DISCLOSURE/CONFLICT OF INTEREST

The Federation of American Societies for Experimental Biology (FASEB) requires that audiences at FASEB-sponsored educational programs be informed of a presenter's (speaker, faculty, author, or contributor) academic and professional affiliations, and the existence of any significant financial interest or other relationship a presenter has with the manufacturer(s) of any commercial product(s) discussed in an educational presentation. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The Program will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

All authors of submitted abstracts completed the disclosure statement in the online submission program. Invited speakers who are not required to submit an abstract received a form in the mail that they completed and returned.

Disclosure may include any relationship that may bias one's presentation or which, if known, could give the perception of bias. These situations may include, but are not limited to:

DISCLOSURE KEY

1. stock options or bond holdings in a for-profit corporation or self-directed pension plan
2. research grants
3. employment (full or part-time)
4. ownership or partnership
5. consulting fees or other remuneration
6. non-remunerative positions of influence such as officer, board member, trustee, or public spokesperson
7. receipt of royalties
8. speaker's bureau

For full-time employees of industry or government, the affiliation listed in the *2002 Program and Abstracts* will constitute full disclosure.

Disclosures for invited speakers and abstract presenters are provided at the end of the session listing for invited speakers and directly after the body of an abstract for abstract submissions. If there is no conflict of interest or disclosure listed, this means that the invited speaker and/or abstract presenter indicated no conflicts to disclose.

The disclosure information will correspond to the key above. If disclosures are given, the company name, along with the respective disclosure relationship number will be listed (for example: Company Name, 2, 8.).

Targeted Disruption of Secreted Frizzled-Related Protein (SFRP)-1 in Mice Leads to Decreased Osteoblast and Osteocyte Apoptosis and Increased Trabecular Bone Formation. P. Bodine[1], W. Zhao[1], Y. Kharode[1], L. Borella[1], F. Bex[1], A. Lambert*[2], M. Goad*[2], G. Stein[3], J. Lian[3], B. Komm[1]. [1]Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA, [2]Investigational Pathology, Wyeth Research, Andover, MA, USA, [3]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

SFRP-1 is a secreted Wnt antagonist. We have previously reported that overexpression of SFRP-1 in human osteoblasts antagonizes Wnt-signaling and accelerates apoptosis. In order to determine if SFRP-1 affects osteoblast function in vivo, we generated a knockout (-/-) mouse line that contained the lacZ coding sequence in place of exon 1 of the SFRP-1 gene. SFRP-1 mRNA was expressed in kidneys, bones and other tissues of wild-type (+/+) mice, while beta-galactosidase activity was detected in the same tissues and in osteoblasts and osteocytes of -/- animals. Overall, the -/- mice appeared normal when compared to the +/+ controls. Prior to reaching peak bone mineral density (BMD), the skeletons of the -/- and +/+ mice were similar. However, beginning at 20 weeks of age and extending until 40 weeks, the -/- mice exhibited large increases in trabecular BMD and bone volume when compared to the +/+ controls. Volumetric trabecular BMD, as determined by peripheral quantitative computed tomography, was 24% higher in tibias of the -/- males at 35 weeks of age. Likewise, trabecular bone and mineralized areas determined histologically increased up to 143% in femurs from the -/- males and females at 35 weeks of age. At the same time, the mineral apposition rate as determined by calcein labeling increased up to 8% in femoral trabecular bone of the -/- mice. Femoral trabecular bone volume, number, thickness and connectivity density as determined by high-resolution micro-computed tomography also increased up to 91% in the -/- males and females at 26 and 35 weeks of age. Additionally, lumbar vertebral trabecular bone volume and number as seen by histomorphometry increased up to 61% in the 40-week old female -/- mice. As predicted from in vitro studies, apoptosis of calvarial osteoblasts and osteocytes as determined by TUNEL staining decreased by as much as 56% in the 33-week old -/- females. Finally, in vitro differentiation of bone marrow osteoprogenitors to alkaline phosphatase positive colonies increased up to 5-fold in cells from 26- and 40-week old -/- females. These results indicate for the first time that SFRP-1 is a negative regulator of osteoblast and osteocyte survival, osteoblast differentiation and bone formation in mice. Moreover, deletion of SFRP-1 results in a temporal delay of age-related trabecular bone loss.

Wnt-mediated Signaling via LRP5 and Beta-catenin Induce Osteoblast Differentiation and Mediates the Effects of BMP2. S. Roman Roman[1], B. Vayssière*[1], D. Shi*[2], F. Dunn*[3], R. Baron[1], G. Rawadi*[1]. [1]Proskelia, Romainville, France, [2]CNRS, Paris, France, [3]Aventis Pharma, Romainville, France.

LRP5 deficiency in human results in deficient trabecular bone volume leading to a severe osteoporosis. Furthermore, a mutation in the extracellular domain of LRP5 is genetically associated with higher bone mass in humans. LRP5 functions as a Wnt coreceptor in the canonical signaling pathway that employs β-catenin as a downstream effector. LRP5 is expressed in osteoblasts both during embryonic development and postnatally. We have investigated the involvement of Wnt/LRP5 cascade in osteoblast function by using the pluripotent mesenchymal cell lines C3H10T1/2, C2C12 and ST2 and the osteoblast cell line MC3T3-E1. Wnt1, 2, and 3a induced the expression of alkaline phosphatase (ALP) activity in the pluripotent cells. In contrast, Wnt4 and 5a failed to exhibit the same activity. Unlike Wnt1, 2 and 3a , activation by Wnt4 and 5 does not affect the β-catenin pathway. Confirming a key role of β-catenin, overexpression of a β-catenin stable mutant or treatment with LiCl, which stabilizes cytoplasmic β-catenin by inhibiting GSK3β, mimicked the effect of Wnt1, 2, and 3a. Taken together, this data indicates that ALP induction by Wnt is mediated by β-catenin signaling. We then assessed the involvement of LRP5 in Wnt-mediated ALP induction. Overexpression of either LRP5 dominant negative forms or the LRP5/6 selective inhibitor dickkopf 1 (dkk1) inhibited the induction of ALP by Wnt, indicating that LRP5 is required for this Wnt activity. Using Noggin, a BMP inhibitor, or cyclopamine, an Hedgehog inhibitor, revealed that the induction of ALP by Wnt is independent on the expression of these morphogenetic proteins known to induce ALP. In contrast, blocking Wnt/LRP5 signaling inhibited the ability of both BMP2 and Shh to induce ALP in mesenchymal cells. Unlike BMP2 and Shh, de novo synthesis of proteins is not required for Wnt to induce ALP mRNA. Moreover BMP2 is able to increase Wnt expression in our cells. Altogether these data strongly suggest that the capacity of BMP2 and Shh to induce ALP relies on Wnt expression and the Wnt/LRP5 cascade. Although Wnts did not affect ALP activity displayed by MC3T3-E1 cells, antagonizing the Wnt/LRP5 pathway decreased ALP expression in these cells. Finally, over-expression of dkk1 in MC3T3-E1 inhibited mineralization in a BMP-2-dependent assay. Thus, LRP5-dependent control of ALP expression and bone mineralization could constitute one of the molecular mechanisms leading to the phenotypes displayed by OPPG and HBM patients. In conclusion our data demonstrate a crucial role of Wnt-mediated signaling via LRP5 in osteoblast function.

An Osteoblast-Specific Transcription Factor Required for Osteogenesis In Vivo But Transcribed from a Ubiquitous Gene. X. Yang, T. Schinke, G. Karsenty. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

OSE1 and OSE2 are two osteoblast-specific cis-acting elements present in the promoter of Osteocalcin, the most osteoblast-specific gene. To identify the factor binding to OSE1, provisionally called OSEBF1, we used a biochemical approach and eventually isolated a cDNA encoding it. OSEBF1 is a leucine zipper-containing protein present only in nuclear extracts of osteoblasts. Transient expression of OSEBF1 in non-osteoblastic cells, but of no other leucine-zipper proteins, increases the activity of the Osteocalcin promoter via the OSE1 element, whereas OSEBF1 fails to transactivate reporter constructs containing binding sites for other leucine-zipper proteins. OSEBF1-deficient mice were generated and most of them die perinatally, however the ones surviving beyond birth are dwarf throughout life. Histologic analysis of the OSEBF1-deficient mice showed fewer osteoblasts than in wild-type littermates, a marked decrease in bone mass, and a delayed ossification, demonstrating the biologic importance of this protein. OSEBF1-deficient osteoblasts proliferate 50% slower than wild-type osteoblasts in vitro, indicating that OSEBF1 is a regulator of osteoblast proliferation. Surprisingly, given the osteoblast-specific synthesis of OSEBF1 and the selective bone phenotype of OSEBF1-deficient mice, this protein is transcribed from a ubiquitously expressed gene as demonstrated by Northern blot analysis. Treatment of non-osteoblast cells with a proteasome inhibitor induced OSEBF1 accumulation, its binding to OSE1, transactivation of Osteocalcin promoter, and expression of endogenous Osteocalcin. Furthermore, endogenous inactivation of a specific ubiquitination-conjugating enzyme by RNA interference in NIH3T3 fibroblasts induced the accumulation of OSEBF1 otherwise absent from these cells. In summary, our results identify a novel transcription factor required for osteoblast proliferation and differentiation and present the first example of a cell-specific transcription factor whose expression pattern is regulated post-translationally. The fact that OSEBF1-deficient mice have osteoblasts, albeit a decreased number, suggests that OSEBF1 acts downstream of Cbfa1 or in a Cbfa1-independent pathway.

1004

Cbfb, a Well-Known Regulator of Hematopoiesis, Cooperates with Cbfa1 and Plays a Critical Role in Bone Development. M. Kundu*[1], A. Javed[2], Y. Yang*[1], G. Nuckolls*[3], M. Muenke*[1], J. Lian[2], G. Stein[2], P. Liu*[1]. [1]National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA, [2]Department of Cell Biology, University of Massachusetts, Worcester, MA, USA, [3]National Institute of Arthritis, Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD, USA.

Cbfa1 is essential for bone development in mouse models, and mutations in CBFA1 are found in 65-80% of patients with cleido-cranial dysplasia (CCD), a developmental syndrome characterized by a variety of skeletal and dental defects. Although all Cbfa family members (encoded by Cbfa genes can interact with Cbfb (encoded by Cbfb) and form heterodimeric transcription complexes, a role for Cbfb in bone development has not been demonstrated. Cbfb-/- embryos die during mid-gestation at 12.5 dpc due to severe hemorrhage and absence of definitive hematopoiesis, precluding the evaluation of Cbfb function at later time points. We fused the gene encoding green fluorescent protein (GFP) with the Cbfb gene by homologous recombination in murine embryonic stem (ES) cells. Heterozygous Cbfb-GFP mice had normal life spans and appeared normal. However, homozygous pups died within the first day after birth. While no major defects in hematopoiesis were detected and no bleeding diathesis was apparent, homozygous embryos exhibited a delay in endochondral as well as membranous ossification that was especially evident in the cranial and pelvic bones. The phenotype of these mice was similar to and more severe than that of Cbfa1+/- mice. In situ hybridization and GFP detection showed Cbfb expression in the developing bones. In addition, we demonstrated that Cbfb interacts with Cbfa1 and enhances its transactivation ability. Biochemical studies suggest that Cbfb-GFP represents a hypomorphic allele that maintains sufficient function in hematopoietic cells to bypass the early embryonic lethality, but uncovers a novel role for Cbfb in bone development. Thus, this study provides the first conclusive evidence that Cbfb plays a critical role in bone development and raises the possibility that mutations in CBFB may be responsible for some of the cases of CCD that are not linked to CBFA1 mutations.

1005

Dmp1-Deficient Mice Develop Dwarfism, Chondrodysplasia, and Exhibit Disorganized Bone Mineralization During Postnatal Development. J. Q. Feng[1], L. Ye*[1], D. Chen[2], H. Huang*[1], J. Zhang*[1], Y. Lu*[1], G. Li[3], S. L. Dallas[1], S. E. Harris[1], L. Bonewald[1], Y. Mishina*[4]. [1]Oral Biology, School of Dentistry, University of Missouri-Kansas City, Kansas City, MO, USA, [2]Molecular Medicine, UTHSCSA, San Antonio, TX, USA, [3]Trauma, The Queen's University of Belfast, Belfast, United Kingdom, [4]NIEHS/NIH, Research Triangle Park, NC, USA.

Dmp-1, initially identified in dentin, is an acidic non-collagenous matrix protein that is expressed in osteoblasts and highly expressed in osteocytes. In addition to bone cells, we have also found expression in hypertrophic chondrocytes in both primary and secondary ossification centers. To determine the role of this matrix protein in dentin, cartilage and bone, Dmp1 null mice were generated. These mice appeared normal at birth, but began to exhibit a dwarfism phenotype by three weeks of age that became more profound by 3 months. Bone radiographs revealed skeletal abnormalities such as shortening of the long bones, widening of the metaphysis, kyphosis and delay of secondary ossification. A dramatic reduction in bone mineral density in both the appendicular and craniofacial skeleton was observed using pQCT and verified by von Kossa staining of histological sections. Histological examination of the long bones revealed an extremely disorganized growth plate in which the columnar organization of the hypertrophic zone was disrupted and replaced with clusters of hypertrophic chondrocytes. This disorganized growth plate appeared to be responsible for the presence of an under-mineralized, hyperostotic matrix in place of the normal trabeculae. Cortical bone was undermineralized and disorganized, especially endosteally and there were many discontinuities in the cortex where mineral was absent. By three months of age, the animals exhibited osteoarthritic changes including narrowing of the joint spaces, the formation of bony cysts, and erosion of the joints. Preliminary studies suggest that the disorganized hypertrophic chondrocytes are undergoing increased cell death. Based on these initial analyses, these mice express multiple skeletal abnormalities analogous to the human conditions of dwarfism, chondrodysplasia, and possibly osteoarthritis and conditions of reduced bone mineral density. Therefore, Dmp1 expression is critical for growth plate formation and function leading to the coupling of chondrogenesis with osteogenesis. Dmp1 also appears to play an essential role in mineralization and subsequently, bone remodeling.

Deficiency of CIZ, A Novel Negative Regulator of BMP, Enhances Osterix Gene Expression in Bone, Osteoblastic Differentiation in Culture and BMP- as Well as Ablation-Induced Bone Formation in vivo. M. Morinobu[1], T. Nakamoto*[2], K. Tsuji[1], Z. Shen[1], A. Nifuji[1], H. Yamamoto*[3], H. Hirai*[2], M. Noda[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Dept of Hematology and Oncology, University of Tokyo, Tokyo, Japan, [3]Ehime University, Matsuyama, Japan.

CIZ (Cas interacting zinc finger protein) is a nucleocytoplasmic shuttling protein, which localizes at cell adhesion complex in culture, binds to p130CAS and binds to DNA to act as a transcriptional factor to regulate expression of genes such as those encoding MMPs. CIZ is expressed in osteoblasts in culture and regulates proliferation and type-I collagen gene expression. However, function of CIZ in bone in vivo has not been known. The aim of this study is to elucidate the function of CIZ in bone in vivo. For this purpose we examined the bones in CIZ-deficient (CIZ-KO) mice. The skeletal structures of CIZ-KO mice appeared normal. However, the levels of alkaline phosphatase (ALP) and Osterix mRNA detected by RT-PCR analysis using total RNA from whole long bone were enhanced in CIZ-KO mice. Bone marrow cells obtained from the femora of CIZ-KO mice formed more mineralized nodules than wild-type cells, when cultured in the presence of ascorbic acid and beta-glycerophosphate. These bone marrow cells from CIZ-KO mice also revealed higher basal level ALP activities than the cells from wild-type mice. The ALP activity was enhanced by BMP treatment in wild-type bone marrow cells. Such BMP enhancement was significantly augmented in the bone marrow cells from CIZ-KO mice. To test the hypothesis that CIZ suppresses bone formation activity in vivo, bone marrow ablation was performed. New bone formation was observed after ablation in wild-type mice. In CIZ-KO mice, such new bone formation was significantly enhanced compared to that in wild-type mice. To test whether CIZ deficiency enhances bone formation through augmentation of BMP-effects on bone formation in vivo, BMP-2 was injected every other day for 10 days onto the calvaria to induce orthotopic bone formation. BMP induced bone formation on the calvaria of wild-type mice. CIZ deficiency significantly enhanced BMP induced new bone formation on the calvaria compared to that in wild-type mice. These results indicate that CIZ acts as a novel type inhibitor of BMP-2 signaling in bone in vivo and plays a critical role in the regulation of osteoblastic differentiation and bone formation.

Effects of Parathyroid Hormone, Alendronate, or Both on Bone Density in Osteoporotic Men. J. S. Finkelstein, A. Hayes*, A. Rao*, R. M. Neer. Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

Once daily parathyroid hormone (PTH) administration increases bone turnover and bone mineral density (BMD) and reduces vertebral fracture incidence in osteoporotic men. Because PTH increases both bone formation and bone resorption, it is possible that combining PTH with an anti-resorptive agent will enhance its effects of BMD. To test this hypothesis, we randomly assigned 83 men, age 46-85, whose lumbar spine and/or femoral neck BMD was at least 2 SD below the mean of normal young men to receive: alendronate 10 mg orally daily (ALN, n=28), PTH 40 ug sc daily (PTH, n=27), or both (B, n=28) for 30 months. PTH therapy was begun at month 6. All men had normal serum PTH, 25-OH D, TSH, and testosterone levels at entry and none had disorders or had been treated with medications known to affect bone metabolism. Calcium intake was maintained at 1000-1200 mg/day and serum 25-OH D levels were maintained at or above 15 ng/mL. BMD of the posterior-anterior lumbar spine, proximal femur, total body (without head region), and radius shaft were measured every 6 months by DXA (Hologic 4500A). To date, 36 men (n=13, 9, and 14 receiving ALN, PTH, and B) have completed at least 18 months of therapy. Mean (+SD) changes in BMD and alkaline phosphatase to month 18 are shown in the table:

Group	Lumbar spine	Total hip	Radius Shaft	Total Body	Alk Phosphatase
ALN	6.1 + 2.7*	2.2 + 3.2	0.3 + 2.4	2.9 + 3.7	-18 + 8+
PTH	13.7 + 4.3**	2.6 + 5.5	-0.3 + 2.5	-0.4 + 4.3***	74 + 72++
BOTH	10.7 + 2.9	4.0 + 4.0	1.0 + 2.5	4.0 + 4.0	5 + 38

*P<0.001 vs PTH and B; **P=0.06 vs B; ***P=0.07 vs ALN and P=0.02 vs B; +P=0.07 vs B; ++P<0.001 vs ALN and B

When measured 24 hours after the last PTH dose, 0 of 97 serum calcium determinations were elevated in men treated with PTH alone and 1 of 119 were elevated in men treated with PTH and ALN. When measured 4 hours after the last PTH dose, 4 of 99 serum calcium determinations were elevated in men treated with PTH alone and 2 of 119 were elevated in men treated with PTH and ALN. These data suggest that combining PTH and ALN is superior to PTH alone for total body BMD but that ALN may diminish the anabolic effect of PTH on spine BMD. Moreover, ALN appears to block the ability of PTH to increase alkaline phosphatase production. Combining an anabolic and an anti-resorptive agent has complex effects on BMD, the clinical consequences of which are unknown.

An Activating Calcium Sensing Receptor Mutation Associated with Normocalcemic (Idiopathic) Hypercalciuric Nephrolithiasis. P. T. Christie[1], A. J. Curley*[1], B. Harding*[1], M. R. Bowl*[1], J. J. O. Turner*[1], F. P. Cappuccio*[2], C. B. Langman[3], A. K. Saggar*[2], T. Taylor*[4], R. V. Thakker[1]. [1]Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom, [2]Clinical Genetics, St George's Hospital Medical School, London, United Kingdom, [3]Northwestern University Medical School, Chicago, IL, USA, [4]Department of Paediatrics, St Richard's Hospital, Chichester, United Kingdom.

Calcium sensing receptor (CaSR) mutations are associated with 4 clinical phenotypes: familial hypocalciuric hypercalcemia (FHH), neonatal primary hyperparathyroidism and familial hypercalcemia with hypercalciuria, which are due to loss of function mutations; and autosomal dominant hypocalcemia with hypercalciuria (ADHH), which is due to gain of function mutations. It has also been suggested that some gain of function CaSR mutations may result in idiopathic hypercalciuria (IH) but to date these have not been detected. We reasoned that such CaSR mutations would lead to an early onset of IH and have sought them in 12 unrelated children (10 males and 2 females) who were normocalcemic and developed IH nephrolithiasis early in life, before the age of 4 years. In addition, all 12 of the probands had a family history for IH. Leukocyte DNA samples from the probands were used to search for CaSR mutations. This revealed, in one proband, an abnormality that consisted of a C to T transition at codon 994 (CAC to TAC) which predicts the substitution of the wild type (WT) histidine residue for a tyrosine in the cytoplasmic tail of the CaSR. This His994Tyr missense mutation was demonstrated to co-segregate with IH in the proband's family and to be absent in 110 alleles from 55 unrelated normal individuals. Expression of the mutant and WT CaSRs in HEK293 cells together with an assessment of their responses, as measured by changes in intracellular calcium concentration [Ca] to alterations in extracellular [Ca], revealed the Tyr994 mutant CaSR to have a left-ward shift in the dose-response curve (Tyr994 EC_{50} = 1.43 mM +/- 0.22 versus WT (His994) EC_{50} = 2.74 mM +/- 0.22, $p<0.02$), thereby demonstrating a gain of function. An examination of the mutant sequence indicated that it resulted in a tyrosine kinase phosphorylation consensus sequence and Western blot analysis using transiently-transfected HEK293 cellular extracts and the p-Tyr (PY99) antibody, which detects phosphorylated tyrosine groups in proteins specifically, demonstrated a significantly increased ($p<0.02$) phosphorylation of the mutant CaSR. Thus our results, which report the first CaSR mutation in IH nephrolithiasis, reveal a novel cytoplasmic mutation that increases phosphorylation and activity of the CaSR.

1009

Role of RANK Ligand (RANKL) in Mediating Increased Bone Resorption in Early Postmenopausal Women. G. Eghbali-Fatourechi[1], S. Khosla[1], W. J. Boyle*[2], D. L. Lacey[2], B. L. Riggs[1]. [1]Mayo Clinic, Rochester, MN, USA, [2]Amgen, Thousand Oaks, CA, USA.

Based on studies in rodents, a number of cytokines have been implicated as paracrine mediators of the increased osteoclastogenesis during estrogen (E) deficiency. However, RANKL, the final effector of osteoclastogenesis, has not been shown to be altered by E deficiency, and in vivo studies have not as yet been made on changes in RANKL producing cells in human bone marrow. We have developed a method for isolating bone marrow cells that express RANKL on their surfaces using flow cytometry with fluorescent-labeled osteoprotegerin as a probe. Bone marrow aspirates are passaged through a Ficoll-gradient and 2-color flow cytometry is employed to categorize cells expressing RANKL as marrow stromal cells (MSC), T-cells or B-cells using antibodies against alkaline phosphatase, CD3, and CD19, respectively. Isolated MSC were shown to express bone-related genes and to form mineralized nodules when cultured in a differentiating medium. Thus, we studied 12 premenopausal women (Premps), 11 early (<10 yrs after menopause) postmenopausal women (Postmps), and 13 postmenopausal women (matched for years after menopause) receiving long-term estrogen therapy (Postmps + E). Serum carboxyl-terminal telopeptide (CTx), a marker of bone resorption, was 4366, 6725, and 3192 pM in the Premps, Postmps, and Postmps +E women, respectively (P<0.001). MSC were decreased by 55% (P<0.001, Student-Newman-Keuls test) in the Postmps as compared with the Premps group (consistent with a rapid throughput kinetic model whereby these pre-osteoblastic cells are depleted by the increased demand for osteoblasts on bone surfaces). Values in the Postmps + E women were also higher than in Postmps women but were not different from Premps women. T-cells and B-cells expressing RANKL did not differ among groups. Based on fluorescence intensity, RANKL surface concentration per cell in the Postmps women was increased over that in the Premps women in MSC by 304% (P<0.001), in T-cells by 248% (P<0.01), in B-cells by 238% (P<0.01), and in total RANKL positive cells by 254% (P<0.01). Moreover, in these women, the bone resorption marker, serum CTx, was correlated (P=0.005) with RANKL expression per cell in MSC (r=0.52), T-cells (r=0.46), B-cells (r=0.57), and total RANKL positive cells (r = 0.46), attesting to the biological relevance of our assessment of RANKL expression by bone marrow cells. Although these findings do not exclude contributions by other cytokines, they indicate that upregulation of RANKL on bone marrow cells is a major determinant of increased bone resorption during E-deficiency and that MSC, T-cells and B-cells participate, apparently to a similar extent, in RANKL-mediation of estrogen action.

Absence of Estrogen Receptor α Inhibits the Osteogenic Response to Mechanical Loading. K. C. L. Lee, A. S. Davies*, L. E. Lanyon. The Royal Veterinary College, London, United Kingdom.

Evidence that estrogen receptor α (ERα) is involved in osteoblasts' proliferative response to mechanical strain in vitro led to the hypothesis that the inadequate bone architecture characteristic of post-menopausal osteoporosis reflects less effective adaptation to mechanical loading due to decreased ERα number in bone cells.[1] To ascertain whether ERα is required for adaptive bone (re)modelling in vivo, we loaded the left ulnae of 21 to 24 week old female estrogen receptor α knock out (α ERKO) mice and their wild type (WT) littermates, by non-invasive dynamic axial compression via the flexed carpus and olecranon as previously published for the rat.[2] Forty 3.6N load cycles, engendering peak strains of 2900με and maximum strain rates of 0.1/s at the lateral ulnar midshaft, were applied to the ulna over 10mins, 3 days/wk for 2wks. Right ulnae served as non-loaded controls. Mice were sacrificed 3 days after the last loading day. The response of the cortical bone 3.5mm distal to the midshaft was assessed histomorphometrically using double calcein labels administered on days 3 and 12 of the loading period. The osteogenic response to loading was greatest at this site. In non-loaded control ulnae cortical bone area was the same in α ERKO and WT mice (0.22± 0.01mm^2) and periosteal new bone formation was undetectable. Endosteal bone formation rate (BFR) was 0.10± 0.10 μ m^2/μ m/day in α ERKO controls, significantly lower than 0.51± 0.07μ m^2/μ m/day in WT controls (p<0.05). In WT mice loading stimulated significant increases in both periosteal and endosteal bone formation, resulting in a 10± 1% increase in cortical bone area, compared to 0.3± 0.1% in non-loaded controls (p<0.01). This increase in cortical bone area was due to significant increases in periosteal and endosteal mineralising surfaces (MS), mineral apposition rates (MAR) and BFR (p<0.01). In α ERKO mice the loading-related increase in cortical bone area was 3± 0.6%, which was significantly lower than in WT mice (p<0.01). This was due to failure of the endosteal loading response in α ERKO mice; and 50% and 20% lower loading-induced increases in periosteal MAR and MS respectively in α ERKO mice compared to WT mice. These data show that in mice the absence of functional ERα substantially diminishes bones' osteogenic response to mechanical loading in vivo.

TNAP and PC-1 Control Bone Mineral Deposition by Directly Regulating Pyrophosphate Levels. L. Hessle*[1], K. A. Johnson*[2], H. C. Anderson*[3], R. Terkeltaub*[2], J. L. Millán[1]. [1]The Burnham Institute, La Jolla, CA, USA, [2]VAMC/UCSD, San Diego, CA, USA, [3]University of Kansas Medical Center, Kansas City, KS, USA.

A variety of human skeletal disorders develop due to abnormal levels of inorganic pyrophosphate (PP_i) in bone matrix. Deposition and propagation of hydroxyapatite crystals is suppressed by PP_i, but the metabolism and the proteins responsible for the regulation of this mineralizing inhibitor are poorly known. To address this topic, we have investigated the role of two osteoblast enzymes; Tissue-Nonspecific Alkaline Phosphatase (TNAP) and Plasma Cell glycoprotein-1 (PC-1). Both proteins are present in the membrane-limited matrix vesicles (MVs) that are responsible for the primary seed of hydroxyapatite in the process of ossification. Deleting the TNAP gene (*Akp2*) in mice results in hypophosphatasia characterized by poorly mineralized bones, spontaneous fractures and elevated extracellular concentrations of PP_i. PP_i is primarily produced by the nucleoside triphosphate pyrophosphohydrolase activity of a family of isozymes, with PC-1 being the only member present in MVs. Mice null for the PC-1 gene (*Enpp1*) display hypermineralization abnormalities similar to cartilage calcification in osteoarthritis and ossification of the posterior longitudinal ligament of the spine. We have found that mice lacking both TNAP and PC-1 show the respective correction of the bone mineralization abnormalities that are found in single knockout mice. Morphological normalization of the tibial growth plate in the double null mice was also observed. Furthermore, each allele of *Akp2* and *Enpp1* was found to exhibit a measurable influence on the mineralization status *in vivo*. Unlike primary cells from single knockout mice, *ex vivo* experiments using double knockout osteoblasts and their MVs demonstrate restored levels of PP_i and normalized mineral deposition. Our data identify TNAP and PC-1 as key regulators of the extracellular PP_i concentrations required for controlled bone mineralization. Our results also suggest that inhibiting PC-1 function is a viable therapeutic strategy for hypophosphatasia, a disease that to-date remains an incurable condition. Conversely, interfering with TNAP activity may be used in the treatment of pathologic cartilage calcification and hyperostosis due to local and systemic PC-1 deficiency.

Frzb1, an Inhibitor of Wnt Signaling, is Over-expressed in Chondrocytes from Low Bone Mass Mice. R. F. Klein[1], R. J. Turner*[1], A. S. Carlos*[1], K. A. Vartanian*[1], D. A. Olson*[1], J. N. Kansagor*[1], J. K. Belknap*[2], E. S. Orwoll[1]. [1]Bone and Mineral Unit, Oregon Health & Science University, Portland, OR, USA, [2]Department of Behavioral Neuroscience, Oregon Health & Science University, Portland, OR, USA.

The role of low bone mineral density (BMD) in determining fracture risk is well established and the peak BMD level achieved in early adulthood is a highly heritable trait. In previous studies, using complementary mapping populations derived from C57BL/6 (B6) and DBA/2 (D2) inbred mouse strains, we identified four quantitative trait loci (QTLs) that contribute to BMD variation between these two strains. To explore the genetic architecture of peak BMD, reciprocal congenic strains were developed. QTL regions from Chr 1, 2, 4, & 11, defined by chromosomal molecular markers, were transferred from B6 to D2 and vice versa by 10 cycles of backcrossing. Peak whole body BMD (determined by DEXA in vivo) was significantly increased by D2 alleles on Chr 1 (2%; $p < 0.001$), Chr 2 (2%; $p < 0.02$) and Chr 4 (5%; $p < 0.001$) and by B6 alleles on Chr 11 (5%; $p < 0.0001$). To establish functional links between genotype and phenotype, we used high density oligonucleotide arrays (Affymetrix MG-U74Av2) to measure the relative expression levels of ~ 12,500 genes and ESTs in costal chondrocyte RNA isolated from Chr 2 congenic and D2 background mice. A total of 26 known genes and 7 ESTs reproducibly exhibited at least a 2-fold difference between the two genotypes. Among these candidates, only one - secreted frizzled related protein-3 (sfrp3 or Frzb1) – was located within the Chr 2 QTL (delineated by chromosomal markers D2Mit91 at 37cM and D2Mit164 at 71cM). The Frzb1 gene was up-regulated 4.1 ± 0.2 fold in the low BMD congenic mice. Frzb1 encodes a secreted antagonist of Wnt signaling. The recent identification of mutations in low-density lipoprotein receptor-related protein 5 (LRP5) in humans and now Frzb1 in mice suggests that the Wnt signaling pathway likely plays an important, and previously unrecognized, role in the attainment of peak BMD. Interestingly, the expression levels of a number of muscle-specific genes (myosin, actin, troponin) and proteinases (MMP-3, MMP-13, cathepsin G) were reduced (2 – 6 fold) in the congenic chondrocytes, indicating possible adaptive mechanisms to the increased Frzb1 expression. We suggest that microarray analyses of congenic strains have utility in identifying putative target genes underlying a given BMD QTL and may also elucidate other associated developmental pathways.

PTH-mediated Control of Proteasome-Mediated Degradation of Runx2/Cbfa1: A Pivotal Determinant of the Longevity of PTH-Initiated Anti-Apoptosis Signaling in Osteoblastic Cells. T. Bellido, L. I. Plotkin, C. A. O'Brien, S. C. Manolagas, R. L. Jilka. Endo/Metab. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

The ability of intermittent PTH administration, but not sustained elevation of the hormone, to elicit an anabolic effect on the skeleton may be accounted for by the short-lived nature of PTH-induced anti-apoptosis signals in osteoblasts, a phenomenon demonstrated earlier using cultured osteoblastic cells and time course analysis. Specifically, it was previously shown that PTH causes transient protein kinase A (PKA)-mediated phosphorylation

and thereby inactivation of the pro-apoptotic Bad. As shown elsewhere in this meeting, Bad phosphorylation, as well as CREB- and Runx2/Cbfa1-mediated transcription, are required for the anti-apoptotic effect of PTH. Based on these observations, and evidence that PTH stimulates ubiquitin/proteasome-dependent degradation of Runx2/Cbfa1 in osteoblastic cells, and that cAMP promotes proteasome-mediated degradation of CREB in other cell types, we hypothesized that PTH-induced degradation of Runx2/Cbfa1 and/or CREB contributes to the short-lived nature of anti-apoptosis signaling. We now report that 10 μM lactacystin, an irreversible inhibitor of proteasomal-dependent proteolysis, prolonged by at least four-fold (from 6 to 24h) the duration of the anti-apoptotic action of PTH in OB-6 osteoblastic cells. Moreover, this effect of lactacystin was completely abrogated by expression of dominant negative Runx2/Cbfa1. On the other hand, expression of a dominant negative CREB did not influence the effect of lactacystin. Consistent with the critical role of Runx2/Cbfa1 level as a determinant of the longevity of the survival effect of PTH, overexpression of wild type Runx2/Cbfa1 prolonged the anti-apoptotic effect of PTH to the same extent as lactacystin. These results indicate that PTH upregulation of proteasome-mediated degradation of Runx2/Cbfa1 contributes to the short-lived nature of anti-apoptosis signaling. Moreover, they show that the stability of Runx2/Cbfa1 is a pivotal determinant of the longevity of the PTH-initiated survival signaling; and hence, of the ability of PTH to deliver repeated and self-limiting anti-apoptotic signals when administered in a pulsatile fashion, but not when elevated in sustained fashion.

