with valid BMD and P1NP measurements. The final data set included 72 women, without a hip fracture, from the subcohort, and 80 women with a hip fracture. Cox proportional hazards regression adapted for the case-cohort design was performed with penalized splines of P1NP and with tertiles of serum P1NP as explanatory variables. The lowest hazard ratio (HR) was observed in the 2nd tertile, which was used as reference. All analyses were adjusted for age by method.

RESULTS: Serum P1NP levels ranged from 13 to 124 ng/mL (median 44 ng/ mL). Unadjusted spline analysis revealed no significant relation between P1NP and the risk of hip fracture. Compared to the 2nd tertile of P1NP, HR for hip fracture in the 1st tertile was: 1.26 (95% CI: 0.60 – 2.65), and in the 3rd tertile: 1.69 (95% CI: 0.53-2.53). Adjusted for baseline BMD, a significant higher risk was seen in the 1st tertile of P1NP, compared to the 2nd tertile (HR: 3.37 (95% CI: 1.24 – 8.61), p=0.012).

CONCLUSION: A weak relation between P1NP and hip fractures was found in the unadjusted analyses. Adjusted for BMD, the current analyses revealed low P1NP to be a risk factor for hip fractures. The mechanisms causing high fracture risk among those with the lowest P1NP levels remain to be elucidated.

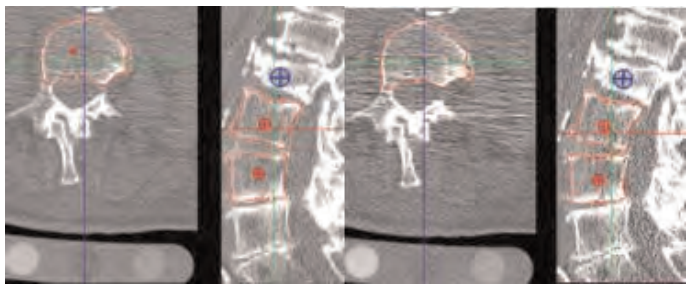
A Low Dose 3D QCT Protocol for the Spine. Oleg Museyko[1], Axel Heinemann[2], Matthias Krause[3], Claus-C Glueer[4], Klaus Engelke*[5]. [1]University of Erlangen-Nuremberg, Germany, [2]Institute for Forensic Medicine, University of Hamburg, Germany, [3]Institute for Osteology & Biomechanics, University of Hamburg, Germany, [4]Christian Albrechts Universitaet zu Kiel, Germany, [5]University of Erlangen, Germany

Purpose: To develop a low dose 3D QCT protocol for in-vivo measurements of the spine.

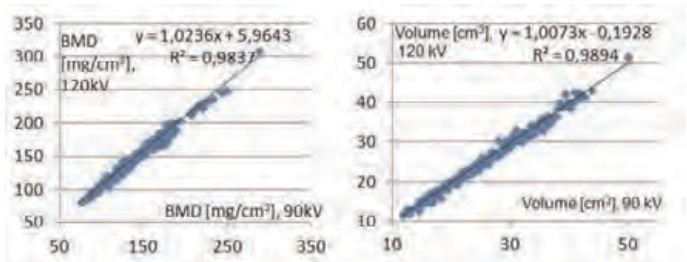
Methods: QCT datasets of T6-L4 from 27 cadavers (190 vertebrae) were scanned twice on a Philips MX8000: with 120kV and 100 mAs and a lower dose protocol with 90 kV and 150 mAs. Reconstruction diameter was 15 cm, slice thickness 1.3 mm, and convolution kernel was 'B' for both scans. A BDC calibration phantom (QRM Möhrendorf, Germany) was used for conversion of HU to BMD values. MIAF-Spine was used to analyze total vertebral body volume and BMD (Figure 1). Additionally, mean and standard deviation of the HU values obtained in the three cylindrical phantom inserts (0, 100, and 200 mg/cm^3) were measured in each of the 27 dataset pairs. All parameters were compared between the two scans using matched pair t-tests (Wilcoxon signed rank test for the volume) and Pearson correlations coefficients (r). Dose reduction was estimated using ImpactDose software (CT Imaging, Erlangen).

Results: Effective dose values for the 90kV are approximately 60% lower compared to the 120kV protocol. BMD values were highly correlated but a significant offset ($p < 0.001$) indicates differences in field inhomogeneity; segmented volume was not affected by the lower kV ($p > 0.5$) (Figure 2). All correlation coefficients were significant ($p < 0.001$). Noise in the images assessed by the standard deviation of the HU values of the phantom inserts of the vertebrae were significantly higher in the 90 kV scans: 20.8 ± 4.7 HU vs. 16.2 ± 3.0 HU, 22.0 ± 4.9 HU vs. 17.1 ± 2.9 HU, and 23.3 ± 5.0 HU vs. 18.0 ± 3.1 HU in the phantom insert with 0, 100, and 200 mg/cm^3, respectively.

Conclusions: As expected, noise values were higher in the 90 kV protocol. However, increased noise had no effect on the segmentation of the periosteal surface. The difference in calibrated BMD values indicates differences in the scan field inhomogeneity at 90 and 120kV requiring different corrections. As the correlation between BMD values at 90 and 120kV was very high a linear correction approach, e.g., based on the scans of the European Spine Phantom will suffice to obtain the same BMD results at 90 and 120kV.



MPRs of a patient scanned with 120 kV (left) and 90 kV (right). Periosteal segmentation is shown



Correlation of BMD and volume of the of the 90 kV protocol against the established 120kV protocol

FE-based bone strength can classify femoral neck fractures in a case-control retrospective study. Enrico Schileo*[1], Cristina Falcinelli[2], Luca Balistreri[3], Fabio Baruffaldi[3], Saverio Gnudi[1], Aldo Toni[1], Ugo Albisinni[1], Francesco Ceccarelli[4], Luigi Milandri[5], Marco Viceconti[6], Fulvia Taddei[3]. [1]Istituto Ortopedico Rizzoli, Italy, [2]Laboratorio di Bioingegneria Computazionale, Istituto Ortopedico Rizzoli, Italy, [3]Laboratorio di Tecnologia Medica, Istituto Ortopedico Rizzoli, Italy, [4]Clinica Ortopedica, Università di Parma, Italy, [5]Ortopedia Programmata, Ospedale di Faenza, Italy, [6]Department of Mechanical Engineering, The University of Sheffield, United Kingdom

Introduction: Personalised Finite Element (FE) models from Computed Tomography (CT) data are superior to bone mineral density (BMD) in predicting femoral strength *in vitro* [1].

However, results similar to BMD were obtained *in vivo*, in retrospective classification of generic prevalent fractures [2] and in prospective classification of femoral fractures [3].

The aim of this work is to test, in a case-control retrospective study, the ability of a different, validated FE modelling procedure [4] to: (i) discriminate between groups of proximal femoral fractures and controls; (ii) individually classify fractures and controls.

Methods: 55 women (22 low-trauma proximal femur fractures and 33 controls) were enrolled in 3 clinical centres in Emilia Romagna region, Italy. All received CT and DXA exams (in acute conditions for fractures) with a standardised protocol.

Femoral neck aBMD was measured from DXA.

FE models were built from CT (right femur for controls, intact for fractured) [4]. Differently from existing works, FE strength was calculated for a range of 12 physiological directions of hip joint reactions [5] and 10 fall directions [6]. Bone strength (in stance and fall) was the minimum load inducing on the femoral neck surface an elastic principal strain value greater than the yield limit [7].

Fracture classification was analysed through logistic regressions and AUC of ROC curves.

Results and Discussion: Mean FE strength was significantly lower in fractured cases (Table 1). Differences were greater than those: obtained for aBMD; reported in [8].

Logistic regression on single variables

All classifiers were significant ($p<0.001$, AUC=0.88 for both stance and fall strength, slightly higher than [2,3]; $p=0.02$, AUC=0.72 for aBMD). The statistical power of the logistic regressions [9] was >0.9 for strength, 0.86 for aBMD, mildening the small sample numerosity.

Logistic regressions on multiple variables

Only strength was retained significant ($p<0.001$, AUC=0.88) when including aBMD in the regression.

Cases and controls were not age matched, but adding age to the logistic regression, FE strength and age (but not aBMD) remained significant, with AUC=0.95.

In summary, the proposed FE method may be superior to aBMD in the classification of femoral fractures.

First Demonstration of Microdamages in the Alveolar Bone in vivo Using Computerized Magnification Radiography with Emphasis of Surface Unevenness by Changing Light's Direction to Achieve a 3D Effect.
Yoshitomo Takaishi*[1], Seizaburo Arita[2], Mitsugi Honda[3], Takeshi Sugishita[1], Aiko Kamada[4], Takashi Ikeo[4], Takami Miki[5], Takuo Fujita[6], Masahiro Nakajima[7], Katsura Ueda[8]. [1]Takaishi Dental Clinic, Japan, [2]Department of Life & Medical Sciences, Doshisha University, Japan, [3]Department of Radiology, Okayama University Hospital, Japan, [4]Osaka Dental University, Japan, [5]Osaka City University Medical School, Japan, [6]Katsuragi Hospital, Japan, [7]Second Dept. of Oral & Maxillofacial Surgery, Japan, [8]Dept.of Oral Anatomy, Osaka Dental University, Japan

Purpose: Microdamages, indicating resistance, failure and repair of the bone like material fatigue, have so far been studied only histologically in resected specimens and never in vivo by radiography. By applying surface unevenness emphasizing normal map method on computed dental micro-radiogram (Bone Right) of the alveolar bone from human first mandibular premolar, microdamages were identified and compared with those histological ground specimens from the same site after surgical resection. Correlations among the distribution density of microdamages, alveolar bone mineral density (al-BMD), lumber bone mineral density (LBMD) and fracture were calculated and possibility of predicting fracture by these parameters evaluated.

Materials and Methods: The portion of surgically removed alveolar bone containing radiologically demonstrated microdamages was subjected to dental radiography, enlarged and subjected to normal map for 3D-like emphasis of ups and downs. The specimen was then decalcified and dehydrated with 10% EDTA2 for 2 months, embedded in paraffin, deparaffinized, stained with HE and pictured, to test an agreement in the picture of microdamages with the histological specimens.

In 31 postmenopausal women (59-65 years of age), alveolar bone adjacent to the mandibular first premolar was subjected to enlargement and 3D-like silhouetting to confirm microdamages and their special distribution density, constructing a correlation diagram with fractures of spine and other sites, al-BMD, LBMD measured by Hologic 4500 divided by young adult mean, gingival depth, alveolar thickness (alveolar bucco-lingual distance 6 mm below the enamel-cement junction), BMI (body weight / height^2) and age.

Results: Excellent agreement between microdamages shown by 3D-like silhouetting of the enlarged X-ray film of the alveolar bone and those found on histological specimens.

Microdamage density distribution showed positive correlations with age and number of spine fractures and other sites at coefficients of variation of 0.462 ($p<0.01$) and 0.722 ($p<0.01$) respectively, and negative correlations with LBMD-T and al-BMD at -0.651 ($p<0.01$) and -0.637 ($p<0.01$).

Conclusion: Density distribution of microdamages in human alveolar bone showed significant positive correlations with age and fracture of the spine and other sites, negative correlations with al-BMD and LBMD(T), suggesting a usefulness in alarming bone fragility and risk of fracture.

SA0295

In Vivo Study of Trabecular and Cortical Bone in Young Adults with Varying Trajectories of Bone Development using Multi-Row Detector CT Imaging.
Punam K. Saha, Ryan Amelon*, Yinxiao Liu, Cheng Li, Dakai Jin, Cheng Chen, Jessica Fishbaugher, Elena Letuchy, CHADI CALARGE, Kathleen Janz, Douglas Hornick, Julie Eichenberger-Gilmore, Trudy Burns, James Torner, Steven Levy. University of Iowa, USA

In contrast to DXA, multi-row detector computed tomography (MD-CT) imaging generates unique bone quality information such as volumetric bone density, isolation of trabecular from cortical bone mineral density (BMD), and characterization of micro-architecture. Using advanced image processing algorithms, MD-CT based new trabecular and cortical bone parameters were assessed in four groups of young adults with varying clinical histories likely to impact bone development.

Nine athletes (6 male/3 female), 9 participants (4 male/5 female) with cystic fibrosis (CF), and 11 participants (5 male/6 female) on continuous treatment with a selective serotonin reuptake inhibitor (SSRI) for at least one year were recruited (age: 18-23 year). Age-sex-BMI-similar healthy controls (42 male/46 female)were selected from the Iowa Bone Development Study (IBDS) cohort. MD-CT scans of the distal tibia were acquired on a 128 slice Siemens Flash scanner at 120kV, 200mAs, pitch: 1, 0.3mm slice-thickness and 10cm scan-length. A Gammex phantom was used to calibrate CT Hounsfield units into BMD (mg/cc). Cortical bone (CB) thickness (CB-Th) and porosity (CB-Poro) (over 12-16% of tibia), trabecular bone (TB) volumetric BMD (TB-vBMD), mean surface width (TB-SW), network length (TB-NL), TB thickness (TB-Th), and marrow spacing (M-Sp) (over 4-6% of tibia) were computed.

Pairwise comparisons between IBDS controls and participants from the three other groups revealed that athletes had thicker CB while participants with CF and those on SSRI therapy had reduced CB-Th, as well as compromised TB-vBMD and TB micro-architecture (Table 1). Notably, differences in bone micro-architecture measures, compared to bone density measures, most prominently distinguished the two clinical groups from the controls (Table 1). Figure 1 presents color-coded TB plate/rod classification for one BMI-matched female representative from each of the four study groups; the healthy female and the athlete have similar TB structure, while the two participants from the clinical groups have compromised TB structure.

Advanced MD-CT image processing algorithms are well-suited for *in vivo* skeletal assessment, capturing differences in volumetric and micro-architectural properties of cortical and trabecular bone. Our preliminary findings require confirmation in a larger sample, where various potential confounders are accounted for.

This study was funded by NIH grants: R01-AR054439, R01-DE012101, UL1-RR024979, and UL1-TR044206.

Table 1: Row 1: Mean ± SD values of various CB and TB measures (CB-Poro and TB-NL have no unit) for healthy controls from the IBDS cohort. Row 2-4: Mean ± SD of percentage difference from controls for age-sex-BMI-similar athletes, participants with CF, and participants on SSRI. Statistical significance of pairwise t-test comparisons – †: p-value >0.5 (statistically non-significant), *: p-value < 0.05; **: p-value < 0.01; ***: p-value < 0.005.

Table 1

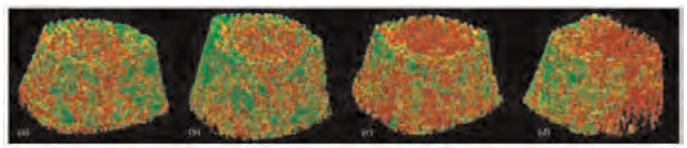

Figure 1: Color-coded illustration of trabecular bone (TB) plate/rod classification for a healthy female IBDS control (a) and sex- and BMI-matched athlete (b), a participant with confirmed diagnosis of cystic fibrosis (CF) (c), and another participant on continuous treatment with a selective serotonin reuptake inhibition (SSRI) (d). Both the healthy control and the athlete have more TB plates colored in green as compared to the two participants. No apparent difference in TB is observed between the control and the athlete; between the two participants, the CF participant has some signs of nonhomogeneous bone loss. However, this observation needs to be confirmed in a larger study and the implications further investigated.

Influence of Glucocorticoids on Trabecular Bone Score in Patients With Rheumatoid Arthritis.
Vladyslav Povoroznyuk*[1], Tetyana Karasevska[2], Berengere Aubry-rozier[3], Nataliia Dzerovych[2], Didier Hans[3]. [1]Institute of Gerontology AMS Ukraine, Ukraine, [2]Institute of Gerontology NAMS Ukraine, Ukraine, [3]Lausanne University Hospital, Switzerland

Introduction. Bone disorders are the main extra-articular complications of rheumatoid arthritis (RA). Patients with RA have a greater risk of osteoporosis and fracture than the general population. Rheumatoid arthritis (RA) is a chronic inflammatory rheumatic disease and a frequent cause of secondary osteoporosis induced by the chronic inflammatory condition and a long-term glucocorticoid therapy (GC).

The aim of this study is to evaluate the influence of GC on the trabecular bone score (TBS), bone mineral density (BMD) and TBS dynamics during one year in patients with RA.

Materials and methods. 134 examined women with RA (age 52.5±12.8 years; height 162.6±6.4 cm, weight 68.2±13.7 kg, duration of disease 9.1±7.5 years, duration of postmenopausal period 7.6±7.2 years) were divided into three groups: first group, G1, includes 37 patients who did not use GC, second group, G2 – 50 patients who used GC in a dose of more than 5 mg of prednisolone for more than 3 years, third one, G3 – 47 patients who took GC only at the exacerbated stage for less than 6 month. All the patients had been taking methotrexate as a basic treatment.

BMD of total body, PA lumbar spine, proximal femur and forearm were measured using the DXA method (Prodigy, GEHC Lunar, Madison, WI, USA) and PA spine TBS was assessed by means of TBS iNsight® software package installed on our DXA machine (Med-Imaps, Pessac, France). Evaluation of TBS dynamics in the patients of G1 & G2 groups during the year was conducted on the background of ongoing therapy which included doses of GC (for the patients of second group) and/or without any osteotropic treatment.

Results. The 3 groups did not differ as to age, basic anthropometric parameters, duration of disease and duration of postmenopausal period in these groups. TBS in G2 was significantly lower compared to G1 (TBSL1-L4: 1.147±0.168 vs 1.250±0.135; t=-3.07; p=0.003), and G3 compared to G1 (TBS L1-L4: 1.274±0.138; t=3.95; p=0.0002). However, there were no differences of BMD of PA spine and hip among groups. Only forearm BMD in the second group was significantly lower compared to the first one (0.583±0.176 g/cm2 vs 0.675±0.229 g/cm2; t=-2.18; p=0.032). Spine TBS decreased by 1.4% after one year for G1 and by 5.8% for G2.

Conclusion. For patients who are GC-users, TBS, but not BMD, reflects bone microarchitecture deterioration which is an indicator for those patients to of a higher vertebrae and non-vertebral risk of fracture. TBS is a determinant of bone state and must be monitored during the long-term treatment with GC.

Multimodality imaging and its utility to monitor marrow damage for cancer survivor bone health studies. Luke Arentsen[1], Keenan Brown[2], Susanta Hui*[1]. [1]University of Minnesota, USA, [2]Mindways Software, USA

Purpose: Cancer treatment induced bone marrow damage adversely affects bone health leading to an increased risk of osteoporotic fractures. Using the imaging procedures dual energy CT (DECT) and Water-Fat MRI (WFMRI) will provide the etiology of bone loss over time in greater detail. The goal is to develop a DECT technique to estimate marrow composition for use in women undergoing chemotherapy and radiation treatment.

Methods: Commencement of a pilot clinical study includes patients treated with radiation (5), Chemotherapy (6), and oophorectomy alone (4). A one year longitudinal study is used to compare change in marrow fat measured using WFMRI and DECT scans. WFMRI imaging was used to generate high-resolution, 3D signal fat fraction (sFF) maps extending from mid-femur to L3. This same region is scanned using dual source CT scan of 80 and 140 kVp energies within few hours of MRI scan. Identical ROIs were analyzed in WFMRI and DECT images to compare marrow composition. Attenuation properties of alcohols are accurately modeled in diagnostic x-ray energies (80 & 140kVp) using Siemens CT scanner. Water and intralipid used to as external reference for both modalities. Posterior adipose tissue and psos muscle used as internal control. Comparison of predicted and measured attenuation signals is used to assess accuracy.

Results: A 100% accuracy of rank correlation was observed between measured test solution densities and the theoretical model predictions that are based upon independent x-ray scatter calculations. A high correlation is seen between WFMRI YM assessment and DECT (r=0.813) (Figure). Individual treatment groups also showed a high correlation from baseline to 6 month and 1 year follow-up. post treatment, marrow fat increased significantly in both the L4 vertebral marrow (p=0.04) in chemotherapy patients and L5 for patients who received radiation. Chemotherapy changes were more uniform in space, whereas the radiation-induced changes were largest in marrow regions inside and close to the target radiation field.

Conclusions: The DECT may be an alternative and and effective method to estimate accurate bone marrow fat composition in cancer survivor as validated by WFMRI. DECT is routinely acquired as part of clinical care in these cancer patients, making it very practical to acquire. Pilot clinical study results indicate a significant influence of cancer treatment on marrow composition.

Prediction Models for Older Women at High Risk of Unrecognized Radiographic Vertebral Fracture: Simple is Better than Complex. John Schousboe*[1], Harold Rosen[2], Tamara Vokes[3], Jane Cauley[4], Steven Cummings[5], Michael Nevitt[6], Dennis Black[6], Eric Orwoll[7], Deborah Kado[6], Kristine Ensrud[8]. [1]Park Nicollet Clinic, University of Minnesota, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]University of Chicago, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]San Francisco Coordinating Center, USA, [6]University of California, San Francisco, USA, [7]Oregon Health & Science University, USA, [8]Minneapolis VA Medical Center / University of Minnesota, USA

Purpose: Decision rules with multiple predictors are recommended to choose who should have lateral spine imaging to detect prevalent radiographic vertebral fracture (PRVFx). It is unclear if models with many predictors discriminate those with and without PRVFx better than simpler models.

Methods: We used data from 4,894 women (mean age 75 yrs, range 68-99) who had lateral spine radiographs at the 3rd Study of Osteoporotic Fractures visit to construct 4 nested logistic models to predict PRVFx (vertebral height ratio >3SD lower than expected); model 1 (age + femoral neck bone mineral density [FNBMD]); model 2 (model 1 +height loss since age 25 yrs); model 3 (model 2 +prior non-vertebral fracture & body mass index (BMI); model 4 (model 3 + grip strength, back pain, smoking, estrogen & glucocorticoid use). We compared model discrimination for PRVFx by Receiver Operating Characteristics curve (AUC) analyses & Net Reclassification Index (NRI, Pepe method).

Results: Age, FNBMD, height loss, non-vertebral fracture, BMI, & smoking were significantly associated with PRVFx, multivariable adjusted (table 1). Model 3 discriminated those with from those without PRVFx as well as a more complex model 4 (table 2), but only minimally better than a simpler model 2.

Conclusion: A model with age, FNBMD, & height loss identifies older women at high risk of PRVFx who would benefit from lateral spine imaging nearly as well as more complex models.

Table 1

Reasons for Referral for BMD Testing among Family Physicians. Sarah Munce*, Sonya Allin, Leslie Carlin, Gillian Hawker, Susan Jaglal. University of Toronto, Canada

Background and Purpose: Clinical practice guidelines in the United States and Canada currently recommend bone mineral density (BMD) testing in specific at-risk populations, including all men and women 65 years and older and those who experience a fragility fracture after age 40 years. In Ontario, Canada in the absence of major restrictions to BMD testing, a sharp increase in testing rates in much younger women, aged 40–44 years, for whom fracture risk is low, has been observed. In the year 2007/2008, BMD testing in women aged 40–59 years accounted for almost half of all BMD tests performed. While this high rate of testing may indicate concern about osteoporosis when approaching menopause, it also suggests unnecessary testing. At the same, there is evidence to suggest undertesting among individuals with advanced age or recent fracture (i.e., high-risk individuals). In order to understand these phenomena, the current study sought to understand the reasons for referral for BMD testing among family physicians (FPs). Analysis: A descriptive qualitative approach was used and involved telephone interviews with FPs, who make the majority of BMD test referrals in the province. Study Sample or Initiative Scope: Twenty-two FPs with practices in Ontario were recruited through an Ontario College of Family Physicians event on osteoporosis and subsequent snowball sampling. The average roster size of each physician was 1280, and the average number of BMD reports they reviewed per week was four. Findings: Overall, FPs indicated a lack of clarity on the appropriate age for referral for baseline BMD testing. This was particularly marked for older men. A tendency for baseline referral at menopause in the absence of other clinical risk factors also emerged which in some cases coincided with a patient's request for a BMD test. Family physicians also indicated uncertainty on the follow-up intervals for

BMD testing, especially for bisphosphonate monitoring. Conclusion: Findings from this qualitative study support what has been documented at the population level and suggest a tendency among FPs to refer younger women (at low risk). Emphasis on referral for high-risk groups and further education on the appropriate intervals for bisphosphonate monitoring is warranted. This may be accomplished via the development and implementation of a standardized requisition tool to assist FPs in making appropriate referrals for BMD testing.

Shedding light on the accuracy of HR-pQCT assessment of cortical porosity through synchrotron μCT at the Canadian Light Source. Britta Jorgenson*[1], Helen Buie[2], Steven Boyd[2]. [1]Schulich School of Engineering, University of Calgary, Canada, [2]University of Calgary, Canada

Cortical porosity (CtPo) increases with age and is associated with the progression of osteoporosis and increased fracture risk. Traditionally, CtPo could only be assessed *in vitro* through analysis of harvested tissue samples. Recently, methods for *in vivo* assessment have been developed by high-resolution peripheral quantitative computed tomography (HR-pQCT); however, spatial resolution limitations (i.e. 82μm voxels) may limit measures of all pore sizes, which can be as small as 30μm. Unresolved pores are manifested as artificially lower measures of tissue mineral density (TMD) due to partial volume effects (PVE). Provided that the true TMD is relatively homogeneous throughout the bone, the apparent reduction in TMD by HR-pQCT due to PVE could be quantified to measure unresolved pores, although the presence of beam hardening artifacts may compromise that approach. This study aims to investigate the accuracy of CtPo as assessed by HR-pQCT. Cortical bone samples (N=14 cubes, 4 donors) were cut from the mid-shaft region of cadaveric tibiae. The samples were scanned by HR-pQCT (Scanco Medical) and were nominally aligned in their original orientation in order to replicate the effects of beam hardening that would be experienced in an *in vivo* scan. The samples were also scanned by synchrotron micro CT (SRμCT, Canadian Light Source, Sask.) at a voxel size of 9μm. Bone tissue was segmented by thresholding (400mg HA/cm^3 for HR-pQCT and 750mg HA/cm^3 for SRμCT). All void voxels were identified as pores and contributed to the CtPo measure. We found that HR-pQCT measurements of CtPo were consistently underestimated relative to measures by SRμCT ($p<0.01$), but there was an excellent correlation with 'ground truth' CtPo from SRμCT ($R^2=0.984$, Figure 1) indicating a strongly systematic error. When focused on larger pore sizes (> 136μm) there is a strong relationship between the two imaging methodologies ($R^2=0.992$). Analysis of pore size distributions suggests that there is a 'cut-off' pore size that can be captured accurately by threshold-based segmentation of HR-pQCT images. Beam hardening did not influence threshold-based CtPo, but the systematic error in BMC resulted in a slightly weaker correlation between BMD and CtPo ($R^2=0.964$). In conclusion, threshold-based CtPo measures do not capture small pores (<136μm), but are highly correlated with 'ground truth' CtPo from SRμCT with a consistent 5% under-estimation of CtPo.

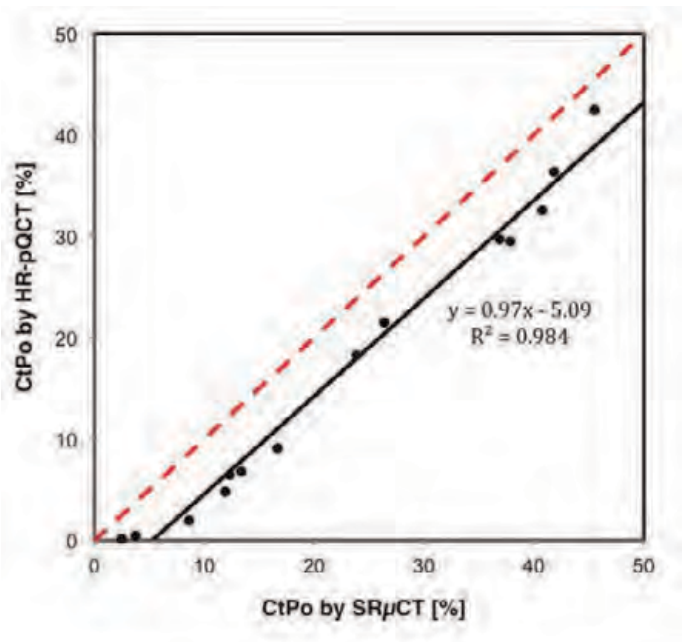

Figure 1: Cortical porosity (CtPo) as measured by threshold-based segmentation of HR-pQCT and SRμCT

Systematic Assessment of Bone Texture by BMA-device complementary to measurement of Bone Mineral Density by DXA in Patients with Bone Gragility Fractures. Sarah Cheriet[1], Jean-François Menard[2], Olivier Vittecoq[1], Alain Daragon*[1]. [1]Department of Rheumatology, Rouen University Hospital, France, [2]Department of Biostatistics, Rouen University Hospital, France

Backbround: Bone mineral density (BMD) is a strong indicator of bone strenght but it seems to be insufficient as many fragililty fractures occur in patients without low BMD. To assess fracture risk properly, it is important to take into account other factors than BMD, such as bone microarchitecture. Bone microarchitecture measures, bone texture parameters, and parameters of bone strenght are shown to be correlated.

Methods: Enrollment included 77 patients with fragility fractures. These study patients filled in a questionnaire on clinical risk factors for osteoporosis. Their BMD was measured by dual-energy X-ray absorptiometry (DXA) at three sites (lumbar spine, femoral neck and forearm). Their bone texture parameters were measured by high resolution X-ray device (BMA^{TM} D3A Medical System) at two sites (femoral neck and forearm).

Results: We found a link between densitometry and texture parameters at the two measurement sites, with a negative correlation at the femoral neck ($p<0.05$) and a positive correlation at the forearm ($p<0.05$). We found a significant and positive correlation between parameters at the same site, but not between parameters from two different sites. The spearman correlation coefficient was positive between densitometric and morphological parameters (weight and BMI), and negative between morphological parameters and texture parameters at the femoral neck ($p<0.05$)

Conclusion: Evaluation of bone texture parameters by BMA^{TM} (D3A Medical System) at two different measurement sites can provide additionnal information to BMD, especially in obese or overweight patients in whom densitometry parameters alone often do not fully reflect risk of fracture.

SA0303

The relationship between bone architecture and density at the hip and at peripheral sites: a comparison of hip QCT and HRpQCT from the QUALYOR cohort. Jean-Baptiste Pialat*[1], Jeremy Bayet[2], Amanda Martinon[3], Pauline Azzano[2], Stephanie Boutroy[4], Anne Marie Schott[3], Eric Lespessailles[5], Roland Chapurlat[6]. [1]INSERM U1033, Team1, Université de Lyon & Hospices Civils de Lyon, France, [2]Université de Lyon, France, [3]Hospices Civils de Lyon et Université de Lyon, France, [4]INSERM U1033 & Université de Lyon, France, [5]Centre Hospitalier Regional, France, [6]E. Herriot Hospital, France

Measures of bone geometry, microarchitecture and volumetric bone mineral density (BMD) may improve the prediction of fragility fracture compared with that provided by areal BMD (aBMD). HRpQCT parameters, however, are obtained at peripheral sites that may not be representative of sites like the hip. So, we have examined the relationship between hip QCT measures and those obtained with HRpQCT.

The QUALYOR cohort is a prospective study on the value of microarchitecture to predict fracture, with 1575 postmenopausal women with a T-score < -1.0 enrolled in Lyon and Orléans (France). Data from 1075 women enrolled in Lyon were used in this analysis. Hip was assessed by QCT using QCT PRO CTXA Hip module for volumetric BMD (vBMD), and Bone Investigational Toolkit for geometric parameters (Mindways Software Inc., Austin, TX, USA). Intra and inter reader (n=2) reproducibility of the QCT analysis was tested using intraclass coefficient of correlation (ICC). Outcomes were correlated to those of hip DXA aBMD and content (BMC)) and densitometric and microarchitectural parameters obtained from radial and tibial HR-pQCT scans.

For QCT-based vBMD, inter operator reproducibility ICC was 0.97 and intra operator reproducibility was 0.82 and 0.94. Geometrical parameters had ICCs in the same range (0.79-0.97), except eccentricity (ICC=0.70). Hip vBMD assessed by QCT was well correlated with aBMD for total hip ($r=0.73$) and femoral neck ($r=0.66$); both $p<0.0001$. Comparison with HR-pQCT density parameters showed moderate correlations for total bone BMD ($r=0.53$ for tibia and $r=0.43$ for radius). Trabecular vBMD of the hip was correlated with trabecular vBMD at the tibia ($r=0.28$) and at the radius ($r=0.32$), all $p<0.0001$. Negative correlations were found between cortical density of the hip and the tibia ($r=-0.15$) or the radius ($r=-0.14$), $p<0.0001$. Most femoral neck geometrical outcomes showed significant correlations with cortical perimeter and trabecular area, with almost similar range for tibia ($0.36<r<0.57$; all $p<0.0001$) and radius ($0.31<r<0.51$; all $p<0.0001$). Femoral neck average cortical thickness was correlated with cortical thickness at the tibia ($r=0.35$) and the radius ($r=0.27$),$p<0.0001$.

In conclusion, QCT reproducibility is excellent for density analysis and good for geometry. We found a moderate correlation between hip and distal limbs density and structure.

Trabecular Bone Score (TBS) Variations in Type 2 Diabetes Mellitus. Ruban Dhaliwal*, Joseph Spadaro, Chaitali Ghosh, Jennifer Kelly, Arnold Moses. State University of New York Upstate Medical University, USA

Introduction: Type 2 diabetes mellitus (T2DM) is a risk factor for osteoporotic fractures despite higher average bone mineral density (BMD) as measured by dual-emission X-ray absorptiometry (DXA). We sought explanations to this paradox by investigating variations in trabecular microarchitecture as evaluated by trabecular bone score (TBS). The aim of our study was to assess the ability of TBS to discriminate between women with and without T2DM.

Methods: We conducted a cross-sectional comparison of 37 women with T2DM and 43 controls, ages 30 to 90 years. Lumbar spine BMD was measured by DXA (GE Lunar iDXA) and TBS was calculated by examining pixel variations within the DXA images using a TBS iNsight software (Med-Imaps SA, France).

Results: The mean (SD) lumbar spine BMD (1.165 $\pm$ 0.174) was higher in T2DM women as compared to the control group (1.051 $\pm$ 0.125, p= 0.001). In contrast, mean TBS was lower in T2DM (1.218 $\pm$ 0.134 vs. 1.298 $\pm$ 0.133, p= 0.009), regardless of age. Hemoglobin A1c within the two sub-groups (defined using a cut off A1c of 7%) in T2DM showed a negative relationship with TBS, although not statistically significant (A1c $\leq$ 7%: n=14, 1.258 $\pm$ 0.153; A1c $>$ 7%: n=23, 1.193 $\pm$ 0.119, p= 0.156).

Conclusion: These data demonstrate that trabecular microarchitecture is altered in T2DM. TBS and BMD displayed opposite performance. Trabecular microarchitecture as assessed by TBS is a determinant of bone quality independent of BMD in T2DM. In addition, it seems that TBS is lower in poorly controlled T2DM. These initial data suggest that better glycemic control may improve bone quality as measured by TBS and trabecular microarchitecture assessment may also help explain the paradox of fractures at a higher BMD in T2DM.

Ultrasonic Assessment of BMD at the 1/3 Radius. Emily Stein[1], Gangming Luo[2], Polly Young[3], Stanley Rosenfeld[4], Jonathan Kaufman*[2], Alfred Rosenbaum[4], Elizabeth Shane[1], Robert Siffert[5]. [1]Columbia University College of Physicians & Surgeons, USA, [2]CyberLogic, Inc., USA, [3]Columbia University, USA, [4]Computerized Diagnostic Scanning Associates, USA, [5]The Mount Sinai School of Medicine, USA

The objective of this study was to evaluate a new clinical ultrasound device (UltraScan 650, CyberLogic, Inc., New York, NY, USA) in terms of its ability to estimate BMD at the 1/3rd radius (1/3R). The device (Fig. 1) rests on a desktop and is portable, and permits real-time evaluation of the radial bone mineral density (BMD). The device measures in thru-transmission two (2) net time delay (NTD) parameters, NTD_{DW} and NTD_{CW}. NTD_{DW} is defined as the difference between the transit time of an ultrasound pulse through soft-tissue, cortex and medullary cavity, and the transit time through soft tissue only of equal overall distance. NTD_{CW} is defined as the difference between the transit time of an ultrasound pulse through soft-tissue and cortex only, and the transit time through soft tissue only again of equal overall distance. The square root of the product of these two parameters is a measure of the BMD at the 1/3R as would be measured by DXA. Two clinical IRB-approved studies were carried out; one measured 60 adults (age range 22-84, 68% female) at the 1/3R using ultrasound and DXA (range = 0.45-0.92 g/cm^2). The other study measured both arms of 3 adults at 16 locations along the radius from the 1/3 to the 10% location, using ultrasound and DXA. Linear regression between DXA (1/3R) BMD and the square root of the product NTD_{DW} * NTD_{CW} for the sixty subjects produced a linear correlation coefficient of 0.93 ($P<0.001$). Linear regression between DXA BMD and the square root of the product NTD_{DW}* NTD_{CW} for the 3 subjects (a total of 108 data points along the forearm from 1/3 to 10%) produced a linear correlation coefficient of 0.90 ($P<0.001$). We found that forearm ultrasound measurements yield results that are very closely associated with those from DXA. The results also show that the ultrasound measurements are robust with respect to radial cross-section, as changes that occur from the 1/3 to 10% locations did not significantly interfere with the ability to estimate BMD. These results are also consistent with previous computer simulation and *in vitro* studies, in terms of the ability to estimate radial bone mass. In conclusion, although x-ray methods are effective in bone mass assessment, osteoporosis remains one of the most undiagnosed diseases in the world. The research described here should enable significant expansion of the identification of bone loss as occurs in osteoporosis using an ultrasonic desktop device that can serve as a proxy for DXA BMD at the 1/3R.

BMD and FRAX have Limited Ability to Identify Women with Breast Cancer who Fracture. Beatrice Edwards*[1], William Gradishar[2], Maureen Smith[2], Jennifer Pacheco[2], Jaimee Holbrook[2], June McKoy[2], Beatrice Nardone[2], Stephani Tica[2], Victoria Godinez Puig[2], Alfred Rademaker[2], Andrew Bunta[3], Paula Stern[4], Steven Rosen[2], Dennis West[2]. [1]MD Anderson Cancer Center, USA, [2]Northwestern University, USA, [3]Northwestern University Feinberg School of Medicine, USA, [4]Northwestern University Feinberg School of Medicine Department of Molecular Phar, USA

Purpose: There is a rising number of older breast cancer survivors. The CDC analyzed the SEER database between 2006 and 2007, identifying that of 11.2 million cancer survivors, 7 million are women, and 90% were women. The most common survivors were breast cancer. Our objective was to analyze whether clinical risk factors, Bone Mineral Density (BMD) or Fracture Risk Assessment Tool (FRAX) can identify women with breast cancer who fracture.

Methods: The study population consisted of breast cancer participants who participated in a genetic databank within a National Cancer Institute Comprehensive Cancer Center. Demographic, clinical and treatment characteristics were abstracted from the electronic medical record (EMR). Record abstraction was manually performed in selected cases.

Results: A total of 439 women with breast cancer were assessed; 79 women sustained fractures during the observation period (116 fractures), fractures occurred at multiple skeletal sites in 27 cases. The prevalence of fractures was 18%. Baseline characteristics revealed that women who sustained fractures were mostly Caucasian (91%, p=0.08), and had a family history of osteoporosis (36.9%, p=0.03). The time to fracture was 4.0 years (range 0-12 years) from diagnosis. Fracture cases had lower BMD at the femoral neck 0.86 $\pm$ 0.13 gm/cm^2 (T score = -1.0, p = 0.04) than non-fracture cases, although BMD was in the low normal range. Suprisingly, 90% women who fractured had a BMD Tscore>-2.5 and 55% had a T-score above -1.0. FRAX calculation was similar in both groups. Cox proportional hazard analysis failed to identify specific risk factors for fractures.

Conclusion: Fractures occur shortly after commencing cancer therapy. Occurrence of fractures in breast cancer raises the possibility of cancer-induced impairment in bone quality. BMD and FRAX calculation were not able to identify women who fractured.

SA0308

Gender- and skeletal site- differences of maternal and paternal inheritance for the peak bone mass in their offsprings. Kyoung Min Kim*[1], Sung Hee Choi[2], Soo Lim[2], Sang Wan Kim[3], Hak-Chul Jang[2], Chan Soo Shin[4]. [1]Seoul National University Bundang Hospitatl, South Korea, [2]Department of Internal Medicine, Seoul National University College of Medicine, South Korea, [3]Seoul National University Boramae Hospital, South Korea, [4]Seoul National University College of Medicine, South Korea

Peak bone mass is a major determinant for the risk of developing future osteoporosis. Thus, achieving optimal peak bone mass is the best measure against osteoporosis and subsequent fractures. Even though environmental components also influence bone mass accrual, peak bone mass might be largely programmed by inheritance. However, it is still not known to what extent genetic factors actually affects peak bone mass and whether the degree of genetic influences differs according to the parents-offspring pairs. The aim of this study was to investigate the degrees of maternal or paternal inheritance according to the gender and skeletal sites. This study was based on data acquired in the Fourth Korea National Health and Nutrition Examination Survey (KNHANES IV), and consisted of 510 offsprings (260 daughters and 250 sons) with an age range of 20 - 35 yrs, and 767 their parents (380 mothers and 387 fathers). The bone mineral density (BMD) was driven from dual energy x-ray absorptiometry (Discovery W, Hologic, Bedford, MA). Most of the offsprings' BMDs were strongly correlated with their parents' site-equivalent BMDs with varying degrees except for lumbar spine BMD in son-father pairs. The relationships were generally high in daughter-mother pairs but generally low in father-son pairs, and the most strong correlation was observed in lumbar spine for daughter-mother pairs ($r=0.441$, $p<0.001$). We also compared offsprings' Z score according to their parents' site-equivalent Z score groups (Z score <-1.0, $-1.0 \leq$Z score $\leq+1.0$, Z score $>+1.0$). Daughters' lumbar spine Z score increase as the mothers' Z score increase (p for trend <-0.001) with mean difference of 0.7 to 0.8 Z score. These positive trends were also observed in most other skeletal sites and most other pairs except in lumbar spine for son-father pairs and in femur neck for son-mother pairs. In comparison of influences by analyzing with AUC, maternal and paternal inheritance affects similarly on daughter's lumbar spine and femur neck BMD as body mass index (BMI) does. In sons, parental inheritance also affects lumbar spine BMD with similar level of BMI, but hereditary effects were little lower on femur neck and total hip. Genetic factors influence much on peak bone mass with variable degrees according to the skeletal site or gender. Lumber spine is more likely to be affected by heredity than femur, and even though paternal inheritance also expressed, maternal inheritance affects more strongly on bone.

Non-Osteoporotic Low-Trauma Fractures and the Burden of Re-Fracture And Mortality. Jacqueline Center*, Dana Bliuc, Nguyen Nguyen, Tuan Nguyen, John Eisman. Garvan Institute of Medical Research, Australia

Background: Approximately half of all fragility fractures occur in people with non-osteoporotic BMD. However, it is unclear whether these fractures still result in high re-fracture and mortality risk. This study aimed to determine the total burden of re-fracture and mortality according to BMD levels for all low trauma fractures.

Methods: 714 women and men 60+ from the Dubbo Osteoporosis Epidemiology Study with incident fractures were followed for re-fracture and mortality (April 1989-Dec 2012). Femoral neck BMD was measured close to initial fracture. Initial fractures were classified as: hip, vertebral and non-hip non-vertebral (NHNV). Re-fracture rates were compared to general population initial fracture rate and mortality rates were compared to age-adjusted population mortality rates.

Results: There were 528 fragility fractures in women (49% non-osteoporotic and 61% osteoporotic) and 186 in men (67% non-osteoporotic and 33% osteoporotic). Following initial fracture, 251 women and 55 men re-fractured and 249 women and 115 men died. The risk of re-fracture was highest for those with osteoporosis [women: 3.24 (95% CI, 2.72- 3.86) and men: 3.83 (95% CI, 2.81-5.21)] but was still elevated for those with osteopenia [women: 2.11 (95% CI, 1.70- 2.63) and men: 3.38 (95% CI, 2.23-5.11)] and normal BMD [women: 1.99 (95% CI, 1.19- 3.31) and men 2.11 (95% CI, 1.19- 3.76)]. Increased risk was observed in the non-osteoporotic group for all fracture types. The propensity to fall appeared to play a role in re-fracture risk in women with normal BMD [RR; 2.12 (95% CI, 1.22- 3.67)] but not in men.

In women, mortality risk was increased for all levels of BMD [normal BMD: 2.16 (1.34-3.48); osteopenia 1.32 (1.05- 1.66) and osteoporosis 1.71 (1.45- 2.02)]. Hip fractures dominated the high mortality seen in osteopenic women and NHNV fractures the high mortality in women with normal BMD. In men increased mortality rates were observed in those with osteoporosis [SMR 2.67 (95% CI, 1.98- 3.60)] and osteopenia [SMR 2.21 (95% CI, 1.67- 2.92)], but not in those with normal BMD [SMR 1.0 (95% CI, 0.6- 1.7)].

The population attributable risk of re-fracture for non-osteoporotic fractures was 69% for women and 72% for men. Population attributable risk for premature mortality was 39% for women and 22% for men.

Conclusion: Non-osteoporotic low-trauma fractures were associated with increased and substantial risk of re-fracture and mortality for both women and men.

SA0310

Prevalence of vertebral fractures and densitometric osteoporosis in Spanish adult men. The Camargo cohort study. Jose Olmos[1], José L. Hernández[2], Josefina Martínez[2], Pilar García-Velasco[3], Daniel Nan[2], Sheila Ruiz[2], Jesús González-Macías*[2]. [1]Hospital Universitario M. Valdecilla, Spain, [2]Department of Internal Medicine, Hospital Universitario Marqués de Valdecilla-IFIMAV, Universidad de Cantabria. RETICEF, Spain, [3]Centro de Salud de Camargo, Spain

Aims: To estimate the prevalence of vertebral fracture and densitometric osteoporosis in men over 49 years from Cantabria, Spain.

Methods: A community-based population of 1062 men older than 49 yrs (range 50-98) was evaluated. Data regarding risk factors for osteoporosis and fractures were collected by means of a structured questionnaire. BMD at lumbar spine (LS), femoral neck (FN) and total hip (TH) was determined by DXA (Hologic, QDR 4500), and lateral X-rays of the thoracic and lumbar spine were taken. Osteoporosis was defined as a T-score of 2.5 or more below the young men average, and vertebral fractures were diagnosed and classified according to Genant's semiquantitative method.

Results: Te mean ($\pm$SD) age of participants was 65.9 ± 17.8 years. The prevalence of all vertebral fractures considered as whole was 17.1% (n=182), and that of moderate and severe fractures considered separately, about 5% (moderate: 4% [n=42]; severe: 1.3% [n=14]). As expected, prevalence of fractures rose with age: from 9.3% at the age of 50-54 years to 23.0% in men 75 years and older. Twelve percent (n:126) of men had densitometric osteoporosis, with marked differences between the spine and the hip (10.6% at the LS, 2.3% at the FN and 0.6% at the TH). Osteopenia was seen in 41% of men (34% in LS [n:361], 37% in FN [n:394] and 20% in TH [n:214]). Contrary to vertebral fractures prevalence, the prevalence of densitometric osteoporosis did not change very much with age (11% in the youngest group [50-54 years] and 14% in the oldest group [75 years and older]).Only 5% of the osteoporotic patients had a previous diagnosis of the disease.

Conclusions: The most striking data of our results is the huge difference between the percentage of patients with densitometric osteoporosis at the hip and that at the spine. This is a fact that must be taken into account by those considering hip BMD measurement enough for diagnosis. Besides, figures reported here are similar to those previously reported in other European countries.

Trabecular Bone Score Improves Prediction Ability for Vertebral Fracture over 10 Years in Middle-aged and Elderly Women Evaluated by Reclassification Improvement Measures: The Japanese Population-based Osteoporosis (JPOS) Cohort Study. Masayuki Iki*[1], Junko Tamaki[2], Yuho Sato[3], Eiko Kadowaki[1], Namiraa Dongmei[1], RENAUD WINZENRIETH[4], Sadanobu Kagamimori[5], Yoshiko Kagawa[6], Hideo Yoneshima[7]. [1]Kinki University Faculty of Medicine, Japan, [2]Kinki University School of Medicine, Japan, [3]Jin-ai University, Japan, [4]Center of Bone diseases, Lausanne University Hospital, Lausanne, Switzerland, France, [5]University of Toyama, Japan, [6]Kagawa Nutrition University, Japan, [7]Shuuwa General Hospital, Japan

Aims: To evaluate whether trabecular bone score (TBS) improves the prediction ability achieved by bone mineral density (BMD) for vertebral fractures (VFx) over 10 years in middle-aged and elderly women.

Methods: Among 900 women aged 50 to 79 years selected randomly from 3 areas of Japan, 728 completed the baseline survey and at least one follow-up over 10 years. Each survey included spinal imaging by absorptiometry and spine BMD measurement (QDR4500A, Hologic, USA). TBS was calculated at baseline in the same vertebrae using TBS iNsight software (Med-Imaps, France). Incident vertebral fracture was determined when a vertebral height was reduced by 20% or more during follow-up and the vertebra satisfied McCloskey-Kanis criteria or Genant's grade 2 fracture. Prediction validity of BMD and TBS was evaluated by the area under receiver operating characteristic curve (AUC) and newly developed and more powerful reclassification improvement measures, integrated discrimination improvement (IDI) and net reclassification improvement (NRI).

Results: Among 685 women (mean age, 64.2 ± 8.2 years) with no conditions affecting bone metabolism, 102 suffered incident VFx (17.3/103 person-years). These women were older and had lower BMD and TBS than those with no fractures.

Participants were classified into TBS tertile groups within each stratum of BMD (normal, osteopenia and osteoporosis, defined according to WHO criteria). Lower BMD and TBS of participants were both significantly associated with higher incidence rates of VFx (both $p<0.001$). Interestingly, the lowest TBS group in osteopenic women had a higher risk of VFx than the highest TBS group in osteoporotic women (22.9 vs 15.8/1000 person-years, respectively) (Fig).

The area under receiver operating characteristic curve (AUC) of TBS and BMD combined was 0.702 for VFx prediction and only marginally greater than the AUC of BMD alone (0.669, $p=0.086$). However, the reclassification improvement measures showed significant increases in classification accuracy achieved by BMD and TBS in combination compared with BMD alone (IDI: 0.028 (95% confidence interval (CI): 0.011, 0.046); NRI: 0.234, (95% CI: 0.024, 0.443)).

Conclusions: Lower TBS was associated with a higher risk of VFx over 10 years independently of BMD in middle-aged and elderly Japanese women. TBS could effectively improve fracture prediction by BMD alone.

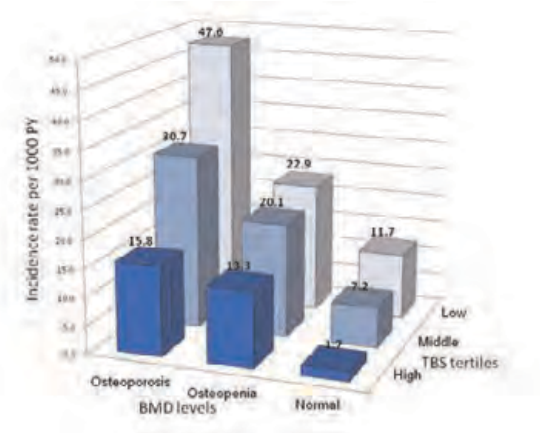

Fig. Incidence rates of vertebral fractures in TBS tertile groups within BMD strata.

Adherence to a Vegetable-fruit-soy Dietary Pattern or the Alternate Healthy Eating Index is Associated with Lower Hip Fracture Risk among Singapore Chinese. Zhaoli Dai*[1], Lesley Butler[2], Rob M. van Dam[3], Li-Wei Ang[4], Jian-Min Yuan[2], Woon-Puay Koh[5]. [1]Saw Swee Hock School of Public Health, National University of Singapore, Sgp, [2]Division of Cancer Control & Population Sciences, University of Pittsburgh Cancer Institute, Pittsburgh, Pennsylvania, USA; Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA, USA, [3]Saw Swee Hock School of Public Health, National University of Singapore, Singapore, Singapore, [4]Epidemiology & Disease Control Division, Ministry of Health, Singapore, Singapore, [5]Saw Swee Hock School of Public Health, National University of Singapore, Singapore; Duke-NUS Graduate Medical School Singapore, Singapore, Singapore

Evidence for a relationship between the overall diet and fracture risk is scarce with mixed results. We studied the diet-hip fracture association by assessing two distinct Chinese dietary patterns in Singapore, namely the vegetable-fruit-soy (VFS) and the meat dim-sum (MDS) patterns, as well as the Alternate Healthy Eating Index 2010 (AHEI 2010), which was created based on the foods and nutrients consistently predictive of chronic disease risk in the U.S.

We used prospective data from the Singapore Chinese Healthy Study, a population-based cohort of 63,257 Chinese men and women aged 45-74 years at recruitment between 1993 and 1998. Dietary patterns were identified from the baseline habitual dietary intakes, which were recorded using a validated food frequency questionnaire. We derived the VFS (23 vegetable, 4 fruit and 5 soy food items) and the MDS (18 meat, 7 rice and 5 noodle items) patterns by principal component analysis (a posteri approach). The overall dietary quality was estimated according to the AHEI 2010, which reflects adherence to healthier food choices in disease prevention (a priori method). Quintile cutpoints of each dietary score were derived based on the distribution of the whole cohort and were examined in relation to hip fracture incidence using Cox regression after adjusting for potential confounders.

A total of 1,630 incident hip fracture cases were identified via record linkage with the nationwide hospital discharge database through 2010, after excluding 103 prevalent cases at recruitment. The VFS pattern had moderate correlation with the AHEI 2010 (r=0.42). We observed strong dose-dependent inverse associations for both higher scores of the VFS pattern and the AHEI 2010 with hip fracture risk (p for trend<0.0001) (Figure 1). Compared with the lowest quintile, subjects in the highest quintile had a 34% lower hip fracture risk (95% CI: 22% to 45%) for the VFS pattern and a 27% lower risk (95% CI: 15% to 38%) for the AHEI 2010. Results were similar in both genders. The MDS pattern was not associated with hip fracture risk.

This is the first study demonstrating that the risk of hip fracture may be reduced by a healthy dietary pattern defined either as a typical Chinese diet rich in fruits, vegetables and soy, or as a pattern with greater adherence to healthier food choices recommended for chronic disease prevention. Our findings support the importance of promoting an overall healthy diet to protect against osteoporotic fractures.

Figure 1. Hazard ratio (HR) of hip fracture according to quintile of the VFS pattern score and the AHEI 2010 score for overall (n=63,154), the Singapore Chinese Health Study

Impact of a Theory-Based Osteoporosis Education Intervention and BMD Screening on Calcium and Vitamin D Intake in Older Men and Women. Katherine McLeod*[1], Shanthi Johnson[2], Drona Rasali[3]. [1]Faculty of Kinesiology & Health StudiesUniversity of Regina, Canada, [2]Saskatchewan Population Health & Evaluation Research Unit, University of Regina, Canada, [3]University of Regina, Canada

Purpose: Adequate calcium and vitamin D intake play an important role in prevention and management of osteoporosis and related fracture. However, the majority of at-risk men and women are not engaging in these health behaviours. We determined the impact of a theory-based osteoporosis education intervention and BMD screening on older men and women's decisions to start or increase total calcium and vitamin D intake (food and supplement). Methods: A 6-month randomized controlled trial was carried out in Saskatchewan, Canada. Eligible subjects were recruited from a local hospital and included men and women 50 years of age and older, referred by their physician for BMD screening for the first time. Subjects (N = 203, mean age = 59.7 years, SD 7.1) were randomly assigned to an intervention group (n = 102) or usual care group (screening alone) (n = 101). After screening, and prior to discussing results with a physician, subjects completed a 3-day food diary, health history questionnaire and reported use of all supplements. The intervention group also received theory-based osteoporosis education using constructs of the Revised Health Belief Model as a guiding framework. The intervention included a package of print material and calcium/vitamin D magnets, short video, and one-on-one discussion. Six months post-baseline, subjects completed a series of follow-up questionnaires and 3-day food diary. Results: At baseline, intervention and usual care groups had mean total calcium intake (1,152.0 mg/day and 1,173.1 mg/day, respectively) and vitamin D intakes (778.4 IU/day and 773.3 IU/day, respectively) below recommendations. At 6-month follow-up total calcium and vitamin D intake increased in both groups; however, there was a significant mean difference in calcium (250.4 mg/day) and vitamin D (242.5 IU/day) intake in the intervention group compared to usual care (p = .03). Overall, 58.6% and 69.7% started or increased calcium and vitamin D intake, respectively. In multivariate adjusted models, receiving osteoporosis education intervention, low total calcium intake and not taking vitamin D supplements at baseline were associated with change in intake. Conclusions: Theory-based osteoporosis education intervention improved calcium and vitamin D intake in newly screened older men and women. Taking health beliefs into consideration when developing and implementing education interventions may be useful in both research and practice for osteoporosis prevention and management.

Can Changes in FRAX Probability Be Used to "Treat-to-Target"? A Clinical Feasibility Study. William Leslie*[1], Lisa Lix[1], Suzanne Morin[2], Sumit Majumdar[3], Helena Johansson[4], Eugene McCloskey[5], Anders Oden[6], John Kanis[7]. [1]University of Manitoba, Canada, [2]McGill University, Canada, [3]University of Alberta, Canada, [4]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [5]University of Sheffield, United Kingdom, [6]Consulting statistician, Sweden, [7]University of Sheffield, Belgium

Background: FRAX is intended to select individuals for treatment based upon fracture risk. It is unknown how responsive FRAX is to treatment or whether it can serve as a target for guiding duration of therapy

Objective: To describe predictors of change in FRAX probability in older women.

Methods: We identified 11,049 untreated women age >50 years undergoing baseline and subsequent DXA examinations (1998-2011) in a large clinical database for the Province of Manitoba, Canada. By linking to a population-based data repository, we identified relevant risk factors, any intervening osteoporosis treatment (OTX), and incident fractures to March 2011. FRAX probabilities for major osteoporotic fracture (MOF) and hip fracture (HF) were computed for each DXA scan using the subject's most current (updated) FRAX input variables. Changes in FRAX probabilities from baseline were stratified by testing interval (1-3y, 3-5y and >5y) and OTX expressed as medication possession ratios (MPR=0 [reference], <0.50 [low], 0.50-0.79 [moderate], 0.80+ [high]). Odds ratios (OR) for predictors of change in FRAX probability and hazard ratios for incident fractures were adjusted for baseline risk.

Results: Over time, median FRAX probabilities increased in all MPR categories, including high MPR women despite increased BMD (Table). Although OTX attenuated increases in FRAX score (p-for-trend <.001), differences were small (<1%) and within the range of rounding error. Only 1.6% of high MPR women had a decrease in MOF probability over 5%, while 9.0% had a decrease in HF probability over 1%. Compared with MPR=0, OTX was associated with smaller increases in MOF FRAX probability (lowest versus highest change quartile): OR 2.3 (95%CI 1.8-2.9) for MPR <0.50, 7.3 (95%CI 5.6-9.6) for MPR 0.50-0.79, 12.0 (95%CI 9.5-15.2) for MPR 0.80+. Changed FRAX inputs associated with change in MOF probabilities in decreasing order of importance were: BMD, age, glucocorticoids, prior fracture, alcohol, rheumatoid arthritis, smoking, and BMI. Similar findings were seen for changes in HF probability. Overall and stratified by treatment, changes in FRAX probability did not contribute to prediction of future MOF or HF.

Conclusions: FRAX probabilities generally increase over time, and are only weakly affected by treatment. This finding was true even among the most highly adherent women. Few women had clinically important reductions in FRAX probabilities, nor did change in FRAX probabilities enhance fracture prediction.

Interval	Treatment	N	Δ MOF with BMD	Δ HF with BMD	Δ BMD Lumbar spine	Δ BMD Femoral neck
1-3 years	None (MPR=0)	1277	0.7 (0.3:1.3)	0.2 (0.0:0.5)	-1.2% (-3.9:1.7)	-1.3% (-4.2:1.3)

Lumbar Spine Trabecular Bone Score (TBS) combined with FRAX improves fracture prediction: The Manitoba BMD Cohort. William Leslie*[1], John Kanis[2], Olivier Lamy[3], Helena Johansson[4], anders oden[5], Eugene McCloskey[5], Didier Hans[6]. [1]University of Manitoba, Canada, [2]University of Sheffield, Belgium, [3]University Hospital, Switzerland, [4]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [5]University of Sheffield, United Kingdom, [6]Lausanne University Hospital, Switzerland

TBS, a novel gray-level measurement derived from lumbar spine DXA image texture, is related to microarchitecture and fracture risk independently of BMD. FRAX estimates the 10-year probability of hip and major osteoporotic fracture (MOF) using risk factors that act independently of femoral neck BMD. We assessed the value of combining FRAX probability with lumbar spine TBS.

42,170 women age >50 years at the time of baseline DXA were identified in a database of all clinical results for Manitoba, Canada. Lumbar spine TBS was calculated blinded to clinical parameters and outcomes. Health service records were assessed for FRAX covariates at the time of DXA and for incident non traumatic MOF and hip fracture codes to March 31st 2011. FRAX probabilities were calculated with BMD. Cox proportional hazards models including competing mortality were developed for time to first fracture based upon TBS (continuous or tertiles), osteoporosis medication use, and FRAX probability. Two-way interactions between TBS and FRAX risk factors were tested. Additional models included lumbar spine BMD and the spine-hip T-score "offset".

The mean age of the population was 65.7 ± 9.5 y. During mean 5.6 y, incident MOFs were identified in 2661 women (674 hip fractures). Lower lumbar spine TBS and higher FRAX probabilities were found in fracture vs non fracture women (all P<0.001). TBS modulated fracture risk after adjustment for treatment and individual FRAX risk factors (hazard ratio [HR] per SD reduction in TBS: MOF 1.21 [95% CI 1.16-1.250, P<0.001; hip fracture 1.14 [95% CI 1.05-1.23), P=0.001). Results were largely unaffected by including lumbar spine BMD or spine-hip T-score "offset" in the model. A preliminary method to adjust FRAX probability based upon lumbar spine TBS tertile is shown in the Table. When used to reclassify fracture risk, this gave a significant increase in integrated discrimination index for MOF (+1.3%, P<0.001) and hip fracture (+1.3%, P<0.001), with net reclassification improvement +4.6% for MOF (P<0.001). There was an age interaction with larger TBS effects in younger than older women age for MOF (P<0.001) and hip fracture (P=0.002).

In summary, an incremental improvement in fracture prediction was seen by using lumbar spine TBS in combination with FRAX. An approach that addresses the age-TBS interaction may be required. If validated in other prospective cohorts, lumbar spine TBS may become clinically useful for enhancing fracture prediction from FRAX.

	Change to Major Osteoporotic Fracture probability	Change to Hip Fracture probability
If L1L4TBS is in the lowest tertile:	Increase 25%*	Increase 30%*
If L1L4TBS is in the middle tertile (referent):	No change	No change
If L1L4TBS is in the highest tertile:	Decrease 21%*	No change
*P<0.001

SA0319

Correlation between early Micro-Architectural Changes and Patient-Rated Wrist Pain and Disability 12 weeks after a Distal Radius Fracture. Joost De Jong*[1], Ursina Meyer[2], Sandrine Bours[3], Paul Willems[4], J. J. Chris Arts[4], Peter Brink[5], Tineke Van Geel[6], Bert Rietbergen[7], Joop Van Den Bergh[8], Piet Geusens[9]. [1]Maastricht University Medical Center, The Netherlands, [2]Department of Human Movement Sciences, Maastricht University, Netherlands, [3]Maastricht University Medical Centre, The Netherlands, [4]Department of Orthopaedic surgery, Maastricht University Medical Centre, Netherlands, [5]Department of Trauma Surgery, Maastricht University Medical Centre, Netherlands, [6]Maastricht University, The Netherlands, [7]Eindhoven University of Technology, The Netherlands, [8]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands, [9]University Hasselt, Belgium

Factors affecting patient-reported pain and disability after distal radius fractures are essential elements in understanding the process of fracture healing. High resolution peripheral quantitative computed tomography (HR-pQCT) combined with micro finite element analysis (μFEA) allows to assess changes in bone mineral density (BMD), micro-architecture and calculated biomechanical competence during fracture healing. We assessed the association between these early changes and wrist-specific pain and disability at 12 wk post-fracture in postmenopausal women with a stable distal radius fracture.

Eighteen women (aged 68±8 yr) with a stable, conservatively treated distal radius fracture were recruted. At four visits (1-2, 3-4, 6-8, 12 wk post-fracture), patients rated their pain and disability using Patient Rated Wrist Evaluation (PRWE; range 0-100) and

Quick Disabilities of the Arm Shoulder and Hand (QuickDASH; 0-100) questionnaires, and a visual analogue scale (VAS; 0-100) with higher values indicating worse status. At each visit, BMD, micro-architecture and mechanical parameters of the fracture region were assessed by HR-pQCT and μFEA, and serum bone markers [procollagen type-I N-terminal propeptide (P1NP) and carboxy-terminal telopeptide of type I collagen (ICTP)] were measured. Pain and disability at visit 4 were linearly regressed on changes in bone parameters from visit 1 to 2, adjusted for number of days post-fracture.

PRWE at 12 wk (mean 42±29) correlated negatively with the increase in trabecular BMD [β=-0.95 (95%CI: -1.75 to -0.16) mgHA·cm^{-3}, p=0.02], positively with the change in trabecular separation [208 (14.6 to 401) mm, p=0.04], and negatively with the change in torsional stiffness [-0.14 (-0.28 to -0.004) kN·mm·rad^{-1}; p=0.04]. Further, PRWE at 12 wk correlated positively to the change in ICTP [12.0 (-0.032 to 24.0) μg/l; p=0.051]. Comparable results were found for QuickDASH, but not for the VAS-score. Adjusting for DXA T-score, fracture type, fracture at dominant side or serum vitamin D levels did not affect the results.

Changes in the trabecular density, torsional stiffness and bone resorption during the first weeks after radius fracture were correlated with the pain and disability at 12 wk post-fracture. These results suggest that assessment of changes in micro-architectural parameters during early stages of fracture healing could provide valuable information for predicting the clinical outcome of distal radius fractures.

Efficacy of a Hospital-Based Fracture Liaison Service in the Secondary Prevention of Osteoporotic Fractures. Elizabeth McAninch*[1], Violet Lagari[2], Sanford Baim[3]. [1]University of Miami/Jackson Memorial Hospital, USA, [2]University of Miami, USA, [3]Miller School of Medicine, University of Miami, USA

Despite the high prevalence of osteopenia and osteoporosis, these conditions remain underdiagnosed and -treated, resulting in undue morbidity and economic burden. The ASBMR advocates for secondary fracture prevention by formal implementation of Fracture Liaison Services [Eisman, et al. Making the First Fracture the Last Fracture: ASBMR Task Force Report on Secondary Fracture Prevention. JBMR. 2012;27(10):2039-46]. The University of Miami Hospital offers a unique setting for implementation of such a service as it exemplifies an "open" healthcare system. Here we propose our plan to create the University of Miami Hospital Fracture Liaison Service (UMH FLS).

The UMH FLS is an in-hospital consult service staffed by osteoporosis experts that will identify patients aged 50 and over admitted with acute fractures. The UMH FLS provides comprehensive osteoporosis assessments and direct physician-to-patient education about the diagnosis and implications of having osteoporosis. During the patient encounter we will perform a thorough history and physical exam to determine the etiology of the fracture, provide verbal/written osteoporosis patient education, refer the patient for outpatient follow up for initiation of FDA-approved osteoporosis treatment when medically appropriate, and refer to specialized physical/occupational osteoporosis therapy inclusive of a home falls prevention program. Informed consent will be obtained during the inpatient encounter that will allow the UMH FLS to send questionnaires and directly contact participants at 3 months and annually for a total of five years post-discharge through an IRB-approved protocol. The questionnaire will ascertain participant osteoporosis outcome measures such as information regarding health status (specifically incident fractures) and compliance with physician follow up, medical therapies, DXA tests, and physical/occupational therapy. To assess for benefit of the UMH FLS, we will perform a three-year retrospective analysis of incident fractures through chart review.

We hypothesize that implementation of the hospital-based UMH FLS will improve care for patients with osteoporotic fractures in a cost-effective manner resulting in subsequent prevention of secondary fractures. If evidence confirms reduced morbidity, mortality and economic burden as a result of the UMH FLS, this would further support the adoption of our methodology as a standard of care in the treatment of inpatients with acute osteoporotic fracture.

Fracture Burden For Men, In Relation To Osteopenia And Osteoporosis Defined By Male And Female Reference Data For Areal Bone Mineral Density. Julie Pasco*[1], Stephen Lane[1], Sharon Brennan[2], Elizabeth Timney[1], Gosia Bucki-Smith[1], Amelia Dobbins[1], Mark Kotowicz[3]. [1]Deakin University, Australia, [2]The University of Melbourne, Australia, [3]Deakin University School of Medicine, Australia

Purpose: The purpose of this study was to quantify fracture risk associated with osteopenia and osteoporosis in older men, defined by areal bone mineral density (BMD) and using cut-points derived from male and female reference data.

Methods: In this prospective analysis we followed 619 men aged 60-93 years (median 74.4yr) for a median 6.4yr, after baseline BMD assessments (performed 2001-6) as part of the Geelong Osteoporosis Study. Based on WHO criteria, and using male reference data, 207 men had normal BMD at the femoral neck, 357 were osteopenic and 55 osteoporotic. Using female reference data, corresponding numbers were 361, 227 and 31, respectively. Participants were followed until the end of 2010, or until sustaining a fracture, death, or emigration. Post-baseline fractures were ascertained radiologically.

Results: During the study 130 men died, 15 left the region, 63 sustained at least one fracture. Using male reference data, most (86.6%) of the fractures occurred in men without osteoporosis on BMD criteria (17.9% with normal BMD, 68.7% with osteopenia) whereas 13.5% of the fractures occurred in men with osteoporosis. The pattern differed when female reference data were used; while most fractures arose from men without osteoporosis (88.2%), the burden shifted from those with osteopenia (35.0%) to those with normal BMD (53.2%).

Conclusions: Categories of decreasing BMD defined increasing risk of fracture. Although men with osteoporotic BMD were at greatest risk, they made a relatively small contribution to the total burden of fractures. Using male reference data, two-thirds of the fractures arose from men with osteopenic BMD. However, using female reference data, approximately half of the fractures arose from those with normal BMD.

FRAX in combination with Lumbar Spine Trabecular Bone Score (TBS) better discriminates vertebral fracture than BMD, TBS or FRAX alone: The OsteoLaus Study. Olivier Lamy*[1], Marc-Antoine Krieg[2], Delphine Stoll[3], Berengere Aubry-rozier[4], Marie Metzger[5], Didier Hans[4]. [1]Chief of the Bone Unit, Switzerland, [2]University Hospital, Switzerland, [3]MD, Bone Unit, University hospital, Switzerland, [4]Lausanne University Hospital, Switzerland, [5]Bone Unit, University hospital, Switzerland

Osteoporosis (OP) is a systemic skeletal disease characterized by a low bone mineral density (BMD) and a micro-architectural (MA) deterioration. TBS, a novel gray-level measurement derived from lumbar spine DXA image texture, is related to microarchitecture and fracture risk independently of BMD. FRAX estimates the 10-year probability of hip and major osteoporotic fracture (MOF) using risk factors that act independently of femoral neck BMD. We assessed the value of combining FRAX probability with lumbar spine TBS versus each parameter alone in discriminate vertebral fracture from controls. The OsteoLaus cohort (1500 women 50 to 80 years living in Lausanne, Switzerland) started in 2010. Clinical risk factors for osteoporosis / fracture, FRAX, lumbar spine and hip BMD, VFA by DXA and microarchitecture evaluation by TBS are recorded in OsteoLaus. Preliminary results are reported. Sensitivity and specificity in regard to vertebral fracture grade 2/3 has been calculated for all Bone modalities as stand-alone or combined approaches. A first approach to adjust FRAX by TBS has been applied. Integrated discrimination index and net reclassification improvement have also been investigated. We included 911 women: mean age 65.2+/-7.9 y, BMI 25.7+/-4.4, mean lumbar spine BMD 0.931+/-0.16(T-score -1.04 SD), TBS 1.289+/-0.100. As expected, correlation between BMD and site matched TBS is low (r2=0.16). Prevalence of VFx grade 2/3 and MOF are 7.5% and 15.0% respectively. Sensitivity and specificity for different combination can be found in the table. When used to reclassify fracture risk, this gave a significant increase in integrated discrimination index for VFx (+2.5%, P<0.001), with net reclassification improvement +7.6% for VFx (P<0.001).

While the optimal threshold for TBS should be investigated, an incremental improvement in fracture identification was seen by using lumbar spine TBS in combination with FRAX. If validated in prospective cohorts, lumbar spine TBS may become clinically useful for enhancing fracture prediction from FRAX. Such simple way to take TBS into account would allow the use of current medical society recommendation regarding osteoporosis management with only minor adaptation.

Hip Fracture Trends in Denmark 1980-2010 with Age-Period-Cohort-effects.
Bjorn Rosengren*[1], Jonas Björk[2], Cyrus Cooper[3], Bo Abrahamsen[4]. [1]Skåne University Hospital Malmö, Lund University, Sweden, [2]Unit for Medical Statistics & Epidemiology at R&D Centre Skåne, Skåne University Hospital, Sweden, [3]University of Southampton, United Kingdom, [4]University of Southern Denmark, Denmark

Background: The origin of the recent levelling-off in hip-fracture incidence in several settings is unknown.

Methods: Using Danish national inpatient data for individuals aged ⩾50 years during 1980-2010, we examined annual number and incidence of hip fractures and age, period, and cohort effects by log-likelihood estimates in Poisson regression models. Age adjustment was done by direct standardization, time-trend analysis by linear regression, and identification of breakpoints in linear trends by join-point analyses.

Results: There were 240 121 hip fractures, 74% in women. Before 1993, the annual age-standardized hip fracture incidence increased (2.8% per year [95% confidence interval 2.3% to 3.3%]), and the annual number of hip fractures increased (4.4% per year [3.8% to 5.0%]). After 1993, the age-standardized hip fracture incidence decreased (-1.2% per year [-1.5% to -0.9%]) and the number of hip fractures was stable (-0.3% per year [-0.7% to -0.0%]).

The combined period+cohort effects were more marked in men, with an incidence rate ratio (IRR) ranging from 0.4 to 1.2 depending on 6-year birth cohort and 0.7 to 1.1 depending on 3-year period. In women the corresponding results were IRR 0.8 to 1.4 and 0.9 to 1.2.

Analyses of specific cohort effects (estimated by deviations from underlying linear trends in cohort) in the full APC-model showed higher risk in men born 1900-1926 and in women born 1897-1938. The corresponding specific period analyses revealed increasing risk for men with later period while a higher risk was evident in the middle of the examination period for women.Conclusion

The annual age-standardized hip fracture incidence has decreased in Denmark since 1993, resulting in a stable annual number of hip fractures. The magnitude of the period+cohort effects suggests a risk modulation in parity with other established risk factors for hip fracture. Gender-specific differences may partly result from changes in hormone-replacement or anti-osteoporosis therapy.

How to Adjust the Overestimate of the Incidence of Major Osteporotic Fracture When Using Summary Data.
Thor Aspelund*[1], Kristin Siggeirsdottir[1], Elias Gudmundsson[1], Brynjolfur Y Jonsson[2], Brynjolfur Mogensen[3], Vilmundur Gudnason[4], Gunnar Sigurdsson[3]. [1]Icelandic Heart Association, Iceland, [2]Skane University Hospital, Sweden, [3]Landspitalinn University Hospital, Iceland, [4]Icelandic Heart Association Research Institute, Iceland

Major osteporotic site (MOS) fracture is a fracture of any of hip, vertebral, distal forearm or proximal humerus. This event is common and the risk increases with age. It is important to have a reliable estimate of the incidence for better management of resources and to recognize who is at risk. When individual data is not available an estimate can be constructed by adding up the incidence of the individual fracture types which may be easier to obtain. This results in an overestimate because individuals can sustain fractures of different types. Knowledge about the overlap can be used to calibrate the MOS fracture incidence estimate.

The Icelandic Reykjavik Study is a population based cohort study of men and women with almost 19000 participants recruited between 1967 and 1992. We used the fracture registration associated with the Reykjavik Study to estimate the MOS fracture incidence (any-of-4), the incidence of the 4 fracture types and their sum (sum-of-4). The incidence was estimated for men and women from age 45 to 90. The ratio between the sum-of-4 to any-of-4 was computed to estimate the magnitude of the overestimate due to overlap by sex and age.

The overestimate was about 3% for the age group 45-49, 10% for the age group 65-69, and increased linearly up about 22% for the age 85-89. These results about the overlap were in strong agreement with results from the Malmö study in Sweden. This means that the overlap adjustments from the Malmö study could be applied to the sum-of-4 from the Reykjavik Study to provide almost identical MOS fracture incidence estimates (any-of-4) as directly estimated from the Reykjavik Study. This supports the methodology of adding incidence of individual fracture types and then apply overlap adjustments from the Malmö study to construct MOS fracture incidence, which has been used as a calibration for FRAX when individual data is not available.

Impact of a Fragility Fracture on Quality of Life 6 and 18 Months Post Fracture.
Claudia Beaudoin*[1], Sonia Jean[2], Louis Bessette[3], Louis-Georges Ste-Marie[4], Jacques P. Brown[3]. [1]Centre de recherche du CHU de Québec, Canada, [2]INSTITUT NATIONAL DE SANTÉ PUBLIQUE DU QUÉBEC, Canada, [3]CHU de Quebec Research Centre, Canada, [4]CHUM, Canada

Purpose: To assess the health-related quality of life (HRQoL), over time, in women (⩾ 50 years) after a fragility fracture (FF). Methods: In the Recognizing Osteoporosis and its Consequences in Quebec programme, a cohort of women who recently suffered from a FF were recruited from hospitals and an administrative database-generated list. The HRQoL was assessed with the EQ-5D health questionnaire which was mailed to women 6 and 18 months post fracture. In the EQ-5D questionnaire, 5 dimensions of health were covered (mobility, self-care, usual activities, pain/discomfort and anxiety/depression) and the perception of general health was evaluated using a visual analogue scale where 0 represents the worst health and 100, perfect health. As a comparison group, data from a general population cohort of 262 women from Alberta aged ⩾ 50 years were used (Johnson et al, 2000). In women suffering each fracture type, the mean health perception score and the proportion of women reporting problems were compared with the reference population using age-weighted chi-square and student tests. Results: 1979 and 1927 women completed the EQ-5D questionnaire at 6 and 18 months, respectively. Six months following a hip/femur fracture, the proportions of women reporting problems with self-care (18%), usual activities (52%), pain/discomfort (83%) and anxiety/depression (45%) were significantly greater than in women from the general population (Figure 1). Problems with usual activities (51%), pain/discomfort (79%) and anxiety/depression (41%) remained significantly greater 18 months after a hip/femur fracture (Figure 2). For women who suffered a humerus fracture, the proportion reporting problems was also significantly greater for self-care (17%) and pain/discomfort (79%) at 6 months, and for pain/discomfort (70%) at 18 months when compared to the general population. Having suffered an ankle/tibia/fibula/foot or a forearm/elbow/wrist fracture did not result in a significant impact on the EQ-5D. At 6 and 18 months, the general health perception for women with a hip/femur fracture (mean scores of 69 and 70, respectively) was significantly lower than that in the general population (mean score of 75). Conclusions: This study shows that the HRQoL of women who suffered a hip/femur or humerus fracture remains lower than in the general population even 6 months post FF. After 18 months, some dimensions of quality of life in women with a previous FF at some fracture sites are still compromised.

Clinical and Economic Characteristics of Hip Fracture Patients in the United States with Poor Health Outcomes. Zhanglin Cui*[1], Yang Zhao[2], Lei Chen[3], Yi Chen[4], Russel Burge[1]. [1]Eli Lilly & Company, USA, [2]Novartis Pharmaceuticals Corporation, USA, [3]Eli Lilly, USA, [4]inVentiv Health Clinical, USA

Purpose: To identify characteristics of hip fracture patients with or without muscle disuse atrophy/weakness (MAW, identified by ICD-9 code); predictors of poor post-fracture outcomes (high costs, high healthcare utilization, long hospitalization); and subgroups at increased risk for poor outcomes.

Methods: Thomson Reuters MarketScan® data were used to identify United States (US) patients aged ⩾50 years, with inpatient hospital stays for hip fracture Jan 2006 - Sep 2010. Patients had ⩾12 months of continuous enrollment, prior to the index hospitalization, and 12 months following the discharge date, with no hip fracture diagnoses 7 days - 1 year prior to the index date. Predictive characteristics of patients with poor outcomes were identified via multiple logistic regression analyses. Poor outcomes subgroups were identified by classification and regression tree (CART) analyses.

Results: Commercial (n=5,350) and Medicare (n=29,643) patients with hip fracture were identified (mean age: 57.9 and 81.8 years, respectively). More than 10% of each cohort had osteoarthritis, osteoporosis, diabetes, chronic pulmonary disease, or tumors. Prior hospital stays, outpatient visits, and emergency room visits were common (⩾25%) among patients. The mean index hospitalization costs were $31,051 (commercial patients) and $19,331 (Medicare patients). Index stay durations were about 6 days in both cohorts. On average, post-fracture, 1-year, all-cause healthcare costs ($41,718) were higher than costs for the previous 1 year ($28,852; $p<0.05$). Compared to patients without MAW, patients with MAW had greater 1-year healthcare utilization and costs ($p<0.05$). In multiple logistic regression analyses, greater post-fracture costs were associated with higher prior hospitalization counts, prior emergency room visit counts, length of index hospital stay, and Charlson Comorbidity Index (CCI), as well as with discharge status,; diagnosis of rheumatoid arthritis or osteoporosis; and prior use of antidepressants, anticonvulsants, muscle relaxants, opioids, and oral corticosteroids (all $p<0.05$). From CART analysis, subgroups of high-cost patients included those with MAW, longer prior hospitalizations, and high CCI score. Subgroups of patients with longer hospital stays included those with MAW and longer prior hospitalizations.

Conclusions: Among US patients with hip fractures, poor post-fracture outcomes were associated with MAW, prior hospitalizations, comorbidities, and medications.

Osteoporosis Treatment after Vertebral and Hip Fractures: Analysis of a Managed Care Population in the US. Ankita Modi[1], Amber Wilk[2], Chun-Po Steve Fan[3], Shiva Sajjan*[1], Panagiotis Mavros[1]. [1]Merck & Co., Inc., USA, [2]Virginia Commonwealth University, USA, [3]AsclepiusJT LLC, USA

Purpose: It is recommended that fractures patients be treated with pharmacological treatment for osteoporosis to mitigate subsequent fracture risk. This study examined osteoporosis treatment use after vertebral or hip fractures in a US managed care population. Methods: A retrospective analysis using i3 Invision Datamart, a large claims database, from January 2003 to June 2012 (study period) was conducted. Women ⩾ 50 years of age with vertebral and/or hip fracture during the study period with continuous enrollment 24 months before (pre-index) and 12 months after (post-index) the first fracture (index date) were included. Women with Paget's disease or malignant neoplasms were excluded. Fractures were identified using ICD-9 diagnosis codes. Osteoporosis treatment included bisphosphonates (alendronate, ibandronate, risedronate, zoledronic acid) and non-bisphosphonates (calcitonin, raloxifene, teriparatide, denosumab), which were identified by NDC and HCPCS codes. Charlson comorbidity index (CCI) was used to quantify a patient's overall comorbid conditions. Pre- and post-index osteoporosis treatment use was assessed by fracture site. Results: 11,433 women ⩾ 50 years of age (7,834 vertebral; 3,599 hip fracture) were included in the study. Hip fracture patients were on average older than the ones with vertebral fracture patients (71.3 *vs*. 66.8 years, $p<.001$). Hip fracture patients had a significantly higher average CCI than vertebral fracture patients (1.5 *vs*. 1.3, $p<.001$). Despite occurrence of fracture, 82.1% of patients did not receive treatment within the 3-month post-index period, and 77% remained untreated at 1-year post-index. The number of hip fracture patients not receiving treatment within 3-month and 1-year post-index periods was significantly higher than that of the vertebral fracture patients (3-month untreated rate: 81.6% *vs*. 69.4%, $p< .001$; 1-year untreated rate: 75.0% *vs*. 62.5%, $p<.001$). Among those treated within 3-month (1-year) post-index, the average time between fracture and treatment were 13.8 (46.5) and 20.7 (65.4) days for vertebral and hip fracture patients, respectively. Conclusions: This study shows a high rate of undertreatment of osteoporosis with medications after patients experienced vertebral and hip fractures despite treatment recommendations for these high-risk patients. This warrants a need for further education regarding osteoporosis management for patients with prior fractures.

Prevalence and Predictive Capacities of Different Definitions of Severe Osteoporosis. Claudie Berger*[1], Lisa Langsetmo[2], David Goltzman[3], George Ioannidis[4], Jerilynn Prior[5], Youb Chalabi[6], Robert Josse[7], Stephanie Kaiser[8]. [1]CaMos, McGill University, Canada, [2]Canandian Multicenter Osteoporosis Study, Canada, [3]McGill University, Canada, [4]McMaster University, Canada, [5]University of British Columbia, Canada, [6]Eli Lilly, Canada, [7]St. Michael's Hospital, University of Toronto, Canada, [8]Dalhousie University, Canada

Severe osteoporosis is variously defined. We assessed the prevalence, risk factors, use of antiresorptive therapy, and risk of subsequent fragility fracture (ffx) associated with different definitions of severe osteoporosis.

We examined 2187 men and 5566 women aged 50 years (y) and older from the Canadian Multicentre Osteoporosis Study (CaMos). Participants had a questionnaire and bone mineral density (BMD) measurements at baseline (1995-7) and were contacted annually for 14 y about incident ffx. We defined 6 groups of severe osteoporosis: (1) BMD T-score (L14 or total hip or neck) <-2.5; (2) definition 1 and prior 4-ffx (hip, back, forearm/wrist, shoulder); (3) at least 2 ffx (any site excluding hands, feet, skull); (4) BMD T-score (L14 or total hip or neck) <-3; (5) FRAX 4-ffx risk >20%; and (6) FRAX 4-ffx risk >20% and a prior 4-ffx. Logistic regressions were used to assess the odds ratios (OR) of 14-y incident ffx for severe osteoporosis compared to normal participants (T-score [L14 and total hip and femoral neck] >-1 and no prior ffx).

The Canadian prevalence of severe osteoporosis varies by definition (Table 1); it is higher with T-scores versus prior ffx or FRAX scores. At baseline, the antiresorptive use in Canadian women with severe osteoporosis was 16-25% and near zero in men. After 5-y (2000-2), antiresorptive use more than doubled in women with severe osteoporosis (by definitions 1-4) and varied from 4-15% in men. In women, older age, lower body mass index (BMI), shorter height, non use of hormone therapy, family history of osteoporosis and lower SF-36 physical health component score were associated with severe osteoporosis irrespective of definition. Current use of cigarettes, less alcohol intake, more sedentary hours/day, lower dietary calcium intake and no use of calcium and vitamin D supplements were related to one or more of the definitions. In men, older age and lower BMI were related to all severe osteoporosis definitions. The ORs for 14-y incident ffx for severe osteoporosis versus controls are shown in Figure 1. FRAX scores gave the highest ORs for 14-y incident ffx but also showed the widest confidence intervals.

Elevated ffx risk was observed in those with severe osteoporosis by all definitions, but was highest among those with a history of ffx, thus establishing priority for those with prior ffx. Those without previous ffx are a much more prevalent subgroup but are still at substantial risk of future ffx.

Table 1: Canadian prevalence of severe osteoporosis at baseline by six definitions in women and men aged 50 and older.

Definition of severe osteoporosis	Women	Men
T[1] <-2.5	35.1	16.7
T[1] <-2.5 & ≥ 1 prior 4-ffx[2]	6.1	1.5
≥ 2 prior ffx (any site[3])	4.7	3.0
T[1] < -3	25.0	13.1
FRAX 4-ffx risk > 20%	9.4	0.4
FRAX 4-ffx risk > 20% & ≥ 1 prior 4-ffx[2]	3.2	0.2

[1] T-score is L14 or total hip or femoral neck
[2] 4-ffx = fragility fracture of the hip, back, forearm/wrist, or shoulder
[3] Excluding head, hand, foot

Secular Trends in the Incidence of First Hip, Clinical Vertebral, Distal forearm and Proximal Humerus Fractures in Icelandic Men and Women in 1989-2008. Gunnar Sigurdsson*[1], Kristin Siggeirsdottir[2], Elias Gudmundsson[2], Brynjolfur Y Jonsson[3], Brynjolfur Mogensen[4], Thor Aspelund[2], Vilmundur Gudnason[5]. [1]Landspitali, Iceland, [2]Icelandic Heart Association, Iceland, [3]Skane University Hospital, Sweden, [4]Landspitalinn University Hospital, Iceland, [5]Icelandic Heart Association Research Institute, Iceland

Incidence estimate for first fracture of hip, vertebra, distal forearm and proximal humerus is available in Iceland for the age group 70-85 between the years 1989 and 2008. This allows examination of secular change in the incidence of these major osteoporotic sites (MOS) fractures. It is important to quantify the trend of this public health problem in an ageing population, with 7.1% over the age of 70 in 1989, 8.4% in 2009 and projected to be 10% in 2020.

The Reykjavik Study is a population based cohort study of men and women with almost 19000 participants recruited between 1967 and 1992. We used the fracture registration associated with the study to estimate the incidence of the MOS fractures. In 1967 the participants were of age 33-64 and in 1989 enough participants had reached the age of 70. The follow-up period was divided into 5 time periods: 1989-1992,1993-1996,1997-2000,2001-2004 and 2005-2008. The incidence of first fracture was estimated for the age group 70-85 in each period using life table methods: the number of new fractures was counted and the total person time computed for those without previous fracture. The incidence was then reported per 100000 person years. The estimate for each period was analyzed using a generalized linear model, assuming a Poisson distribution for the number of fractures with person years as offset to estimate the rates. The estimates were age standardized using the population of Iceland in 2008. A linear and quadratic change in the incidence rate was tested using polynomial contrasts.

The hip fracture rate increased for women between the period 1989-1992 and 1997-2000. After that the rate decreased, ending with a 20% lower rate in the period 2005-2008 compared to 1997-2000 (p=0.039), and ending in 7% lower rate than in 1989-1992. The age standardized rate in 2005-2008 was 500 events per 100000 person years. In contrast, the rates for men have been increasing (p=0.0078) until 2001 when it leveled off. The rate in 2005-2008 was 40% higher than the rate in 1989-1992, ending in 326 events per 100000 person years. Female/male ratio changed from 2.6 to 1.7 during the 20 year period.

In comparison the incidence for the other MOS fractures increased until year 2001 for men and women and showed similar decline for both sexes during the last decade. In contrast the hip fracture incidence in men remains unchanged during the last decade, possibly indicating different underlying contributors to these secular changes.

Site-specific Associations between Fracture and Height, Weight and Body Mass Index in Postmenopausal Women: GLOW Registry. [1]University of Cambridge School of Clinical Medicine, United Kingdom, [2]Center for Outcomes Research, UMASS Medical School, USA, [3]St. Joseph's Hospital, Canada, [4]University of Verona, Italy, [5]Center for Metabolic Bone Disease & Division of Geriatric Medicine, Bel, [6]E. Herriot Hospital, France, [7]University of Southampton, United Kingdom, [8]Autonomous University of Barcelona, Spain, [9]University of Massachusetts, USA, [10]University of Pittsburgh, USA, [11]Fred Hutchinson Cancer Research Center, USA, [12]Helen Hayes Hospital, USA, [13]Royal North Shore Hospital, Australia, [14]VU Medical Center, The Netherlands, [15]Alfried Krupp Krankenhaus Steele, Germany, [16]Hospital Cochin, France, [17]University of Alabama at Birmingham, USA, [18]Columbia University College of Physicians & Surgeons, USA, [19]Cedars-Sinai/ UCLA, USA, [20]Mercy Health Osteoporosis & Bone Health Services, USA

Introduction: Low body mass index (BMI) is a well-established risk factor for fracture in postmenopausal women. However, recent data indicate that high BMI, whilst protective for some fractures, is associated with increased risk of others. The aim of this study was to investigate the relationships of weight, BMI and height with incident clinical fracture at multiple sites in postmenopausal women.

Methods: GLOW is an observational longitudinal study of non-institutionalized women aged ⩾55 years recruited from 723 primary physician practices in 10 countries. Self-administered questionnaires were mailed, and data collected included demographics, co-morbidities, and previous and incident fractures. For each of 10 fracture sites (hip, spine, wrist, pelvis, rib, upper arm/shoulder, clavicle, ankle, lower leg, upper leg) we modelled the time to incident fracture over a 3-year period using the Cox proportional hazards model and fitted the best linear or non-linear models containing height, weight and BMI.

Results: 3,628 of 52,939 women (6.9%) sustained an incident clinical fracture during the 3-year follow-up period. As expected, adjusted hazard ratio (HR) per increase of 5 kg/m2: 0.80 (95% CI 0.71, 0.90), p=0.0002; 0.83 (0.76, 0.92), p=0.0001; 0.88 (0.83, 0.94), p<0.0001; respectively, whereas for ankle fractures linear weight showed the strongest association: adjusted HR 1.05 (95% CI 1.02, 1.07) per 5-kg increase (p<0.001). For upper arm and clavicle fractures, only linear height was significantly associated: adjusted HR per 10-cm increase 0.85 (95% CI 0.75, 0.97), p=0.02; and 0.73 (95% CI 0.57, 0.92), p=0.009; respectively. For pelvic and rib fractures, the best model was for non-linear BMI or weight (p=0.05 and p=0.03, respectively), with inverse associations at low BMI/body weight and positive associations at high values.

Conclusions: The relationships between fracture and weight, BMI and height are site-specific. BMI and weight show the strongest associations, with the exception of clavicle and upper arm fractures. The direction of effect of BMI and weight on fracture risk and the linearity of the relationship varies according to fracture site. These different associations may reflect, at least in part, effects of weight and BMI on bone mineral density, bone geometry, and the patterns of and protective response against falling.

The Burden of Osteoporotic Fracture: Epidemiology and Health-care Utilisation in Older Adults, 1997-2010. Sonia Jean*[1], Philippe Gamache[2], Louis Bessette[3], Étienne Belzile[4], Suzanne Morin[5], Mathieu Gagné[2], Jacques P. Brown[3]. [1]INSTITUT NATIONAL DE SANTÉ PUBLIQUE DU QUÉBEC, Canada, [2]Institut national de santé publique du Québec, Canada, [3]CHU de Quebec Research Centre, Canada, [4]Centre du recherche du CHUQ-CHUL, Canada, [5]McGill University, Canada

Purpose: Information on health-care utilization related to osteoporotic fractures is essential for allocation budget and resources planning. The purpose of this population-based study was to examine trends in incidence rates, utilisation of hospital and surgical care of non-vertebral osteoporotic fractures in women and men 50 years and older.

Methods: Using a validated algorithm based on physicians' cliams databases, 390,298 patients (69.5% women) were identified with an incident fractures at non vertebral osteoporotic sites between 1997 and 2010 in the province of Quebec, Canada. Fractures were grouped by anatomical sites as occuring at the hip/femur,

pelvis, forearm/wrist, shoulder/humerus, tibia/fibula, or ankle/foot. Administrative databases of health services available to all residents in Quebec were used to establish fracture-related hospitalisations and surgical care. Data were linked by a unique personal identifier, creating a longitudinal cohort of health resource utilization. According to fracture site, we examined trends in incidence rates, utilization of hospital and surgical care over the study period. Joinpoint regression and linear regression analysis were use to test for linear change in trends.

Results: During the study period, the age-standardized incidence rates fell for the majority of osteoporotic fracture sites in both sexes (Figure 1). The mean annual linear percent change (APC) varied between -1.6 and -3.3 percent for hip/femur and foot/ankle fractures, respectively (Table1). Only pelvic fractures did not show a significant decline. Although hip/femur fractures continue to represent the highest rates of health resources utilization, the proportion of surgery (90%) and hospital (90%) care remained constant over time (Table 2 and 3). For pelvic fractures, surgery care increased slightly during the study period and hospitalisation remained constant but high. For all other fracture sites, surgery and hospital care related to fracture treatment became more common during the study thus imposing heavy pressure on health care resources.

Conclusions: Because of changes in surgical procedure rates related to osteoporotic fracture, the burden of these fracture on health care resources utilization increased over time. With an aging population and an increased prevalence of these fractures, strategies to improve osteoporosis management need to be introduced to reduce the burden on health care resources.

Association of Genetic Variants Detected by Whole Genome Sequencing with Fracture Risk. Scott Wilson*[1], David Evans[2], Brent Richards[3], Josine Min[2], Klaudia Walter[4], Nicole Soranzo[4], Richard Durbin[4], Nicholas Timpson[2], on behalf of the UK10K Consortium .[4]. [1]University of Western Australia, Australia, [2]University of Bristol, United Kingdom, [3]McGill University, Canada, [4]Wellcome Trust Sanger Institute, United Kingdom

Fracture risk is heritable, but the genes involved remain largely unknown. A recent meta analysis of GWAS for fracture identified fourteen BMD-associated loci that were also associated with fracture risk however a substantial proportion of the heritability of fracture risk remains to be explained. We undertook a GWAS of fracture using whole genome sequence data available on the ALSPAC cohort to detect additional loci relevant to fracture risk.

Whole genome sequencing (WGS) to an average 6.5x coverage using next-generation sequencing technology was performed on the Avon Longitudinal Study of Parents and Children (ALSPAC) discovery cohort (n = 2000) as part of the UK10K project. Imputation was performed on existing data from high density SNP arrays using 1000genomes and UK10K reference panels in 3450 individuals in the replication cohort. All fractures recorded by age 11 years were included in the association analysis which was performed with SNPTEST. GWAS meta-analysis of discovery and replication studies was conducted using GWAMA.

We aim to report on the results of this genome-wide association study assessing a comprehensive collection of genetic variants down to and below 1% minor allele frequency (MAF). In preliminary analyses, among fifty loci that were identified with $P < 1E-5$, seventeen loci were in the vicinity of a gene with a credible role in bone. Odds ratios ranged 0.58 - 4.57 and 58% of these loci had MAFs less than 0.05. Four of the loci that showed suggestive association had not been previously identified in dbSNP or 1000genomes and 16% of loci were multi-nucleotide variants.

Although the pathophysiology of fracture in children may differ from that of fragility fracture in adults with osteoporosis, these data should aid researchers in prioritising loci for focused genotyping studies relevant to fracture.

Attenuated Monocyte Apoptosis, A New Mechanism For Osteoporosis Suggested By A Transcriptome-Wide Study Of Monocytes. Yaozhong Liu, Yu Zhou, Yongjun Liu, Lei Zhang, Jian Li, Qing Tian, Jigang Zhang, Hong-Wen Deng*. Tulane University, USA

Background: Osteoporosis is caused by excessive bone resorption (by osteoclasts) over bone formation (by osteoblasts). Monocytes are important to osteoporosis by serving as progenitors of osteoclasts and produce cytokines for osteoclastogenesis.

Objective: To identify osteoporosis genes by microarray analyses of monocytes in high vs. low hip BMD (bone mineral density) subjects.

Method: Microarray analyses of monocytes were performed using Affymetrix 1.0 ST arrays in 73 Caucasian females (age: 47-56) with extremely high (mean ZBMD =1.38, n=42, 16 pre- and 26 postmenopausal subjects) or low hip BMD (mean ZBMD=-1.05, n=31, 15 pre- and 16 postmenopausal subjects). Differential gene expression analysis in high vs. low BMD subjects was conducted in the total cohort as well as pre- and post-menopausal subjects. Focusing on the top differentially expressed genes identified in the total, the pre- and the postmenopausal subjects (with a p <5E-03), we performed replication of the findings in 3 independent datasets of microarray analyses of monocytes in: 1) 80 Caucasian females (40 high vs. 40 low BMD subjects); 2) 19 Caucasian females (10 high vs. 9 low BMD subjects); and 3) 26 Chinese females (14 high vs. 12 low BMD subjects).

Result: We identified (in the 73 subjects) and successfully replicated in all the 3 independent datasets 2 genes, DAXX and PLK3. Interestingly, both genes are apoptosis induction genes and both down-regulated in the low BMD subjects. In addition, among the list of genes (n = 102) that are replicated in the largest replication cohort containing the 80 subjects, 2 other genes (PDCD5 and VDAC1) that are ranked at the top (7th and 17th, respectively, based on meta-analysis p values) are also apoptosis induction genes and down-regulated in the low BMD subjects. Overall, our result may suggest that there might be a lower apoptosis activity of monocytes in the low BMD subjects.

Conclusion: Our study for the first time suggested a lower apoptosis rate (hence an increased survival) of monocytes, an important osteoclastogenic cell, as a novel mechanism for osteoporosis.

Copy Number Variations are associated with Bone Mineral Density: A large-scale genome-wide analysis in the Framingham Study. Wen-Chi Chou*[1], Kannabiran Nandakumar[2], David Karasik[3], Ching-Ti Liu[4], Adrienne Cupples[4], Douglas Kiel[1], Yi-Hsiang Hsu[5]. [1]Hebrew SeniorLife, USA, [2]Hebrew Senior Life Harvard Medical School, USA, [3]Hebrew SeniorLife; Bar Ilan University, USA, [4]Boston University School of Public Health, USA, [5]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

Bone mineral density (BMD) is a complex phenotype with high heritability. Our previous genome-wide SNP association study identified more than 56 BMD loci in Caucasian populations, explaining < 6% of BMD variation. Copy number variation (CNV), a type of genomic structural variation, accounts for > 20% variation of the human genomic structure between individuals. CNVs may explain the missing heritability of BMD. Thus, we conducted a genome-wide CNV association analysis with BMD in Framingham Study participants.

This study included 7,451 adult Caucasians (4,126 men and 3,325 women) with mean age of 55 years. BMD at lumbar spine (LS) and femur neck (FN) was measured by dual energy X-ray absorptiometry. CNVs were estimated using Affymetrix 500K genotyping array and PennCNV package. A CNV was defined as a DNA segment longer than 1 kbp and composed of at least three consecutive genotyping probes. Under an additive genetic model, we employed a linear mixed effects model to account for family relatedness, and also adjusted for age, sex, estrogen usage, menopause status, cohorts within the Framingham Study and principal components for population stratification. To correct for multiple-testing, a genome-wide significant cutoff ($p < 4 \times 10^{-6}$) was defined by a false-discovery rate as less than one false-positive result among the genome-wide significant findings. Up to 6,398 individuals had valid CNV calls and information on covariates.

Two CNVs (at chrom 2q14.2 and 6q25.3) and four (at chrom 5q23.1, 15q22.31, 17p13.1 and 17q21.2) were significantly associated with LS BMD and FN BMD, respectively. The length of the CNVs ranged from 133 kbp to 1,025 kbp. The most significantly associated CNV with $p = 1.9 \times 10^{-20}$ was located at chromosome 15q22.31 (*SMAD6*). The Smad6 protein inhibits signaling of bone morphogenetic proteins. Among 6,398 individuals included in the association analysis of the CNV, 5 had this CNV. Individuals with deleted CNVs had lower FN BMD. In addition, we identified three genome-wide suggestive CNVs associated with BMD at $p < 2.7 \times 10^{-6}$.

In summary, we identified six genome-wide significant CNVs and three genome-wide suggestive CNVs associated with FN BMD or LS BMD in the Framingham Study. To replicate the CNV-BMD associations, we are performing analyses in independent samples. The newly identified CNVs in this study may provide additional biological information regarding the genetic determinants of BMD and may explain some of the missing heritability.

Family-based genome wide association reveals genetic determinants of total body bone mineral density and fat content in adults of Northern European descent. Yi Zhang*[1], Jack Kent[2], Bradford Towne[3], Stefan Czerwinski[4], Tom Dyer[2], Michael Olivier[5], Ulrich Broeckel[5], Omar Ali[5], Diana Cerjak[5], Roland James[5], Ahmed Kissebah[5], John Blangero[2], Robert Blank[6]. [1]Medical College of Wisconsin, USA, [2]Texas Biomedical Research Institute, USA, [3]Wright State University, USA, [4]Wright State University Boonshoft School of Medicine, USA, [5]Medical College of Wisconsin, USA, [6]University of Wisconsin, USA

Background Bone mineral density (BMD) is correlated with total body mass and muscle mass but its relationship to fat mass has not been well characterized. We study the genetic basis of obesity and the metabolic syndrome in a family-based cohort of Northern European descent. The purpose of this study is to examine the correlation between BMD and % body fat (BF%) and to identify shared genetic determinants for both.

Methods We studied 401 subjects (18-84ya) from 39 extended families. Each family was recruited through an obese proband (BMI≥30) with at least one obese sibling and one never-obese (BMI≤27) and at least one parent willing to participate. We measured total body BMD and body composition by dual-energy X-ray absorbtiometry (DXA) and evaluated the heritability and genetic correlation of BMD and BF% with the genetic software SOLAR. We adjusted BMD for age, sex, and weight and BF% for age, age^2 and sex following stepwise regression. We conducted genome-wide association (GWA) analysis in SOLAR using ~2.5×10^6 empirical and imputed SNPs.

Results Heritability of whole body BMD was 0.54 ± 0.09 and BMD was negatively genetically correlated with BF% (ρ_G=-0.24 ± 0.13; p=0.085). In sex-specific and combined-sex GWAs, the most significant associations with BMD included: in men

only, rs9386528 ($p=1.6\times10^{-7}$) located 100kb upstream of the first exon of UFL1, a negative regulator of NF-kappaB activity; and SNPs in the microRNA gene MIR548A3 ($p=7.87\times10^{-6}$ in women, $p=5.32\times10^{-6}$ in both sexes). In both sexes, strong associations near the inositol 1,4,5-trisphosphate receptor 1 gene ITPR1 are shared by both BMD and BF% ($p=7\times10^{-8}$). In mice, spontaneous ITPR1 mutations are known to cause decreased body size, muscle abnormalities and early aging. Several of our top associations map to genes or gene families, including ITPR1, identified by other human GWA studies for obesity-related or regional BMD traits.

Conclusion In a family cohort recruited through obese probands, we identified shared and specific genetic factors underlying total body BMD and fat content. We are now replicating the most significant associations in an independent family cohort (n=1,286) of similar ancestry.

Background: Low lumbar vertebral BMD is heritable and associated with vertebral fracture, pain, height loss, and mobility restriction in older adults. Areal BMD is confounded by bone size and common degenerative conditions and cannot distinguish between trabecular and cortical compartments. Genetic association studies using volumetric QCT may identify genes that affect vertebral trabecular BMD.

Methods: We performed inverse-variance fixed-effects meta-analysis using ~2.7 million imputed SNPs from six genome-wide association studies for trabecular vBMD of the lumbar spine (L2 or L3 vertebra). Cohorts included Age Gene/Environment Susceptibility Study (AGES), Framingham Study, Family Heart Study, Healthy Aging and Body Composition (Health ABC), Multi-Ethnic Study of Osteoporosis (MESA), and Osteoporotic Fractures in Men (MrOS), for a total of 12,287 adult participants. Additive genetic models were tested using HapMap II imputed datasets, with adjustment for age, weight, clinic site and population stratification principal components. In familial studies, linear mixed effects models were used to account for relatedness. Genome-wide significance level was 5×10^{-8}, and suggestive level was $p < 5 \times 10^{-6}$ after overall genomic control correction and considering consistent effect sizes across all cohorts ($I^2 < 50$ and p for heterogeneity c^2 test $> 5 \times 10^{-5}$).

Results: Genome-wide significant SNPs for trabecular vBMD were found in loci previously reported for LS BMD, on 1p36.12 (near *WNT4* and *ZBTB40*), 1q43 (near *FMN2* and *GREM2*), and 13q14 (*TNFSF11*); and one new locus, 5p13 (*SLC1A3*). We also identified 6 loci as genome-wide suggestive SNPs that have previously been reported for LS BMD (Table). Five additional suggestive loci were newly identified and include 3p21.31 (*PLXNB1*), 3q26.1 (*BCHE*/*ZBBX*), 10q25 (*DUSP5*), 12p13.3 (*CACNA1C*), and 12q21.3 (*ATP2B1*).

Conclusion: GWAS of trabecular vBMD by QCT confirm previous findings from meta-analyses of lumbar spine BMD by DXA. In addition, several new loci were identified that may also explain some heritability in vertebral vBMD specific to the trabecular compartment. For example, *SLC1A3* (aka *GLAST*) is involved in glutamate signaling necessary for osteogenic mechanical loading. *PLXNB1,* which encodes receptors on osteoblasts for semaphorin 4D, is involved in IGF-1 signaling and osteoblast mobility. Variants in these newly discovered genes deserve further evaluation for their roles in vertebral osteoporosis and fracture risk if replicated in other studies.

Identification of Novel Genes and Regulatory Network Modules for Bone Mineral Density by Integrated Analyses of Transcriptome, miRNAome and Methylome Data. Li-Jun Tan[1], Tianhua Niu*[2], Jigang Zhang[2], Chuan Qiu[2], Yu Zhou[2], Hui Shen[3], Jian Li[2], Shu-Feng Lei[1], Xiang-Ding Chen[1], Hong-Wen Deng[3]. [1]College of Life Sciences, Hunan Normal University, China, [2]Center for Bioinformatics & Genomics, Dept of Biostat & Bioinformatics, Tulane University SPHTM, USA, [3]Tulane University, USA

Aim: MicroRNA expression (ME), DNA methylation (DM), and mRNA gene expression (GE) may work interactively to form essential gene regulatory networks. An integrated analysis of these multi-level functional genomic/epigenomic data may provide higher power to identify novel genes and network modules that would be otherwise miassed at individual-omic level analysis.

Methods: We performed a pilot multi-omics study at ME, DM and GE levels for a sample of 5 extremely low (bottom 15 percentile) hip bone mineral density (BMD) (Age: 24.41 ± 1.23 Yr) and 5 extremely high (top 15 percentile) hip BMD (Age: 23.76 ± 1.59 Yr) women in Hunan, CHina. ME, DM, and GE levels were measured from the same peripheral blood monocytes (PBMs) by Affymetrix miRNA 2.0 Array, Methylated DNA ImmunoPrecipitation-sequencing (MeDIP-seq), and Human Exon 1.0 ST Array, respectively. Traditional (correlation, clustering) methods and advanced MAGIA[2] tool were applied in integrated analysis.

Results: In ME-GE correlation analysis, *hsa-mir-34a* (High BMD vs Low BMD, $P = 9.76\times10^{-4}$), which is critical for bone development, is top miRNA negatively correlated with *FLOT2* mRNA expression (ρ = -0.82). In DM-GE correlation analysis, *ADAMTS5*, which as associated with cartilage growth, is the top known gene negatively correlated with its promoter methylation (ρ = -0.85). In MAGIA[2] analysis, total 38 network modules were revealed for ME-GE joint analysis for entire data (n=10). Of 9 modules with $\geqslant$ 5 nodes, hub genes *GATA3*, *ATF2*, *FOXC1*, *hsa-mir-17*, and *hsa-mir-let7c* have been previously associated with osteoporosis-related phenotypes. *SMOC1* gene was also detected.