1014

Unsuspected Megakaryocyte-Osteoblast Interaction Results in Increased Bone Formation in Mice Deficient in the Transcription Factors GATA-1 and p45 NF-E2. M. A. Kacena[1], K. M. Wilson*[1], M. L. Bouxsein[2], M. C. Horowitz[1]. [1]Orthopaedics, Yale University School of Medicine, New Haven, CT, USA, [2]Orthopedic Surgery, Beth Israel Deaconess Medical Center, Boston, MA, USA.

GATA-1 and p45 NF-E2 are transcription factors required for megakaryocyte (MK) differentiation and ultimately platelet formation. Loss of GATA-1 and p45 NF-E2 results in a developmental arrest of MK differentiation with an accumulation of MKs in the spleen and bone marrow. An unanticipated, marked 250% increase in osteoblast number and trabecular and cortical bone volume was also observed in these mice. A 4500% increase in trabecular bone volume was measured for the entire femoral medullary canal. The strikingly similar bone phenotype in both animal models led us to explore the novel interaction between osteoblasts and MKs from GATA-1 and p45 NF-E2 mutant mice. When calvarial osteoblasts from either wild-type or mutant mice were co-cultured with mutant MKs, osteoblast proliferation was increased up to 6 fold. To determine whether osteoblasts were activated by MK derived soluble factors, osteoblasts were cultured with and without conditioned medium (CM) from mutant MKs. MK CM failed to enhance osteoblast proliferation. To define the requirement for cell-to-cell contact, osteoblasts were separated from the MKs by a cell impermeable membrane in transwell cultures. As a control, MKs and osteoblasts were cultured in direct contact. No osteoblast proliferation occurred when the membrane separated the cells. Osteoblast proliferation was similarly enhanced when cultured in direct contact with either irradiated or mitomyicin-C treated mutant MKs. The wealth of evidence points to a mutant MK-osteoblast mediated response that enhances osteoblast proliferation. This proliferation should result in increased bone formation. Indeed, adoptive transfer of mutant spleen cells into irradiated recipients caused increased bone formation, supporting this idea. This mechanism would account for the increased number of osteoblasts seen in vivo and the bone phenotype in both GATA-1 and p45 NF-E2 deficient mice. A MK-osteoblast interaction of this type represents a novel anabolic pathway for new bone formation.

1015

Signaling via β-catenin Directs Osteogenic Lineage Allocation Independent of cbfa1. G. Mbalaviele, S. Sheikh*, S. Cheng, J. P. Stains, R. Civitelli. Div. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA.

β-catenin, a component of adhaerens junctions, is also part of the *wnt* signaling system, modulating the activity of Tcf/Lef transcription factors. Mutations of critical components of this pathway, including LRP5, profoundly affect skeletal development or bone mass acquisition, and transcriptionally active β-catenin prevents adipogenesis. To test the hypothesis that β-catenin signaling is involved in mesenchymal lineage allocation to osteogenic cells, we generated a retroviral vector carrying a β-catenin mutant lacking the N-terminal moiety of the molecule (ΔN151). This truncation removes the domain required for proteolytic cleavage, resulting in a stable, transcriptionally active β-catenin. Transduction of ΔN151 in the uncommitted, multipotential C3H10T1/2 cells resulted in a 2-fold increase in osteocalcin mRNA abundance (assessed by real time RT-PCR), without significant effects on other markers of osteogenic differentiation. However in cells expressing ΔN151, BMP-2 (50 ng/ml for 7 days) produced greater increases in alkaline phosphatase activity (12- vs. 6-fold) and mRNA abundance for osteocalcin (16- vs. 2-fold) and bone sialoprotein (1.8- vs. 0.9-fold), relative to control cells, suggesting a synergism between β-catenin signaling and BMP-2. Intriguingly, cbfa1 mRNA was, if anything decreased by ΔN151 expression and its abundance after BMP-2 stimulation was not different than that of unstimulated control cells, indicating that β-catenin enhancement of BMP-2 response is independent of cbfa1. One week post-confluence, ΔN151 expressing C3H10T1/2 cells formed multilayered, nodular "domes", a few of them alizarin red positive. In the presence of BMP-2, massive calcification occurred, covering >50% of the tissue culture dishes. No such changes were seen in cells transduced with an empty vector, even in the presence of BMP-2, indicating that activation of the canonical β-catenin pathway is necessary to fully commit C3H10T1/2 to the osteogenic pathway. Consistent with this hypothesis, transfection with a β-catenin mutant lacking the armadillo repeats domain, which accumulates in the nucleus and inhibits β-catenin signaling, almost completely (>90%) prevented BMP-2 induced stimulation of alkaline phosphatase in both C3H10T1/2 cells and the undifferentiated but committed MC3T3-E1 cells. Therefore, β-catenin directs osteogenic lineage allocation, enhancing uncommitted cell responsiveness to osteogenic factors, such as BMP-2. Signaling via β-catenin is a fundamental component of the osteoblast phenotype, acting independently or downstream of cbfa1.

Opposing Roles of Osterix and TGFß Inducible Early Gene in Osteoblast Differentiation Downstream of Cbfa1/Runx2. S. A. Johnsen*, M. Subramaniam, T. J. Ruesink*, T. C. Spelsberg. Biochemistry & Molecular Biology, Mayo Clinic & Foundation, Rochester, MN, USA.

Cbfa1/Runx2 has been shown to play an important role in skeletal formation and the differentiation of osteoblasts. However, emerging evidence suggests that additional factors are necessary for the formation of mature osteoblast cells. The Krüppel-like zinc finger transcription factors Osterix (Osx) and TGFß inducible early gene (TIEG) are induced at different points following bone morphogenetic protein (BMP)-2 treatment in pre-osteoblastic cells and regulate the transcription of differentiation markers. Osx was recently cloned and identified as a BMP-2 inducible gene that is required for skeletal development and the formation of mature osteoblasts in vivo. Osx binds to an Sp1 element and functions downstream of Cbfa1/Runx2 to activate transcription of the osteoblast specific gene osteocalcin. Interestingly, like Osx, TIEG appears to regulate osteoblast differentiation downstream of Cbfa1/Runx2 since TIEG overexpression does not affect Cbfa1/Runx2 expression. However, in contrast to Osx, TIEG is a transcriptional repressor and down-regulates osteocalcin secretion and gene expression. We now show evidence that TIEG directly represses the osteocalcin promoter. This repression appears to be independent of Cbfa1/Runx2 since the promoter region regulated by TIEG is upstream of the OSE2 (Cbfa1/Runx2 binding site). Furthermore, Cbfa1/Runx2 overexpression does not reverse the repression by TIEG. However, we now show that TIEG binds to an Sp1 element and may thus compete with Osx for binding to the same sequences in target gene promoters. Thus we propose a model in which TIEG and Osx play differing roles at distinct points in osteoblast differentiation. In our model TIEG is rapidly induced following BMP-2 treatment and may serve to restrict the expression of late genes in osteoblast differentiation (i.e., osteocalcin). However, later in the differentiation pathway, Osx is expressed and displaces TIEG at target gene promoters thereby activating transcription of the late osteoblast differentiation markers. This new model provides insight into the regulation of osteoblast differentiation downstream of Cbfa1/Runx2.

Four And A Half Lim Protein 2 (FHL2) Stimulates Osteoblast Proliferation And Differentiation. C. F. Lai[1], L. R. Halstead[1], P. McLoughlin*[2], B. W. Schafer*[2], P. H. Chu*[3], J. Chen*[3], X. Cao[4], D. A. Towler[1], S. L. Cheng[1]. [1]Division of Bone and Mineral Diseases, Washington University, St. Louis, MO, USA, [2]University of Zurich, Zurich, Switzerland, [3]University of California, La Jolla, CA, USA, [4]University of Alabama, Birmingham, AL, USA.

Integrin αvβ5 is one of the most abundant integrins expressed by human osteoblasts (HOB). This integrin governs osteoblast interaction with bone sialoprotein, osteopontin, and vitronectin. It has been well established that the cytoplasmic domain of integrin β subunit is essential in transmitting the signals induced by integrin-matrix interaction. In order to elucidate the function of αvβ5, we employed the yeast two-hybrid screening using an U2OS cDNA library as prey to identify proteins interacting with the cytoplasmic domain of β5. Out of 36 clones sequenced, one was identical to the full length FHL2. Immunoprecipitation and Western blotting confirmed the interaction of αvβ5 with FHL2 in HOB. Immunostaining and confocal examination indicated that FHL2 co-localized with αvβ5 at the focal adhesion sites. FHL2 was also detected in the nuclei. Employment of FHL2 deletion constructs and the Lim domain mutants in yeast two-hybrid assays indicated that the whole molecule of FHL2 was required for interaction with β5. To gain insight into the role of FHL2 in osteoblast function, we generated an MC3T3-E1 osteoblastic cell line overexpressing FHL2 by using a Flag-tagged FHL2. The Flag-tagged FHL2 was localized at the focal adhesion sites and in the nuclei. Cell adhesion to fibronectin and vitronectin were enhanced in FHL2 cells, which could derive, in part, via the higher β3 and β5 integrin levels in these cells. Cell proliferation, alkaline phosphatase activity, and osteopontin and bone sialoprotein levels were also elevated in FHL2 cells. Matrix mineralization and the upregulation of osteocalcin by Cbfa1 were enhanced in these cells. Examination of the calvarial sections derived from FHL2 deficient, with concomitant LacZ knock-in, mice indicated that FHL2 was expressed in osteoblasts and cells in the osteogenic front. Since this expression pattern was similar to that of FGF receptors and FHL2 expression was upregulated by FGF2, we analyzed the relationship between FHL2 and FGF2. FHL2 potentiated the stimulatory effects of FGF2 on osteocalcin expression and AP-1 and CRE activities. FHL2 also enhanced the FGF2-induced cell migration on type I collagen. In conclusion, FHL2 is expressed in osteoblasts and the osteogenic front. In osteoblasts, FHL2 co-localizes with αvβ5 at the focal adhesion site and is present in the nuclei. FHL2 upregulates osteoblast growth and differentiation and synergizes Cbfa1 and FGF2 activities. Thus, FHL2 may play an important role in bone formation.

New Insights into Calcineurin Aα Function and Signaling. E. Abe[1], X. B. Wu[1], M. Lu*[1], X. Zhang*[1], B. S. Moonga[1], S. Epstein[1], H. C. Blair[2], L. Sun[1], M. Zaidi[1]. [1]The Mount Sinai Bone Program and Bronx VA GRECC, New York, NY, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA.

Calcineurin Aα, a ubiquitously expressed Ca^{2+}/calmodulin-sensitive phosphatase, is a target for two of the most widely used immunosuppressants, cyclosporine (CsA) and tacrolimus (FK506). We found that calcineurin Aα and Aβ are expressed in both osteoblasts and osteoclasts. Deletion of the calcineurin Aα gene resulted in dramatic osteoporosis evident from a decrease in bone mineral density at the femur, tibia and lumbar spine. This was associated with reduced cortical thickness and a ~40% reduction in bone formation in tetracycline double labeling studies. Osteoblast progenitors, measured as colony-forming units-fibroblasts (CFU-Fs), in bone marrow cultures of calcineurin $Aα^{-/-}$ mice showed no decrease when compared to wild type littermates. Likewise, the inhibition of calcineurin Aα by CsA and FK506 resulted in unchanged CFU-F counts. In contrast, there was a marked reduction in osteoclast formation from hematopoetic progenitor cells in calcineurin $Aα^{-/-}$ mice, as well as in wild type cultures treated with CsA or FK506. An action of calcineurin Aα on osteoblast differentiation was evident from a dramatic increase in alkaline phosphatase activity of MC3T3.E1 cells transduced with a TAT-calcineurin Aα fusion protein. Together, the results provide compelling evidence that calcineurin Aα has a key role in bone formation without affecting the osteoblast progenitor pool. In parallel, chemical cross-linking studies, immunoprecipitation experiments, and phosphatase activity assays revealed that calcineurin Aα bound to and dephosphorylated not only the transcription factor, NFATc, but also the transcription inhibitor, IκBβ. This interaction resulted in the modulation of a variety of genes. Most notably, cells transfected with calcineurin Aα displayed a dramatic increase in NFATc1 and type 1 ryanodine receptor expression and a decrease in the phosphorylated form of IκBβ. Likewise, deletion of the calcineurin Aα gene in the $Aα^{-/-}$ mouse resulted in a marked reduction in NFATc and NFκB (p50, p65 and c-Rel) expression and an increased expression of phosphorylated IκBβ. The results suggest that calcineurin, through its phosphatase activity, not only dephosphorylates NFATc, but also dephosphorylates IκBβ to enhance its binding to the NFκB members thus preventing their nuclear localization. Taken together, our results demonstrate that calcineurin Aα is a key regulator of osteoblastic bone formation, and that this effect may be exerted not only through the traditional NFATc pathway, but also *via* the dephosphorylation of IκBβ, an interaction that we demonstrate for the first time in any eukaryotic cell.

1019

Structure/Function Study of the RANK Cytoplmasic Domain in Osteoclast Differentiation and Function Using a Chimeric Receptor Approach. H. Yang[1], P. Patel*[1], D. Hoang*[1], S. L. Teitelbaum[2], F. Ross[2], S. Takeshita[2], K. Chennareddy*[1], X. Feng[1]. [1]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]Pathology, Washington University School of Medicine, St Louis, MO, USA.

RANKL, a member of the TNF-α superfamily, plays a pivotal role in osteoclast (OC) differentiation and function. RANKL exerts these effects by binding to its receptor RANK expressed on OC precursors and mature OCs. As a member of the TNF receptor superfamily, RANK may transduce intracellular signaling by recruiting intracellular signaling molecules such as TRAFs. Several groups have previously characterized the RANK functional domains that may interact with TRAFs. However, the data from these studies are conflicting. Furthermore, these studies were performed in cells unrelated to OCs, thus, the relevance of these data to OC biology remain unknown. We have developed a tool that permits us to carry out a detailed structure/function study of the RANK cytoplasmic domain in OC differentiation and function using authentic OCs. Using a retroviral technology, we expressed a chimeric receptor containing the extracellular domain of TNFR1 linked to the transmembrane and cytoplasmic domains of RANK in authentic OC precursors isolated from TNFR1/R2 double knockout mice. Treatment of the chimera-expressing OC precursors with TNF-α, as a RANKL surrogate, plus M-CSF, generates OCs, indistinguishable from those induced by RANKL and M-CSF. Most importantly, OCs generated using the chimeric receptor approach are fully capable of resorbing bone. Previously, several studies suggested that six putative TRAF-binding sites (pTRAF1, ILLMTREE at a.a.286-293; pTRAF2, PSQPS at a.a.349-353; pTRAF3, PFQEP at a.a.369-373; pTRAF4, VYVSQTSQE at a.a.537-545; pTRAF5, PVQEET at a.a.559-564; pTRAF6, PVQEQG at a.a.604-609) and two tyrosines (Y345 and Y468) in the RANK cytoplasmic tail may be involved in transducing RANK intracellular signaling. To investigate the role of the putative TRAF sites and two tyrosine residues in OC differentiation, we mutated these six putative TRAF sites and two tyrosine residues individually in the chimeric receptor constructs. The mutant chimeras were used to repeat the osteoclastogenesis assays described above. Our data indicate that all 8 mutant chimeras were still capable of mediating OC formation. In summary, we have developed a chimeric receptor strategy for identifying the RANK functional domains involved in OC differentiation and function. Moreover, using this chimeric receptor approach, we have demonstrated that six putative TRAF binding sites and two tyrosine residues, which have been suggested to be implicated in RANK signaling, are not essential for OC formation.

1020

Targeted Overexpression of Osteoprotegerin (OPG) in Osteoblasts Provides In Vivo Evidence for a Direct Role of Periosteal Osteoclasts in Normal Bone Growth. F. J. Asuncion*[1], D. M. Danilenko*[2], J. Li[1], D. Hill*[2], S. Kaufman*[2], C. R. Dunstan[1], D. L. Lacey[1], W. S. Simonet[1]. [1]Metabolic Disorders, Amgen, Thousand Oaks, CA, USA, [2]Pathology, Amgen, Thousand Oaks, CA, USA.

OPG was first characterized as a functional in vivo osteoclast inhibitor through the analysis of mice that expressed OPG under control of the human ApoE promoter (Cell 89:309-319 (1997)). ApoE-OPG transgenic mice, which express OPG predominately in the liver, exhibit increased trabecular bone density with total occlusion of the bone marrow space in high-expressing animals. However, apoE-OPG mice lack club-shaped bones, impaired tooth eruption and retarded bone growth typical of osteopetrotic mouse models. Both endosteal and periosteal osteoclasts are present in apoE-OPG mice in areas that express RANKL (OPG ligand) by in situ hybridization, but only endosteal osteoclasts show reduced numbers and activity. There are sufficient numbers of functional osteoclasts to allow for normal bone growth and modeling but are not sufficient to allow for remodeling of the primary spongiosa resulting in the observed phenotype. The unique features of this osteopetrotic model were hypothesized to be a result of hepatic OPG expression which resulted in high circulating levels of OPG that may not have sufficient access to all bone compartments. To test this hypothesis, transgenic mice overexpressing OPG in functional osteoblasts, the site of endogenous OPG expression, have been generated utilizing a rat Collagen1a1 promoter. In contrast to the apoE-OPG mice, the rCol1a1-OPG mice have undetectable levels of circulating OPG, yet exhibit more typical, severe osteopetrosis with impaired tooth eruption, retarded growth, and club-shaped, sclerotic long bones. The numbers of osteoclasts both on the periosteum and endosteum in the rCol1a1-OPG are markedly reduced compared to the apoE-OPG mice being most reminiscent of the phenotypes of RANK and RANKL KO mice. In summary, the apoE-OPG and rCol1a1-OPG mouse studies describe two phenotypically distinct osteopetrotic mouse models which result from OPG-mediated differential inhibition of subpopulations of osteoclasts on the surfaces of hypertrophic growth plate cartilage, trabecular and cortical bone, likely due to the cellular source of transgenic OPG expression.

Systemic TNFa Promotes Erosive Bone Resorption by Increasing the Number of CD11b+ Osteoclast Progenitors in the Periphery Which Are Dependent on RANK Signaling for Osteoclastogenesis. P. Li*, E. M. Schwarz, R. J. O'Keefe, B. F. Boyce, L. Xing. University of Rochester, Rochester, NY, USA.

TNFa, a potent osteoclastogenic factor, has been shown to act directly on cells in the osteoclast lineage, or indirectly by affecting the production of the essential osteoclast differentiation factor RANKL by osteoblasts. The mechanism by which TNFa increases osteoclastogenesis in vivo is unknown. Furthermore, there is controversy in this field as to whether TNFa induces osteoclastogenesis in the absence of RANKL. To elucidate the mechanism of TNFa-mediated osteoclastogenesis in vivo, we used TNFa transgenic (hTNF-Tg) and RANK knockout mice, and studied the effects of chronic TNFa exposure on osteoclast (ocl) precursor differentiation and the requirement of RANKL/RANK in this process. Splenocytes from hTNF-Tg mice 1) formed more ocls (#ocl/well 432+14 vs 55+28 in wt mice); 2) had an increase in the frequency of CD11b+ (10.7% vs 1.2% in wt mice) and CD11b+/c-Fms+ cells (4.0% vs 0.4% in wt mice). Only CD11b+ cells sorted by FACS formed ocls, indicating that CD11b can be used as a marker of ocl progenitors in spleen. Enhanced osteoclastogenesis and increased CD11b+ cells in hTNF-Tg mice were prevented by in vivo administration of the TNFa antagonist, Etanercept. Treatment of hTNF-Tg mice with a RANK antagonist, RANK:Fc (10 mg/kg, ip, daily for 2 weeks) dramatically reduced ocl numbers in arthritic joints (2.3+1.4/tibia and 0.3+0.2/erosion surface vs 138.3+13.8/ tibia and 5.3+0.6/erosion surface in PBS group), but did not decrease CD11b+ ocl progenitor frequency. Consistent with these findings, hTNF-Tg mice in a RANK null background have severe osteopetrosis and no ocl, but increased CD11b+ ocl precursors. Thus, chronic TNFa increases osteoclastogenesis through two distinct mechanisms in vivo: 1) it increases the pool of CD11b+ osteoclast progenitors through a RANKL/RANK independent mechanism; and 2) it stimulates osteoclast formation via a RANKL/RANK dependent mechanism.

Unoccupied $\alpha_v\beta_3$ Integrin Transmits a Positive Death Signal in Osteoclasts. H. Zhao, F. P. Ross, S. L. Teitelbaum. Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Cell/matrix detachment is a general inducer of programmed cell death, an event mediated by loss of integrin/ligand association. Because $\alpha_v\beta_3$ is the major integrin expressed by the osteoclast (OC) we asked if its occupancy promotes survival of the resorptive cell. Thus, we generated wild type (WT) pre-OCs by treating bone marrow macrophages (BMMs) with M-CSF and RANKL for three days at which time they express TRAP, and as assessed by western blot, the β_3 integrin. The cells were lifted and placed on selective matrix proteins. Consistent with the posture that $\alpha_v\beta_3$ occupancy promotes survival, OCs plated on native collagen, a protein not recognized by the integrin, undergo apoptosis, as detected by ELISA, four fold faster that OCs plated on the $\alpha_v\beta_3$ ligand, vitronectin ($p<.001$). To further explore the role of $\alpha_v\beta_3$ in OC apoptosis, pre-OCs generated from WT and $\beta_3^{-/-}$ mouse BMMs were placed in suspention and apoptosis determined, with time. Surprisingly, $\beta_3^{-/-}$ pre-OCs, in suspension, undergo a rate of apoptosis only 40-60% of that of their WT counterparts ($p<.01$) indicating that unoccupied $\alpha_v\beta_3$ transmits a positive

death signal. Supporting this conclusion, activation of the activator caspase, caspase-8, and the executioner caspase, caspase-3, both of which mediate OC apoptosis, is blunted in suspended $\beta_3^{-/-}$ pre-OCs. We have shown that the resorptive defect of $\beta_3^{-/-}$ OCs can be rescued by transduction of WT β_3 cDNA but not one bearing a $S^{752}P$ mutation. To determine if the same holds as regards OC apoptosis, we constructed lentivirus vectors encoding GFP, WT β_3 or β_3 $S^{752}P$. $\beta_3^{-/-}$ BMMs were transduced with each viral construct at an efficiency of 60-90%. Pre-Ocs were generated and placed in suspention culture. Once again, $\beta_3^{-/-}$ cells were protected against apoptosis, as were those bearing the GFP construct ($p<.001$). Similar to its effect on bone resorption, transduced WT β_3 normalized the apoptotic rate of $\beta_3^{-/-}$ pre-OCs. Unexpectedly, however, β_3 $S^{752}P$ transductants also died at a rate indistinguishable from WT. In conclusion, 1). Deletion of $\alpha_v\beta_3$ protects OCs from apoptosis, 2). Cell death in non-matrix attached OCs is due principally to positive death signals transmitted by unoccupied $\alpha_v\beta_3$ integrin, 3). β_3 $S^{752}P$, which is essential for OC function, does not participate in $\alpha_v\beta_3$-derived death signals.

RANK-TRAF6 Interaction: A New Target for Therapeutic Intervention of Osteolytic Disease. A. Poblenz*[1], M. Kalidas*[2], N. K. Shevde*[3], B. Lamothe*[4], K. Du*[1], S. Singh*[5], H. Wu*[6], J. E. Price*[7], J. W. Pike[3], B. G. Darnay[1]. [1]Bioimmunotherapy, University of Texas MD Anderson Cancer Center, Houston, TX, USA, [2]Medical Breast, Baylor College of Medicine, Houston, TX, USA, [3]Biochemistry, University of Wisconsin-Madison, Madison, WI, USA, [4]Pharmacology, Yale University, New Haven, CT, USA, [5]Imgenex, Inc., San Diego, CA, USA, [6]Biochemistry, Weill Medical College of Cornell University, New York, NY, USA, [7]Cancer Biology, University of Texas MD Anderson Cancer Center, Houston, TX, USA.

Breast cancer-induced osteolytic lesions are associated with increased morbidity secondary to pathologic fractures, hypercalcemia, and nerve compression syndromes. Elucidating the exact interaction between breast cancer cells and the bone microenvironment would aid in the development of new therapeutic agents. Receptor activator of NF-kB (RANK) and its ligand (RANKL) are essential mediators of osteoclastogenesis. RANK signals through tumor necrosis factor receptor-associated factors (TRAFs), and we have previously identified a unique TRAF6-binding motif in RANK which is distinct from the interaction domains for the other TRAFs. Furthermore, a peptide from RANK (residues 342-349) has been co-crystallized with the TRAF-C domain of TRAF6 and its structure indicates distinct molecular interactions. The importance of TRAF6 in osteoclastogenesis, like that of RANK and RANKL, is highlighted by null mice, which develop severe osteopetrosis and lack osteoclasts. Since TRAF6 appears to be the critical adaptor molecule, we developed a novel, cell-permeable TRAF6 decoy peptide (T6DP), which specifically targets the interaction of TRAF6 with RANK. We demonstrate that T6DPs inhibit RANKL-mediated signaling and osteoclast differentiation of RAW264.7 cells and primary mouse monocytes. In co-culture assays of RAW264.7 cells with breast cancer cell lines T47D or MDA-MB-468, T6DP treatment abolished their ability to induce osteoclast differentiation. To examine whether T6DPs could inhibit bone destruction associated with bone metastasis, we have developed an in vivo mouse model, in which the breast cancer cell line SUM 149 is injected into the proximal tibia of a nude mouse, and after 4 weeks, the mice develop osteolytic lesions. Preliminary results indicate that treatment of these mice with wild-type T6DP, but not mutant T6DP, prevents osteolysis induced by the breast cancer cell line. Thus, disruption of the RANK-TRAF6 interaction may prove useful as a novel target for the development of therapeutic agents for diseases of the bone.

C-Fos Over-expression Induces Osteoclastogenesis Independent of RANK Signaling. T. Yamashita[1], L. Xing[1], P. Li*[1], E. M. Schwarz[1], W. C. Dougall[2], B. F. Boyce[1]. [1]Univ of Rochester Med Ctr, Rochester, NY, USA, [2]Immunex Corporation, Seattle, WA, USA.

Neither RANKL nor RANK knockout mice form osteoclasts due to a cell autonomous defect downstream from RANKL/RANK interaction, which activates a number of signaling pathways and leads to gene transcription. Analysis of c-fos knockout and NF-kB p50/p52 double knockout (dKO) mice has identified an essential role for AP-1 and NF-kB transcription factors in osteoclastogenesis, but the relative roles of these molecules that mediate RANK signaling in osteoclastogenesis remain poorly understood. To address this issue, we prepared splenocytes derived from 3-5 week-old RANK-/- and NF-kB dKO mice as a source of osteoclast precursors and determined by FACS analysis that cells from both types of mice express the osteoclast precursor antigen, CD11b. We cloned the gene for each subunit of the transcription factor families, AP-1 (c-Fos, Fra-1) or NF-kB (p52, p105 (the p50 precursor) and p65) into the pBabe vector and transfected these into the packaging cell line, Plat-E. We then infected spleen cells with retrovirus supernatants from the virus producing cells. Ten days after virus infection, cells were fixed and stained for TRAP to evaluate TRAP+ cell numbers. TRAP+ cells formed only in the wells containing RANK-/- splenocytes infected with the c-Fos expressing virus (102+/-21 per cm2). In particular, unlike the findings in similar published experiments using c-fos-/- splenocytes, Fra-1 expression did not rescue the defect in osteoclastogenesis in RANK-/- or NF-kB dKO splenocytes. Almost all of the cells formed in response to c-Fos retroviral expression were mononuclear. c-Fos-induced TRAP+ cell formation from RANK-/- splenocytes was not enhanced by co-infection with NF-kB p65, p52 or p105, or with Fra-1. Thus, only c-Fos over-expression appeared to induce osteoclast precursor formation in the absence of RANK dependent signaling, but this was insufficient to induce their fusion to form functional mature osteoclasts.

1025

Osteoblast Specific Expression of 11β-HSD2 in Transgenic Mice Abrogates Steroid-Induced Apoptosis and Attenuates Loss of BMD and Strength. R. S. Weinstein, C. A. O'Brien, J. A. Crawford*, S. C. Manolagas. Div. of Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ of Ark for Med Sci, Little Rock, AR, USA.

Studies in rodents and humans have elucidated that the adverse effects of glucocorticoid (GC) excess on the skeleton result from decreased osteoblastogenesis and osteoclastogenesis, increased prevalence of osteoblast and osteocyte apoptosis, as well as an extension of the life span of osteoclasts at the early stages of hypercortisolemia. Decreased intestinal calcium absorption, urinary calcium losses, secondary hyperparathyroidism and hypogonadism have also been implicated as mechanisms of the deleterious effects of GC excess on bone. To dissect the contribution of the effects of GCs on osteoblastic/osteocytic cells from effects on osteoclasts or extraskeletal actions, we generated a transgenic mouse in which GC action on osteoblastic/osteocytic cells was blocked by overexpression of 11ß-HSD2. As previously shown, 11ß-HSD2 overexpression under the control of the osteocalcin gene promoter (OG2) resulted in rapid pre-receptor inactivation of GCs and thereby spared osteoblastic cells from the pro-apoptotic effects of GCs in vitro. Northern blot analysis of RNA prepared from various tissues indicated that the transgene is specifically expressed in bone. We now report that after 35 days of prednisolone administration (2.1 kg/mg/day) to 6-month-old mice overexpressing the 11ß-HSD2 gene, loss of spinal BMD was reduced by 40% ($p<0.02$), as compared to administration of the same dose of prednisolone to wild-type litter mates. In a second experiment, 28 days of prednisolone administration decreased vertebral compression strength by 45% in wild-type animals while strength was maintained in the transgenic mice ($p<0.02$). These findings suggest that GC -induced loss of compression strength may principally result from abnormal bone quality rather than quantity. In support of this contention, the expected increase in osteoblast and osteocyte apoptosis due to GC excess, as noted in wild-type mice, did not occur in 11β-HSD2 transgenic animals. Moreover, cancellous osteoblast numbers were maintained in the transgenic animals receiving prednisolone. Based on this and evidence that GCs prolong osteoclast survival, we conclude that direct effects of GCs on osteoblastic/osteocytic cells account for as much as 40% of their negative effect on bone mass; the remaining probably resulting from increased osteoclastic resorption. Furthermore, direct effects of GCs may account for practically their entire deleterious effects on osteoblast/osteocyte viability and the ensuing loss of bone strength.

1026

Transgenic Expression of 11ß-hydroxysteroid Dehydrogenase in Osteoblasts Reveals an Anabolic Role for Endogenous Glucocorticoids in Bone. L. B. Sher[1], H. W. Woitge[1], J. R. Harrison[2], D. J. Adams*[3], B. E. Kream[1]. [1]Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Orthodontics, University of Connecticut Health Center, Farmington, CT, USA, [3]Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, USA.

In humans, glucocorticoid excess leads to bone loss, primarily by decreasing bone formation. Yet, glucocorticoids promote osteogenesis in a variety of bone organ and cell culture models. The relation of the anabolic effect of glucocorticoids in vitro to the physiological actions of glucocorticoids in vivo is a long-standing question in bone biology. To elucidate the role of endogenous glucocorticoids in bone, we previously developed transgenic mice in which a 2.3 kb Col1a1 promoter fragment drives 11β-hydroxysteroid dehydrogenase (11β-HSD2) expression in mature osteoblasts. 11β-HSD2 metabolically inactivates endogenous glucocorticoids, thereby reducing glucocorticoid signaling. Two phenotypic assessments of bone of wild-type (WT) and transgenic (TG) littermates were made: collagen synthesis rates in organ cultures of six- to eight-day old calvariae, and trabecular bone morphometric parameters of 7- and 24-week old vertebrae and femurs. To measure collagen synthesis rates, calvariae were cultured in the presence or absence of cortisol for 96h and labeled with [^{3}H] proline for the final 2h of culture. The inhibitory effect of 300 nM cortisol on percent collagen synthesis was blunted in TG calvariae, demonstrating that the transgene was active. The baseline percent collagen synthesis was 32% lower in TG calvariae (n=28) compared to WT (n=37): 18.7±0.9 vs. 27.4±0.9, mean±SEM, $p<0.0001$. A similar difference was seen in an additional TG line. Trabecular bone, as measured by microcomputed tomography at 7- and 24- weeks of age, was effected in L3 vertebrae, but not in distal femurs, of Tg (n=10) females compared to WT (n=10). At both time points, bone volume (BV/TV) was decreased, although this difference was not significant ($p=0.066$ & 0.055, respectively). At both time points, trabecular number (TbN) was significantly lower in TG compared to WT females, (3.14±0.12 vs. 3.87±0.17 & 2.97±0.12 vs. 3.74±0.20, mean±SEM, $p<0.003$) respectively. These changes were not seen in males. Trabecular thickness was unchanged in both males and females. Our data demonstrate that endogenous glucocorticoids are required for normal levels of collagen synthesis in neonatal calvariae, suggesting that disruption of glucocorticoid signaling in vivo impairs osteoblast differentiation and/or function. Moreover, our data suggest that endogenous glucocorticoids may exert site- and sex-specific anabolic effects in bone.

1027

A Selective Androgen Receptor Modulator (SARM) Displays Dissociated Activity on Bone and Seminal Vesicles in Mice. C. Robin-Jagerschmidt*[1], P. Clément-Lacroix[1], D. Minet*[1], V. Hippomène*[2], M. Gaillard-Kelly[2], R. Baron[1], M. Resche-Rigon[1]. [1]Proskelia, Romainville, France, [2]Aventis, Romainville, France.