Conclusion: Integrated approach may uncover novel genes and combinatorial network patterns in multi-dimensional omic data for complex phenotypes such as osteoporosis, which could have significant implications for clinical applications and fundamental basic research.

Effects of vitamin D and Exercise on Bone Health and Physical Performance in Elderly Women: Preliminary Results. Kirsti Uusi-Rasi*[1], Saija Karinkanta[1], Pekka Kannus[1], Kari Tokola[1], Christel Lamberg-Allardt[2], Harri Sievänen[1]. [1]UKK Institute for Health Promotion Research, Finland, [2]University of Helsinki, Finland

This two-year randomized (double blind for vitamin D) placebo-controlled intervention trial assessed the effects of exercise and vitamin D on bone traits and physical performance in elderly Finnish women. 409 women aged 70 to 80 years were randomly assigned into four groups: 1) 20 µg of vitamin D + exercise (D+Ex+), 2) 20 µg vitamin D + no exercise (D+Ex-), 3) placebo + exercise (D-Ex+), and 4) placebo + no exercise (D-Ex-). The inclusion criteria were no regular exercise more than twice a week at baseline, at least one fall during the previous year, and no contraindication to exercise. Measurements were done at baseline and at 24 months. The final data were obtained from 360 women. Supervised exercise training was given twice a week for 12 months, and once a week for the subsequent 12 months.

In addition to DXA-measured femoral neck BMD and pQCT-measured distal tibia trabecular density (TrD), maximal isometric lower limb extension force, timed-up and-go (TUG) time, and normal walking speed were assessed. Generalized linear models with log link function were used in estimating between-group differences using age, height, weight, and baseline value as covariates. Femoral neck BMD declined significantly more in D-Ex- group ($p=0.04$) than in the other groups, while tibial TrD showed no significant change in any group. The lower limb extension force improved in exercisers ($p<0.001$) more than in non-exercisers, while vitamin D had no effect on this variable. Neither exercise nor vitamin D affected walking speed, but exercise slightly improved the TUG time ($p=0.07$). Lack of vitamin D supplementation and exercise suggested negative interaction on TUG time ($p=0.069$).

Neither exercise nor vitamin D improved femoral neck BMD or tibial TrD among elderly women, but both of these factors were needed to prevent femoral bone loss. Exercise improved force and slightly the TUG time, whereas vitamin D had no effect on these variables.

Nancy-Brabois, France, [8]Centre Hospitalier Victor Dupouy, France, [9]Service de Rhumatologie, C.H. Victor Dupouy, France, [10]Service de Rhumatologie, France, [11]Unité ETP Rhumatologie, Centre Hospitalier régional Metz-Thionville, France, [12]Hôpital Saint Antoine, France

Background and objective: Real life experience and health beliefs impact quality of life and adherence to medication.

The objective was to understand perceptions and educational needs of patients with different types of osteoporosis. The aim was to target patients perspective to help the construction of educational programs.

Methods: Focus group were conducted among 18 post-menopausal women with osteoporotic fractures (2 groups), 10 post-menopausal women without osteoporotic fractures (2 groups), 14 men with osteoporosis (2 groups) and 10 patients with corticosteroid (CS) -induced osteoporosis (2 groups). Each group included 4 to 10 patients in 7 different cities. A semi directive interview guide was used, developed by the multidisciplinary workgroup SOLID'OS including rheumatologists, health care professionals, members of a patient association. Thematic analysis was performed.

Results: A wide range of health beliefs was found: OP is considered as a natural consequence of aging or on the contrary leads to dramatic feelings and self-depreciation. Patients are in fear of new fractures and consequently limit their daily life activities. Patients with CS-induced osteoporosis take better care of the causal disease than of OP. Men have negative perceptions and have difficulties coping with the loss of their functional abilities.

Patients have a rather good knowledge of treatment except for CS treated patients whose knowledge is lower. Some patients are confident in health care providers and medication efficacy whereas others focus on adverse effects and doubt of the benefit of treatments. All patients need support and look for evidence of treatments efficacy. Patients show a great interest for non-pharmacologic management such as calcium intake and physical activity. Errors are frequent about calcium and milk.

Patients are looking for follow up by health professionals to enhance their motivation. They show preferences for group education close to their place of residence. Men often go on the Internet for brief information and like booklets. Education should include physical activity, fall prevention and dietetics.

Conclusion: This qualitative study showed that patients' perspective differ according to gender and type of osteoporosis. A personalized assessment of patients' needs and objectives should be performed before inclusion in educational programs. Patients are interested by non-pharmacological treatments and prefer group education.

Adding VFA to DXA Changes Clinical Classification and Improves Detection of Fracture Risk. Jay Ginther*, Dixie Burk. Cedar Valley Bone Health Institute of Iowa, USA

Problem:

Even patients with known vertebral fractures and vertebroplasties can have "osteopenia" or "normal BMD" by DXA. Doing VFA on those patients I judged to need it, I was always correct. That meant I was missing some vertebral fracture deformities. How many?

Methods:

We performed VFA on every DXA patient from February 2010 through September 2012. 941 patients were evaluated with VFA for the first time. We had 792 women and 149 men with a mean age of 65 years. All DXA and VFA were read by the same ISCD Certified clinician.

Results:

By DXA alone 44.6% were Osteoporosis, 40.3% Low BMD, and 15.1% Normal BMD. Adding VFA, 76.6% were Osteoporosis, 18.1% Low BMD, and 5.1% Normal BMD. 32.0% of the time, adding VFA changed the clinical diagnosis. Further analysis by grades and numbers of vertebral deformities are presented.

Conclusions:

1. This study presents less than 1000 patients from a small referral practice, and may not be typical of the general population.

2. Many patients were sent to us because their primary physicians could not confirm osteoporosis by DXA alone. Many patients had "mush for bone" at the time of orthopedic surgery.

3. 48 patients had Normal Bone Mineral Density combined with grade 2 vertebral deformities. Most of those morphometric fractures were not apparent clinically.

4. 25% of our patient population were improperly classified Normal or Low Bone Mineral Density, despite grade 3 or grade 2 vertebral deformities, when studied by DXA alone.

5. These numbers are of sufficient magnitude that a much larger, multi-center study should be organized.

OO.RR. San Giovanni di Dio e Ruggi D'Aragona, Salerno, Italy, [9]Department of Ortopedic & Rehabilitation University of Naples, Italy, [10]University of Torino, Italy, [11]Azienda Ospedaliera Universitaria Di Bologna, Italy, [12]Reumatology Unit Ospedale San Camillo, Rome, Italy, [13]Reumatology Unit, Presidio Ospedaliero A. Galateo, Lecce, Italy, [14]Department of Medicine, Surgery & Neurosciences, University of Siena, Italy

Osteoporosis and fractures often coexist with other diseases and may be also associated with the use of different drugs. In order to improve our knowledge about major disorders associated with bone fragility and the skeletal effects of related treatments we performed a multicentric national survey in 1710 consecutive women (mean age 67.9 ± 10 yrs). To this aim a detailed questionnaire including general characteristics and risk factors, medication use, fracture history and medical diagnoses was performed during outpatient service for skeletal disorders in postmenopausal women. For all subjects the presence of osteoporosis was assessed by DXA analysis. Based on WHO criteria, osteoporosis was observed in 55% of women, while prevalent fractures were described in 50% of cases (of which 68%, 27%, and 5% occurred in osteoporotics, osteopenics or normal women, respectively). The high prevalence of osteoporosis and fractures in this population (likely due to the clinical setting of recruitment) allowed us to separately assess the effect of comorbidity on bone density (BMD) and bone fragility. When DXA criteria for osteoporosis were used (and after adjusting for age) depression, rheumatoid arthritis, gastrointestinal disorders, chronic renal failure and chronic obstructive pulmonary disease (COPD) were more prevalent in osteoporotic and osteopenic women than in normal women. A similar but not significant trend was observed for hypertension and Parkinson disease. Conversely, a slight but not significant prevalence of normal BMD levels was observed in patients with type 2 but not type 1 diabetes. Of interest and consistent with the observations using DXA criteria, when women with or without fractures were compared, we evidenced a significant association between fracture prevalence and depression, rheumatoid arthritis, gastrointestinal disorders and COPD. However we also evidenced a BMD-independent association between fractures and other disorders such as type 1 and 2 diabetes and ischemic heart disease. The latter association was less evident in subjects treated with beta blockers. Moreover, despite mean BMD levels were increased and the prevalence of osteoporosis was lower in patients with

osteoarthritis (OA), fractures were more prevalent in patients with either generalized OA or OA of the hip and spine. Among the different medications, corticosteroids, ACE inhibitors, proton pump inhibitors, and SSRI were significantly associated with fracture prevalence.

Fall Risk in Relation to Bioavailable Vitamin D: The Osteoporotic Fractures in Men (MrOS) Study. J Cai Gillis*[1], Lynn Marshall[1], Jodi Lapidus[1], Iva Miljkovic[2], Amy Warriner[3], Jeffrey Curtis[3], Tien Dam[4], James Shikany[5], Peggy Cawthon[6], Rene Chun[7], Martin Hewison[8], Michael Nevitt[9], Eric Orwoll[1], Carrie Nielson[1]. [1]Oregon Health & Science University, USA, [2]Department of Epidemiology, University of Pittsburgh, USA, [3]University of Alabama At Birmingham, USA, [4]Columbia University Medical Center, USA, [5]University of Alabama at Birmingham School of Medicine, USA, [6]California Pacific Medical Center Research Institute, USA, [7]UCLA/ Orthopedic Hospital Research Center, USA, [8]University of California, Los Angeles, USA, [9]University of California, San Francisco, USA

Purpose: Bioavailable 25-hydroxyvitamin D (bio25(OH)D) is that fraction of total 25(OH)D not bound to vitamin D binding protein (DBP). However, little is known about effects of bio25(OH)D on health outcomes. Vitamin D effects on neurological and muscular outcomes might manifest in a higher fall risk among those with lower levels of bio25(OH)D. In this study, we evaluated associations of bio25(OH)D and total 25(OH)D with risk of falls in elderly men.

Methods and Results: The MrOS study enrolled 5,994 ambulatory men ⩾65 years old from March 2000 to April 2002 at 6 sites in the US. Total 25(OH)D assays were performed in serum obtained at enrollment from 1,608 randomly chosen participants. Of these, a random sample of 678 was selected for additional assays to estimate free and bio25(OH)D.

Bio25(OH)D levels were estimated using validated mathematical models that account for DBP concentration and genotypically determined binding affinity. Falls were self-reported every 4 months by mailed questionnaires during 12 months of follow-up. We used log-binomial regression models to obtain relative risk (RR) estimates for any fall in relation to bio25(OH)D quartile. All models were adjusted for age, BMI, race, season of blood draw and clinic site. Potential confounders included medications, self-reported comorbidities and physical activity; confounding was assessed by a change in the RR of ⩾10%. Four participants were missing fall information.

In the sample of 674, the mean (±sd) for bio25(OH)D was 12.98 (±5.65) nmol/L and for total 25(OH)D was 62.2 (±19.9) nmol/L. A fall was reported by 195 men (29%). Bio25(OH)D was correlated with total 25(OH)D (r=0.55) and fall risk did not significantly vary according to total 25(OH)D quartile.

Regression analysis showed a 0.66 (RR) for the 3rd quartile of bio25(OH)D compared to the highest (95% CI: 0.45-0.96). No significant association was observed for the two lowest quartiles of bio25(OH)D compared to the highest quartile.

Conclusions: Bio25(OH)D was more strongly associated with falls than total serum 25(OH)D The 3rd quartile of bio25(OH)D had a significantly lower risk than the 4th quartile. Those in the highest quartile for bio25(OH)D did not have a significantly lower proportion of falls compared to the other quartiles. Future research should examine the possibility of nonlinear associations for bio25(OH)D levels.

Femoral Cortical Index: Is the Really Strength of Femur?. Cecilia Rao*[1], Monica Celi[1], Maurizio Feola[1], Valerio Tempesta[1], Elena Gasbarra[1], Umberto Tarantino[2]. [1]University of Rome Tor Vergata, Italy, [2]Università degli Studi di Roma Tor Vergata, Italy

The femoral cortical index (FCI) assesses bone stock using the ratio between the diameter of the femoral shaft and the thickness of the cortical bone calculated 10 cm distal to the center of the small trochanter in an AP view X-Ray of the femur. It's not clear if low values ??of FCI may be associated with a condition of altered bone metabolism and bone fragility in fractured patients. Aim of our study is to evaluate a possible association among low values ??of FCI, risk factors, comorbidities and serum 25 hydroxyvitamin D levels and to establish the importance of FCI as a potential predictor of a new fracture.

Materials and Methods. We conducted a retrospective study on 160 consecutive patients (44 men and 116 women) (range 60 to 103 ya) surgically treated for hip fractures in 2012,after informed consent in our Orthopaedic Department and that never received any medical treatment for osteoporosis. FCI has been calculated by routine clinical radiographs of the pelvis both on fractured femur and on the opposite side. For each patient, we analyzed the presence of comorbidities (such as diabetes, hypertension, IRC, rheumatoid arthritis),osteoporosis risk factors and blood levels of vitamin D, usually evaluated in our patients with fragility fractures.

Results. Average values ??of FCI were 0.42 (range 0.18 to 0.58) at the fractured femur and 0.48 at the opposite side (range 0.25 to 0.66) with a statistically significant difference ($p = 0.002$). At the fractured side an average value of 0.45 was found in men, and of 0.40 in women. Patients with severe hypovitaminosis D (serum concentration <12 ng / ml) had a minor FCI compared to those with a moderate deficiency (0.41 vs. 0.46, $P < 0.01$). The presence of comorbidities or osteoporosis risk factors had a different influence on the values of FCI.

Conclusion. In our study, we found a correlation among low values of FCI, clinical factors related to bone fragility and severe hypovitaminosis D in elderly patients with hip fractures. Comorbidities and risk factors have a different weight in FCI variations, while the severe hypovitaminosis has a major impact on it. As described in the literature regard the DXA limitations in elderly FCI could be an useful tool in terms of bone fragility evaluation and fracture risk prediction. As osteoporosis causes a cortical bone trabecolarization that leads to fracture, this index can therefore give a measure of specific cortical bone at low cost using a X-ray standard examination.

FRAX® Predicts Future Falls in Elderly Men. MrOs Sweden. Helena Johansson*[1], Anders Odén[2], Magnus Karlsson[3], Bjorn Rosengren[3], Osten Ljunggren[4], Eugene McCloskey[5], John Kanis[6], Claes Ohlsson[7], Dan Mellström[8]. [1]Swedish University of Agricultural Sciences, The Biomedical Center, Sweden, [2]WHO Collaborating Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, UK, United Kingdom, [3]Skåne University Hospital Malmö, Lund University, Sweden, [4]Uppsala University Hospital, Sweden, [5]University of Sheffield, United Kingdom, [6]University of Sheffield, Belgium, [7]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [8]Centre for Bone & Arthritis Research (CBAR), Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, Sweden

FRAX® calculates 10-year fracture probability from readily obtainable clinical risk factors (CRFs) in men and women with or without BMD. Falls is an established risk factor for future fracture risk but is not included in FRAX as a separate input variable. The aim of the present study was to determine whether FRAX without information on falls risk was associated with future falls risk in elderly men, since some of the risk factors used by FRAX may be related to future fall risk.

We studied the relationship between FRAX and the risk of falls in 1990 elderly men recruited to the MrOS study from the general population in Sweden. Baseline data included clinical risk factors used by FRAX, age, BMI, BMD at femoral neck and FRAX probabilities. Incident falls were captured during an average of 1.8 years follow up (maximum 3.0 years). An extension of Poisson regression was used to investigate the relationship between FRAX, other risk variables and the time-to-event hazard function of falls. All associations were adjusted for age and time since baseline.

At baseline 15% of the men had fallen during the preceding 12 months (past falls) and 34% experienced one or more falls during follow up (incident falls). Past falls were a significant risk factor for incident falls (HR 2.90; 95% CI 2.44-3.44). The risk of incident falls increased with increasing FRAX probabilities at baseline (HR per SD=1.23; 95% CI=1.14-1.33). The association between incident falls and FRAX remained after adjustment for past falls (HR per SD=1.19; 95% CI = 1.11-1.29). In men with high fracture probabilities (>18%) FRAX was a predictor of falls (HR 1.40; 95% 1.15-1.72). The prevalence of past falls increased with increasing fracture probability (r=0.10; 95% CI 0.06-0.15).Although falls are not included as an input variable in FRAX, FRAX significantly captures a component of the fracture risk associated with falls.

Hip Fracture In Early Stages of Type 2 Diabetes: A Population-Based Cohort Study. Daniel Prieto-alhambra*[1], Daniel Martinez-Laguna[2], Cristian Tebé[3], Xavier Nogues[4], Adolfo Diez-Perez[5]. [1]University of Oxford, United Kingdom, [2]GREMPAL Research Group, IDIAP Jordi Gol Primary Care Research Institute; Primary Care Department, Institut Català de la Salut, Spain, [3]Agencia de Qualitat i Avaluació Sanitàries de Catalunya, Spain, [4]Institut Municipal D'Investigació Mèdica, Spain, [5]Autonomous University of Barcelona, Spain

PURPOSE

We study the association between recently diagnosed type 2 diabetes mellitus (T2DM) and hip fracture risk. Secondly, we assess the key predictors of hip fracture among newly diagnosed T2DM patients, and provide a clinical tool to assess their risk based on these.

METHODS

We conducted a population-based cohort study using data from the SIDIAP Database (www.sidiap.org). SIDIAP contains clinical information from primary care electronic medical records, hospital admissions, and pharmacy invoice data for >5 million patients (80% of the population) in Catalonia, Spain.

Participants were all newly diagnosed T2DM patients registered in SIDIAP in 2006-2010 (T2DM cohort). Up to 3 diabetes-free controls were matched to each T2DM participant on age, gender, and primary care practice.

Main outcome was incident hip fracture, ascertained using ICD10 codes. Main exposure was T2DM status.

We used Fine and Gray survival modelling to estimate risk of hip fracture according to T2DM status accounting for competing risk with death, and adjusted for body mass index, previous fracture and use of oral glucocorticoids.

Secondly, backwards stepwise Fine and Gray regression was used to identify key predictors of hip fracture in the T2DM cohort, among a list of a priori defined potential risk factors: history of cataracts, stroke, IHD, T2DM complications (polineuropathy, nephropathy), anti-osteoporosis medications, body mass index, smoking, alcohol drinking, and history of falls and fractures. The estimated coefficients were used to create a clinical predictive tool, which was tested for discrimination and calibration using ROC curves, and predicted/observed rates for each risk decile respectively.

RESULTS

444/55,275 diabetic patients sustained a hip fracture (Incidence Rate 2.7/1,000 person-years) compared to 776/113,448 matched controls (2.4/1,000): unadjusted SHR 1.11 [0.99-1.24], adjusted SHR 1.20 [1.06-1.35].

Key predictors of hip fractures in T2DM patients are shown in the enclosed Table. The proposed predictive tool had an area under the ROC curve of 0.74 [95%CI 0.72-0.77], and discrepancies between predicted and observed risk were seen only for extreme risk deciles [see Figure].

*CONCLUSIONS*Newly diagnosed T2DM patients are at a 20% increased risk of hip fracture even in the early stages of disease. We propose a simple predictive tool, which can be used to identify diabetic patients at high risk of hip fracture at the time of T2DM diagnosis.

TABLE. Key predictors of hip fracture in T2DM patients.

Predictors	Beta	Score
Male Gender	-0,649	-6
Age (per 1 year above 75)	0,117	1
BMI (per 1 kg/m2 above 30)	-0,037	0
Previous fracture	1,252	13
Previous IHD	0,341	3
Previous nephropathy	0,579	6
Oral glucocorticoids	0,03	0
Age x Nephropathy	0,057	-1
Male Gender x Oral glucocorticoids	0,681	7

FIGURE. Calibration of the provided predictive tool: observed (red) versus predicted (blue) risk in each risk decile.

Identifying Barriers and Facilitators of Informed Consent for an Osteoporosis Pragmatic Clinical Trial. Rachael Moloney[1], Donna Messner[1], Kenneth Saag[2], Jeffrey Curtis[2], Amy Warriner[2], Nicole Wright*[2], Phillip Jeffrey Foster[2]. [1]Center for Medical Technology Policy, USA, [2]University of Alabama at Birmingham, USA

Purpose: Community practice-based osteoporosis research is critical for assessing the effectiveness of osteoporosis therapies, yet obtaining informed consent (IC) is a major barrier to conducting randomized trials in these practice settings. Our goal was to identify deficiencies and develop approaches to improve the IC process for osteoporosis pragmatic clinical trials (PCTs) by collecting perspectives on barriers and facilitators to conducting PCTs. We also explored streamlining consent through the use of an innovative iPad-based tool. Methods: We interviewed physicians and practice staff key informants (KIs), from two practice-based research networks having a range of experiences with IC and PCTs in practice, to understand challenges they face when conducting PCTs with daily clinical practice, and whether an iPad-based tool might streamline screening and IC procedures. Results: We completed 18 physician interviews and 3 staff interviews. Practices sizes varied: solo practice (1 attending physician; n=4), small practices (2-4 attending physicians; n=6), medium (5-6 attending physicians; n=10), and a large multi-group practice (n=1). Seven KIs were from rural practices, 7 from suburban and 7 from urban practices. We found heterogeneity in the types of barriers encountered and preferences for incorporating informed consent in their workflow. KIs differed on how best to introduce the iPad, where to do so, who should do it, how long IC should take, whether IC is a "workable" process, and other questions. Physicians and staff having experience doing clinical trials tended to suggest more modifications for iPad programming and have more expectations for flexibility in iPad use in practice. KIs from rural practices were more likely to be concerned about low verbal and technological literacy of their patient populations. However, most KIs were optimistic about the use of iPad technology for reducing administrative burden. Conclusion: KI interviews revealed heterogeneity in composition and staffing of practices, procedures used (or thought likely to be used) for screening and informed consent, and attitudes on which patients might benefit most from using the iPad tool for learning about a clinical trial and giving consent. Protocols that incorporate practice preferences and allow for some controlled flexibility in screening and consent procedures may improve in feasibility and reduce some of the barriers to practice participation and successful recruitment.

Increased Serum Low-Density Lipoprotein and Triglycerides Negatively Affect Cortical Bone in Women with a High Body Mass Index. Peter Dellatore*[1], Deeptha Sukumar[1], Yvette Schlussel[1], Xiangbing Wang[2], Claudia Pop[1], Sue Shapses[1]. [1]Rutgers University, USA, [2]Robert Wood Johnson Medical School, USA

Hyperlipidemia, associated with a high fat diet, has been shown to negatively affect bone. In addition, high levels of oxidized low density lipoprotein (LDL) may attenuate the anabolic effect of intermittent parathyroid hormone on bone. In this cross-sectional study, we examined the effect of lipids on bone mineral density (BMD), bone geometry, and strength parameters, and the interaction with serum parathyroid hormone (PTH) in 248 obese and overweight women (ages 24-73 years of age, body mass index (BMI) of 29.4 $\pm$ 3.9 kg/m^2). Areal BMD was measured by dual energy x-ray absorptiometry and a subset were measured for volumetric BMD (vBMD), bone geometry, and strength parameters using peripheral quantitative computed tomography at the tibia. Serum 25-hydroxyvitamin D, PTH, calcium, total cholesterol, triglycerides (TAG), LDL, and high-density lipoproteins were measured. Multiple linear regression analysis was used to determine the effects of serum hormones, lipids and calcium on bone. Overall, there was no detrimental effect of any lipid fraction on trabecular (Tb) bone and the effect was positive on some bone variables. However, most cortical (Crt) bone parameters were negatively affected by serum lipids. The inverse relationship between LDL and Crt vBMD ($r = -0.42$; $p < 0.02$) accounted for 18% of the variance in premenopausal women that was still present when controlling for body weight. To estimate how LDL affects bone without oxidized particles, we examined the LDL/HDL ratio on bone and found no negative correlation with bone. In contrast, LDL and LDL/HDL were both positively correlated with Tb vBMD. This may suggest that oxidized LDL is causing the negative effect on Crt vBMD, but has no effect on Tb vBMD. In postmenopausal women, TAG either showed a significant or inverse trend with Crt BMC, area, periosteal circumference and the stress strain index. In addition, a multiple regression model to examine the interaction between serum PTH and lipid fractions on bone showed a negative association between TAG and areal BMD at the spine and hip. Serum PTH also strengthened the negative association between TAG and Crt bone parameters. In conclusion, these data show that there is a detrimental effect of serum lipids on cortical bone parameters. This could partially explain poor bone quality found previously in obese subjects that may be worse for those with high serum lipid levels.

Racial/ethnic Differences in Bone Loss among Aging Men are Attributable to Variation in Socioeconomic Status, Morbidity and Health Behaviors. Andre Araujo*[1], Gretchen Chiu[1], Benedetta Bartali[1], Thomas Travison[2], Mary Bouxsein[3], Joseph Zmuda[4]. [1]New England Research Institutes, USA, [2]Brigham & Women's Hospital, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]University of Pittsburgh Graduate School of Public Health, USA

Rates of osteoporotic fractures are lower in some racial/ethnic groups, due in part to higher peak bone mass. However, racial/ethnic variation in rates of bone loss is poorly understood, particularly among men. We used data from the BACH/Bone Survey, a longitudinal population-based cohort study of racially diverse (Black, Hispanic, and White) men to examine the impact of race/ethnicity on rates of bone loss. A total of 692 (70% of eligible) men with average age 51 ± 12y at baseline completed follow-up 7.0 ± 0.6y later. Femoral neck bone mineral density (fnBMD) was assessed by DXA. Race/ethnicity was self-identified. Multivariable linear regression was used to examine the association of race/ethnicity with annualized percent (%) change in fnBMD, controlled for baseline fnBMD, age, household income, smoking, diabetes, self-rated health, physical activity, and BMI. Mean total bone loss was 0.04 g/cm^2, for an annualized decline of -0.006 g/cm^2/y. Mean (relative standard error (RSE)) % decline in fnBMD was -0.67(0.30)%/y, with steeper declines in men ⩾70y (1.01(0.12)%). Bone loss rates were greater in Black (0.75(1.1)%) and Hispanic (0.73(0.06)%) vs. White (0.58(0.05)%) men, differences which were reduced with adjustment for baseline age and fnBMD, and eliminated with multivariable adjustment (Table). Baseline covariates contributing most to between-subject variations in bone loss were age (32%), income (20%), fnBMD (13%), and smoking (11%). Income was strongly and consistently associated with bone loss, even after adjustment for covariates, including race/ethnicity. The estimated mean differences in bone loss between lower vs. higher income groups were reduced by approximately 50% with adjustments for income, lifestyle factors, and health status (Table). In summary, rates of hip bone loss in this cohort are consistent with previous studies in men, and are about half the rate of similar-aged women. Self-identified minority men experienced greater bone loss, due apparently to disproportionate exposure to lower income, illness, smoking, and other factors. While race/ethnicity may embed genetic/biological/social factors that are strongly associated with bone mass cross-sectionally, the contributions of income and other potentially modifiable factors appear to overpower the role of race/ethnicity in explaining variations in rates of bone loss with aging in men.

Table. Femoral neck bone loss by race/ethnicity and HH income

Model	Category	Mean % bone loss/y (95% CI)	% difference vs. ref	p-value vs. ref
Race, Unadjusted	Black	-0.75(-0.86,-0.64)%	29%	0.0273

Relationship between specific antidepressants use and bone mineral density – A longitudinal study on postmenopausal women. Päivi Rauma[1], Risto Honkanen*[1], Heikki Kroger[2], Marjo Tuppurainen[2], Lana Williams[3], Heli Koivumaa-Honkanen[4]. [1]University of Eastern Finland, Finland, [2]Kuopio University Hospital, Finland, [3]The University of Melbourne, Australia, [4]University of Oulu, University of Eastern Finland, Lapland Hospital District, Finland

The relationship between antidepressants and lower bone mineral density (BMD) has been suggested mainly in cross-sectional studies. The purpose was to study this relationship longitudinally by taking into account possible differences between subgroups of antidepressants.

The study population consisted of the 1988 women (born in 1932-41) of the Kuopio Osteoporosis Risk Factor and Prevention (OSTPRE) Study cohort. Subjects responded to postal enquiries in 1999 and 2004 and underwent femoral BMD densitometry after enquiries. Information on antidepressants (ATC-codes: N06A, N06CA) purchased from pharmacies in 1999-2004 was obtained from the National prescription register of Finland. Tricyclic antidepressants (TCA; N06AA, N06CA01), selective serotonin reuptake inhibitors (SSRI; N06AB), other (N06AX) and multiple use were used as subgroups. The association between use of antidepressants and femoral BMD change over 5 years was studied with multivariate linear regression including age, body mass index, weight change, dietary calcium, smoking, alcohol use, grip strength, suffering from depression and use of bisphosphonates, hormone replacement therapy and corticosteroids as covariates.

A total of 319 women had purchased antidepressants in 1999-2004. Out of them, 86 had used only TCA, 106 SSRI, 53 other antidepressant and 74 women two or more kinds of antidepressants. Mean femoral BMD was 0.881g/cm2 (SD 0.123) at baseline and bone loss in 1999-2004 was -0.006g/cm2 (SD 0.047). Bone loss was 80% greater (p=0.130) in antidepressant users than non-users. In TCA users it was 200% (p=0.032), in SSRI users 50% (p=0.555) and in multiple antidepressants users 111% (p=0.254) greater. On the contrary, mean BMD did not decrease during the study period in the group of other antidepressant users and bone loss was 104% less than in non-users (p=0.419). In multivariate analyses, higher number of purchased antidepressant packages demonstrated higher annual bone loss (%) in TCA's (B=-0.018, p=0.098), SSRI's (B=-0.031, p=0.006) and multiple use (B=-0.006, p=0.248), while increasing number of packages decreased bone loss (B=0.025, p=0.012) in the users of other antidepressants.

In conclusion, use of TCA or SSRI antidepressants seems to be associated with higher but use of other antidepressants with lower postmenopausal bone loss.

Serotonin Transporters in Bone: A Longitudinal Study of Bone Turnover After Initiation of Selective Serotonin Reuptake Inhibitors in Older Adults. Elizabeth Haney*[1], Melanie Abrahamson[1], Zunqiu Chen[1], Yiyi Chen[1], Amy Eshleman[1], Kimberly Vesco[2], Elizabeth Eckstrom[1], Martha Gerrity[1], Eric Orwoll[1], Jodi Lapidus[1], Michael Bliziotes[3]. [1]Oregon Health & Science University, USA, [2]Kaiser Permanente Center for Health Research, USA, [3]OHSU/Portland VA Medical Research Center, USA

Identification of a functional serotonin signaling system in osteoclasts, osteocytes and osteoblasts has led to theories about the role of serotonin in bone metabolism. Selective serotonin reuptake inhibitors, or SSRIs, are commonly prescribed antidepressant medications that potently and specifically block the serotonin transporter. We undertook a prospective cohort study of SSRI users and non-users to evaluate markers of bone turnover in patients starting SSRIs (users) compared to those not on SSRIs (non-users).

Men and women over age 50 starting SSRIs were recruited for prospective measurements of n-telopeptide (NTX, Osteomark, adjusted for creatinine), osteocalcin (OC, Immulite), and bone mineral density (BMD); controls (non-users) were recruited on the basis of gender, age and clinic site. To compare differences between groups we conducted t-tests/rank sum and created linear regression models accounting for potential confounders.

Overall the SSRI users (n=92) were more likely than SSRI non-users (n=105) to report history of anxiety (67.4% vs 13.3%, p<0.0001) and depression (33.7% vs. 5.8%, p<0.0001). SSRI users had higher scores on objective measures of anxiety and

depression, and were less likely than non-users to have a parental history of hip fracture (3.3% vs 11.4%, p=0.03). Baseline OC levels were 9.3 (SD 5.3) for the SSRI users and 8.6 (SD 4.0) for the SSRI non-users group (p=0.7); baseline NTX were 45.0 (SD 29.1) for the SSRI users and 39.0 (SD 18.) for the non-users (p=0.42) respectively. There was no difference in the change in OC and NTX between SSRI users and non-users at 3 months (OC: -0.15, 95% CI -1.12, 0.83 vs -0.13, 95% CI -0.81, 0.56; NTX: -1.62, 95% CI -6.7, 3.5 vs 1.4, 95% CI -2.2, 5.0). There were no significant differences in biomarkers or BMD change at 12 months. Limiting our analysis to the 50 SSRI users who were taking their SSRI for a full 12 months did not change these results; nor did adjusting for BMI, depression and season.

This prospective study showed no difference between SSRI users and non-users in the change in bone turnover or BMD after initiation of SSRIs. Despite potential limitations (non-randomized study, small size, potential for varied time on SSRI prior to baseline assessment), these results do not support a direct negative effect of SSRIs on bone metabolism as measured by OC and NTX. Further studies to understand serotonin-bone interactions, and to confirm the effect of SSRIs on bone are warranted.

Using FRAX® to Evaluate Incidental Osteoporotic Vertebral Fractures in Patients Treated with Bisphosphonate. Yuji Kasukawa*[1], Naohisa Miyakoshi[1], Toshihito Ebina[2], Michio Hongo[1], Koji Nozaka[1], Yoshinori Isikawa[1], Toshiaki Aizawa[3], Yoichi Shimada[1]. [1]Akita University Graduate School of Medicine, Japan, [2]Kakunodate General Hospital, Japan, [3]Kitaakita General Hospital, Japan

Introduction: According to Japanese guidelines, the FRAX®-determined cut-off value (15%) of a 10-year probability of experiencing major osteoporotic fractures with low bone mass and younger than 75 years old is recommended to start the treatment for osteoporosis. However, the cut-off value for when to initiate pharmacological treatment to effectively prevent osteoporotic fracture is still unclear. The purpose of this study was to first determine the risk of major osteoporotic fractures by FRAX® before treatment for osteoporosis. Then, we evaluated the effects of cut-off value on incidental osteoporotic vertebral fracture in the patients with bisphosphonate treatment.

Patients and Methods: We enrolled 74 osteoporotic women older than 60 years of age in this study. We used FRAX® to evaluate the risk of major osteoporotic vertebral fractures in patients younger (n=31) or equal to or older (n=43) than 75 years old before treatment with risedronate (17.5 mg/week). The prevalent and incidental vertebral fractures were evaluated radiographically at the beginning of treatment and at the final follow-up. We measured bone metabolic markers including serum cross-linked N-telopeptide of type 1 collagen (NTX) and bone alkaline phosphatase (BAP) at the beginning of treatment. We also determined the bone mineral density (BMD) by dual-energy X-ray absorptiometry from the distal third of the forearm.

Results: The risk of major osteoporotic vertebral fractures in patients ⩾ 75 years (27.1%) was significantly higher than that of patients < 75 years (16%) ($p<0.001$). Prevalent vertebral fractures were observed in 12 patients < 75 years (38.7%) and in 21 patients ⩾ 75 years (48.8%) at the beginning of treatment. The BMD of patients < 75 years was significantly higher than that of patients ⩾ 75 years (p=0.0001). Twenty-seven patients < 75 years (87.1%) and 40 patients ⩾ 75 years (93.0%) continued treatment. Incidental osteoporotic vertebral fractures were observed in 2 patients < 75 years (7.4%) and 7 patients ⩾ 75 years (17.5%). Within their age groups, there were no significant differences in the risk of major osteoporotic vertebral fractures at the beginning of treatment between patients with or without incidental osteoporotic vertebral fractures (< 75 years, 20.5% and 16.2%, respectively ; ⩾ 75 years 30.9% and 27.6%, respectively). There were also no significant differences in the changes of bone metabolic markers and BMD between patients with and without incidental osteoporotic vertebral fractures.

ConclusionsUsing FRAX® to evaluate the risk of major osteoporotic vertebral fractures at the beginning of treatment, we found no significant differences between patients with and without incidental osteoporotic vertebral fractures during risedronate treatment.

Herriot Hospital, France, [21]Center for Metabolic Bone Disease & Division of Geriatric Medicine, Bel, [22]St. Joseph's Hospital, Canada, [23]University of Verona, Italy

AIM: To examine when, where and how fractures occur in postmenopausal women.

PATIENTS AND METHODS: We analyzed data from the Global Longitudinal Study of Osteoporosis in Women (GLOW), including women age ⩾55 from Australia, Belgium, Canada, France, Germany, Italy, The Netherlands, Spain, US and UK. Women completed questionnaires including fracture data at baseline and years 1, 2 and 3.

RESULTS: Among 60,393 postmenopausal women, 4122 incident fractures were reported (86% non-hip, non-vertebral [NHNV], 8% vertebral, 6% hip). Hip fractures were more likely to occur in spring, with little seasonal variation for NHNV or clinical spine fractures. Hip fractures occurred equally inside or outside the home, whereas 65% of NHNV fractures occurred outside and 61% of vertebral fractures occurred inside the home. Falls preceded 68-86% of NHNV and 68-83% of hip fractures among women aged ≤64 to ⩾85 years, increasing with age. Between 40% and 50% of vertebral fractures were associated with falls in all age groups except those >85, when only 24% occurred after falling (Fig1).

CONCLUSION: Only hip fracture had a seasonal variation, with a higher proportion in spring. Hip fractures occurred equally within and outside the home, spine fractures more often in the home and NHNV fractures outside the home. Falls were a proximate cause of most hip and NHNV fractures.

Association of Bone Marrow Sphingosine 1-Phosphate Levels with Osteoporotic Hip Fractures. Seong Hee Ahn*[1], Jung-Min Koh[2], Sun-Young Lee[3], Seongeun Byun[4], Beom-Jun Kim[2], Seung Hun Lee[1], Jae Suk Chang[4], Ghi Su Kim[1]. [1]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [2]Asan Medical Center, South Korea, [3]Asan Institute for Life Sciences, South Korea, [4]Division of Orthopedic Surgery, Asan Medical Center, University of Ulsan College of Medicine, South Korea

Objective: Sphingosine 1-phophate (S1P) has been discovered to be a critical regulator of bone metabolism. Very recently, we found that higher circulating S1P levels were associated with higher rate of prevalent osteoporotic fracture in human.

Methods: This was a cross-sectional study of 16 patients who underwent hip replacement surgeries. Bone marrow fluids were obtained during hip surgeries, and the S1P levels were measured using a competitive ELISA assay. Bone mineral densities (BMDs) at various skeletal sites were obtained using dual energy x-ray absorptiometry.

Results: Among 16 patients, 4 patients were undergone operations due to hip fractures, and the others were done by any other causes. Bone marrow S1P levels were significantly lower in patients with hip fractures than in those without, before and after adjusting for confounding factors (P = 0.047 and 0.025, respectively). We failed to demonstrate significant associations between bone marrow S1P levels and any BMD values (γ = 0.026 - 0.482, P = 0.171 - 0.944).

Conclusions: In conjunction with our previous findings, these suggest that the effects of gradient between peripheral blood and bone marrow, but not S1P itself, may be the most critical on bone metabolism.

Keywords: Sphingosine 1-phosphate, osteoporotic fracture, bone density

The 3 Chinese Herbs extracts Mixture Reverse Glucocorticoid-Induced Osteoporosis in Rat. Jian Wang*[1], Hongxin Zheng[2], Fang Yang[2], Dezhi Tang[3], Tianfang Li[4], Hui Zhu[2], zhangguo Zhang[2]. [1]Liaoning University of Traditional Chinese Medicine, USA, [2]Liaoning University of Traditional Chinese Medicine, China, [3]Shanghai University of Traditional Chinese Medicine, , [4]Rush University Medical Center, USA

Objective – To investigate the effect of the mixture of extracts from 3 Chinese Herbs, namely, pilose antler, epimedium, and oyster, (PEO), on glucocorticoid-induced osteoporosis (GIO) in rats.

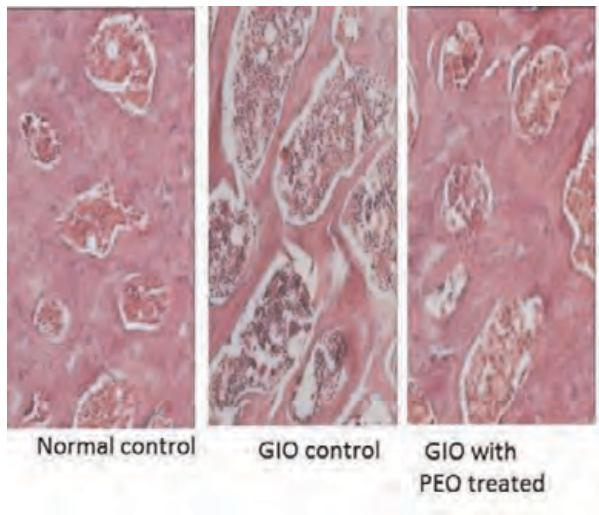
Methods – A Rat GIO model was established by intramuscular injection of dexamethasone (2.5mg/kg, twice per week, for 9 weeks). The GIO rats were treated with intragastric administration of PEO for 9 weeks, and then were sacrificed. Bone mineral density (BMD) and histological changes of femoral heads were evaluated. Femoral head samples were harvested and the mRNA and protein expression of Runx2, Osterix, Msx2 and Dlx5 in bone tissues. Normal bone tissue and the samples from the GIO rats without PEO were used as controls.

Results – PEO treatment increased BMD in the GIO rats. Histological examination demonstrated that PEO treatment improved the structural integrity of bone in GIO rats. Morphological analysis demonstrated better bone trabecular condition, more compact structure, less remaining bone remodeling space, and reduced bone marrow cavities, in the PEO treated rats. PEO treatment increased the mRNA and protein expression of Runx2, Osterix, and Dlx5 and decreased the mRNA and protein expression of Msx2 in bone tissues.Conclusion – (1) The rat GIO model can be established successfully by intramuscular injection with dexamethasone. (2) In the GIO rats, Msx2 expression was significantly up-regulated, while the expression of Runx2Dlx5 and Osterix was dramatically decreased. (3) The PEO, traditional Chinese medicine compounds, prevent and decelerate bone loss in GIO rat by down-regulating Msx2 expression and up-regulating expression of Dlx5, Runx2 and Osterix in bone tissue.

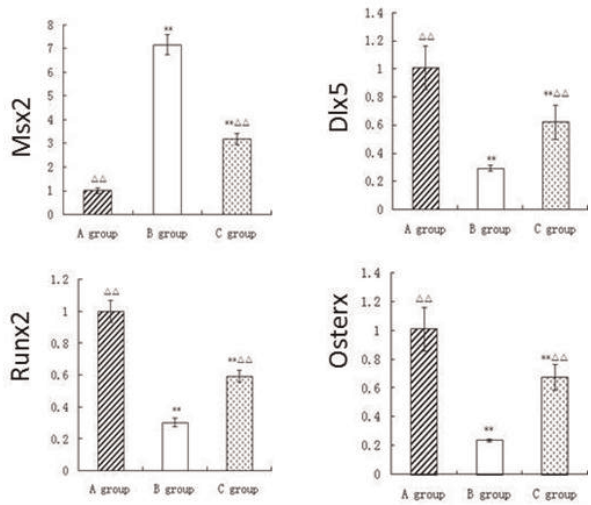
Group	n	Femur BMD (g/cm²)
normal control	22	0.1080±0.0072△△
OP control	21	0.0993±0.0059**
OP PEO treated	18	0.1062±0.0061△△

**:compared with normal control,$P<0.01$;
△△: compared with OP control ,$P<0.01$

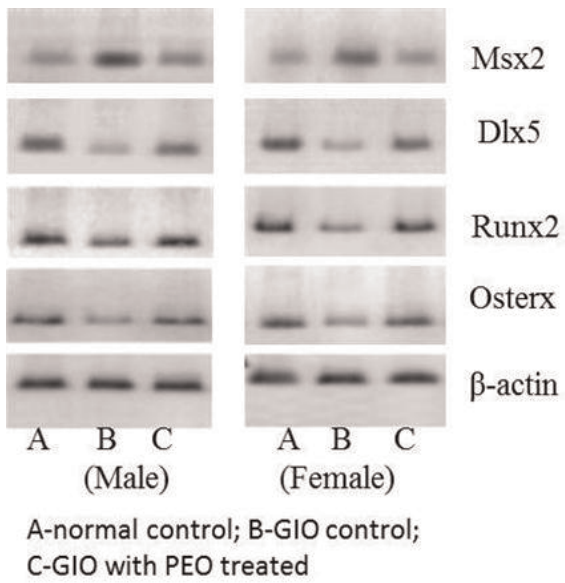
PEO prevents dexamethasone mediated bone loss in rat



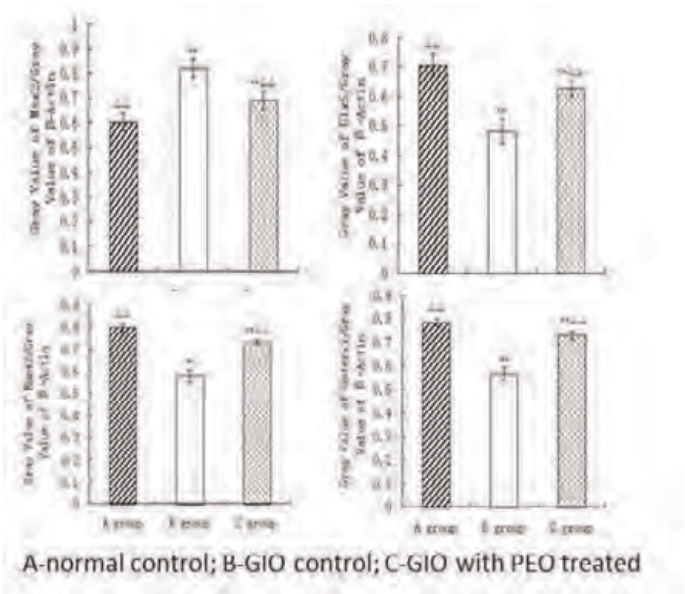
PEO reverses trabecular bone condition of GIO rat



PEO down-regulate mRNA expression of Msx2 and up-regulate mRNA expression of Dlx5 Runx2 and Osterix



PEO decreases Msx2 and increases Dlx5 Runx2 and Osterix protein level in bone tissues



Relative protein level of Msx2 Dlx5 Runx2 and Osterix in bone tissue

Analysis of 48-hr Profiles of Melatonin and the Bone Resorption Marker Crosslinked N-terminal Telopeptide of Collagen I (NTx) in Blind Women With and Without Light Perception. Melissa St. Hilaire[1], Erin Flynn-Evans[1], Suzanne Higginbotham[2], Paula Witt-Enderby*[3], Steven Lockley[1]. [1]Division of Sleep Medicine, Department of Medicine, Harvard Medical School, Brigham & Women's Hospital, USA, [2]Division of Clinical, Social & Administrative Sciences, School of Pharmacy, USA, [3]Duquesne University, School of Pharmacy, USA

There is some evidence that bone metabolism displays a diurnal rhythm in humans that may be influenced by melatonin production, the light/dark cycle, or both. We took advantage of a natural model of altered melatonin timing in blind individuals both with (LP) and without light perception (NLP) to assess these relationships across 24 hours. The current analysis included urine samples from 35 blind female participants (17 LP, 18 NLP). Menopause stage was reported by all participants; 13 were pre-menopausal (6 NLP), 8 were peri-menopausal (5 NLP) and 14 were post-menopausal (7 NLP). Urine was collected across a 48-hr period at 4-hr intervals during wake and at 8-hr intervals overnight. Levels of 6-sulfatoxymelatonin (aMT6; ng/hr) and NTx (BCE nM/hr), corrected for both the urine volume and sampling interval, were analyzed. Both aMT6 and NTx were fit by a cosinor model to determine significant 24-hr rhythms. The results from this analysis reveal that (1) aMT6 had a significant fit 24-hr rhythm for all but 7 participants; (2) NTx did not have a significant 24-hr rhythm except in 3 participants; (3) significant day-to-day variability was observed in the 24-hr NTx outputs; (4) no relationships were found between NTx levels and light perception status or menopause stage with aMT6 acrophase timing (Night vs. Day); (5) 24-hr NTx output of the participants with aMT6 acrophases occurring during the biological night was not significantly different from the 24-hr NTx output of the participants with aMT6 acrophases occurring during the biological day; (6) the 24-hr NTx output was not significantly different between participants with or without light perception; (7) trends towards increases in NTx levels were observed in postmenopausal (combined LP and NLP) vs. premenopausal women (combined LP and NLP; p=0.08) and between perimenopausal women with LP vs. NLP (p=0.07). Future studies should continue to examine the relationship between bone metabolism rhythms in blind individuals with NLP to determine the influence of the melatonin rhythm independent from the influence of the light-dark cycle and should also assess the influence of menopausal status.

B Cell Dysregulation Promotes HIV-induced Bone Loss. Kehmia Titanji*, Ashwani Vunnava, Anandi Sheth, Jeffrey Lennox, Ighovwerha Ofotokun, M. Neale Weitzmann. Emory University School of Medicine, USA

Background: Adaptive immune responses potently impact the skeleton as a consequence of the immuno-skeletal interface, a convergence of cells and cytokine effectors mediating critical albeit different functions in both organ systems. HIV infection assaults adaptive immunity and is associated with high rates of osteoporosis and bone fractures, but the mechanisms remain obscure. Bone-degrading osteoclasts are regulated primarily by the ratio of Receptor-Activator of NF-kappaB (RANKL), the key osteoclastogenic cytokine, to that of its decoy receptor and physiological inhibitor, osteoprotegerin (OPG). Using the HIV-1 transgenic rat model, we recently reported severe skeletal destruction due to increased B cell RANKL expression, compounded by reduced B cell OPG expression, favoring enhanced osteoclastogenesis. These findings suggested that HIV-induced bone loss is aligned with dysregulation of B cell function. In the current study we have attempted to ratify this putative mechanism by translating our basic research findings back into the human system.

Methods: In a prospective cross-sectional comparative study, we characterized the immunoskeletal profile of 45 HIV- and 45 ARV-naïve HIV^+ volunteers. We studied the distribution of B and T cell subsets, cellular activation profile, and production of OPG and RANKL by flow cytometry. We also measured plasma levels of bone turnover markers, C-terminal telopeptide of collagen (CTX-bone resorption) and osteocalcin (OCN–bone formation) by ELISA.

Results: Our data revealed a profound immune activation signature characteristic of HIV/AIDS, as well as a 50% elevation in bone resorption (CTX) in the HIV^+ compared to the HIV^- population ($p = 0.001$). Importantly, similar to our animal studies, we observed a 30% down-regulation of B cell expression of OPG ($p < 0.5$), concurrent with significant up-regulation of RANKL production (60%, $p = 0.001$), reflecting an imbalance in the RANKL/OPG ratio in a direction that favors enhanced bone degradation. Interestingly, this imbalance was age-associated and even more pronounced in individuals >40 years, consistent with higher stress fracture rates in this group.

Conclusions: These data validate our basic research findings, and suggest that dysregulation in B cell function leading to a switch from bone protecting OPG to bone degrading RANKL expression during HIV-infection contributes to viral-induced bone loss in ARV-naïve HIV^+ individuals.

Circulating Sclerostin, Bone Turnover Markers and BMD In Type-2 Diabetic Women Treated With Metformin or Pioglitazone. Mohammed-Salleh Ardawi*[1], Daad Akbar[2], Abdulrahman Al-Shaik[2], Maimoona Ahmed[2], Mohammed Qari[3], Abdulrahim Rouzi[1], Rajaa Raddadi[4]. [1]Center of Excellence for Osteoporosis Research & Faculty of Medicine, Saudi Arabia, [2]Center of Excellence for Osteoporosis Research & Department of Internal Medicine & KAU Hospital,Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [3]Center of Excellence for Osteoporosis Research & Department of Haematology, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, [4]Center of Excellence for Osteoporosis Research, King Abdulaziz University, Saudi Arabia

Background: Sclerostin is involved in the regulation of bone formation through the inhibition of the Wnt/β-catenin signaling pathway. Type 2 diabetes mellitus (T2DM) have an increased risk of fractures that is increased by thiazolidinediones (TZDs) therapy. We hypothized that abnormal sclerostin production contributes to the pathogenesis of increased osteofragility in T2DM treated with TZDs.

Methods: We examined the association between circulating sclerostin levels and the changes in bone turnover markers (BTMs) [including: s-P1NP, s-bone ALP, p-CTX, and u-NTX], and bone mineral density (BMD) [lumbar spine (L_1-L_4); neck femur] [measured by DXA] among 280 women diagnosed with T2DM and treated with either metformin (MET) (850mg twice daily) (n=140) or pioglitazone (PIO) (30mg once daily) (n=140). Baseline values of serum sclerostin, BTMs and BMD were compared with age- and body mass index (BMI)- matched healthy controls (n=280).

Results: Compared with controls, T2DM women had significantly higher serum sclerostin levels (56.78 ± 11.66 vs 41.22 ± 9.35 pmol/L, $P<0.001$), and lower p-CTX ($P<0.001$) and u-NTX ($P<0.001$); but similar s-P1NP and s-bone-ALP levels, respectively. After 12 months of treatment, serum sclerostin levels increased by 48% in PIO-treated and decreased by 27.3% in MET-treated women ($P<0.0001$); whereas BMD [lumbar spine (L_1-L_4) and neck femur] significantly decreased ($P<0.05$) in PIO-treated (% change, -4.46 ± 3.22%) with no marked changes in MET-treated ($P=0.351$) women following therapy.

Conclusions: Women with T2DM had higher serum sclerostin levels than age- and BMI-matched healthy controls, and such levels further increased following therapy with PIO, which is also associated with increased p-CTX and u-NTX and decreased BMD values. Such observations suggest that higher sclerostin levels may be involved in the pathogenesis of increased osteofragility in women with T2DM in general which maybe aggravated by TZDs therapy.

Premenopausal women with idiopathic osteoporosis and those with anorexia nervosa have similar bone structural defects but differ in terms of marrow fat. Anna Kepley[1], Wei Shen[2], Laurel Mayer[2], Elizabeth Shane[3], Julia Weigel[2], Lindsay Kenney[2], Polly Young[2], Chiyuan Zhang[2], Robert Recker[2], Joan Lappe[4], Adi Cohen*[1]. [1]Columbia University Medical Center, USA, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA, [4]Creighton University Osteoporosis Research Center, USA

Bone marrow adipocytes and osteoblasts share a common mesenchymal precursor. Reciprocal relationships between these cells have been implicated in several forms of osteoporosis, including anorexia nervosa (AN). However, animal studies also suggest that the adipocytes and osteoblasts can be regulated independently.

In a transiliac bone biopsy study, we reported that premenopausal women with idiopathic osteoporosis (IOP) have substantially lower trabecular bone volume fraction, and abnormal trabecular and cortical microarchitecture compared to healthy premenopausal controls. Marrow fat (MF) was significantly higher in IOPs than controls, even after controlling for their lower bone volume fraction. Because IOP women had lower BMI than controls, we hypothesized that IOPs would have a bone phenotype similar to women with AN, who also have both bone structure defects and increased MF. We recruited 11 women with IOP (spine or hip Z score ≤ -2.0 and/or low trauma fracture, normal menses, no eating disorder, no secondary cause of osteoporosis), 12 women with AN studied within 3 wks of inpatient admission (% ideal body wt 73±5; yrs amenorrheic 7±5; 7/12 with history of fracture) and 28 premenopausal Controls (C; normal BMD and menses, no fractures). Areal BMD and body composition were measured by DXA, volumetric BMD/microarchitecture by HR-pQCT (Scanco AG), and MF fraction of the L3 vertebra and the femoral neck by 1H-magnetic resonance spectroscopy (MRS). Age was similar and body composition differed as expected (Table). While BMD and bone structure defects were remarkably similar between AN and IOPs, those with AN had higher MF, particularly at the spine. Spine MF correlated with age (r=0.45,p=0.02) and femoral MF with whole body fat (r=0.41,p=0.03) in C, but neither age nor body fat correlated with MF in IOP or AN. While radial vBMD and cortical thickness correlated directly with MF at the spine (both r=0.42,p=0.02) and femur (r=0.37-0.41,p=0.03-0.049) in C, inverse relationships were seen between spine MF and tibial cortical thickness (r=-0.78,p=0.003) and femur MF and total hip BMD (r=-0.65,p=0.02) in IOPs. MF did not correlate with amenorrhea or BMD variables in this AN cohort. We conclude that despite quite similar deficits in BMD and microarchitecture, IOPs have significantly less marrow adiposity than women with AN. Further research is required to investigate potential mechanisms for the differences in relationships between fat and bone in IOP and AN.

Vitamin D status and response to treatment of vitamin D in Korean women initially diagnosed as osteoporosis. Sung Soo Kim*[1], Jin Ju Kim[2]. [1]Chungnam National University School of Medicine, South Korea, [2]Chungnam National University Hospital, South Korea

Background: The aim of this study is to evaluate whether the recommended dose is appropriate in vitamin D deficient patients.

Methods: This was a prospective study. Women (n = 30) first diagnosed with osteoporosis were recruited in outpatient clinic. They were recommended to be exposed to sun light for more than 30 minutes a day. Subjects were divided into 3 groups according to serum 25-hydroxyvitamin D_3 (25OHD) status: deficiency (less than 20 ng/mL), insufficiency (20 to 30 ng/mL) and sufficiency (30 ng/mL or more). Insufficient and sufficient patients received the recommended dose (1000 IU/day) but deficient patients received recommended or double dose (1800 to 2000 IU/day). We compared 25OHD levels at baseline and after vitamin D supplementation for 12 months.

Results: Mean (SD) serum 25OHD concentration at baseline was 17.60 (8.44) ng/mL and the proportion of deficient, insufficient and sufficient groups were 66.7% (20/30), 20.0% (6/30) and 13.3% (4/30) respectively. All insufficient patients achieved optimal level (30 ng/mL or more) with the recommended dose. However, 63.6% (7/11) of the deficient patient with recommended dose achieved optimal level and 88.9% (8/9) of those with double dose did (P = 0.016).

Conclusions: One third of osteoporotic women treated with recommended dose of vitamin D may not achieved optimal level of 25OHD if they have deficient level of 25OHD. They may require double dose of vitamin D in case of deficient level of 25OHD.

Identification of proteins important for male osteoporosis from human peripheral blood monocytes. Yingchun Zhao*, Lan Zhang, Hualin Huang, Yao-Zhong Liu, Yong-Jun Liu, Fei-Yan Deng, Hong-Wen Deng. Tulane University, USA

Introduction: Osteoporosis is a major public health problem, mainly characterized by low bone mineral density (BMD), which is largely genetically determined with gender-specificity. Although women generally have lower BMD than men, men suffer significantly higher mortality rate upon osteoporotic fractures. However, current studies have been largely focused on female osteoporosis. Low BMD may result from bone resorption (by osteoclasts) exceeding bone formation (by osteoblasts). Peripheral blood monocytes (PBMs) are precursor cells for osteoclasts. We are utilizing PBMs, which are directly isolated from male subjects with high or low BMD, for protein profiling with subcellular extraction and 2D-nanoLC-ESI-MS/MS^E for the purpose of identifying proteins important for male osteoporosis.Method: PBMs are isolated from the whole blood with the negative immunomagnetic separation method. We used ProteoExtract Subcellular Proteome Extraction kit to isolate proteins of membrane, cytosolic, nuclear, and cytoskeletal fractions. After trypsin digestion, the peptide mixture is separated with 2-dimensional NanoAquity System. The five fractions generated from the high pH first dimension LC are further separated with the reverse phase second dimension LC. The separated peptides were analyzed with Synapt G2 MS^E system. Data collection was controlled by Masslynx 4.1. Protein identification and quantification were performed in PLGS 2.4. Data analysis was performed in SPSS and Excel.Results: We have recruited and phenotyped 120 males at peak bone mass ages of 25-50 based on low and high hip BMD values. We are using half of the sample (30 low vs. 30 high BMD subjects) for protein profiling. After searching against IPI database (v3.83), a typical profiling generated 3275 proteins for cytoplasm fraction, 3203 proteins for membrane fraction, 1037 proteins for nuclear fraction, and 967 proteins for cytoskeletal fraction with a total of 8483 proteins. We identified 33 upregulated and 3 downregulated proteins (low BMD vs high BMD) in cytosolic component; 87 upregulated and 17 downregualted proteins in membrane component; 4 upregulated and 3 downregualted proteins in nuclear component; and 39 upregulated and 30 downregulated proteins in cytoskeletal component. Western blot validation of selected significant proteins is being carried out. Functional study wil be pursued for those validated significant proteins.

Serum Dickkopf1 (DKK1): Relationship With Bone Metabolism And Atherosclerotic Disease In Type 2 Diabetes Mellitus. Rebeca Reyes-García*[1], Pedro Rozas-Moreno[2], Antonia Garcia-Martin[3], Beatriz Garcia-Fontana[4], Sonia Morales-Santana[4], Manuel Munoz-Torres[5]. [1]Hospital Rafael Méndez, Spain, [2]Endocrinology Division. Hospital General de Ciudad Real. Ciudad Real, Spain., Spain, [3]Hospital Comarcal del Noroeste, Spain, [4]Hospital Clínico San Cecilio, Spain, [5]Hospital Universitario San Cecilio, Spain

Type 2 diabetes (T2DM) is a risk factor for osteoporotic fractures and cardiovascular disease. The Wnt signaling pathways are involved in diverse develop mental and physiological processes, including anabolic effects on bone and

atheroesclerotic disease (AD). Dickkopf-1 (DKK1) is a potent inhibitor of Wnt signaling. The aims of our study were to evaluate serum DKK1 levels in a cohort of T2DM patients and to analyze its relationships with bone metabolism and AD. We studied 122 subjects: T2DM patients (n: 72, mean age 58,2 ± 6 years) and non-diabetic subjects (n:54, mean age 55,4 ± 7 years). BMD was measured by DXA. The presence of AD (cerebrovascular disease, peripheral arterial disease, ischemic heart disease) was recorded. Intima-media thickness (IMT) was determined by Doppler ultrasonography and aortic calcification by evaluation of lateral view conventional X-rays. We no found significant differences in DKK1 between groups. Serum DKK1 concentrations were significantly higher in females in total sample (24,3 ± 15,2 vs 19,6 ± 10,2 pmol/L, p = 0,046) and in T2DM group (27,5 ± 17,2 vs 19,8 ± 8,9 pmol/L, p = 0,025). There was a positive correlation between serum DKK1 and LS BMD in total sample (r = 0,183, p = 0,048). However, we no found a significant relationship with osteoporosis diagnosis or morphometric vertebral fractures. Serum DKK1 was significantly higher in T2DM patients with AD (26,4 ±14,5 pmol/L vs 19,1 ± 11,6 pmol/L, p = 0,026) and also in patients with abnormal IMT (26,4 ± 15,1 pmol/L vs 19,8 ± 11,3 pmol/L, p = 0,038). DKK1 levels were independent predictors of the presence of AD in T2DM independently others atherosclerotic risk factors (odds ratio: 1,064, 95% confidence interval: 1,107–1,125; p = 0,028). In the ROC curve analysis, In the ROC curve analysis to evaluate the usefulness of sclerostin as a marker for high risk of AD, the area under the curve was 0,667 (95% confidence interval: 0,538-0,795; p = 0,016). A concentration of 17,3 pmol/L or higher showed a sensitivity of 71,4 % and a specificity of 60 % to identify an increased risk of AD. In conclusion, we no found sigificant differences in DKK1 between T2DM and circulating DKK1 levels are higher in T2DM with AD.

Second generation antipsychotic drugs have direct effects on the skeleton via G-protein coupled neural receptors: Implications for bone and energy metabolism. Karen Houseknecht[1], Katherine Motyl*[2], Rachel Mayer[3], Shail Patel[3], Deborah Barlow[3], John Streicher[3], Daniel Brazeau[3], Clifford Rosen[4]. [1]University of New EnglandCollege of Pharmacy, USA, [2]1Maine Medical Center Research Institute, USA, [3]University of New England, USA, [4]Maine Medical Center, USA

Second generation antipsychotics (SGAs) are widely prescribed to treat psychiatric disorders in adults and children. The pharmacology of SGAs is complex: they potently antagonize multiple G protein coupled receptors (GPCRs) including dopamine (D2), serotonin (5-HT), α2 and H1. Side effects of SGAs include obesity and type 2 diabetes. Recent evidence indicate SGAs such as risperidone (RIS) increase fracture risk and reduce bone mineral density in humans; the underlying pharmacological mechanisms are unknown. Our hypothesis is that SGA therapy is associated with significant bone loss, and this adverse side effect occurs via multiple mechanisms including directly binding to, and antagonizing receptors on bone cells. The specific aims of this study were 1) determine if GPCR targets of SGA action in the CNS are expressed in bone cells, 2) determine if RIS accumulates in bone marrow following oral dosing and 3) determine if RIS has direct effects on osteoblast gene expression and function. GPCR gene expression was determined by qPCR analysis using MC3T3 cells during proliferation and following exposure to osteoblast differentiation media. D2, 5HT-2A & 5HT-2C receptor mRNA was expressed in MC3T3 cells (comparable to brain control), and expression was induced upon differentiation. Interestingly, expression was highest at day 7 of differentiation, and then returned to levels comparable to proliferating osteoblasts by day 21, suggesting these receptors are important for osteoblast differentiation and/or function. Drug exposure in plasma and bone marrow was determined in mice dosed orally with RIS (1.0 mg/kg) by LC/MS/MS detection. RIS and the active metabolite, 9-OH-RIS were present in bone marrow, consistent with plasma exposure. Finally, MC3T3 cells were differentiated in the presence of vehicle, 6, 30 or 150 nM RIS, representing sub-clinical, clinical and supra-clinical exposure, respectively. Alkaline phosphatase and Von Kossa mineral stain were not changed by RIS, despite the previously known reduction in osteoblast function in vivo. However, RIS did suppress expression of osteoprotegerin (OPG), the soluble decoy receptor for RANKL. This finding is consistent with low OPG expression and high osteoclast activity that we have previously demonstrated in mice and increased osteoclast number that we have shown in primary osteoclasts treated with RIS. Furthermore, RIS had dose-dependent effects on ATF4 and osteocalcin expression, including suppression of these factors at clinical and supra-clinical levels, which could negatively affect glucose homeostasis in vivo. These data support the notion that adverse SGA effects on bone and metabolism may be mediated, at least in part, by direct effects on bone cells in vivo.

Comparison of Analgesic Action of and Vertebral Collapse Prevention by Teriparatide and Risedronate Administration for Fresh Osteoporotic Vertebral Fracture. Hiroyuki Tsuchie*[1], Naohisa Miyakoshi[2], Yuji Kasukawa[2], Tomio Nishi[1], Hidekazu Abe[1], Masaaki Takeshima[1], Toyohito Segawa[2], Yoichi Shimada[2]. [1]Ugo Municipal Hospital, Japan, [2]Akita University Graduate School of Medicine, Japan

Purpose: Vertebral fracture is often seen in aged osteoporotic patients, and it causes a decline in activities of daily living. Because teriparatide has a potent osteogenic effect, it is expected to promote bone union after fracture and reduce fracture-related pain. Therefore, we evaluated the analgesic action of and vertebral collapse prevention by administering teriparatide to fresh vertebral fracture patients, comparing the effects with those of risedronate administration.

Methods: Seventeen patients with fresh osteoporotic vertebral fracture (24 vertebrae) hospitalized for treatment (male/female: 2/15, mean age: 80 years) participated in the present study. They were administered either teriparatide or risedronate for osteoporosis treatment based on their choice, and 8 patients (14 vertebrae) were administered teriparatide (PTH group, male/female: 1/7, mean age: 82 years), and 9 patients (10 vertebrae) were administered risedronate (RIS group, male/female: 1/8, mean age: 80 years). We compared serum cross-linked N-telopeptide of type I collagen (NTX), bone-specific alkaline phosphatase (BAP), calcium (Ca), inorganic phosphorus (IP), the visual analogue scale (VAS), hospitalization period, vertebral collapse rate compared to that at the initial visit, and local kyphotic angle of fractured vertebrae compared to the initial visit.

Results: At the start of treatment, there was no significant difference in the age, laboratory examinations, bone mineral density, VAS, vertebral collapse rate, and local kyphotic angle between the 2 groups. At 8 weeks after the initial visit, VAS in the PTH group was significantly lower than in the RIS group ($P<0.05$).At 4 and 8 weeks after the initial visit, the differences in the vertebral collapse rate and local kyphotic angle in the PTH group were significantly lower than in the RIS group ($P<0.01$, respectively). There was no significant difference in the hospitalization period.

Conclusions: Teriparatide is more promising for analgesia and the prevention of vertebral collapse progression after osteoporotic fresh vertebral compression fracture than risedronate.

Early Bone Resorptive Response to Teriparatide Predicts Bone Density Outcome at 2 Years. Richard Bockman*[1], Erik Nielsen[2], Wei-Ti Huang[2]. [1]Hospital for Special Surgery, Weill Cornell Medical College, USA, [2]Hospital for Special Surgery, USA

Not all patients show improved bone mineral density (BMD) with Teriparatide (TPTD), an expensive and prolonged osteoanabolic therapy for osteoporosis (OP). As an approach to improving and predicting BMD outcome, we analyzed early metabolic bone parameters and BMD changes in OP patients newly treated with TPTD. The clinical course of 78 patients with severe OP (mean T score at lumbar spine -2.7) who were prescribed TPTD was monitored by measuring bone specific alkaline phosphatase (BSAP) and N-terminal bone collagen protein (NtX) markers every 4 months and Lumbar Spine (LS)-BMD measured at 2 years. Responders were defined as showing greater than 3.5% increase in LS-BMD at 2 years. Sixty percent (59/78) of TPTD-treated patients were ''Responders'' at the end of two years of study. There were no significant differences in BMD, BMI, mean 25 OH Vit D, serum calcium, creatinine, age, gender, or history of prior fractures at baseline between Responders and Non-responders. The peak BSAP and NtX response was seen at 4 months, Fig 1. There were no differences in the BSAP response for Responders and Non-responders. A significant difference in the magnitude and duration of the NtX elevation was seen in the Non-responder population. This difference is more evident in the plot of the ratio of NtX to BSAP, Fig 2. Using a Generalized Estimating Equations (GEE) analysis, the Responders had an 11.6 unit lower NtX value compared to Non-responders across the 2 years with a p-value=0.0014. This result remained significant after adjusting for potential confounders or effect modifiers such as 25 OH Vit D, calcium, creatinine levels, or BMI, age, gender, prior fracture history, or prior bisphosphonate use. No significant difference in the mean BMD increase was seen in the patients who were naïve or those previously treated with bisphosphonates (9.11 vs 8.44%). In summary, no difference in the BSAP response was seen between the Responders and Non-responders. The Non-responding patients showed a greater and more prolonged increase in NtX across the 2 years of study, even after adjustment for gender, age and history of prior fracture. Baseline parameters and prior bisphosphonate therapy had no significant effect on final BMD outcome. In conclusion, an

early robust increase in the resorptive response predicted an attenuated response to TPTD therapy. Initiation of antiresorptive therapy after 4 months of starting TPTD therapy may abrogate non-response thereby improve overall BMD outcomes.

Overlapping and Follow-up of Alendronate to Teriparatide Results in Continuing Volumetric Bone Mass Increase Measured by Quantitative Computed Tomography. Christian Muschitz*[1], Roland Kocijan[2], Wolfgang Schima[3], Judith Haschka[2], Afrodite Zendeli[4], Astrid Fahrleitner-Pammer[5], Heinrich Resch[6]. [1]St. Vincent's Hospital, Austria, [2]St. Vincent Hospital Vienna, Austria, [3]Department of Radiology - St. Vincent Hospital, Austria, [4]The VINFORCE Study Group - St. Vincent Hospital - Medical Department II, Austria, [5]Medical University Graz, Austria, [6]Medical University Vienna, Austria

Purpose: After 9 months of teriparatide (TPTD) treatment the combination of alendronate (ALN) and TPTD for the consecutive 9 months results in enhanced bone mineral density (BMD) gain when compared with 18 months of TPTD monotherapy. Use of raloxifene (RAL) instead of ALN was less advantageous. During a subsequent 12 months maintenance therapy, hip BMD only increased in the ALN group. Our aim was to investigate changes of cortical and trabecular bone by quantitative computed tomography (QCT).

Methods: 125 postmenopausal women (mean age 71.7±8.5 ys, 91.5% fracture prevalence, 95.7% prior antiresorptive treatment > 2 ys) were randomized after 9 months of TPTD treatment into three open-label groups for another 9 months: ALN (70 mg/week, 41 pts) or RAL (60 mg/day, 37 pts) added to TPTD treatment or TPTD monotherapy/Ca+Vit D group (47 pts). After TPTD termination, patients were maintained on their respective treatment regime for another 12 months. All subjects received 1g calcium/800 IU vitamin D daily. Trabecular bone in 2nd lumbar vertebra (L2), cortical and trabecular bone in total hip and femoral neck were measured at randomization, end of TPTD and of the maintenance by QCT (Siemens Somatom Definition AS+).

Results: L2 bone volume changed by (mean %±SD) 12.1±4.5, 14.6±8.9 and 7.2±7 during combination and 21.9±8.3, 23.6±10 and -3.9±5.7 % ($p < 0.001$ for all) at the end of maintenance treatment for the ALN, RAL and Ca+Vit D groups, respectively. Ca+Vit D group was inferior to the other groups at both time points ($p<0.01$). The corresponding changes of trabecular bone in the total hip were 10.7±4.4, 5.1±2.3 and 4.8±2.6 as well as 16.7±4.4, 8±3.2 ($p < 0.001$ for all) and -0.4±4% (n.s.), respectively. Changes in both time points were superior in the ALN group. The increase of the RAL was greater than of the Ca+Vit D group at the end of the maintenance ($p=0.02$). In contrast, cortical bone in the total hip changed by 6.6±2.2 ($p < 0.001$), -1.7±5.8 ($p=0.01$) and 2.8±3.1 ($p=0.002$) and 13.8±2.9, -3.9±6 ($p<0.001$ both) and 0.7±3.3% (n.s.), respectively. In both intervals, cortical bone increased in the ALN group significantly more than in the other groups ($p<0.001$). The decrease observed in the RAL group was significantly different from changes in the Ca+Vit D group.

Conclusion: Continuation of ALN after its addition to the second 9 months of an 18-month TPTD treatment cycle resulted in a robust increase especially in cortical bone of the hip in severe postmenopausal osteoporosis.

Alendronate Sodium/Vitamin D_3 Combination Tablet versus Calcitriol for Osteoporosis in Chinese Postmenopausal Women: A 6-Month, Randomized, Open-Label, Active-Comparator Controlled Study with a 6-Month Extension Phase. Zhenlin Zhang*[1], Er Yuan Liao[2], Bo Xia Wei[3], Hua Lin[4], Li Wang[5], De Cai Chen[6], Hai Tang[7], Wei Hong[8], Yong Qiang Hao[9], Yong De Peng[10], Liang He[11], Zhao Heng Hu[12], Fang Wei[13], Jue Wang[13], Arthur Santora[14]. [1]Shanghai Sixth People's Hospital, Shanghai Jiaotong University School of Medicine, China, [2]The Second Xiangya Hospital of Central South University, China, [3]Peking Union Medical College Hospital, China, [4]Nanjing Drum Tower Hospital, China, [5]TianJin Hospital, China, [6]West China School Of Medicine, West China Hospital, Sichuan University, China, [7]Beijing Friendship Hospital, Capital Medical University, China, [8]Huadong Hospital Affiliated to Fudan University, China, [9]Shanghai Ninth People's Hospital, China, [10]Shanghai First People's Hospital, China, [11]Beijing Jishuitan Hospital, China, [12]Peking University People's Hospital, China, [13]Merck Sharp & Dohme Corp., China, [14]Merck Sharp & Dohme Corp, USA

Purpose: Postmenopausal osteoporosis is a major health concern in China; however, the prevalence of vitamin D insufficiency in treated patients is not fully recognized in the clinical setting. Alendronate/Vitamin D3 may offer therapeutic benefits by modifying bone resorption and mineralization. Our objective was to investigate the efficacy and safety of alendronate 70 mg/vitamin D_3 5600 IU (ALN/D5600) as compared with calcitriol in Chinese postmenopausal women.

Methods: Postmenopausal women over 55 years of age with osteoporosis (low BMD with or without prior non-pathological fracture) were eligible. A total of 219 patients were randomized to receive 70 mg ALN/D5600 once weekly (n=111) or calcitriol 0.25 mcg once daily (n=108) for 12 months. The primary efficacy endpoint was percent change from baseline in the lumbar spine BMD at month 6. BMD was measured by a Hologic or Lunar DXA machine at baseline, month 6 and 12. Hypercalciuria was prespecified as an event of interest for safety evaluation.

Results: Baseline characteristics were similar, and 30.7% of patients had a baseline 25(OH) D level <15ng/mL. Women who received ALN/D5600 had significantly greater increases in BMD compared with those receiving calcitriol. At month 6, percent changes from baseline of lumbar spine BMD were 3.54%, 1.59% in ALN/D5600 and calcitriol treated groups. Mean treatment difference (±SE) was 1.95±0.56% between groups ($p<0.001$). Results of key secondary and exploratory analyses favored ALN/D5600. At month 12, mean differences in BMD percent changes from baseline were 2.92±0.59% at the lumbar spine, 2.53±0.65% at the total hip, 2.89±0.96% at the femoral neck, and 2.28±1.01% at the trochanter ($p<0.05$ for all comparisons). Mean differences at month 6 in P1NP and s-CTx percent changes from baseline were -41.35%, -50.49%, respectively ($p< 0.001$ for both comparisons). ALN/D5600 treatment was associated with a 96% reduction in the proportion of patients with serum 25(OH) D <15 ng/mL at Month 12 (1.0% vs. 25.5% with calcitriol, $p<0.001$). Hypercalciuria was less frequent in the ALN/D5600 group (0.9% vs. 2.8%, p=NS). The overall safety profile was similar between groups. The proportion of patients with fracture was lower in the ALN/D5600 group (0.9% vs. 3.7%).

Conclusions: ALN/D5600 once weekly is superior to calcitriol in BMD increase at the lumbar spine, bone turnover marker decrease, and vitamin D insufficiency correction in Chinese women with osteoporosis. ALN/D5600 is well tolerated.

Bone Mineral Density Increases with Monthly i.v. Ibandronate Injections Contribute to its Fracture Risk Reduction in Primary Osteoporosis: 3-Year Analysis of the Phase III MOVER Study. Hiroshi Hagino*[1], Toshitaka Nakamura[2], Masako Ito[3], Tetsuo Nakano[4], Junko Hashimoto[5], Masato Tobinai[6], Hideki Mizunuma[7]. [1]Tottori University, Japan, [2]National Center for Global Health & Medicine, Japan, [3]Nagasaki University Hospital, Japan, [4]Tamana Central Hospital, Japan, [5]Chugai Pharmaceutical Corporation Limited, Japan, [6]Chugai Pharmaceutical Co. Ltd., Japan, [7]Hirosaki University, Japan

Purpose: The MOVER (MOnthly intraVenous ibandronatE versus daily oral Risedronate) study compared the efficacy and safety of monthly i.v. ibandronate (IBN) with oral risedronate (RIS) in patients (pts) with primary osteoporosis. The aim of the study was to show non-inferiority of IBN versus RIS in the incidence of non-traumatic vertebral fractures. We present 3-year efficacy data and examine the relationship between bone mineral density (BMD) increases and vertebral fracture risk reduction.

Methods: MOVER was a randomized, double-blind study in ambulatory pts aged ⩾60 years with fragile bone fracture, BMD of the lumbar spine L2–L4 or proximal femur (hip and femoral neck) <80% of the young adult mean (T-score: –1.7, –1.6, and –1.4), and 1–5 vertebral fractures in the thoracic and lumbar spine. 1265 pts were randomized to receive i.v. IBN 0.5 or 1 mg/month + oral daily placebo, or oral RIS 2.5 mg/day (licensed Japanese dose) + monthly i.v. placebo.

Results: The per-protocol set comprised 1134 pts (IBN 0.5 mg n=376, IBN 1 mg n=382, RIS n=376). Baseline patient characteristics were balanced across the groups. Over 3 years, cumulative incidences of new/worsening vertebral fractures were 19.9% (95% CI 15.6–24.1) for IBN 0.5 mg, 16.1% (95% CI 12.2–19.9) for IBN 1 mg, and 17.6% (95% CI 13.6–21.6) for RIS. Both IBN doses were non-inferior to RIS (non-inferiority limit 1.55): 0.5 mg, hazard ratio (HR) 1.09 (95% CI 0.77–1.54); 1 mg, HR 0.88 (95% CI 0.61–1.27). The 1 mg IBN group showed a 27% relative risk reduction in the incidence of the major six non-vertebral fractures, and a 15% reduction in total clinical fractures versus RIS. BMD gains were substantial at all sites and significantly improved from baseline with all treatments after 6 months. Fracture-free pts achieved greater hip BMD gains with 1 mg IBN (3.4%) than with RIS (2.1%). Hip BMD gains after 6 months predicted the future risk reduction of vertebral fractures. Reductions in bone turnover markers were substantial with all treatments after 3 months.Conclusions: These data show non-inferiority of monthly i.v. IBN to the licensed Japanese daily oral dose of RIS in reducing the incidence of vertebral fractures in Japanese pts with osteoporosis. The results suggest that BMD gains after 6 months of treatment with 1 mg i.v. monthly IBN could lead to vertebral fracture risk reduction. Monthly 1 mg IBN injections could be an alternative option for the long-term treatment of osteoporosis in Japanese pts.

Differential Effects of Intravenous Bisphosphonates on First-dose Acute-phase Reactions in a Clinical Setting. Albrecht Popp*, Renate Senn, Helene Buffat, Christoph Senn, Philipp Popp, Ivanka Curkovic, Kurt Lippuner. Department of Osteoporosis, University Hospital & University of Berne, Switzerland

Introduction: Intravenously administered aminobisphosphonates (BP) such as zoledronate 5 mg once yearly (ZOL) and ibandronate 3 mg every three months (IBN) are first line therapies of postmenopausal osteoporosis. First-dose acute-phase reactions (APR) are common side-effects occurring within 24 to 72 hours after IV BP administration. In the randomized controlled pivotal trials (RCTs) with ZOL and IBN, reported APR rates were 31.6% after a BP washout period dependent on previous use (HORIZON study)[1] and 4.9% after exclusion of women with oral BP use in the previous 6 months or any previous use of IV BP (DIVA study)[2], respectively. The aim of the present study was to determine the APR rate after the first IV infusion of ZOL or IBN under conditions of daily practice.

Methods: Consecutive postmenopausal women with osteoporosis treated with either IV ZOL or IBN at the Department of Osteoporosis of the University Hospital of Berne, Switzerland, were included. All patients completed a standardized recall questionnaire administered by a trained physician three months after the first IV infusion. Recorded signs and symptoms during the first 3 days after IV infusion were: myalgia, arthralgia, pyrexia, tiredness, nausea, chills, and vertigo, with the presence of one or more items being regarded as an APR. The prevalence of first-dose APR was compared between ZOL and IBN, overall as well as in BP-naïve and BP-pretreated patients.

Results: First-dose IV BP was administered to 725 women (314 IBN and 411 ZOL). Groups did not significantly differ with regard to mean age, BMI, BMD, and prevalent vertebral fractures. APR were reported by 302 women (42%), significantly more frequently with ZOL (N=197, 48%) than with IBN (N=105, 33%), $p < 0.001$. Women in the IBN group were significantly more likely to have received prior HRT (10 vs. 5%, p=0.011) or prior BP therapy (72 vs. 62%, p=0.006). However, among BP-naïve patients, APR remained significantly more frequent in women after ZOL than IBN (69% vs. 38%, $p < 0.001$). When comparing BP-pretreated with BP-naïve patients, the APR rate was significantly lower with ZOL ($p < 0.001$) but not with IBN (p=0.289).

Conclusion: After first-dose IV BP administration, APR were consistently more frequent than reported in pivotal RCTs and more frequent with ZOL than with IBN. Pretreatment with a BP reduced the rate of first-dose APR in patients treated with ZOL only.

Effect of Denosumab Two Years Therapy in Women with Osteoporosis and Contraindications to Oral Bisphosphonates on Bone Mineral Density – One Centre Open Study Results. Andrzej Sawicki*. Synexus Poland, Poland

Andrzej Sawicki

Medical Centre Synexus, Warsaw, Poland

Objectives: In FREEDOM trial denosumab treatment was well-tolerated and significantly increased BMD. The aim was to evaluate whether osteoporotic women with contraindication to oral bisphosphonates treatment (e.g. GERD) or intolerance or resistance, have positive effect on bone mass after denosumab as in FREEDOM study patients, in open study in one out-patients clinic. We report observational BMD results from the first 2 years of treatment.

Materials/Method: The study was performed in 85 women with osteoporosis aged 29 to 87 with contraindication to oral bisphosphonates treatment or intolerance or resistance. Bone Mineral Densitometry (BMD) was assessed by Hologic 4500 before and after 6, 12, 18 and 24 months denosumab treatment and calcium and vitamin D daily.

Results:

Table1 : Percentage change in BMD from baseline and after 6, 12, 18 , 24 months denosumab

Note: number of patients in 6, 12, 18, 24 months groups is not the same.

Denosumab treatment was well accepted and tolerated.

Conclusions: These data demonstrated that denosumab treatment for up to 2 years in patients with contraindication to oral bisphosphonates treatment or intolerance or resistance was associated with continued gains in BMD in patients and have similar positive effect on bone mass as in FREEDOM study patients.

SA0384

Effect of odanacatib on BMD and fractures: Results from Bayesian univariate and bivariate meta-analyses. Olga Gajic-Veljanoski*[1], George Tomlinson[2], Jeevitha Srighanthan[3], Jonathan Adachi[4], Robert Josse[5], Jacques P. Brown[6], Angela M. Cheung[7]. [1]University Health Network, Canada, [2]Dalla Lana School of Public Health, University of Toronto, Canada, [3]Osteoporosis Program, University Health Network, Toronto, Canada, [4]St. Joseph's Hospital, Canada, [5]St. Michael's Hospital, University of Toronto, Canada, [6]CHU de Québec Research Centre, Canada, [7]University Health Network-University of Toronto, Canada

Odanacatib (ODN) is a selective cathepsin K inhibitor that increases BMD and is currently in Phase 3 development for fracture prevention.

We systematically reviewed Medline, EMBASE, Cochrane library, conference proceedings and bibliographies, and included RCTs that compared ODN 50mg/week

to placebo for at least 12 months and reported BMD and / or fractures as adverse events. We used Bayesian univariate and bivariate meta-analyses to estimate the efficacy of ODN on BMD and fractures in current trials and to predict these in a future trial. Bayesian bivariate meta-analysis accounts for all available data and within- and between-study correlations between the treatment effects on BMD and fractures.

Of 31 potentially eligible articles, 6 articles describing 4 RCTs (788 patients, duration 1-5 years) were included. Table shows the effect of ODN on BMD based on Bayesian univariate meta-analysis. Bayesian bivariate meta-analysis resulted in similar results with narrower credible intervals. Greater duration of ODN use was associated with greater percent increase in BMD: LS BMD by 1.3%/year (95%CrI [Credible Interval]: 0.1, 2.2), TH BMD by 1.1%/year (95%CrI: 0.5, 1.7) and FN BMD by 1.1%/year (95%CrI: 0.4, 1.8). The predicted mean increase in BMD over 1-3 years, adjusted for the effect on fractures, in a future trial ranged between 2.3% and 7.5% for LS, 1.4% and 5.1% for TH, and 1.5% and 5.2% for FN. ODN for 2-3 years decreased odds of all fractures (population OR=0.3, 95%CrI: 0.1, 0.8). After accounting for the effect on BMD, ODN over 1-3 years decreased future odds of all fractures by 50% (future OR=0.5, 95%CrI: 0.1, 1.6). Evidence weighted odds of any benefit on both bone outcomes were 9:1 in current and future trials. Our estimates remained robust in sensitivity analyses.

In conclusion, we predict that ODN will increase BMD and decrease all fractures in the Phase 3 fracture outcome trial. Whether our prediction of benefit is in a similar range to that observed remains to be seen.

Table. Effect of ODN on BMD: Bayesian univariate meta-analysis

Duration of Treatment Years	Lumbar Spine (LS) Mean Difference, % (95% CrI)	Total Hip (TH) Mean Difference, % (95% CrI)	Femoral Neck (FN) Mean Difference, % (95% CrI)
1 year	4.0 (1.6, 6.5)	2.1 (-0.1, 4.3)	2.2 (0.0, 4.4)
2 Years	4.6 (1.9, 7.3)	3.4 (1.1, 5.7)	3.8 (1.4, 6.2)
1-3 Years	5.0 (2.6, 7.4)	3.4 (1.3, 5.6)	3.4 (1.3, 5.8)
1-5 Years	5.2 (2.8, 7.7)	3.4 (1.3, 5.7)	3.7 (1.4, 5.9)

Efficacy and Safety of Zoledronic Acid in Postmenopausal Osteoporosis Patients Between 50-65 Years Old. NURTEN ESKIYURT*[1], Rezzan Gunaydin[2], Belgin Erhan[3], Hatice Bodur[4], Mehmet Kırnap[5], Vesile Sepici[6], Banu Kuran[7], Gulay Dincer[8], Hatice Ugurlu[9], Bulent Butun[10], Serhan Sevgi[11], Merih Sarıdogan[12]. [1]Istanbul University, Turkey, [2]Izmir Training & Research Hospital, Turkey, [3]Istanbul Physical Treatment & Rehab. Training & Research Hospital, Turkey, [4]Ankara Numune Trainig & Research Hospital, Turkey, [5]Erciyes University Faculty of Medicine, Turkey, [6]Gazi University Faculty of Medicine, Turkey, [7]Sisli Etfal Training & Research Hospital, Turkey, [8]Ankara University Faculty of Medicine, Turkey, [9]Necmettin Erbakan University Faculty of Medicine, Turkey, [10]Akdeniz University Faculty of Medicine, Turkey, [11]Novatis Pharma, Turkey, [12]Istanbul University Cerrahpasa Faculty of Medicine, Turkey

Purpose : Although many osteoporosis patients are under 65 years old, studies evaluating the response to bisphosphonates (BP) have usually focused on older (>65 years) postmenopausal patients . In this study, the efficacy and safety of single IV infusion of zoledronic acid 5 mg on both bone mineral density (BMD) and serum bone turnover markers were assessed in ''relatively younger'' (50-65 years old) population of postmenopausal osteoporosis (PMO) patients.

Methods: 112 PMO patients 55-65 years of age (mean age 58.4) were enrolled in this open label, prospective, 1 year, multicenter (12 centers) study. 101 patients (90.2%) of them completed the trial The change in BMD in lumbar spine (L1-L4) and femoral neck assessed by DEXA at 12 months were the primary endpoints. The serum bone turnover markers (procollagen 1N-terminal peptide (P1NP) and C-telopeptide (CTX)) were evaluated at 6 and 12 months as secondary endpoints. Safety evaluation was based on adverse event (AE) reporting. The study was approved by institutional and central ethics committees.

Results: Zoledronic acid increased BMD in femoral neck and lumbar spine at 1 year versus baseline by 5.2% and 13.1%, respectively. ($p<0.001$ for both in per protocol population). Serum P1NP and CTX levels decreased significantly versus pretreatment values at 6 and 12 months. The mean P1NP level was 51.3 ± 22 ng/ml at baseline and decreased to 18.5 ± 10.5 ng/ml and 21.9 ± 10.5 ng/ml at 6 and 12 months respectively ($p<0.001$ for both). The mean serum CTX level which was 345.6 ± 161.7pg/ml at baseline decreased to $125,4 \pm 78.8$ pg/ml and 164.6 ± 9.7 pg/ml at 6 and 12 months, respectively ($p<0.001$ for both). 42 patients (37.5%) experienced 88 AEs which were mostly (77.3%) mild and moderate in severity. Myalgia (n=29) and arthralgia (n=10) were the most common adverse events. 7 serious AEs were observed in 2 (1.8%) patients: concurrent coronary artery disease and acute myocardial infarction in one patient and concurrent nausea, vomiting, hypotension, cholelithiasis and cholecystectomy in the other patient. No cases of deterioration of renal function, atrial fibrillation or osteonecrosis of the jaw were observed. Deterioration of renal functions, atrial fibrillation and osteonecrosis of jaw attributed to BFs were not observed. No patient was withdrawn from the study due to AEs.

Conclusion: Single infusion of zoledronic acid 5mg was associated with significant improvements in BMD and serum bone turnover markers in 50-65 years old PMO patients and favorable overall tolerability profile. The efficacy and safety profile of zoledronic acid infusion observed in this study conforms to the results of previous studies conducted in elderly (>65 years) patients.

Efficacy and Safety Results from a Six Month Double-Blind Study Comparing 60 mg Denosumab (DMAb) and Placebo in Korean Postmenopausal Women with Osteoporosis. Jung-Min Koh*[1], Han-Jin Oh[2], Il Hyung Park[3], In-Ju Kim[4], Moo-Il Kang[5], Sung-Kil Lim[6], Yong-Ki Min[7], Yoon-Sok Chung[8], Yil-Seob Lee[9], Barbara Kravitz[10], Brian Waterhouse[10], Antonio Nino[10], Lorraine Fitzpatrick[10]. [1]Asan Medical Center, South Korea, [2]Cheil General Hospital, Kwandong University, South Korea, [3]Kyungpook National University Hospital, South Korea, [4]Pusan National University Hospital, South Korea, [5]Seoul St. Mary's Hospital, South Korea, [6]Yonsei University College of Medicine, South Korea, [7]Samsung Medical Center, South Korea, [8]Ajou University School of Medicine, South Korea, [9]GlaxoSmithKline Pharmaceuticals, South Korea, [10]GlaxosmithKline Pharmaceuticals, USA

Purpose: To determine the efficacy and safety of denosumab compared with placebo in Korean postmenopausal women with osteoporosis.

Methods: This randomized, double-blind, placebo-controlled multicenter study in Korea enrolled 135 postmenopausal women with osteoporosis, aged 60-90 years, with serum 25(OH) vitamin D $\geq$50 nmol/L. Other inclusion criteria included a screening DXA BMD equivalent to a T-Score <-2.5 and $\geq$ -4.0 at either the lumbar spine or total hip. Changes in BMD at the lumbar spine, total hip, femoral neck, and trochanter, serum bone turnover markers, (s-CTx and s-PINP), and safety were evaluated. All subjects received daily supplements of oral calcium (at least 1000 mg) and vitamin D (at least 400 IU). All sites obtained approval from their Ethics Committees and all subjects signed informed consent.

Results: Treatment groups were comparable at baseline and mean age was 66.5 years (SD 4.83). After 6 months of treatment the difference in mean % changes from baseline between DMAb and placebo was statistically significant at the lumbar spine (primary endpoint), total hip, femoral neck and trochanter (Table 1). After 6 months of treatment the difference in median % changes from baseline between DMAb and placebo was statistically significant for s-CTx and s-PINP (Table 2). No new safety signals were detected with 55% DMAb and 48% placebo subjects experiencing adverse events. Six subjects (DMAb) and two (placebo) experienced serious adverse events; none attributed to study drug by investigators.

Conclusions: After 6 months of treatment, DMAb statistically significantly increased BMD at the lumbar spine, total hip, femoral neck and trochanter and significantly decreased serum bone turnover markers, s-CTx and s-PINP compared to placebo. No new or unexpected safety signals were detected.

This study was sponsored by GlaxoSmithKline Pharmaceuticals.

Table 1 BMD Results by Anatomical Site

6 Month Difference between DMAb and Placebo in % change from baseline in BMD	Model Adjusted Mean	95% CI	p-value
Lumbar spine	3.2%	(2.1%, 4.4%)	<0.0001
Total hip	1.7%	(1.0%, 2.4%)	<0.0001
Femoral neck	1.4%	(0.4%, 2.3%)	0.0042
Trochanter	2.0%	(0.8%, 3.2%)	0.0012

Table 2 Serum Bone Turnover Markers

6 Month Difference between DMAb and Placebo in % change from baseline	Median	95% CI	p-value
s-CTx	-52%	(-61%, -43%)	<0.0001
s-PINP	-48%	(-57%, -39%)	<0.0001

Efficacy Results:Comparing Denosumab and Placebo

Factors associated with negative BMD response to Risedronate. Ryoichi Muraoka[1], Ryo Okazaki*[2]. [1]Ajinomoto Phamaceuticals Co, Ltd., Japan, [2]Teikyo University Chiba Medical Center, Japan

Objectives: Risedronate (RIS) has been shown to inhibit osteoporotic fractures and widely used in the world. However, there are some non-responders in terms of BMD increase. We performed post-hoc analyses of two RIS Phase III trials (including the Phase III trial of once-a-month 75 mg tablet) conducted in Japan to explore factors associated with negative BMD response to RIS.

Subjects and methods: 1261 subjects whose serum 25(OH)D were measured prior to RIS administration and lumber spine BMD data were available both at the baseline and at least once after RIS treatment were analyzed (once-a-day 2.5mg: 641 patients, once-a-week 17.5mg: 228 patients, once-a-month 75mg: 392 patients). In those trials vitamin D supplementation was not given. Subjects were classified into non-responders (NR)(n=118) whose BMD change was equal to or less than 0% and responders (R) (n=1143). We conducted logistic regression analyses in which NR was a response variable. Baseline serum(s) 25(OH)D, sBAP, urinary(u) NTX, and uCTX levels were transformed into dichotomous variables with cut-off values at 16 ng/mL (the 1st quartile of the study population), 21.1 U/L, 35.3 nmolBCE/mmol-Cr, 184.1 ug/mmol-Cr (mean+1.0 SD for Japanese premenopausal women), respectively. Comorbid diseases, demographic profiles, drug adherence (actual number of tablets taken/ prescribed number by the protocol * 100), existing vertebral fracture, and baseline BMI, Ca and P were also added as independent variables.

Results: Among those variables, 4 factors were significantly associated with NR: low 25(OH)D [OR (odds ratio) 1.978, P= 0.018], low BAP (OR 1.959, P= 0.0028), presence of hypertension (OR 0.610, P = 0.0409), and poor drug adherence (1% decrease OR 1.026, P= 0.0490). In subjects with low 25(OH)D, 14.0% were NR, whereas 8.1% in higher 25(OH)D group (P= 0.0032). Those results were not different among once-a-day, once-a-week, once-a-month treatment groups.

Conclusions: These results confirm that vitamin D deficiency is an easily correctable condition associated with a poor response to RIS. Serum 25(OH)D level should be adequately increased prior to RIS treatment to ensure positive BMD response to RIS.

The Effect of 6 versus 9 Years of Zoledronic Acid Treatment in Osteoporosis: A Randomized Extension to the HORIZON-Pivotal Fracture Trial (PFT). Dennis Black*[1], Ian Reid[2], Jane Cauley[3], Steven Boonen[4], Felicia Cosman[5], Ping Leung[6], Peter Lakatos[7], Zulema Man[8], Steven Cummings[9], Trisha Hue[1], Guoqin Su[10], Christina Bucci-Rechtweg[11], Monique Tan[10], Paul Aftring[10], Richard Eastell[12]. [1]University of California, San Francisco, USA, [2]University of Auckland, New Zealand, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]Center for Metabolic Bone Disease & Division of Geriatric Medicine, Bel, [5]Helen Hayes Hospital, USA, [6]Chinese University of Hong Kong, China, [7]Semmelweis University Medical School, Hungary, [8]Centro Médico TIEMPO, Argentina, [9]San Francisco Coordinating Center, USA, [10]Novartis pharmaceuticals, USA, [11]Novartis Pharmaceuticals Corporation, USA, [12]University of Sheffield, United Kingdom

Purpose: Zoledronic acid 5 mg (ZOL) used annually for 3 years is effective in increasing bone mineral density (BMD) and decreasing fractures. BMD and fracture results from the extension to 6 years suggested that patients at high risk of fracture may benefit from maintenance of BMD and reduced risk of new vertebral fracture with continued annual ZOL therapy up to 6 years. This subsequent extension will assess efficacy and long term safety of ZOL in post-menopausal women with osteoporosis after 9 consecutive annual doses.

Methods: 190 women who had received ZOL for 6 years in both the core and extension-1 studies were randomized to 3 additional years of ZOL (Z9) or placebo (Z6P3). The primary endpoint for comparison of Z9 with Z6P3 is percentage change in total hip (TH) BMD at Year (Y) 9 vs. Y6. Secondary endpoints include TH and femoral neck (FN) BMD at Y7, Y8, and Y9 vs. Y0, at Y7 and Y8 vs Y6, and FN at Y9 vs Y6; biochemical markers (β-C-terminal telopeptides of type 1 collagen [β-CTx], procollagen type 1 amino-terminal propeptide [P1NP] and bone-specific alkaline phosphatase [BSAP]) at Y7, 8 and 9 vs Y6; exploratory endpoints include incidence of clinical and vertebral fractures after Y6 and safety.

Results: Among the women randomized, the mean age was 78 years with 28% over age 80. 63% were from Europe, 32% from N/S America and 6% from Asia. The last patient was seen in April 2013. As of the time of this submission, the study remains blinded. However, the data will be unblinded and analyses completed by August 2013, so results may be presented during the meeting.

Conclusion: This extension will provide unique data on the effect of 9 annual injections of ZOL on BMD.

The Pharmacokinetics of Odanacatib 50 mg Are Not Affected by Severe Renal Insufficiency. Aubrey Stoch*[1], Chengcheng Liu[2], Stefan Zajic[3], Rose Witter[2], Julie Stone[2], Anish Mehta[2], Patrice Auger[4], Daria Stypinski[4], Nancy Wang[4], Anne Hohnstein[4], William Smith[5], Harry Alcorn[6], Thomas Marbury[7]. [1]Merck Sharp & Dohme, USA, [2]Merck Sharp & Dohme Corp., USA, [3]Merck Research Laboratories, USA, [4]Celerion, USA, [5]Volunteer Research Group/ Graduate School of Medicine, University of Tennessee, USA, [6]DaVita Clinical Research, USA, [7]Orlando Clinical Research Center, USA

Objectives: Odanacatib, a selective cathepsin-K (CatK) inhibitor, is in development for the treatment of osteoporosis. Approximately 10% of the clearance of odanacatib is believed to be due to renal elimination. This study was done to determine the effect of severe renal insufficiency on odanacatib pharmacokinetics, pharmacodynamics, and tolerability.

Methods: In this open-label, single-dose study, odanacatib was orally administered to subjects (age: 40-79 years) with severe renal insufficiency (defined as a creatinine clearance of <30 mL/min) and healthy control subjects (creatinine clearance $\geqslant 90$ mL/min), matched for age, gender, and body mass index (BMI). Plasma and urine samples were collected for the analysis of odanacatib concentrations and biomarkers at predose and at specified time points over 15 days postdose. An analysis of covariance (ANCOVA) model was used to analyze odanacatib $AUC_{0-\infty}$ on log scale. The $AUC_{0-\infty}$ geometric mean ratio (GMR) was determined to evaluate the similarity of pharmacokinetics between the two groups based on the 90% CI for the GMR contained within the comparability bounds of (0.40, 2.50). C_{max} was analyzed in a similar fashion. Summary statistics were computed for T_{max} and apparent terminal $t_{1/2}$. Bone biochemical markers (serum NTx and urine NTx/Creatinine) were also assessed to evaluate pharmacodynamics; a linear mixed effect model was used for the analysis of these parameters. Adverse events (AEs) were monitored throughout the study and evaluated for severity and relation to study medication at study visits.

Results: The GMRs (90% CI) for $AUC_{0-\infty}$ and C_{max} were 1.62 (1.17, 2.24) and 1.47 (1.19, 1.80), respectively. The geometric mean half-life for odanacatib 50 mg was 74.2 hours subjects with renal impairment and 80 hours in the healthy matched controls. At 168 hours postdose, Least Square (LS) Mean (95% CI) serum NTx values were -36.5 (-47.30,-23.38) [renal impairment] and -43.2 (-53.39, -30.76) [healthy]; LS Mean (95% CI) urine NTx/Cr values were -59.3 (-65.81, -51.51) [renal impairment] and -43.4 (-52.83, -32.08) [healthy]. There were no serious AEs or discontinuations due to AEs. Mild headache was the most common drug-related AE and was reported in 1 patient in the renal impairment group and 1 patient in the healthy control group.

Conclusions: There were no meaningful differences between subjects with severe renal impairment compared with healthy-matched controls in odanacatib 50 mg pharmacokinetics, as assessed by comparison of $AUC_{0-\infty}$ values, or its pharmacodynamics, as assessed by change from baseline in serum NTx and urine NTx/Cr. Odanacatib 50 mg was generally well tolerated in patients with severe renal impairment.

SA0392

Baseline characteristics of a prospective observational study in Germany, Austria, Greece and Belgium to evaluate medication-taking behavior of women with postmenopausal osteoporosis (PMO) receiving denosumab (DMab) in clinical practice. Nikolaos Papaioannou*[1], Astrid Fahrleitner-Pammer[2], Maurille Feudjo Tepie[3], Gerd Moeller[4], Eddie Zhang[3], Peyman Hadji[5]. [1]University of Athens, KAT Hospital, Greece, [2]Medical University Graz, Austria, [3]Amgen Ltd, United Kingdom, [4]Amgen (Europe) GmbH, Switzerland, [5]Philipps-University of Marburg, Germany

Purpose: Persistence to osteoporosis therapy is important for optimal outcomes, particularly reduced fracture risk. Therapies with frequent administration schedules are associated with poor adherence and persistence which may negatively affect their fracture risk reduction. A large observational study is being conducted to evaluate

persistence and adherence to 6-monthly subcutaneous DMAb injections. We report baseline data from this study.

Methods: This ongoing, non-interventional study plans to enroll 1500 women with PMO receiving DMab in clinical practice in Germany, Austria, Greece and Belgium. Data recorded as per clinical practice is collected for 2 years after enrolment, with pts expected to return every 6 months as part of their routine care and no additional procedures required. Study outcomes include pt characteristics, and persistence and adherence to DMab at 12 and 24 months. Centers in Belgium started enrolment later than other countries, and did not have baseline data at the time of this analysis. Hence we report data from pts enrolled at 101 centers in Germany, Austria and Greece.

Results: As of February 2013, 1200 pts had enrolled and were included in the analysis; with half (n=600) enrolled at sites in Germany, and one-quarter (300) each at sites in Austria and Greece. Pts had multiple co-morbidities, with PMO diagnosed, on average, 6 years prior to enrolment (Table 1). Approximately half of all pts had prior osteoporotic fracture (Table 1); over 80% had received PMO therapy prior to enrolment with the majority receiving oral bisphosphonates (Table 2). Baseline DXA assessments were not mandatory, and were available (at the physician' discretion) for 83% (n=991) of pts. Mean (SD) baseline BMD T-scores at total hip (n=674) and lumbar spine (n=948) were -2.0 (0.84) and -2.7 (0.98), respectively.

Conclusions:

These baseline data provide valuable information regarding pts being prescribed DMab in routine clinical practice in Germany, Austria and Greece. The pts enrolled in the current study have baseline characteristics typical of the general PMO population, i.e. multiple co-morbidities, history of osteoporotic fracture. Moreover, the majority of pts had received PMO therapies prior to initiating Dmab yet baseline BMD remained low. Future data from this study will provide additional insights regarding persistence with DMab in women with PMO.

Healthcare Consequences Associated With Non-Compliance in a Managed Care Population. Ankita Modi*[1], Jackson Tang[2], Ethel Siris[3], Shuvayu Sen[1]. [1]Merck & Co., Inc., USA, [2]AsclepiusJT LLC, USA, [3]Columbia University College of Physicians & Surgeons, USA

OBJECTIVE: To examine consequences associated with non-compliance to osteoporosis (OP) medication in terms of fracture rates and healthcare resource utilization

METHODS: A retrospective analysis using i3 Invision Datamart (Ingenix, Eden Prairie, MN) from January 1, 2001 to December 31, 2010 (study period) was conducted. Women ⩾55 years of age who initiated an OP medication (alendronate, ibandronate, risedronate, zoledronate, raloxifene, calcitonin, teriparatide) during the study period and had enrolled in the database for 3 consecutive years: 1 year before the index prescription (baseline), a compliance year (year 1), and a follow-up year (year 2) were included in the study. Subjects were excluded if they had Paget's disease or diagnosis of malignant neoplasm. Non-compliance to OP medication was defined as medication possession ratio (MPR) <0.8 during year 1 (MPR = total number of days' supply/365 days). Occurrence of OP-related hip, vertebral, and non-vertebral fracture and healthcare resource use were assessed during year 2. Logistic regression was conducted to assess the association of non-compliance on occurrence of fractures and healthcare resources and Poisson regression was conducted to assess the association with number of healthcare events.

RESULTS: Among 57,913 women who met eligibility criteria, 34,483 (59.5%) were non-compliant to OP therapy during year 1 (mean [SD] age, 64.2 [8.9] years). Compared to compliant patients (N=23,430 (40.5%)), a significantly higher proportion of non-compliant patients developed vertebral (0.79% vs. 0.48%), hip (0.42% vs. 0.25%) and non-vertebral (1.93% vs.1.52%) fractures during year 2 (all p<0.01). Logistic regression showed that non-compliance was associated with a higher likelihood of fractures (Odds ratio (OR): 1.19, 95%CI: [1.06,1.30]) and hospitalization occurrence (OR: 1.16, 95%CI: [1.10,1.23]). Poisson regression showed that non-compliance was associated with more hospitalization stays (incidence rate ratio: 1.27, 95%CI: [1.19,1.33]).

CONCLUSION: Rate of non-compliance was found to be high in a managed care population with osteoporosis. Non-compliance was associated with a higher rate of osteoporotic fractures and healthcare utilization. The results emphasize the importance of good treatment compliance in order to achieve optimal treatment benefit and thereby reduce the burden that osteoporosis and its associated fractures place on individuals and healthcare systems.

Non-pharmacological Strategies used by Patients at High Risk for Future Fracture to Manage Fracture Risk - A Qualitative Study. Joanna Sale*[1], Monique Gignac[2], Gillian Hawker[3], Dorcas Beaton[4], Earl Bogoch[1], Fiona Webster[3], Lucy Frankel[1], Victoria Elliot-Gibson[1]. [1]St. Michael's Hospital, Canada, [2]University Health Network, Canada, [3]University of Toronto, Canada, [4]Keenan Research Centre, St Michael's Hospital, Canada

Purpose: We examined patients' understanding of bone health and self-management decisions regarding bone health and fracture risk, particularly behaviours other than medication use and seeking diagnostic testing.

Methods: A phenomenological (qualitative) study was conducted. English speaking patients 65+ years old, who were ''high risk'' for future fracture and prescribed pharmacotherapy after being screened through a post-fracture osteoporosis initiative were eligible. Patients were interviewed for 1-2 hours and were asked to discuss perceptions of bone health status (bone densitometry results, perceived fracture risk), recommendations received for bone health, and lifestyle changes since their most recent fracture. We analyzed the data guided by Giorgi's methodology.

Results: We interviewed 21 fracture patients (6 males, 15 females), aged 65 to 88 years old. With the exception of one participant, all participants appeared to understand that they had low bone mass and were at risk of sustaining another fracture. Most participants (n=20) were predominantly concerned about being careful and they focused their responses on personal and environmental factors that they perceived to be modifiable. Participants also spoke about strategies to manage their bone health such as exercise, having a healthy diet and taking supplements, and using aids and devices. Non-pharmacological strategies used by patients appeared to be independent of current use of pharmacotherapy.