Both androgens and estrogens are essential for skeletal development and maintenance in men. However the determination of age-associated hypogonadism in men (andropause) is not as clear as it is in women, partly due to the slow and gradual decrease of testosterone level over time. The protective effects of androgen replacement therapy (ART) on bone mass and muscle strength in males are nevertheless well recognized. Testosterone has been shown to normalize bone mineral density and biochemical parameters of bone turnover in hypogonadal men. However, increased risk of clinically progressive prostate carcinoma as well as precipitation or exacerbation of benign prostatic hyperplasia compromise the prolonged utilization of androgens. Searching for tissue selective compounds, we have previously shown that cyproterone acetate, initially an anti-androgen used in the treatment of prostate cancer, behaves as an androgen receptor agonist in osteoblasts, decreasing IL-6 secretion similarly to DHT (Robin-Jagerschmidt et al. 1999, ASBMR, F460). In order to test its effects *in vivo*, we used a model of osteopenia in male mice. Twelve week-old C57Bl/6 mice were orchidectomized and treated with pTesto, or DHT (2.5mg/kg/d, pellet), for 4 weeks. Orchidectomy induced a significant (30 ± 4%) trabecular bone loss in long bones (tibia), and increased bone turnover. Serum osteocalcin (OC) and urinary deoxypyridinolin (D-Pyr) were increased 2 weeks after orchidectomy and remained elevated for two additional weeks. DHT and pTesto treatment normalized OC and (D-Pyr) levels to sham control. Both compounds fully prevented the decrease in seminal vesicle weight induced by orchidectomy. Cyproterone acetate (30mg/kg/d s.c.) was also able to prevent the ORX-induced bone loss at both trabecular and cortical sites, but did not increase seminal vesicle weight of ORX mice. More interestingly, when administrated in combination with DHT (2.5mg/kg/d), cyproterone acetate antagonized at least 85% of the DHT effects on the seminal vesicles, but did not counteract the bone sparing effects of DHT. These results demonstrate that cyproterone acetate displays *in vivo* tissue selective agonist activity. Such SARMs are promising drugs for the prevention of osteoporosis in aging men.

1028

Constitutive Expression of 25-Hydroxyvitamin D3 1 alpha-Hydroxylase in a Human Melanoma Cell Line: Autocrine Regulation by Endogenous PTHrP Production. D. C. Huang[1], R. L. Horst[2], D. Goltzman[1], R. Kremer[1]. [1]Medicine, Mcgill University, Montreal, PQ, Canada, [2]USDA, Agriculture Research Svc., National Animal Disease Center, Ames, IA, USA.

Tumoral expression of 25-hydroxyvitamin D3 1 α-hydroxylase has previously been reported in a human small cell lung cancer cell line. Here we report a human melanoma cell line which can synthesize 1,25-dihydroxyvitamin D3 [1,25-(OH)2D3] from its inactive precursor 25-hydroxyvitamin D3 (25-OHD3). This cell line also expresses PTHrP and was used as a model to examine the autocrine regulation between 25-hydroxyvitamin D3 1 α-hydroxylase and PTHrP. 1,25-(OH)2D3 and PTHrP expression and production were identified and quantified by Northern blot analysis, radioimmunoassays and HPLC. Normal human melanocytes were also examined for PTHrP and 1 α-hydroxylase expression. Northern blot analysis revealed high levels of 1 α-hydroxylase gene expression in this melanoma cell line. Cloning and sequencing of 1 α-hydroxylase cDNA from the melanoma cells identified a transcript identical to that observed in human renal cells and keratinocytes. Enzyme kinetic studies revealed a Km for 1 α-hydroxylase of 500 nmol/litre, with a maximum velocity of 3.5 ng/h/ml/10exp6 cells. This activity was inhibited following transfection with 1 α-hydroxylase antisense cDNA. Addition of substrate 25-OHD3 significantly inhibited cell growth, PTHrP expression and production, and induced morphological changes similar to the effect observed with 1,25-(OH)2D3. Targeted disruption of the PTHrP gene in this cell line totally eliminated PTHrP production and resulted in a drastic reduction of 1 α-hydroxylase activity by over 80% as compared to the parent cell line. Although normal human melanocytes expressed low levels of PTHrP no detectable expression or activity of 1 α-hydroxylase was found. This is the first report of 1 α-hydroxylase expression by human melanoma cells and its autocrine regulation by PTHrP in a reciprocal positive/negative feed back loop.

1029

Comparison of Mice with Deletions of the 25OH Vitamin D_3-1α Hydroxylase (1αOHase), of the Vitamin D Receptor (VDR), and of Both, Suggest an *In Vivo* Role for VDR-Dependent and Independent Regulation of Calcium and Skeletal Homeostasis. D. K. Panda[1], D. Miao[1], R. Huo*[1], G. N. Hendy[1], D. Goltzman[2]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Medicine, McGill University Health Centre and McGill University, Montreal, PQ, Canada.

We compared calcium and skeletal homeostasis in mice homozygous for targeted disruption of the 1α(OH)ase gene [1αOHase$^{-/-}$], the VDR gene [VDR$^{-/-}$], and both genes [1αOHase$^{-/-}$; VDR$^{-/-}$]. All mice were fed normal chow (1% calcium, 0.9% phosphorus) with high calcium (15%) in drinking water and were analyzed at 9 weeks. Serum calcium was: 10.8 ± 0.3 mg/dl in wild-type (WT) littermates; 8.8 ± 0.4 mg/dl in 1α(OH)ase$^{-/-}$ mice, 7.1 ± 0.5 mg/dl in VDR$^{-/-}$ mice; and 6.4 ± 0.2 mg/dl in 1α(OH)ase$^{-/-}$; VDR$^{-/-}$ mice. Serum 1,25$(OH)_2D_3$ concentrations were 64.2 ± 10.4 pg/ml in WT, 498 ± 36.7 pg/ml in VDR$^{-/-}$, and were undetectable in both mutants deficient in 1α(OH)ase. Parathyroid glands were enlarged in all 3 mutants. Radiologic analysis revealed a progressive reduction in long bone size and extent of mineralized bone from WT to 1αOHase$^{-/-}$ to VDR$^{-/-}$ to 1α(OH)ase$^{-/-}$; VDR$^{-/-}$. Animal size also was progressively reduced from WT (23 ± 1.4 g) to 1α(OH)ase$^{-/-}$ (21 ± 0.9 g) to VDR$^{-/-}$ (16.4 ± 0.8 g) to 1α(OH)ase$^{-/-}$; VDR$^{-/-}$ (12.3 g). Histological analysis revealed a very widened, disorganized cartilaginous growth plate in the two models deficient in 1α(OH)ase; in contrast, in VDR$^{-/-}$ mice, the growth plate was only slightly thickened compared to WT and was better organized. Trabecular bone was reduced in the VDR$^{-/-}$ mice with increased TRAP-positive osteoclasts and was poorly mineralized. Trabecular bone was increased in both 1α(OH)ase$^{-/-}$ models with increased osteoblast numbers and decreased TRAP-positive osteoclasts but was poorly mineralized in the compound mutants. Trabecular mineralization therefore seemed dependent on ambient calcium levels. In these models, therefore, hypocalcemia correlated better with VDR than with 1α(OH)ase status; normalization of the cartilaginous growth plate occurred in the absence of VDR but not in the absence of 1α(OH)ase; and increased trabecular bone volume, increased trabecular osteoblasts and decreased TRAP-positive osteoclasts correlated with the absence of 1,25$(OH)_2D_3$ rather than with VDR deficiency. These *in vivo* results suggest that in regulating skeletal and calcium homeostasis, vitamin D can exert effects that may be dependent on or independent of the VDR.

Rickets in VDR Null Mice Is Secondary to Decreased Apoptosis of Hypertrophic Chondrocytes. M. M. Donohue*, M. B. Demay. Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA.

The absence of a functional VDR in mice and humans leads to hypocalcemia, hyperparathyroidism, hypophosphatemia, rickets and osteomalacia. By 24 days of age, VDR knockout mice have an expansion in the layer of hypertrophic chondrocytes, characteristic of rickets; however, prevention of abnormal mineral ion homeostasis by instituting dietary therapy by 18 days prevents rickets, demonstrating that the VDR is not required for normal growth plate maturation. We, therefore, hypothesized that rickets, in the absence of a functional VDR, is a consequence of impaired mineral ion homeostasis. Analyses of rachitic growth plate morphology demonstrated normal resting and proliferating chondrocyte layers in the VDR knock-out mice; however a 2.1 fold expansion of the hypertrophic chondrocyte layer was present at 24 days of age. Recent studies have demonstrated that extracellular calcium plays a role in chondrocyte maturation. We, therefore, examined markers of chondrocyte differentiation in the rachitic VDR null growth plate. In situ hybridization analyses revealed normal expression of hypertrophic chondrocyte markers in the tibial growth plate of 24 day old VDR knock out mice suggesting that the increase in hypertrophic chondrocyte layer was not secondary to impaired differentiation. Furthermore, expression of VEGF was not altered in the VDR null growthplate. We then addressed whether the expansion of the hypertrophic chondrocyte layer in the VDR null mice was secondary to increased proliferation or decreased apoptosis. BrdU labeling failed to demonstrate a difference in proliferation between VDR knock-out and control animals in both the proliferating chondrocytes (42.1% vs. 42.0%) and hypertrophic chondrocytes (1.2% vs. 4.7%). The lower percent BrdU incorporation in the hypertrophic chondrocytes of the VDR null mice is due to an increase in the total number of hypertrophic chondrocytes rather than a decrease in the number of proliferating cells. Apoptosis was evaluated following in vivo labeling with Annexin-V-biotin. In contrast to control littermates, no detectable annexin-V biotin was seen in the growth plate of the VDR null mice, suggesting that an impairment in programmed cell death led to expansion of the hypertrophic chondrocyte layer. Normalization of the growth plate phenotype in VDR null mice with normal mineral ions is consistent with in vitro studies demonstrating that inorganic phosphate induces chondrocyte apoptosis. Thus, our data support the hypothesis that impaired mineralization in the region of the hypertrophic chondrocytes, in the setting of abnormal mineral ion homeostasis, markedly attenuates apoptosis, leading to the characteristic findings of rickets.

Improved Survival Rate and Bone Status in Senile Female Mice Lacking Estrogen Receptor-beta. H. Z. Ke[1], H. Qi[1], D. T. Crawford*[1], H. A. Simmons[1], Q. Zhang*[2], T. A. Brown[1], D. N. Petersen[1], W. S. S. Jee[2], D. D. Thompson[1]. [1]Pfizer Global Research and Development, Groton, CT, USA, [2]University of Utah, Salt Lake City, UT, USA.

The purpose of this study was to compare the differential response to long-term aging and ovariectomy (OVX) between estrogen receptor-beta (ER-b) knockout (BERKO) senile female mice and wild-type littermate controls (WT) in survival rate and bone status. Fourteen WT and 14 BERKO mice were necropsied at 13 months of age and served as basal controls. The remaining WT and BERKO mice were sham-operated or OVX, and were necropsied at 8 months post-surgery. By 21 months of age, only 5 of 14 (35.7%) mice survived in the WT-sham group, while 14 of 16 (87.5%) survived in the BERKO-sham group. There were 9 of 13 (69.2%) survivors in the WT-OVX group, and 10 of 15 (66.7%) in the BERKO-OVX group. These results indicate that the survival rate in senile female mice lacking ER-b is increased as compared with WT. OVX increased the survival rate in WT but not BERKO senile female mice. At 13 months of age, PQCT analysis showed that BERKO mice had significantly higher total content (+30%), cortical content (+32%) and trabecular density (+48%) at the distal femoral metaphysis (DFM) and significantly higher total content (+19%) and cortical content (+17%) at the femoral shafts (FS) as compared with WT mice. The higher bone mass was accompanied with a lower bone resorption and bone turnover in BERKO mice. There was a significant decrease in total content (-34%), cortical content (-30%) and trabecular density (-19%) at the DFM and a significant decrease in total content (-15%) and cortical content (-13%) at the FS in WT mice from 13 to 21 months of age. In BERKO mice, there was no significant difference in total content, cortical content and trabecular density at the DFM, while there was a significant increase in total and cortical content at the FS from 13 to 21 months of age. Micro-CT analysis of the DFM showed that the trabecular bone volume decreased significantly from 13.6% at 13-month-old to 5.0% at 21-month-old in WT mice, while this parameter increased from 25.6% to 33.4% during this period in BERKO mice. These results indicate that ER-b knockout completely protected against age-related cancellous and cortical bone loss between 13 to 21 months of age. At 8 months post-OVX, cancellous and cortical bone mass significantly decreased to the same levels in WT-OVX and BERKO-OVX mice, despite BERKO mice had higher bone mass at the time of OVX. These results indicate that ER-b knockout does not protect against bone loss induced by OVX. In summary, our data showed that ER-b knockout improved the survival rate and completely protected against age-related bone loss, but failed to protect against OVX-induced bone loss in these senile female mice.

Interchangeable Ligand/Receptor Interactions Mediate ERK Activation and the Pro- and Anti- Apoptotic Effects of Estrogens and Androgens on Murine Osteoclasts and Osteoblasts from Females and Males: A Molecular Explanation of the In Vivo Equivalence of their Skeletal Actions in either Sex. J. R. Chen[1], S. Kousteni[1], L. Han[1], A. M. Vertino[1], L. K. McCauley[2], A. A. Ali[1], T. Bellido[1], R. S. Weinstein[1], C. A. O'Brien[1], R. L. Jilka[1], S. C. Manolagas[1]. [1]Division of Endocrinology and Metabolism, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, U/sity of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]School of Dentistry, U/sity of Michigan, Ann Arbor, MI, USA.

Estrogens restore bone mass in males with androgen deficiency, whereas nonaromatizable androgens can protect the female skeleton against the adverse effects of estrogen deficiency. Based on this and evidence, reported elsewhere in this meeting, that estradiol (E_2) or dihydrotestosterone (DHT) administration to gonadectomized mice results in equivalent effects on osteoclastogenesis, osteoblastogenesis and BMD irrespective of the sex of the replaced animal, we investigated the specificity of the ligand/receptor interaction in murine bone cells from females and males. The sex of the donor mice in these experiments was determined by Southern blot analysis of genomic DNA isolated from livers, using a cDNA probe specific for the Y chromosome. Osteoblasts or osteoclasts from females and males exhibited indistinguishable levels of ERα, ERβ or AR expression, as determined by semi-quantitative RT-PCR or staining with specific receptor antibodies. E_2 or DHT (10^{-11} - 10^{-7} M) prevented etoposide-induced apoptosis of calvaria osteoblasts and stimulated osteoclast apoptosis in a dose dependent manner and with identical efficacy, in cells from females and males. The identical potency of E_2 and DHT on the lifespan of osteoblasts and osteoclasts resulted from the ability of the ER (α or β) or the AR to transmit ERK-activated signals with similar efficiency irrespective of whether the ligand was an estrogen or an androgen. Indeed, all the effects of E_2 or DHT on osteoblasts or osteoclasts were blocked by either the ER antagonist ICI 182,780 or the AR antagonist flutamide; and this phenomenon was reproduced in HeLa cells transiently transfected either with ERα, ERβ or AR alone. Strikingly, E_2 stimulated ERK phosphorylation, prevented osteoblast, and stimulated osteoclast apoptosis in cells obtained from mice lacking both ERα and ERβ (DERKO), provided by P. Chambon. As in the wild type control, all the effects of E_2 in the DERKO cells could be prevented by either ICI 182,780 or flutamide. These results suggest that the equivalence of the bone protective effects of estrogens and androgens in males and females results, at least in part, from interchangeable ligand/receptor interactions in bone cells from either sex.

Prevention of Ovariectomy-Induced Bone Loss in β_3 Integrin Knockout Mice. H. Zhao*, F. P. Ross, S. L. Teitelbaum, D. V. Novack. Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Both blocking and β_3 knockout mouse studies have established that $\alpha_v\beta_3$ integrin is essential for optimal osteoclastic bone resorption. However, the role of $\alpha_v\beta_3$ in the pathogenesis of postmenopausal osteoporosis had not been explored. In this study, 2-month old female wild type (WT) and β_3 integrin knockout (KO) mice were ovariectomized (OVX) or sham-operated (sham). Thirty days after operation bone mineral density (BMD, mg/cm^2) was measured by DEXA (Pyximus). As shown in Table 1, ovariectomy induced a 7% decrease ($p< 0.05$) in whole body BMD in WT mice, while KO mice showed a statistically insignificant rise in BMD. BMD was 12-15% lower in WT mice at the femoral neck and lumbar vertebrae following OVX, while these parameters remained unchanged in KO mice. Isolated tibiae were subjected DEXA, then processed for histomorphometric analysis of TRAP-stained sections. Tibial BMD was unaffected by OVX in KO mice, compared to a 12% drop in OVX WT mice. Consistent with this, KO mice fail to show the OVX-induced increase in osteoclast surface (OCS/BS) and decrease in trabecular bone volume (BV/TV) seen in WT mice (Table 2). We conclude that the absence of $\alpha_v\beta_3$ confers protection against OVX-induced osteoporosis. These findings confirm the critical role of $\alpha_v\beta_3$ integrin in bone resorption and indicate that inhibitors of this integrin may be useful in preventing postmenopausal osteoporosis.

Tob-Deficiency Prevents Ovariectomy-Induced Bone Loss through the Enhancement of Osteoblastic Differentiation in Bone Marrow Stromal Cells to Augment Bone Formation (BFR/MAR) In Vivo. M. Usui*[1], Y. Yoshida*[2], K. Tsuji[1], I. Ishikawa*[3], A. Nifuji[1], T. Yamamoto*[2], M. Noda[1]. [1]Molecular Pharmacology, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan, [2]Tokyo University, Tokyo, Japan, [3]Periodontology, Tokyo Medical and Dental University, Tokyo, Japan.

Tob(Transducer of ErbB2) is a member of novel antiproliferative family. Tob-deficient mice reveal high levels of bone mass in adult, due to increase in bone formation without major alteration in bone resorption. Furthermore, Tob acts as an inhibitor against BMP-induced Smad signaling (Cell, 2000). We recently observed that Tob-deficiency preserves bone mass even after the bone loss due to ovariectomy (OVX). However, the mechanisms underlying this phenomenon have not been known. The aim of this paper was to elucidate the cellular mechanism, which causes Tob-deficiency effects on OVX-induced bone loss. In vitro nodule formation (NF) assay conducted using bone marrow cells (BMCs) obtained 14days after OVX revealed about 5-hold enhancement in NF in BMCs from ovariectomised (OVXed) mice compared to sham-operated (Sh-) mice in wild type (WT) group. In the case of Tob-deficient (TD) BMCs, the levels of NF in Sh-group were similar to those in the Sh-WT group. However, OVX-induced enhancement of NF was significantly more in the BMCs from TD mice compared to the BMCs from OVXed WT mice. The number of osteoclast (OC) developed in the bone marrow cultures treated with dexamethasone and vitamin D was enhanced by about 80% in OVXed group compared to Sh-WT mice. In contrast to Tob-deficiency enhancement of NF, OC development induced by OVX was similar between TD and WT mice. Based on such enhancement in the osteoblastic (OB) activity in BMCs in culture, we evaluated OB activity in vivo based on histomorphometry. Mineral apposition rate (MAR) was enhanced by OVX in WT mice as reported previously. In TD mice basal levels of MAR in Sh-mice was high and comparable to the high levels of MAR in OVXed WT mice. Interestingly, OVX in TD mice enhanced MAR significantly compared to the Sh-group in TD mice. Similarly bone formation rate (BFR) was enhanced by OVX in WT mice and the basal levels of BFR in TD mice in Sh-group was comparable to that in OVXed WT mice. OVX further enhanced BFR significantly compared to the Sh-mice in TD background. OVX increased the spleen weight (SW) in WT mice. In Sh-TD mice, SW was similar to the corresponding SW in OVXed WT mice. Intriguingly, however, OVX did not further enhance SW in TD mice. These data indicate that Tob-deficiency prevents OVX-induced bone loss through the enhancement of OB differentiation in bone marrow environment and this results in the augmentation in BFR and bone mass gain in vivo.

Local Glucocorticoid Activation Mediates the Effect of Glucocorticoids on Bone. M. S. Cooper[1], A. Blumsohn[2], P. E. Goddard*[1], W. A. Bartlett*[1], C. H. Shackleton*[3], R. Eastell[2], M. Hewison[1], P. M. Stewart*[1]. [1]Medical Sciences, University of Birmingham, Birmingham, United Kingdom, [2]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [3]Children's Hospital Oakland Research Institute, Oakland, CA, USA.

Glucocorticoid excess decreases bone formation and BMD, and increases fracture risk but these effects are difficult to predict in any given individual. We recently described expression of 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) in osteoblasts where this enzyme generates active cortisol (or prednisolone) from inactive cortisone (or prednisone). In vitro, this enzyme regulates glucocorticoid action in osteoblasts and thus we hypothesized that this enzyme modulates the clinical effects of glucocorticoids on bone. We have now defined the determinants of variation in the response of bone markers to glucocorticoid therapy. 20 healthy males (age 31±8; mean±SD) took 5mg prednisolone twice daily orally for 7 days. 24hr urinary steroid metabolites (by GC/MS), BMD and biochemical bone markers (osteocalcin (OC), N-terminal propeptide of type I collagen (PINP), serum C-telopeptide of collagen cross-links (βCTx) and PTH) were measured before steroids and repeated at days 4 and 7. Prednisolone absorption, prednisone generation and steroid half-lives were subsequently determined (by HPLC) post oral prednisolone (5mg at 0900). OC and PINP both decreased at days 4 and 7 (29±11ng/ml vs 18±8 and 19±8 for OC; 67±24ng/ml vs 52±19 and 52±16 for P1NP; all $p<0.001$) but βCTx and PTH did not change significantly. There was a negative correlation between 11β-HSD1 activity (measured as the urinary (THF+alloTHF)/THE ratio) at baseline and OC at days 4 and 7 (r=-0.58 and -0.56; both $p<0.01$) and PINP at day 4 (r=-0.51; $p<0.05$). There was no correlation with measures of glucocorticoid inactivation (11β-HSD2 activity: urinary cortisol/cortisone ratio), total steroid metabolites, BMD, peak prednisolone or prednisone level, or prednisolone half-life. The relationship between 11β-HSD1 activity and bone formation markers could reflect either systemic or osteoblastic steroid generation. 11β-HSD1 activity did not predict increased prednisolone area under the curve or circulatory half-life thus it is unlikely that systemic activity mediates the observed relationship. Urinary 11β-HSD1 activity predicts the response of bone formation markers to glucocorticoids, explaining approximately a third of variability between individuals. This appears to reflect increased local generation of active glucocorticoids within osteoblasts. Measures of 11β-HSD1 activity predict the skeletal response to glucocorticoids and may form the basis of a test to predict individual susceptibility.

Down-regulation of Interleukin-11 may be Involved in the Pathogenesis of Glucocorticoid-induced Osteoporosis. S. Kido, D. Inoue, S. Kato*, Y. Ito*, T. Matsumoto. Department of Medicine and Bioregulatory Science, University of Tokushima, Tokushima, Japan.

We have reported that Fos family transcripton factors including deltafosB, and an AP-1 target interleukin (IL)-11, are induced by mechanical stress and PTH in an ERK-dependent manner. Conversely, marrow stromal cell AP-1 activity and IL-11 expression is reduced by aging. Importance of IL-11 is underscored by recent observations that transgenic mice over-expressing IL-11 exhibit high bone mass due to enhanced bone formation and are protected from aging-associated bone loss. In the present study, we investigated a role for IL-11 in the pathogenesis of glucocorticoid (GC)-induced osteoporosis, characterized by suppressed bone formation. As we have already shown, fluid shear stress (FSS) as well as treatment with PTH, dibutylyl cAMP, TPA and calcium ionophore all induced fosB/deltafosB and IL-11 mRNA expression by primary osteoblasts (POB) obtained by sequential digestion of newborn mouse calvariae. In vivo treatment of mice with PTH also resulted in two to three fold induction of IL-11 mRNA expression in tibiae and femurs as assessed by quantitative real-time PCR analysis. Interestingly, the induction of IL-11, both in vitro and in vivo, was almost completely abolished by pretreatment with dexamethasone (Dex), while induction of fosB/deltafosB remained intact. Furthermore, Dex treatment of ST2 cells stably transfected with an IL-11 promoter-luciferase construct almost completely suppressed both basal and induced luciferase activities. These results are consistent with an idea that Dex inhibits IL-11 transcription by blocking AP-1 activities. In order to further elucidate a role for IL-11 in GC-induced osteoporosis, we next examined its effects on osteoblast apoptosis. As previously reported, Dex and etoposide induced POB apoptosis as evidenced by DNA ladder formation. Calvarial cell fractionation revealed that Dex-induced apototosis occurs mostly in fraction V representing mature osteoblasts. We found that IL-11 inducers such as FSS and PTH as well as IL-11 itself strongly blocked the apoptosis. Furthermore, anti-apoptotic effects of PTH was partially reversed by an anti-IL-11 neutralizing antibody. Both PTH and IL-11 blocked DEX-induced down-regulation of Bcl-2 while levels of Bax stayed the same. Finally, in vivo analysis using IL-11 transgenic mice suggested that over-expression of IL-11 partially suppressed Dex-induced OB apoptosis. We therefore conclude that IL-11 is an osteogenic cytokine which not only promotes early osteoblastogenesis but also enhances osteoblast survival and that down-regulation of IL-11 may be associated with osteoblast apoptosis and thereby contributes to bone loss induced by GC excess.

Resolution of Effect Following Alendronate: Six-Year Results from the Early Postmenopausal Interventional Cohort (EPIC) Study. M. McClung[1], R. Wasnich[2], M. Omizo*[1], C. Christiansen[3], P. Ravn*[3], D. Hosking[4], M. Wu*[5], A. Kaur*[5], A. M. Mantz*[5], S. Snodgrass[5], A. Santora[5]. [1]Oregon Osteoporosis Center, Portland, OR, USA, [2]Radiant Research / Honolulu, Honolulu, HI, USA, [3]CCBR, Ballerup, Denmark, [4]City Hospital, Nottingham, United Kingdom, [5]Merck Research Laboratories, Rahway, NJ, USA.

Alendronate[1] (ALN) is indicated for the prevention of osteoporosis to maintain bone mass and reduce the risk of future fracture.[2,3] Women who received ALN 5 mg for 6 years experienced significant, persistent gains in mean lumbar spine and hip BMD, that were maintained. In contrast, BMD steadily decreased in the placebo (PBO) group. The objective of this report is to assess the effect of discontinuation. We now report the change in BMD after treatment was discontinued following 2-4 years of therapy with ALN or estrogen/progestin (E/P). Healthy postmenopausal women (n=1609), aged 45-59 years, mean T-score spine BMD -0.8 were initially randomized to ALN 2.5 or 5 mg daily, or PBO (stratum 1 and 2), or E/P (stratum 1 only). After 2 or 4 years, ALN was switched to PBO in a portion of women. E/P women were off therapy in Years 5 and 6. BMD was measured at the lumbar spine, hip, forearm and total body at baseline, and then annually. Percent change during Years 5 and 6 was used to assess the resolution of effect. Women in stratum 1 who previously received E/P for 4 years generally had significantly greater mean BMD loses at the lumbar spine (-8.3%), hip sites (TH, -5.5%; FN, -6.1%; T, -7.9%), and forearm (-2.8%) during Years 5 and 6 which were greater losses than in those who had received ALN 5 mg for 4 years.

Mean Percent Change in BMD during Years 5 & 6

Treatment	**Lumbar Spine†**		**Total Hip**		**Femoral Neck**		**Trochanter**		**Distal one-third forearm**	
Yr 1-2/3-4/**5-6**	**n**	**%**	**n**	**%**	**N**	**%**	**n**	**%**	**n**	**%**
PBO/PBO/**PBO**	139	-0.72*	138	-0.43	138	-0.88**	138	-0.67*	138	-1.34***
ALN 5/5/**5**	96	0.02	94	0.14	94	0.34	94	0.57	95	-0.45
ALN 5/5/**PBO**	88	-2.07***	89	-1.85***	89	-1.58***	89	-1.71***	89	-1.93***

Within Group: * p≤ 0.05 ** p≤ 0.01 *** p≤ 0.001; PBO, Placebo daily; ALN 5, Alendronate 5 mg daily

Bone loss resumes when ALN 5 mg daily is discontinued after 4 years albeit at a rate slower than that following E/P therapy. BMD at the end of 6 years remained significantly higher in women who previously received alendronate 5 mg for 4 years than in those who were never treated with alendronate.

Non-Vertebral Fracture Benefit from Oral Ibandronate Administered Daily or with a Unique Drug-Free Interval: Results from a Pivotal Phase III Study in postmenopausal osteoporosis (PMO). R. Recker[1], J. A. Stakkestad*[2], T. Weber[3], S. Cohen[4], P. Delmas[5], R. Schimmer*[6], P. Mahoney*[6], J. Kilbride*[6]. [1]Creighton University School of Medicine, Omaha, NE, USA, [2]CECOR AS, Haugesund, Norway, [3]Duke University Medical Center, Durham, NC, USA, [4]Metroplex Clinical Research Center, Dallas, TX, USA, [5]Hôpital Edouard Herriot, Lyon, France, [6]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Although effective, current oral bisphosphonates are associated with relatively stringent dosing requirements that may be inconvenient to some patients, potentially reducing compliance and jeopardizing therapeutic outcome. Intermittent oral dosing may provide a more convenient option. Recent results from a large double-blind, multinational study (BONE: Bonviva® Osteoporosis Trial in North America and Europe) demonstrated that oral ibandronate, given daily or intermittently with a dosing interval of >9 weeks, significantly reduces vertebral fracture (VF) risk in women with established PMO (Delmas P, et al. IOF World Congress on Osteoporosis 2002; abstract O37). In this study, 2,946 patients (aged 55-80 years, at least 5 years since menopause) with PMO (1-4 prevalent VFs, lumbar spine bone mineral density [BMD] T-score<-2.0 SD) were randomized to oral ibandronate either daily (2.5mg) or intermittently (20mg every other day for 12 doses at the start of each 3-month cycle) or placebo for 3 years. All patients received daily oral calcium (500mg) and vitamin D (400IU). Both ibandronate regimens provided significant BMD increases at the lumbar spine and hip versus placebo and reduced markers of bone turnover to within the range of premenopausal levels. VF risk was significantly reduced by 62% (p=0.0001) and 50% (p=0.0006) with the daily and intermittent regimens, respectively, over 3 years. No statistically significant reduction was seen in non-VFs. However, the study population was at low risk for such fractures, with a minority of women (30.5%) having low femoral neck BMD at baseline (T-score ≤-2.5 SD), and >30% of patients having a femoral neck BMD T-score >-1.6 SD. Daily and intermittent oral ibandronate reduced the incidence of clinical fractures by 66% (p=0.0058) and 50% (p=0.0461) and non-VFs by 69% (p=0.013) and 37% (p=0.22), respectively, relative to placebo in a higher-risk subgroup (femoral neck BMD T-score >-3.0 SD). Thus, daily and intermittent oral ibandronate significantly reduced the risk for new morphometric and clinical VFs. The daily regimen provided significant reduction in the incidence of non-VFs in a higher-risk subgroup, even though the overall population was at low risk for non-VFs. These results support the potential of ibandronate to become an important alternative to current treatments in PMO.

1039

Effects of Parathyroid Hormone, Alendronate, or Both on Bone Density in Osteoporotic Postmenopausal Women. R. Neer, A. Hayes*, A. Rao*, J. Finkelstein. Endocrine Unit, Mass. General Hospital, Boston, MA, USA.

Once-daily parathyroid hormone (PTH) administration increases bone formation and bone mineral density (BMD) and reduces vertebral and non-vertebral fractures in osteoporotic postmenopausal women, but does not eliminate fragility fractures. Because PTH also increases bone resorption, combining it with an anti-resorptive agent may enhance its effectiveness. To test this hypothesis, we randomly assigned 93 such women whose lumbar spine and/or femoral neck BMD T-score was ≤ minus 2.0 to receive alendronate 10 mg orally daily (ALN, n=31), PTH 40 ug sc daily (PTH, n=31), or BOTH (n=31) for 30 months. PTH treatment started at month 6. All women had normal serum PTH, 25-OH D, and TSH levels at entry. None had other disorders that (or took medications that) affect bone metabolism or BMD. Calcium intake was maintained at 500-1500 mg/day and serum 25-OH vitamin D was maintained >15 ng/mL. BMD of the posterior-anterior lumbar spine, proximal femur, radius diaphysis, and total body (without head region) were measured every 6 months by DXA (Hologic 4500A). To date, 53 women (n=19, 19, and 15 receiving ALN, PTH, or BOTH, respectively) have completed at least 12 months of therapy. Mean (±SD) percent changes in BMD and serum alkaline phosphatase to month 12 are:

Group	Vertebrae	Total Hip	Radius Diaphysis	Total Body	Alk P'tase
ALN	4.7 ± 3.3	0.9 ± 5.3	2.2 ± 2.9	2.1 ± 2.8	- 18 ± 15
PTH	7.5 ± 5.0	0.1 ± 7.5	- 2.2 ± 3.1 *	0.5 ± 4.1	96 ± 61 **
BOTH	7.3 ± 2.3	3.6 ± 6.2	0.1 ± 3.0	2.5 ± 2.9	6 ± 25

* p < 0.05 vs. ALN * * p < 0.01 vs. ALN

Adding ALN reduced the PTH-induced increase in serum alkaline phosphatase, reduced the incidence of PTH-induced mild, transient, hypercalcemia, and did not alter PTH's effects on vertebral BMD (substantially trabecular bone). The superior changes in total hip, radius diaphysis, and total body BMD suggest that ALN prevents PTH-induced losses of cortical bone mineral. Co-administration of PTH+ALN illuminates bone resorption-formation interactions; prolonged co-administration is likely to improve the treatment of postmenopausal osteoporosis.

Combination Therapy for Prevention/Treatment of Osteoporosis in Elderly Women: A Randomized, Double-Blind, Placebo-Controlled, NIH-Sponsored Clinical Trial. S. L. Greenspan[1], N. M. Resnick*[2], R. A. Parker*[3]. [1]Osteoporosis Prevention & Treatment Center, University of Pittsburgh, Pittsburgh, PA, USA, [2]Division of Geriatric Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [3]Biometrics Center, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA.

Although antiresorptive agents have been shown to increase bone mass, there are few head to head comparisons of single agents, combination therapy, or their impact on unselected community-dwelling, elderly women with or without a uterus. Four-hundred-eighty-five women age 65 or older (65-91 years, mean 72±5 years) from the Boston area with a low bone mass entered a 3-month, open-label run-in with hormone replacement therapy (HRT). Three-hundred-seventy-three completers were randomized into a double-blind, placebo-controlled, 3-year trial with 1) Prempro® or Premarin® (HRT), 2) alendronate (ALN) 10 mg/day, 3) HRT + ALN (COMB), or 4) placebo (PLB). All received supplementary calcium and vitamin D. Results are presented as mean±SEM of percent changes at 3 years analyzed on an intention to treat basis.

Percent Bone Mineral Density (BMD) Increase from Baseline

	Total Hip***	Trochanter**	Femoral Neck***	PA Spine***	Lateral Spine***
HRT	3.0±0.5#	4.0±0.7#	1.8±0.5#	6.8±0.6#	7.1±0.8#
ALN	4.1±0.4#	5.4±0.6#	2.6±0.5#	7.4±0.6#	8.4±0.8#
COMB	5.4±0.4#	6.9±0.6#	3.6±0.5#	9.2±0.7#	10.3±0.8#
PLB	-0.8±0.5	-1.0±0.6	-0.7±0.6	0.9±0.5#	1.2±0.7
COMB vs. HRT	2.4±0.6***	2.9±0.9***	1.8±0.7*	2.3±0.9**	3.3±1.1**
COMB vs. ALN	1.3±0.6*	1.5±0.8	1.0±0.7	1.8±0.9*	2.0±1.1

# P < 0.05 vs baseline * P < 0.05, ** P < 0.01, *** P <0.001 between all groups or between pairs of groups

There were no statistically significant differences between those who discontinued during run-in and those who were randomized. Baseline clinical characteristics, adverse events and compliance were similar across groups, with 90% retention at 3 years. BMD increased at all sites in all treatment groups, with the greatest increase in the COMB group. Although the BMD gain in the ALN group was greater at all sites compared to HRT, there were no statistically significant differences between these two groups. BMD at the spine and hip were higher in women in the COMB group compared with women in the HRT or ALN groups. We conclude that: 1) unselected elderly women do well on HRT, ALN, or COMB, 2) after 3 years, gains in BMD in women on HRT or ALN were similar, and 3) COMB provides a significantly greater increase in BMD than does HRT or ALN alone. These data support the need for a large trial powered to assess the relative efficacy in fracture reduction with combination therapy.

1041

Improved 3-Dimensional Microstructure of Cancellous and Cortical Bone in a Multicenter, Double-Blind, Randomized and Placebo Controlled Study of Teriparatide [rhPTH(1-34)]. Y. Jiang[1], J. Zhao[1], E. F. Eriksen[2], O. Wang*[2], H. K. Genant[1], B. H. Mitlak[2]. [1]Osteoporosis and Arthritis Research Group, University of California, San Francisco, CA, USA, [2]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA.

Teriparatide injection (rDNA origin) [rhPTH(1-34)] significantly increased areal bone mineral density (aBMD) at the lumbar spine and proximal femur, had no effect or decreased aBMD at the distal radius, and decreased both vertebral and nonvertebral fractures in a Fracture Prevention Trial of postmenopausal women with osteoporosis (Neer et al., NEJM 2001). In this study, the effects of teriparatide were measured on cancellous and cortical bone from iliac crest bone biopsies from a subset of women enrolled in the Fracture Prevention Trial. For the 3-dimensional micro-computed tomography (3DμCT), paired biopsies were obtained from women in the placebo group (n=19) and the combined teriparatide treated group [20 μg (n=18) and 40 μg (n=14)] at baseline and after 18 ± 5 months (mean ± SD) (range 12-24 months). The 3D cancellous and cortical structural parameters were measured directly using a Scanco μCT with isotropic resolution of 17 μm^3, without stereological model assumptions as in 2D histomorphometry. These parameters provide an estimate of bone biomechanical properties and mechanical competence of bone. All specimens underwent blinded assessment. Compared to placebo, teriparatide treatment significantly increased cancellous bone volume fraction (BV/TV; mean ± SEM) (60% ± 26% vs. -2% ± 10%, P=0.075; ΔBV/TV, 0.025 ± 0.014 vs. -0.024 ± 0.015, P=0.033), decreased the cancellous structure model index (-12% ± 7% vs. 25% ± 15%, P=0.016), and increased cancellous connectivity density (40% ± 13% vs. -5% ± 9%, P=0.021) and cortical bone thickness (29% ± 9% vs. -2% ± 7%, P=0.029), teriparatide vs placebo, respectively. There was no significant difference in cortical porosity between placebo and teriparatide-treated groups. In summary, teriparatide treatment resulted in an increase in cancellous bone volume and connectivity, shifted the trabeculae towards a more plate-like structure, and increased the thickness of cortical bone without increasing cortical porosity. These changes in cancellous and cortical bone morphology contribute to the increased biomechanical competence and may explain the reduced vertebral and nonvertebral fracture incidence demonstrated after teriparatide treatment.

Prevention of Bone Loss After Cardiac Transplantation with Alendronate or Calcitriol: Efficacy and Safety. E. Shane[1], V. Addesso*[1], P. Namerow*[1], S. Maybaum*[1], R. Staron*[1], S. Lo*[1], M. Zucker*[2], S. Pardi*[2], D. Mancini*[1]. [1]Columbia University, New York, NY, USA, [2]Beth Israel Medical Center, Newark, NJ, USA.

The first year after cardiac transplantation (CTX) is characterized by high rates of bone loss and vertebral fracture (VF). Bone mineral density (BMD) declines 5% -10% at the spine (LS) and femoral neck (FN); VF incidence ranges from 18% - 35%. To prevent this important complication of CTX, we conducted a 1-year, double-masked, randomized clinical trial (RCT) in which the efficacy and safety of alendronate (ALN; 10 mg QD) and calcitriol (1,25D; 0.25 μg BID) were evaluated. Subjects (n=149) were randomized to ALN (n=74) or 1,25D (n=75), 21 +/- 11 days after CTX. Bone loss was compared between treatment groups and to a nonrandomized group of subjects (CON; n=25) who declined to participate in the RCT. All participants received daily calcium (Ca; 1000 mg) and vitamin D (1000 IU) and immunosuppressive therapy (prednisone, cyclosporine). Baseline BMD was similar at the LS (ALN, 1.047 ± 0.15; 1,25D, 1.059 ± 0.17; CON, 1.087 ± 0.17 g/cm2), FN (ALN, 0.837 ± 0.16; 1,25D, 0.836 ± 0.15; CON, 0.819 ± 0.12 g/cm2) and total hip (TH; data not shown). The 3 groups were similar with respect to gender, race, age, renal function, serum /urine Ca. Bone loss (% change from baseline at 1 year +/- S.E.M.) was analyzed by intent-to-treat (ITT) and on a subset (n=104) verified to have completed the RCT on study medications (VC). Bone loss was minimal in treated groups and did not differ between ALN and 1,25D. Both sustained significantly less bone loss than CON (Table 1).

Table 1

SITE/ANALYSIS	ALN	1,25D	CON
LS/ITT	-0.7 +/- 0.5	-0.9 +/- 0.7	-2.7 +/- 1.0
LS/VC *	+0.7 +/- 0.5	+0.5 +/- 1.2	-2.7 +/- 1.0
FN/ITT **	-1.4 +/- 0.6	-2.0 +/- 0.8	-5.9 +/- 1.0
FN/VC ***	-1.2 +/- 0.8	-0.3 +/- 0.9	-5.9 +/- 1.0
TH/ITT *	-1.4 +/- 0.4	-2.2 +/- 0.6	-4.1 +/- 1.0
TH/VC **	-0.8 +/- 0.5	0.9 +/- 0.5	-4.1 +/- 1.0

*p≤.04; **p≤.002; ***p≤.0001 compared to CON

The 3 groups did not differ by prednisone or cyclosporine dose, hospitalizations, infections, rejections or GI symptoms. However, elevated urine Ca (> 300 mg/g), serum creatinine (> 3 mg/dl) and low creatinine clearance (< 30 ml/min) were more frequent in 1,25D than ALN (p=0.04 to 0.02). In summary, subjects randomized to ALN or 1,25D did not sustain significant bone loss, nor did rates of bone loss differ between ALN and 1,25D groups at any site or time. In contrast, CON subjects sustained significant bone loss at all sites. We conclude that both ALN and 1,25D prevent bone loss after CTX. However, the potential for deleterious effects of 1,25D on urine Ca excretion and renal function and the need for biochemical monitoring makes ALN a more convenient and safer choice in this setting.

Cumulative Effects of Calcium Supplementation and Physical Activity on Bone Accretion in Prepubertal Period: A Randomized Double-Blind Placebo-Controlled Trial. D. Courteix[1], C. Jaffré*[1], E. Lespessailles[2], C. Benhamou[2]. [1]Inserm ERIT-M 0101 and LPM University of Orléans, Orléans, France, [2]Inserm ERIT-M 0101, Orléans, France.

High calcium intake (Ca+) during childhood has been suggested to increase bone mass accrual. Physical activity (PA) has been shown to improve the bone mineral density especially during the circumpubertal period of growth. The combined effects of Ca+ and PA are not identified in prepubescent subjects. In a double-blind, placebo-controlled study, 115 healthy prepubertal girls aged 9.9 ± 1.2 yr were randomly allocated two powder products containing either 800 mg of calcium phosphate (Ca+) or not (placebo, Ca-) on a daily basis for 1 yr. The group was composed of 63 sporty (PA+, 7.3 ± 4 $hr.wk^{-1}$) and 50 non active (PA-, 1.2 ± 0.8 $hr.wk^{-1}$) children. The final experiment concerned 4 groups : [PA+,Ca+] n=12, [PA+,Ca-] n=41, [PA-,Ca+] n=10 and [PA-,Ca-] n=21. Areal bone mineral density (BMD) at 6 skeletal sites and body composition were determined by dual-energy x-ray absorptiometry. Bone age was calculated and the daily spontaneous calcium intake was assessed in each subject by a frequency questionnaire. All the tests were performed at baseline and 1yr by the same person. The 1-year bone gain was assessed by a 2 factors (PA and Ca) ANOVA with repeated measures (baseline, 1yr) analysis. At each investigation there was no difference between groups for bone age, height and weight. Spontaneous Ca intake was the same in each groups at baseline then the Ca+ groups had a significant greater intake for the period of investigation (1783 ± 499 vs. 972 ± 313, $p<0.001$). The sporty girls were found leaner than the controls at each test. BMD gains were significantly greater in [PA+,Ca+] than in other groups at the Total body (+6.3 %, $p<0.05$), lumbar spine (+11 %, $p<0.05$), Femoral neck (+8.2 %, $p<0.02$), Ward's triangle (+9.3 %, $p<0.01$). There was no difference between the other groups. In conclusion these data suggest that 1) the calcium supplementation increases the effect of physical exercise on bone mineral acquisition in prepuberty, 2) the calcium supplementation without physical activity is unable to improve the BMD acquisition during this period. Physical exercise that is known to stimulate the bone accretion needs a high calcium intake to be completely efficient. By contrast calcium supplementation without physical activity is unable to stimulate the BMD gain. In such a situation it has been shown that only the subjects characterised by a low spontaneous calcium intake can draw benefit from the calcium supplement. These results indicate that both physical activity and calcium intake should be encouraged at a prepubertal age in order to increase bone density.

Microarray Analyses Identified NF-kB to Be the Target of Osteopontin-Dependent Regulation of Gene Expression in the Bone of Mice Subjected to Tail-Suspension. M. Ishijima[1], Y. Ezura[2], K. Tsuji[1], S. R. Rittling[3], H. Kurosawa*[4], D. T. Denhardt[3], M. Emi*[2], A. Nifuji[1], M. Noda[1]. [1]Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Nippon Medical School, Kawasaki, Japan, [3]Rutgers University, Piscataway, NJ, USA, [4]Juntendo University, Tokyo, Japan.

Osteopontin-null (OPN-/-) mice showed resistance to unloading-induced bone loss (J Exp Med 2001, J Bone Miner Res 2002). However, molecular mechanisms underlying the phenomenon have not been known. To obtain further insight into the role of OPN in mediating mechanical stress effect on bone, we carried out microarray analyses on the genes expressed in bone marrow in the hindlimbs of mice subjected to tail-suspension for 1 week. After tail-suspension, mRNA was obtained from bone marrow cells of the femora. Complementary DNA pools obtained based on the RNA obtained from bone marrow cells of the femora were subjected to microarray analysis. Genes regulated by tail-suspension in both wild type and OPN-/- mice were identified and the specific gene expression pattern due to the presence or absence of OPN in response to tail-suspension was investigated. Unloading induced reduction in bone mass in wild type, while such reduction of bone mass in response to unloading was not observed in OPN-/- mice, used for the microarray analyses. Transcription of ten genes was enhanced by tail-suspension in wild type but not in OPN-/- mice. On the other hand, transcription of 4 genes was enhanced by tail-suspension in OPN-/- but not in wild type mice. Among these genes, expression levels of NF-kB p105 subunit gene in bone marrow cells of the femora were enhanced by tail-suspension in wild type mice. In contrast, they were not altered in OPN-/- mice. Furthermore, expression levels of Bax gene were enhanced by tail-suspension in bone marrow cells of the femora in OPN-/- mice, however such enhancement was not observed in wild type mice after tail-suspension. These observations were confirmed by RT-PCR analyses in both wild type and OPN-/- mice. Expression levels of bone sialoprotein (BSP), which is also one of the bone matrix proteins containing an RGD-sequence, were enhanced by tail-suspension in both wild type and OPN-/- mice. However, the enhancement rate was significantly more in OPN-/- mice compared to that in wild type mice. While p53 mRNA expression was up regulated in bone marrow cells by tail-suspension in wild type mice as reported previously, this up-regulation of p53 gene expression by tail-suspension was no longer observed in OPN-/- mice. In conclusion, OPN plays a crucial role in mediating signals of mechanical stress in bone marrow cells through the regulation of NF-kB and apoptosis related genes.

Osteoprotegerin Mitigates Spaceflight-Induced Changes in Mouse Bone Mass, Density and Mineral Composition. T. A. Bateman[1], S. Morony[2], V. L. Ferguson[1], S. J. Simske*[1], D. L. Lacey[2], K. S. Warmington*[2], Z. Geng[2], H. L. Tan[2], V. Shalhoub[2], C. R. Dunstan[2], P. J. Kostenuik[2]. [1]BioServe Space Technologies, University of Colorado, Boulder, CO, USA, [2]Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA.

The effects of microgravity on mouse bone have not been previously studied. This experiment characterized the effects of spaceflight (SF) on the skeleton of mice treated with or without OPG, a protein that blocks osteoclast formation and activity. 10-week-old female C57/B6J mice (n=12/group) received a single injection (SC, 24 h pre-launch) of either OPG (20mg/kg) or vehicle (VEH). Mass and age-matched ground control (GC) mice received similar treatments. An age-matched group was sacrificed at launch and served as baseline (BL) controls. 24 SF mice spent 12-days in orbit on Space Shuttle flight STS-108. Upon landing, SF/VEH femur dry mass was lower compared to GC/VEH mice ($p<0.001$: 7%). OPG significantly increased femoral dry mass in both SF and GC conditions ($p<0.001$: 12% 9%, respectively). Compositional analysis of these femurs indicated that both SF and OPG had significant effects on the mineral mass of bone (Min-M). Whole bone Min-M and percent mineral composition (%Min) were lower in SF/VEH mice compared to GC/VEH ($p<0.01$: 10% 3%, respectively). SF/OPG had a greater Min-M and %Min than SF/VEH ($p<0.001$: 15% 3%, respectively). Organic bone mass (Org-M) was less influenced by SF and OPG. SF decreased Org-M by a non-significant 3% (vs. GC/VEH) and OPG increased Org-M by 6% (vs. SF/VEH: $p<0.05$). SF/VEH had lower epiphysis %Min compared to BL ($p<0.01$: 3%), suggesting a decline in material properties from pre-flight conditions. From a structural perspective, femur mid-diaphysis cross-sectional area was reduced for SF/VEH compared to GC/VEH ($p=0.05$), though changes in principle moments of inertia were not significant. pQCT analysis of the lumbar vertebra (L5) revealed a relative deficit in both total and cortical BMD in SF/VEH mice compared to GC/VEH ($p<0.01$). OPG blocked these SF-induced changes ($p<0.01$). Serum and mRNA (humeral diaphysis) analyses suggest relative changes in bone formation and resorption that may have contributed to the SF-induced osteopenia. A significant decline in mRNA expression of osteocalcin combined with a trend towards lower serum osteocalcin levels indicates a reduction in bone formation. Increased bone resorption in SF mice was suggested by a trend towards increased mRNA expression of the pro-resorptive cytokine RANK ligand with no changes in OPG mRNA expression. These data demonstrate that spaceflight causes a relative osteopenia in mice that alters bone material properties to a greater degree than structural properties. A single OPG treatment prevented these changes.

Rest-Inserted Loading: A Mild Yet Potently Osteogenic Stimulus for the Aged Skeleton. S. Srinivasan, S. C. Agans*, N. Y. Moy*, S. L. Poliachik*, T. S. Gross. Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA.

Mechanical loading has the potential to be perceived as an intensely anabolic stimulus by bone cells and tissue. However, the osteogenic response to mechanical stimuli is markedly suppressed in the aged skeleton and, in particular, mild and low-magnitude forms of physical activity have proved ineffective in building bone mass in the elderly. We recently found that inserting rest (or unloaded) intervals between mechanical loading cycles transformed non-stimulatory low-magnitude regimens into potent osteogenic stimuli in young animals. Here, we extend our observations and test the hypothesis that low-magnitude rest-inserted mechanical loading is osteogenic in the aged skeleton. The right tibiae of aged C57BL/6 mice (21 Months, n=18) were subject to a 50 cycle/day, 2-week loading protocol utilizing the non-invasive murine tibia model. Animals were randomly assigned to one of three groups: a) low-magnitude repetitive loading (inducing peak normal strain of 900 με at the tibia mid-shaft), b) high-magnitude repetitive loading (inducing 2200 με at the mid-shaft), and c) rest-inserted loading wherein a 10-s rest interval was inserted between each of 50 low-magnitude (900 με peak strain) load cycles. Activation of periosteal bone formation at the tibia mid-shaft was examined via calcein incorporation. The contralateral control tibiae in the aged animals exhibited minimal mean (± S.E.) periosteal bone formation (0.03 ± 0.01 $\mu m^3/\mu m^2/d$) and was not different between groups ($p=0.49$). While exposure to 50 cycles/d of high-magnitude loading (almost 2.5 fold the strain magnitude induced via low-magnitude loading) was sufficient to enhance bone formation compared to controls (0.12 ± 0.03 $\mu m^3/\mu m^2/d$, $p = 0.03$), low-magnitude repetitive loading (similar in magnitude to that encountered during mild functional activity) did not significantly enhance bone formation (0.075 ± 0.04 $\mu m^3/\mu m^2/d$, $p=0.12$). In contrast, inserting10-s of rest between each of 50 low-magnitude load cycles significantly enhanced bone formation compared to controls (0.14 ± 0.04 $\mu m^3/\mu m^2/d$, $p=0.05$), an 87% increase compared to low-magnitude repetitive loading. Our results suggest that rest-inserted loading provides a subtle yet potently osteogenic stimulus that enables sustained activation of the aged periosteum despite the limited availability of osteoprogenitor cells and the increased propensity for fully differentiated osteoblasts in aged bone tissue to undergo apoptosis. Given the ease of implementation of this novel stimulus (inserting an unloaded rest interval between load cycles), low-magnitude rest-inserted loading holds promise for building bone mass in the frail elderly.

A Genetic Compensatory Mechanism for Preventing Disuse Related Bone Loss. S. Judex[1], R. Garman*[1], M. Squire*[1], L. Donahue[2], C. Rubin[1]. [1]Biomedical Engineering, SUNY Stony Brook, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Despite the clear impact of subtle genetic variations on achieving and retaining bone quantity and quality, it is less clear to what extent the genome influences the response of the skeleton to catabolic pressure. We have recently demonstrated a genetic basis for the sensitivity of trabecular bone to the removal of its mechanical environment; hindlimb suspension significantly reduced bone formation rates (BFR) in the proximal tibia of genetically distinct BALB/cByJ (BALB) mice but not in C57BL/6J (B6) or C3H/HeJ (C3H) mice. Here, we used micro-computed tomography (μCT) to assess the structural impact of this catabolic stimulus in three strains of mice. Adult (16wk) B6, BALB, and C3H mice were subjected to either hindlimb suspension or free cage activity (n~10 per group) in protocols up to 3wk. Upon sacrifice, distal femurs were scanned at a resolution of 11μm and indices of bone quantity and architecture were computed for both metaphyseal trabecular bone and its surrounding cortical shell. Mechanical disuse severely reduced fractional trabecular bone volume by 57% ($p<0.001$) in BALB mice while no significant amount of trabecular bone tissue was lost in either C3H or B6 mice. This large decrease in bone quantity was accompanied by compromised bone architecture as indicated by a 35% decrease in connectivity density ($p<0.03$). In contrast to the genetically dependent sensitivity of trabecular bone, the endocortical envelope significantly increased in size in all three strains of mice (between 9% and 18%, $p<0.05$). The larger endocortical envelope led to a significant smaller cortical bone volume in B6 (-8%, $p<0.008$) and BALB (-18%, $p<0.001$) mice as their periosteal envelopes were not affected by disuse. In C3H mice, however, disuse concomitantly increased the volume of the periosteal envelope by 10% ($p<0.02$), leaving cortical bone volume unchanged in this strain. These data indicate that the efficacy of a strongly catabolic stimulus heavily relies on genetic makeup, both for trabecular and cortical bone. C3H mice displayed a unique genetic mechanism that was able to compensate for the loss of bone at the endocortical surface with increased bone formation at the periosteal surface, demonstrating bone's ability to orchestrate a complex response to the loss of functional weigthbearing. Extrapolated to the genetically heterogeneous human population, our data may explain the large individual variability in bone loss observed during bedrest, spaceflight, or aging. Current work is exploiting the differences in mechanosensitivity between these three strains of mice to identify the genetic basis of bone's adaptive response to the loss of functional weightbearing.

Effect of Gender and Estrogen on the Skeletal Sensitivity to Mechanical Loading. T. L. N. Jarvinen*[1], P. Kannus*[2], I. Pajamaki*[1], T. Vuohelainen*[1], J. Tuukkanen[3], M. Jarvinen*[1], H. Sievanen*[2]. [1]Dept. of Surgery, University of Tampere, Tampere, Finland, [2]UKK Institute, Tampere, Finland, [3]University of Oulu, Oulu, Finland.

The aim of this study was initially to evaluate whether there is any difference in the skeletal responsiveness to mechanical loading between female and male rats. In experiment #1, 5-week-old littermates of 25 male and 25 female rats were randomised into either free-cage activity (CTR) or treadmill training (EX) for a period of 14 weeks. Using peripheral quantitative computed tomography (pQCT) and mechanical testing of the femoral neck, we observed that the skeletal responsiveness to external loading was clearly lower in females than in males. Also, relative to the mechanical demands placed on the skeleton, the bones of the young female rats were considerably denser (>50%) than those of the males. To ensure that the observed changes (growth/puberty-related condensation of female bones and the lower responsiveness to loading) were not restricted only to the rapid period of growth, we repeated the first experiment with 33-week-old rats and observed virtually identical responses in these mature rats. To follow these findings further, we hypothesized that if estrogen was attributable for the observed deposition of extra stock of mineral into female bones and the subsequent lower responsiveness to mechanical loading, then withdrawal of estrogen should not only result in a reduced bone density, but also an increased response to loading. Accordingly, in experiment #3, 60 littermates of 3-week-old female rats were first SHAM-operated or ovariectomized (OVX) and then further randomized to EX- or CTR-groups, respectively. At the end of a 16-week intervention, our pQCT and mechanical testing analysis showed not only the anticipated effect of reduced bone density in the OVX rats (~ -20% vs. SHAM), but also the hypothesized better response to mechanical loading in these estrogen-depleted rats. In conclusion, our series of three experiments suggest that as such estrogen has very little primary effect on the sensitivity of female bone to mechanical loading, but rather deposits extra stock of mineral into female bones in puberty. This estrogen-driven extra condensation of the female skeleton persists into adulthood, simultaneously damping the responsiveness of the female skeleton to loading.

The skeletal responsiveness (EX vs. CTR, in %) of rats to mechanical loading in experiments #1-3.

Novel Role of Vitamin D in Electrolyte, Volume and Blood Pressure Homeostasis: 1,25-Dihydroxyvitamin D3 Is a Negative Endocrine Regulator of the Renin-Angiotensin System. Y. Li[1], J. Kong*[1], M. Wei*[1], Z. Chen*[2], S. Liu*[3], L. Cao*[1]. [1]Medicine, University of Chicago, Chicago, IL, USA, [2]Anesthesiology, Washington University, St. Louis, MO, USA, [3]Biomedical Engineering, Northwestern University, Evanston, IL, USA.

The renin-angiotensin system plays a central role in the regulation of blood pressure, electrolyte and volume homeostasis. Inappropriate activation of the renin-angiotensin system has been implicated as one major potential risk factor for hypertension, heart attack and stroke. Clinical studies have revealed an inverse relationship between plasma 1,25-dihydroxyvitamin D3 [1,25(OH)2D3] concentrations and the blood pressure and/or the plasma renin activity in both normotensive men and patients with essential hypertension, and vitamin D treatment has been shown to reduce blood pressure as well as plasma renin activity and angiotensin II (Ang II) levels in hypertension patients. However, the mechanism is unknown. To explain these observations we hypothesize that vitamin D is a negative regulator of renin expression in vivo, and have tested this hypothesis in animal models and cell cultures. We found that renin expression and plasma Ang II production were increased several fold in vitamin D receptor (VDR) null mice, leading to hypertension, cardiac hypertrophy and increased water intake. The elevation of blood pressure in VDR null mice was abolished by captopril, an angiotensin-converting enzyme inhibitor, confirming that the rise in blood pressure is indeed due to elevation of Ang II. However, the high basal renin level does not abrogate the salt- and volume-sensing mechanisms that control renin synthesis. In wildtype mice, inhibition of 1,25(OH)2D3 biosynthesis also led to an increase in renin expression, whereas injection of 1,25(OH)2D3 reduced renin expression. We further showed that the vitamin D regulation of renin expression is independent of calcium metabolism, since the renin up-regulation was still detected in pre-weaned normocalcemic VDR null mice as well as in adult VDR null mice whose serum calcium had been normalized by dietary treatment, but not in hypocalcemic Gcm2 null mice. Furthermore, we demonstrated that 1,25(OH)2D3 markedly suppressed renin mRNA expression as well as renin gene promoter activity in cell cultures by a VDR-mediated mechanism. These data provide the first direct evidence that 1,25(OH)2D3 is a novel and potent negative endocrine regulator of the renin-angiotensin system, and plays a critical role in maintaining the homeostasis of electrolytes, volume and blood pressure. They also have implications for the potential use of vitamin D analogues as preventive or therapeutic anti-hypertension agents.

WINAC(WSTF Including Nucleosome Assembly Complex) Is a Novel Chromatin Remodeling Complex Modulating Vitamin D Receptor(VDR)Transactivation. H. Kitagawa[1], J. Yanagisawa*[2], R. Fujiki*[1], D. Matsui*[1], T. Matsumoto[3], S. Kato[2]. [1]Nuclear Information, IMCB, Tokyo, Japan, [2]Nuclear Information, IMCB,CREST, Tokyo, Japan, [3]First Department of Internal Medicine, University of Tokushima school of Medicine, Tokushima, Japan.

Many complexes interact with nuclear receptors for their ligand-dependent transactivation through modulating chromatin structure in the promoters of a set of target genes. Distinct classes of co-regulator complexes like DRIP/TRAP complex, p160 family complex, and TRRAP/GCN5 complex are shown to interact with nuclear receptors in a ligand-dependent way. But still other unknown complexes are assumed to support VDR transactivation in different ways. Using GST fused VDR ligand binding domain (LBD) as a bait, we purified nuclear complexes associated with liganded VDR-LBD from HeLa nuclear extracts, and identified WSTF(Williams syndrome transcription factor) as one of the interactants. WSTF has been reported to be one of the candidate genes causing Williams syndrome, which often accompanies infantile hypercalcemia. To examine WSTF function in VDR transactivation, we purified a VDR interacting WSTF complex using Flag-tagged WSTF stably expressing cells. Using MALDI TOF-MS and Western blotting, we found that the complex designated 'WINAC' is a novel SWI/SNF related ATP dependent chromatin remodeling complex composed of at least 12 components. In vitro chromatin reconstitution and disruption assay showed that this complex modifies chromatin configuration through recognizing VDR in a ATP-dependent way. A ChIP analysis showed that this complex is recruited on some VDR target gene promoters in a ligand- independent way and regulates vitamin D metabolism through VDR-mediated target genes expression. Some components of the WINAC are shared with those of other complexes involved in DNA replication, suggesting that this complex has multiple functions by bridging multiple complexes. Finaly we confirmed that VDR transactivation is abnormal due to low expression of WSTF in Willliams syndrome patients using primary culture cells of their skin fibroblasts. These results provide a new insight into the transcriptional mechanism of VDR ,the calcium metabolism through VDR transactivation, and the target gene therapies of Williams syndrome.

Activation of PKC by Gαq Results in Osteopenia by Blocking Osteoblast Differentiation. N. Ogata[1], S. I. Roth*[2], H. Kawaguchi[3], G. V. Segre[1]. [1]Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA, [2]Department of Pathology, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA, [3]Orthopaedic Surgery, University of Tokyo, Tokyo, Japan.

To examine the role of Gαq-mediated signaling in bone, we generated two independent lines of transgenic (TG) mice that overexpress constitutively-active Gαq (mutation of Q209L) in osteoblasts with a hemagglutinin tag, driven by the 2.3-kb osteoblast-specific, mouse pro-α 1 (I) collagen promoter. Specific expression of the TG was determined by RT-PCR of mRNA extracted from bones of TG mice, but not from other tissues. TG mice were indistinguishable from wild-type (WT) mice at birth. However by 2 weeks of age, they exhibited progressive shortening of their limbs and lower weights (60% of WT), and reduced bone mineral density at 8 weeks (70% of WT). Both long bones and calvariae of TG mice had thinner cortices, consisting predominantly of woven bone, and increased osteocytes with irregular spacing and rounder lacunae. Trabecular bone was markedly reduced and long-bone fractures were common, but osteoid seams were not widened. Bone volume/total volume and bone formation rate/bone surface were reduced to 40% and 10%, respectively, at both 4 and 8 weeks of age compared to WT mice. Neither osteoclast number nor activity (eroded surface/bone surface) were abnormal. In situ hybridization demonstrated reduced expression of osteoblast-related mRNAs and slightly increased expression of Gαq in the bones of TG mice. In vitro, both primary osteoblasts derived from TG neonatal calvariae and bone marrow stromal cells flushed from TG long bones showed significantly reduced collagen synthesis and ALP activity and virtually no mineralization, compared to WT osteoblasts. Osteocalcin gene expression in TG osteoblasts was nearly absent, while type I collagen and osteopontin expression were slightly decreased, indicating that differentiation of TG osteoblasts was blocked. Addition of the PKC inhibitor, GF109203X, to both WT and TG osteoblasts in culture increased ALP activity to nearly the same absolute level. However, [^{3}H]-TdR incorporation by WT and TG osteoblasts was indistinguishable. Overexpression of Gαq in osteoblasts results in severe osteopenia with immature bone and fractures. We propose that Gαq-mediated activation of PKC in WT and TG osteoblasts plays a crucial role in bone formation by inhibiting differentiation of osteoblasts.

Conditional Knockout of *PTHrP* in Osteoblasts Leads to Premature Osteoporosis. D. Miao, B. He*, X. K. Tong*, D. Goltzman, A. C. Karaplis. Medicine, McGill University, Montreal, PQ, Canada.

Intermittent administration of parathyroid hormone-related peptide (PTHrP) in vivo has an anabolic effect on bone. The precise molecular and cellular bases for the anabolic action of PTHrP, however, remain unclear and efforts to elucidate these mechanisms in PTHrP knockout mice have been compromised by the perinatal lethality of these animals. To overcome this obstacle, we have used cell-specific, Cre-mediated recombination in mice to selectively disrupt PTHrP expression only in osteogenic cells, while maintaining normal expression levels of the protein in all other tissues. Toward this objective, PTHrP$^{+/flox}$ (exon 4 of PTHrP flanked by loxP sites) mice carrying the *Cre* recombinase transgene under the control of the 2.3-kb fragment of the murine pro-α1(I) collagen gene promoter (Col I), were crossed with mice homozygous for the floxed PTHrP allele to generate mice with osteoblasts lacking the PTHrP gene (PTHrP$^{flox/flox}$;cre$^{col\ I}$). Serum calcium, PTH and 1,25-dihydroxy vitamin D_3 levels were normal in 6-week-old PTHrP$^{flox/flox}$;cre$^{col\ I}$ mice, compared to PTHrP$^{flox/flox}$ sex-matched littermates (controls). On the other hand, bone density at the femur and tibia, as measured by PIXImus densitometer, was decreased by 6.4% and 9.0%, respectively, in PTHrP$^{flox/flox}$;cre$^{col\ I}$ mice compared to control animals. Trabecular bone volume was also affected, and was decreased by 33% and 36% in femurs and tibiae, respectively, from newborn, and 34% and 47% from 6-week-old PTHrP$^{flox/flox}$;cre$^{col\ I}$ mice. Histomorphometric analysis revealed that osteoblast number and surface, osteoid thickness, and trabecular thickness were all decreased significantly in 6-week-old PTHrP$^{flox/flox}$;cre$^{col\ I}$ mice. This was further substantiated by immunohistochemistry, as areas positive (immunoreactivity in bone matrix and/or osteoblasts) for type I collagen, osteocalcin, and osteopontin staining in the metaphysis of femurs of 6-week-old PTHrP$^{flox/flox}$;cre $^{col\ I}$ mice were reduced compared to their wild type counterparts. Bone formation rate was also reduced, as assessed by histomorphometry following double-calcein labeling. Furthermore, osteoclast number and surface were also significantly reduced. These results unequivocally demonstrate that osteoblast-derived PTHrP exerts anabolic effects in bone by promoting osteoblast function and identify it as a key factor to be targeted in the therapeutic intervention for osteoporosis.