Conclusions: Awareness of fracture risk was accompanied by a number of positive lifestyle changes in participants' lives such as being careful and engaging in exercise. Future research needs to evaluate how lifestyle changes such as being careful mitigate fracture risk.

Patterns and Predictors of Osteoporosis Medication Switching in Low-Income Elderly Patients. Daniel Solomon*[1], David Chandler[2], Erika Brown[3], Helen Mogun[3], Jessica Myers Franklin[3]. [1]Harvard Medical School, USA, [2]Amgen, USA, [3]Brigham & Women's Hospital, USA

Background: Patterns and predictors of osteoporosis (OP) medication switching have not been well described.

Methods: An analysis of health and pharmacy insurance claims for a large cohort of low-income Medicare beneficiaries qualifying for state drug benefits (Pennsylvania PACE and New Jersey PAAD programs) for the years 1998-2008 was undertaken. Inclusion criteria for subjects were documented Medicare claims for 180 days (baseline) and no receipt of OP medications during the baseline (i.e., bisphosphonate, raloxifene, calcitonin, teriparatide, or hormononal therapy). All subjects were required to start an OP medication, and this was considered the start of follow-up. Baseline patient and prescriber characteristics were assessed in multivariable Cox regression models to identify correlates of adding or switching an OP medication. Clinical events after baseline (fractures, bone mineral density (BMD) testing, and visits with endocrinologists or rheumatologists) were also examined as correlates.

Results: Of 125,954 new users of OP medications, the mean age was 78 years, with 97% being female, and 92% of subjects were white. OP medication prescribers included endocrinologists/rheumatologists (6.2%), orthopedic surgeons (1.0%), PCPs (internists/FPs/GPs/OB-GYN) (64.9%), others (3.7%), and missing (24.1%). Of these subjects, 23% added or switched OP medications during follow-up, with the first addition or switch occurring a mean of 739 days after baseline; 4% added or switched more than once. In adjusted models, baseline variables that correlated with switching or adding and OP medication included: older age; female gender; the use of calcitonin, raloxifene, or teriparatide (compared with bisphosphonate); prescription from an endocrinologist/ rheumatologist or an orthopedic surgeon (versus PCPs); prior fracture; the use of steroids; prior malignancy; more prescription drugs or MD visits; and a prior osteoporosis diagnosis. Black race, prior BMD, increased comorbid conditions, and more acute care hospitalizations correlated with a reduced likelihood of switching or adding. However, the strongest predictors of switching or adding were post-baseline events: fractures, BMD testing and specialist visits.

Conclusion: Adding or switching OP medications is not uncommon and correlated with specific patient or prescriber characteristics. The frequency of adding and switching OP medications suggests the value of long-term sequential treatment strategy trials.

Active Vitamin D3 Analog (eldecalcitol) Improves Muscle Strength and Dynamic Balance in Postmenopausal Osteoporotic Women. Kimio Saito*[1], Naohisa Miyakoshi[2], Michio Hongo[2], Yuji Kasukawa[2], Yoichi Shimada[3]. [1]Akita University, Japan, [2]Akita University Graduate School of Medicine, Japan, [3]Department of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan

INTRODUCTION: Eldecalcitol, an active vitamin D3 analog, increases bone mass in osteoporotic patients. Additionally, it may reduce the incidence of falls, as has been reported with vitamin D. It is speculated that improvement of muscle strength or balance ability by eldecalcitol is one of the mechanisms by which it reduces the incidence of falls. However, details about the effects of eldecalcitol on trunk muscle strength and balance control remain unclear. The purpose of this study was to quantitatively evaluate whether eldecalcitol improves trunk muscle strength and balance control in postmenopausal osteoporotic women.

METHODS: Thirty-one postmenopausal women (mean age, 74 years) diagnosed with osteoporosis were enrolled in this prospective study and randomly divided into the following two groups: 1) the eldecalcitol group (n=17), which was prescribed eldecalcitol (0.75 μg/day) and alendronate (35 mg/week); and 2) the alendronate group (n=14), which was prescribed alendronate alone, serving as a control for eldecalcitol. Trunk muscle strength, including back extensor strength and iliopsoas strength, was measured. Static standing balance with a stabilometer was performed for static balance evaluation. Dynamic sitting balance with a dynamic stabilometer and the Timed Up and Go Test were performed for dynamic balance evaluation. These evaluations were recorded at the beginning of treatment and six months after the treatment.

RESULTS: No significant difference was observed in static standing balance before and after the treatment in both groups.Eldecalcitol significantly increased back extensor strength ($p=0.0011$) and iliopsoas strength ($p=0.0343$), and improved both dynamic sitting balance ($p=0.0496$) and the results of the Timed Up and Go Test ($p=0.0016$) after six months of treatment compared with their values at the start of treatment. However, alendronate alone treatment did not result in significant changes in these parameters.

CONCLUSIONS: The results of the present study demonstrate that eldecalcitol increases trunk muscles strength, including back extensor strength and iliopsoas strength, and improves dynamic balance within six months of treatment. Improvement in trunk muscle strength and dynamic balance by eldecalcitol may reduce the risk of falls in osteoporotic women.

Fracture?, Think Osteoporosis: Rehabilitation of Patients Post Hip Fracture. George Ioannidis*[1], Naomi Dore[1], Pauline Fisher[2], Courtney Kennedy[1], Lisa Dolovich[1], Jonathan Adachi[3], Leo Farrauto[1], Alexandra Papaioannou[2]. [1]McMaster University, Canada, [2]Hamilton Health Sciences, Canada, [3]St. Joseph's Hospital, Canada

Background: Hip fracture patients are at high risk for recurrence. Appropriate pharmacotherapy reduces this risk and is associated with reduced mortality after hip fracture, but a care gap exists for fracture prevention in these patients. This evaluation determined rates of osteoporosis treatment and bone mineral density (BMD) testing in hip fracture patients following discharge from a rehabilitation unit. Methods: A prospective cohort study of hip fracture patients aged > 50 on an inpatient rehabilitation unit in 2008 and 2011. Patients were seen by a nurse specialist, and encouraged to see their family physician for further assessment and treatment. Physicians were sent a letter indicating the need to follow up with their patient. Patients were contacted following discharge from hospital to determine treatment rates.Results: Of 310 eligible hip fracture patients admitted to the rehabilitation unit in the years studied, 207 patients were reached post-discharge and provided data. For the entire cohort of n=207, the mean age was 81.4 (SD 9.14) years, and 57/207 (27.5%) were male. Of patients who were not previously taking osteoporosis medication, 50% of patients had osteoporosis treatment initiated by six months following discharge. By 2 months following discharge, 46% of patients in the 2008 cohort had a new BMD performed or scheduled, while this was true for 14% of patients from the 2011 cohort. In 2011, approximately 75% of patients had seen their family physician by 6 months following discharge. Discussion: Rates for osteoporosis treatment and BMD were higher than those reported in the literature for patients not enrolled in case manager programs. BMD testing declined from 2008 to 2011. Lower treatment rates may be due to concerns regarding bisphosphonates. There remains room for improvement for follow up with family physicians.

VitaminD Supplementation Protocol in Osteoporosis: Chart Review. Vithika Sivabalasundaram*[1], Sandra Kim[2], Ina Radziunas[3], Sophie Jamal[1]. [1]The University of Toronto, Canada, [2]Women's College Hospital, University of Toronto, Canada, [3]Women's College Hospital, Canada

Introduction: There is strong evidence that vitamin D supplementation prevents against fractures, and many treatment options for osteoporosis require adequate vitamin D stores for improved efficacy. Current guidelines recommend supplementation to a target 25-OH vitamin D level of 75 nmol/L (30 ng/ml) or greater. The ideal dosing strategy to achieve this target however remains undetermined. In addition, given the high cost of vitamin D serum testing, a cost effective method of restoring and monitoring vitamin D levels is required. The purpose of this study is to evaluate the efficacy of a newly developed dosing protocol to guide vitamin D supplementation and testing.

Methods: This chart review gathered clinical information from 376 subjects seen in the Osteoporosis Program at Women's College Hospital who were found to be 25-OH vitamin D deficient (<50 nmol/L) or insufficient (50-74 nmol/L) and underwent treatment with the Vitamin D Protocol. This protocol outlined a specific algorithm for physicians to replace vitamin D. Patients were instructed to repeat blood work in 6 months. Patients with the following medical co-morbidities were excluded: renal failure, hypercalcemia, hypercalciuria, renal calculi and teriparatide therapy.

Results: 376 charts were reviewed and of the 325 eligible subjects, 169 (52%) completed post-protocol blood work. The mean increase in 25-OH vitamin D after treatment was 23.0 +/- 31.1 nmol/L. 56% of subjects achieved the target 25-OH Vitamin D level of 75 nmol/L or greater following the protocol. Patients with a post-protocol 25-OH vitamin D level <75 nmol/L were more likely to have a malabsoprtion syndrome (18.9% vs 7.4%, $p=0.02$) and took longer to complete their post protocol blood work (9.3 vs 7.9 months, $p=0.002$). Other demographic and clinical factors such as gender, age, BMI, baseline BMD and history of fragility fracture were similar in both groups.

Conclusion: This is the first protocol for vitamin D supplementation to be studied and demonstrates a significant improvement in vitamin D levels by nearly 50%. Compliance in our study was low with 52% of patients completing blood work. Among patients who completed their blood work within 6 to 6.9 months, 77% achieved target 25-OH vitamin D level of > 75 nmol/L, while only 45% of those who did blood work after 9 months reached target. Overall, this protocol was found to be safe and effective in those who demonstrated adequate compliance through timely blood work.

SA0399

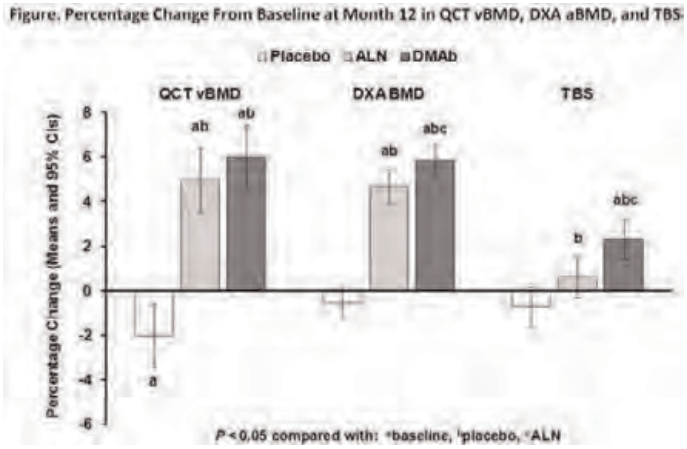
Changes in Lumbar Spine QCT, DXA, and TBS in Postmenopausal Women With Low Bone Mass Treated With Denosumab, Alendronate, or Placebo. Thierry Thomas*[1], Angela M Cheung[2], Elizabeth Shane[3], Jose R Zanchetta[4], Ann Kearns[5], Didier Hans[6], Celia JF Lin[7], Matthew Austin[7], Cesar Libanati[7]. [1]INSERM U1059, University Hospital of St Etienne, France, [2]University of Toronto, Canada, [3]Columbia University, USA, [4]Instituto de Investigaciones Metabólicas, Argentina, [5]Mayo Clinic, USA, [6]Lausanne University Hospital, Center of Bone Diseases, Switzerland, [7]Amgen Inc., USA

Patients who suffer from osteoporosis require treatment with therapies aimed at reducing the risk of fracture. Fracture risk at the spine is significantly influenced by trabecular bone. Quantitative computed tomography (QCT) and dual x-ray absorptiometry (DXA) allow for bone mineral density (BMD) measurement at the spine, and BMD is a robust indicator of fracture risk. Trabecular bone score (TBS), a novel gray-level measurement derived from spine DXA image texture, is related to microarchitecture and fracture risk independently of BMD. Denosumab (DMAb) is associated with greater gains in BMD compared with oral bisphosphonates. In a recent Japanese study, this larger improvement in BMD was associated with a larger reduction in vertebral fracture with DMAb compared with alendronate (ALN; Nakamura, ASBMR 2012). To further characterize the trabecular response with

DMAb and ALN, we compared QCT vBMD, DXA aBMD, and TBS from spine scans obtained in postmenopausal women with low BMD.

Postmenopausal women aged 50 to 70 years with low BMD at the spine or total hip were randomized in a double-blind, double-dummy fashion to DMAb (60 mg SC every 6 months), branded ALN (70 mg orally every week), or placebo (pbo) for 12 months (Seeman, *JBMR* 2010). Lumbar spine QCT vBMD, DXA aBMD, and TBS were measured from scans obtained at baseline and month 12.

There were 215 women (73 DMAb, 68 ALN, 74 pbo) who had TBS values at baseline and month 12. Mean age was 60 and at the lumbar spine, mean QCT vBMD was 90.4 mg/cm^3, mean DXA aBMD T-score was –2.4, and mean TBS was 1.234. Overall, QCT vBMD, DXA aBMD, and TBS decreased with pbo; increased or were maintained with ALN; and improved, compared with both pbo and ALN, with DMAb (Figure). At baseline, TBS was better correlated with QCT vBMD (r = 0.42, $P < 0.001$) than with DXA aBMD T-score (r = 0.13, $P = 0.051$). TBS percentage changes did not positively correlate with those in QCT vBMD or DXA aBMD in any of the treatment groups (Table). In postmenopausal women with low BMD, DMAb increased QCT vBMD, DXA aBMD, and TBS compared with ALN and pbo over 12 months. QCT trabecular vBMD correlated moderately with TBS but changes with therapy did not, suggesting that TBS changes are not biased by BMD changes. These data support the concept that TBS acquires information not captured by standard bone density and warrant further investigation of the clinical significance of the changes in TBS in response to therapies.



Figure

Table. Correlation Between Percentage Change From Baseline to Month 12 in DXA aBMD and TBS and QCT vBMD and TBS by Treatment

	Placebo	ALN	DMAb
DXA aBMD and TBS	n = 74 r = –0.31 *P* = 0.007	n = 68 r = 0.20 *P* = 0.110	n = 73 r = 0.08 *P* = 0.497
QCT vBMD and TBS	n = 68 r = 0.06 *P* = 0.646	n = 63 r = 0.10 *P* = 0.439	n = 69 r = 0.14 *P* = 0.241

Cortical Bone Parameters at the Hip in Response to Denosumab vs Placebo and the Clinical Relevance of These Changes in Postmenopausal Women With Osteoporosis <75 and ⩾75 Years Old. Harry K. Genant*[1], Tony M. Keaveny[2], Carol Zapalowski[3], Klaus Engelke[4], Thomas Fuerst[4], David L. Kendler[5], Christopher Recknor[6], Steven Boonen[7], Andrea Wang[3], Paula Dakin[3], Cesar Libanati[3], Michael R. McClung[8]. [1]UCSF & Synarc Inc., USA, [2]UC Berkeley & O.N. Diagnostics, USA, [3]Amgen Inc., USA, [4]Synarc Inc., USA, [5]University of British Columbia, Canada, [6]United Osteoporosis Centers, USA, [7]Leuven University, Belgium, [8]Oregon Osteoporosis Center, USA

Purpose: Cortical bone deterioration is now recognized as an important contributor to the exponential increase in fracture risk seen in women around the 8th decade of life. Treatment efficacy data in this group of women at higher risk for fracture are lacking with existing therapies. In FREEDOM, denosumab (DMAb) treatment resulted in improvements in both the cortical and trabecular bone compartments, with significant gains in hip volumetric BMD (vBMD), hip cortical thickness and mass, as well as hip strength. In addition, DMAb significantly reduced the risk of hip fracture in postmenopausal women with osteoporosis at higher risk for fracture. To further explore these associations, we evaluated the effects of DMAb on cortical bone parameters in women <75 and ⩾75 years of age.

Methods: In FREEDOM, women received DMAb 60mg or placebo Q6M for 36 months and daily calcium and vitamin D. Hip QCT scans were obtained at baseline and at months 12, 24, and 36, in a subset of women (51 DMAb; 48 placebo). These scans were analyzed in a blinded-to-treatment manner at 36 months to measure hip vBMD using MIAF; hip cortical thickness and mass using bone mapping; and hip strength using FEA. The analyses included subjects with observed data at baseline and month 36.

Results: In women <75 (n=57) and ⩾75 (n=42), DMAb resulted in similar and significant increases in hip vBMD and cortical thickness and mass compared with baseline and placebo at 36 months ($p<0.02$; Fig. 1). These improvements were associated with significant increases in hip integral and cortical strength compared with baseline in both age groups ($p<0.02$; Fig. 2). In general, for placebo-treated subjects, a significant decay in measured parameters of cortical bone at the hip was observed in women ⩾75 but not in those <75.

Conclusion: With DMAb treatment, increases in hip vBMD, cortical thickness and mass, and resulting strength, were observed regardless of age (<75 and ⩾75). Consistent with available literature, decreases in measured cortical parameters were observed in women ⩾75 in the placebo group. The observed significant improvements in cortical bone parameters in women ⩾75 with DMAb compared with placebo, and perhaps more importantly compared with baseline, may be particularly relevant as they are occurring at a time when cortical bone is deteriorating and fracture risk is exponentially increasing. DMAb may be addressing the mechanism of decay responsible for this increased nonvertebral fracture risk.

Treatment Criteria of Osteoporotic Vertebral Compression Fractures(VCFS). Mashood Siddiqi*[1], Giovanni Anselmetti[2], Jason Bernard[3], Christian Kasperk[4], Thomas Blattert[5], Charles Court[6], Daniel Fagan[7], Hendrik Fransen[8], Patrick Fransen[9], Tarun Sabharwal[10], Frederic Schils[9], Rupert Schupfner[5]. [1]University Hospital AintreeLiverpool, United Kingdom, [2]Interventional Radiologist, Italy, [3]Orthopaedic Surgeon, United Kingdom, [4]University of Heidelberg, Germany, [5]Trauma Surgeon, Germany, [6]Orthopaedic surgeon, France, [7]Spinal Surgeon, United Kingdom, [8]Interventional Radiologist, Belgium, [9]Neurosurgeon, Belgium, [10]Interventional Radiologist, United Kingdom

Objective To establish / refine criteria for the appropriate treatment of VCF at the patient-specific level and to translate these criteria into clinically useful recommendations.

Material and Methods Using the RAND/UCLA Appropriateness Method (RAM)[1], a European multidisciplinary panel of 12 experts (Interventional radiologists, Orthopaedic, Spinal, Trauma and Neuro Surgeons and Internists) assessed the appropriateness of non-surgical management (NSM), vertebroplasty (VP), and balloon kyphoplasty (BKP) for 128 hypothetical patient profiles. These were combinations of clinical factors considered relevant to treatment choice (time since fracture, MRI findings, impact and evolution of symptoms, spinal deformity, ongoing fracture process, and pulmonary dysfunction). After two individual rating rounds and meetings, appropriateness statements were calculated for all clinical scenarios.

Results Appropriateness outcomes showed specific patterns for the three treatments. For three-quarters of the profiles, only one treatment was considered appropriate: NSM 25%, VP 6%, and BKP 45%.A detailed decision-tree analysis showed pronounced patterns of appropriateness in relation to combination of clinical conditions. Based on these figures, the panel formulated a set of summary recommendations.(Table 1)

Conclusions ThisRAND-UCLA study provides recommendations for treatment of osteoporotic VCFs at the level of individual patients which are more specific than currently available guidelines.

	Usually appropriate	Usually inappropriate
NSM	• Negative MRI • Positive MRI and no other unfavourable conditions	• Proof of ongoing fracture process • ≥2 other unfavourable factors
VP	• Positive MRI, time since fracture ≥ 6 weeks and no spinal deformity	• Negative MRI and presence of spinal deformity
BKP	• Ongoing fracture process • Positive MRI and ≥1 other unfavourable factors	• Negative MRI and time since fracture ≥ 3 months • Negative MRI, time since fracture 6 weeks – 3 months and moderate impact of symptoms

Variations in Patients Receiving DXA Across Three Health Care Systems. Mollie Giller[1], Nicole Wright[2], Fredric Wolinsky[1], Thuy Nguyen[1], Douglas Roblin[3], Kenneth Saag[2], Peter Cram*[4]. [1]University of Iowa Hosptials & Clinics, USA, [2]University of Alabama at Birmingham, USA, [3]Kaiser Permanante of Georgia, USA, [4]University of Iowa, USA

Purpose: Currently, in the United States (US) DXA screening is recommended for men and women meeting certain specified criteria. Clinical practice guidelines exist for DXA and are designed, in part, with the purpose of reducing variations in care. However, little is known about variations in geographic or center-specific differences in patients receiving DXA. We used a detailed clinical registry from a large multicenter trial to examine variation in patients receiving DXA across three diverse healthcare systems.

Methods: We identified 3,454 patients enrolled in the Patient Activation After DXA Receipt Notification (PAADRN) Study (Clinical Trials # NCT01507662) who received DXAs at three sites between February 1, 2012 and February 28, 2013: 1) The University of Iowa (UI) (N=765); 2) University of Alabama Birmingham (UAB)(N=1369); and Kaiser Permanente Georgia (KP)(N=1320). We compared demographics (age, sex), prior receipt of DXA, and osteoporosis specific knowledge of patients across the three sites.

Results: Mean ages of patients receiving DXA at the three sites were 63.8 at UI, 67.3 at UAB, and 68.4 and KP (P<.001). The percentage of DXA recipients who were men was 29.2% at KP, 16.2% at UI, and 6.6% at UAB (P<.0001). The proportion of patients who had not received a prior DXA varied from 50.6% at KP to 27.7% at UI and 17.5% at UAB (P<.0001). The mean score on osteoporosis knowledge scale (the 'Osteoporosis and You' instrument) was 8.0 at UI, 7.4 at UAB, and 7.5 at KP (P=<.0001).

Conclusion: There were significant differences in the characteristics of patients receiving DXA across three large healthcare systems as well as the osteoporosis knowledge of these patients. These results highlight variability in clinical practice surrounding osteoporosis even in an era of practice guidelines.

SA0405

Bone Anabolic Effect of Sclerostin Antibody is Maintained with Antiresorptive Agents in Osteopenic, Ovariectomized Rats. Yanfei Ma*[1], Qianqiang Zeng[1], Rick Cain[1], Mary D Adrian[1], Guilherme V Rocha[1], Anita Harvey[1], Matthew J Hamang[1], Jonathan D Lucchesi[1], Henry Bryant[1], Venkatesh Krishnan[1], Victor Obungu[1], Stuart Kuhstoss[1], Masahiko Sato[2]. [1]Eli Lilly & Company, USA, [2]Lilly Research Labs, USA

Sclerostin is a protein known to be a negative regulator of bone formation. Sclerostin inhibition with selective monoclonal antibodies has been shown to stimulate bone formation and robustly enhance bone mass and strength in ovariectomized (OVX) rats. We examined maintenance of the bone gains stimulated by sclerostin antibody (ab) treatment followed by treatment with antiresorptive agents raloxifene (Ral), alendronate (ALN) or a reduced frequency of sclerostin-ab treatment. Eight month old rats were ovariectomized and allowed to lose bone for 2 months. Animals were treated with a chimeric sclerostin ab, 10mg/kg/week sc for 6 weeks, followed by different maintenance treatments for an additional 8 weeks. Treatment groups (n=8-10/group) included : a) vehicle, b) raloxifene (Ral) 3mg/kg/d sc, c) alendronate (ALN) 28μg/kg/twice per week sc, d) sclerostin ab one injection at week 10. Sclerostin ab weekly treatment for 6 weeks completely restored OVX induced bone mineral content and bone mineral density (BMD) loss in lumbar vertebrae (LV) and BMD in femoral neck (FN) to sham levels. The increased bone mass was accompanied by significantly improved bone strength compared to OVX control in LV, mid-femur (MF) and FN. Switching to vehicle or a single sclerostin ab injection resulted in gradually declining BMD in LV, distal femur (DF), FN and MF, with the BMD loss reaching statistical significance in LV. Bone strength of LV, MF and FN also tended to decline when animals were switched to vehicle or sclerostin ab single injection groups. BMD and bone strength gains were largely maintained or slightly increased with Ral or ALN at all sites. By the end of the 8-week maintenance period, BMD and bone strength in all groups previously treated with weekly sclerostin ab were still significantly higher than those in the OVX controls, with the exception of the sclerostin ab single injection group, where the bone strength of the FN declined to a level not significantly different from OVX control. Histomorphometric analyses are ongoing. Our data confirm the robust bone anabolic effects with a sclerostin monoclonal antibody, but BMD and strength declined when treatment was discontinued. Our data also suggest antiresorptive agents such as alendronate or raloxifene treatment can maintain the bone mass and strength stimulated by sclerostin ab treatment in osteopenic, OVX rats.

SA0406

Bone Formation Response in Mice During Administration and Following Rechallenge With an Antibody to Sclerostin. Martyn Robinson*[1], Kevin Greenslade[2], Jose Joby[2], Zofia Stencel[2], Hishani Kirby[2], Gill Holdsworth[2], Adrian Moore[2]. [1]UCB-Celltech, United Kingdom, [2]UCB Pharma, United Kingdom

Dosing with antibodies to sclerostin (Scl-Ab) has been shown to lead to a rapid increase in bone formation in animal models and in human clinical trials. However, the initial rapid rate of bone formation often attenuates during longer administration of the antibody (1, 2).In the current study, 8-10 week old BALB/c mice dosed with Scl-AbI exhibit a marked increase in circulating levels of the bone formation marker P1NP that peaks 4 days after dosing and returns to baseline after 7 days. After five doses of Scl-AbI (weekly, 10mg/kg sc) the peak serum PINP level (64ng/ml) was significantly lower than in age-matched animals dosed with Scl-AbI for the first time (101ng/ml). An increase in P1NP was observed after each administration of Scl-Ab, but the fifth dose only resulted in a 24% increase in P1NP levels (% increase from predose to peak levels measure 4 days later) whilst age-matched animals dosed for the first time showed a 130% increase. The difference in P1NP response between the two groups was not due to differences in antibody exposure or to changes in the kinetics of the P1NP response. Mice that had received five doses of Scl-AbI (showing an attenuated P1NP response) were allowed an 8 week interval with no further doses of

Scl-AbI. After 8 weeks these animals were again dosed with Scl-AbI and produced a P1NP response that was similar to that seen in age-matched animals dosed with Scl-AbI for the first time (increases in P1NP of 111% versus 109% after first Scl-AbI exposure). This suggests that re-challenge with Scl-AbI can be timed to overcome the attenuated response to Scl-AbI seen after multiple doses. A further 6 doses with Scl-AbI (weekly) again resulted in an attenuated response to Scl-AbI, which was again reversed after a second 8 week period without dosing. Each dosing interval was associated with significant increases in whole body areal BMD and each dosing interruption resulted in a decline in areal BMD

In conclusion, we have demonstrated that i) bone formation, as assessed by a serum biomarker, rapidly and significantly increased after Scl-AbI administration, ii) that while this increase in bone formation was observed with continued dosing, its magnitude was markedly attenuated compared to the first exposure; and iii) that a first-dose level increase in bone formation can be achieved after a period of Scl-AbI discontinuation.

Combined Effects of Treadmill Exercise and Sclerostin Antibody in Ovariectomized Rats. Hechmi Toumi[1], Delphine Benaitreau*[1], Michael Ominsky[2], Claude Laurent Benhamou[3], Eric Lespessailles[4], Stephane Pallu[5]. [1]EA4708 I3MTO University of Orleans, France, [2]Amgen Inc., USA, [3]CHR ORLEANS, France, [4]Centre Hospitalier Regional, France, [5]EA 4708 - I3MTO Orléans, France

Bone formation and bone mineral density (BMD) have been shown to be enhanced by physical activity (Maurel *et al.*, J Bone Spine. 2013) as well as by administration of sclerostin antibody (Scl-Ab; Li *et al.*, J Bone Miner Res, 2010). Purpose: The current study investigated whether a combination of both could provide a further improvement by comparing the effect of a modest dose of sclerostin antibody, physical exercise, and the combination of both on bone formation and strength in a rat osteopenia model. Method: Sixty Wistar female 9 month old rats (mass 341 $\pm$ 24 g) were divided into five groups that received subcutaneous injections twice weekly: (1) Sham: saline + no exercise, (2) OVX: ovariectomized + saline + no exercise, (3) OVX+E: OVX + saline + exercise, (4) OVX+S: OVX + Scl-Ab (Scl-AbVI, 5 mg/kg) + no exercise, and (5) OVX+S+E: OVX + Scl-Ab + exercise. The exercise protocol consisted of 1 hour intermittent running, 5 days a week for a 14 week period. BMD was measured by DXA before training and after. Morphological properties of the trabecular bone from femurs were analyzed by micro-CT and mechanical properties were generated by 3 point bending at the femur midshaft. Serum osteocalcin (OCN) and N-telopeptide of type I collagen (NTX) were evaluated at termination. Results: Exercise attenuated the increase in fat mass after OVX, without an effect on lean mass. Scl-Ab treatment had no effect on lean or fat mass, independent of exercise status. Bone mass was greater in the Scl-Ab groups, with significant increases in whole body BMD, distal femur trabecular BV/TV, and femur cortical volume compared to OVX controls. Cortical bone volume was significantly higher in the Scl-Ab groups compared to the other groups. Exercise alone or in combination with Scl-Ab had no effect on these parameters. Exercise resulted in an increase in cortical porosity compared to OVX controls, an effect that was abrogated by Scl-Ab treatment. Ultimate load, Young's modulus and stiffness were significantly lower in OVX and OVX+E, and were significantly increased by Scl-Ab treatment compared to Sham. Exercise significantly decreased NTX but did not affect OCN, while Scl-Ab increased OCN with a non-significant decline in NTX. Conclusions: Low dose Scl-Ab was effective at increasing bone formation, bone mass, and strength in OVX rats. The current intermittent treadmill training produced no notable effect in OVX rats alone nor when combined with sclerostin antibody, other than a decrease in serum NTX.

Therapeutic Potential of Sclerostin Antibody in Extreme Disuse-induced Bone Loss after Spinal Cord Injury: a Preclinical Study. Weiping Qin*[1], Xiaodong Li[2], Jay Cao[3], Lauren Collier[4], Yuanzhen Peng[5], Jiliang Li[6], Hua Zhu (David) Ke[2], William A. Bauman[4], Christopher Cardozo[4]. [1]Bronx Veterans Affairs Medical Center, USA, [2]Amgen, Inc., USA, [3]USDA ARS, USA, [4]James J. Peters Veteran Affairs Medical Center, USA, [5]The Mount Sinai School of Medicine, USA, [6]Indiana University Purdue University Indianapolis, USA

The rapid and extensive sublesional bone loss after spinal cord injury (SCI) is a difficult medical problem that has been refractory to available interventions tested to date (1-3). Inhibition of sclerostin by sclerostin monoclonal antibody (Scl-Ab) has been shown to increase bone formation and improve bone mass and strength in animal models of bone loss due to estrogen deficiency and immobilization (4). Scl-Ab also increased bone mineral density (BMD) in healthy men and postmenopausal women (4). In addition, sclerostin has been proposed as a potential mediator of mechanotransduction (5). Therefore, we hypothesized that sclerostin could be responsible for the bone loss due to SCI and, if so, that sclerostin inhibition with Scl-Ab could provide a hopeful solution for this challenging medical problem. To test our hypotheses, we first performed complete spinal cord transection in sclerostin knockout (SOST $^{-/-}$) mice and wild type (WT) controls. Eight weeks after SCI, significant bone loss was observed at the distal femur and proximal tibia in WT mice. However, no bone loss was observed in SOST $^{-/-}$ mice. These findings suggest that sclerostin mediates sublesional bone loss after SCI. To explore the therapeutic potential of sclerostin inhibition in SCI, male Wistar rats underwent complete spinal cord transection; 7 days after SCI, the rats were treated with Scl-Ab at 25 mg/kg/week or vehicle for 7 weeks. SCI resulted in significant decreases in BMD (-25%) and trabecular bone volume (-66%) at the distal femur. Scl-Ab completely prevented the loss of BMD and trabecular bone volume. Additionally, in SCI rats administered Scl-Ab, Tb.Th was increased to levels above values for non-SCI controls, and Tb.N tended to be higher than SCI controls. Preliminary histomorphometric analysis demonstrated that Scl-Ab increased trabecular bone formation. In cultures of bone marrow cells, SCI increased the number of $TRAP^{+}$ multinucleated cells as well as mRNA levels of osteoclast differentiation markers, and reduced the number of osteoblasts and mRNA levels of the osteoblast differentiation markers. None of these deleterious changes were observed in the Scl-Ab-treated group. In summary, our findings indicate that Scl-Ab fully prevented sublesional loss of BMD and metaphysis trabecular bone volume by increasing bone formation and decreasing bone resorption, strongly suggesting that Scl-Ab may represent a promising novel approach to mitigate the striking bone loss after SCI.

ALX-0141, An Anti-RANK-L Targeting Nanobody®, Increases Bone Mass in Cynomolgus Monkeys. Rana Samadfam*[1], Sandy Jacobs[2], Maarten Van Roy[2], Aidan McGuire[3], Pieter Schoen[2], Judith Baumeister[2], Susan Y. Smith[1], Josefin-Beate Holz[2]. [1]Charles River Laboratories, Canada, [2]Ablynx NV, Belgium, [3]Charles River Laboratories, United Kingdom

Nanobodies are therapeutic proteins based on the smallest functional fragments of naturally occurring heavy chain only antibodies. The trivalent Nanobody ALX-0141 targets RANK-L with high specificity and inhibits osteoclast differentiation, activation and survival. The pharmacological effect of long-term treatment with ALX-0141 on bone was evaluated. Cynomolgus monkeys (3-3.5 years old) received ALX-0141 at 5, 50 or 100 mg/kg or the vehicle control (formulation buffer) by repeated subcutaneous administration using a single dose every 2 weeks during 26 weeks. For each gender, 4 animals/group were sacrificed at the end of treatment and 2 animals/group (in the control and the high dose group) were sacrificed after an additional 26-week recovery period. Blood was collected for analysis of serum biochemistry and bone turnover markers (CTx-1, P1NP, and TRAPC5b) at pre-treatment and during the treatment and recovery period. At necropsy, whole femur and lumbar vertebrae were collected for bone densitometry evaluation by DXA and pQCT.

Treatment of cynomolgus monkeys with ALX-0141 resulted in marked suppression of bone turnover markers in all dose groups. Positive effects on bone mass were noted at the lumbar spine and femur, most markedly for the males. A higher magnitude of response was noted for trabecular bone (up to 140% increase) compared to cortical/subcortical compartment (up to 30% increase) at the lumbar spine and distal femur metaphysis. Overall the greatest effects were seen at the highest dose level. The effects on bone densitometry persisted through the 26-week treatment-free period for male animals, but not for females.

In conclusion, treatment of cynomolgus monkeys (males and females) with ALX-0141 for 26 weeks resulted in marked suppression of bone turnover markers and positive effects on bone mass with increases in BMC and BMD at the lumbar spine and femur, most notably in males. Results were consistent with the expected pharmacology of ALX-0141 and support the further development of ALX-0141 in bone-related disorders.

Effect of Dosing Interval Duration of Intermittent Ibandronate Treatment on the Healing Process of Femoral Osteotomy in a Rat Fracture Model. Tasuku Mashiba*[1], Takeshi Manabe[2], Ken Iwata[3], Tetsuji Yamamoto[3]. [1]Kagawa University Faculty of Medicine, Japan, [2]Kinashi Obayashi Hospital, Japan, [3]Kagawa University, Japan

Purpose

The effects of bisphosphonate treatment schedule on fracture healing have not previously been tested. We evaluated the effect of ibandronate dosing interval duration on the healing process following surgical 'fracture' (osteotomy), especially callus remodeling, geometrical changes and mechanical properties of fractured bone using a rat femoral fracture model.

Materials and methods

6-week-old rats (n = 160) underwent transverse osteotomy at the midshaft of the left femur, and were then allocated into vehicle control (CNT) or an ibandronate treatment group: 5 μg/kg/day (DAY; 5 days/week), 75 μg/kg once every 3 weeks (I-3), 150 μg/kg once every 6 weeks (I-6), resulting in the same total ibandronate dose over the study. Rats were sacrificed after 6 or 18 weeks. Fractured femur was evaluated by radiograph, pQCT, histomorphometry and mechanical testing.

Results

At 18 weeks, all fracture lines had disappeared in the CNT and I-6 groups; approximately 10% of fracture lines remained in the DAY and I-3 groups (Fig.1). Ibandronate-treated groups showed large callus areas around the fractures, which shrank between 6 and 18 weeks after surgery; the extent of shrinkage decreased with shorter dosing interval (Fig.2). In histomorphometry, callus remodeling was suppressed by ibandronate; this became more apparent at shorter dose intervals. The structural properties of osteotomized femora were increased in the DAY group compared with CNT, but intrinsic material properties reduced inversely and became closer to those of the CNT in response to increased dosing interval.

Conclusion

Ibandronate induced formation of large calluses around osteotomies but delayed woven bone remodeling into lamellar bone and reduced intrinsic material properties in a rat fracture model. Extending the dosing interval of intermittent ibandronate treatment appeared to reduce the suppression of callus remodeling caused by ibandronate that would have delayed healing after osteotomy.

Efficacy of odanacatib versus alendronate in the treatment of bone loss in orchidectomized male rabbits. Charles Chen*[1], Brenda Pennypacker[2], Mary Belfast[3], Le Thi Duong[2]. [1]Merck & Co., Inc., USA, [2]Merck Research Laboratories, USA, [3]Merck & Company, USA

Odanacatib (ODN) is a selective cathepsin K inhibitor demonstrated to increase bone mass in postmenopausal women with osteoporosis. The aim of this study was to compare the effects of ODN vs. alendronate (ALN) on bone mass and remodeling in orchidectomized (ORX) male rabbits, a preclinical model of male osteoporosis. Skeletally mature (11-mo.old) male rabbits were either sham-operated (n=20) or ORX (n=24/group). After 7.5 mo., ORX-animals exhibited decreased levels of testosterone and estradiol by 89% and 46%, respectively, and reduced lumbar vertebral areal bone mineral density (LV aBMD) by 5% vs Sham. ORX rabbits were randomized to either vehicle (Veh), ALN (300μg/kg/wk, sc) or ODN (1.5 and 6mg/kg, daily in food, providing ~1- and ~7-fold of clinical exposure, respectively) treatments for 14 mo. LV5-6DXA, urine and serum were collected at 0, 3, 6, 9, 12 and 14 mo. Calcein labeling (15-d) was administered prior to necropsies. Longitudinal LV.BMD was significantly increased in ORX-rabbits treated with ODN 1.5mg/kg by 9-19% and 6mg/kg by 6-27% vs Veh, and compared to an increase by 9% in the ALN group at study end. Persistent and significant reductions of the bone resorption marker helical peptide of collagen type I (HP) were observed in animals treated with both ODN doses (43-71% and 47-62%), compared to ALN (24-50%) vs Veh throughout the study. Levels of the bone formation marker bone specific alkaline phosphatase (BSAP) were significantly reduced (16-34%) in the ALN group, maintained with ODN 1.5mg/kg and trended up (16-30%) with ODN 6mg/kg compared to Veh. Terminal histomorphometry of LV3 showed that Veh-treated ORX-rabbits had decreased BV/TV by 19% ($p<0.05$) vs Sham. ALN tended to increase BV/TV by 13% (p=0.124) vs Veh. ODN at both doses significantly increased BV/TV by 55-57% ($p<0.001$) vs Veh, and 37-39% ($p<0.001$) above ALN. Interestingly, ODN treatment for 14 mo. reduced lumbar spine formation parameters, including MS/BS by 41-44%, BFR/BS by 51-52% and MAR by10-15%. Compared to ALN and Veh, trabecular osteoclast surface and number were higher ($p<0.001$) in both ODN groups. Taken together, this study demonstrated proof of concept for the cathepsin K inhibitor ODN dosed in treatment mode was highly efficacious in restoring lumbar spine bone mass in ORX male rabbits, supporting the clinical evaluation of ODN for the treatment of osteoporosis in men.

Short-Term Effects of Zoledronic Acid and Teriparatide on Microcrack Density in Ewes: Comparison between Iliac Crest and Lumbar Vertebra. Nathalie Portero-Muzy*[1], Pascale Chavassieux[2], Evelyne Gineyts[1], Marlène Pierre[1], Roland Chapurlat[1]. [1]INSERM UMR 1033 et Université de Lyon, France, [2]INSERM UMR1033, Université De Lyon, France

Iliac crest bone biopsies are used to assess the mechanism of action of therapeutic agents, yet there is little data comparing this site to sites prone to fracture. We have previously shown in ewes that zoledronic acid (ZOL) markedly depressed the bone turnover, by a different magnitude at the 1st lumbar vertebra and iliac crest. Teriparatide (TPTD) induced an augmentation of the static parameters of bone formation and resorption only in LV1 ($p<0.05$) (1). Bisphophonates have been suggested to trigger the formation of microcracks, in contrast to TPTD.

The purpose of this study performed in ewes was to compare the microcrack density (Cr.Dn) at the iliac crest and lumbar vertebra, 3 months after either vehicle (CTRL) or one single dose of 10 mg ZOL or 20 μg/day TPTD. The microcrack analysis was performed after bulk-staining of the specimens with 5 mM xylenol orange in 70% ethanol. In CTRL, microcracks were mainly observed in cortical bone at LV1 and IC with Cr.Dn twice as great at IC as at LV1. After ZOL, Cr.Dn significantly increased in cortical bone both at LV1 and IC ($p < 0.01$), with a same magnitude (x 2.75). In trabecular bone, the augmentation in Cr.Dn was similar at IC and LV1, but the mean Cr.Dn was greater at LV1 than at IC. This increased Cr.Dn was associated with a marked diminution of the bone turnover and DPD content. Cr.Dn and MS/BS were negatively and significantly correlated, regardless of type of treatment, at IC and LV1 ($0.003<p<0.03$). In all three treatment groups, DPD content in cortical bone was significantly and negatively correlated with Cr.Dn at LV1 ($p\leq0.04$). After TPTD, no significant change of Cr.Dn was observed at both sites.

In conclusion, this study performed in ewes shows that the early effects of ZOL and TPTD on bone turnover, collagen crosslinks content and microcrack density are observed both at IC and LV1, but with a different magnitude according to the skeletal site. To fully understand the mechanisms underlying the anti-fracture efficacy of osteoporosis therapies, the distinction of bone sites appears meaningful.

Dietary Dried Grape Improves Bone Calcium Retention in Ovariectomzied Rats. Emily Hohman*[1], Connie Weaver[2]. [1]Purdue University, USA, [2]Purdue University, Dept of Nutrition Science, USA

Grapes and their associated phytochemicals have been extensively investigated for beneficial effects on cardiovascular health, cancer prevention, and other chronic diseases, but the effect of grape consumption on bone health has not been determined. We previously found short term benefits of dietary grape products on reducing bone turnover in ovariectomized (OVX) rats. To determine long term benefits to bone and to further investigate mechanisms, we conducted an 8-week feeding study in 5-month-old OVX rats. Sprague Dawley rats were ovariectomized at 3 months of age and then were given a single dose of ^{45}Ca to pre-label bones at 4 months of age. Following a one month equilibration period, baseline ^{45}Ca excretion was determined as a measure of baseline net bone turnover. Rats (n=22/group) were then randomized to a modified AIN93M diet containing 25% freeze dried grape powder or control diet for 8 weeks. Urinary ^{45}Ca excretion was monitored throughout the study to determine changes in net bone turnover. Calcium balance was assessed after 1 week and 8 weeks on the experimental diets, and calcium kinetics were measured after 8 weeks. At sacrifice, femurs, tibias, and vertebrae were collected for microCT imaging, 3-pt bending, and reference point indentation. Rats consuming the grape powder diet had improved net bone calcium retention compared to rats fed the control diet. We conclude that consumption of grape products may improve bone health in the postmenopausal state.

Effects of Vitamin C and Minodronate on Bonemineral Density, Quality, and Strength in Vitamin C-deficient Rats. Toyohito Segawa*[1], Naohisa Miyakoshi[1], Yuji Kasukawa[1], Hiroshi Aonuma[1], Hiroyuki Tsuchie[2], Yoichi Shimada[1]. [1]Akita University Graduate School of Medicine, Japan, [2]Ugo Municipal Hospital, Jpn

[Introduction] Minodronate inhibits bone resorption and increases bone mineral density (BMD), helping to prevent osteoporotic fractures. Preventive effects on fractures are reduced in the elderly. Deficiency of vitamin C (ascorbic acid, AA) in aged people, which is related to bone quality, may be one reason for reduced bone quality and reduction of bone strength. However, the efficacy of AA supplementation and minodronate on BMD, bone quality, and strength in AA deficiency is unclear. This study evaluated the efficacy of AA supplementation and minodronate administration on BMD, bone quality, and strength in AA-deficient rats.[Materials and Methods] AA-deficient rats (Osteogenic Disorder Shionogi Rats) were bred with normal concentration AA water (2 mg/mL) until 4 months of age and with low concentration AA water (0.5 mg/mL) thereafter until 8 weeks to develop vitamin C deficiency (n=40). Thereafter, rats were assigned to one of the following groups: 1) AA-deficient (AA-) group receiving low concentrations of AA water, 2) AA supplementation (AA+) group receiving normal concentrations of AA water, 3) AA-deficient and minodronate (0.15 mg/kg body weight, once a week subcutaneous injection) administration (AA-M) group, and 4) AA supplementation and minodronate administration (AA+M) group (n=10 in each group). After 4 weeks, the bilateral femora and right tibia were harvested. Right proximal femur was used for BMD measurement, and left femur was evaluated for bone strength by femoral neck compression test and three-point bending test of diaphysis. Right proximal tibia was used to measure collagen maturity by Fourier transform infrared spectroscopy (FTIR) for bone quality evaluation.[Results] BMD in the AA+M group was significantly higher than in the other groups ($p<0.05$). Bone strength indices including maximum load, bone breaking force, and breaking energy in the femoral neck compression test and three-point bending test of diaphysis in the AA+ and AA+M groups were significantly higher ($p<0.05$) than in the AA- group. Collagen maturity evaluated by FTIR showed no significant differences among groups; however, the AA+ group showed higher values ($p=0.09$) than the AA- group regardless of minodronate administration. [Discussion and Conclusion] AA deficiency resulted in reduced bone strength. The combination of AA supplementation and minodronate increased BMD and bone strength in AA-deficient rats, suggesting that AA supplementation may improve bone quality.

Eldecalcitol Improves Endothelial Function Deteriorated by the Oxidative Stress in the Femoral Artery and Prevents Bone Loss in Ovariectomized Rats. Koichi Endo[1], Ken-ichi Serizawa*[2], Satoshi Takeda[2], Yoshihito Tashiro[2], Kenji Yogo[2]. [1]Chugai Pharmaceutical Co., Ltd., Japan, [2]Product Research Department, Chugai Pharmaceutical Co., Ltd., Japan

Eldecalcitol (ED-71; ELD), a 2β-hydroxypropyloxy derivative of 1a,25(OH)2D3, is an active vitamin D3 analog and used for the treatment of osteoporosis in Japan since 2011. Although native vitamin D is reported to exert a protective effect on endothelial dysfunction in diabetes or renal disease, the protective effects of vitamin D3 in osteoporosis remain unclear. This study evaluated the endothelial protective effect of the pharmacological dosage of ELD in osteoporosis of ovariectomized (OVX) rats. Female Sprague-Dawley rats (12-weeks old) were ovariectomized. ELD (20 ng/kg) was orally administered 5 times a week for 4 weeks from one day after surgery. Four weeks after the surgery, flow-mediated dilation (FMD) as an indicator of endothelial function was measured by high-resolution ultrasound in the femoral artery of living rats. After vertebrae had been harvested, the BMD of the L2-L4 vertebrae was measured by DXA. FMD was significantly reduced in the OVX + vehicle group (OVX+v) compared with the sham group (Sham). ELD restored the reduction of FMD in OVX (Sham: 14.3 ± 2.5, OVX+v: 8.2 ± 1.5, OVX+ELD: 15.0 ± 1.1%, mean$\pm$SD, n=7-8). Nox4 expression (a NADPH oxidase component) and nitrotyrosine content (a marker of peroxynitrite) increased and eNOS dimer/monomer ratio was decreased in OVX rat femoral arteries, indicating eNOS dysfunction in OVX rat femoral arteries. In femoral arteries of OVX rats, PPARγ expression decreased and NF-κB p65 expression increased. ELD reduced Nox4 expression and nitrotyrosine content in OVX rat femoral arteries and improved the eNOS coupling state. In addition, ELD increased PPARγ expression and decreased NF-κB p65 expression in femoral arteries of OVX rat. The BMD of the L2-L4 vertebrae in OVX+v was significantly lower than that of Sham. The treatment with ELD prevented OVX-induced reduction of BMD of the vertebrae (Sham: 145.4 ± 7.4, OVX+v: 133.9 ± 6.6, OVX+ELD: 152.9 ± 7.3 mg/cm2). ELD slightly increased plasma Ca concentration (Sham: 8.8 ± 0.1, OVX+v: 8.5 ± 0.1, OVX+ELD: 9.1 ± 0.2 mg/dL). These results suggested that ELD ameliorated endothelial dysfunction in OVX rats. An antioxidative effect of ELD was thought to improve eNOS coupling state at the pharmacological dosage in osteoporosis model. ELD would be expected to exert as an osteoporotic therapeutic agent with additional value, improving endothelial function, for osteoporosis patients.

Effects of AB-25E9, a Monoclonal Antibody Targeting Siglec-15, on Biomarkers of Bone Remodeling in Estrogen-Deficient Cynomolgus Monkeys. Julie Laurin*, Mauricio Lemus, Elisabeth Viau, Anna Moraitis, Martine Pagé, Gilles Tremblay, Mario Filion. Alethia Biotherapeutics, Canada

Siglec-15, an immunoglobulin-like sialic acid-binding receptor, is expressed specifically on the surface of osteoclasts and plays a role in their normal differentiation and function. In rodent models, administration of a Siglec-15 antibody resulted in increased bone mineral density and decreased serum TRAP5b levels, indicating a direct effect on osteoclasts in vivo. Interestingly, the results from these studies suggested that inhibiting Siglec-15 also stimulated bone formation. To explore the effects of Siglec-15 inhibition on bone biomarkers in primates, we administered the humanized monoclonal antibody targeting Siglec-15, AB-25E9, to estrogen-deficient female cynomolgus monkeys.

Two intravenous injections of vehicle (PBS) or AB-25E9 at 10 mg/kg were administered to two groups at an 8-week interval with a follow-up period of 6 months. Estrogen deficiency was induced by the repeated subcutaneous administration of a gonadotropin-releasing hormone agonist every 4 weeks starting 3 months prior to administering AB-25E9 and throughout the follow-up period. Serum and urine samples were collected weekly to evaluate the bone resorption and formation biomarkers, determine the PK profile of AB-25E9 and monitor for the presence of antibody-drug antibodies (ADA).

Treatment with AB-25E9 rapidly decreased bone resorption biomarkers (urinary NTx, serum CTx and TRAP5b) by 30% to 45% demonstrating the anti-resorptive properties of AB-25E9. Strikingly, the bone formation biomarkers (osteocalcin and BSAP) did not rapidly decrease and were minimally affected. The decrease in the levels of bone resorption biomarkers began to attenuate at approximately Week 6, which coincided with the appearance of ADAs. Interestingly, this attenuation was not observed before Week 20 in animals where little or no ADAs were detected. In agreement with these findings, the decline in AB-25E9 serum concentrations was faster in animals in which ADAs were detected. In monkeys that were negative for ADAs, the terminal elimination half-life of AB-25E9 ranged between 5 – 12 days.Taken together, the biomarker profiles presented here show that AB-25E9 has anti-resorptive activity and maintains bone formation estrogen-deficient cynomolgus monkeys. These results underscore the novel mechanism of action of AB-25E9 and highlight its potential for osteoclast-targeted therapy of bone-related diseases.

Effects of alfacalcidol and ED-71/eldecalcitol alone or in combination with risedronate in ovariectomized rats: histomorphometric analysis. Tetsuo Yano*[1], Mei Yamada[1], Makoto Shiozaki[2], Daisuke Inoue[3]. [1]Ajinomoto Pharmaceuticals Co., LTD, Japan, [2]Ajinomoto Pharmaceuticals, Japan, [3]Teikyo University Chiba Medical Center, Japan

Background/Aim: We previously demonstrated efficacy of eldecalcitol (ED-71), a new 1a,25(OH)2D3-derivative, on ovariectomy-induced osteoporosis in rats. ED-71 improved both trabecular and cortical bone architecture in micro-CT analysis at least to a similar extent that alfacalcidol (ALF) did, when combined with risedronate (RIS).

We report here results of histomorphometric analysis in ovariectomized rats treated with ED-71 and ALF, each alone or in combination with RIS

Methods: Female Sprague Dawley rats at 24 weeks of age were divided into one sham-operated and five ovariectomized groups (1: vehicle, 2: ED-71, 3: ALF, 4: RIS, 5: RIS + ED-71, and 6: RIS + ALF). RIS (3.5 μg/kg, s.c.) and ED-71 (0.2 μg/kg, p.o.) were given twice per week for 16 weeks. ALF (0.4 μg/kg, p.o.) was given three times per week for 16 weeks. Bone strength and histomorphometry were measured at 16 weeks treatment. BMD and bone architecture were evaluated every 4 weeks by micro CT.

Results: At 16 weeks, cortical thickness and area in RIS, ED-71, RIS + ALF and RIS + ED-71 was significantly increased, compared with vehicle. And maximum load of ED-71, RIS, RIS + ED-71, and RIS + ALF groups was significantly increased, compared with vehicle. In histomorphometric analysis, structural indices of trabecular bone in vehicle deteriorated, compared with sham. These parameters in ED-71 + RIS and ALF + RIS showed a greater improvement than that in monotherapy. Mineralizing surface and bone formation rate were significantly decreased by combination therapy. The number of mini-modeling in ED-71 + RIS and ALF + RIS was also significantly decreased, compared with vehicle. The change of the number of mini-modeling in RIS and ED-71 + RIS was significantly greater than that in the ED-71 monotherapy group.

Conclusions: Combination therapy with RIS and active vitamin D3 derivatives significantly improved bone histomorphometry greater than each alone. RIS + ED-71 was at least as efficacious as RIS+ALF in improving bone histomorphometry, validating the combination of risedronate and ED-71 as a treatment option for osteoporosis caused by estrogen withdrawal.

Green tea polyphenols improve bone matrix in alcohol-induced bone loss of young male rats. Chwan-Li Shen*[1], Susan Bergeson[1], Peter Syapin[1], Raul Dagda[1], Jia Jia Chen[1], Jennifer Graef[2], Gordon Brackee[1], Brenda Smith[2]. [1]Texas Tech University Health Sciences Center, USA, [2]Oklahoma State University, USA

Our previous studies have shown that the osteo-protective effects of green tea polyphenols (GTP, green tea extract) in various bone loss models. In this study, we used the same approach of green tea supplementation in drinking water to evaluate GTP's impacts on bone health along with safety in a binge drinking-induced bone loss model. Forty-eight 30-day-old SD male rats were assigned to a 2 (placebo vs. alcohol i.p. at 3 g/kg body weight on 3 consecutive days/week) × 3 (0, 0.1%, and 0.5% (w/v) GTP in drinking water) factorial design for 6 weeks. Bone parameters [femoral and lumbar vertebrae-4 (LV-4) area (BMA), bone mineral content (BMC), and bone mineral density (BMD)] were measured by dual-energy absorptiometry. Bone turnover biomarkers [serum osteocalcein (OC) and tartrate-resistant acid phosphatase-5b (TRAP-5b)] were measured using respective ELISAs. Blood chemistry panels were determined by an automatic chemical analyzer. Data were analyzed by two-way ANOVA followed by Fisher's LSD test. Throughout the study period, alcohol administration reduced body weight and food consumption, while GTP supplementation reduced water consumption. The blood chemistry results show that alcohol administration significantly decreased albumin, glucose, alkaline phosphatase, and amylase levels; increased globulin, phosphorus, creatine kinase, cholesterol, and potassium levels; and had no effect on protein, calcium, blood urea nitrogen, creatinine, aspartate aminotransferase, alanine aminotransferase, sodium, and chloride. GTP supplementation significantly suppressed alkaline phosphatase levels and had no impact on other blood chemistry parameters. Regarding bone aspects, 6-week alcohol administration lowered BMA, BMC, and BMD of the femur and LV-4, as well as serum TRAP-5b, but had no impact on serum OC. Supplementation of GTP into the drinking water for 6 weeks increased BMC of the femur (P=0.091) and LV-4 (P=0.016) as well as BMD of the femur (P=0.030) and LV-4 (P=0.068). GTP had no effect on scanned BMA and serum OC, and tended to increase serum TRAP-5b concentration (P=0.092). There was an interaction between the alcohol administration and GTP dosage in serum TRAP-5b. This study demonstrates that GTP supplementation in drinking water can increase bone matrix through suppressing bone turnover rate in young male rats administered with alcohol, an animal model of binge drinking.