Expression of a Constitutively Active PTH/PTHrP Receptor in Bone Marrow Stromal Cells Leads to Expansion of Hematopoietic Stem Cells in vivo and in vitro. L. M. Calvi[1], G. B. Adams*[2], D. P. Olson*[2], M. C. Knight*[1], F. R. Bringhurst[1], E. Schipani[1], P. Divieti[1], H. M. Kronenberg[1], D. T. Scadden*[2]. [1]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [2]Partners AIDS Research Center and MGH Cancer Center, MGH, Boston, MA, USA.

In severe cases of primary hyperparathyroidism, fibrosis of the bone marrow cavity has been reported, and is associated with anemia in some cases. We recently described transgenic mice (col1-caPPR) in which a constitutively active PTH/PTHrP receptor (caPPR) is expressed under the control of the alpha1(I) collagen promoter. These transgenic mice have increased trabecular bone volume and an expanded stromal-like cell population with a fibrotic appearance. In situ hybridization identifies these stromal-like cells as preosteoblasts at different stages of differentiation. Our goal was to use this transgenic model to study the role of the activated PPR in modulating the ability of bone marrow stromal cells to support hematopoiesis. While the hematocrit of col1-caPPR mice was decreased, as in cases of hyperparathyroidism with marrow fibrosis, the number of hematopoietic stem cells as assessed by both flow cytometric analysis and long-term culture initiating cell (LTC-IC) analysis was surprisingly increased in the bone marrow from transgenic vs normal littermates. In primary bone marrow stromal cell cultures from adult transgenic mice and normal littermates, expression of the transgene was confirmed by Northern blot analysis and in situ hybridization. When normal hematopoietic cells were cultured in the presence of transgenic stromal cells in LTC-IC assays, the frequency of hematopoietic stem cells was significantly increased. In addition, treatment of normal stromal cells with rPTH(1-34) was sufficient to reproduce the enhanced support of the hematopoietic stem cell population. Interestingly, bone marrow stromal cell cultures from transgenic mice had an increased proportion of alkaline phosphatase positive cells, reproducing the increased osteoblastic population seen in vivo. In conclusion, PTH treatment of bone marrow stromal cells increased their ability to support hematopoietic stem cells. Since stromal cells isolated from mice expressing the caPPR only in the osteoblastic lineage also increased support of hematopoietic stem cells, this action of PTH was probably mediated by activation of the PPR in the stromal cell compartment. This surprising effect of activation of the PPR on bone marrow stromal cells points out a novel role of PTH in mediating stroma-hematopoietic cell interactions, and may have important therapeutic implications for the expansion of hematopoietic stem cells in bone marrow transplantation and recovery.

Dramatic High Turnover Osteoporosis and Focal Sclerosis in a TSH (Thyrotropin) Receptor Null Mouse Reveals a Critical Role for TSH as a Negative Regulator of Bone Remodeling. M. Zaidi[1], R. Marians*[1], X. B. Wu[1], S. Dolgilevich*[1], Y. Li*[2], H. Blair[2], T. F. Davies*[1], E. Abe[1]. [1]The Mount Sinai Bone Program and Bronx VA GRECC, New York, NY, USA, [2]University of Pittsburgh, Pittsburg, PA, USA.

We report, for the first time, that TSH receptors (TSHRs) negatively regulate bone remodeling. TSHR null mice generated by disrupting exon 1 of the TSHR gene were profoundly osteoporotic with a marked reduction in bone mineral density at the femur, tibia and lumbar spine. Histological analysis revealed focal sclerosis, woven bone, and disorganized collagen: hallmarks of rapid bone turnover that are reminiscent of pagetic bone. Tetracycline double labeling showed an increased bone formation rate. Osteoblast progenitors in bone marrow cell cultures counted as fibroblastoid and osteoblastoid colony forming units (CFU-F and CFU-OB) were also markedly elevated. Likewise, hematopoetic stem cell cultures showed enhanced TRAP-positive osteoclast formation. Together, the results argue strongly for the TSHR as a negative regulator of osteoblast and osteoclast formation and function. Notably, all of these effects were equally profound in TSHR heterozygotes as in homozygotes indicating a surprising but profound effect on bone of halving the TSHR content. That the bone phenotypes of thyroxine-replete and hypothyroid homozygotic mice were virtually undistinguishable attests further to a direct action of TSHRs on bone remodeling that was not exerted through thyroid hormone action. We next explored the localization of TSHRs to bone cells by following the expression of GFP integrated at the TSHR deletion site. Both CFU-Fs and osteoclast precursors in bone marrow cell cultures derived from TSHR deficient mice showed intense GFP fluorescence. Dual photon confocal scanning microscopy of the inner table of the skull likewise confirmed GFP localization to osteoblasts *in situ*. That TSHRs were expressed in wild type bone tissue and marrow cell cultures was further confirmed by real time RT-PCR and (or) immunoblotting. The functional significance of the TSHR in negatively regulating osteoclast formation was further confirmed by demonstrating a marked inhibition of TRAP-positive osteoclast formation from TSHR-overexpressing RAW264 cells. Likewise, recombinant TSH inhibited osteoclast formation in wild type mouse marrow cell cultures as well as osteoblast differentiation in progenitor cell lines. Overall, therefore, the localization of the TSHR to bone cells, its direct regulation of osteoclast and osteoblast formation and function, and the significant impact on bone of its absence, when taken together, reveal a *hitherto* yet uncharacterized role for the TSHR and its ligand, TSH, in the negative regulation of bone remodeling.

1055

Mutations In Type 2a Sodium-Phosphate Co-Transporter (NPT2a) Gene Cause Renal Phosphate Leak Associated With Osteoporosis Or Urolithiasis In Human. D. P. Prié*[1], V. Huart*[1], G. Planelles*[2], G. Friedlander*[1], B. Grandchamp*[3], C. M. Silve[1]. [1]Hôpital Bichat, Inserm U426, Explorations Fonctionnelles, Paris, France, [2]Faculté Necker, Inserm U467, Paris, France, [3]Hôpital Bichat, Biochimie B, Paris, France.

Epidemiologic studies have identified familial aggregation for both bone demineralization and renal calcium stone formation, findings compatible with the influence of genetic factors in these disorders. The search for gene variants predisposing to these common diseases, however, has generally yielded negative results. Both of these disorders are likely to be genetically heterogeneous, in which case a variety of different biological abnormalities may contribute in producing the clinical phenotype in individual patients. Low serum phosphate concentrations due to a decrease in renal phosphate reabsorption have been reported in some patients with urolithiasis or bone demineralization suggesting that genetic factors leading to a decrease in renal phosphate reabsorption can contribute to these diseases. In the kidney, phosphate is reabsorbed in the proximal tubule by the type 2a sodium-phosphate co-transporter (NPT2a). We tested the hypothesis that mutations in the NPT2a gene may account for renal phosphate leak associated with urolithiasis or bone demineralization. We sequenced the coding region of the NPT2a gene from 20 hypophosphatemic patients. Two non-synonymous mutations were found at the heterozygous state, one in a male patient with urolithiasis and one in a female patient with severe bone demineraliza-

tion (bone mineral density: at the lumbar spine 0.639 g/cm2, Z-score-4.3; at the femoral neck 0.679 g/cm2, Z-score –2,7). Both patients exhibited an increase in urinary calcium excretion and calcitriol serum concentration. These mutations were absent in 200 alleles from control subjects. The function of the mutated proteins was analyzed by the injection of increasing concentrations of wild type or mutated NPT2a RNA in Xenopus laevis oocytes. These experiments demonstrated a decrease in Na-dependent phosphate uptake and phosphate-induced currents in oocytes expressing the mutated NPT2a proteins. These results provide the first evidence that mutations in the NPT2a gene are responsible for hypophosphatemia and urinary phosphate leak in humans. The identification of functional variants of the NPT2a gene in patients with hypophosphatemia associated with urolithiasis or bone demineralization also provides genetic evidence that a defect in renal phosphate reabsorption may indeed be one of the multigenic components that contribute to the pathogenesis of these two common diseases.

Mutations in the Gene Encoding Osteoprotegerin Cause Idiopathic Hyperphosphatasia. B. Chong*[1], M. Hegde*[1], M. Fawkner*[1], J. Seidel*[2], B. Tuysuz*[3], B. Yuksel*[4], M. Coker*[5], H. Cassinelli*[6], C. Tau*[6], D. Love*[7], T. Cundy[7]. [1]Molecular Genetics Laboratory, Auckland Hospital, Auckland, New Zealand, [2]International Hyperphosphatasia Collaborative Group (IHCG), Jena, Germany, [3]IHCG, Istanbul, Turkey, [4]IHCG, Adana, Turkey, [5]IHCG, Izmir, Turkey, [6]IHCG, Buenos Aires, Argentina, [7]University of Auckland, Auckland, New Zealand.

Idiopathic hyperphosphatasia (MIM 239000) is a rare bone disease characterised by progressive deformity, a propensity to fracture and very high bone turnover. We studied a family with 3 affected siblings and established linkage of the disorder to a locus on 8q24, using a genome-wide scan. The gene *TNFRSF11B* encoding osteoprotegerin (OPG), which lay within this locus, was an obvious candidate, given the critical role of OPG in regulating osteoclastogenesis. We examined genomic DNA of 10 subjects with hyperphosphatasia (from 8 families) for mutations in *TNFRSF11B* and its promoter. The subjects ranged in age from 2 to 29 years. All had long bone deformity and short stature (≤3rd centile). Plasma alkaline phosphatase activity was 4 to 13 times the upper limit of age-appropriate normal ranges. Mobility was significantly impaired in 7/10 subjects, and 6/10 had enlargement of the skull (≥98th centile). Primers were designed to amplify the promoter region and 5 exons of the OPG in order to screen for deletion/insertion and splicing mutations. Mutations were detected in two of the four families reporting parental consanguinity. The first family had three affected subjects with a homozygous in-frame 3bp deletion in exon 3, resulting in the loss of an Asp residue at position 182. This mutation lies within the region crucial for OPG function, and is predicted to cause disruption of the loop structure necessary for correct folding of the molecule. The second family had a much larger 20bp homozygous deletion, also in exon 3. This 20bp deletion, which lies outside the region crucial for OPG function, is expected to result in aberrant transcript splicing and premature termination of translation. No mutations in *TNFRSF11B* or its promoter region were identified in the six other families. This study demonstrates that mutations in the gene for OPG can cause autosomal recessive idiopathic hyperphosphatasia; however, this syndrome is apparently genetically heterogeneous.

A Novel Mutation in OPG That Causes Familial Idiopathic Hyperphosphatasia Impairs OPG Capacity to Inhibit Bone Resorption. C. A. Middleton-Hardie, T. Cundy, T. Banovic*, I. R. Reid, J. Cornish, D. Naot. Medicine, University of Auckland, Auckland, New Zealand.

Genetic analysis of a large family with Familial Idiopathic Hyperphosphatasia, a rare autosomal recessive bone disease, identified linkage to a region of chromosome 8q that contains the gene for OPG. (See Abstract by B. Chong et al. for details.) Sequencing of this gene in members of the family identified an in-frame 3 base pair deletion resulting in the deletion of an aspartate residue at position 182, within the critical TNF-receptor like region. The aim of our study was to determine whether this mutation causes loss of function of OPG, and could therefore be the cause of the highly accelerated bone turnover seen in the patients. Wild-type and mutant OPG cDNA were cloned into pcDNA3.1(-)/myc-HisA vector and expressed in HEK293 cells. The conditioned media containing the recombinant proteins were collected, concentrated and tested for their ability to inhibit bone resorption in a neonatal murine calvarial organ culture. We demonstrated that conditioned medium containing wild type OPG inhibited bone resorption, whereas the conditioned medium containing the mutant protein had no effect (%45Ca release, means±SEM: control, 23±1.2; wild type OPG 14±0.83; mutant OPG 24±1.9, p<0.0001, Student's t test). We also investigated altered post-translational modification of the mutant protein. Western blot analysis demonstrated that the mutant protein had a lower electrophoretic mobility than the wild type. Following deglycosylation with N-glycosidase F, both proteins appeared to be of similar size, suggesting that the mutant protein is hyper-glycosylated. The importance of glycosylation to OPG's biological activity is being elucidated. These data indicate that the absence of functional OPG protein in the patients results in the severe phenotype. It is possible that the bone deformities of these patients could be alleviated by administration of recombinant wild-type OPG, similar to the effects shown in studies of OPG administration to OPG knockout mice.

Dissociation of the Skeletal from the Reproductive Effects of Sex Steroids with an Activator of Nongenotropic Estrogen-Like Signaling (ANGELS), in Both Females and Males: A Lead to a Bone Anabolic, Sex Neutral Hormone Replacement Therapy. S. C. Manolagas, L. Han, A. M. Vertino, J. R. Chen, A. A. Ali, T. Bellido, R. S. Weinstein, C. A. O'Brien, R. L. Jilka, S. Kousteni. Division of Endocrinology and Metabolism, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, U/sity of Arkansas for Medical Sciences, Little Rock, AR, USA.

Certain synthetic non-phenolic ligands of the estrogen (ER) or androgen (AR) receptor can activate cytoplasmic kinases, without affecting classical transcription. To elucidate the mechanism of action and the spectrum of the biologic activities of such class of compounds on bone and reproductive tissues, we examined a) downstream consequence of ERK activation, b) in vitro effects on the life span of murine osteoblasts and osteoclasts, and c) in vivo effects on bone and reproductive tissues of female and male mice, using a prototypic ANGEL, designated ABX102. We report that like classical estrogens, activation of a Src/Shc/ERK pathway or downregulation of JNK by ABX102 led to potent downstream modulation of the activity of Elk-1/SRE and AP-1 respectively. Also like estrogens, ABX102 dose dependently (10^{-12} - 10^{-7} M) attenuated osteoblast and stimulated osteoclast apoptosis, with identical efficacy in cells from female and male mice. For the in vivo studies, we administered ABX102 to ovariectomized (OVX) or orchidectomized (ORX) 8 month-old Swiss Webster mice, and compared its effects, at a dose of 7.6 mg per 60 day release pellet, to a replacement dose of either 17β-estradiol (E_2) or dihydrotestosterone (DHT): 0.025 mg or 10 mg per 60 day release pellets, respectively. The dose for ABX102 was chosen based on its lower binding affinity (~300-fold) for the ER, compared to E_2. At 6 weeks, the gonadectomy-induced loss of BMD was restored by E_2 replacement in females and DHT replacement in males, as expected. OVX females receiving ABX102 exhibited greater BMD than those receiving E_2, in both the femur and the spine; and greater compression strength of the lumbar vertebrae. ABX102 also prevented the bone loss induced by orchidectomy, and was superior to DHT at the spine. In sharp contrast to E_2, ABX102 did not suppress the OVX-induced increase in serum osteocalcin. Unlike E_2 or DHT, ABX102 had no effect on the uterus or the seminal vesicles of the gonadectomized mice. Hence, ligands that can activate only the nongenotropic function of the ER (or AR) represent an advantageous class of pharmacotherapeutic agents (true anabolic as opposed to antiresorptive) and sex neutral for the management of osteopenic states; and perhaps a rational therapy for sex hormone deficiencies in postreproductive life, at large.

Ten-Year Efficacy and Safety of Alendronate in the Treatment of Osteoporosis in Postmenopausal Women. R. Emkey[1], I. Reid[2], A. Mulloy[3], R. Correa-Rotter[4], M. Favus[5], H. Bone[6], J. Gupta*[7], A. LaMotta*[7], A. Santora[7]. [1]Radiant Research, Wyomissing, PA, USA, [2]Auckland Hospital, Auckland, New Zealand, [3]Medical College of Georgia, Augusta, GA, USA, [4]Instituto Nacional de la Nutricion Salvador Zurian, Tlalpan, Mexico, [5]University of Chicago, Chicago, IL, USA, [6]Michigan Bone and Mineral Clinic, Detroit, MI, USA, [7]Merck Research Labs, Rahway, NJ, USA.

Alendronate sodium* (ALN), a specific inhibitor of osteoclastic bone resorption, reduced the risk of vertebral fractures and progressively increased BMD over 3 yrs in a study of 994 postmenopausal osteoporotic women. We reported 7 yr results from 350 women who, after 5 years of continuous ALN treatment, participated in a double-blind 2 yr extension (Yrs 6-7), and now report the results for 247 women who entered an additional 3 yr extension (Yrs 8-10). During Yrs 6-10, patients in the ALN 5 and 10 mg groups remained on their prior ALN dose. Patients in the ALN 20/5/placebo (A-PBO) group (20 mg for 2 yrs, 5 mg for 3 yrs) received placebo in Yrs 6-10. A significant increase in spine BMD of 2.25 % for ALN 10 mg and 1.60 % for 5 mg groups was found during Yrs 8-10. At the hip and total body, prior increases in BMD were maintained during Yrs 8-10. Forearm BMD was stable with 10 mg but decreased slightly with 5 mg. Women in the A-PBO group who had not been treated with ALN since the end of Yr 5 showed no significant change in BMD at both spine and total body, but small decreases in hip and forearm BMD occurred during Yrs 8-10. Cumulative 10 yr spine BMD increases were 13.7 % with ALN 10 mg and 9.8 % with 5 mg. After the initial 18 mo, each additional yr of treatment with ALN 10 mg increased spine BMD by 0.73 % vs. 0.57 % with ALN 5 mg. The safety and tolerability profiles of ALN 5 and 10 mg were similar to placebo during both Yrs 8-10 and Yrs 6-10. The 3 yr incidences of non-vertebral fractures during Yrs 8-10 were 8.1, 11.5, and 12.0 % in the ALN 10 mg, 5 mg and A-PBO groups. The 3 yr incidences in the original cohort during Yrs 1-3 were 8.5 % (pooled ALN) and 10.7 % (placebo). Although patients were older in Yrs 8-10, the expected age-related increase in fracture risk was not observed. Neither stress fractures nor fracture malunion were reported. We conclude that ALN treatment is effective for 10 yrs and is generally well tolerated. Spinal BMD continues to increase over 10 yrs and other skeletal benefits are maintained. Non-vertebral fracture data indicate no change in risk over time, and suggest that fracture risk reduction is maintained during continued treatment. Discontinuation of ALN after 5 years leads to bone loss at non-spine sites, and continued treatment with ALN through 10 years yields sustained skeletal benefits.

Interleukin-6 Genetic Variation and the Effects of Estrogens and Dietary Calcium on Bone Mass: The Framingham Osteoporosis Study. S. L. Ferrari[1], D. Karasik[2], J. Liu*[3], S. Karamohamed*[3], A. G. Herbert*[3], A. L. Cupples*[4], D. P. Kiel[2]. [1]Div. of Bone Diseases, University Hospital, Geneva, Switzerland, [2]Div. of Aging, Harvard Medical School, Boston, MA, USA, [3]Framingham Heart Study Genetics Laboratory, Boston University School of Medicine, Boston, MA, USA, [4]Dept of Epidemiology and Biostatistics, Boston University School of Public Health, Boston, MA, USA.

Genetic factors make an important contribution to peak bone mass, but their influence on bone mass in the elderly remains poorly appreciated. IL-6 is a pleiotropic cytokine playing a central role in bone remodeling. We have previously reported two G>C variants at position –174 and –572 in the IL-6 promoter which influenced IL-6 expression and were associated with levels of bone resorption in postmenopausal women. In this study, we examined interactions between IL-6 polymorphisms and non-genetic factors, including estrogen status, physical activity, smoking, dietary calcium, vitamin D and alcohol intake, on femur BMD (neck, FN, trochanter, FT, and Ward's area) in unrelated women (n=817, mean age ±sd =60.3 ±9.4 yrs) and men (n=737, 59.6 ±9.3 yrs) from the Framingham's Offspring Cohort. IL-6 promoter haplotypes were directly determined by allele-specific PCR and genotypes confirmed by DNA mass spectrometry. Frequency of the GG, GC and CC genotypes was, respectively, 36%, 50% and 14% at –174, and 89%, 11% and <0.5% at –572 positions. Significant interactions (p = 0.009 to 0.09) affecting age-adjusted BMD were found in women between IL-6 –174 genotypes and estrogen status, calcium intake, and years since menopause. Thus, BMD was higher in CC compared to GG women with calcium intake below 940 mg/d (n=383, percentage difference=10.6%, pANOVA=0.002, 6.7%, p=0.05 and 5.6%, p=0.024, at Ward's, FT and FN, respectively); in postmenopausal women not receiving ERT (n=408, 9.4%, p=0.02, 6.6%, p=0.05 and 5.2%, p>0.05); and in women who were >15 years past menopause (n=309, 12.6%, p=0.016, 10,2%, p=0.025 and 8.4%, p=0.017). In contrast, no significant association was observed in models that considered only the main effects of IL-6 polymorphisms, nor in women who were either estrogen-repleted, or less than 15 years since menopause, or whose calcium intake was above 940 mg/d, nor in men (n = 737). In summary, the IL-6 gene promoter variant –174C is associated with preserved hip BMD in subjects at increased risk of osteoporosis, such as older women, postmenopausal women without ERT and those with low calcium intake. Considering the role of estrogens and calcium on regulating IL-6 expression and bone turnover, it is plausible that interactions between these factors and variants in the IL-6 gene regulatory region contribute to bone mass determination in aging women.

The Anabolic Effect of Parathyroid Hormone Is Impaired in Bones of Fgf2 Null Mice. M. M. Hurley[1], Y. Okada[2], T. Sobue[1], X. Zhang[1], L. Xiao*[1], Y. Tanaka*[2], M. Ito*[3], N. Okimoto*[4], T. Nakamura*[2], J. Coffin[5], C. J. Rosen*[6], T. Doetschman*[7]. [1]Medicine, Univ of CT Hlth Cntr, Farmington, CT, USA, [2]Univ of Occ & Environ Hlth, Kitakyushu, Japan, [3]Univ of Nagasaki, Nagasaki, Japan, [4]Univ of Occ & Environ Hlth, Kitakyushu, Japan, [5]Univ of Montana, Missoula, MT, USA, [6]Jackson Lab, Bangor, ME, USA, [7]Univ of Cincinnati, Cincinnati, OH, USA.

Intermittent administration of parathyroid hormone (PTH) stimulates new bone formation in mice, aged rats and humans. However, the mechanism by which PTH increases bone formation is not established. Basic fibroblast growth factor (FGF-2) is a potent bone anabolic agent when administered intermittently to young and aged rats in vivo and Fgf2-/- mice develop low bone mass with aging. Since PTH increased FGF-2 mRNA and protein expression in osteoblasts and the acute hypercalcemic effect of PTH is diminished in Fgf2-/- mice, we assessed whether the anabolic effect of PTH was impaired in Fgf2-/- mice. Eight week old Fgf2+/+ and Fgf2-/- male mice were weighed and injected s.c. once daily with vehicle or PTH 1-34 (8 µg/kg body wt) for 30 days. Mice were injected with calcein (0.6 mg/kg) on day 18 and day 24 to assess new bone formation. There were no significant differences in body wt pre and post PTH in either genotype. Serum calcium obtained 24 h after the last injection was similar in vehicle and PTH treated mice of both genotypes. Micro-CT and dynamic histomorphometry of the distal femoral metaphysis is shown below. PTH significantly increased parameters of bone formation in Fgf2+/+ mice but the changes were smaller and not significant in Fgf2-/- mice. Similar results were obtained in 6 week old male and 15 month old female mice. Bone mineral density (BMD) was measured in femurs excised from Fgf2+/+, Fgf2+/- and Fgf2-/- mice that were treated with PTH (16 µg/kg body wt) for 10 days. BMD was increased by 18% (p<0.05) in PTH treated bones from Fgf2+/+; 3% in Fgf2+/- mice and reduced by 3% in bones from Fgf2-/- mice. Serum IGF-1 was not significantly different between vehicle and PTH treated mice of each genotype. We conclude that endogenous Fgf2 is a critical mediator of the anabolic effect of PTH, on bone in mice.

Parameters of bone formation in femoral metaphysis of Fgf2+/+ and Fgf2-/- mice

	Fgf2+/+ Vehicle	Fgf2+/+ PTH	Fgf2-/- Vehicle	Fgf2-/- PTH

Intermittent PTH Fails to Restore Deficient Bone Mass and Microarchitecture in Male Mice Null for ß-Arrestin2. M. L. Bouxsein[1], D. Sternlight*[1], V. Glatt*[1], D. Pierroz*[2], S. L. Ferrari[2]. [1]Orthopedic Biomechanics, Beth Israel Deaconess Medical Center, Boston, MA, USA, [2]Division of Bone Diseases, University Hospital, Geneva, Switzerland.

ß-arrestins are cytoplasmic molecules which mediate the internalization and desensitization/resensitization of the parathyroid hormone (PTH)/PTH-related protein receptor. We previously reported that 6 month-old female mice null for ß-arrestin2 (ß-arr2 KO) had normal skeletal morphology, but decreased bone mass and altered trabecular architecture compared to wild-type (WT) littermates. To investigate whether this was due to a deficiency in peak bone mass acquisition and/or accelerated bone loss, we evaluated bone mass longitudinally by pDXA in 4 to 24 wk-old ß-arr2 KO and WT mice (n=84 females and 86 males). In addition, to study the role of PTH in this process, 12 wk-old male and female mice were matched for weight and either sacrificed immediately, or received intermittent PTH (80 µg/kg/d, sc) or vehicle (VEH) for 4 wks (n=6-12/group). Changes in bone mass and microarchitecture were analyzed in vivo by pDXA, and ex vivo by µCT, respectively. Both male and female KO had a modestly lower bone mass at all skeletal sites by 8 wks, which persisted until peak bone mass was achieved (ie, Total Body BMC: -5.5% for males, -8.4% for females, p<0.005 for both). KO also had a lower body weight at all timepoints (-1.4 g in males, p<0.005; -1.2 g in females, p=0.03). In the PTH study, VEH-WT females had higher total body BMC (+8.4%, p=0.01), cortical thickness (+14%, p=0.003) and vertebral trabecular BV/TV (+10%, p=0.18) after 4 wks compared to baseline, with similar trends seen in VEH-WT males. In contrast, these variables did not increase in VEH-KO females, and in KO-males, vertebral trabecular BV/TV and trabecular number actually declined (-18% to -20%, p<0.005 for both). Intermittent PTH significantly increased total body BMC, as well as cortical and trabecular bone parameters in WT males and females (+9 to 30%). A similar anabolic response was seen in PTH-KO females. In contrast, in KO males, PTH failed to increase trabecular and cortical BV/TV, resulting in a persistent decline in bone mass. Compared to VEH, osteocalcin levels were significantly increased (+50%) by PTH treatment and positively correlated to changes in total body BMC in all groups (r= 0.46 to 0.63, p<0.01), except for KO males (r=0.14, ns). Taken together, these data indicate that ß-arr2 is important in regulating both acquisition and maintenance of bone mass. Altered PTH bioactivity in the absence of ß-arr2 may be implicated in the premature bone loss observed in KO males. The mechanism(s) by which ß-arrestins influence peak bone mass acquisition remains to be elucidated.

Mammary Epithelial Cell PTHrP Secretion During Lactation: Regulation by a Calcium Sensing Mechanism In Vitro and In Vivo. J. N. VanHouten*[1], P. R. Dann*[1], M. C. Neville*[2], E. M. Brown[3], J. J. Wysolmerski[1]. [1]Yale University School of Medicine, New Haven, CT, USA, [2]University of Colorado Health Sciences Center, Denver, CO, USA, [3]Brigham and Women's Hospital, Boston, MA, USA.

During lactation, the breast mediates the transfer of large quantities of calcium from the maternal circulation into milk. This process is associated with marked increases in bone turnover and significant bone loss in lactating mothers. Furthermore, it has been suggested that PTHrP, secreted by mammary epithelial cells may participate in the regulation of bone turnover and bone loss during lactation. Therefore, we wondered if the breast was a calcium-sensing organ and if mammary epithelial cells regulated PTHrP secretion in response to changes in extracellular calcium concentration. In order to address these questions, we first examined the expression of the calcium sensing receptor gene in normal breast tissue in mice. By RT-PCR and by Affymetrix gene profiling, we have found that the CaSR gene is expressed in lactating, but not pregnant or virgin breast tissue. Immunohistochemistry for the CaSR demonstrated that it is expressed on epithelial cells within the lactating breast. When mammary epithelial cells from normal mice are cultured in lactogenic media, PTHrP secretion is suppressed in a linear fashion by raising extracellular calcium concentrations from 0.5 through 10mM. Increasing concentrations of neomycin also progressively suppress PTHrP secretion by primary cultures of mammary epithelial cells, suggesting that the effect of calcium on PTHrP secretion is mediated by the CaSR. Finally, placing lactating mice on a low calcium diet (0.01%) induces relative hypocalcemia and increases PTHrP levels in milk. These data suggest that the lactating breast senses calcium and that mammary epithelial cells adjust PTHrP secretion in response to changes in extracellular calcium concentration. Interestingly, the effects of raising the extracellular calcium concentration on PTHrP secretion by lactating mammary epithelial cells mirror the effects of raising calcium concentrations on PTH secretion by parathyroid cells, and are the opposite of the effects described in breast cancer cell lines. The regulation of PTHrP secretion by the CaSR is likely to contribute to the overall regulation of calcium metabolism during lactation and the transfer of calcium from mother into milk.

1064

The Transcription Factor GCMB Induces Expression of PTH in HEK 293T Cells. C. Ding, A. Maret*, M. A. Levine. Pediatric Endocrinology, Johns Hopkins University, Baltimore, MD, USA.

The *GCMB* gene, a human ortholog of the Drosophila gene glial cells missing (*gcm*), is expressed exclusively in parathyroid cells and regulates parathyroid gland development. Involvement of *GCMB* in parathyroid cell embryogenesis has been demonstrated by "loss of function" studies, wherein human subjects or transgenic mice lacking *GCMB/Gcm2* fail to develop parathyroid glands. Here we have used a "gain of function" approach to test whether *GCMB* could endow HEK293 cells with parathyroid cell characteristics. Transient transfection of 293T cells with green fluorescent protein (GFP) fusion constructs contain-

ing either *Drosophila* (d)GCM or human (h)GCMb showed intense fluorescence in the cell nucleus, confirming expression and appropriate nuclear localization of these proteins. Co-transfection of 293T cells with a luciferase reporter plasmid containing six tandem copies of the GCM-binding site plus plasmids containing dGCM or hGCMb produced 200- and 10-fold increases in luciferase activity, respectively, confirming that dGCM is a much stronger transactivator than hGCMb. To test transactivation of endogenous genes, we transfected 293T cells with either vector alone or plasmids containing dGCM or hGCMb and after 48 hours isolated total RNA. RNA was analyzed by RT-PCR using oligonucleotide primers that spanned introns in order to distinguish amplification of mRNA from contaminating genomic DNA. Cells that had been transfected with hGCMb expressed mRNA encoding for PTH, but not for the calcium sensing receptor. By contrast, cells that transfected with dGCM or vector alone did not express either PTH or calcium sensing receptor. To determine whether PTH mRNA was effectively translated into protein, we performed immunocytochemistry with a monoclonal antibody to the amino-terminus of human PTH. 293T cells transfected with hGCMb showed strong cytoplasmic staining, confirming ectopic expression of immunoreactive PTH in these cells. In conclusion, our data show that expression of hGCMb is sufficient to induce PTH production in 293 cells. By contrast, expression of dGCM, a stronger transactivator than hGCMb, did not induce PTH expression in these cells, suggesting that naturally occurring transcription factors in 293T cells may act in concert with ectopic hGCMb but not with dGCM to induce PTH expression. Finally, ectopic expression of PTH but not calcium sensing receptors in 293 cells expressing hGCMb suggests that under our present conditions acquisition of parathyroid cell characteristics is incomplete. Additional studies, including microarray analysis and regulated PTH secretion, of stably transfected 293 and other cell lines will be required to characterize more fully the transactivation potential of hGCMb.

1065

In Vivo Role of Stimulatory G Protein (Gs) in Cartilage Development. M. Bastepe[1], L. Weinstein*[2], H. M. Kronenberg[1], H. Juppner[1], U. Chung[1]. [1]Endocrine Unit, Mass. Gen. Hosp., Boston, MA, USA, [2]Niddk, NIH, Bethesda, MD, USA.