SA0423

Icariin exerts an osteogenic effect in OVX-mice via suppression of ERK and stimulation of p38 MAPK. Qin Bian*[1], Zhu Yang[2], Yongjian Zhao[2], Xiangyin Mao[3], Shufen Liu[2], Jianhua Huang[4], Zinyin Shen[4], Yongjun Wang[2]. , [2]Department of Orthopaedics & Traumatology, Longhua Hospital, Shanghai University of Traditional Chinese Medicine, China, [3]Institute of Life Science, Fudan University, China, [4]Institute of integrated Traditional Chinese Medicine & Western Medicine, Huashan Hospital, Fudan University, China

Objective—Icariin (ICA), an extract from epimedium, has been reported to be effective in promoting bone formation. The objective of the study is to search for the molecular targets of Icariin (ICA) in bone mesenchymal stem cells (bMSCs) from the mice with ovariectomy (OVX)-induced osteoporosis.

Methods—Six-month-old Imprinting Control Region (ICR) mice that underwent OVX were treated with ICA. After 3 months, bone mass was evaluated by microcomputed tomography, morphometry and immunohistochemical detection. BMSCs were isolated from the femur and tibia to observe the self-renewal and differentiation capacity using Colony. forming unifibroblastic (CFU-F), Colony. forming adipocyte (CFU-Adipo) and alkaline phosphatase (ALP) staining. Real time RT-PCR and ALP detection were performed to observe the osteogenetic effects of ICA on bMSCs *in vitro*. In addition, the expression of 26991 genes of bMSCs *ex vivo* at 2 weeks after ICA-treatment was measured and analyzed using microarray and pathway analysis. The signaling pathway was further explored by western blot assay and inhibitors of p38 and ERK: SB203508 and PD98059.

Results—Micro-CT displayed a decrease in bone mass at 3 month after OVX. ICA treatment increased the trabecular thickness (Tb.Th), osteoblast while decreased osteoclast number, elevating osteocalcin (OC) protein levels *in vivo* and facilitating the self-renewal and osteoblastic differentiation of bMSCs *ex vivo*. The osteogenic related genes ALP, BSP and Runx2 expressions were upregulated by ICA treatment and 10-5M showed the strongest effect in ALP assay in vitro. Pathway analysis from *in vivo* data revealed that the core genes acted by ICA were highly involved in MAPK signaling pathway. Further study demonstrated ICA suppressed ERK1/2 while stimulated p38 MAPK phosphorylation to promote osteoblastic differentiation *in vitro*.

Conclusion— Icariin promotes bone formation in OVX-mice. The suppression of ERK and stimulation of p38 might be involved in the process.

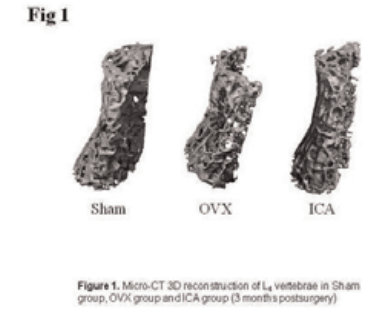

figure 1

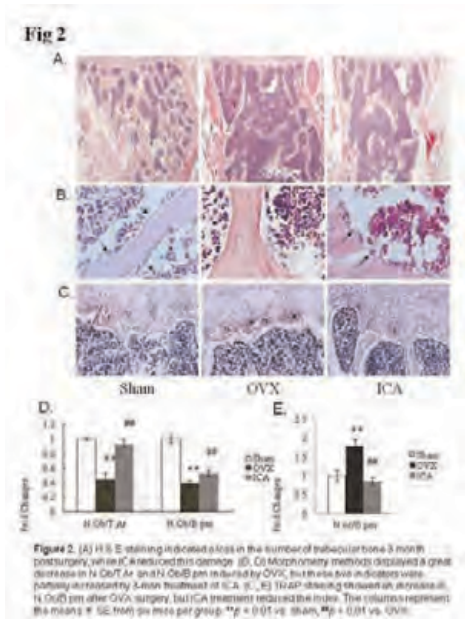

figure 2

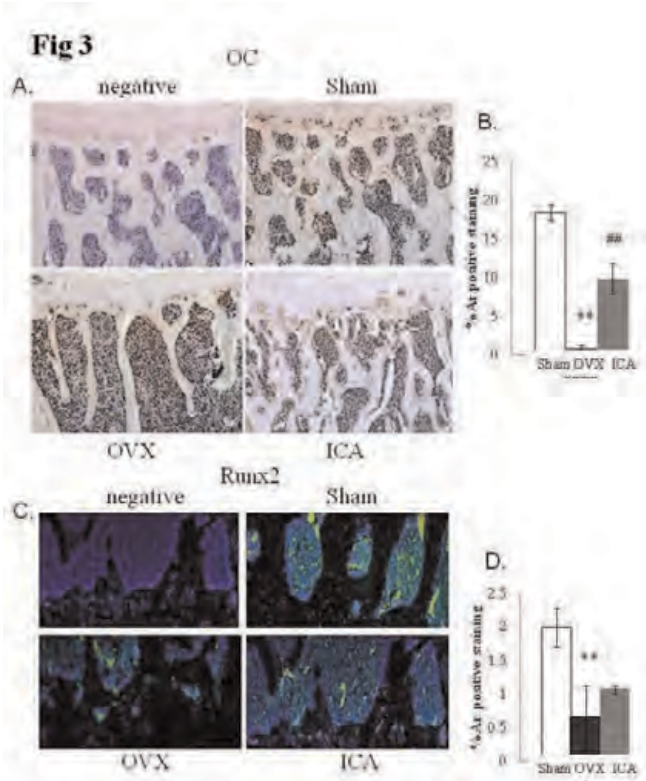

Figure 3. Reduced positive staining for OC (brown) and Runx2 (green) was observed, especially on the surface of bone lacuna in the OVX group. In the ICA group, OC protein was increased but Runx2 protein had little changes. The columns represent the means ± SE from six mice per group. $^{**}p < 0.01$ vs. sham, $^{\#\#}p < 0.01$ vs. OVX.

figure 3

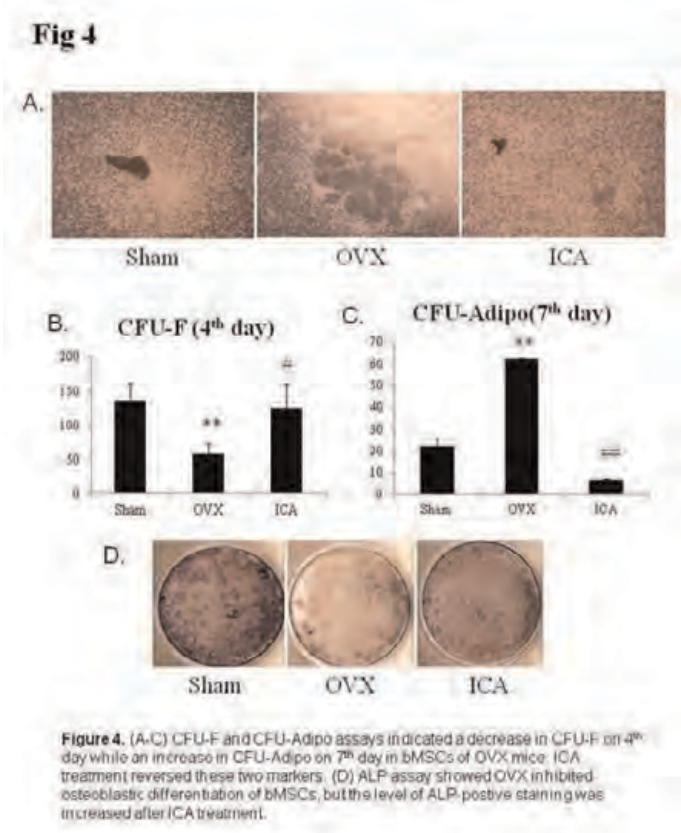

Figure 4. (A-C) CFU-F and CFU-Adipo assays indicated a decrease in CFU-F on 4th day while an increase in CFU-Adipo on 7th day in bMSCs of OVX mice. ICA treatment reversed these two markers. (D) ALP assay showed OVX inhibited osteoblastic differentiation of bMSCs, but the level of ALP-postive staining was increased after ICA treatment.

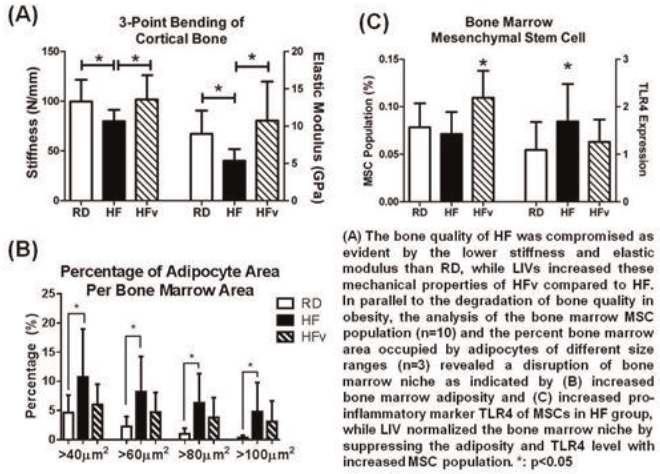
Improved Bone Quality in Diet-Induced Obesity by Low Intensity Vibrations is Paralleled by Suppressed Bone Marrow Adiposity and Reduced Pro-Inflammatory State of Mesenchymal Stem Cells. M. Ete Chan*[1], Benjamin Adler[1], Danielle Green[1], Gabriel Pagnotti[1], Vihitaben Patel[2], Denis Nguyen[2], Clinton Rubin[3]. [1]Stony Brook University, USA, [2]Biomedical Engineering Department, Stony Brook University, USA, [3]State University of New York at Stony Brook, USA

Obesity-induced chronic inflammation has recently been recognized to increase the risk of both type 2 diabetes and bone fracture in part due to disruptions to the bone marrow niche. Mechanical signals delivered via low intensity vibrations (LIV) have been shown to improve obesity-induced deterioration of bone via influencing the bone marrow niche and promoting the osteogenic potential of mesenchymal stem cells (MSCs). In addition to being the progenitor of bone-forming osteoblasts, MSCs possess an immunomodulatory property which could alter the inflammatory status of the bone marrow niche. To explore how LIV influences the bone marrow environment and, more particularly, the skeletal-immune system interplay during obesity, a murine model of diet-induced obesity was adopted in this study. In an 8-week study, thirty 5w old male C57BL/6J mice were divided into 3 groups (n=10): regular diet (RD; 10 kcal% fat), high fat diet (HF; 45 kcal% fat) and high fat diet with LIV (HFv). LIV was delivered via a vertically oscillating plate (30min/day, 5 day/wk at 90Hz and 0.2g) to HFv, while HF and RD were sham-handled. The obese phenotype was evident in HF and HFv with a +12% higher body mass relative to RD ($p=0.01$). Biomechanical testing showed that the tibiae of HF had lower stiffness (-22%) and elastic modulus (-45%) than RD ($p=0.03$), indicating an increased fracture risk in obesity (Fig. A). The compromised bone quality in HF was paralleled by the disturbance of bone marrow niche as indicated by an increased bone marrow adiposity (Fig. B) and increased pro-inflammatory marker toll like receptor 4 (TLR4) of MSCs ($p<0.05$) (Fig. C). Interestingly, LIV increased the stiffness and elastic modulus of tibia in HFv by +27% and +108% compared to HF ($p=0.02$), respectively. Accompanying these improvements are the reduction of bone marrow adiposity (Fig. B), the increase of bone marrow MSC populations (+53%) and the reduced expression of TLR4 (-25%) in HFv relative to HF ($p<0.05$) (Figs. B and C). This study shows that obesity disrupts the bone marrow niche by increasing bone marrow adiposity and by promoting inflammation. LIV improves the bone marrow composition via lowering the adipose burden and regulating the number and immunomodulatory properties of MSCs in the bone marrow, which improves the bone quality and decreases fracture risk.



(A) The bone quality of HF was compromised as evident by the lower stiffness and elastic modulus than RD, while LIVs increased these mechanical properties of HFv compared to HF. In parallel to the degradation of bone quality in obesity, the analysis of the bone marrow MSC population (n=10) and the percent bone marrow area occupied by adipocytes of different size ranges (n=3) revealed a disruption of bone marrow niche as indicated by (B) increased bone marrow adiposity and (C) increased pro-inflammatory marker TLR4 of MSCs in HF group, while LIV normalized the bone marrow niche by suppressing the adiposity and TLR4 level with increased MSC population. *: p<0.05

Small Bone Size and Compromised Bone Strength Characterize the Tibia in Young Amenorrheic Exercising Women. Rebecca Mallinson*[1], Nancy Williams[2], Daniel Schiferl[3], Emily Southmayd[1], Mary Jane De Souza[1]. [1]Pennsylvania State University, USA, [2]The Pennsylvania State University College of Medicine, USA, [3]Bone Diagnostic, Inc., USA

An energy- and estrogen-deficient environment contributes to low bone mineral density (BMD) in amenorrheic athletes; however, habitual exercise is beneficial for bone strength. To determine the opposing effects of menstrual dysfunction and exercise on bone health in amenorrheic athletes, it is essential to assess both bone mass and geometry. The purpose of this study is to determine if exercising amenorrheic (ExAm) and eumenorrheic (ExEu) women differ with respect to volumetric BMD (vBMD), bone geometry, and estimated bone strength at the tibia. Exercising women were categorized as ExAm if they reported no menses for the past 3 months or ExEu if they reported ⩾10 menstrual cycles in the past 12 months. Body composition and areal BMD were assessed by dual-energy x-ray absorptiometry. vBMD, bone geometry, and muscle area at the tibia were measured by peripheral quantitative computed tomography, and the bone strength index (BSI) and strength strain index (SSI) were calculated at the distal and proximal tibia, respectively. ExAm (n=13) and ExEu (n=12) women aged 20.6 years did not differ in height, body mass index (BMI), age of menarche, or hours of habitual physical activity. Body mass (p=0.023) and lean mass (p=0.014) were lower in ExAm women compared to ExEu women, but fat mass was similar between groups. Duration of amenorrhea in ExAm women was 343 days; 69% and 33% of ExAm and ExEu women, respectively, reported prior episodes of amenorrhea. No differences in vBMD, bone area, or BSI were observed between groups at the distal tibia. At the proximal tibia, ExAm women had smaller total bone area (ToA, p=0.005), periosteal circumference (PCircum, p=0.005), SSI (p=0.010) and muscle area (p=0.016) compared to ExEu women but greater cortical vBMD (p=0.048). Lean mass ($p<0.001$) and habitual physical activity ($p<0.03$) were positively correlated with ToA, PCircum, and SSI at the proximal tibia; whereas, fat mass and BMI were positively correlated with vBMD and BSI at the distal tibia ($p<0.05$). Compromised bone size and strength at the proximal tibia of ExAm women may indicate that the normal response of bone to mechanical loading is attenuated in an energy- and estrogen-deficient environment that persists into adulthood; however, lean mass may also play a role in the differences in bone size and strength between groups. Lean mass may strongly influence bone strength at proximal sites; whereas, nutritionally-related factors may be more influential at distal sites.

A Dual Isotope Hybrid μCT-PET System Reveals Functional Heterogeneity of Bone Lining Cells and Longitudinal Changes in Marrow from Local Radiation and Chemotherapy. Masashi Yagi*[1], Luke Arentsen[1], Yutaka Takahashi[1], Leslie Sharkey[1], Masahiko Koizumi[2], Cory Xian[3], Clifford Rosen[4], Douglas Yee[1], Susanta Hui[1]. [1]University of Minnesota, USA, [2]Osaka University, Japan, [3]University of South Australia, Australia, [4]Maine Medical Center, USA

Despite the increase of long-term cancer survivors, the impact and mechanism of radiation and/or chemotherapy on normal bone and bone marrow are not well characterized. μCT-PET in a mice model allows investigation of the entire skeleton and monitoring of functional changes by imaging radiotracer behavior in vivo. We report the skeletal and marrow response to clinically relevant local radiation and chemotherapy using μCT-PET and reveal a potentially important role for bone lining cells in mediating the skeletal response to local and systemic injury.

Mice were given systemic methotrexate (MTX, 2.5mg/kg, 3 days) or 16Gy local radiation to legs. Longitudinal FDG (days -4, 2) and NaF (days -3, 3, 7, 14, 29) μCT-PET scans were performed (Fig. 1). Eight skeletal regions were monitored. Distal femora were harvested for cellular histology.

We observed significant functional heterogeneity throughout the skeleton for bone mineral remodeling as measured by NaF (<0.0001, Fig. 2) and marrow metabolic function (FDG) (<0.0001, Fig. 3). Radiation caused an early decrease in marrow metabolic function, consistent with histologic studies, in which marrow cellularity was drastically reduced in day 3 post radiation (Table). We found a high correlation (R=0.90) between pre- and post-radiation FDG uptake. This supports the idea of an initial physiological status that predicts the response to treatment. It also suggests that marrow cells post treatment (day 30) are as metabolically active as pre-treatment. The early increase in NaF uptake (<0.05, Fig. 4) post-radiation (day3) was associated with an increase in sinusoid and lining cells in endosteal regions of the skeleton (Table). There were also significant distant effects (outside radiation sites) measured by both tracers that may be due to increased cytokines and vascular permeability. Acute MTX induced inflammation also causes an early increase in NaF uptake, and both local radiation and chemotherapy shows similar patterns of NaF changes over time (Fig. 5). Reduction in NaF uptake over time is a result of diminished mineralization due to a change in bone remodeling.

Dual isotope μCT-PET revealed functional heterogeneity of the skeleton in response to local radiation or chemotherapy. These studies demonstrate an important role for bone lining cells in mediating the skeletal and possibly the marrow response to injury. This methodology also establishes a translational model for studying the skeletal health of cancer survivors.

Bone Density in Apheresis Donors compared to Whole Blood donors. Carolien Boot[1], Jessie Luken[2], Peter van den Burg[2], Wim de Kort[2], Rianne Koopman[2], Hans Vrielink[2], Natasja van Schoor[1], Martin Den Heijer[3], Paul Lips*[1]. [1]VU University Medical Center, The Netherlands, [2]Sanquin Blood Supply, Netherlands, [3]VU Medical CenterPostbus 70571007 MB Amsterdam, The Netherlands

Apheresis donation is a procedure in which blood components, such as platelets or plasma, are separated and collected from whole blood. During the procedure the processed blood is returned to the donor. Trisodium citrate complexing calcium is used as an anticoagulant. This complexing can cause symptomatic hypocalcemia and hypomagnesemia. In the first 24 hours after donation an increase of serum parathyroid hormone (PTH) is seen. The potential long-term consequences are not known, such as decrease of bone mineral density, or occurrence of osteoporosis. The aim of the study was to compare bone mineral density of postmenopausal apheresis donors with postmenopausal whole blood donors.

This pilot study was done in 20 female postmenopausal apheresis donors (mean age 62.7 years old, SD 3.9) who underwent plasma apheresis donation more than 100 times in the last 15 years. Controls were 20 female whole blood donors (mean age 62.7 years, SD 3.9). Both groups underwent a DXA scan, and blood samples were collected (including 25-hydroxyvitamin D, PTH, serum C-terminal telopeptide (CTx) and procollagen type 1 N-terminal propeptide(P1NP)). Potential risk factors for osteoporosis were assessed by a questionnaire. Absolute bone mineral density of the lumbar spine was 1.00 (SD 0.18) in apheresis donors and 0.92 (SD 0.12) in whole blood donors ($p = 0.09$). T-scores of the lumbar spine were -0.45 (SD 1.57) in apheresis donors and – 1.18 (SD 1.10) in whole blood donors (p 0.099). Absolute bone mineral density of the hip was 0.86 (SD 0.12) and 0.88 (SD 0.14) in apheresis donors and whole blood donors respectively ($p=0.88$). T-scores of the hip were -0.71 (SD 0.90) in apheresis donors and -0.63 (SD 1.15) in whole blood donors ($p=0.83$) 25-hydroxyvitamin D was in apheresis donors 58.6 nmol/L (SD 17.6), in whole blood donors 52.4 nmol/L (SD 18.5), PTH was respectively 6.4 pmol/L (SD 1.8) and 6.7 pmol/L (SD 1.9). 25-hydroxy vitamin D and PTH levels were not different between the groups.

With regard to bone mineral density no significant difference between apheresis donors and whole blood donors was found. However, in the apheresis group a trend towards a higher bone mineral density was suggested. This could possibly be caused by a short PTH elevation resulting in an anabolic response. On the basis of our pilot study apheresis donation appears to be safe. To gain more knowledge further investigation with larger study groups has to be done

Early Dental Implant Stability Correlates with Bone Turnover in Bisphosphonate Exposed Patients. Pamela Taxel MD*, Denise Ortiz MPH, David Shafer DMD, David Pendrys DDS PhD, Susan Reisine PhD, Kandasamy Rengasamy, D.D.S., Martin Freilich DDS. University of Connecticut Health Center, USA

Purpose: To assess the relationship between dental implant stability and bone turnover in patients with or without bisphosphonate (BP) exposure for the treatment of osteopenia or osteoporosis.

Methods: One dental implant site was evaluated in 72 postmenopausal women with a spectrum of bone health enrolled in a descriptive ''best practice'' prospective cohort study. BP exposure at enrollment was categorized as ''never'' or ''past/current'' exposure. Per dental guidelines, participants were asked to discontinue BPs around dental implant placement. Implant stability was assessed by resonance frequency analysis (RFA ISQ value) at surgery and eight weeks following implant placement.

Measurement of sCTX, a marker of bone turnover, was obtained pre-treatment, one and eight weeks following implant surgery.

Results: The patients' mean age was 61.6 ± 5.2 years and 68% were osteopenic or osteoporotic; 25 of 72 participants (35%) were "past/current" BP users. At implant placement the average RFA ISQ value for the entire sample was 65.6 ± 10.9 (values > 50 considered adequate), and increased 8 weeks post-surgery to 75.2 ± 8.3 ($p<0.01$). The "never" and "past/current" groups each had RFA ISQ increases from implant placement to 8 weeks ($p<.01$, respectively). Among "past/current" BP users there was a significant negative correlation between RFA ISQ and sCTX values at one week ($r_s=-.56$, $p<0.01$) and eight weeks ($r_s=-.47$, $p<0.05$). A similar relationship was not seen in "never" users.

Conclusion: Dental implant stability as measured by RFA ISQ increased equally in "never" or "past/current" BP users between implant placement and eight weeks post-surgery consistent with successful osseointegration. However, in "past/current" BP users lower bone turnover was associated with higher short-term implant stability, as measured by RFA ISQ. The relevance of this finding to long-term dental implant stability is unclear at the present time. Thus, these interim findings require further long-term follow-up and investigation in a larger population with and without BP exposure to determine if implant stability is improved by exposure to antiresorptive medications.

Factors Associated with Nonunion in 97 Consecutive Type 2 and Type 3 Odontoid Fractures in Elderly Patients. Debra Sietsema*[1], Michael Merrick[2], Casey Smith[2], Tan Chen[3], Scott Russo[4], Clifford Jones[1], James Stubbart[4]. [1]Orthopaedic Associates of Michigan; Michigan State University, USA, [2]Grand Rapids Medical Education Partners, USA, [3]Michigan State University, USA, [4]Orthopaedic associates of Michigan, USA

Purpose: Odontoid fractures are the most common cervical spine injury in older adults and have high rates of morbidity and mortality. The purpose of this study was to determine factors that were associated with nonunion in odontoid fractures. Methods: Between 2002 and 2011, 97 consecutive patients, age 65 years and over, with type 2 and type 3 odontoid fractures were treated at a single Level I trauma center, were followed in a single private practice, and retrospectively evaluated. Radiographs were reviewed and fusion was determined by flexion/extension x-rays, CT scan, or both. Twenty-three mortalities occurred prior to six months post-injury, and they were excluded from the fusion analysis. One patient was lost to follow-up prior to evaluation for fusion. Results: There were 31 (42%) males and 42 (58%) females with a mean age of 80 (range 65-93) who were evaluated for fusion of their type 2 (55, 75%) or 3 (18, 25%) odontoid fracture. Mean body mass index was 26.9 (range 17.1-37.5). The overall fusion rate in the 73 patients who were living at the time of fusion analysis was 71.2%. Patients treated with non-operative management had a lower rate of fusion (31/51, 60.8%) compared to patients who were treated with surgery (21/22, 95.5%), ($x^2=0.003$). Males had a lower fusion rate (18 of 31, 58.1%) than females (34 of 42, 81%), ($x^2=0.033$). Fusion was affected by comorbidities. Those with fusion had a lower Charlson score (1.65) than those who did not fuse (2.67) (t=-2.045, sig =0.045). Additionally, congestive heart failure (CHF) was a significant independent medical comorbidity associated with nonunion. Out of the 21 patients who were found to have nonunion, 8 had a diagnosis of CHF at the time of admission (38.1%). 52 patients were found to have a fusion of their odontoid fracture, and only 4 of those patients had congestive heart failure (7.7%), ($x^2=0.002$). Factors without statistical significance included age, BMI, tobacco use, sagittal fracture displacement, direction of displacement, type of odontoid fracture, odontoid angle, time to surgery, method of non-operative management, time to discontinuation of rigid collar, and operative technique. Conclusion: Factors associated with nonunion in older patients with odontoid fractures include: non-operative treatment, males, higher numbers of medical comorbidities, and congestive heart failure.

DXA vs QCT Imaging of the Knee in People with Spinal Cord Injury. Apoorv Prasad[1], William Edwards[2], Kristine Herrmann[1], Danielle Barkema[1], Narina Simonian[1], Renita Yeasted[1], Karen Troy[2], Thomas Schnitzer*[1]. [1]Northwestern University, USA, [2]University of Illinois at Chicago, USA

Purpose: Bone loss is a common consequence of spinal cord injury (SCI) and is associated with a marked increase in fractures, particularly at sites around the knee. DXA measurement of the distal femur has been advocated to assess bone status though comparison with QCT has not been reported. This study was undertaken to compare DXA measurement to QCT imaging at the distal femur and proximal tibia.

Methods: A convenience sample of 31 individuals with SCI was studied; 11 were evaluated within 4 months of acute injury and the remainder had their injury for > 2yrs. Imaging of the knee by both QCT and DXA (Hologic QDR4500A) was accomplished within a 2 week timeframe in each individual. DXA of the knee was performed in duplicate. QCT data were analyzed to evaluate integral, trabecular and cortical BMD of three regions of the knees–distal femoral epiphysis, distal femoral metaphysis and proximal tibial epiphysis—per Drillis and Contini anthropometric proportionality constants (1966). DXA analysis utilized forearm software and a similar anatomic approach as the QCT analysis, with duplicate values for each region averaged. Correlation coefficients (Pearsons' r) were calculated using SPSS to evaluate correlations between site-specific DXA and QCT values.

Results: The study population was 67.7% male, average age 36.4 ± 13.6 yr, duration of SCI 11.4 ± 12.6 yr. There was excellent correlation between DXA and QCT trabecular and integral BMD measurements at the femoral epiphysis, femoral metaphysis and tibial epiphysis ($r>0.9$, $p<0.001$ for all), but weaker correlation between DXA and QCT cortical BMD values (Table 1).

Conclusions: A strong correlation exists between the DXA BMD and the integral and trabecular, but not the cortical, QCT values of the knee in all regions. QCT alone provides information regarding cortical bone status, important in assessing bone strength and fracture risk in SCI populations.

Table 1. Pearson's r for Regions of the Knee: DXA vs QCT

	Integral	Trabecular	Cortical
Femoral epiphysis	0.96	0.96	0.39
Femoral metaphysis	0.93	0.92	0.53
Tibial epiphysis	0.94	0.94	0.73

Table 1

Postpartum Osteoporosis and 1,25-Dihydroxyvitamin D-Mediated Hypercalcemia. Stephanie Stein*[1], Elizabeth Streeten[2]. [1]University of Maryland Medical Center, USA, [2]University of Maryland School of Medicine, USA

Background: During pregnancy and lactation, PTHrP secretion increases and serum levels correlate with postpartum bone loss but eucalcemia is maintained. In both postpartum osteoporosis and hypercalcemia, excessive PTHrP is usually the mediator. We report a case of postpartum osteoporosis with apparent 1,25(OH)2D-mediated hypercalcemia.

Clinical Case: A healthy 29 y.o. female presented 2 months postpartum with acute back pain and multiple atraumatic vertebral fractures. Her pregnancy was uncomplicated, and she had breastfed since delivery. MRI showed compression fractures of T8-12 and L1-5. She had no prior fracture and no family history of osteoporosis. Labs showed: serum Cr 0.6 mg/dL, hematocrit 37.5%, Ca 9.6 mg/dL, P 4.5 mg/dL, Mg 2.0 mg/dL, 25(OH)D 43 ng/ml, 1,25(OH)2D 41 pg/mL (nl 18-72), PTH 8 pg/mL (nl 12-68), TSH 1.8 uIU/mL, alkaline phosphatase (AP) 202 units/L (nl 38-126), SPEP/UPEP normal. Repeat labs 2 weeks later showed: Ca 12.5 mg/dL, 1,25(OH)2D 25 pg/mL, PTH <4 pg/mL, PTHrP 5 pg/mL (nl 14-27), AP 189 units/L, C-telopeptide 1185 (nl 64-640), prolactin 15.5 ng/mL. Serum Ca prior to pregnancy was normal. DXA Z-scores: L2-4 -2.5, total hip -1.9, femoral neck -1.8. Given her suppressed PTH and PTHrP with inappropriately normal 1,25(OH)2D, lymphoma and granulomatous diseases were considered. PET/CT was negative. She stopped breastfeeding and was given IV zoledronic acid 4 mg. Her back pain improved and 3 weeks later Ca was 9.0 mg/dL.

Discussion: We present a case of postpartum osteoporosis with hypercalcemia, high bone turnover, suppressed PTH and PTHrP and inappropriately normal 1,25(OH)2D consistent with upregulation of 1α-hydroxylation independent of PTH and PTHrP.

Treatment with intravenous ibandronate does not affect renal function - a 24 months prospective controlled trial on renal function. Doris Wagner*[1], Georg Werkgartner[2], Hans Jörg Mischinger[2], Alexander R Rosenkranz[3], Karl Fenzl[4], Astrid Fahrleitner-Pammer[1]. [1]Medical University of Graz, Austria, [2]Department of Surgery, Divison of General Surgery, Medical University of Graz, Austria, [3]Department of Internal Medicine, Division for Nephrology, Medical University of Graz, Austria, [4]Roche Austria GMBH, Austria

Introduction: Renal safety of intravenous qualterly ibandronate (IBN) treatment has been questioned. Only measured glomerular filtration rates depict renal function accurately. This study aimed to investigate a potential effect of IBN on the measured GFR.

Patients and Methods: 79 patients who all suffered from osteoporosis (OPO) related to a past liver transplantation - were divided into two groups and enrolled into the study at the timepoint of IBN administration. The TRT group (patients with OPO) received 3 mg IBN, calcium and Vitamin D supplementation CTR group (patients without OPO) calcium and Vitamin D supplementation. The GFR was measured using the Inulin clearance (IC) at the start of IBN as well as 12 and 24 months thereafter. Spine X rays, BMD measurement at the distal radius and the femoral neck and serum markers were performed for group assignment and 12 and 24 months thereafter.

Results: The median IC was 65.4 mL/min1.73m2 in TRT and 66.7 mL/min1.73m2 in CTR patients at baseline. The IC decreased throughout the study period (CTR patients 12 months: -4.2 mL/min1.73m2, TRT patients 24 months: -6.7 mL/min1.73m2; CTR patients 12 months: -5.3 mL/min1.73m2, TRT patients 24 months: -7.5 mL/min1.73m2) in both groups but did not differ in between. Serum cross laps as well as TRAP 5b decreased significantly in TRT patients (-51% sCTX, -34% TRAP 5b, p vs baseline: 0.0001) but increased in CTR patients (+11% sCTX, + 15% TRAP 5b, p vs baseline: 0.05). T scores at the femoral neck and the distal radius increased in TRT patients (overall increase: + 16% femoral neck, + 27% distal radius, p vs baseline both : 0.001).

Conclusion: Renal function did not differ significantly between patients with and without IBN throughout the study so IBN treatment seems to be safe for OLT patients.

Pharmacogenomics Of Bisphosphonate Treatment In Paget's Disease Of Bone: Retrospective And Prospective Analysis. Daniela Merlotti*[1], Fernando Gianfrancesco[2], Domenico Rendina[3], Riccardo Muscariello[3], Teresa Esposito[2], Beatrice Franci[4], Barbara Lucani[4], Stella Campagna[4], Laura Cresti[4], Pasquale Strazzullo[3], Ranuccio Nuti[1], Luigi Gennari[1]. [1]University of Siena, Italy, [2]Institute of Genetics & Biophysics - National Research Council of Italy, Italy, [3]Department.of Clinical & Experimental Medicine, University of Naples Federico II, Italy, [4]Dept. Medicine Surgery & Neurosciences University of Siena, Italy

Mutations in *SQSTM1* gene have been identified in up to 15-20% of patients with Paget's disease of bone (PDB). In a preliminary analysis we evidenced a reduced response to iv pamidronate in *SQSTM1* mutation carriers (*SQSTM1*+). In order to confirm and extend this observation, we investigated the effect of *SQSTM1* mutation and polymorphisms in 3 genes associated with PDB (*TNFRSF11A* rs1805034; *OPTN* rs1561570; *TNFRSF11B* rs2073617) on the response to the treatment with different bisphosphonates. As first, genetic analysis was performed retrospectively in 335 patients involved in previous studies with clodronate (CLN) 1500 mg every 6 months (n=84), pamidronate (PAM) 60mg iv every 6 months (n=75), risedronate (RIS) 30 mg/day for 2 months (n=57), neridronate (NER) 200mg im o iv (n=61) and zoledronic acid (ZOL) 4mg or 5 mg iv (n=48). Overall, *SQSTM1*+ patients had an increased disease severity and showed a reduced response to CLN or PAM than *SQSTM1*- patients (biochemical response at 6 months 37% vs 82% with CLN and 31% vs 60% with PAM, $p<0.001$, respectively in *SQSTM1*+ vs *SQSTM1*-). Despite carriers of *TNFRSF11A* rs1805034 CC genotype had increased PDB severity, there was no association between this genotype and the response to any treatment. Conversely, there was an increased prevalence of TT carriers of rs1561570 (*OPTN*) in nonresponders than responders to CLN. Normalization after the first CLN course was achieved in 69% of CC vs 42% of TT carriers despite no significant differences in disease extension or activity, and this effect increased when *SQSTM1*- patients were considered. A similar but not significant trend was observed for PAM. Conversely, RIS, ZOL and NER were effective in most patients without any association with *SQSTM1* or other gene polymorphisms. We then designed a prospective analysis in patients treated with iv ZOL 5mg (n=130) or NER 200mg (n=70) and followed-up for more than 3 years (range 3-6 yrs). After the infusion no treatment was given except in case of relapse. Even though most patients achieved biochemical remission after the first NER course for more than 12 months, there was a trend for an earlier relapse in *SQSTM1*+ vs *SQSTM1*-patients (22 ± 11 vs 36 ± 15 months, $p=0.07$). Conversely most ZOL treated patients achieved biochemical remission independent of *SQSTM1* mutation and did not need retreatment. These results suggest that PDB patients with *SQSTM1* mutation may require a more aggressive treatment regimen for long-term disease remission.

Glucocorticoid Receptor in Inflammatory Bone Disease and Osteoporosis: New Mechanisms of Action and new functional relevant Target Genes identified. Ulrike Baschant[1], Stephanie Wittig-Blaich[1], Mubashir Ahmad[1], Jeanette Knoll[2], Torsten Kroll[2], Stephan Culemann[2], Alexander Rauch[2], Gerhard Krönke[3], Markus Seibel[4], Hong Zhou[4], Aspasia Ploubidou[2], Jan Tuckermann*[5]. Clinic III, University of Erlangen, Germany, [4]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, [5]University of Ulm, Germany

Glucocorticoids (GCs) belong to the standard therapy of rheumatoid arthritis (RA), a severe auto-immune inflammatory bone disease. One major side effect of GCs affects the bone itself leading to GC induced osteoporosis (GIO), the most prevalent form of secondary osteoporosis.

GCs act via the glucocorticoid receptor (GR) that can alter gene expression by binding as a dimer to GC response elements in the promoter region of target genes or by interacting with and thus interfering with other transcription factors as a monomer. Using conditional and functional selective targeted mutations of the GR in mice, we previously established that dimerization of the GR in IL-17 producing T cells is indispensable for the anti-inflammatory effect in antigen-induced arthritis (PNAS 2011 108:19317). Now, we demonstrate that, surprisingly, in the K/BxN serum induced arthritis model GR dimer dependent gene regulation in non-hematopoietic cells (presumably in mesenchymal cells) is critical for the anti-inflammatory effects of GCs. Thus, for immunosuppression of arthritis GR dimerization is required in distinct cell types, which are of hematopoietic and mesenchymal origin.

In a model of GIO we previously showed that unexpectedly interaction of the GR monomer with AP-1, but not NF-kB in osteoblasts is decisive for bone loss (Cell Metabolism 2010 11:517).

Here, we report the identification of novel GR monomer-regulated target genes, employing a micro-array and functional genomics combined approach. In addition we describe a screening platform for the search for new GR agonist-derivatives not affecting osteoblast function.

Taken together, our approach gives new insights into GC action on arthritis and bone integrity that can be translated into new concepts for anti-inflammatory therapies preventing GIO.

Calmodulin Mediates 1α,25(OH)$_2$D$_3$-Induced Activation of CaMKII in Osteoblasts. Sharon Hyzy[1], Maryam Doroudi*[2], Barbara Boyan[3], Zvi Schwartz[2]. [1]Georgia Tech, USA, [2]Georgia Institute of Technology, USA, [3]Virginia Commonwealth University, USA

Objective: Vitamin D plays an important role in maintaining bone and mineral homeostasis. 1α,25-dihydroxyvitamin D3 [1,25D3], an active metabolite of vitamin D3, is known to exert its rapid membrane-mediated effects via receptor (Pdia3) in caveolae, activating phospholipase-A2 (PLA2)-activating protein (PLAA) and Ca2+/calmodulin-dependent protein kinase II (CaMKII) and stimulating PLA2, resulting in prostaglandin-E2 (PGE2) release and PKC activation. We previously reported that PLAA is required for mediating the signal from Pdia3 receptor to cytosolic PLA2 (cPLA2). Further investigations confirmed the binding of PLAA to Pdia3 within 9 minutes after 1,25D3 treatment indicating that PLAA mediates the signal from Pdia3 receptor complex via a direct protein interaction. However, it is not clear how PLAA mediates the signal from caveolae to CaMKII, and signaling molecules linking PLAA to CaMKII remain to be identified. Previous reports suggested melittin, which has a region of homology with PLAA, binds tightly to calmodulin (CaM) in the presence of calcium. CaM is also a known regulator of CaMKII activation. The aim of this study was to evaluate if and how calmodulin mediates 1,25D3-activated CaMKII. Method: MC3T3-E1 osteoblasts were treated with 1,25D3 for 9 minutes. Whole cell lysates (WCL) were collected for plasma membrane fractionation and immunoprecipitation experiments. To investigate the effects of CaM inhibition on 1,25D3 membrane-mediated pathway, cells were pretreated with W-7, a CaM-specific inhibitor, for 30 minutes and next treated with 1,25D3 for 9 minutes. Activities of PKC, CaMKII and PGE2 release were measured. Results: Western blots of the plasma membrane fractions indicated that CaM was present in the plasma membranes with its greatest concentration in fraction 3, which represents caveolae microdomains. Intensity analysis of CaM bands indicated that 1,25D3 treatment reduced the abundance of CaM in caveolae. CaM was immunoprecipitated with PLAA protein complex from WCL treated with 1,25D3. No protein interactions between Pdia3/CaM and Cav-1/CaM were detected. CaM-specific inhibitors reduced CaMKII and PKC activities and PGE2 release in response to 1,25D3 treatment in a dose-dependent manner. Conclusion: Taken together, the results suggest that CaM plays a crucial role in mediating 1,25D3 rapid actions. CaM serves as a linking protein mediating the signal from PLAA protein complex to CaMKII. Supported by the Price Gilbert, Jr. Foundation.

Effect of Combined Calcium and Vitamin D Supplementation on Insulin Secretion and Insulin Sensitivity in Vitamin D-deficient Adults at High Risk of Type 2 Diabetes. Claudia Gagnon*[1], Robin Daly[2], André Carpentier[3], Zhong X. Lu[4], Catherine Shore-Lorenti[5], Ken Sikaris[4], Sonia Jean[6], Peter Ebeling[7]. [1]Centre hospitalier universitaire de Québec, Université Laval, Canada, [2]Centre for Physical Activity & Nutrition Research, Deakin University, Australia, [3]Department of Medicine, University of Sherbrooke, Canada, [4]Melbourne Pathology, Australia, [5]Department of Medicine, NorthWest Academic Centre, The University of Melbourne, Western Health, Australia, [6]INSTITUT NATIONAL DE SANTÉ PUBLIQUE DU QUÉBEC, Canada, [7]The University of Melbourne, Australia

Epidemiological data indicate that low serum 25-hydroxyvitamin D (25OHD) levels and calcium intake increase the risk of developing type 2 diabetes (T2D). This 6-month double-blinded placebo-controlled trial examined whether vitamin D and calcium supplementation improves insulin sensitivity and secretion as well as cytokines, adiponectin, osteocalcin, lipids and blood pressure in adults with low vitamin D status (serum 25OHD ≤22 ng/mL) who were at high risk of T2D (with prediabetes or an AUSDRISK score ⩾15). Ninety-five adults were randomized to receive combined calcium carbonate (1,200 mg) and cholecalciferol (2,000-6,000 IU to target 25OHD >30 ng/mL) daily or matching placebo pills. A 75g 2-h OGTT with repeated measures of glucose, insulin and C-peptide was performed at 0 and 6 months. Indices of insulin sensitivity (HOMA2%S; Matsuda index) and insulin secretion (insulinogenic index using C-peptide) were calculated. The lipid profile, CRP, TNF-α, IL-6, adiponectin, total and uncarboxylated osteocalcin were also assessed at 0 and 6 months. Analyses were performed on the 80 participants who completed the baseline and final visits (treatment n=35; placebo n=45). Participants were middle-aged adults (mean age 55 years; 69% women; 69% European background) at high risk of T2D (mean BMI 31 kg/m^2; 60% with impaired glucose tolerance). Supplement compliance was similar between the groups for calcium (treatment=81%; placebo=77%) and vitamin D (treatment=88%; placebo=86%). Mean baseline 25OHD was 18 ng/mL and increased to 36 ng/mL in the treatment group but remained unchanged in controls (16 ng/mL). Overall, 91% of participants in the treatment group achieved a 25OHD >30 ng/mL at 6 months. There were no significant changes in insulin sensitivity assessed by HOMA2%S or by Matsuda index, or insulin secretion, in either the treatment and placebo groups (Table 1). Moreover, treatment did not affect blood pressure, lipids, cytokines, adiponectin, total or uncarboxylated osteocalcin levels. These results remained unchanged after adjustment for potential confounders. No participant developed hypercalcemia but 6 participants in the treatment and 3 in the placebo group developed hypercalciuria (>300 mg/d). In conclusion, high-dose vitamin D and calcium supplementation to a target 25OHD level of >30 ng/mL for 6 months did not change OGTT-derived measures of insulin secretion and sensitivity in adults with low serum 25OHD at high risk of T2D.

Table 1. Change in insulin sensitivity and insulin secretion after 6 months of calcium and vitamin D supplementation or placebo.

	Treatment (n=35)	Placebo (n=45)	P value*	Adj. P value**
HOMA2%S				
Baseline	54 (43, 83)	44 (30, 82)	0.07	
6 months	56 (40, 74)	43 (30, 74)	0.09	
Change	-2 (-12, 8)	-3 (-10, 5)	0.75	0.61
Matsuda Index				
Baseline	44 (33, 68)	36 (23, 57)		
6 months	40 (30, 66)	35 (24, 46)		
Change	1 (-8, 9)	-1 (-8, 6)	0.72	0.34

The Metabolite 24R,25-dihydroxyvitamin D Plays a Role in Primary Human Bone Cell Differentiation. Karen Van Der Meijden*, Paul Lips, Nathalie Bravenboer. VU University Medical Center, The Netherlands

Vitamin D plays an essential role in human skeletal health and mineral homeostasis. Human bone cells are able to synthesize the active metabolite 1,25-dihydroxyvitamin D (1,25(OH)$_2$D) from its precursor 25-hydroxyvitamin D (25(OH)D) by the enzyme 1α-hydroxylase (CYP27B1). Locally synthesized 1,25(OH)$_2$D might affect bone cell differentiation in an autocrine or paracrine way. In vitro, both 1,25(OH)$_2$D and 25(OH)D can stimulate bone cell differentiation, although the actions of 25(OH)D probably occur through hydroxylation into 1,25(OH)$_2$D. On the other hand, human bone cells may also convert 25(OH)D to 24R,25(OH)$_2$D as bone cells express CYP24. Therefore the aim of this study was to examine whether the actions of 25(OH)D occur via hydroxylation into 1,25(OH)$_2$D and to investigate whether 24R,25(OH)$_2$D can affect bone cell differentiation as well.

Primary human bone cells, obtained as outgrowth of bone trabeculae from the iliac crest, were electroporated with either CYP27B1-silencing RNA or non-targeting RNA. The reduction of CYP27B1 mRNA was determined after 48 hours using RT-qPCR. The electroporated cells were cultured in the presence of 0 or 400 nM 25(OH)D for 3 days and mRNA expression of alkaline phosphatase and osteocalcin was determined as markers for osteoblast differentiation. Primary human bone cells were also cultured in the presence of 0, 100, 200 or 400 nM 24R,25(OH)$_2$D for 3 days and mRNA expression of alkaline phosphatase, collagen type 1, osteocalcin, osteopontin, as well as CYP27B1, VDR and CYP24 was determined.

CYP27B1-silencing RNA reduced the mRNA expression for 60% compared to the non-targeting cells. The alkaline phosphatase and osteocalcin mRNA expression was increased in response to 25(OH)D both in the CYP27B1-silenced cells as in the non-targeting cells. The metabolite 24R,25(OH)$_2$D stimulated the mRNA expression of alkaline phosphatase, osteocalcin and osteopontin significantly, although collagen type 1 mRNA did not respond to 24R,25(OH)$_2$D. Furthermore, 24R,25(OH)$_2$D significantly increased CYP24 mRNA expression. CYP27B1 and VDR mRNA expression were not affected by 24R,25(OH)$_2$D.

These results suggest that the actions of 25(OH)D on osteoblast differentiation not only occur via hydroxylation into 1,25(OH)$_2$D. The metabolite 24R,25(OH)$_2$D may play a role in bone cell differentiation as well by regulating gene expression. In addition, this metabolite is also able to stimulate its own synthesis leading to higher local availability of 24R,25(OH)$_2$D.

Thyroid hormones decrease plasma 1α,25-dihydroxyvitamin D levels through directly and indirectly transrepression of the renal 25-hydroxyvitamin D_3 1α-hydroxylase gene (CYP27B1). Hironori Yamamoto*[1], Mina Kozai[2], Tomohiro Kagawa[2], Nagakatsu Harada[2], Shoko Ikeda[2], Otoki Nakahashi[2], Yutaka Taketani[2], Ken-ichi Takeyama[3], Shigeaki Kato[4], Eiji Takeda[5]. [1]University of Jin-ai, Japan, [2]University of Tokushima, Japan, [3]University of Harvard, USA, [4]Fukushima Medical University, Japan, [5]University of Tokushima School of Medicine, Japan

Hyperthyroid patients have been reported to have low levels of plasma 1α,25-dihydroxyvitamin D ($1,25(OH)_2D$), however, its detailed mechanism is still poorly understood. The present study determined whether renal 25-hydroxyvitamin D-1α-hydroxylase (CYP27B1) gene expression was negatively regulated by thyroid hormones. 3,3',5-tri-iodothyronine (T_3)-induced hyperthyroid mice showed marked decreases in plasma $1,25(OH)_2D$ levels and in renal expression of CYP27B1 mRNA. In addition, we observed that T_3 administration significantly decreased plasma $1,25(OH)_2D$ and renal CYP27B1 mRNA levels that were increased by low calcium diet, and induced hypocalcemia in mice fed a low calcium diet. Promoter analysis revealed that T_3 decreases the basal transcriptional activity of the CYP27B1 gene through thyroid hormone receptors (TRα, TRβ1) and the retinoid X receptor α (RXRα) in renal proximal tubular cells. Interestingly, we identified an everted repeat negative thyroid hormone response element (1α-nTRE) overlapping the sterol response element (SRE) and the TATA-box -50 to -20 bp from the human CYP27B1 gene transcription start site. We also established that CYP27B1 gene transcription is positively and negatively regulated by SRE-binding proteins (SREBPs) and T_3-bound TRβ1/RXRα via the 1α-nTRE. Furthermore, the renal SREBP-1c mRNA expression was down-regulated by T_3. These results suggest that transcriptional repression of the CYP27B1 gene by T_3-bound TRs/RXRα and SREBPs, acting through the 1α-nTRE, results in decreased renal CYP27B1 expression and plasma 1,25(OH)2D) levels.

Role of the stathmin gene in development of prostate cancer bone metastasis. Rongrong Zhang*[1], Asim Abdel-Mageed[1], Babatunde Oyajobi[2], Hong-Wen Deng[1], Ming Zhao[1]. [1]Tulane University, USA, [2]University of Texas Health Science Center at San Antonio, USA

Prostate cancer (PCa) has a propensity to metastasize to the skeleton and causes osteosclerotic and osteolytic lesions. In the bone microenvironment, PCa cells which possess osteoblast and osteoclast properties interact with bone remodeling cells. However, the molecular mechanisms responsible for the role of bone microenvironment in development of PCa metastasis are yet to be elucidated. Recently, we have identified stathmin, a microtubule targeting protein, as a powerful regulator of bone remodeling. Null for stathmin in mice resulted in a skeletal phenotype attributed to dysfunction of both osteoblasts and osteoclasts. The stathmin gene (oncoprotein 18) is associated with a number of malignancies, including PCa. Therefore, we hypothesize that deficiency of stathmin will diminish PCa metastatic bone lesions by altering osteoblastic and osteoclastic bone remodeling in the bone microenvironment. To test the hypothesis, first, we generated immunodeficient stathmin knockout (KO) mice by crossbreeding the stathmin KO mice with immunodeficient Rag2 null mice in which both T and B cell functions are depleted. Then, we performed tumor inoculation studies on these mice. PCa C4-2B cells, which are capable of causing both osteolyitc and osteoslerotic metastasis, were inoculated by intra-cardiac injection into stathmin/Rag2 double knockout (dKO) mice ($STMN^{-/-};Rag2^{-/-}$), control mice ($STMN^{+/+};Rag2^{-/-}$), and non-immunodeficient wild-type mice ($STMN^{+/+};Rag2^{+/+}$). X-ray and micro-computed tomography (μCT) scanning 6 weeks after tumor inoculation showed that while all wild-type $STMN^{+/+};Rag2^{+/+}$ mice did not develop any bone metastasis, all $STMN^{-/-};Rag2^{-/-}$ and $STMN^{+/+};Rag2^{-/-}$ mice developed bone metastasis as evidenced by both osteolyitc lesions in metaphyseal regions of both the tibia and femur and osteoslerotic lesions on cortical bone of tibia. However, compared to $STMN^{+/+};Rag2^{-/-}$ control mice, stathmin deficiency in $STMN^{-/-};Rag2^{-/-}$ dKO mice substantially reduced both osteolyitc and osteoslerotic metastases. Histology provides further evidence for bone metastasis in these mice. These results demonstrate that stathmin plays a critical role in development and progression of PCa bone metastasis, suggesting that targeting the stathmin gene, which not only inhibits tumor growth but also alters the bone microenvironment, could be a promising therapeutic approach for PCa bone metastasis.

Osteosarcoma Cells modulate Bone Microenvironment via Extracellular Membrane Vesicle Biogenesis and Calcium Signaling Pathways. Rama Garimella*[1], Laurie Washington[2], Janalee Isaacson[3], Ossama Tawfik[4], Raymond Perez[5], Peter Rowe[1], Julian Vallejo[3], Madoka Spence[3], Marco Brotto[6]. [1]University of Kansas Medical Center, USA, [2]Division of Medical Clinical Oncology, Department of Internal Medicine, The University of Kansas Medical Center, USA, [3]Muscle Biology Research Group, School of Nursing & Health Studies, University of Missouri-Kansas City, USA, [4]Department of Pathology, The University of Kansas Medical Center, USA, [5]Division of Medical Clinical Oncology, Department of Internal Medicine, The University of Kansas Cancer Center, The University of Kansas, USA, [6]University of Missouri - Kansas City, USA

In recent years, the role of exosomes or nano-sized extra-cellular membrane vesicles (EMVs) as modulators of tumor microenvironment is a topic of emerging interest in cancer-bone interaction. The role of EMVs in osteosarcoma (OS), a highly aggressive bone tumor is not known. It is our hypothesis that calcium signaling in the OS bone microenvironment induces cytoskeleton rearrangements in tumor cells, stimulates Ca-dependent EMV biogenesis, and modulates OS invasion via secretion of EMV-derived growth factors and enzymes. The long term goal of the study is to investigate the role of exosomes or EMVs in OS pathobiology. We had previously demonstrated the presence of EMVs in the preclinical bioluminescent osteosarcoma orthotopic mouse (BOOM) model. In the current study, we have successfully isolated EMVs from the conditioned media of 143B human osteosarcoma cell cultures using differential ultracentrifugation, demonstrating that OS cells shed extra-cellular membrane vesicles. Nano-particle tracking analysis of 143B-EMVs indicated their size range to be 50-200 nm. Transmission electron microscopy confirmed the ultra-structure of 143B-EMVs, and detected the presence of both vesicular and perivesicular hydroxyapatite like-mineral, and multivesicular bodies (MVBs). Detection of MVBs and presence of exosome-specific biomarker CD-9 suggest that 143B-derived EMV preparations include exosomes. Biochemical characterization of 143B-EMV cargo demonstrated the presence of MMP1 and MMP13. To our best knowledge, the expression of MMP1 and MMP13 in 143B-derived EMVs is a novel finding. The role of calcium influx in vesicle biogenesis and cancer progression is a subject of immense interest. In this study, we observed that 143B cells actively mobilize calcium in the presence of ionomycin in a dose dependent manner, and cause cytoskeleton rearrangement as detected by calcium fluorescent imaging. Pre-treatment with 10μM forskolin, an adenylate cyclase activator increased calcium mobilization of 143B OS cells and induced cytoskeleton rearrangements leading to vesicular biogenesis. These findings suggest that the calcium response of osteosarcoma cells is sensitized by forskolin, and EMVs are modulated by adenylate cyclase activation. In conclusion, our results suggest a novel role for cAMP/calcium dependent pathway as a candidate mechanism for EMV biogenesis in the OS bone microenvironment.