Stimulatory G protein (Gs) transduces signals from various cell-surface receptors to intracellular adenylate cyclases, which generate the second messenger, cAMP. The α subunit of Gs (Gsα) is encoded by GNAS1 (mouse homolog encoded by Gnas). Heterozygous inactivating mutations in one of the 13 exons of GNAS1 encoding Gsα cause Albright's Hereditary Osteodystrophty (AHO) and related disorders. The in vivo role of Gs signaling in skeletal development is still largely unknown, due to early embryonic lethality of mice homozygously missing the Gnas exon 1 ($Gnas^{E1/E1}$) or exon 2 ($Gnas^{E2/E2}$) and due to absence of easily detectable phenotypes in growth plate chondrocytes heterozygous for the mutations. We have generated chimeric mice containing wild-type and $Gnas^{E2/E2}$ cells. Exon 2 of the Gnas gene not only encodes Gsα but also contributes to other alternatively spliced transcripts such as XLα s, NESP55 and A/B. $Gnas^{E2/E2}$ chondrocytes phenocopy PTH/PTHrP receptor $(PPR)^{-/-}$ cells in the growth plate by ectopically undergoing hypertrophy. Heterozygous mutant cells also ectopically hypertrophy in the growth plate, but to a lesser extent than $PPR^{-/-}$ cells and $Gnas^{E2/E2}$ cells. XLαs mRNA is expressed at very low levels even in the wild-type growth plate. However, heterozygous cells with a mutant paternal allele ($Gnas^{+/pat\ E2}$) have more severe phenotypes than cells with a mutant maternal allele ($Gnas^{+/mat\ E2}$), suggesting that XLαs expressed only from the paternal allele may play a role similar to that of Gsα in chondrocyte differentiation. Introduction of rat Gsα cDNA into $Gnas^{E2/E2}$ ES cells as a CMV promoter-driven transgene and generation of chimeras with these transfected cells lead to a complete reversal of ectopic hypertrophy in chimeras, when cAMP response to cholera toxin in the transfected ES cells is completely restored in vitro. In other lines, in which the cAMP response is partially restored, a partial reversal similar to that found using $Gnas^{+/E2}$ cells is seen. Thus, Gs is sufficient to mediate signaling through the PTH/PTHrP receptor in the growth plate. In conclusion, these data strongly suggest that signaling through the PTH/PTHrP receptor is mediated mainly by Gs in growth plate chondrocytes. Furthermore, they also suggest that $Gnas^{+/E2}$ cartilage has haplo-insufficiency of Gs signaling.

Distinct Roles of Individual Signaling Pathways Activated by the PTH/PTHrP Receptor in Endochondral Development Ex-Vivo. J. Guo, U. Chung, R. F. Bringhurst, H. M. Kronenberg. Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Chondrocyte differentiation in the endochondral growth plate is delayed in mice expressing exclusively a mutant form of the PTH/PTHrP receptor ("DSEL') that activates adenylyl cyclase normally but not phospholipase C (PLC). This phenotype in DSEL homozygous (PTHRD/D) mice is quite distinct from that observed in mice lacking the PTH/PTHrP receptor, in which chondrocyte diffferentiation is accelerated during endochondral development. To further analyze how specific signals generated by the PTH/PTHrP receptors may affect chondrocyte differentiation, PTHR+/- and PTHRD/- were mated, and E14.5 metatarsal and tibia rudiments from the resulting litters were cultured in serum-free medium in vitro. Mineralization of cartilage, as viewed serially with a dissecting microscope, gradually expanded distally from the center of the metatarsal rudiments of PTHR+/- embryos during 7 days in culture. In previous studies in vivo, hemizygous PTHR+/- mice exhibited normal growth plates. In rudiments from PTHR-/- mice, mineralization was more extensive and extended much farther toward the articular surfaces, whereas the appearance of mineralized cartilage was greatly delayed in hemizygous PTHRD/- rudiments during this period of culture. As shown by in situ hybridization analysis, the domain of chondrocytes expressing collagen type X and osteopontin was dramatically decreased in size by treatment with hPTH(1-84) for 3 days in both PTHR+/- and PTHRD/- rudiments, whereas no effect of hPTH (1-84) on PTHR-/- rudiments was observed. This inhibitory effect was mimicked by treatment with forskolin, a stimulator of adenylyl cyclase, and [Gly1, Arg19]hPTH(1-28), a PTH analog that cannot activate PLC. In contrast, hypertrophy of chondrocytes was augmented by incubation of rudiments with active phorbol ester. These findings indicate that in mediating the action of PTHrP or PTH, the PTH/PTHrP receptor exerts both an inhibitory and a stimulatory effect on differentiation of growth plate chondrocytes, depending on the specific signal generated by the receptor. We have further observed that treatment with 100 nM PTH for either 6 hr or 3 days caused dramatic down-regulation of Cbfa-1 in both PTHR+/+ and PTHRD/D rudiments, as shown by in situ hybridization analysis. These results suggest that PLC-independent signaling via the PTH/PTHrP receptor may retard chondrocyte differentiation, at least, in part, via the Cbfa-1 transcriptional activation pathway, since mice lacking Cbfa-1 exhibit a delay in chondrocyte differentiation during endochondral development.

Biglycan Is Essential for BMP-4 Stimulated Osteoblast Differentiation. X. Chen, T. Xu*, M. Young. Craniofacial and Skeletal Diseases Branch, National Institutes of Dental and Craniofacial Research, NIH, Bethesda, MD, USA.

Biglycan (bgn) is a small leucine rich proteoglycan that is enriched in extracellular matrices of skeletal tissues. Previously, we reported that bgn-deficient (knockout, KO) mice developed age-related bone lose with a phenotype that resembled osteoporosis, that is due to a defect in the proliferation and differentiation of osteoblast precursors. It was also found that osteoblasts obtained from bgn-KO mice accumulated less mineral than those from wild type (wt) mice in the presence of BMP-2/4 in vitro. In the present study, our hypothesis was that biglycan plays a role in BMP-4 stimulated osteoblast differentiation. To test this hypothesis, we examined how bgn-KO osteoblasts responded to BMP-4 in the regulation of Cbfa1, and whether the BMP-4 signaling transduction pathway was involved. Cells were harvested from newborn animals by repeated digestions with collagenase and cultured until 80% confluent. The cells were treated with BMP-4 for 48 hours, and Cbfa1 was detected in the lysed cells by Western blot analysis. The data showed that the bgn-KO cells produced a significantly lower level of Cbfa1 with or without BMP-4 treatment compared to wt cells. To further study the decreased production of Cbfa1 in the bgn-KO cells, we transfected the cells with a promoter that contains 6 copies of the consensus sequence (OSE2) for Cbfa1 linked to a luciferase promoter. Based on the data of the luciferase assay, BMP-4 did not elevate the level of activity in the bgn-KO cells (0.28 ± .05 vs. 0.29 ± 010). In contrast, the wt cells significantly increased the activity level from 0.35 ± 0.05 to 0.56 ± 0.17 ($p = 0.03$, $n = 5$) after BMP-4 treatment. This indicated that bgn-KO cells did not respond to BMP-4 in the production and function of Cbfa1. To further understand why there was the differential response to BMP-4 in the bgn-KO cells, we examined the signaling pathway, particularly the active phosphorylated Smad1 (p-Smad1) and BMP type I receptor by Western blot analysis. The data showed that p-Smad1 was lower in bgn-KO than wt cells after the cells were treated with BMP-4 for 30 minutes. Surprisingly, we found that bgn-KO cells over expressed the type I receptor in both the untreated and treated cells with BMP-4 compared with wt cells. Overall, the results suggested that bgn-KO cells responded poorly to BMP-4, which in turn causes a reduction in Cbfa1 production. It may also explain our previous observation that bgn-KO cells reduce the expression of BSP, osteopontin, osteocalcin, and accumulate less mineral during the differentiation process. We propose that biglycan is required for BMP-4 stimulation, and may act by modulating BMP-4 or other growth factors in control of osteoblast function.

Biglycan and Decorin Have Overlapping Roles in the Commitment, Proliferation, Differentiation, and Survival of Osteoblasts and Their Precursors. Y. Bi*[1], X. Chen[1], T. Xu*[1], R. V. Iozzo*[2], M. F. Young[1]. [1]NIH, Bethesda, MD, USA, [2]Thomas Jefferson University, Philadephia, PA, USA.

Small leucine-rich proteoglycans (SLRPs) are extracellular molecules that bind to collagens and growth hormones to regulate cell growth and matrix assembly. Biglycan (BGN) and decorin (DCN), two members of class I SLRPs, are predominantly expressed in bone. Because the functions of BGN and DCN in bone formation may, at least partially, be compensated by each other in single knockout animals, we created BGN and DCN double-knockout (DKO) mice. DKO mice exhibit osteopenia earlier and more severely than the BGN or DCN single knockout mice. In this study, we examined the cellular and molecular mechanisms that underline the accelerated bone loss in DKO mice. To assess the number of osteogenic stem cells, we compared the colony forming efficiency (CFU-F) in DKO bone marrow stromal cells (BMSCs) with wild type (WT) cells. We previously reported that the number of CFU-F was only significantly decreased at 12 (24%) and 24 weeks (52%) of age in BGN KO cells compared to WT cells. In the present study, we found that the number of CFU-F in DKO cells was decreased by 66 ± 6 % (n=6) compared to WT cells as early as two months of age. Thus, the CFU-F decreases earlier and is more pronounced in DKO than in BGN KO, which is consistent with their skeletal phenotypes. To better understand the mechanisms of the decreased number of CFU-F in the DKO, we examined the expression of over 100 genes related to apoptosis. Interestingly, several genes of the TNF receptor family (TNFR1, TNFRSF11A, and DR6) and a potential ligand (LT-b) of TNF receptors were highly expressed in the DKO osteoblast precursors, indicating that BGN and DCN may protect cells against apoptosis via TNF-induced pathways. Next, we determined the potential of BMSCs differentiating into functional bone forming cells using a mineralization assay. The results showed that calcium accumulation was significantly lower (47.5 ± 1.5%) in the cultures of DKO BMSCs compared to WT BMSCs after normalization for protein content. The DKO cultures were observed microscopically to have greater cell numbers than WT cultures. This led us to speculate that the DKO cells may have a higher proliferation rate than WT cells. To confirm this, we determined the proliferation of osteoblast precursors using the MTT assay. The proliferation rate of osteoblast precursors from DKO mice was 25 ± 5% (n=5) higher than cells from WT mice. Taken together, we postulate that the small leucine-rich proteoglycans, BGN and DCN, have overlapping functions in regulating the commitment, proliferation, differentiation, and survival of osteoblasts and their precursors.

The Matricellular Protein, Thrombospondin-2, Has Opposing Effects on Osteogenic and Adipogenic Differentiation of Marrow-derived Mesenchymal Stem Cells. K. D. Hankenson. Department of Orthopaedic Surgery, University of Michigan, Ann Arbor, MI, USA.

Matricellular proteins (MP) are a functional group of extracellular matrix molecules that modulate structural matrix formation and function, growth factor/cytokine activity, and cell physiology. Mice with targeted deletions of MP genes show abnormalities in bone modeling and remodeling. Specifically, thrombospondin-2 (TSP2)-null mice show an increase in endosteal bone formation that occurs coincident with an increased number of marrow-derived mesenchymal stem cells (MSC). TSP2 functions as an autocrine inhibitor of MSC cell-cycle progression and may contribute to maintaining MSC quiescence. The purpose of this study was to determine whether TSP2 can also affect MSC differentiation. The ability of MSC to support osteoclastogenesis (TRAP+, multinucleated cells), form mineral (Alizarin red), and develop into adipocytes (Oil red O) was studied. WT spleen cells and RAW 264.7 cells (neither of which produce appreciable TSP2) were cultured on confluent MSC monolayers in the presence of vitamin D and dexamethasone (DEX). TSP2-null and WT MSC supported osteoclastogenesis equivalently. An examination of osteoblastogenesis in the presence of beta-glycerophosphate showed that recombinant TSP2 expedited mineralization of both TSP2-null immortalized MSC and ST2 cells, in addition to limiting proliferation. Whereas mineralization in TSP2-null immortal cells was not observed until d 28, in the presence of TSP2, mineral was observed on d 21. When TSP2 was added to TSP2-null and ST2 cells that were induced to form adipocytes (DEX/insulin/IBMX treatment), the proportion of lipid containing cells was substantially decreased (15% of control). To determine the domain of TSP2 that imparts the positive osteogenic and negative adipogenic effects, four recombinant TSP2 fragments were studied in comparison to full-length TSP2. The three type I repeats were required for inhibition of proliferation and promotion of mineralization; however, the type I repeats were not required for inhibition of adipogenesis. These results demonstrate that the effect of TSP2 on MSC behavior is not monotrophic, as was originally proposed. We postulate that TSP2 in vivo, in addition to modulating the proliferation of early-stage MSC, promotes bone formation and inhibits adipogenesis. In the TSP2 knockout mice these alternative roles may be masked by the dominant effect of increased MSC number. Furthermore, based on the study of TSP2 fragments, we conclude that the promotion of mineralization and inhibition of adipogenesis are not linked events, and that inhibition of adipogenesis does not occur secondary to inhibition of proliferation.

Targeted Expression of a Constitutively Active Mutant of MEK1 in Chondrocytes Inhibits Endochondral Ossification and Rescues the Phenotype of FGFR3 Deficient Mice. S. Murakami*[1], S. McKinney*[1], D. Givol*[2], B. de Crombrugghe*[1]. [1]Department of Molecular Genetics, U.T.M.D.Anderson Cancer Center, Houston, TX, USA, [2]Weizmann Institute of Science, Rehovot, Israel.

In order to examine the role of the MAPK pathway in chondrocyte differentiation, we generated transgenic mice that overexpress a constitutively active mutant of MEK1 (S218/222E, Δ32-51) in chondrocytes using 6 kb promoter/intron sequences of *Col2a1*. Three lines of transgenic mice that show cartilage specific expression of the transgene were established. All three lines exhibited a dwarf phenotype similar to human achondroplasia, a dwarfism syndrome caused by activating mutations in FGFR3. Skeletal preparations showed shortened axial and appendicular skeletons, mid-facial hypoplasia, and dome-shaped cranium. Histological examination of the growth plate of long bones revealed incomplete hypertrophy of chondrocytes and narrower hypertrophic zone in transgenic mice compared to wild-type littermates. In addition, formation of secondary ossification centers and ossification of carpal bones were delayed in transgenic animals. Since these mice showed mid-facial hypoplasia at birth, we examined the endochondral ossification process in the cranial base during embryonic development. Histological examination of the head at E15.5 to E17.5 revealed a delay in hypertrophic differentiation of chondrocytes in the cranial base. Ossification of basisphenoid and basioccipital bones was delayed, and morphologically smaller chondrocytes persisted in these transgenic mice. Immunohistochemical analysis showed reduced staining for collagen type X and persistent expression of Sox9, a master transcription factor that inhibits hypertrophic differentiation of chondrocytes. These observations indicate that the MAPK pathway inhibits hypertrophic differentiation of chondrocytes and negatively regulates bone growth. In order to test the hypothesis that skeletal overgrowth in FGFR3 deficient mice is caused by the reduced activity of the MAPK pathway, we crossed these transgenic mice with FGFR3 deficient mice. Expression of a constitutively active mutant of MEK1 in chondrocytes of FGFR3 null mice inhibited skeletal overgrowth, indicating activation of the MAPK pathway is sufficient to overcome the growth promoting effects of FGFR3 deficiency. Since the MAPK pathway is a major component of FGF signaling, our observations strongly suggest that regulation of bone growth by FGFR3 is at least in part mediated by the MAPK pathway. Increased activity of the MAPK pathway could account for the dwarf phenotype in achondroplasia and thanatophoric dysplasias, two human genetic diseases that are caused by activating mutations in FGFR3.

1071

The Transcription Factor Sox9 Has Essential Roles in Successive Steps of the Chondrocyte Differentiation Pathway and Is Required for Expression of Sox5 and Sox6. H. Akiyama[1], M. C. Chaboissier*[2], J. F. Martin*[3], A. Schedl*[2], B. de Crombrugghe*[1]. [1]Molecular Genetics, MD Anderson Cancer Center, Houston, TX, USA, [2]Institute of Human Genetics, University of Newcastle, Newcastle, United Kingdom, [3]Alkek Institute of Bioscience and Technology, Texas A&M System Health Science Center, Houston, TX, USA.

To examine whether Sox9 is essential during the sequential steps of chondrocyte differentiation, we have used the Cre/loxP recombination system to generate mouse embryos in which either Sox9 is missing from undifferentiated mesenchymal cells of limb buds or the Sox9 gene is inactivated after chondrogenic mesenchymal condensations. Mice harboring a conditional ("floxed") allele of Sox9, in which exons essential for Sox9 function were flanked by loxP recombination sequences, were intercrossed with transgenic mice that expressed Cre recombinase under control of either Prx1 or Col2a1 regulatory sequences. Prx1-Cre deletion of Sox9, which occurred in undifferentiated mesenchymal cells of limb buds, resulted in very short limbs completeyly lacking chondrogenic mesenchymal condensations and limb skeleton formation. Expression of transcripts for a series of patterning proteins that mark the different axis of limb buds was comparable in mutants and wild-type limb buds. In contrast, expression of Sox5 and Sox6, as well as that of bone morphogenetic protein receptor-1b, was completely downregulated, and expression of Runx2/Cbfa1 was severely inhibited in mutant limb buds. Embryos harboring Col2a1-Cre, in which Sox9 was deleted after chondrogenic mesenchymal condensations were established, exhibited a severe generalized chondrodysplasia, similar to that in Sox5; Sox6 double-null mutant mice. In these Sox9-/- mutants, most cells were arrested as condensed mesenchymal cells and did not undergo overt differentiation into chondrocytes. Furthermore, chondrocyte proliferation was severely inhibited, and characteristic columns of proliferating chondrocytes were absent. The presence of hypertrophic chondrocytes suggested that some cells underwent overt chondrocyte differentiation but that as soon as the Sox9 gene was inactivated they were promptly converted into hypertrophic chondrocytes. Moreover, expression of Indian hedgehog, Patched1, parathyroid hormone-related peptide (Pthrp), and Pth/Pthrp receptor were downregulated in mutant embryos. We conclude that Sox9 is needed during successive steps of the chondrocyte differentiation pathway and is required for Sox5 and Sox6 expression during chondrogenesis.

Mutation in cGMP-dependent Protein Kinase 2 Causes Dwarfism in a Novel Rat Mutant, MRI, through Uncoupling of Proliferation and Differentiation of Chondrocytes. H. Chikuda[1], K. Hoshi[1], T. Shimoaka[1], T. Akune[1], H. Kawano[1], K. Kawano[1], K. Nakamura[1], U. Chung[1], K. Komeda*[2], H. Kawaguchi[1]. [1]Orthopaedic Surgery & Tissue Eng., Univ. of Tokyo, Japan, [2]ARC, Tokyo Medical College, Japan.

The miniature rat Ishikawa (MRI) is a naturally occurring mutant which exhibits longitudinal growth retardation caused by an autosomal recessive mutation. Limbs and trunk of MRI (*mri*/*mri*) are 30-40% shorter than those of wild-type (WT or +/+) and +/*mri* littermates, although the mutant is healthy and fertile without major organ abnormalities. To identify the mutation, we performed positional candidate cloning. The *mri* locus was mapped to a genomic region between D14rat76 and D14rat6, in which several candidates were identified by comparative mapping. By sequencing them, we found a 220-bp deletion in the cGMP-dependent protein kinase 2 (cGK2) transcript in MRI, which resulted in a frame shift and a premature stop codon, predicting a truncated product that lacks the kinase domain. cGK2 is an intracellular signaling molecule of C-type natriuretic peptide, an important regulator of endochondral bone formation. Histomorphometric analysis of MRI at 10 weeks showed normal bone density and turnover; however, height of its growth plate was about 2.5-fold that of WT with a thick layer of small and flattened chondrocytes between the proliferative and hypertrophic zones. BrdU labeling and immunohistochemistry / in situ hybridization for differentiation markers (PTH/PTHrP receptor, Ihh, ALP and COL X) revealed that these chondrocytes were abnormal cells that had stopped proliferation but had not started differentiation into hypertrophic chondrocytes. Although the hypertrophic zone was irregular and narrow in MRI, mineralization and blood vessel invasion were normal. Similar impairment of endochondral bone formation was observed during the fracture healing process after osteotomy in the MRI tibiae. We further examined the functions of cultured primary growth plate chondrocytes. Cellular proliferation was similar between MRI and WT; however, differentiation of MRI chondrocytes determined by alcian blue and ALP staining was markedly suppressed compared to that of WT cells. Differentiation of WT chondrocytes was impaired when cocultured with MRI chondrocytes in a double chamber dish separated by a porous membrane, although that of MRI cells was not rescued by WT cells. This suggests that there is an autocrine / paracrine factor(s) which is stimulated by cGK2 dysfunction and prevents chondrocyte differentiation. In conclusion, a mutation in cGK2 causes growth retardation in MRI due to impaired endochondral bone formation. cGK2 may play an important role in the coupling of proliferation and differentiation of chondrocytes.

1073

Interleukin-11 Receptor Signaling Is Required for Normal Bone Remodeling in Male and Female Mice. N. A. Sims[1], B. J. Jenkins*[2], J. M. W. Quinn[3], K. W. Ng[1], T. J. Martin[3], M. T. Gillespie[3], L. Robb*[4], M. Ernst*[2]. [1]Department of Medicine at St. Vincent's Hospital, University of Melbourne, Fitzroy, Australia, [2]Ludwig Institute for Cancer Research, Melbourne, Australia, [3]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [4]Walter and Eliza Hall Institute, Melbourne, Australia.

Interleukins 6 and 11 have been implicated in bone loss in estrogen deficiency due to their ability to stimulate osteoclastogenesis in vitro and to reduced production of IL-6 and IL-11 by stromal cells in the presence of estradiol. Furthermore, the roles of these two cytokines have been linked, with the suggestion that each may compensate for the absence of the other to maintain trabecular bone volume and turnover. To determine whether IL-11 is required for normal bone turnover, we examined the bone phenotype of mature male and female IL-11 receptor knockout mice (IL-11Rα KO). IL-11Rα was disrupted such that no full-length or truncated transcripts were expressed (Robb et al, Blood, 1997). Tibiae from intact 16 week old male and female mice were collected and studied by dynamic bone histomorphometry. In both male and female IL-11Rα KO mice, trabecular bone volume was approximately double that of wild type littermate controls (mean BV/TV ± SEM: female wild type: 6.0 ± 0.9; female IL-11Rα KO: 12.2 ± 1.4, male wild type: 8.9 ± 0.4; male IL-11Rα KO: 14.3 ± 0.5). This high bone volume was associated with a high trabecular number and a low level of bone turnover. For example, osteoblast surface was reduced to less than 50% of wild type levels, osteoclast surface was reduced by 20% and bone formation rate was reduced by 40% compared with wild type littermates. The low bone turnover and high trabecular bone volume in these mice indicate that IL-11Rα signaling is required for normal bone turnover in both male and female mice. Since it has been suggested that IL-6 and IL-11 play similar and complementary roles, with the ability to compensate for the absence of the other, we also examined the bone phenotype of IL-6 KO mice, and mice lacking both IL-6 and IL-11Rα (compound knockouts). As previously reported, the bones of IL-6 KO mice were not significantly different to wild type mice; neither trabecular bone volume nor bone turnover were altered. However, compound IL-6 KO/ IL-11Rα KO mice demonstrated an identical bone phenotype to the IL-11Rα KO, with a high trabecular bone volume and low bone turnover, indicating that normal bone mass and turnover in IL-6 knockouts does not relate to IL-11 compensation. Furthermore, reduced bone turnover and increased bone volume in IL-11Rα null mutants is not mediated by changes in IL-6, nor worsened by its absence.

1074

TGF-b2 Regulates Chondrocyte Differentiation and Proliferation During Embryonic Development. J. Alvarez-Pinera*, A. Mukherjee*, R. Serra. Molecular and Cellular Physiology, University of Cincinnati, Cincinnati, OH, USA.

Indian hedgehog (Ihh) and Parathyroid Hormone related Peptide (PTHrP) regulate the rate and extend of endochondral bone growth through the establishment of a negative-feedback loop in which production of Ihh by prehypertrophic chondrocytes induces PTHrP expression in the periarticular perichondrium which in turn inhibits hypertrophic differentiation. We have shown that PTHrP also acts downstream of transforming growth factor b (TGF-b) in a common signaling cascade to regulate hypertrophic differentiation in embryonic mouse metatarsal cultures. Transgenic mice that express a dominant-negative mutation of the TGF-b type II receptor in skeletal tissue demonstrated increased terminal differentiation and persistent expression of Ihh in growth plate chondrocytes. Since Ihh normally acts as an inhibitor of chondrocyte differentiation it was proposed that TGF-b was required for Ihh-mediated inhibition. Previously we showed that Sonic hedgehog (Shh) a functional substitute for Ihh, stimulates expression of TGF-b2, TGF-b3 and PTHrP in the perichondrium of metatarsal organ cultures. In this study we propose a model where TGF-b acts downstream of Ihh and upstream of PTHrP to regulate hypertrophic differentiation. First, we show using adenovirus mediated gene transduction into the organ cultures that TGF-b signaling in the perichondrium is required for Shh-mediated stimulation of PTHrP expression. We also show that the effects of Shh are specifically dependent on TGF-b2, as metatarsal cultures from TGF-b3 null embryos respond to Shh but cultures from TGF-b2 null embryos do not. The data suggest that TGF-b2 acts as a signal relay between Ihh and PTHrP in the regulation of hypertrophic differentiation. Next, we tested the effect of TGF-b2 treatment in intact and perichondrium free cultures. TGF-b2 treatment inhibited chondrocyte growth and differentiation as well as dramatically enhanced PTHrP expression in the perichondrium. Removal of the perichondrium blocked the ability of TGF-b2 to inhibit bone growth and hypertrophic differentiation. Next the role of TGF-b2 on chondrocyte proliferation and differentiation in vivo was tested using 17.5 day embryos from crosses of TGF-b2+/- mice. TGF-b2-/- embryos showed higher levels of chondrocyte proliferation when compared to wild type littermates. Long bones of TGF-b2-/- embryos also demonstrated higher levels of type X collagen expression than that observed in wild type embryos. These data suggest that TGF-b2 signaling not only plays a main role in the regulation of chondrocyte differentiation acting as a signaling relay between Ihh and PTHrP but also regulates chondrocyte proliferation during embryonic development.

1075

Dramatic Low-Turnover Osteoporosis in a Noggin-Overexpressing Mouse Establishes the Essential Role for Noggin in the Negative Regulation of Osteoblast Differentiation and Bone Formation. X. B. Wu, A. Schneider*, M. Zaidi, E. Abe. The Mount Sinai Bone Program and Bronx VA GRECC, New York, NY, USA.

Here we provide evidence that establishes noggin, a BMP antagonist, as a negative regulator of osteoblast differentiation and bone formation. Mice overexpressing noggin at ~10-fold higher levels in mature osteoblasts under the control of the osteocalcin promoter, OG-2, became overtly osteoporotic at 8 months. This was accompanied by radiological osteopenia coupled with significantly reduced bone mineral density at the lumbar spine, femur and tibia. Histological analysis revealed a marked loss of trabecular bone in the face of modest cortical thinning. Osteoblast differentiation in *ex vivo* bone marrow cell cultures, determined by counting early fibroblastoid and late mineralizing osteoblastoid colony forming units (CFU-Fs and CFU-OBs), was diminished by ~40%. In contrast, TRAP-positive osteoclast formation in hematopoetic stem cell cultures was only marginally reduced indicating a weak effect of noggin-overexpression *in vivo* on osteoclastogenesis. In 4 month-old mice, the bone phenotype remained subtle with histological evidence of disorganized endochondral bone formation and reduced CFU-OB formation in *ex vivo* marrow cell cultures. Bone mineral density, CFU-F counts, and osteoclast formation remained largely unaffected. In parallel *in vitro* studies, we over-expressed noggin or the constitutively activated BMP receptor 1A, ca-ALK-3, in pre-osteoblastic UAMS-33 cells using a retrovirus. Ca-ALK-3 is known to trigger BMP signaling in the absence of ligand, and is thus expected to be insensitive to the BMP antagonist, noggin. We found that noggin-overexpressing osteoblasts displayed decreased differentiation, measured both as alkaline phosphatase activity and osteocalcin expression. The pro-differentiation effects of BMP-2 were expectedly dampened in these cells compared with those infected with empty vector. Osteoblast proliferation, however, remained unaffected. Furthermore, co-culture of noggin-overexpressing cells with hematopoetic osteoclast precursors resulted in a marked reduction in osteoclast formation, consistent with our earlier observation for reduced RANK-L expression in, and hence, the diminished osteoclast-supporting function of osteoblasts treated with recombinant noggin. Ca-ALK-3 over-expressing pre-osteoblasts, in contrast, showed a pronounced enhancement of osteoblast differentiation that was, as expected, mostly insensitive to inhibition by noggin. Together, the results argue strongly for noggin, acting through disruption of BMP action, as a negative regulator of osteoblast maturation and function during adult skeletal remodeling.

1076

Impaired Osteogenic Response of *Bmp6* Null Mice. K. E. McDougall*[1], M. J. Perry[2], T. Whitworth*[2], S. M. Colley*[1], E. J. Robertson*[3], J. H. Tobias[1]. [1]Rheumatology Unit, University of Bristol, Bristol, United Kingdom, [2]Department of Anatomy, University of Bristol, Bristol, United Kingdom, [3]Department of Molecular and Cell Biology, Harvard, Cambridge, MA, USA.

In a recent study of the role of regulatory factors in bone formation, BMP-6 was found to be up-regulated during the osteogenic response of long bones to high-dose estrogen in female mice. To explore the role of BMP-6 in new bone formation induced by estrogen, we investigated whether this response is impaired in *Bmp6* null mice. Other than delayed ossification of the sternum in late gestation embryos, the latter have previously been reported to have a normal skeletal phenotype. A breeding colony of *Bmp6* null mice was established in our animal facility, crossed with resident C57Bl/6 animals. F1 heterozygotic offspring produced were interbred to generate homozygous knockouts and wild-type littermate controls as identified by PCR genotyping. Ten-week-old female wild-type and *Bmp6* null mice were subsequently separated into groups of 7-8, and administered 17beta-estradiol 0, 4, 40, 400, 4000microg/kg/day for 28 days. These doses were selected based on previous studies to identify the full dose-response range for estrogen-induced osteogenesis in mouse long bones. Animals were subsequently sacrificed, long bones removed, and DXA analysis performed on the proximal tibial metaphysis and distal femoral metaphysis using a Lunar PIXI with dedicated mouse software. In line with previous studies where we correlated histological measures of bone formation following estrogen with DXA analysis at these sites, we found a highly significant increase in BMD at the tibial and femoral metaphyses in response to estrogen ($p<0.0001$). However, the response to higher doses of 17beta-estradiol was significantly reduced in *Bmp6* null mice compared to controls (results show mean +/- SEM g/cm^2; *$p<0.01$ versus wild-type mice by one-way ANOVA). We conclude that the osteogenic response of female mouse long bones to high-dose estrogen is impaired in in *Bmp6* null mice, suggesting that BMP-6 plays a non-redundant role in this response that is not fully compensated for by other regulatory pathways.

Sclerostin: An Osteocyte-expressed BMP Antagonist that Inhibits Bone Formation by Mature Osteoblasts. R. L. Van Bezooijen[1], D. Winkler*[2], T. Hayes*[2], M. Karperien[1], A. Visser*[1], L. van der Wee-Pals*[1], H. Hamersma*[3], S. E. Papapoulos[1], J. A. Latham[2], C. W. G. Lowik[1]. [1]Endocrinology, Leiden University Medical Center, Leiden, Netherlands, [2]Celltech Inc., Bothell, WA, USA, [3]Florida Park, Roodepoort, South Africa.

Sclerosteosis is a sclerosing skeletal disorder characterized by generalized progressive bone overgrowth due to loss of the SOST gene product sclerostin. Bone formation is systemically increased, while bone resorption is generally not affected. Sclerostin belongs to the DAN family of BMP antagonists and preferentially binds and inhibits BMP-5 and 6. SOST mRNA expression is restricted to mineralized osteoblastic cultures and, in vivo, to mineralized bone of fetal and neonatal mice. In the present study, using in situ hybridization, we identified osteocytes as the only cells expressing SOST in bone of young adult mice. By immunochemistry, sclerostin protein expression was found to be restricted to osteocytes in human bone specimen of a 22-week-old fetus, a 6-month-old baby, and 16 adults. Interestingly, osteocyte canaliculi and/or lacunae stained positive for sclerostin, suggesting that the protein is transported to neighboring osteocytes or osteoblasts at the bone surface. Specificity of the sclerostin signal was shown by the absence of any signal in bone biopsies of 4 patients with sclerosteosis. Sclerostin treatment of mouse pre-osteoblastic KS483 cell cultures only slightly suppressed alkaline phosphatase activity, an early osteoblast differentiation marker. This is in contrast to other BMP antagonists, such as noggin, that block differentiation of these cells. Sclerostin treatment (1 microg/ml and higher) during specific stages of osteoblast differentiation strongly reduced calcium deposition only when added before onset of mineralization, i.e. before induction of SOST expression. Addition of sclerostin during only the early stages of osteoblast development had no effect. In contrast, noggin blocked calcium deposition when added during only these early stages. In conclusion, sclerostin is a unique BMP antagonist and the first to be associated with a human bone disorder. In contrast to other BMP antagonists, it is specifically expressed by osteocytes and inhibits BMP activity on mature osteoblasts rather than the progenitors and precursors. Sclerostin may be the osteocyte-derived factor controlling the active bone-forming phase of mature osteoblasts as suggested in Marotti's theoretical model. Its absence, as in sclerosteosis, keeps osteoblasts in a state of continuous bone deposition and, as a consequence, increases bone formation.

Targeted Deletion of the TGF-ß type II Receptor in Cartilage. R. Serra, E. Slattery*, P. Sohn*, J. Alvarez*, A. Mukherjee*. Molecular and Cellular Physiology, University of Cincinnati, Cincinnati, OH, USA.

Members of the TGF-ß superfamily are secreted signaling proteins that regulate many aspects of skeletal development. Previously, we demonstrated that dominant-negative interference of TGF-ß signaling in the periosteum/perichondrium of transgenic mice results in increased hypertrophic differentiation in growth plate chondrocytes suggesting a role for the perichondrium in regulating differentiation in the growth plate. Recently, we demonstrated that TGF-ß1-mediated inhibition of growth and hypertrophic differentiation in mouse embryonic metatarsal organ cultures is dependent on the perichondrium. To address the question of the role of TGF-ß signaling directly in chondrocytes, we generated mice with targeted deletion of the TGF-ß type II receptor in cartilage using the cre/lox recombinase system. Mice expressing cre under the control of the type II collagen promoter (Col IIcre) were crossed to mice in which the type II receptor gene was flanked with bacterial loxP sites (TgfbrloxP/loxP). Newborn offspring as well as embryos at 17.5 and 13.5 days of gestation were genotyped to determine the actual versus the expected ratio of each genotype. The ratio of newborn mice with the ColIIcre+/-;TgfbrloxP/loxP genotype was far below expected (7% versus 25%). The ratio of ColIIcre+/-;TgfbrloxP/loxP embryos 17.5 and 13.5 days of gestation were as expected suggesting mice with the ColIIcre+/-;TgfbrloxP/loxP survived until late in gestation but did not survive birth. Next alizarin red/ alcian blue stained skeletons were prepared from embryos at 17.5 days of gestation. Skeletal preparations from ColIIcre+/-;TgfbrloxP/loxP embryos were compared to those from ColIIcre-/-;Tgfbr+/loxP embryos. ColIIcre+/-;TgfbrloxP/loxP embryos were smaller than control embryos. However, no dramatic differences were detected in the length or hypertrophic area of the long bones of the limbs suggesting TGF-ß signaling directly in chondrocytes does not regulate these processes and supporting our model where TGF-ß signals to the perichondrium to regulate development of the long bones. The most dramatic phenotype was observed in the vertebrae. Specifically, each vertebrae was shorter than control and the neural arch and dorsal spine were either absent or not well developed. While the vertebral bodies were only moderately affected, the intervetebral discs were either missing or incomplete. Defects in the connection between the thoracic vertebrae and the ribs were also detected. The data suggest that TGF-ß signaling is critical for proper development of the axial skeleton and we are currently testing hypotheses regarding the mechanism of this regulation.

Quantitative Trait Loci for Spine bone Mineral Density are Linked to Chromosome 19q in Men and Women and to 21q in Women Less Than 50 Years Old. C. M. Kammerer[1], B. D. Mitchell[2], J. L. Schneider*[3], S. A. Cole*[3], J. E. Hixson*[4], R. Perez*[5], R. L. Bauer[5]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University of Maryland School of Medicine, Baltimore, MD, USA, [3]Southwest Foundation for Biomedical Research, San Antonio, TX, USA, [4]University of Texas Health Science Center at Houston, Houston, TX, USA, [5]South Texas Veterans' Health Care Systems, San Antonio, TX, USA.

The San Antonio Family Osteoporosis Study was designed to detect and locate genes that affect bone mineral density (BMD) using data on 34 large, Mexican American families. We performed a genome scan using variance components linkage analysis to detect quantitative trait loci (QTLs) that affect bone mineral density of the spine. Genotypic data on 389 microsatellites (a 9.9 cM map) were available on 657 individuals aged 20 years and older from the largest 23 families. Spine BMD was measured using dual x-ray absorptiometry. Previous analyses of these families revealed that residual heritability of spine BMD was 0.51 overall, but differed between men and women (0.53 vs 0.77), and between women <=50yo and >50yo (0.84 vs 0.56). Therefore, we performed genome scans overall and separately in men (n=258), women (n=399), and women <= 50yo (n=287). Overall, we found suggestive evidence that a QTL on chromosome 19q near locus D19S433 (at 47 cM pter) affects spine BMD (multipoint lod =2.3, nominal p =0.0005). We obtained no evidence for QTLs in men or women analyzed separately (all lods < 1.9), but in women <= 50yo, we obtained significant evidence for a QTL on chromosome 21q near marker D21S1446 at 62cM pter (multipoint lod =3.2, nominal p =0.00006). We also observed suggestive evidence for linkage to 19q in these women (multipoint lods =1.8). Our detection of an additional QTL on 21q in women <=50yo, but not in the other groups, may not be surprising given that heritability of spine BMD was highest among this group. This QTL may also have sex-specific effects on spine BMD. We conclude that QTLs affecting variation in spine BMD may be located on chromosomes 19q and 21q.

1080

Gender Sensitivity for an IGF-I Quantitative Trait Locus (QTL): Defining the Interaction of Estrogen and IGF-I in Peak Bone Acquisition. C. J. Rosen[1], R. Klein[2], E. Orwoll[2], M. L. Bouxsein[1], L. R. Donahue[1], C. Ackert-Bicknell*[1], K. L. Shultz*[1], W. G. Beamer[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Oregon Health Sciences University, Portland, OR, USA.

The strongest quantitative trait loci (QTL) for serum IGF-I in female C3HxB6 F2 mice is located in a 20cM region on Chr 6. This epistatic QTL reduces serum IGF-I and accounts for 8% of the variance among F2 mice. Female N10F2 congenic(6T) mice were constructed so that *c3* alleles from Chr 6 were backcrossed into B6 (N10); female 6T mice have serum and hepatic (but not bone) IGF-I expression 20-25% lower than B6 throughout puberty with smaller femorae and reduced trabecular connectivity. Male 6Ts differ from females by having low serum IGF-I but only at 16 weeks;although femoral BMD is reduced in males, femoral length and area are identical to B6. Hence,based on this gender difference we hypothesized that estrogen might modulate the action of gene(s) contained within this QTL.To test that tenet, we first wanted to establish that the QTL on Chr 6 was gender specific. We measured serum IGF-I in > 300 male and female 16 week mice from 23 BXD RI strains and performed whole genome scanning. An IGF-I QTL for female mice only on Chr 6 (p= 2.3 $x10^{-3}$) mapped to a region identical to the QTL for the C3B6 F2 female mice. In the RIs, there was strong gender x strain effect (p=1.0x 10^{-4}). Next, to test the role of estrogen in modulating IGF-I in the congenic, we ovariectomized 4 month 6Ts and compared them with ovariectomized congenics on B6 carrying a QTL from C3H for BMD but not IGF-I (4T)and ovx'd B6 littermates. Femoral BMD and IGF-I were measured 6 weeks after ovx. Despite similar rates of bone loss post ovx, serum IGF-I increased in 6Ts but not 4Ts or B6;this increase (249 $\pm$ 12 to 289 $\pm$11 ng/ml;p=0.003)brought serum IGF-I levels close to basal sham B6 and ovx B6 levels (IGF-I sham B6:300 $\pm$ 10;ovx B6:306$\pm$30ng/ml). In conclusion the Chr 6 QTL for serum IGF-I: 1) contains an important gene that down-regulates IGF-I expression in several strains of mice; 2) is gender sensitive and exerts it effect on IGF-I during early phases of rapid linear growth and bone acquisition in females; 3) is regulated by endogenous estrogen concentrations. Identifying the gene within this QTL may elucidate the interaction between estrogen, IGF-I and bone acquisition.

Congenic Strain	4-T (n=21)	6-T (n=19)	P: 6-T vs 4-T
% decrease in Tot Fem BMD (ovx vs sham-ovx)	-5.9 +/- 2.3%	-5.2 +/- 1.3 %	0.800
% increase IGF-I (ovx vs sham-ovx)	+0.00 +/- 2.0%	+16.2 +/- 4.1%	0.0003

1081

Characterization of Mutations in the Chloride Channel 7 (ClCN7) Gene That Cause Autosomal Dominant Osteopetrosis, Type II. S. G. Waguespack[1], K. E. White[2], D. L. Koller[3], G. Carn*[2], K. A. Buckwalter*[4], W. E. Evans*[2], M. L. Johnson*[2], M. Kocisko*[2], T. Foroud[3], M. J. Econs[5]. [1]Medicine and Pediatrics, Indiana University, Indianapolis, IN, USA, [2]Medicine, Indiana University, Indianapolis, IN, USA, [3]Medical and Molecular Genetics, Indiana University, Indianapolis, IN, USA, [4]Radiology, Indiana University, Indianapolis, IN, USA, [5]Medicine and Medical and Molecular Genetics, Indiana University, Indianapolis, IN, USA.

Autosomal dominant osteopetrosis, Type II (ADO2) is an uncommon sclerosing bone disorder with a distinct radiographic appearance and unique clinical characteristics. We currently present the results from genetic studies designed to identify the ADO2 gene through a positional candidate approach. Initially, linkage studies were undertaken in our 7 largest kindreds and a summed maximum LOD score of 15.91 was observed at marker D16S521 on chromosome 16p13.3. Critical recombinations in affected subjects further narrowed the putative gene region to a 7.6 cM (3.5 Mb) region between markers D16S521 and D16S3027. Multiple candidate genes were identified in this region, including ATP6L and ClCN7. Mutational analysis of the 3 exons of the ATP6L gene revealed no mutations in affected subjects from 13 different families. Concomitantly, ADO2 was reported to result from mutations in the chloride channel 7 (ClCN7) gene (Cleiren et al. 2001 Hum Mol Genet 10:2861-7). Direct DNA sequencing of ClCN7 exons revealed one novel and two known missense mutations in 5 kindreds, three of which were large families that had previously been linked to this area. Families EOP2, EOP17, and EOP19 shared the same mutation (R286W) in exon 10, family EOP10 had a mutation (R767W) in exon 24, and

EOP8 was found to have a novel mutation (R762L) in exon 24. The latter mutation, which occurred in a sporadic yet typical case of ADO2, was confirmed through repeat sequencing of the proband and RFLP analysis of the proband plus 82 control subjects. In families with non-sporadic cases (EOP2, EOP10, and EOP17), the known ADO2 mutations segregated with the disorder in at least three generations and were not detected in a minimum of 50 control subjects. Mutation analysis of the ClCN7 gene continues in our other osteopetrosis families, including 4 kindreds with suggestive linkage to chromosome 16p13.3. In summary, we report the results of our positional candidate studies to identify the ADO2 gene. In five osteopetrosis families we have identified one novel and two known missense mutations in the ClCN7 gene. Furthermore, our data, in concert with that of others, suggests that genetic heterogeneity does not exist in ADO2. We conclude that mutations in the ClCN7 gene are responsible for the sclerotic bone disorder, ADO2.

1082

Novel Polymorphisms in the Promoter of the 24-Hydroxylase Gene Alter Transcriptional Activity. N. Schuetze[1], O. Poeppelmeier*[2], B. Mentrup*[3], C. Schohe-Reiniger*[2], F. Jakob*[2]. [1]Molecular Orthopaedics, Orthopaedische Universitaetsklinik, Wuerzburg, Germany, [2]Orthopaedische Universitaetsklinik, Wuerzburg, Germany, [3]Abteilung Molekulare Innere Medizin, Medizinische Poliklinik, Wuerzburg, Germany.

24-hydroxylase (24OHase) is involved in controlling local and circulating levels of 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) by inactivating the active hormone to 1,24,25(OH)3D3. Additionally, this enzyme also generates 24,25(OH)2D3 from 25(OH)D3. This metabolite locally plays an important role and signals via a specific membrane receptor. A region within the promoter of the gene 24OHase containing two A-stretches was analyzed by fragment analysis and sequencing using an ABI 310 sequencer. PCR products from genomic DNA were subcloned into the pGL3 basic plasmid. Plasmids were transiently transfected into osteoblasts and chondrocytes by electroporation and promoter activity was measured in triplicate and expressed as luciferase units per µg protein. 24OHase promoter sequences were amplified from 72 human DNA samples. Performing fragment analysis 27 PCR products displayed variations in peak patterns indicative for polymorphisms of the respective genomic DNA. Variations in the length of the oligo-A stretches in the 24OHase promoter were found in 1/3 of the samples and a 5bp insertion was detected in 4 cases. Promoter constructs containing up to 580nt´s downstream of the transcriptional start site representing the published promoter of the 24OHase gene as well as constructs with the detected polymorphisms were transfected into human osteoblasts (hFOB-cells) and chondrocytes (T/C 28-1cells). Marked differences in promoter activity were observed reproducibly in both cell lines (n=7 independent experiments). Addition of 1 or 2 A-residues within the A-stretches enhanced promoter activity 2.5fold and 3fold, respectively, compared to the wild type promoter. The plasmid containing an insertion within the A-stretch displayed a 1.5fold reduced promoter activity. These altered transcriptional activities were obtained at basal conditions (no treatment of cells) and were maintained under conditions of 4-6fold promoter activation due to treatment with 10nM 1,25(OH)2D3. In summary, several new polymorphisms were detected in the promoter of the human 24OHase gene. These sequences markedly influenced promoter activty in vitro. Therefore, the detected novel polymorphisms within the promoter might correspond to altered enzyme activity of 24OHase in vivo within the human population. We conclude that altered transcriptional activities of the alleles of the 24OHase gene in vivo might influence vitamin D metabolism as well as local signaling of 24,25(OH)2D3.

Dissociation of the Genetic and the Epigenetic Defect at the *GNAS1* Locus in Pseudohypoparathyroidism 1b. S. M. Jan de Beur, C. Ding, J. Y. Cho*, M. A. Levine. Medicine and Pediatrics, Johns Hopkins University, Baltimore, MD, USA.

Subjects with pseudohypoparathyroidism 1b (PHP 1b) have renal resistance to PTH and lack Albright hereditary osteodystrophy. By contrast to PHP 1a, levels of Gsα protein are not reduced, and the 13 exons of *GNAS1* that encode Gsα are normal. *GNAS1* has 3 upstream alternative first exons (NESP55, XLαs, and exon A) that are bidirectionally imprinted. The recent demonstration that subjects with PHP 1b have defects in methylation of maternally inherited *GNAS1* alleles suggests that an imprinting defect that affects expression of *GNAS1* in the proximal renal tubule is the basis for this disorder. The specific genetic mutation(s) that accounts for this epigenetic defect is unknown, however. To understand the relationship between the genetic defect and the epigenetic defect in PHP 1b, we studied five multigenerational PHP 1b families. Using linkage analysis, we found that the genetic defect causing PHP 1b maps to a 5.7 cM interval on chromosome 20q13 that includes part of *GNAS1* and regions telomeric to *GNAS1*. Based on this analysis, disease-associated haplotypes were identified. In addition, we analyzed allelic expression and methylation of CpG islands within exon A of *GNAS1* in these five PHP 1b kindreds. cDNA transcribed from total RNA from mononuclear cells or transformed lymphoblasts was amplified with a downstream primer in exon 6 and an upstream primer in exon A of *GNAS1*. PCR products were directly sequenced and allelic expression was determined using polymorphisms in exon 5 or exon A. The methylation status of exon A was determined by sequencing bisulfite-treated genomic DNA or by restriction endonuclease analysis with *NgoM*IV, a methylation-sensitive enzyme. In the PHP 1b kindreds investigated, all subjects with PTH resistance showed loss of methylation of the exon A region on the maternal *GNAS1* allele and/or biallelic expression of exon A-containing transcripts. Moreover, affected subjects had a maternally-inherited, disease-associated haplotype, whereas unaffected subjects who were obligate gene carriers had inherited the same haplotype paternally. Remarkably, analysis of one pedigree demonstrated a novel dissociation between inheritance of the disease-associated locus and the epigenetic *GNAS1* defect as members of the same sibship showed either PTH resistance or PTH responsiveness despite having inherited the same *GNAS1* haplotype from their mother. The absence of the epigenetic defect in subjects who have inherited a defective maternal *GNAS1* allele yet lack hormone resistance indicates that the genetic mutation may be incompletely penetrant, and implies that the epigenetic defect and not the genetic mutation is the cause of renal resistance to PTH in PHP 1b.

The Osteopetrotic Mutation toothless (tl) Is a Loss-of-Function Mutation in the Rat CSF-1 Gene, Confirming a Crucial Role for CSF-1 in Osteoclastogenesis and Endochondral Ossification. W. Van Hul[1], P. R. Odgren[2], L. Van Wesenbeeck*[1], F. F. Safadi[3], S. N. Popoff[3], S. C. Marks[2]. [1]Medical Genetics, University of Antwerp, Antwerp, Belgium, [2]Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA, [3]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA.

The biology and actions of the monocyte/macrophage colony stimulating factor CSF-1 (mCSF) have been elucidated by numerous studies that utilise the naturally occurring CSF-1 frameshift mutation in the osteopetrotic (op) mouse. Along with many abnormalities in the immune and reproductive systems, the op mouse is deficient in bone-resorbing osteoclasts, which over the first few months of life corrects itself. Another rodent osteopetrotic mutation, the toothless (tl) mutation in the rat, has been well-characterized phenotypically, but the genetic lesion has remained unknown. tl is an autosomal recessive mutation whose skeletal consequences include severe osteopetrosis with profound-, unresolving osteoclastopenia, growth deficiency, progressive growth plate chondrodysplasia and abnormal angiogenesis, among other pathologies. Some, but not all, of these benefit from injections of recombinant CSF-1. To evaluate the causal role of the CSF-1 gene in the tl phenotype, we looked for the chromosomal localization of the phenotype-causing gene. Based on the analyses of polymorphic markers in outcrossed animals, evidence was obtained for the assignment of the tl-causing gene to the region of chromosome 2 harboring the CSF-1 gene. Subsequent mutation analysis of the CSF-1 gene in tl rats identified a 10-base-pair duplication in exon 1 resulting in a frameshift mutation and an early stopcodon. The mutated sequence is also present in tl CSF-1 cDNA. The phenotype of the op mouse, caused by a frameshift mutation in exon 4, is far milder than the tl rat: op mice have some osteoclasts, they don't develop the growth plate chondrodystrophy seen in tl rats, and they spontaneously recover over the first few months of life. This difference might be explained if the tl rat represents a genuine CSF-1 loss-of-function mutation and the op mouse is a "leaky" mutation, perhaps due to alternative splicing, as previously proposed. Our findings suggest that a critical re-assessment of studies that have assumed a complete loss of CSF

1085

Rate of Hip Bone Loss Is Greater Among Caucasian vs. African-American Women. J. A. Cauley[1], L. Lui[2], K. L. Stone[2], K. E. Ensrud[3], T. Hillier[4], M. C. Hochberg[5], S. R. Cummings[2]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University of California, San Francisco, CA, USA, [3]University of Minnesota, Minneapolis, MN, USA, [4]Kaiser Center for Health Research, Portland, OR, USA, [5]University of Maryland, Baltimore, MD, USA.

African-American women have higher bone mineral density (BMD) and experience lower fracture rates than Caucasian women. Little is known, however, about the racial/ethnic differences in the rate of bone loss. In the current study, we tested the hypothesis that the rate of hip bone loss is greater in Caucasian women compared with African-American women and in both groups, the rate of bone loss increases with age. We compared 6,007 Caucasian women (mean age 73 yr) with 482 African-American women (mean age 75 yr) enrolled in the Study of Osteoporotic Fractures. Total hip and femoral neck BMD was measured by DXA (QDR 1000 or 2000, Hologic Inc., Bedford, MA). The type of scanner was the same across visits. The average interval between DXA scans was 3.5 years ± 0.4, Caucasians and 2.0 years ± 0.1, African-Americans. Stepwise linear regression was used to compare differences in the rate of bone loss between ethnic groups adjusting for factors previously shown to predict bone loss in Caucasians including age, weight change, smoking, grip strength, estrogen, diabetes and pulse rate. The African-American women had a greater body weight, grip strength, initial BMD and a higher prevalence of diabetes than Caucasian women. There was no difference in current smoking or use of estrogen. The multivariate-adjusted average annualized percent rate of change in bone density among Caucasian and African-American women respectively was -0.57% and -0.33% ($p< 0.0001$) at the total hip and -0.51% and -0.31% ($p=0.04$) at the femoral neck. The annualized rate of bone loss was higher among women age ≥75 compared with women < age 75 in both ethnic groups but within each age group, African-American women lost less bone (Table).

Table: Annualized % Bone Loss in African-American and Caucasian Women by Age

	African-American		Caucasian	
Total Hip	(n)	Mean ± SD	(n)	Mean ± SD
Age < 75	(255)	-0.08 ± 1.9	(4188)	-0.44 ± 1.4
Age ≥ 75	(227)	-0.61 ± 2.1	(1819)	-0.89 ± 1.6
Femoral Neck				
Age < 75	(255)	-0.09 ± 3.1	(4188)	-0.45 ± 1.7
Age ≥ 75	(227)	-0.42 ± 3.5	(1819)	-0.65 ± 1.9

In conclusion, the rate of bone loss was greater among Caucasian than African-American women. But, within each race, the rate of bone loss increased with advancing age, especially among African-American women.

1086

Volumetric Femoral Neck Bone Density as a Single Measure of Hip Fracture Risk in Men and Women. J. R. Center, T. V. Nguyen, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, NSW, Australia.

Proximal femur bone density T-scores are widely used to indicate fracture risk based on epidemiological and non randomized controlled trial data in women. An equivalent cut-off value for men has not been determined although - 2.5 SD is commonly used clinically without adequate supportive evidence, particularly considering areal BMD is higher for men than women. Areal bone density does not account for bone depth, such that a larger bone will generally have a greater areal BMD for the same true volumetric density. The aim of this study was to examine whether volumetric BMD, calculated using estimated mean femoral neck width, may be a more appropriate measure to determine hip fracture risk between men and women. Of 925 women and 658 men followed prospectively for 10.4 ± 2.7 years (mean ± SD) from the Dubbo Osteoporosis Epidemiology Study, 73 women and 23 men had a hip fracture following or within 3 months of a DXA scan. Hip fracture subjects were older than their non-fracture counterparts (77 ± 8 vs 70 ± 7 years, p = 0.0001). Areal BMD was lower in women than men for both hip fracture (0.63 ± 0.11 vs 0.76 ± 0.14 g/cm2, p = 0.0001) and non-fracture subjects (0.81 ± 0.12 vs 0.93 ± 0.15 g/cm2, p = 0.0001). In contrast, although volumetric BMD was also lower in the hip fracture subjects it did not differ between sexes. Volumetric BMD was 0.25 ± 0.04 g/cm3 and 0.26 ± 0.04 g/cm3 for women and men, respectively with hip fractures and 0.31± 0.06 g/cm3 for both women and men without fractures. The sensitivity of a T-score for hip fracture prediction was similar in women for both areal (73%) and volumetric (78%) BMD. However, a volumetric BMD T-score was more sensitive than an areal BMD T-score in men (70% vs 43%) with similar specificity for women (77% vs 75%, men and women, respectively). These data indicate that, with a volumetric estimate of hip BMD, the differences between men and women disappear and that men and women with hip fractures have a similar but lower volumetric BMD than non-fracture men and women. The similar sensitivity of volumetric T-scores in hip fracture prediction between men and women suggest that volumetric femoral neck BMD could be used as a single measure of hip fracture risk in both sexes.

1087

Elderly Long Term Care Residents Continue to Lose Bone, but not Uniformly. K. E. Broe[1], M. T. Hannan[2], C. E. Stewart*[1], D. P. Kiel[2]. [1]Hebrew Rehab Ctr for Aged, Boston, MA, USA, [2]Hebrew Rehab Ctr for Aged & Harvard Med Sch, Boston, MA, USA.

Elderly long-term care (LTC) residents are at high risk of morbidity and mortality due to complications from osteoporotic fracture. Maintaining bone mineral density (BMD) remains a strategy to prevent future fracture in this population. Although longitudinal studies of community-dwelling older persons have shown that bone loss continues into the eighth and ninth decades, the pattern of bone loss among elderly LTC residents has not been clearly established. Therefore, we examined BMD change over two years among residents of a LTC facility in Boston, MA. Participants included 170 residents (123 women, 47 men) aged 69 to 100 years (mean: 88 yrs ±6) who had baseline BMD measured between 1992 and 1997 and at least one annual follow up exam. BMD was measured in g/cm^2 using a Hologic, QDR 1000W at the femoral neck, trochanter, total femur, radial shaft, ultra distal radius and whole body. Rate of BMD change was calculated as sex-specific annual percent change in BMD for each skeletal site. Participants were split into three groups (≤ 85 yrs, 86-91 yrs, and ≥ 92 yrs) and rates of change were compared among age-groups separately by gender. Both women and men had bone loss at all sites. In women, the greatest amount of bone loss occurred at the radial shaft with women losing on average 1.8% per year followed by the total hip site with losses averaging 1.6% per year. In men, the greatest bone loss occurred at the femoral neck with an average loss of 2.3% followed by the total femur (1.5% per year). The whole body site showed the least amount of loss for both women and men. Bone loss did not appear to differ between age-groups at any of the BMD sites (p-trend ≥0.21) except the whole body for which the oldest women (≥ 92 yrs) had significantly increased whole body losses compared with those women in the younger age-groups (mean annual change: ≤ 85 yrs =(+0.3%), 86-91 yrs=(-0.1%), ≥ 92 yrs=(-1.6%), p-trend=0.0005). While all BMD sites, on average, showed bone losses, there was much variability in BMD change. Across all BMD sites, at least 45% of participants had no change (less than ±1%) or actually had an increase in BMD. At the femoral neck site, 28% of participants had no change while an additional 17% had an increase of 1% or more. We conclude that bone loss occurs among elderly LTC residents, but the magnitude of loss does not appear to increase with age. In fact, some residents lost significant amounts of bone while others maintained or even gained BMD. Further understanding of the factors that contribute to BMD change will help in developing additional strategies to care for LTC residents most at risk for bone loss.

1088

Maternal History of Osteoporosis Is Related to Femur Bone Density and Geometry in Men and Women. A. C. Looker[1], T. J. Beck[2]. [1]Natl Ctr Health Stats, CDC, Hyattsville, MD, USA, [2]Johns Hopkins University, Baltimore, MD, USA.

Results from previous studies suggest that family history may affect fracture risk via skeletal factors other than bone density. To address this question, we examined differences in femur neck areal BMD values collected from 5371 non-Hispanic whites ages 20+ years in the third National Health and Nutrition Examination Survey (NHANES III, 1988-94) by reported maternal history of osteoporosis (OP HX). We supplemented the conventional areal BMD data (Hologic QDR 1000) with measurements of areal BMD and geometric properties (subperiosteal width, section modulus, cortical thickness and buckling ratio) made on the same scan data at narrow "cross-sectional" regions traversing the femoral neck and the proximal shaft using a structural analysis program. 221 men and 331 women reported a positive OP HX (e.g., their biological mother had sustained a hip fracture after age 50 years or had a physician's diagnosis of osteoporosis). Differences in bone density and geometry by OP HX were examined after adjusting for potential confounding variables (age, body weight, smoking, personal diagnosis of osteoporosis, health status and hormone use). Several bone parameters differed by OP HX in both sexes at the femur neck, but none differed at the femur shaft. At the neck, those with a positive OP HX had values that differed by ~3-4% (lower for BMD, BMC, cross sectional area, section modulus, and cortical thickness; higher for buckling ratios) from those with a negative OP HX ($p < 0.05$). The relationship between OP HX and these variables did not differ significantly by age in either men or women. In conclusion, regardless of age, both men and women with a positive maternal history of osteoporosis may be at greater risk of femur neck fracture due to thinner cortices and less bone mineral content, which in turn results in potentially less bending strength (section modulus) and greater cortical instability (buckling ratio) at this skeletal site.

The Impact of Magnesium Intake on Fractures: Results from the Women's Health Initiative Observational Study (WHI-OS). R. D. Jackson[1], T. Bassford*[2], J. Cauley[3], Z. Chen[2], A. LaCroix[4], A. Sparks*[4], J. Wactawski-Wende[5]. [1]The Ohio State University, Columbus, OH, USA, [2]University of Arizona, Tucson, AZ, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]WHI Coordinating Center, Seattle, WA, USA, [5]University of Buffalo, Buffalo, NY, USA.

Magnesium (Mg) deficiency has been associated with the development of parathyroid hormone resistance. Previous studies have suggested that higher Mg intakes may be associated with a higher bone mass but there are no data regarding the role of magnesium intake on fracture risk. We examined the relationship between Mg intake and hip, wrist/lower arm and other clinical fractures in 89,717 postmenopausal women age 50-79 years enrolled in the WHI-OS. Total daily Mg intake was defined as the sum of dietary Mg intake ascertained from Food Frequency Questionnaire and supplement use through direct observation by interviewers, coded using the Medispan database. The average daily Mg intake for the cohort was 320.4 mg/day: 246.9± 98.7 mg/d from diet and 73.5± 154.7 mg/d from supplement. During 4.4 years of follow-up, there were 321 hip, 1582 wrist/lower arm and 4712 other clinical fractures. Incidence of hip and other clinical fractures were similar across the quintiles of Mg intake (0.96 hip fractures and 17.94 other fractures/1000 person-years respectively). In contrast, rates of wrist/lower arm fractures increased in participants with the highest Mg intake relative to the four lower quintiles of Mg intake (5.50 fractures versus 4.56 fractures/1000 person-yrs). Using Cox proportional hazards analyses (with adjustment for age, BMI, smoking, alcohol, exercise, current estrogen use, calcium and history of fracture), the relative hazard (RH) associated with the highest quintile of Mg intake (>431 mg/day) was 1.05 (95% confidence interval 0.77-1.43) for hip fracture, 1.21 (1.06-1.38) for wrist/lower arm fracture and 1.02 (0.96-1.10) for other clinical fractures. The relationship of high Mg intake and wrist/lower arm fracture was stronger in women age 50-64 [RH 1.4 (1.11-1.77)] and with current HRT use [RH 1.57 (1.16-2.14)]. Although there was a relationship between higher Mg intake and higher calcium intake, stratification based on calcium intake did not reveal any significant associations. These findings indicate that high Mg intake does not confer a protective effect against fracture and in fact, may increase the risk of wrist/lower arm fractures in the large WHI-OS cohort.

How Many Deaths from Hip Fracture Might Be Prevented. J. A. Kanis[1], H. Johansson*[2], A. Oden*[2], B. Jonsson*[3], O. Johnell*[4], C. De Laet*[5]. [1]WHO Collaborating Centre for Metabolic Bone Diseas, University of Sheffield Medical School, Sheffield, United Kingdom, [2]University of Stockholm, Stockholm, Sweden, [3]Stockholm School of Economics, Stockholm, Sweden, [4]Malmo General Hospital, Malmo, Sweden, [5]Institute for Medical Technology Assessment, Rotterdam, Netherlands.

Excess mortality is well described after hip fracture. They are in part related to co-morbidity and in part causally related to the hip fracture event itself. The aim of this study was to examine the quantum and pattern of mortality following hip fracture. We studied 160,000 hip fractures in men and women aged 50 years or more in 28.8 million person years from the patient register of Sweden using Poisson nmodels applied to hip fracture patients and the general population. At all ages the risk of death was markedly increased immediately after the event. After a period of declining risk, the risk increased at a rate that was higher than that of the general population. The latter function was assumed to account for deaths related to comorbidity and the residuum assumed to be causally related deaths. Causally related deaths comprised 17-32% of all deaths associated with hip fracture (depending on age) and accounted for more than 1% of all deaths in the population aged 50 years or more. Hip fracture was a more common cause for mortality than pancreatic or stomach cancer. Thus, interventions that decreased hip fracture rate by say 50%, would avoid 0.5% or more of all deaths. This conclusion depends critically upon our assumptions concerning avoidable deaths, but to test this assumption on hip fracture mortality would require an intervention trial of more than 2,000,000 patients.

Monitoring Progression of Breast Cancer Cells in Bone/Bone Marrow by Optical Imaging: Bisphosphonates do not Suppress Tumor Growth Rate and Tumor Burden. G. van der Pluijm[1], B. Sijmons*[1], I. Que*[1], J. Buijs*[1], M. Cecchini*[2], C. Löwik[1], S. Papapoulos[1]. [1]Endocrinology, Leiden University Medical Center, Leiden, Netherlands, [2]Urology, University Hospital, Berne, Switzerland.

Bone metastases are common in patients with breast and prostate cancer and cause considerable morbidity and deterioration of the quality of life. Bisphosphonate (Bp) treatment reduces skeletal-related events by inhibiting tumor-induced osteolysis. In addition, local anti-tumor effects of Bps have been reported in vitro and in an in vivo model of metastatic bone disease. In the latter model, however, evaluation of tumor burden was assessed by measuring lytic bone lesion areas (radiographs) and histomorphometric analyses of tumor areas within the bone collar. In most studies, therefore, the suggested reduction in tumor burden is based primarily on the osteoprotective properties of Bps. Recently, we established an extremely sensitive, non invasive, optical imaging method to detect, monitor and quantify luciferase transfected tumor cells (MDA-MB-231/luc+) in vivo. Optical imaging also enables continuous monitoring in the same animal of growth kinetics for each metastatic site and allows the measurement of the overall tumor burden by photon counting (Am. J. Pathol. 160:1143,2002). We applied this model to determine the effects of different Bps on the local progression of human breast cancer cells in the bone/bone marrow microenvironment. One week after intraosseous injection of MDA-MB-231/luc+ cells into the tibiae of nude mice, the animals were treated with various high doses of bisphosphonates (clodronate, pamidronate, olpadronate) previously shown to completely inhibit osteoclastic bone resorption. Bps were either given continuously (mini-osmotic pumps) or by daily s.c. injections for 28 days. As expected, all tested Bps significantly inhibited cancer-induced bone destruction measured by osteolytic bone areas. In contrast, however, the tested Bps did not inhibit tumor progression when quantified by optical imaging (photon counting after 1-2-3-4 weeks) confirmed by histomorphometrical analysis at the end of each experiment. Our data, therefore, provide no evidence of an anti-tumor effect by Bps despite the observed protection of bone integrity.

1092

OPG Inhibits the Progression of Bone Destruction and Skeletal Tumor Burden in Mice With Established Osteolytic MDA-231 Breast Cancer Metastases. S. Morony, K. Warmington*, H. Tan, V. Shalhoub, G. Chow*, C. R. Dunstan, D. L. Lacey, P. J. Kostenuik. Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA.