The Potential Role of JAB1 in Osteosarcoma Pathogenesis. Lindsay Bashur*, Guang Zhou. Case Western Reserve University, USA

Osteosarcoma is the most common malignant primary bone tumor. Osteosarcoma patients with metastases have a survival rate of only 25%. Therefore, a greater understanding of the pathogenesis of osteosarcoma is needed for better diagnosis and treatment. A novel player in tumorigenesis that has emerged is the transcriptional cofactor JAB1 (also named CSN5), through its effects on cell proliferation, differentiation, survival, and cell cycle progression. Our laboratory has recently shown that JAB1 plays critical roles in the successive steps of skeletogenesis *in vivo*. JAB1 has been shown to be over-expressed in different types of cancers, including breast and lung, but has not been studied in bone cancer. Thus, the goal of this study is to determine the potential role of JAB1 in the pathogenesis of osteosarcoma. We first showed, by immunohistochemistry, that JAB1 was highly expressed in twelve osteosarcoma patients' biopsy samples. Next, to determine whether down-regulating JAB1 expression in osteosarcoma reduces tumorigenesis, we knocked down JAB1 expression in the 143B highly metastatic osteosarcoma cell line, using shRNA lentiviral vectors. The *JAB1* knockdown cells exhibited significantly reduced cell proliferation, colony formation, and motility compared with the control cells. In addition, a real-time RT-PCR array of the tumorigenesis pathway suggests that *JAB1* knockdown cells have increased differentiation with elevated *RUNX2* expression. Therefore, these results suggest that down-regulating JAB1 expression in osteosarcoma might reduce tumorigenesis. We will determine whether the down-regulation of JAB1 in 143B cells reduces tumorigenesis *in vivo* in xenograft experiments. On the other hand, to study the consequence of JAB1 over-expression *in vivo*, we have generated *Col1a1-JAB1* transgenic mouse lines using a well-characterized 2.3kb *Col1a1* promoter to over-express JAB1 in osteoblasts specifically. Previous mouse genetic studies have shown that p53 is a critical factor in the development of osteosarcoma, and that JAB1 is a negative regulator of p53 activity in other cancers. Therefore, we will determine whether increased *JAB1* expression promotes bone tumorigenesis *in vivo* in a p53-dependent manner using this novel *Col1a1-JAB1* transgenic mouse model. Ultimately, new therapies based on controlling the JAB1-mediated tumorigenesis will open new avenues for treating osteosarcoma and other skeletal malignancies.

Tumor Suppressive Function of MicroRNA34c in Osteosarcoma. Yangjin Bae*[1], Huan-Chang Zeng[1], Jianning Tao[1], Lisa Wang[1], Jason Yustein[1], Brendan Lee[2]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine & Howard Hughes Medical Institute, USA

MicroRNAs (miRNAs) have been implicated in diverse biological roles including development, cell proliferation, apoptosis, metabolic stress and tumorogenesis.The miR-34 family, tumor suppressive miRNA, is evolutionally conserved and directly regulated by p53 in response to DNA damage and oncogenic stress, inducing apoptosis and cell-cycle arrest. Our recent study of osteoblast-specific gain of function *miR-34c* mice (*Col1a1 2.3 kb-miR34c*) demonstrated a critical role for *miR-34c* during bone development and homeostasis by targeting multiple components of the Notch signaling pathway. We and others have shown that an osteoblast-specific Notch gain of function mouse model can stimulate proliferation of immature osteoblasts while inhibiting their differentiation into mature osteoblasts. Furthermore, this gain of function phenotype leads to the development of osteoblastic tumors and indeed, Notch signaling was also up-regulated in human osteosarcoma (OS) samples. Consistent with this observation, our transcriptional profiling of OS from p53 +/- mice exhibited elevated expression of Notch signaling, which leads to the proliferative and metastatic potential of OS. The genetic and epigenetic alterations in OS lead to a decreased miR-34 expression levels. *Here, we hypothesize that the miR-34 family plays a critical role as a negative regulatior of Notch signaling in osteoblasts and exhibits a potential mechanism to modulate the proliferative effect of Notch in the committed osteoblast progenitors. Hence, perturbation of the crosstalk between miR-34s, p53, and Notch may contribute to the pathogenesis of OS.* To examine whether GOF *miR-34c* can affect OS formation and progression, *Col1a1 2.3kb-miR34c* was crossed with *Col1a1 2.3kb Cre/+; p53 $^{f/f}$* (osteoblast-specific loss of *p53*). We assessed survival, hind limb paralysis, tumor progression and metastases of these mice. Also xenografts was performed using the hOS cell line 143b (p53-/-) stably expressing *miR-34c* (143b-34c) with proper controls to examin OS progression *in vivo*. In our genetic mouse model, we found that *Col1a1 2.3kb-miR34c*; *Col1a1 2.3kb Cre/+; p53 $^{f/f}$* mice significantly increased survival compared to *Col1a1 2.3kb Cre/+; p53 $^{f/f}$* mice. Furthermore, xenograft study showed regression of tumor growth in 143b-34c compared to 143b-controls. Overall, these results suggest that miR-34c acts as a tumor suppressor in osteosarcoma. The underlying molecular mechanism of miR-34c in OS is currently being pursued.

Aged related Gait Disturbance in Fibroblast Growth Factor 2 knockout mice. Toru Nishikawa*[1], Collin Homer-Bouthiette[2], Liping Xiao[2], Morgan Carlson[2], Marja Marie Hurley[3]. [1]Aichi Gakuin University, Japan, [2]University of Connecticut Health Center, USA, [3]University of Connecticut Health Center School of Medicine, USA

Sarcopenia is associated with a progressive degenerative loss of skeletal muscle mass, quality and strength. These symptoms are particularly exacerbated in frail elderly patients where sarcopenia becomes rapidly accelerated for causes still unknown. Fibroblast growth factor 2 (FGF2) plays a critical role in the recruitment of muscle stem cells (satellite cells) for adult regenerative myogenesis. Disruption of the Fgf2 gene in mice results in accelerated age-related bone loss however, the impact of Fgf2 knockout on age-related muscle function has not been reported. We examined whether aging is associated with changes in Fgf2 expression in muscle, and whether disruption of the Fgf2 gene in mice results in phenotypic differences between "resting" and ''exercised'' muscle with age. *Approach:* Fgf2 mRNA and protein levels were determined from tibialis anterior and gastrocnemius hindlimb skeletal muscles harvested from young (2 months) and aged (18 months) wild-type mice. Since previous studies reported that FGF2 and FGF6 have some common properties to support myogenesis, Fgf6 mRNA expression was also determined in muscles from young and aged WT and Fgf2KO mice. To assess whether knockout of the Fgf2 gene resulted in gait disturbances, ventral plate videography (DigiGait) analysis was performed whereby young and aged WT and Fgf2KO mice walked on a transparent treadmill belt. *Results:* A significant decrease in Fgf2 mRNA and protein was evident in muscles from aged WT mice compared with young. Interestingly there was a significant increase in Fgf6 mRNA expression in young Fgf2KO compared with young WT. Gait analysis revealed that hind limb propulsion duration (an indicator of muscle strength) was similar in young WT and Fgf2KO mice, but significantly shorter in aged KO mice (105.6 $\pm$ 57.9 ms) compared with WT littermates (189.6$\pm$65.5 ms $p<0.05$). Additionally, hindpaw eversion (an indicator of muscle weakness) was similar in young WT and Fgf2KO mice, but significantly greater in aged KO mice (12.6$\pm$3.0 ms) compared with WT (9.3$\pm$4.5 ms $p<0.05$). Braking duration (an indicator of ground reaction forces) was similar between young and old WT and KO mice. Since no gait dysfunction was observed between young WT and young Fgf2KO mice, we hypothesize that FGF6 may be able to compensate for FGF2 loss in young, but not aged mice. We conclude that knockout of Fgf2 or age-associated decreases likely contribute to impaired muscle function and the onset of sarcopenia phenotypes.

Age-related switch of bone mass in p47^{phox} deficient mice through increased inflammatory milieu in bone. Jin-Ran Chen*[1], Oxana P. Lazarenko[2], Jian Zhang[2], Kelly Mercer[2], Michael L. Blackburn[2], Thomas M. Badger[2], Martin J. J. Ronis[2]. [1]University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, [2]University of Arkansas for Medical Sciences & Arkansas Children's Nutrition Center, Little Rock, AR 72202, USA

Bone remodeling is age-dependently regulated and changes dramatically during the course of development. Excessive accumulation of reactive oxygen species (ROS), including superoxide, hydrogen peroxide, and hydroxyl radicals, has been suggested to be the leading cause of many inflammatory and degenerative diseases and underlie the effects of ageing. In contrast, how physiological levels of ROS regulate bone remodeling at each life stage remains unknown. In addition to the mitochondrial electron transport chain, the NADPH oxidase (NOX) complex produces a large amount of ROS in the plasma membrane and cytosol. Here, we utilized a p47phox knockout mouse model in which NOX2 activity is lost as the result of loss of an essential cytosolic co-activator to characterize the bone phenotype at both 6 weeks and 24 months of age in male mice. Using peripheral quantitative CT (pQCT), μCT and femur three point bending analyses, in p47phox -/- mice at 6 weeks of age, we found that bone mass (including both trabecular and cortical bone mineral density and bone mineral content), bone volume, trabecular number, and bone strength were all significantly higher compared to wild type mice ($p< 0.05$). On the other hand, in p47phox -/- mice at 24 months of age, bone mass, bone volume and trabecular number were all significantly lower ($p<0.05$), while bone trabecular separation was higher compared to their age-matched wild type controls. Flow cytometric assay showed decreased ROS generation in bone marrow cells from both young and aged p47phox -/- mice compared with their respective controls. Serum bone formation marker alkaline phosphatase was higher in 6-week-old p47phox -/- mice compared to their wild type controls. Serum bone resorption marker TRAP 5b is higher in 24-month-old p47phox -/- mice compared to their wild type controls. While we did not observe any differences in proinflammatory cytokines such as IL6, TNFalpha, RANKL and MMP9 expression in 6-week-old p47phox -/- mice compared to wild type mice, these cytokines were all significantly higher in 24-month-old p47phox -/- mice compared to their wild type controls. These data indicate that the observed age-related switch of bone mass in p47phox deficient mice occurs through an increased inflammatory milieu in bone and that NOX2-dependent physiological ROS signaling suppresses inflammation in ageing. Supported in part by ARS CRIS #6251-51000-005-03S and R01 AA18282 (MJJR).

Bmi1 Plays A Critical Role in Preventing Bone Aging by Inhibiting Oxidative Stress. Qian Wang*[1], Rong Wang[1], Jianliang Jin[2], David Goltzman[3], Dengshun Miao[4]. [1]Nanjing Medical University, China, [2]Nanjing Medical University, Peoples Republic of China, [3]McGill University, Canada, [4]Nunjing Medical University, Peoples Republic of China

We previously demonstrated that Bmi1 deficiency results in premature osteoporosis. In the present study we examined whether the premature osteoporosis caused by Bmi1 deficiency was associated with oxidative stress-induced bone aging. We found that hydrogen peroxide concentration and the content of the lipid peroxidation product malondialdehyde (MDA) were both increased significantly in the bone tissue of 5-week-old Bmi1$^{-/-}$ mice compared with that of WT mice. We next treated 3-week-old Bmi1$^{-/-}$ mice with the antioxidant N-acetylcysteine (NAC, 1mg/ml) in their drinking water, and compared their phenotype with the phenotype of untreated Bmi1$^{-/-}$ and WT mice. NAC supplementation of Bmi1$^{-/-}$ mice resulted in a longer lifespan and increased body weight, although Bmi1$^{-/-}$ mice were not normalized. After 2 weeks, NAC-treated Bmi1$^{-/-}$ mice, when compared to untreated Bmi1$^{-/-}$ mice, displayed significantly increased bone mineral density, cortical and trabecular bone volume, osteoblast numbers, ALP and type I collagen positive areas and mineral apposition rate. The number of bone marrow adipocytes, the percentages of 8-hydroxy-2-deoxyguanosine positive or β-galactosidase positive osteocytes and the protein expression levels of PPARγ, γ-H2AX and p16^{INK4a} were reduced significantly in NAC-treated Bmi1$^{-/-}$ mice compared to untreated Bmi1$^{-/-}$ mice. Simultaneously, hydrogen peroxide concentration and MDA content were reduced significantly, whereas total antioxidant capacity, glutathione concentration, and superoxide dismutase protein and activity levels were increased significantly in NAC-treated Bmi1$^{-/-}$ mice compared to untreated Bmi1$^{-/-}$ mice. The number of total CFU-f and ALP^{+} CFU-f, the expression levels of Runx2 and cell proliferation were increased significantly, while oil Red positive cells and the percentage of apoptotic cells and the expression levels of PPARγ and p16INK4a were reduced significantly. Reactive oxygen species levels were reduced significantly, whereas the gene expression levels of glutathione reductase, glutathione peroxidase 1 and 4, and thioredoxin were up-regulated in bone marrow mesenchymal stem cell ex vivo cultures from NAC-treated Bmi1$^{-/-}$ mice compared to these from untreated Bmi1$^{-/-}$ mice. Nevertheless, all of the above parameters did not reach the normal levels of WT mice. These studies therefore indicate that Bmi1 plays a critical role in preventing bone aging by inhibiting oxidative stress.

Bone Breaks and Heart Aches- the Association between Bone Mass and Vascular Function. Lynae Hanks*[1], Ambika Ashraf[1], Barbara Gower[1], Jessica Alvarez[2], Krista Casazza[3]. [1]University of Alabama at Birmingham, USA, [2]Emory University, USA, [3]UAB, USA

An association between osteoporosis and cardiovascular disease has become apparent, indicating a relationship between bone degeneration and vascular dysfunction– particularly among the elderly and individuals with cardiometabolic abnormalities (i.e., hypertension). Little is known about early coincidental changes in bone and arterial properties, particularly in the context of bone anabolism (as in puberty) and state of relative equilibrium (early adulthood). The objective of this study was to determine if intermediate endpoints of vascular function (i.e. endothelial function, arterial stiffness) are associated with bone mineral content (BMC) in healthy females ages 14-42 years, and if there was a developmental effect in the relationship. In order to more comprehensively understand disease progression, this study also evaluated contribution of factors previously identified to play a role in bone and vascular integrity (i.e., insulin; vitamin D status, 25OHD; markers of inflammation). Endothelial function was assessed by flow mediated dilatation (FMD), arterial stiffness by pulse wave velocity (PWV) and augmentation index (AIx), systolic blood pressure (SBP) using average of three seated sphyngomamometer readings, BMC by DXA, and systemic factors assessed during fasting blood draw. We observed a positive association between SBP and BMC when all subjects were included which was independent of 25OHD, insulin or markers of inflammation. When stratified by age using 19 years as a cut-point, there was an inverse relationship between AIx in adolescent females when insulin ($p<0.10$) or markers of inflammation ($p<0.10$) were included as covariates. Conversely, there was a positive relationship between PWV and AIx in young adult females ($p<0.05$) independent of 25OHD, insulin or markers of inflammation. The link between bone and vascular linkage may be lifestage-dependent. Compromised vessel flow and deficits in bone mineralization early in life when the strength-structure of bone and vasculature are arguably most vulnerable could have profound effects on long-term bone and vascular health. Moreover, in the context of a less dynamic bone remodeling microenvironment, metabolic factors appear to moderate less of an effect than hemodynamics on structural properties centering the bone-vessel relationship.

CK2.1 a novel mimetic peptide, induces cartilage formation in vivo. Hemanth Akkiraju*, Anja Nohe. University of Delaware, USA

The goal of this study was to determine the mechanism of CK2.1, a mimetic peptide of Bone Morphogenetic Protein Receptor type Ia (BMPRIa), on cartilage formation. Osteoarthritis (OA) is a degenerative idiopathic disease characterized by calcification and degeneration of the articular cartilage. Only limited treatment options exist that focus on pain relief. New Treatments that can reverse the process of cartilage deterioration are desperately needed. Growth factors, like Bone Morphogenetic Protein 2 (BMP2), induce chondrogenesis and enhance extracellular matrix (ECM) production of pre-chondrocytes and chondrocytes. However the anabolic effects of chondrocytes, such as production of Collagen type II and Collagen type IX are short lived and result in cartilage hypertrophy in the long term. Chondrocyte hypertrophy leads to production of Collagen type X followed by degeneration of the ECM mediated by upregulation of MMP-13. Recently we identified a new BMP2 receptor interacting protein, Casein Kinase 2 (CK2). We designed novel peptides CK2.1 that release CK2 from the BMPRIa isoform activating the downstream BMP signaling pathways in the absence of BMP2. Treatment of CK2.1 on mesenchymal cells led to the increase of Collagen type II, while articular chondrocytes stimulated with CK2.1 led to the expression of Collagen type II and Collagen type IX. Contrary to BMP2, CK2.1 did not induce Collagen type X and MMP-13 protein expression. Additionally, CK2.1 increased *COMP, CREB, SOX9* mRNA levels in cultured mature articular chondrocytes. To verify the potential of CK2.1 in cartilage formation CK2.1 was injected into the tail vein of C57BL/6J mice. This injection resulted in an increased cartilage production compared to control. Additionally, the hypertrophic region in the growth plate was decreased in comparison to both control and BMP2 injected. Based on these findings we propose that peptide CK2.1 can be used for cartilage growth and repair.

Decreased *Nfat1* Expression Contributes to Dysfunction of Articular Cartilage in Aging Mice. Mingcai Zhang*[1], Qinghua Lu[1], Kenneth Caldwell[1], Jamie Crist[1], Clayton Theleman[1], Jinxi Wang[2]. [1]Department of Orthopedic Surgery, University of Kansas Medical Center, USA, [2]University of Kansas Medical Center, USA

Purpose:NFAT1 (*Nfat1*) is a member of NFAT (nuclear factor of activated T cells) transcription factors.Mice lacking *Nfat1* exhibit normal skeletal development but begin to show articular cartilage degradation and early osteoarthritis (OA)-like changes in young adults, suggesting that *Nfat1* is not required for joint development but is essential for articular cartilage function in young adult mice. However, the effect of *Nfat1* on aging cartilage remains unknown. This study aimed to investigate the role of *Nfat1* in regulation of articular chondrocyte function in aging mice.

Methods:The hip, knee, and shoulder joints were harvested from wild-type BALB/c mice at 5, 12, 15, and 18 months of age for histochemistry, immunohistochemistry, and isolation of RNA, genomic DNA, chromatins, and articular chondrocytes. Total RNA isolated from femoral head cartilage was used for gene expression analysis by quantitative real-time PCR (qPCR).Genomic DNA and chromatins obtained from femoral and humeral head cartilage were used for Methylated DNA immune-precipitation assay and ChIP assay, respectively. *Nfat1* overexpression experiments were performed in cultured articular chondrocytes.

Results:Loss of proteoglycan staining was seen in aging (12 and 18 months) articular cartilage. qPCR revealed a significant decrease in mRNA for *Acan*, *Col2a1*, *Col9a1*, *Col11a1* and a significant increase in *Il1b* expression in aging articular cartilage (Figure 1). *Nfat1* mRNA and protein expression in articular cartilage was significantly decreased after 12 months of age. Forced *Nfat1* expression in the cultured articular chondrocytes of aging mice partially rescued the abnormal metabolic activities. DNA methylation of the *Nfat1* promoter region was low and there was no significant difference between the age groups. In contrast, the levels of histone methylation (H3K4me2, a histone code for transcriptional activation) were significantly decreased in aging articular chondrocytes (Figure 2).

Conclusions:These findings suggest that reduction of *Nfat1* expression causes dysfunction of aging articular chondrocytes which explains, at least in part, the high incidence of joint degeneration or OA in aging individuals. The decrease in *Nfat1* expression in aging articular cartilage is primarily mediated by epigenetic histone methylation.

Key words: *Nfat1*, epigenetics, aging, osteoarthritis, cartilage

microRNAs in the Regulation of Resorption and Healing of Bone Erosions in Rheumatoid Arthritis. Yukiko Maeda*[1], Paul Fanning[1], Jane Lian[2], Ellen Gravallese[1], Melissa Matzelle[1], David Ayers[3]. [1]University of Massachusetts Medical School, USA, [2]University of Vermont, USA, [3]UMass Memorial Medical Center, USA

MicroRNAs (miRNAs) are important regulators of skeletal remodeling and expression of several miRNAs, including miR-23b and miR-132 is modulated in synovial tissues in rheumatoid arthritis (RA). RA is characterized by inflammation of the synovial joint lining that results in the destruction of bone. Focal articular bone loss (erosion) is mediated by osteoclasts, and begins early in the course of disease. Repair of bone erosion is rare despite the use of potent anti-inflammatory therapies, and mechanisms inhibiting bone formation and repair are poorly understood. Since miRNAs have been demonstrated to regulate both inflammation and bone remodeling, we hypothesized that miRNAs might play a regulatory role in the development and repair of bone erosions in RA. Using a modification of the serum transfer model for the study of bone erosion in RA, we have previously demonstrated that in the setting of resolving inflammation, repair of articular bone erosion does occur, accompanied by alterations in the expression of components of the Wnt signaling pathway. Moreover, treatment with TNF suppresses Wnt signaling activity in primary calvarial osteoblasts collected from Wnt reporter (Top-gal) mice. To begin to address the role of miRNAs in these pathogenic events, we performed Fluidigm high-throughput expression profiling of 760 mouse miRNAs in pooled synovial samples from non-arthritic and arthritic (day 10) mice and mice with resolving inflammation (day 21). We also performed gene array (Affymetrix) analysis in the same samples used for miRNA array studies, and compared gene and miRNA array results, followed by gene ontology analysis. We found 136 genes to be down-regulated that are predicted targets of miRNAs that were up-regulated (2 fold) in arthritic compared with non-arthritic synovium. Gene ontology analysis showed enrichment of genes in the Wnt pathway and pathways involved in bone development. We also identified 199 genes to be up-regulated that are predicted targets of down-regulated miRNAs (2 fold) in arthritic compared with non-arthritic synovium. Pathways involved extracellular matrix organization, cell cycle, inflammation, blood vessel and bone development. In conclusion, we identified stage-specific miRNAs in this murine model of RA, including two miRNAs previously reported to play a role in RA, miR-23b and miR-132. Further analysis of miRNAs in these pathways may prove fruitful for developing therapeutic strategies for bone erosion.

Associations between Sarcopenia and Osteopenia/Osteoporosis in 2400 Japanese Women. Naohisa Miyakoshi*[1], Michio Hongo[1], Yoichi Mizutani[2], Yoichi Shimada[1]. [1]Akita University Graduate School of Medicine, Japan, [2]Joto Orthopedic Clinic, Japan

Introduction: Sarcopenia and osteoporosis are both significant health burdens among postmenopausal women. This study examined associations between sarcopenia and osteopenia/osteoporosis in Japanese women and evaluated the prevalence of sarcopenia in women with osteopenia and osteoporosis.

Methods: A total of 2400 Japanese women aged 40-88 years who visited orthopedic clinics and underwent whole-body and regional (lumbar spine and total hip) dual-energy X-ray absorptiometry (DXA) were enrolled in this study. All subjects were orthopedic patients who had minor symptoms (i.e., sprain, contusion, transient joint pain, etc.) and requested examination for osteoporosis, or were examinees in a regional screening program for osteoporosis who were referred to our clinics for confirmation of whether osteoporosis was present. Osteopenia and osteoporosis were defined according to World Health Organization criteria using bone mineral density (BMD) of the lumbar spine or hip. Sarcopenia was defined as a relative skeletal muscle index (RSMI) more than 2 standard deviations below the mean for a young adult reference population, calculated as the appendicular skeletal muscle mass obtained from whole-body DXA divided by height in meters squared.

Results: Significant and marginal/moderate positive correlations were observed between RSMI and lumbar spine/total hip BMDs ($r=0.197$ and $r=0.274$, respectively; $p<0.0001$ each). BMDs of the lumbar spine and total hip showed significant moderate negative correlations with age ($r=-0.270$ and $r=-0.375$, respectively; $p<0.0001$ each), but RSMI showed no association with age in this population ($r=0.056$). When osteopenia/osteoporosis was defined using lumbar spine BMD, prevalences of sarcopenia in subjects with normal BMD, osteopenia and osteoporosis were 10.4%, 16.8%, and 20.4%, respectively. When osteopenia/osteoporosis was defined using total hip BMD, prevalences of sarcopenia in these subjects were 9.0%, 17.8%, and 29.7%, respectively. A chi-square test for independence showed a significant association between sarcopenia and osteopenia/osteoporosis ($p<0.0001$).

Conclusions: These results indicate that sarcopenia is significantly associated with osteopenia and osteoporosis in Japanese women. However, the results should be interpreted with care, as the subject cohort may have suffered selection bias in that all subjects had visited orthopedic clinics.

SU0009

Differential effects of age and menopause on proximal femur structure: a cross-sectional study of 719 Caucasian females aged 20 to 89 years. Richard Prince*[1], Ben Khoo[2], Joshua Lewis[3], Keenan Brown[4], Christopher Cann[5]. [1]Sir Charles Gairdner Hospital, Australia, [2]Medical Technology & Physics, Sir Charles Gairdner Hospital, Perth, Western Australia, Australia, [3]University of Western Australia, Sir Charles Gairdner Hospital, Australia, [4]Mindways Software, USA, [5]University of California, San Francisco, USA

Areal bone mineral density (aBMD), although useful for fracture prediction, obscures changes in cancellous and cortical mass and volume by integrating mass over a planar area of interest. We have previously reported the changes in proximal hip structure over the female life span using DXA (Price R et al., J Clin Densitom 2003; 6: 51). We now analyse the changes in the cancellous and cortical compartments assessed by three dimensional quantitative computed tomography (QCT) techniques to define the cancellous and cortical compartments.

Proximal femur structure was measured in 719 female Caucasians aged 20 to 89 years using QCT (Khoo et al., Osteoporos Int 2009: 20: 1539). CT scanner performance and protocols were characterized using a Mindways QA phantom and QA scans and mineral mass estimates normalized by CT-scanner specific field-uniformity correction using Mindways BIT software (Mindways Software Inc., Austin, Texas USA). Three regions of interest were defined using an algorithm derived from the DXA approach, the femoral neck (FN), trochanter (TR) and intertrochanter (IT). Voxels with a density threshold of greater than 350 mg/cm^3 were classified as cortical. The mineral mass and volume were computed for the integral, cancellous and cortical segments of the regions analysed and modelled using linear or bilinear (split plot) models using goodness of fit criteria without specification of the crossing point.

Integral volume at the femoral neck (FN), trochanter (TR) and intertrochanter (IT) sites expanded linearly from 20 to 89yrs by between 18 and 37% (27 to 175 µl/yr). Cancellous volume increased by between 65 and 79% (58 to 244 µl/yr). Between 20 and 89yrs FN cortical volume decreased linearly by 45% (30 µl/yr) and mass by 43% (18mg/yr) but at both the TR and IT sites cortical volume and mass were constant until menopause and decreased linearly thereafter: volume 42 and 25% (66 and 103 µl/yr): mass 46 and 30% (39 and 97 mg/yr).

At all sites periosteal and endosteal expansion is large and linear from age 20. FN cortical bone mass and volume shows linear contraction with age as previously described. However at the TR and IT sites, before menopause periosteal and endosteal expansion is balanced preserving cortical bone mass and volume, after menopause contraction of the cortical compartments is linear with age. The biomechanical effects of these large changes require further analysis.

Fall risk assessment using muscle mass, muscle strength and timed up and go test in hospitalized adults. Hideki Tsuboi*[1], Jun Hashimoto[2]. [1]Osaka Minami Medical Center, Japan, [2]National Hospital Organization, Osaka Minami Medical Center, Japan

Introduction; Falls in elderly are problems associated with increased morbidity and disability. Falls are also severe problem in hospitalized patients. In many hospitals, the fall risk is assessed by questionnaires provided by their medical safety committees. Therefore, the purpose of this study is to investigate the possibility to assess fall risks by muscle mass in lower extremity, muscle strength and physical performance.

Materials and Methods; 67 patients (44 male, 23 female) were enrolled in this study. The patients had a mean age of 68.8 (39-88) years. 44 patients had gastrointestinal disease, 20 patients lung disease and 3 patients others. All patients were classified in three groups at the time of admission using fall risk assessment questionnaire provided by medical safety committee in our hospital, A; high risk group, B; moderate risk group, C; low risk group. In addition, the muscle mass in lower extremity was measured using by BIA (Bioelectrical Impedance Analysis; MC190,Tanita, Tokyo, Japan) method and Muscle strength was assessed by hand grip strength. Moreover, physical performance assessment was evaluated measuring timed up and go test (TUG).

Results; 4 patients were excluded because of their gait disturbance, therefore, 63 patients were assessed finally. 9 patients (4 male, 5 female) were assessed in Group A, 30 patients (22, 8) were assessed in Group B and 24 (15, 9) were group C. In Group A, muscle mass of lower extremities were 12.9 ± 2.7 kg in male and 10.8 ± 2.0 kg in female respectively. In Group B, 16.1 ± 2.2 and 11.3 ± 1.8 respectively, and in Group C, 16.4 ± 2.7 and 11.4 ± 1.8 respectively. Hand grip strength in Group A were 25.8 ± 2.5 kg in male and 12.3 ± 4.5 kg in female respectively, in Group B; 25.6 ± 8.3 and 14.1 ± 5.0 respectively, and in Group C; 30.3 ± 9.1 and 17.5 ± 7.6 respectively. TUG in Group A were 9.3 ± 2.0 sec. in male and 13.7 ± 0.6 sec. in female respectively, in Group B; 8.2 ± 2.6 and 10.7 ± 2.1 respectively, and in Group C; 7.9 ± 1.9 and 6.8 ± 1.8 respectively.

Discussions and Conclusion; This study shows that results of muscle mass in lower extremities, hand grip strength and TUG were tend to decrease as the assessment for fall risks was worse. In male, muscle mass were reflected more clearly in fall risks, on the other hand, TUG were reflected more clearly in fall risks in female. Therefore, these examinations may be useful as a screening test for assessment for fall risk in hospitalized patients.

SU0011

Investigating the predictive ability of gait speed and quadriceps strength for incident falls in community-dwelling older women at high risk of fracture. David Scott*[1], Geoffrey Nicholson[2], Amanda Stuart[3], Peter Ebeling[1], Kerrie Sanders[4]. [1]The University of Melbourne, Australia, [2]The University of Queensland, Australia, [3]Department of Clinical & Biomedical Sciences, The University of Melbourne, Barwon Health, Australia, [4]NorthWest Academic CentreThe University of MelbourneWestern Health, Australia

Purpose: Sarcopenia, the age-related decline in skeletal muscle mass and function, is an independent predictor of falls in older adults. Recent consensus operational definitions of sarcopenia call for assessment of gait speed (GS), but this may not always be clinically practical. We aimed to determine whether quadriceps strength (QS) has similar predictive ability to GS for assessing falls risk in community-dwelling women at high risk of fracture.

Methods: 135 female participants (mean $\pm$ SD age 76.7 ± 5.0 years; range 70–92) of the Vital D study were randomly selected to participate in a sub-study. At baseline, QS was measured using a handheld dynamometer and self-selected GS was assessed using the GaitRITE system. Low QS and GS were defined as <7.0kg (based on lowest tertile) and <1.0m/s (based on International Working Group on Sarcopenia criteria), respectively. Incident falls were reported monthly by participants for mean $\pm$ SD 3.7 ± 1.2 years. Receiver operating characteristic (ROC) curves, adjusted Cox proportional hazards regression models, and Kaplan-Meier survival curves were obtained to determine the ability of QS and GS to predict incident falls.

Results: N = 99 (73%) participants fell a total of 355 times during the follow-up period (mean fall rate 83 per 100 person years). 32 and 36% of participants were classified as having low QS and GS, respectively, and 15% had combined low QS and GS. There was a moderate positive correlation between QS and GS ($r = 0.39$; $P < 0.001$). The accuracy of both measures for predicting incident falls was poor but ROC curves revealed a larger area under the curve for QS than GS (0.69 vs 0.61; $P = 0.198$). Adjusted Cox proportional hazards regression models demonstrated that the relative hazard for incident falls decreased by around 10% per additional kg of baseline QS (Hazard ratio [95% CI]: 0.90 [0.83, 0.98]), but there was no change in risk according to GS. There was a significant difference for time to first fall for those with low compared to those with normal QS (Figure 1), with estimated mean survival times of 1.54 [1.02, 2.06] vs 2.23 [1.82, 2.64] years, respectively. No significant differences in time to first fall were observed between those with low vs normal GS ($P = 0.161$).

Conclusions: In older women, QS may be a better predictor of incident falls than GS. The easily-performed QS test may be preferable to a GS test for sarcopenia assessment in clinical settings.

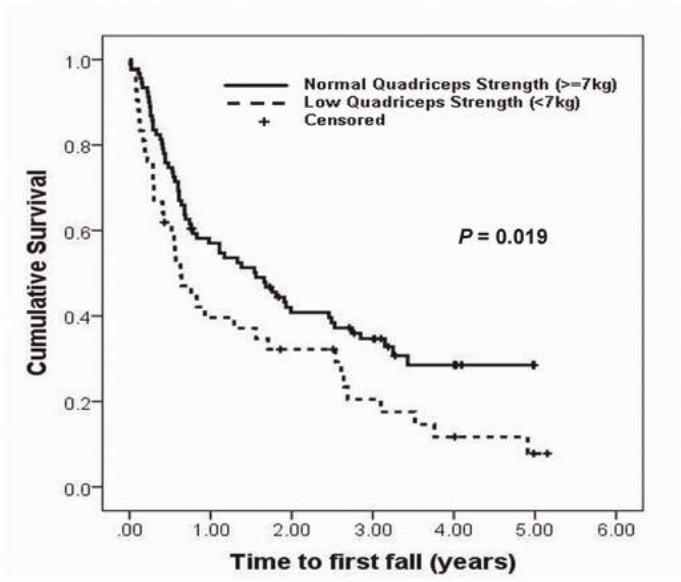

Figure 1. Kaplan-Meier survival curves for incident falls according to quadriceps strength

Physical Ability Tests Predict Incident Falls – A Prospective Study of 3014 Men in MrOs Sweden. Bjorn Rosengren*[1], Jan-Ake Nilsson[2], Osten Ljunggren[3], Eva Ribom[4], Dan Mellstrom[5], Mattias Lorentzon[6], Claes Ohlsson[7], Magnus Karlsson[1]. [1]Skåne University Hospital Malmö, Lund University, Sweden, [2]Clinical & Molecular Osteoporosis Unit, Dep of Orthopedics & Clinical Sciences, Skåne University Hospital, Lund University, Sweden, [3]Uppsala University Hospital, Sweden, [4]Department of Surgical Sciences, University Hospital, Sweden, [5]Sahlgrenska University Hospital, Sweden, [6]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [7]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

Background: Propensity to fall is a major risk factor for fracture and interventions that reduce fall risk have been identified in RCTs. It is however clinically demanding to identify high risk individuals suitable for intervention. As low physical ability is associated with falls we investigated the predictive ability of simple physical test.

Methods: 3014 ambulatory men aged 69-81 years in the MrOs Sweden population based study performed simple physical ability tests at baseline (Right and left hand grip strength (RGS and LGS ; kg/cm^2), timed stands test (TST; s), 6 m walking test (6WT; s and 6WS; number of steps) and narrow walking test (NWT; s). Incident falls were recorded tri-annually by a mailed questionnaire.

Due to the repeated assessment of falls, where some participants did not answer all questionnaires (86% completed all three questionnaires, 11% two, 2% one and 1% none) the probability of falling within a 4-month tri-annual evaluation cycle of one year was estimated by generalized estimating equations. We utilized Odds Ratio to estimate the relative risk (RR) with 95% CI.

The men were stratified into quartiles for each test where after we estimated the age-adjusted RR for falls between those in the worst quartile and others. We also evaluated the effect on fall risk of each 1 SD deterioration in the tests.

Results: During the first year 595 men (22%) reported at least one fall (in ages 69-72 years 22%, in ages 73-76 years 20% and in ages 77-81 years 26% (p<.001)).

Each 1 SD lower performance in a test was depending on the particular test associated to a 10-20% higher incident fall risk (RR RGS 1.2 (1.1, 1.3), LGS 1.2 (1.1, 1.3), TST 1.2 (1.2, 1.3), 6WT 1.1 (1.1, 1.2), 6WS 1.2 (1.1, 1.3) and NWT 1.2 (1.1, 1.2)).

Men in the lowest quartile of a test had depending on the particular test a 30-60% higher incident fall risk compared to other men (RR RGS 1.3 (1.1, 1.6), LGS 1.5 (1.2, 1.8), TST 1.4 (1.2, 1.7), 6WT 1.6 (1.4, 1.9), 6WS 1.5 (1.3, 1.8) and NWT 1.4 (1.2, 1.7)).

Men in the worst quartile of all of the three tests LGS, TST and 6WT (n=139) had a 70% higher fall risk compared to other men (RR 1.7 (1.2, 2.3) while men in the worst quartile of all 6 tests (n=68) had a 60% higher risk (RR 1.6 (1.0, 2.6).

ConclusionSimple physical ability tests predict incident falls. One test seems as effective as combinations of tests. The use of a single simple test to facilitate identification of high fall risk individuals is advocated.

Possible Pathways for the Association of Appendicular Skeletal Muscle Mass with Leptin, Insulin, Myoglobin and Inflammatory Markers. Zhao Chen*[1], Andriene Grant[1], Walter Klimecki[2], Nicole Wright[3], Chengcheng Hu[4], Jennifer Wright[1], Scott Going[1], J. Skye Nicholas[5], Patricia Thompson[1]. [1]The University of Arizona, USA, [2]University of Arizona Pharmacology & Toxicology, USA, [3]University of Alabama at Birmingham, USA, [4]University of Arizona College of Public Health, USA, [5]University of Arizona Mel & Enid Zuckerman College of Public Health, USA

Background: Age-related skeletal muscle loss is common and may be associated with changes in quality of life and disability. Understanding the biological mechanisms regulating loss of skeletal muscle mass (SMM) in the aging population is critical for implementing prevention and intervention strategies. Previously we have reported associations between total SMM and selected biomarkers, including leptin, insulin and inflammatory factors in postmenopausal women from the Women's Health Initiative (WHI). The overall goal of this study was to investigate potential pathways for these observed associations with appendicular SMM (ASMM). Methods: Appendicular lean mass from Dual-energy X-ray Absorptiometry (DXA) was used to estimate ASMM. Serum biomarkers were analyzed using a multiplex immunoassay that measures 89 biomarkers in parallel. A total of 1,001 women from WHI were included in the analysis. Simple and multiple linear regression analysis, random forest analysis as well as path analysis was used to explore biological mechanisms for the association between ASMM and biomarkers. Age, weight, height, race/ethnicity and percent body fat were covariates in the multiple linear regression analysis and random forest analysis. Results: Loss of ASMM with aging was greater than loss in total body SMM. Further, leptin, insulin and myoglobin levels were more consistently correlated with ASMM in the simple and multiple linear regression analysis, even after the adjustment for multiple comparisons. For predicting ASMM, leptin and insulin were the most important measured biomarkers. In addition, factor-VII (β = -0.023, p<0.001), MIP-1 beta (β = -0.016, p= 0.0017), EN-RAGE (β = 0.008, p= 0.007) and IgM (β = -0.010, p =0.0367), were significantly associated with ASMM even after adjusting for leptin, insulin and myoglobin. Conclusion: We observed a significant association between inflammation and ASMM, but inflammatory factors were not strong predictors of ASMM. Relative to inflammation, leptin and insulin were stronger predictors of ASMM. Age, race/ethnicity and body size only partially attenuated the association between ASMM, leptin and insulin, suggesting that leptin and insulin affect ASMM through pathways other than body size.

Precision and Monitoring Time Intervals for pQCT-Derived Muscle Area and Density in Community-Dwelling Older Adults. Andrew Frank*[1], W.P. Olszynski[2], Saija Kontulainen[1]. [1]University of Saskatchewan, Canada, [2]Midtown Professional Center (#103), Canada

Peripheral quantitative computed tomography (pQCT) is an imaging tool designed for the estimation of bone properties. Musculoskeletal research has also applied pQCT to measure muscle area and muscle density (a surrogate of inter- and intramuscular adipose infiltration). Despite the growing use of pQCT-derived muscle measures, precision values for older adults have not yet been reported. Measurement precision and follow-up data can be used to calculate the monitoring time interval (MTI); an estimate of the time required between measurements where 50% of population will demonstrate a significant age-related change. MTI's are needed to inform and optimize pQCT-based study designs in aging populations. Our objective was to determine the precision error, as well as overall and age-specific MTIs for pQCT-derived muscle area and density in a cohort of older women.

Women (N=115) age 60 to 90 (mean 73.9, SD 7.9y) were recruited from the Saskatoon Cohort of the Canadian Multicentre Osteoporosis Study.Repeated pQCT scans were acquired an average of 347 (SD 15) days apart at 65% of radius and 66% of tibia length to determine forearm and lower leg muscle area and density. A subsample of these participants (n=35), mean age 73.7 (SD 7.7) years were randomly selected for the calculation of short-term precision error by repeated scans 9.7 (SD 3.6) days apart. Precision error was calculated as a percentage using a root mean square coefficient of variation (CV_{rms}%). MTI was calculated as the least significant change (2.77*CV_{rms}%) divided by the median annual percent change. MTIs were calculated for the entire cohort and age decades (60-69, 70-79, 80+).

The precision error for pQCT muscle measures were 2.2% and 3.6% for muscle area and 1.4% and 1.9% for density in the forearm and lower leg respectively. For the entire cohort, MTIs were 3 and 19 years for muscle area, and 18 and 6 years for density, in the forearm and lower leg respectively. From the youngest to oldest decades, forearm MTIs were 4, 2, & 3 years for muscle area, and 13, 35 & 19 years for density. In the lower leg MTIs were 91, 62, & 4 years for muscle area, and 8, 7, & 5 years for density.

The most practical monitoring time intervals for muscle properties in community-dwelling older women is forearm muscle area at 2-4 years, and lower leg muscle density with 5-8 years. The MTIs vary with baseline age. These results will inform and streamline longitudinal study design in musculoskeletal health & aging.

Severity of Thoracic Curvature Increases Lung Function Decline: The Framingham Study. Elizabeth Samelson*[1], George O'Connor[2], L Adrienne Cupples[3], Yanhua Zhou[3], Elana Brochin[4], Douglas Kiel[5], Harold Rosen[6]. [1]Hebrew SeniorLife, Harvard Medical School, USA, [2]Boston Medical Center, USA, [3]Boston University, USA, [4]Institute for Aging Research, USA, [5]Hebrew SeniorLife, USA, [6]Beth Israel Deaconess Medical Center, USA

Older adults with hyperkyphosis, or excessive forward curvature of the thoracic spine, suffer greatly from this common condition and its associated reduction in quality of life. Impaired pulmonary function, as measured by spirometry, predicts both mortality and functional limitation. Although hyperkyphosis is clinically recognized to restrict lung expansion, there are no prospective studies that have quantified its impact on pulmonary function impairment. We conducted a prospective study to evaluate severity of kyphosis and subsequent declines in pulmonary function in older women.

Participants included a convenience sample of 193 women in the Framingham Original Cohort (mean age, 63 years; range, 50-79) who had thoracic spine x-rays in 1975-76. We measured baseline kyphosis angle (KA), in degrees, from T4 to T12. Pulmonary function testing was used to measure the volume of air exhaled in 1 second (forced expiratory volume, FEV1) at 4 clinical examinations over 13-years of follow-up. Linear mixed effects regression was used for longitudinal analysis to estimate the association between baseline KA and decline in lung function, adjusted for baseline age, height, weight, vertebral fracture, smoking, and physical activity.

Mean KA at baseline was 40♂ in women and ranged from 4-76♂ (median=40♂, IQR=18♂). During 13 years of follow-up, FEV1 declined a mean of 234 ml (18 ml/yr) and ranged from a decrease of 810 ml (62 ml/yr) to an increase of 880.0 (68 ml/yr). Women with the greatest severity of baseline KA had the greatest decline in FEV1 (TABLE). Mean decline in FEV1 over 13 years was 368 ml, 453 ml, and 532 ml in women in the lowest, middle, and highest (most severe) tertile of KA, respectively (trend, p=0.03).

We found that older women with more severe kyphosis experienced greater declines in pulmonary function over 13 years than women with less severe kyphosis, independently of smoking, vertebral fracture, and other confounding factors. The 164 ml excess decline for women in the highest compared to the lowest tertile is more than half the impact of smoking on FEV1 (estimated at 312 ml/13 yr). Efforts to prevent or slow progression of kyphosis may reduce the burden of pulmonary function impairment, an important cause of morbidity and mortality in older adults.

Decline in Forced Expiratory Volume in 1 Second (FEV1, ml) over 13 Years of Follow-Up, According to Severity of Baseline Kyphosis Angle (KA°), Framingham Original Cohort

Kyphosis Angle (KA°) Tertile	Range	Decline in FEV1 (ml) over 13 Years Mean (95% Confidence Interval)*
Low	4-33°	368 ml (262-473)
Medium	34-46°	453 ml (381-525)
High**	47-76°	532 ml (427-638)

Skeletal Muscle Function Deficit. Rosaly Correa-de-Araujo*. National Institute on Aging, National Institutes of Health, USA

Considerable efforts have been taken to better characterize and define sarcopenia in an attempt to help identify patients who might benefit from available therapeutic or preventive interventions, and to support the development of new therapeutic approaches. Throughout the years, the work of numerous international groups resulted in the addition of performance criteria to muscle mass alone or inclusion of both lean mass and gait speed as diagnostic criteria for sarcopenia. More recently, the Foundation for the National Institutes of Health (FNIH) Sarcopenia Project established criteria for clinically relevant low muscle mass and low muscle strength through the identification of strength and muscle mass cutpoints and the demonstration of the relationship between mobility impairment and these cutpoints. With the evolving concepts of sarcopenia, a better terminology is needed to reflect not only sarcopenia's original definition (loss of muscle mass), but also to embrace the alterations in muscle strength and function that ultimately may lead to mobility disability. The author proposes Skeletal Muscle Function Deficit (SMFD) as such terminology and will discuss the rationale of how it can provide a framework for the diagnosis and potential therapeutic approaches to sarcopenia and age-related muscular dysfunctions.

SU0017

Strength-to-weight ratio in population studies: toward a definition of sarcopenic-obesity that is relevant for mobility limitation. Robert McLean*[1], Marian Hannan[1], Joanne Murabito[2], Alyssa Dufour[1], Douglas Kiel[1]. [1]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [2]Framingham Heart Study & Boston University School of Medicine, USA

Both sarcopenia and obesity are associated with mobility limitations in older adults, and risk may be highest when both co-exist as sarcopenic-obesity. Thus identification of sarcopenic-obesity is essential for prevention and treatment, yet no consensus definition exists. Current definitions classify sarcopenia as low absolute strength. We propose that low strength-to-weight ratio (SWR) is more relevant because insufficient strength relative to body weight is a main cause of physical limitations. Our objective was to compare a sarcopenic-obesity definition that classifies sarcopenia based on low absolute strength with one based on SWR, and determine their associations with mobility limitations. Participants were 557 older adults (age 72-98 years, 62% women) from the Framingham Original Cohort (1992-93). Maximum grip strength was measured (kg), and sarcopenia was defined as the lowest sex-specific tertiles of 1) absolute grip strength and 2) grip SWR (grip strength/body weight). Obesity was defined as BMI ⩾30 kg/m^2. Sarcopenic-obesity categories (sarcopenic-obesity, sarcopenia only, obesity only, neither) were defined 2 ways: based on absolute grip strength and grip SWR. For each sarcopenic-obesity definition, logistic regression was used to calculate prevalence odds ratios (OR) for mobility limitations (self-reported inability to walk ½ mile or up and down 1 flight of stairs) for the sarcopenia only, obesity only and sarcopenic-obesity groups relative to neither. Models were adjusted for sex, age, high school education, current smoking, >3 alcoholic drinks/week, and number of comorbidities. The SWR-based definition reclassified 54% of obesity only to sarcopenic-obesity, and 34% of sarcopenia only to neither (Table 1). For the low strength definition, odds of mobility limitation was similar (OR=4.2) for the obesity alone and sarcopenic-obesity groups (Table 2). For the SWR definition, sarcopenic-obesity was most strongly associated with mobility limitation (OR=5.0), but obesity alone was not (OR=1.0). Associations for sarcopenia alone were similar for both definitions (OR=2.3). Our results show that a sarcopenic-obesity definition based on low SWR may better describe the synergistic relation between sarcopenia and obesity since obesity may not be associated with mobility limitation when strength is sufficient for body weight. Further refinements of sarcopenia and obesity criteria are needed before a consensus definition is established.

Table 1. Classification for 2 sarcopenic-obesity definitions among 557 elderly men and women in the Framingham Original Cohort.

Absolute grip strength, BMI	Grip strength-to-weight ratio, BMI: Neither	Sarcopenia only	Obesity only	Sarcopenic-obesity	Total
Neither	281	10	0	0	291
Sarcopenia only	54	98	0	0	152
Obesity only	0	0	37	44	81
Sarcopenic-obesity	0	0	0	33	33
Total	335	108	37	77	557

Table 1

Table 2. Prevalence odds ratios* (95% CI) for mobility limitation for 2 sarcopenic-obesity definitions among 557 elderly men and women in the Framingham Original Cohort.

	Absolute grip strength, BMI	Grip strength-to-weight ratio, BMI
Neither	1.0	1.0
Sarcopenia only	2.3 (0.9, 5.8)	2.3 (0.9, 5.8)
Obesity only	4.2 (1.5, 11.7)	1.0 (0.1, 8.5)
Sarcopenic-obesity	4.2 (1.1, 15.6)	5.0 (2.0, 12.3)

Bisphosphonate Rescues Cartilage from Trauma Damage by Promoting the Spontaneous Calcium Signaling in Chondrocytes. Yilu Zhou*, Lauren Resutek, Christopher Price, Liyun Wang, X. Lucas Lu. University of Delaware, USA

Our previous study found that systemic injection of zoledronic acid (ZA), a bisphosphonate for bone loss treatment, could suppress the development of post-traumatic osteoarthritis in the DMM (destabilization of medial meniscus) mouse model. We hypothesized that the presence of bisphosphonate could recover the

cartilage from traumatic damage under *in vitro* culture, and that the chondro-protective function of ZA is related to the calcium signaling of chondrocytes.

Cartilage allografts from calf knee joints were cultured in medium with serum (10% FBS) or without serum for four weeks to evaluate the adverse effects of serum on cartilage. Another two groups of allografts were exposed to serum medium for 1 week to simulate joint bleeding, followed by a 4-week serum-free culture with or without the presence of 1 mM zoledronic acid. Longitudinal mechanical properties of allografts were measured weekly. In order to record the spontaneous calcium responses of *in situ* chondrocytes, the allografts were dyed with Fluo-8 and imaged on a confocal microscope.

The adverse effects of serum on mechanical integrity of cartilage were correlated with the spontaneous calcium responses of *in situ* chondrocytes. At day 28, the Young's modulus was 0.17 MPa in serum group and 0.9 MPa in the non-serum group. The responsive rate of chondrocytes dropped constantly from 18% (day 1) to 7% (day 29) in the serum group, while the non-serum group remained at 20%. For damaged cartilage with 1-week serum exposure, the Young's modulus of allografts increased more than 200% after 4-week rescuing culture in medium contained ZA, while non-ZA group showed a 56% increase (Fig A). In the non-ZA group, 19% of chondrocytes showed spontaneous calcium responses in 15 minutes of imaging, and this value remained constant for 4 weeks. Interestingly, the responsive percentage of cells in ZA treated group increased simultaneously with culture time (Fig B). Linear regression proved that the responsive rate is also positively correlated with the tissue stiffness. Further image processing showed that presence of ZA promoted the calcium signaling of chondrocytes residing in the explants.

We conclude that zoledronic acid directly regulates the metabolic activities of chondrocytes in cartilage. Treatment with ZA can rescue the mechanical integrity of cartilage after trauma damage induced by serum exposure. The chondro-protective effect of ZA is correlated with the intracellular calcium signaling in chondrocytes.

In Very Early Rheumatoid Arthritis Bone Changes can be Detected by Peripheral Quantitative Computed Tomography but not Dual-Energy X-ray Absorptiometry. Mart Kull*[1], Raili Müller[2], Annika Aart[2], Riina Kallikorm[2], Margus Lember[2]. [1]University of Tartu, Estonia, [2]University of Tartu, Department of Internal Medicine, Estonia

Background: Rheumatoid arthritis (RA) is a chronic debilitating autoimmune disease resulting in progressive joint damage. The presence of bone changes is known to be a prognostic factor of the disease and predicts later morbidity.

We aimed to compare peripheral computed tomography (pQCT) with dual energy x-ray absoptiometry (DXA) in detecting the effect of rheumatoid arthritis on bone parameters in very early rheumatoid arthritis.

Methods: Our study recruited 46 consecutive early RA patients (mean age 51.8 years and average time from diagnosis 33 days). All patients underwent a laboratory panel and thorough physical examination and tender/swollen joint counts. Bone mineral changes were assessed by pQCT (Stratec XCT2000, Germany) and DXA (GE Lunar, US) measurements of the forearm.

Association of bone parameters with disease indices were studied using multivariate linear regression method. Models for radius trabecular bone mineral density and area (pQCT), cortical bone mineral density and area (pQCT), ultradistal radius BMD (DXA) and radius distal third BMD (DXA) were generated using age, time from diagnosis, DAS28 score, CRP level, rheumatoid factor and aCCP positivity, 25(OH) vitamin D, parathyroid hormone level, usage of glucocorticoid treatment and the HAQ score as independent variables.

Results: In early RA patients the DAS28 disease score was independently associated with radial bone cortical density (p=0.04), trabecular density (p=0.01) and trabecular area (p=0.008; Table) when measured by pQCT. DXA measured bone mineral density and bone area in the trabecular (radius ultradistal region) and cortical (distal third of radius) regions did not show a significant association with disease parameters (p>0.05) in this patient cohort.

Conclusion: In this very early stage of RA (~1 month from diagnosis) independent associations of bone mineral density with disease indicators are already seen with pQCT but not with DXA. This suggests that pQCT is a more sensitive method for the detection of early RA associated bone changes in the forearm.

p-value		Independent variable	Model r^2	Age	CRP	DAS28 score	GCS treatment	25(OH)D	RF positive	aCCP positivity	HAQ score	PTH	Time from diagnosis

MicroRNAs Are Related to Progression of Osteoarthritis (OA) in the DMM (destablization of medial meniscus) Mouse Model. Paul Fanning*[1], Christopher Raskett[2], Eric Mick[3], Yukiko Maeda[1], Nicholas Farina[4], Ellen Gravallese[1], Gary Stein[5], David Ayers[6], Jane Lian[7]. [1]University of Massachusetts Medical School, USA, [2]Dept. of Orthopedics & Rehabilitation, University of Massachusetts Medical School, USA, [3]Dept. of Quantitative Health Sciences, University of Massachusetts Medical School, USA, [4]Dept. of Biochemistry, University of Vermont Medical School, USA, [5]University of VermontCollege of Medicine, USA, [6]UMass Memorial Medical Center, USA, [7]University of Vermont, USA

MicroRNAs (miRNAs)have emerged as key regulators of normal cellular processes and metabolic pathways in the skeleton and are associated with disease. Studies of OA tissue have identified gain and loss of miRNAs that reflect loss of the articular surface, tissue degradation, pain and inflammation. Here we addressed the temporal and spatial changes in miRNA expression from the onset and during progression to late stage of degeneration of the joint surface, not represented in samples from the terminal stage of total joint replacement. The DMM model mimics the events that occur in human disease including initial fibrillation of articular cartilage (day 10 after surgery), erosion of the cartilage matrix, active chondrocytes at the margins of degenerated tissue (days 12 – 21) and finally the beginning of sclerotic bone lesions by day 10 increasing through day 28. In n=5 mice per group (5 time points and controls), we compared expression of miRNAs using a Q-PCR array of 678 miRNAs (Fluidigm, UMASS High Throughput Gene Expression Core). Samples microdissected from the medial and lateral compartments of the operated knee were examined to better asses miRNAs of the OA disease state compared to the spared control tissue in the same mouse. Raw data was analyzed after applying the modified global means normalization to the raw data prior to miRNA expression analyses. A total of 243 miRNA were expressed with ~100miRNAs with 3 fold or at any one time point in the OA tissue and were clustered into several different expression patterns during the time course. Subgroups of these RNAs were linked to functional activities through analyses of their targets that formed networks related to angiogenesis, growth factor signaling ((TGFB, IGF, PDGF, FGF, Wnt), inflammation (cytokines and chemokines), apoptosis and kinase pathways. The functional activities of miRNAs with the highest fold changes that have not been previously reported in OA, are being further examined for their biological effects in chondrocytes. Many miRNAs we find exhibiting stage –dependent expression in the DMM mouse model, had been reported in human OA tissue (e.g miR -155, miR 34a, , miR 140, miR 27). Hence, these miRNAs have the potential for diagnostic value and intervention of OA.

Notch Inhibition Prevents Inflammatory Bone Loss by Targeting Mesenchymal Stem Cells. Hengwei Zhang*[1], Matthew Hilton[2], Jennifer Anolik[1], Zhenqiang Yao[1], Brendan Boyce[2], Lianping Xing[1]. [1]Univeristy of Rochester, USA, [2]University of Rochester Medical Center, USA

Notch plays critical roles in maintaining bone homeostasis by regulating the functions of osteoblasts and osteoclasts. However, its role in common bone disorders is less clear. We reported that Notch is activated in mesenchymal stem cells(MSCs) from TNF transgenic(TNF-Tg) mice, a model of inflammatory osteoporosis and rheumatoid arthritis(RA) and the Notch inhibitor DAPT prevents bone loss in TNF-Tg mice. To determine if this effect of DAPT in TNF-Tg mice is directly mediated by MSCs, we used a SCID mouse tibial defect model in which we filled the defects with a scaffold of decalcified bone matrix into which we injected CFU cells from DAPT or vehicle treated TNF-Tg mice and assessed new bone formation using uCT and histomorphometry. Cells from DAPT treated mice formed significantly more new bone in defects compared with cells from vehicle treated mice(BV/TV: 21 ± 3 vs $14\pm2\%$; new bone area: 0.027 ± 0.002 vs $0.017\pm0.003mm^2$). To determine if TNF activates Notch in MSCs *in vivo,* we used Hes1-GFP mice, which have been used to visualize Hes1-expressing neural stem cells. $CD45^-GFP^+$ cells from Hes1-GFP mice express MSC markers(61% $Scal1^+$, 68% $CD105^+$ and 99% $CD31^-$), formed CFU-ALP^+ colonies and expressed low levels of Runx2. TNF injection (0.5mg/d/inj x 5d) significantly increased the #s of $CD45^-Hes1^+$ cells in bone marrow of Hes1-GFP mice compared to PBS treated mice(2.5 ± 0.8 vs 0.3 ± 0.1 x10^5 cells). $CD45^-Hes1^+$ cells from TNF treated mice expressed high levels of *Hes1* and formed fewer CFU-ALP^+ colonies. We observed no change in OC formation or $CD45^+Hes1^+CD11b^+/Gr\text{-}1^{-/low}$ OC precursor numbers. Scattered Hes1-GFP^+ cells were observed in bone marrow sections and some of them are adjacent to the endosteal surfaces of trabecular bones. TNF significantly increased the #s of Hes1-GFP^+ cells adjacent to the endosteal surface(#s/femur: 115 ± 15 vs 43 ± 8 in PBS treated mice). To determine if elevated Notch and reduced obl differentiation occur in human RA, we examined expression levels of Notch target genes and Runx2 in $CD45^-$ cells from peripheral blood of 12 patients with active RA who were not on biologics and 15 healthy controls(HCs). Similar to findings in TNF-Tg RA mice, increased Notch(*Hes1*: 3.85 ± 1.4; *Hey1*:2 ± 0.5 fold) and decreased Runx2(*Runx2*: 0.5 ± 0.1 fold) expression was detected in RA patients compared to HCs. Our data suggest that chronic inflammation leads to abnormal Notch activation in MSCs. Notch inhibition is a potential therapeutic approach for inflammatory bone loss.

SU0022

Prevention of Osteoarthritis by Combination of Proteoglycan 4 and Interleukin 1 Receptor Antagonist Expression. Zhechao (Merry) Ruan*[1], Kilian Guse[1], Ayelet Erez[1], Vincenzo Cerullo[1], Brian Dawson[1], Michael Heggeness[1], Francis Gannon[1], Brendan Lee[2]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine & Howard Hughes Medical Institute, USA

Purpose: Osteoarthritis (OA) is characterized by degeneration of articular cartilage, and is the top three cause of chronic disability. Although its prevalence is rising globally with aging of the population, current therapy is limited to symptomatic relief and in severe cases, joint replacement surgery. We aim to develop novel therapeutic modalities by intra-articular over-expression of proteoglycan 4 (Prg4) and interleukin 1 receptor antagonist (Il1ra). In addition, we aim to investigate the related mechanism in the pathogenesis of OA.

Methods: To study the effects of long-term expression of Prg4 on OA, we over-expressed Prg4 in intra-articular space by generating transgenic mice and intra-articular injection of helper-dependent adenoviral vectors (HDV) in wild type mice. To enhance the therapeutic index of HDV based treatment, we modified HDV to retarget chondrocytes and delivered Prg4 in combination of Il1ra. To investigate the related mechanism of OA pathogenesis, we performed gene expression profiling of mouse articular cartilage obtained by laser capture micro-dissection (LCM), in vitro cell studies and analysis of human OA gene profiling.

Results: Long-term Prg4 expression under the type II collagen promoter (Col2a1) does not adversely affect skeletal development but protects from developing signs of age-related and post-traumatic osteoarthritis. Moreover, intra-articular injection of HDV expressing Prg4 protects against the development of post-traumatic osteoarthritis. The therapeutic index increases by 10 fold when we either inject HDV modified to retarget chondrocytes or perform combinatorial injection of Prg4 and Il1ra. Gene expression profiling of mouse articular cartilage obtained by LCM shows that Prg4 expression inhibits the transcriptional programs that promote cartilage catabolism and hypertrophy. Results from in vitro cell studies and analyses of available human OA datasets are consistent with the predictions of this model.

Conclusions: Our data offer long-term intra-articular expression of Prg4 and Il1ra by HDV delivery as a potential chondro-protective approach to OA treatment and provide insight into the mechanisms for OA development.

Gender Different Pleotropic Bone-Muscle Relationship in The Elderly: From A Nationwide Survey (KNHANES IV). Ji Hye Huh*[1], Kwang Joon Kim[2], Kyeong Hye Park[3], Jo Eun Kim[4], Kyoung Min Kim[5], Yumie Rhee[6], Sung-Kil Lim[7]. [1]Division of Endocrinology & Metabolism, South Korea, [2]Severance Hospital, South Korea, [3]Executive Healthcare Clinic , Severance Hospital, South Korea, [4]Division of Endocrinology & Metabolism,Department of Internal, South Korea, [5]Department of Internal Medicine, Bundang Seoul National University Hospital, South Korea, [6]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea, [7]Yonsei University College of Medicine, South Korea

Context: There is a clear evidence of genetic pleiotropy between the muscle and the bone. However, there are few studies concerning gender differences in the effect of low muscle mass on bone and glucose and lipid metabolism in elderly subjects.

Objective: To assess the gender-specific influence of muscle mass on the bone and metabolic parameters.

Design and Setting: A population-based, cross-sectional study from the Fourth Korea National Health and Nutrition Examination Surveys (2008-2009).

Participants: A total of 5,003 men and 6,500 women aged 10 and older who completed the body composition examination using a dual-energy X-ray absorptiometry (DXA) were recruited. A total of 2,264 participants (940 men and 1,324 women) whose age ranged from 65 to 92 years were further analyzed.

Main outcome measurements: Those whose muscle mass was lower by one standard deviation or greater from the mean of young healthy subjects were allocated into sarcopenia group, and the others were classified as the control group. BMD at the spine and the hip was measured using DXA.

Results: The peak muscle mass accrual was obtained at age of 20-39 years in men and 40-59 years in women. The age-related trend in bone and muscle coincided in men but not in women. Femoral neck (FN) and total hip (TH) BMD were highly correlated with muscle mass in both genders. However, in women, this correlation was not significant in lumbar spine(LS). In addition, this positive correlation was stronger in cortical bone-rich FN or TH than in trabecular bone-rich LS, and it was stronger in men than in women. There was a strong correlation between muscle mass and femoral cortical thickness in both genders. Subjects with sarcopenia were at a higher risk for osteoporosis at FN, TH and LS in men, and in TH and FN in women. Muscle mass and metabolic profiles did not show any remarkable association.

Conclusion: Our largest population based study showed that subjects with low muscle mass were more prone to deterioration of the bone, especially cortical bone, than to altered glucose and lipid metabolism in elderly populations. This muscle-bone relationship was more prominent in men than in women. The gender differences in acquisition and age-related loss in bone and muscle tissues may be important and helpful for development of gender-specific preventive strategies and treatment options for sarcopenia and osteoporosis in the elderly.

Larger Bone Size is Associated With Increased Risk of Forearm Fracture in Young Girls. Mikko Maatta*[1], Christa Hoy[1], Douglas Race[1], Lindsay Nettlefold[1], Leigh Gabel[1], Kishore Mulpuri[2], Heather Macdonald[1], Heather McKay[1]. [1]University of British Columbia, Canada, [2]Child & Family Research Institute, Canada

The incidence of distal forearm fractures in children and adolescents has risen in recent decades. However, the relationship between bone microstructure, bone strength and fracture risk during growth is not clear. Thus, we aimed to compare distal radius bone microstructure and strength between girls and boys without a history of forearm fracture (NF group) with those who sustained a low to moderate energy forearm fracture (Fx group). We assessed bone microstructure of the non-dominant (NF) and non-fractured (Fx) distal radius (7% site) using high-resolution pQCT (Scanco Medical) in 57 pre- and early pubertal girls (10.7 y $\pm$ 1.5, 30 NF, 27 Fx) and 62 boys (12.0 y $\pm$ 1.6, 20 NF, 42 Fx). Standard morphological outcomes included total bone mineral density (Tt.BMD), trabecular bone volume ratio (BV/TV), trabecular thickness (Tb.Th) and number (Tb.N). We used a customized auto-segmentation algorithm to determine total bone area (Tt.Ar), cortical BMD (Ct.BMD), thickness (Ct.Th) and porosity (Ct.Po), and applied finite element analysis to estimate bone strength (failure load, FLoad). We used ANOVA to compare bone outcomes across Tanner stages I, II and III in girls and boys. To determine whether bone outcomes were predictive of fracture, we fit sex-specific logistic regression models for each bone outcome, and adjusted for forearm length, maturity (Tanner stage) and percent body fat (DXA, Hologic QDR 4500W). Girls in the Fx group had significantly higher percent body fat compared with NF girls (15%, p=0.03). Girls in NF group had significantly higher Ct.BMD at Tanner stage III compared with Tanner stage I (11%, p=0.04). This maturity difference in Ct.BMD was absent in the Fx group. Ct.Th was significantly lower in Fx girls compared with their NF peers at Tanner stage II (11%, p=0.04). The FX girls also had significantly larger Tt.Ar than NF girls at Tanner stage II (14%, p=0.04). The higher Tt.Ar in Fx girls was associated with a significantly

higher fracture risk (OR=1.03 per 1 unit increase, p=0.03). Trabecular microstructure, Ct.Po and FLoad were not associated with fracture in girls or boys. With growth-related increases in bone size a concomitant increase in cortical thickness and BMD may be necessary to prevent fracture in girls. Factors that underpin fracture during growth are sex-specific. In girls, the influence of excess adiposity on fracture risk requires further study.

Age effect on pediatric longitudinal BMD by multiple loci uncovered in adult BMD-related GWAS meta-analyses. Babette Zemel*[1], Heidi Kalkwarf[2], Mingyao Li[3], Sandra Deliard[4], Cecilia Kim[4], Liming Qu[3], Rosetta Chiavacci[4], Donna Paulhamus[4], Joan Lappe[5], Vicente Gilsanz[6], Hakon Hakonarson[4], Sharon Oberfield[7], John Shepherd[8], Benjamin Voight[3], Andrea Kelly[4], Struan Grant[1]. [1]Children's Hospital of Philadelphia, USA, [2]Cincinnati Children's Hospital Medical Center, USA, [3]University of Pennsylvania, USA, [4]The Children's Hospital of Philadelphia, USA, [5]Creighton University Osteoporosis Research Center, USA, [6]Children's Hospital Los Angeles, USA, [7]Columbia University Medical Center, USA, [8]University of California, San Francisco, USA

Objective: Genome wide association studies (GWAS) have identified over 70 loci associated with adult bone density and/or osteoporosis. Discerning which of these loci impact bone development early in life has not been systematically investigated. We tested the associations of these single nucleotide polymorphisms (SNPs) with areal bone mineral density (aBMD) of the spine, total hip, femoral neck, distal 1/3 radius and bone mineral content (BMC) of total body less head (TBLH) in a well-characterized cohort of European American children.

Methods: The Bone Mineral Density in Childhood Study was a multi-center, longitudinal study of children ages 5 to 19. aBMD/BMC was measured annually (up to 7y) using Hologic DXA devices. Growth, puberty stage, dietary intake and physical activity were also measured. Biospecimens were genotyped on the Illumina OmniExpress BeadChip (>700,000 SNPs). Principal component analysis confirmed self-reported European ancestry. Longitudinal mixed effects models tested associations between aBMD/BMC Z-scores and 77 SNPs previously identified in adulthood, accounting for sibships and multiple observations per subject. Models were adjusted for height and BMI Z-score, age, sex, puberty, calcium intake and physical activity. A SNP x age interaction term was tested to determine if associations were age dependent. A P-value of 0.05 was considered statistically significant, as these are previously identified SNPs.

Results: Over 4,000 observations on ~690 subjects were evaluated. Numerous GWAS-established adult bone density loci were associated with aBMD/BMC independent of known covariates such as growth and physical activity, especially when a SNP x age interaction term was included (see Table). Interestingly, this interaction was consistently observed for *ARHGAP1, FOXL1, SMG6, WNT16, LRP4 and TNFRSF11B* at all skeletal sites.

Conclusions: These findings suggest that multiple variants originally associated with adult bone density exert effects earlier in life. Most notably, these longitudinal models revealed age-dependent effects during childhood that would otherwise have gone undetected.

Table. SNPs assocoated wtih aBMD/BMC in children in models with and without an age interaction

Association Between Lower Extremity Muscle Mass and Bone Structure in Individuals With Unilateral Cerebral Palsy. Harshvardhan Singh*[1], Christopher Modlesky[1], Freeman Miller[2], Brianne Mulrooney[1], Jacques Riad[3]. [1]University of Delaware, USA, [2]AIduPont Hospital for Children, USA, [3]Astrid Lindgrens Children's Hospital, Sweden

Cerebral palsy (CP) is associated with underdeveloped bone structure which results in low bone strength. This may be ascribed to underdeveloped musculature; however, no studies have investigated the relationship between muscle mass and bone structure in individuals with CP. The objective of this study was to examine the relationship between interlimb differences in muscle mass and structure and strength of the midtibia in individuals with spastic unilateral CP. Ambulatory individuals with unilateral CP (n = 30; 13 to 24 years) and a Gross Motor Function Classification of 1 or 2 were studied. All participants were classified as type 0 or 1 using the Winters classification based on sagittal plane gait analysis. Magnetic resonance images of the tibia (0.5 cm thick and 1.0 cm apart) were collected from both lower limbs. Mass of the hip adductors, quadriceps, hamstrings, plantarflexors, and dorsiflexors, and cortical volume, medullary volume, total volume, and estimates of bone strength [section modulus (Z) and polar moment of inertia (J)] for images at the level of the middle-third of the tibia were analyzed using custom software (Interactive Data Language, Boulder, CO). Regression analyses showed that interlimb differences in quadriceps mass was positively related to interlimb differences in cortical volume ($r = 0.577$, $p = 0.001$), total volume ($r = 0.636$, $p = 0.0004$), Z ($r = 0.662$, $p = 0.0002$) and J ($r = 0.648$, $p = 0.0003$) at the midtibia. An inverse relationship between hamstrings mass and cortical volume ($r = -0.446$, $p = 0.022$), Z ($r = -0.459$, $p = 0.018$), and J ($r = -0.443$, $p = 0.023$) at the midtibia was found but the relationships were weaker. None of the other muscle groups were related to any bone measures. Compared to the unaffected limb, lower muscle mass may be a significant contributor to the poor structural development of the midtibia in individuals with unilateral CP. Future studies should investigate if specific strengthening of the quadriceps could lead to increased bone strength at the tibia.

Bone mass, Bone microarchitecture (TBS) and anthropometric measurements during childhood growth in Spanish girls. Luis Del Rio[1], Renaud Winzenrieth*[2], Catherine Cormier[3], Silvana Di Gregorio[4]. [1]Cetir Centre Medical, Spain, [2]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [3]AP-HP Groupe Hospitalier Cochin, France, [4]CETIR Centre Mèdic, Spain

The aim of the present study was to evaluate bone mass and bone micro-architectural texture as assessed by TBS (Trabecular Bone Score) modification at spine during childhood growth in girls.

The study group was composed of 415 healthy girls aged between 2 and 17 years old. Height, weight and BMI Z-scores were evaluated and compared to The WHO Child Growth Standards. Pubertal stage was evaluated using Tanner score. The areal BMD (aBMD) was assessed at spine L1-L4 using a prodigy densitometer (GE-LUNAR, USA). Pseudo 3D BMD (vBMD) was calculated based on cylindrical model proposed by Kroeger et al. (Bone Mineral, 1992). TBS was evaluated using TBS iNsight v2.0 (Medimaps, France). The LMS statistical method proposed by Cole and Green (Stat Med, 1992) was used to construct aBMD, vBMD and TBS age-related curves using R software (v2.15.3).

Mean age, Weight, Height and BMI Z-scores were respectively 10.9 ± 4.4 years, -0.22 ± 1.3, -0.44 ± 1.3 and 0.02 ± 1.2 SD respectively. Positive significant correlations ($p<.05$) exists between TBS and age, BMI, aBMD and vBMD ($r= 0.39, 0.27, 0.47$ and 0.43 respectively). Height, weight and BMI followed normal pattern with age (data not show).aBMD increases with the growth with an acceleration at the puberty (as presented figure 1 a). This finding is consistent with the data of Kalkwarf et al (JCEM 2007). When normalized by the 3D volume, effect of puberty on vBMD is more visible (see figure 1b). Before the puberty, vBMD trend seems to be flat. Concerning TBS, we observed first a decreasing phase until the puberty follow by an increasing phase until 17 (fig 1c).

DXA can be used to assess trabecular bone microarchitectural texture, as assessed by TBS, in children with a high degree of reliability. Age-related TBS curve can be useful, in complement to the BMD curve, to help clinician to identify children with bone microarchitectural modifications induced by chronic diseases or drug therapies.

SU0029

Cortical Bone Fragility Contributes to Fractures in Children. Sandra Iuliano-Burns*[1], Qingju Wang[1], Xiaofang Wang[2], Ali Ghasem-Zadeh[2], Roger Zebaze[1], Yohann Bala[3], Ego Seeman[1]. [1]Austin Health, University of Melbourne, Australia, [2]University of Melbourne, Australia, [3]University of Melbourne, Dept. of Medicine, Australia

Fractures are common in children, with up to 50% of boys and 40% of girls fracturing by the age of 18 years, and with reduced bone mineral density (BMD) observed in fracture cases. The highest incidence coincides with the pubertal growth spurt, when there is a transient reduction in volumetric vBMD and cortical thickness. We hypothesize that deficits in cortical thickness and increased cortical porosity are present in children with fractures.

We recruited 54 children (28 males, 26 females) with low trauma fractures and imaged their distal metaphyses of the contralateral radius and tibia using high-resolution peripheral quantitative computed tomography (Xtreme CT, Scanco, Switzerland). Cortical porosity, degree of mineralization (tissue mineralization density), and dimensions of the transitional zone (area between the hard cortex and trabecular bone) were determined using StrAx 1.0 software. Fracture case was compared to 54 age (11.9 $\pm$ 2.9 vs 11.7 $\pm$ 2.8 yrs), height (152.4 $\pm$ 16.7 vs 150.7 $\pm$ 15.2 cm) weight (46.6 $\pm$ 15.6 vs 45.8 $\pm$ 15.3 kg) and maturity matched controls.

Bone total cross sectional area was similar in cases and controls (total area; 224 $\pm$ 66 v 208 $\pm$ 59 mm2) however, compared to controls, distal radius cortical vBMD was 5% lower in cases (773 $\pm$ 114 vs. 819 $\pm$ 135 mg HA/cm3, $p < 0.05$) due to their 6% higher porosity (53 $\pm$ 8 vs. 50 $\pm$ 9%, $p < 0.05$) and 3% lower tissue mineralization density (61 $\pm$ 3 vs. 63 $\pm$ 3%, $p < 0.0001$). These differences were most evident in pre-pubertal boys ($n = 26$) in whom those with low trauma fractures had 26% thinner cortices (0.30 $\pm$ 0.07 vs 0.41 $\pm$ 0.12mm, $p < 0.01$), and a 9% wider transitional zone (2.77 $\pm$ 0.19 vs 2.55 $\pm$ 0.30 μm, $p < 0.05$) than controls. Fracture cases had greater trabecular area (107 $\pm$ 27 vs 84 $\pm$ 28 mm2, $p < 0.05$) with thicker (0.08 $\pm$ 0.01 vs 0.07 $\pm$ 0.0 mm, $p < 0.01$), fewer (1.8 $\pm$ 0.2 vs 2.1 $\pm$ 0.3 1/mm, $p < 0.01$) and more separated trabeculae (0.49 $\pm$ 0.08 vs. 0.41 $\pm$ 0.06 mm, $p < 0.01$) than controls. Similar deficits in bone structure were observed at the tibia with 6% lower cortical vBMD ($p < 0.05$), 2% lower tissue mineralization density ($p < 0.001$), and 9% higher porosity ($p < 0.05$) observed in all cases relative to controls.

We infer that material and structural abnormalities in the cortex contribute to bone fragility during accelerated growth in children and predispose to fractures should a fall occur.

Development of a New Tool for Evaluating Bone Mineralization as a Function of Age in Pediatric Patients. Joyce Keyak*[1], Liliane Gibbs[2], Sandra Murray[3], Antoine Hamedi-Sangsari[4], Diana Lubyanaya[5], AiChun Chen[5]. [1]Department of Radiological Sciences, University of California, Irvine, USA, [2]Pediatric Radiology, RADNET; & Department of Radiological Sciences, University of California, Irvine, USA, [3]University of California, Irvine & Miller Children's Hospital, Long Beach, USA, [4]School of Biological Sciences, University of California, Irvine, USA, [5]Department of Mathematics, University of California, Irvine, USA

Evaluating the underlying etiology of bone fractures in pediatric patients is an essential part of good medical practice but can be challenging because bone mineralization and size change with age. Knowledge of bone mineralization and size as a function of age is essential for differentiating fractures of healthy bones from fractures of diseased bones. Dual-energy x-ray absorptiometry, the most common method for evaluating bone mineral, provides areal measures of bone size and density that cannot distinguish thinner bones from lower density bones. In contrast, quantitative CT (QCT) scans provide true volumetric measures of bone size and density. CT scans are ordered routinely in pediatrics to diagnose injury or disease and could be used concurrently to evaluate bone mineralization. Thus, we are developing a CT scan-based tool and normative database to evaluate bone mineralization in pediatric patients.

We performed a pilot study using anonymized QCT scans of 9 male patients, age 3-17y, who were imaged for reasons unrelated to this study. Volume (V), bone mineral content (BMC) and bone mineral density (BMD) in one slice through the middle of each vertebral body were determined in the mineralized portions of T9 through L5. V and BMC were normalized to a 3mm-thickness. Linear regression was performed to quantify V, BMC and BMD at each level of the spine as a function of age.

Age predicted V ($p \leq 0.005$) and BMC ($p \leq 0.02$) at all spinal levels, but only predicted BMD at T10 ($p=0.04$) (Fig. 1). Standard errors of the estimates (SEE), which quantify scatter about the regression lines, were 11-19% of the mean V and 16-35% of the mean BMC. SEE was 6% of the mean BMD at T10, but the standard deviation (SD) was 8-17% of the mean BMD at each level, without the need to control for age.

This pilot study showed that V and BMD in 9 male patients age 3-17y were measured with a promising level of precision (SEE and SD=6-19%), despite substantial age-related anatomical variation. Developing this method for differentiating between healthy and diseased bone will require study of additional subjects, including girls of all ages, children under age 12 (who were underrepresented here), and patients with bone disease (to be evaluated as positive controls). Confidence limits for V, BMC and BMD of healthy bone as a function of age will then be established. Patients whose bone falls outside these limits would be considered abnormal and would be subject to further diagnostic testing.

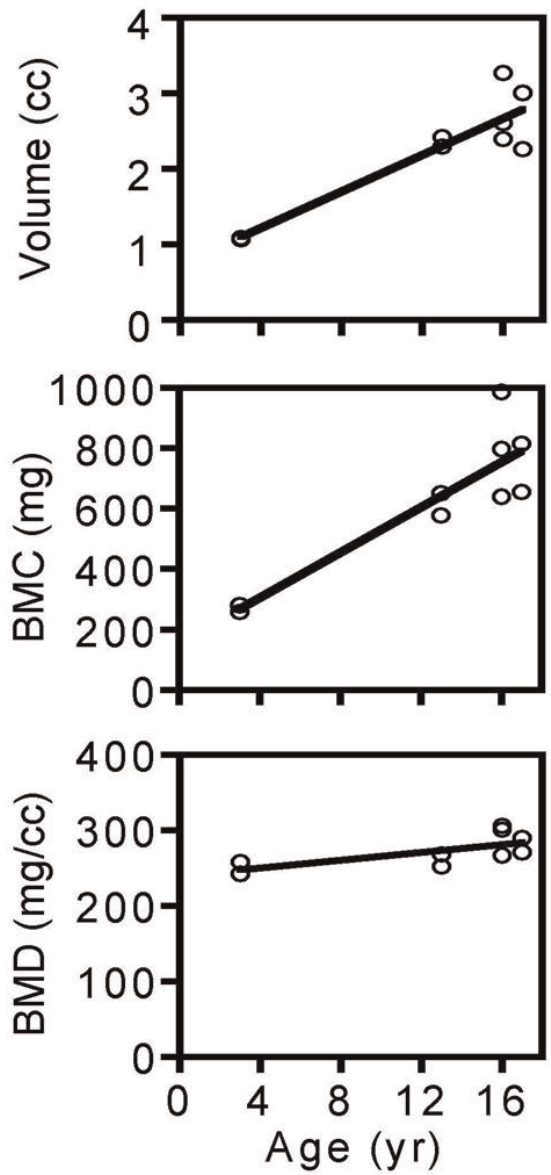

Fig. 1. T10 vertebral body volume, BMC and BMD versus age

Maternal Pregnancy Vitamin D Status and Offspring Bone Health: A Systematic Review and Meta-analysis. Nicholas Harvey*[1], Christopher Holroyd[1], Georgia Ntani[1], Kassim Javaid[2], Philip Cooper[1], Rebecca Moon[1], Zoe Cole[1], Tannaze Tinati[1], Nicholas Bishop[3], Keith Godfrey[4], Elaine Dennison[1], Janis Baird[1], Cyrus Cooper[1], UK Vitamin D in Pregnancy Working Group[1]. [1]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [2]NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, United Kingdom, [3]Academic Unit of Child Health, University of Sheffield, United Kingdom, [4]MRC Lifecourse Epidemiology Unit, University of Southampton, & NIHR Southampton Biomedical Research Centre, University of Southampton & University Hospital Southampton NHS Foundation Trust, United Kingdom

We aimed to elucidate whether 1) maternal circulating 25(OH)-vitamin D [25(OH)D] during pregnancy is associated with maternal and neonatal bone health; and 2) maternal supplementation with vitamin D in pregnancy leads to an improvement in these outcomes. Other health outcomes were also assessed.

Major electronic databases were searched from inception till June 2012, together with hand-searching of bibliographies and author contact. Primary outcomes: Maternal osteomalacia; Neonatal hypocalcaemia, rickets and bone mass. Secondary outcomes: Maternal quality of life; Neonatal body composition and bone mass, later offspring health (including asthma, diabetes, immune disease). We performed systematic review and where possible meta-analysis. All assessments were performed by two reviewers and according to UK CRD guidance.

After screening of 16,841 citations, 172 remained, with 73 finally included (including 10 clinical trials). There was considerable heterogeneity between the studies and for most outcomes there was conflicting evidence; however modest positive relationships were found between maternal serum 25(OH)D and 1) offspring birth weight in meta-analysis of 3 observational studies using log-transformed 25(OH)D concentrations; 2) offspring cord blood or postnatal calcium concentrations in a meta-analysis of 6 intervention studies (all found to be at high risk of bias); and 3) offspring bone mass in 5 observational studies judged to be of good quality, but which did not permit meta-analysis.

Although there was weak evidence to support a relationship between maternal 25(OH)-vitamin D status and offspring birth weight, bone mass and serum calcium concentrations, these findings were limited by their observational nature or low quality and risk of bias. High-quality intervention studies to investigate these outcomes would be appropriate, but the current evidence base is insufficient to directly inform clinical practice.

SU0032

Pre- and Early Post-Natal Methylphenidate Exposure and Rat Skeletal Development. David Komatsu*[1], David Fealey[2], Alexandra Filippi[2], Lacey Schwab[3], Jordan Fakhoury[4], Panayotis Thanos[5], Sherry A Ferguson[6]. [1]Stony Brook University, Dept. of Orthopaedics, USA, [2]School of Medicine, Stony Brook University, USA, [3]Department of Materials Science & Engineering, Stony Brook University, USA, [4]Department of Biology, Stony Brook University, USA, [5]Behavior Neuropharmacology & Neuroimaging Lab, Medical Department, Brookhaven National Laboratory, USA, [6]Division of Neurotoxicology, National Center for Toxicological Research/FDA, USA

The psychostimulant methylphenidate (MP) is widely prescribed to treat Attention Deficit Hyperactivity Disorder (ADHD). Although MP effectively attenuates ADHD symptoms, chronic treatment has been associated with significant growth impairment in children and adolescents. Moreover, our recent results have shown that chronic exposure of adolescent rats to MP not only impairs skeletal growth, but is also associated with less mineralized and biomechanically inferior bones. Approximately 4.4% of adults are diagnosed with ADHD and many of these are women of reproductive age. However, insufficient data exist regarding the use of MP during pregnancy. Our recent data in adolescent rats suggest that pre- and early post-natal MP treatment might produce similar alterations in skeletal development. To test this, Sprague Dawley dams were orally treated 3x/day with vehicle, MP-Low (2 mg/kg), MP-Medium (6 mg/kg), or MP-High (14 mg/kg) from gestational days 6-21. The pups were orally treated 2x/day with the same total daily dose (i.e., 0, 6, 18, or 42 mg/kg/day) as their dam on postnatal days 1-21, at which time bone samples were obtained. Samples (N=5-11/sex/treatment group) were analyzed and compared by 2-way ANOVA (sex, treatment, and interaction) with alpha=0.05. Length and diameter of left tibiae were measured with calipers but there were no significant treatment or sex differences. MicroCT was used to quantify cortical parameters at the mid-diaphysis and trabecular parameters at the distal metaphysis of left femora. Mid-diaphyseal periosteal volume was the sole parameter to show a significant treatment effect, with comparisons indicating that the MP-Low group was increased relative to vehicle. Comparisons of mid-diaphyseal periosteal and endosteal volume, trabecular spacing, and distal endosteal volume identified significant sex effects, with male values higher in all instances. There were no significant treatment by sex interactions. Overall, these data suggest that pre-natal and early post-natal exposure to MP may not adversely affect rat skeletal development. However, definitive conclusions cannot be reached until our analyses, in terms of both outcomes and full statistical power, have been completed. These studies are ongoing and their completion should allow determination of the extent to which developmental exposure to MP adversely affects rat skeletal development. Such data will provide much needed guidance to clinicians treating pregnant ADHD patients.

Relationships between Muscle Power, Force, Density and Bone Quality in Children, Adolescents and Young Adults. Leigh Gabel*, Heather McKay, Danmei Liu, Heather Macdonald. University of British Columbia, Canada

Purpose: The growing skeleton continually adapts to mechanical forces imposed by muscular contractions. Thus, we aimed to determine the influence of direct and surrogate measures of muscle power, force and density on bone quality.

Methods: We used high-resolution pQCT (HR-pQCT, Scanco Medical) to measure bone quality (bone macro-, microstructure, BMD and bone strength) at the distal tibia (8% site) in 173 females (14.5 y $\pm$ 3.9) and 146 males (15.5 y $\pm$ 3.4) who were participants in the UBC Healthy Bones III Study. Bone outcomes included total area (Tt.Ar, mm2) and bone mineral density (Tt.BMD, mg HA/cm3), trabecular bone volume ratio (BV/TV), thickness (Tb.Th, mm), number (Tb.N, 1/mm) and cortical density (Ct.BMD, mg HA/cm3), porosity (Ct.Po, %) and thickness (Ct.Th, mm). We applied finite element analysis to estimate bone strength (ultimate stress, UStress, MPa). We directly measured maximum muscle power from a single two-legged jump using a force plate (Watts, Novotec/Stratec Leonardo) and estimated muscle power from vertical jump height (VJH, cm) obtained with a Vertec device (Fitness Source). We used pQCT-derived muscle cross-sectional area (MCSA, mm2) at the tibial midshaft (50% site) as an estimate of muscle force and measured muscle density (mg/cm3) at the midshaft with pQCT (Novotec/Stratec XCT3000). We fit sex-specific multivariable regression models adjusting for maturity (menarcheal status in females, Tanner stage in males) and tibia length (surrogate for moment arm).

Results: All measures of muscle power and force were positively related (r=0.41-0.86; $p<0.001$). Muscle power explained 2-9% of the variance in all bone quality outcomes with the exception of Tb.Th and Ct.BMD in females and Tb.Th, Ct.Po and UStress in males. VJH explained 1-3% of the variance in Tb.Th, BV/TV, Tt.BMD and UStress in females and Tb.Th and Ct.Th in males. MCSA explained 2-15% of the variance in all bone quality outcomes with the exception of Tb.Th, Ct.BMD, and Ustress in females and Ct.Po and UStress in males. Muscle density was not an independent predictor of bone outcomes in females or males.

Discussion: Direct measures of muscle power and MCSA were significant predictors of bone quality and explained a similar amount of variance. Thus, either measure can be used to characterize the relationship between muscle and bone quality. In addition, our results indicate that muscle density is not a key determinant of bone quality in healthy children, adolescents and young adults.

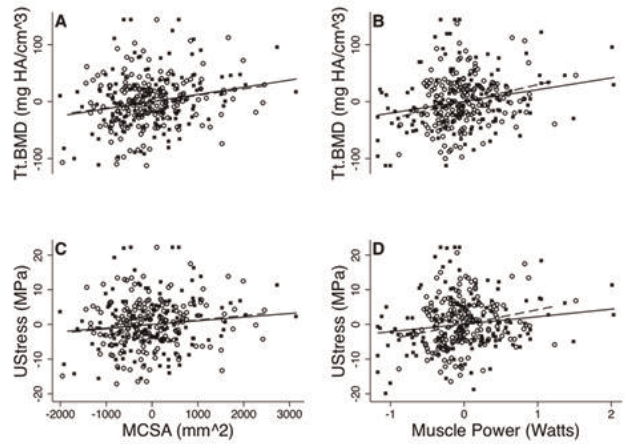

Figure 1. Relationships between residuals of MCSA, muscle power and bone quality (adjusted for maturity and moment arm) in females (open circles and dashed line) and males (solid squares and line).

Relationships between residuals of MCSA, muscle power and bone quality

Cessation of Ambulation Not Corticosteroid Exposure Results in a Dramatic loss of Trabecular Bone Density in Boys with Duchenne Muscular Dystrophy (DMD). Nicola Crabtree*[1], Natalie Bebbington[1], Heather McMurchie[2], Helen Roper[2], Nicholas Shaw[1]. [1]Birmingham Children's Hospital, United Kingdom, [2]Heart of England Hospital, United Kingdom

Fifty children were studied, 14 healthy boys (HB), 13 boys with DMD who remained ambulant (DMD-RA) and 23 boys with DMD who lost ambulation (DMD-LA). All boys with DMD were taking oral steroids. Peripheral quantitative computed tomography was used to measure bone geometry, density, strength and muscle mass of the non-dominant tibia. Measurements were made at baseline, 12 and 24 months at the distal metaphysis and mid diaphysis sites. Differences between the three groups were evaluated using ANOVA and a repeated measures model. There were no significant differences in age between the groups, mean age was 9.4(2.7), 8.7(1.9), 8.8(1.8) years for HB, DMD-RA and DMD-LA, respectively. There was no significant difference in steroid exposure between DMD groups. However, boys who lost ambulation had significantly lower muscle function. Healthy boys had significantly greater trabecular bone density (26%) than boys with DMD ($p<0.001$). However, the rate of change of trabecular bone density was only significant for boys who lost ambulation. By 2 years non-ambulant boys had 51% less trabecular bone than their healthy age matched peers (See Figure 1). Previous work has suggested that loss of ambulation can be predicted by assessment of muscle function.

Since this study highlights the dramatic loss of bone density with loss of ambulation it is likely that functional assessment can help identify the point at which medical intervention to strengthen bones should be considered.

Trabecular Bone Microarchitecture Impairment in Juvenile Systemic Lupus Erythematous (JSLE) with Low BMD for Chronological Age. Rosa Pereira*, Juliane Paupitz, Glauce Lima, Liliam Takayama, Jackeline Alvarenga, Luciana Seguro, Eloisa Bonfa. Faculdade de Medicina da Universidade de São Paulo, Brazil

Introduction: Young women with Lupus (SLE) are at high risk of low bone mass and fractures. Besides the effects of bone density, changes in microarchitecture also play an important role in bone disease in these patients. The objective of this study was to analyze bone microarchitecture in juvenile SLE (JSLE) patients with low and normal bone mineral density (BMD) for chronological age and clinical risk factors, glucocorticoid (GC) use and vitamin D status.Patients and Methods: Fifty-two JSLE female patients were evaluated. Demographic, anthropometric and clinical data including disease duration, disease activity score (SLEDAI) and GC use were recorded by interview and chart review. BMD and Vertebral Fracture Assessment (VFA) were analyzed by Dual-energy X-ray absorptiometry (DXA). Bone microarchitecture was measured using High-Resolution peripheral Quantitative Computed Tomography (HR-pQCT) at the distal radius and tibia. 25-hydroxyvitamin D levels were measured by radioimmunoassay. The patients were divided according BMD: low BMD for chronological age (Z-score of lumbar spine/or whole body ≤-2.0) n=20 and normal BMD for chronological age (Z-score of lumbar spine/or whole body >-2.0) n=32.Results: No difference was found between the 2 groups regarding age, body mass index, disease duration, SLEDAI. Patients with low BMD used higher GC maximum dose (48.75±20.12 vs. 30.54± 24.11 mg; p=0.006) and GC cumulative dose (92.84±72.32 vs. 46.76±58.71 g; p=0.02). Patients with low BMD also presented lower vitamin D levels (20±4.53 vs. 25.07± 8.92ng/mL;p=0.041), higher percentage of patients with fractures (25 vs. 6%;p=0.05) and higher number of total fractures (6 vs. 1.5%;p=0.002). Regarding HR-pQCT, patients with low BMD had lower values of bone microarchitecture parameters in distal radius (Table 1) and tibia (Table 2) as described below. Conclusion: The trabecular bone microarchitecture was significantly impaired in JSLE with low BMD for chronological age. GC use, lower vitamin D concentrations were also parameters related to low BMD. Further studies are necessary to assess the contribution of bone microarchitecture in the risk of fractures in JSLE patients.

Gnathodiaphyseal Dysplasia due to Mutations in the Cleavage Site of the C-propetide region of *COL1A1*: a Form of Osteogenesis Imperfecta with Bone Fragility, Increased Bone Mineral Density and Fibro-osseus Lesions of the Skull and Jaw. Emma Duncan*[1], Aideen McInerney-Leo[2], Andreas Zankl[2], Matthew Brown[3]. [1]Royal Brisbane & Women's Hospital, Australia, [2]University of Queensland Diamantina Institute, Australia, [3]Diamantina Institute of Cancer, Immunology & Metabolic Medicine, Australia

We report a mother and son with increased bone fragility, irregular bone density and fibro-osseus lesions in the skull and jaw, suggestive of the disorder gnathodiaphyseal dysplasia, but in whom sequencing revealed no mutation in Anoctamin-5 (*ANO5*), previously described as a causative gene for this condition. Whole exome sequencing revealed a de novo mutation A1218T in *COL1A1* in the mother, also inherited by her affected son. The mutation alters an amino acid within the C-propeptide region which is required for cleavage of the C-propeptide from the fibrillar collagen component during collagen maturation. Similar mutations have been reported in patients with a clinical picture of osteogenesis imperfecta but with normal or increased bone density. We conclude that C-propeptide mutations in *COL1A1* not only cause an unusual form of osteogenesis imperfecta with paradoxically increased bone mass, but also manifest other abnormalities including irregular bone density and fibro-osseus lesions in the skull and jaw. Further, we suggest that cases of gnathodiaphyseal dysplasia that are negative for *ANO5* be evaluated for mutations in the C-propeptide cleavage region of procollagen type 1.

Etanercept Administration to Neonatal SH3BP2 Knock-In Cherubism Mice Prevents TNF-α-induced Inflammation and Bone Loss. Teruhito Yoshitaka[1], Shu Ishida[2], Tomoyuki Mukai[2], Ernst Reichenberger[3], Yasuyoshi Ueki*[1]. [1]University of Missouri-Kansas City, School of Dentistry, USA, [2]University of Missouri-Kansas City, USA, [3]University of Connecticut Health Center, USA

Cherubism is a craniofacial disorder caused by gain-of-function mutations in the signaling adaptor protein, SH3BP2. In a mouse knock-in model for cherubism, we previously demonstrated that homozygous mutant mice develop T/B cell-independent systemic macrophage inflammation leading to bone erosion and joint destruction, while cherubism lesions in humans appear to be primarily limited to jaw bones. Previously we identified a critical role of TNF-α in this disease as inflammation and bone destruction were rescued in TNF-α-deficient cherubism mice. In the current study, we examined whether postnatal administration of etanercept, an anti-TNF-α antagonist, can prevent or ameliorate disease progression in cherubism mice. Neonatal (1 week old) homozygous mutants, where active inflammation has not yet developed, were treated twice/week for 7 weeks with a high dose (25mg/kg) or low dose (0.5mg/kg) etanercept. High dose treatment effectively rescued facial swelling in all mutants (n=7), as well as bone loss in the jaws and calvariae (n=7, $p<0.05$). Destruction of joints was fully rescued in all high dose-treated mutants. Moreover, the high dose treatment group showed a significant decrease in lung ($2.7\pm2.3\%$ vs. $9.1\pm4.0\%$) and liver ($0.1\pm0.1\%$ vs. $10.6\pm5.0\%$) inflammatory lesions ($p<0.05$). No significant effect was observed in low dose and vehicle (PBS)-treated groups; low-dose group ($9.6\pm5.6\%$ in lung, $9.9\pm7.2\%$ in liver, n=6) and vehicle group ($9.1\pm4.0\%$ in lung, $10.6\pm5.0\%$ in liver, n=6). However, when 10-week-old adult cherubism mice with fully active inflammation were treated with etanercept for 7 weeks (n=7), while high dose treatment effectively reduced liver inflammation ($4.1\pm3.5\%$ in etanercept group vs. $10.6\pm6.1\%$ in PBS group), the high dose administration did not rescue facial swelling and did not decrease bone loss and lung inflammation ($7.4\pm4.3\%$ vs. $5.2\pm2.7\%$). Mutant macrophages express more IL-1β in response to TNF-α and in turn IL-1β induces more TNF-α production in mutant macrophages, suggesting that IL-1β-driven inflammation may be responsible for the reduced effectiveness of etanercept treatment in the adult. Taken together, our study suggests that anti-TNF-α therapy may be an effective prophylactic treatment in young cherubism patients, if treated before establishment of inflammation or bone resorption. Therefore, early genetic diagnosis and early treatment with anti-TNF-α antagonists may be important to prevent or ameliorate cherubism lesions in humans.

Sclerostin Antibody Increases Cortical Bone Thickness in a Rapidly Growing Brtl/+ Model of OI by Inducing Bone Formation on Quiescent or Resorbing Surfaces. Benjamin Sinder*[1], Joseph Salemi[1], Michael Ominsky[2], Michelle Caird[1], Joan Marini[3], Kenneth Kozloff[4]. [1]University of Michigan, USA, [2]Amgen Inc., USA, [3]National Institute of Child Health & Human Development, USA, [4]University of Michigan Department of Orthopaedic Surgery, USA

Osteogenesis imperfecta (OI) is a genetic collagen-related disorder characterized by brittle bones, which presents most severely in children. Treatment with sclerostin antibody (Scl-Ab) has been shown to increase bone formation and bone strength with modest reductions in bone resorption in murine models of OI (Sinder et al JBMR 2013). Using 3 week-old male Brtl/+ mice with dominant OI, that carry a G349C substitution on one col1a1 allele, we previously showed that 5 weeks of Scl-Ab (25mg/kg, 2x week) increased femoral cortical bone mass and strength (Sinder et al, ASBMR 2012). Here, we performed dynamic histomorphometry to examine Scl-Ab effects on the spatial pattern of bone formation in these rapidly growing mice.

Mineralizing surface (MS/BS) and mineral apposition rate (MAR) were quantified from WT and Brtl/+ femurs contralateral to those previously tested (n=5-7/group). Fluorescent labels given 1 week and 1 day before sac were analyzed on a cortical section immediately distal to the third trochanter. To assess spatial variation across the cortex, MS/BS and MAR were quantified separately on periosteal and endosteal surfaces in the posterior and anterior quadrants using a method similar to Bivi et al (JBMR 2012).

We confirmed a strong posterior-shifting cortical drift in untreated WT and Brtl/+, with MS/BS near 100% on the posterior periosteal surface and anterior endosteal surface (Figure). On the opposing surfaces (posterior endosteal and anterior periosteal) where resorption would be expected to occur consistent with drift direction, MS/BS was much lower (0-38%). Scl-Ab increased MS/BS on these low bone-forming surfaces in both WT and Brtl/+ mice (Table). On high bone-forming surfaces, MAR was marginally elevated (posterior periosteal) or slightly reduced (anterior endosteal). This slight decrease in anterior endosteal MAR may be compensatory to the robust increase in anterior periosteal bone formation. Regardless of the mechanism, Scl-Ab increased cortical thickness in both the anterior and posterior compartment of Brtl/+.

In this study, Scl-Ab increased cortical thickness in Brtl/+ and WT mice by activating bone formation on regions of the cortex that typically undergo resorption as part of a modeling drift. These results highlight the ability of Scl-Ab to activate new bone formation on quiescent or resorptive surfaces, while maintaining the modeling based bone formation that occurs in rapidly growing animals.

3D Visualization of Reference-Point Indentation in Human and Murine Bone. John Jameson*[1], Alexander Proctor[2], Carolyne Albert[3], Gerald Harris[3]. [1]Lawrence Berkeley National Lab, USA, [2]Active Life Scientific, USA, [3]Orthopaedic & Rehabilitation Engineering Center, Department of Biomedical Engineering, Marquette University, USA

Traditional techniques for assessing bone strength and fracture resistance such as 3 or 4-point bending of whole bones or machined beams are well-developed but destructive. Recently, Reference-Point Indentation (RPI) has been introduced as a minimally destructive method of determining bone tissue properties at physiologically relevant length scales [1-2]. However, to date there is no data showing the 3D damage mechanisms associated with RPI. The purpose of this study was to use high-resolution imaging to visualize RPI tests of human and murine bone, as well as to compare indents from healthy and pathological tissue.

Femora from healthy mice and a mouse model for severe osteogenesis imperfecta (oim; $N_{control}=N_{oim}=3$, Age=12wks) were extracted and tested with repeated RPI measurements (BioDent Hfc, Active Life Scientific, Inc.) along the long axis of the bone using a maximum force of 5 N at 2 Hz for 7 cycles. Each indent was imaged by synchrotron radiation on the X-ray microtomography (SRμCT) beamline at the Advanced Light Source (ALS, Berkeley, CA) with a nominal pixel size of 1.33 μm. Similar imaging was performed on indents from a healthy human tibia donated from an unrelated cadaver study.

Oim femora showed inferior material behavior as assessed by RPI measures (Table 1). On average, first cycle indentation distance (ID), ID increase (IDI), total ID (TID), and creep ID (CID) were higher in oim bones compared to controls, while the slope of the unloading portion of the first cycle (US) was reduced. SRμCT images of representative damage regions revealed an increase in the degree of micro-cracking in oim bone compared to controls (Fig 1-2). Healthy human bone also appeared to display evidence of crack bridging, a common extrinsic toughening mechanism (Fig 3).

The results of this preliminary study suggest that RPI is an effective method for evaluating differences in the material behavior of healthy versus oim mouse bone. Similar trends in RPI parameters have been reported in control versus diabetic rat bone, which is known to exhibit increased fragility [2]. For the first time, we also show how SRμCT can be used to complement RPI testing by providing valuable 3D information on sub-surface fracture behavior. In oim bone, increased micro-cracking is likely a toughening mechanism required to mitigate the reduced initiation toughness.

A New Viewpoint on Using Glycine to Prevent and Treat Rats' Osteoporosis.

Jingkun Zhang*. Nankai University, Peoples Republic of China

Abstrat: This study will show a new viewpoint about osteoporosis(OP), which proposes that the lack of glycine is the main cause for OP. Glycine determines the structure and properties of bone matrix.Scientifically added glycine and let it participate in the transform of bone trabeculae, in which process to optimize and strengthen the structure of bone trabeculae and further to repair the damaged bone matrix, is the biological route to prevent and treat osteoporosis. The SD rat osteoporosis model was made by removing SD female rat's two ovaries. In order to overcome the barriers of the small intestine, the glycine was replaced by glycine chelated calcium(GCC) in this experiment. In addition to the GCC group, three control groups (ovariectomized group, bisphosphate group, sham operated group) were all fed for 100 days, then were executed and the microstructure of their femur trabeculae were detected. The trabeculae of the GCC group is orderly, grossus and presents prominent mechanical properties, while the group of bisphosphate is disorderly and with serious obstacles of metabolism. All 12 parameters of dynamic and static morphometry in GCC group rats' bone structure are significantly better than the corresponding bisphosphate group. Some important physical parameters in the GCC group's bone structure, e.g. BMD?strength and deflection of femur, are remarkable higher than the sham operated group, which indicated that some important physical properties of rats' femur are notable improved. Effectively added glycine and let it participate in the bone metabolism, not only can treat osteoporosis, but also can conspicuously prevent osteoporosis.

Key words:glycine, osteoporosis, treat, prevent

A Proteome Profile of Fragile Human Bones. Corinne Thomas*, Dmitri Zagorevski, Grazyna Sroga, Pankaj Karande, Deepak Vashishth. Rensselaer Polytechnic Institute, USA

Introduction: Bone fragility fractures are a leading health concern in many countries, including the United States. Currently, the susceptibility of bone to fragility fracture is assessed through a dual-energy X-ray absorptiometry (DXA) scan which measures bone mineral density (BMD), or by peripheral quantitative computed tomography (pQCT) which is expensive and inaccessible to many patients[1]. None of the assessment techniques account for the chemical modifications in bone that occur with age and health. BMD may not be enough to accurately predict bone fragility and a recent study by our group[2] demonstrated that the levels of the proteins osteopontin, osteocalcin, and the advance glycation end products (AGEs) of collagen are better predictors of bone fracture than BMD. The objective of this study was to develop a mass spectrometry protocol that will allow for a comparison of the proteome of healthy bone to fragile bone, and identify any other potential targets that may characterize bone quality.

Methods: The mass spectrometry protocol was developed and optimized using in vitro glycation of synthesized peptide fragments mimicking those of osteocalcin. Bone samples from donors aged 29 - 89 years old were selected to provide a wide range of bone quality for comparison. These samples were powdered and the proteins extracted for proteomic analysis. The separated proteins were subjected to proteolytic digestion from a variety of proteases. The digests were then analyzed using MALDI-TOF mass spectrometry as well as LCMS.

Results: Glycation of peptide samples caused a peak shift in the MALDI spectrum. Depending on the protease treatment and age of the donor, select peaks were lost or demonstrated a shift in bone samples. Peak shift occurred in areas where the mass of a peptide fragment changed due to a modification such as glycation, and the loss of peak was associated with the loss of a polypeptide fragment was not formed due to the cleavage site being blocked. The differing fragments shown with each enzyme (Figure 1) allowed for specific proteins and their modifications to be identified.

Altered Chemokine Signaling in Fracture Callus in Response to Binge Alcohol Exposure. Roman Natoli*[1], Rachel Nauer[1], John Callaci[2]. [1]Loyola University Medical Center Chicago, USA, [2]Loyola University of Chicago, USA

Alcohol use increases the risk of impaired fracture healing, however the underlying mechanisms are not well understood. Using a clinically relevant paradigm, our laboratory has shown that binge alcohol exposure prior to creation of a stabilized fracture in rodents impairs fracture healing, leading to defects in callus size, tissue composition, and strength, and suggesting possible impairment in mesenchymal stem cell (MSC) homing to or activity at the injury site. It is known that MSCs are recruited to healing fractures through chemokine interactions such as stromal cell-derived factor-1 (SDF-1)/CXCR4 and osteopontin (OPN)/CD44. Therefore, we hypothesized that alcohol exposure may deregulate SDF-1 and/or OPN signaling in the fracture callus during early stages of healing.

Adolescent male C57BL/6 mice were exposed to a binge alcohol (EtOH) paradigm. Exposure consisted of a 20% EtOH in saline solution administered via intraperitoneal (IP) injection at a dose of 2g/kg for 3 days 1 week prior to injury and then 3 consecutive days leading up to fracture. Control mice were given equal volume of saline IP. On the day of injury the tibia was stabilized with a stainless steel pin with subsequent surgical creation of a fracture. Saline or EtOH exposure was continued daily after injury. Mice were euthanized at 3 and 7 days post-fracture, and protein was isolated from intact contralateral tibiae and the calluses of fractured limbs. OPN levels were assessed via Western blotting and SDF-1 via ELISA. Data were analyzed using a 2-way ANOVA with Tukey's post-hoc testing.

Histologic examination revealed diminished external callus in the EtOH group consisting of undifferentiated mesenchymal tissue. Protein analysis showed decreased SDF-1 and OPN levels at 3 days post-fracture in control and EtOH fracture calluses compared with contralateral tibiae. At 7 days post-injury, calluses from control mice showed a significant increase in OPN expression compared to contralateral tibiae; this change was not observed in mice exposed to EtOH (Fig. 1). In contrast, SDF-1 levels remained decreased in the fracture callus in both control and EtOH exposed mice at 7 days. These results suggest impaired fracture healing following binge alcohol exposure may be related to changes in OPN/CD44 signaling at the fracture site. This finding has implications for understanding the mechanisms underlying alcohol-deficient fracture repair and the possible clinical use of MSCs as a cell based therapy.