OPG, a RANKL decoy receptor, inhibits osteoclast formation and activation by preventing RANKL-RANK interactions on osteoclasts and their precursors. We previously demonstrated that OPG treatment started at the time of MDA-231 cell inoculation inhibited tumor-associated osteolysis and reduced skeletal tumor burden (Morony et al, Cancer Res 61: 4432, 2001). The present study tested whether OPG treatment would prevent the progression of osteolysis and skeletal tumor burden after MDA-231 lesions were already established in bone. Nude female mice were inoculated in the left ventricle with MDA-231 tumor cells. Three weeks later, digitized radiographs of all mice were analyzed to quantify the area of osteolytic lesions. Mice without radiographic evidence of osteolysis were excluded from the study. The remaining mice were allocated to groups that had similar average baseline areas of osteolysis. At baseline, group means for area of osteolysis ranged from 0.88 to 0.99 mm2/mouse (n=13-15/group). One group of tumor-bearing mice was sacrificed prior to treatment for the histological determination of baseline skeletal tumor burden (1.87 ± 0.6 mm2/mouse). Mice were treated with PBS (vehicle) or with OPG (3 mg/kg, SC) on days 23, 24, 27, 29, and 31 post inoculation, and were sacrificed on day 31. The radiographic area of osteolysis increased by 400% during PBS treatment (3.31 ± 0.44 mm2/mouse, p<0.01) and decreased by a non-significant 19% (0.81 ± 0.19 mm2/mouse) during OPG treatment. Histologically, skeletal tumor burden increased 210% (5.79 ± 1.32 mm2/mouse, p<0.01) during PBS treatment, while the increase during OPG treatment was a non-significant 32% (2.47 ± 0.82 mm2/mouse). The differences in osteolysis and skeletal tumor burden between OPG and PBS treated groups were statistically significant (p<0.01). OPG treatment also reduced the number of osteoclasts per mm2 of skeletal tumor area by 96% vs. PBS treated mice (p<0.01). The inhibitory effect of OPG on skeletal tumor burden might be related to the inhibition of bone resorption. A direct effect of OPG on tumor cells was not supported by cell culture studies. Neither OPG nor RANKL had any effect on MDA-231 cell number during 48 h of culture with various concentrations of fetal bovine serum. These data support the hypothesis that OPG indirectly inhibits MDA-231 tumor burden in bone via its potent antiresorptive effects. The ability of OPG to suppress the bone destruction and the skeletal tumor burden associated with established osteolytic lesions underscores the potential utility of OPG as a therapeutic option for the treatment of metastatic bone disease.

1093

Gene Transfer of Osteoprotegerin-Fc Inhibits Osteolysis and Disease Progression in a Murine Model of Multiple Myeloma. P. Doran[1], S. J. Russell*[1], D. Chen*[2], S. M. Greiner*[1], J. Ludvigson*[1], S. Khosla[1], B. L. Riggs[1]. [1]Mayo Clinic, Rochester, MN, USA, [2]Amgen Inc., Thousand Oaks, CA, USA.

Multiple myeloma has major adverse skeletal effects, including bone pain, pathologic fractures, and hypercalcemia, that are only transiently and incompletely reversed by currently available therapy. Osteoprotegerin (OPG) potently inhibits osteoclast differentiation and activation, but, if used therapeutically, it or the more prolonged-acting OPG-Fc-fusion protein analog require repeated subcutaneous injections. Gene therapy has shown promise in the treatment of various malignancies. Thus, as proof-of-principle for antiresorptive gene therapy of osteolytic bone disease, we evaluated the effect of *ex vivo* OPG-Fc gene transfer in a murine model of multiple myeloma. In this model, injection of human ARH-77 cells into 6-week-old SCID mice results in severe osteolytic lesions. In the therapeutic group, the injected ARH-77 cells were stably transduced with the OPG-Fc-fusion protein gene using a replication-incompetent lentiviral vector (OPG-Fc, n=18). Effects were compared with those in positive control mice (PC, n=19) injected with the same number of ARH-77 cells that were similarly transduced with a non-expressing control vector, and with those in negative control mice (NC, n=20) that did not receive ARH-77 cells. The mean ± SEM level of serum OPG-Fc levels obtained at sacrifice was undetectable (<0.02 ng/mL) in the control groups but was 966 ± 239 ng/mL at sacrifice (P<0.001) in the OPG-Fc expressing group. None of the NC mice developed any disease manifestations. The median time for onset of partial paraplegia was 22 days in the PC as compared to 30 days in the OPG-Fc mice (P<0.001), and complete paraplegia occurred in 84% of PC as compared to 39% of OPG-Fc mice (P<0.001). Total body BMD was greater at 4 weeks in the OPG-Fc mice (0.0404 ± 0.0004 g/cm^2) than in the PC and NC mice (0.0394 ± 0.0003, P=0.05 and 0.0393 ± 0.0003, P=0.04, respectively). Osteolytic radiographic lesions developed in 78% of PC mice, but in only 17% of the OPG-Fc expressing mice (P<0.001). There were similar differences when osteolytic lesions were quantified by number, diameter, and the sum of diameters (all P<0.001). Finally, median survival time was 32 days compared with 37 days in the PC and OPG-Fc groups, respectively (P=0.005). In conclusion, our finding that *ex vivo* OPG-Fc gene transfer dramatically attenuates the skeletal manifestations of murine multiple myeloma suggests that therapeutic gene transfer using this or other genes offers considerable promise as a novel therapy for neoplastic bone disorders, either alone or in combination with conventional therapies.

Bisphosphonates Induce Apoptotic Prostate Cancer Cell Death in Vitro. J. C. Dumon*[1], F. Journé*[1], N. Khedoumi*[1], L. Lagneaux*[2], J. J. Body[1]. [1]Lab. of Endocrinology and Breast Cancer Research, Inst. J. Bordet, Free University of Brussels, Brussels, Belgium, [2]Lab. of Hematology, Inst. J. Bordet, Free University of Brussels, Brussels, Belgium.

Bone tissue is the most common site of distant metastases in breast and prostate cancers. Bisphosphonates have been shown to reduce the morbidity rate of metastatic bone disease from breast cancer and, quite recently, also from prostate cancer. These effects are attributed to their powerful inhibitory activity on osteoclast-mediated bone resorption. We have shown that bisphosphonates also induce human breast cancer cell death in vitro (Fromigué et al., JBMR 2000). We have now investigated their effects on the survival, growth and death of prostate cancer cells (PC3) in vitro after 1, 2, 4 and 6 days of incubation. We tested four bisphosphonates at doses ranging from 10-8 to 10-4M: clodronate (Clod), ibandronate (Iban), pamidronate (Pam), and zoledronate (Zole). The inhibitory effects on PC3 cells viability (evaluated by the MTT test) were maximal at 10-4M and this concentration was used for further experiments. The MTT results are summarised below as % of control cell survival (mean±SEM). Total DNA content was also decreased at day 6: to 46±6% for Clod, to 31±3% for Iban, to 46±2% for Pam, and to 4±0.2% for Zoledronate. FACS experiments showed that, at day 1, there was already a marked decrease (except for clodronate) in the number of cells in "Synthesis and Mitosis" phases (decreases of 24% for Iban, 57% for Pam, and 43% for Zole). At day 4, according to the bisphosphonate, 50% to 90% of the cell population was apoptotic. In conclusion, bisphosphonates caused an early inhibition of prostate cancer cell proliferation followed by cell death, essentially through apoptosis. Zoledronate was the most potent compound with an almost complete cell death at day 6. Such effects could contribute to the beneficial role of bisphosphonates in the treatment and the prevention of prostate cancer-induced bone disease.

	Clod	Iban	Pam	Zole
Day 1	100±5	95±5	85±12	89±5
Day 2	101±12	90±3	67±5	71±7
Day 4	80±5	75±12	56±15	71±6
Day 6	77±7	70±6	49±9	16±6

Apomine, a Novel Bisphosphonate Ester, Is a Potent Antiproliferative Drug: A Comparison with Risedronate. N. Lameloise*, Y. Guyon-Gellin*, S. Nolli*, P. Villemin*, P. Latin*, D. Masson*, E. J. Niesor. Biosciences and Pharmacology, Ilex Oncology Research, Versoix, Geneva, Switzerland.

Apomine, a novel bisphosphonate ester, increases HMG-CoA reductase degradation *in vitro*, thus depleting the isoprenoid pool generated by the mevalonate-isoprenoid-cholesterol (MIC) synthetic pathway. On the other hand, risedronate has been shown to inhibit farnesyl-PP synthase, another enzyme of the MIC pathway. Therefore, Apomine and risedronate may act on cell proliferation by decreasing Ras/Rho isoprenylation. Apomine has been shown to inhibit bone metastasis *in vivo* after intracardiac injection of breast cancer cells (MDA-MB-231) in mice. The aim of this study was to assess the antiproliferative activity of Apomine *in vitro* and *in vivo* in comparison to risedronate. *In vitro* studies were performed in breast cancer MDA-MB-231 cells mutated for K-ras and in H-ras-transfected 3T3 fibroblasts (PAP-2 cells). Both cell lines were incubated in the presence of Apomine (0.1-20 µM) or risedronate (1-200 µM) for 6, 24, and 48 hours. Cell number and apoptosis rate were measured. In MDA-MB-231 cells, Apomine inhibited cell proliferation (IC50 = 5 µM) and risedronate had no effect on cell growth even at the highest concentration (200 µM). In PAP-2 cells, Apomine inhibited cell proliferation (IC50 = 8 µM), whereas risedronate showed only a mild antiproliferative activity (IC50 = 80 µM). *In vivo*, tumours were induced by s.c. injection of MDA-MB-231 or PAP-2 cells in a nude mice xenograft model. Animals were treated either with Apomine or risedronate (50 mg/kg in diet), and tumour growth was then evaluated twice weekly. In MDA MB-231 injected mice, Apomine inhibited tumour growth by -31% and -25% after 6 and 17 days of treatment, respectively. In PAP-2 injected mice, Apomine inhibited tumour growth by -59% and -39% on days 8 and 14, respectively. Risedronate did not show any antiproliferative effect with either cell line in this xenograft model. The present study shows that Apomine, which enhances HMG-CoA reductase degradation, is antiproliferative *in vitro* and *in vivo* in two different Ras-dependent cell lines (MDA-MB-231 and PAP-2). In direct comparison, risedronate has no significant antiproliferative activity.

Bone Microenvironment Triggers IGF-I Release from Prostate Carcinoma. J. Rubin[1], L. Chung*[2], X. Fan[1], L. Zhu*[1], T. C. Murphy*[1], M. S. Nanes[1], C. J. Rosen[3]. [1]Medicine, VAMC & Emory University, Decatur, GA, USA, [2]Winship Cancer Center, Emory University, Atlanta, GA, USA, [3]Jackson Laboratory, Bar Harbor, ME, USA.

Prostate carcinoma has a propensity to metastasize to the skeleton, inducing a characteristic osteoblastic response from the local cell population. The cancer cell itself takes on characteristics of bone cells, expressing RUNX2/cbfa1, osteocalcin and RANKL. Interestingly, OPG infusion has been shown to prevent bone metastasis in a nude mouse model (Wang 2001). Clinical data has suggested that IGF-I levels may be related to the advancement of disease in the bone compartment. We recently reported that IGF-I both upregulated bone cell RANKL expression, and downregulated OPG expression (Rubin ASBMR 2001). This suggested that IGF-I might have multiple influences on prostate metastatic disease, e.g., increasing bone turnover through alteration of RANKL/OPG and influencing osteoblast proliferation and function. In the study presented here we used human prostate carcinoma cell lines: LNCaP originating from lymph node (LN) metastasis, C4-2 which was derived from chimeric prostate tumors derived from co-inoculation with LNCaP and a bone stroma cell line (MS) in castrated nude mice, and C4-2B which was passed in castrated mice and derived from bone metastases (Thalmann 1994, 2000). LNCaP expressed very low levels of RANKL mRNA while C4-2 and C4-2B had high levels as assessed by RT-PCR. 24-h treatment of cell lines with 100 ng/ml IGF-I stimulated RANKL expression in LNCaP, as expected, but had no effect on the constitutively high expression of the highly metastatic C4-2 and C4-2B lines. We next measured IGF-I secretion by these lines using a sensitive RIA that detects as low as 0.2 ng/ml IGF-I. Serum-free conditioned media of LNCaP contain no measurable IGF-I in 24 or 48 hours. IGF-I secretion elevated substantially in C4-2 cells which was measurable at 24 h, doubling at 48 h, but was 1/10 the levels secreted by C4-2B line at 0.5 ng/ml at 24 h, and 0.92 ng/ml at 48 h (or 2.5 ng/mg protein). IGF-BP3 was not detectable in the conditioned media thus increasing the potential bioavailability of IGF-I. In sum, our results suggest that interaction of prostate carcinoma with the bone microenvironment results in a stably upregulated IGF-I axis which includes elevated RANKL and bone remodeling. Whether this is a pre-selected trait, i.e., an a priori requirement for bone anchorage and growth, or a result of "adaptive" events leading to aberrant signals in the bone environment which upregulate IGF-I expression in metastatic cells, will be important to understand in an effort to treat aggressive androgen-independent prostate carcinoma.

1097

DeltaFosB Isoforms Are Able to Interact with the Osteoblast Transcription Factor Runx2 and Synergistically Regulate its Promoter Activity. M. Wu[1], G. Rowe*[1], M. Kveiborg[1], G. Rawadi[2], P. Ducy[3], W. Horne[1], R. Baron[1], G. Sabatakos[1]. [1]Yale University, New Haven, CT, USA, [2]Aventis Pharma, Paris, France, [3]Baylor College of Medicine, Houston, TX, USA.

ΔFosB, an alternative splice form of the *fosb* transcript, is a member of the AP-1 family of immediate-early transcription factors that have been implicated in the regulation of bone metabolism. Previous work showed that overexpression of ΔFosB in transgenic mice under the control of the NSE promoter results in osteosclerosis. This effect was shown to be cell autonomous to the osteoblast lineage since *ex vivo* studies demonstrated that increased levels of ΔFosB and Δ2ΔFosB, an N-terminally truncated isoform of ΔFosB, led to increased expression of osteoblast markers (collagen type 1, osteocalcin, osteopontin, and Runx2), and increased mineralization. In order to explore the mechanism by which ΔFosB and Δ2ΔFosB regulate bone formation and osteoblast differentiation, we used a gal-4 based yeast two-hybrid screen to identify novel binding partners of ΔFosB and Δ2ΔFosB. ΔFosB strongly autoactivated the reporter, and therefore only Δ2ΔFosB was used in the screen. Three independent clones isolated in the screen were identified as Runx2, a transcription factor that has been shown to be required for skeletogenesis. The interaction of Δ2ΔFosB with Runx2 in yeast was confirmed by directed two-hybrid activation of beta-galactosidase activity. In addition, transient co-transfection experiments in C3H10T1/2 cells showed that both ΔFosB and Δ2ΔFosB interacted with Runx2. Thus, Δ2ΔFosB and Runx2 both interact with each other and upregulate Runx2 expression. To determine the mechanism of transcriptional regulation of the Runx2 promoter by ΔFosB isoforms and Runx2, we performed transient co-transfections of Runx2 with a human Runx2 promoter luciferase reporter. As previously shown, Runx2 can activate its own promoter. ΔFosB and Δ2ΔFosB alone are not able to activate the Runx2 promoter; however, co-transfection of Runx2 with ΔFosB resulted in a synergystic increase in promoter activity. Deletion analysis of the Runx2 promoter revealed region-specific differences in the synergistic activities of ΔFosB and Δ2ΔFosB with Runx2 on OSE2 elements in the distal and proximal Runx2 promoter. In conclusion, ΔFosB isoforms are not only able to interact with Runx2, but also regulate the transcriptional activity of the Runx2 promoter in a synergistic manner. These mechanisms may be, at least in part, responsible for the increased bone formation in ΔFosB transgenic mice.

1098

Severe Osteopenia with Increased Osteoclast Progenitors in Pax5 Deficient Mice. M. C. Horowitz[1], Y. Xi[1], D. L. Pflugh*[1], D. G. T. Hesslein*[1], D. G. Schatz*[1], J. A. Lorenzo[2], A. L. M. Bothwell*[1]. [1]Yale University School of Medicine, New Haven, CT, USA, [2]University of Connecticut Health Center, Farmington, CT, USA.

Recent evidence demonstrates a relationship between B lymphopoiesis and osteoclastogenesis. The Pax5 gene encodes for the transcription factor B cell lineage specific activation factor (BSAP) which is required for B lymphocyte development. Mice deficient in Pax5 have a developmental arrest of B cell differentiation at the pro-B cell stage, which results in the absence of mature B lymphocytes and the presence of multipotential pro-B cells in the bone marrow. Pax5 deficient mice are severely runted and rarely live past 20 days. We characterized the bone phenotype of Pax5 wild-type (+/+), heterozygous (+/-) and homozygous mutant (-/-) mice to examine if Pax5 -/- mice had an altered bone phenotype. Mice were analyzed by histomorphometry and biochemistry. Spleen and bone marrow cells were used as sources of osteoclast precursors. Bones from Pax5 -/- mice were strikingly osteopenic 15 days after birth (BV/TV 66% less than +/+ controls), with increased numbers of osteoclasts (>100% increase), and decreased trabecular number (>50% loss). The number of osteoblasts in Pax5 -/- bones and their function in vitro were not different from +/+ controls. In addition, Pax5 was not expressed by primary wild-type osteoblasts in Northern analysis. To investigate the origin of the in vivo increase in osteoclasts, Pax5 -/- or +/+ spleen cells were cultured with M-CSF and RANKL and multinucleated, $TRAP^+$ cells counted. Cells from Pax5 -/- spleen produced 5-10 times more osteoclast-like cells (OCL) than did controls. Culture of Pax5 -/- but not +/+ spleen cells resulted in the development of cell lines that when stimulated with M-CSF and RANKL formed large, multinucleated OCLs. The OCLs were functionally mature as they produced abundant resorption pits when cultured on bovine cortical bone slices. Pax5 -/- cell lines could also be sustained in culture for up to 6 weeks without added growth factors. Essentially all cells in these long-term cultures expressed the monocyte markers CD11b/Mac-1, CD115/c-fms (the M-CSF receptor), and CD16/32 (FcRγIII/II) as assessed by flow cytometry. These data imply that the markedly decreased bone mass in Pax5 -/- mice resulted from an increase in the number of osteoclast precursors and were not due to insufficient or defective osteoblasts. Because Pax5 is expressed exclusively in the B cell lineage, the data imply that cells in the B cell lineage ($B220^+$, $c\text{-}kit^+$) regulate osteoclast progenitor differentiation and/or may be capable of differentiating into osteoclast precursor cells.

1099

RAIN, A Novel Intracellular Molecule that Associates with RANK and Negatively Regulates Osteoclastogenesis. A. Poblenz*[1], K. Du*[1], B. Lamothe*[2], N. K. Shevde[3], J. W. Pike[4], B. G. Darnay[1]. [1]Bioimmunotherapy, University of Texas MD Anderson Cancer Center, Houston, TX, USA, [2]Pharmacology, Yale University, New Haven, CT, USA, [3]Biochemistry, Univerisity of Wisconsin-Madison, Madison, WI, USA, [4]Biochemistry, University of Wisconsin-Madison, Madison, WI, USA.

Receptor activator of NF-kB (RANK) and its ligand (RANKL) are essential mediators of osteoclastogenesis. RANK utilizes tumor necrosis factor receptor-associated factors (TRAFs) to activate signal transduction pathways. In an effort to identify other factors that interact with the cytoplasmic domain of RANK, we screened a human thymus library with the RANK cytoplasmic domain using a yeast two-hybrid approach. Of the 13 clones we identified in this screen, five clones encoded the C-terminal region of TRAF2. One other clone specifically interacted with RANK. Based upon its function in osteoclastogenesis, this clone was termed RAIN (RANK Associated Inhibitor). We cloned both the mouse and human homologues which contain 241 and 242 residues, respectively. RAIN is a novel protein with no identifiable domains or motifs. To demonstrate interaction of RAIN with endogenous RANK, we transfected RAW264.7 with FLAG-tagged RAIN and it coprecipitated with endogenous RANK. Furthermore, RAIN was demonstrated to interact with TRAF2, TRAF5, and TRAF6. To understand the function of RAIN, we established RAW264.7 cells stably expressing RAIN. In these stable clones, RAIN appeared to block 50% of NF-kB activity induced by RANKL, but did not have any adverse effects on ERK or JNK activation. In addition, in the RAIN stable clones, RANKL was not able to induce

osteoclast differentiation. Thus, it appears that RAIN is a negative regulator of osteoclast differentiation. Furthermore, RANKL treatment of RAW264.7 cells caused induction of RAIN mRNA and protein, which begins on day 2 and continues through day 5. Next, we established RAW264.7 cells stably expressing anti-sense RAIN to knock out the function of RAIN. Surprisingly, we observed increased osteoclast differentiation, which was observed as early as day 2. Thus, we have identified a novel protein that interacts with RANK and TRAFs and negatively regulates RANKL-mediated osteoclastogenesis.

Bone Specific DeltaFosB Induced Osteosclerosis Is Independent of Adipogenesis. M. Kveiborg, G. Sabatakos, R. Chiusaroli, M. Wu, W. Grant*, W. C. Horne, W. M. Philbrick, R. Baron. Yale University School of Medicine, New Haven, CT, USA.

The AP-1 family of transcription factors plays important roles in bone cell function. Previous findings demonstrated that transgenic mice overexpressing ΔFosB, a splice variant of FosB, under the control of the neuron-specific enolase (NSE) promoter develop a progressive and severe osteosclerosis, shown to be, at least in part, due to autonomous effects of ΔFosB on cells of the osteoblastic lineage. In addition, adipogenesis is inhibited in the NSE-ΔFosB mice, with decreased abdominal fat and decreased number of bone marrow adipocytes. Given that the NSE promoter directs expression of ΔFosB to several different tissues, including bone and adipose tissue, it is not clear if the fat phenotype is due to direct autonomous effects on cells of the adipocyte lineage. To further understand the mechanisms of ΔFosB action in osteoblast versus adipocyte differentiation, we have generated transgenic mice expressing ΔFosB under the control of the mouse osteocalcin promoter (OG2), which directs transgene expression specifically to osteoblastic cells beyond the branching point of adipocyte versus osteoblast commitment. Complete histomorphometric analysis of two independent founder lines showed that targeting the ΔFosB transgene to osteoblasts results in a significant increase in bone formation. At 10 weeks of age, trabecular bone volume was more than doubled (16.2±5.1 vs. 7.9±2.3 BV/TV, $p<0.05$), and the dynamic parameters of bone formation were also significantly increased (mineralizing surface: 43.2±1.7 vs. 32.5±5.2 MS/BS, $p<0.05$, mineral apposition rate: 1.6±0.1 vs. 1.2±0.2, $p<0.05$, and bone formation rate: 255.2±18.1 vs. 141.8±33.9 BFR/BS, $p<0.005$). Similar to NSE-ΔFosB transgenic mice, no changes in bone resorption parameters, such as osteoclast surface and osteoclast number were observed. These results clearly demonstrate that ΔFosB-induced osteosclerosis is a direct effect of ΔFosB overexpression in osteoblasts. In contrast to the recurrence of the osteosclerotic phenotype, no differences were observed in either abdominal fat or number of adipocytes in the bone marrow of OG2-ΔFosB transgenic mice. Thus, these findings indicate that when ΔFosB is induced specifically in osteoblasts and at late stages of differentiation, osteosclerosis can be mediated independent of decreased adipogenesis.

Endothelial Nitric Oxide Synthase Is an Important Regulator of Osteoblast Growth and Differentiation. F. Afzal*[1], M. Nohadani*[2], P. L. Huang*[3], J. M. Polak*[2], L. D. K. Buttery[2]. [1]Cell Biology, UMASS, Worcester, MA, USA, [2]Cell Biology and Tissue Engineering, Imperial College, London, United Kingdom, [3]Cardiovascular Research Center, Harvard Medical School, Charlestown, MA, USA.

We have previously reported that the nitric oxide (NO) signaling pathway contributes to osteoblast function. However, the mechanisms underlying the NO-mediated effects on osteoblast lineage cells are yet to be determined. In this study, we evaluated the contribution of NO and specific NOS enzymes involved in the control of osteoblastic bone formation in vivo using rat and eNOS-null mice models. Our results show that in rat calvarial osteoblasts, inhibition of endogenous NO synthesis by NΩ-Nitro-L-Arginine (L-NNA) significantly delayed the osteoblast differentiation process as evidenced by reduction of alkaline phosphatase activity (ALP) and mineralized bone nodule formation. Growth and differentiation assays using eNOS KO-derived osteoblasts revealed a significant decrease in both their proliferation and their differentiation compared to their WT littermates. In addition, RT-PCR analyses revealed significant reductions in osteocalcin (OCN) and core binding factor (Cbfa1) gene expression in osteoblasts from eNOS KO mice. Rescue experiments ex-vivo showed that this impaired growth and differentiation could be totally restored to WT levels after addition of the exogenous NO donor S-nitroso-N-acetyl-DL-penicillamine (SNAP) to eNOS KO-derived osteoblasts. Mechanical properties of long bones from 8 and 12 week old eNOS KO mice and their corresponding WT controls were also assessed. The eNOS KO mice at 8 weeks had significantly reduced bone elasticity and strength, and reduced bone hardness. Furthermore, our results show that total bone mineral density (BMD) as well as calvarial, pelvic/femoral, spinal BMD is also significantly reduced in the eNOS KO mice at 8 weeks. These parameters were modestly reduced at 12 weeks. The bone abnormalities were completely prevented after treatment of 4 week old eNOS KO mice with the NO donor glyceryl trinitrate as determined by DEXA, microhardness tests and osteocalcin levels. Taken together, our studies demonstrate that the eNOS enzyme is a major regulator of NO-mediated osteoblast cell signalling. Our in vivo data clearly show that the bone abnormalities in the eNOS KO mice are age-dependent suggesting an implication of this second messenger during early stages of bone formation and periods of rapid growth in postnatal mice.

Adenoviral Gene Therapy Using an Anti-Proliferative Mutant of PTHrP Completely Prevents Arterial Re-Stenosis. N. M. Fiaschi-Taesch*, K. K. Takane*, S. Masters*, A. F. Stewart. Endocrinology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA.

Coronary and peripheral vascular disease are increasingly treated using angioplasty approaches. Re-stenosis results in late failure in approximately 20-50% of patients undergoing angioplasty. PTHrP is produced in the arterial wall, is upregulated by vascular injury, by balloon distention and by vasoconstrictors, and acts as a vascular smooth muscle (VSM) relaxant. These effects of PTHrP are believed to be principally paracrine and/or autocrine. PTHrP also has a nuclear/nucleolar localization signal (NLS) in the 88-106 region. In cultured A-10 VSM cells, stable expression of PTHrP lacking an NLS (delta-NLS) markedly inhibits proliferation in VSM cells. These observations suggest that gene delivery of delta-NLS-PTHrP might be effective in preventing arterial re-stenosis is following angioplasty. Methods: Male Sprague-Dawley rats (450-600 g) underwent left common carotid balloon injury followed by local arterial delivery of: 1) buffer alone with no virus; 2) recombinant adenovirus encoding beta-galactosidase (Ad-lacZ); or, 3) delta-NLS (Ad-delta-NLS). The right carotid was left undisturbed and used as a normal control. Two weeks following surgery, the rats were sacrificed, both carotids were fixed, and quantitative histomophometric analysis was performed on the injured and contralateral non-injured carotid arteries. Results: As can be seen in the Table, and as expected, angioplasty alone (no adenovirus) resulted in marked neointimal hyperplasia (re-stenosis). Angioplasty followed by Ad-lacZ resulted in indistinguishable findings, indicating that adenovirus neither worsened nor ameliorated the re-stenosis (neointima formation). In dramatic contrast, Ad-delta-NLS resulted in striking and essentially complete inhibition of arterial re-stenosis, with complete patency of the lumen. These results were highly statistically significant. In summary, local treatment of the arterial lumen wall at the time of angioplasty with Ad-delta-NLS dramatically and completely inhibits arterial re-stenosis in rats. This approach may be useful in treating human coronary and peripheral arterial disease.

	Neointima Area (mm2)	Media Area (mm2)	Neointima/Media Ratio

1103

Fracture Risk Following Bilateral Oophorectomy in Elderly Women: A Population-Based Study. L. J. Melton[1], S. Khosla[2], G. D. Malkasian*[3], S. J. Achenbach*[1], A. L. Oberg*[1], B. L. Riggs[2]. [1]Health Sciences Research, Mayo Clinic, Rochester, MN, USA, [2]Internal Medicine, Mayo Clinic, Rochester, MN, USA, [3]ObGyn, Mayo Clinic, Rochester, MN, USA.

Estrogen (E) deficiency is largely responsible for age-related bone loss in elderly women, and those with the lowest serum E levels are at greatest risk of bone loss and fractures. It is controversial, however, whether the postmenopausal ovary is an important source of the androgens that are the substrate for endogenous E production after menopause or whether they are mainly adrenal in origin. Therefore, it is unclear whether bilateral oophorectomy in postmenopausal women might have unexpected adverse effects on the skeleton. To assess the practical significance of this potential problem, we estimated long-term fracture risk among the inception cohort of Olmsted County, MN, women who underwent bilateral oophorectomy (median age, 62 yr) for a benign condition in 1950-87 following a natural menopause (median, 50 yr). In a population-based retrospective cohort study, these 338 women were followed for 5627 person-years (median, 16 years per subject) during which 192 women experienced 511 fractures (72% from moderate trauma). Compared to expected rates among community women, statistically significant increases were seen for fractures at most axial sites, such as the vertebrae (standardized incidence ratio [SIR], 3.01; 95% CI, 2.46-3.66), as well as the proximal femur (SIR, 1.51; 95% CI, 1.15-1.96) and distal forearm (SIR, 1.47; 95% CI, 1.06-1.99). Overall, there was a significant increase in the risk of any osteoporotic fracture (moderate trauma fracture of the hip, spine or distal forearm: SIR, 1.54; 95% CI, 1.29-1.82) but almost as big an increase in any other fracture (SIR, 1.33; 95% CI, 1.11-1.57). In multivariate analyses, the independent predictors of overall fracture risk were age, anticonvulsant or anticoagulant use ≥ 6 months and a history of alcoholism or prior osteoporotic fracture; obesity was protective. Risk factors for any osteoporotic fracture included age, anticonvulsant use, history of prior osteoporotic fracture or kyphosis and more recent year of oophorectomy, while thiazide use was protective. Hormone replacement therapy was associated with a 10% reduction in overall fracture risk (hazard ratio [HR], 0.90; 95% CI, 0.64-1.28) and a 20% reduction in osteoporotic fractures (HR, 0.80; 95% CI, 0.52-1.23) but neither was statistically significant. Our demonstration of a 50% increase in osteoporotic fracture risk among women who underwent bilateral oophorectomy following natural menopause is consistent with the hypothesis that androgen production by the postmenopausal ovary is protective against fractures induced by estrogen deficiency.

1104

Femoral Neck Bone Loss Predicts Risk of Hip Fracture in Elderly Women. T. V. Nguyen, J. R. Center*, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

In postmenopausal women, measurement of femoral neck bone mineral density (FNBMD) predicts hip fracture risk, and improvement in BMD with antiresorptive therapy are associated with decreased fracture rate. However, it is not clear whether short-term bone loss is an independent risk factor for hip fracture. To address this question, 724 elderly women of the Dubbo Osteoporosis Epidemiology Study were studied. The women aged 60+ years (as at June 1989), had been followed for a median of 8.6 years, and had had at least two FNBMD measurements prior to the fracture event. During the follow-up period, 43 women suffered a hip fracture, who had multiple measurements of BMD prior to the event. Apart from lower baseline BMD and higher age, the [mean ± SD] annual rate of bone loss for fracture women was -2.1 ± 4.2 %, significantly greater than in non-fracture women (-0.76 ± 2.8%; p = 0.005). Lumbar spine (LS) BMD among hip fracture women also decreased at a significantly higher rate than among those without a fracture (-1.1 ± 3.4% vs. +0.1 ± 2.02%; p <0.01). In Cox's proportional hazards model (univariate analysis), each 5% decrease in FNBMD and LSBMD was associated with a 1.8-fold (1.2 - 2.8) and 2.8-fold (1.5 - 5.4) increase in hip fracture risk, respectively. In multivariate analysis, after adjusting for age in a proportional hazards model, each 0.1 g/cm^2 loss of FNBMD was associated with a relative risk (RR) of 3.1 (95% CI: 1.6 - 6.1) for fractures at the hip, comparable to a 0.1 g/cm^2 difference in baseline hip fractures (RR 3.6, 95% CI: 2.7 - 4.8). These results suggest that bone loss at the femoral neck is an independent predictor of hip fracture risk in elderly women, and help explain why a modest improvement in BMD induced by antiresorptive therapy is associated with greater reduction in fracture risk that is predicted from cross-sectional BMD studies.

Effects of Olpadronate on Children with Osteogenesis Imperfecta: A Double-blind Randomized Clinical Study. D. Kok*[1], C. Uiterwaal*[2], R. Engelbert*[3], A. Van Dongen*[4], M. Jansen*[5], H. Pruijs*[1], A. Verbout*[1], D. Schweitzer[6], R. J. B. Sakkers[1]. [1]Orthopedic Surgery, UMCU, Utrecht, Netherlands, [2]Julius Centre, UMCU, Utrecht, Netherlands, [3]Pediatric Physiotherapy, UMCU, Utrecht, Netherlands, [4]Nuclear Medicine, UMCU, Utrecht, Netherlands, [5]Pediatrics, UMCU, Utrecht, Netherlands, [6]Internal Medicine, Reinier de Graaf Groep, Delft, Netherlands.

The purpose of this study was to evaluate the effects of Olpadronate (dimethyl-APD) on children with osteogenesis imperfecta (OI) in a double-blind randomized placebo-controlled study of two years. Thirty-four children of at least 4 years old participated in this study. To be able to measure a difference in functional outcome, only children with a restricted level of ambulation were included. Excluded were those children with prior or current use of bisphosphonates. Half of the children were treated with Olpadronate tablets in a dose of 10mg/m2/day, the others received placebo tablets. The whole group was treated with calcium and vitamin D in a dose of respectively 500mg/m2/day and 400 I.U./day, as recommended for growing children. Lumbar BMD was measured at the beginning of the study and at one and two years of follow-up with DEXA (Hologic QDR 2000W, Waltham, MA). Functional parameters were measured every six months. Level of ambulation was assessed using the criteria of Bleck (non-walker, therapy or exercise walker, household walker, neighbourhood and community walker with or without the use of crutches). Community walkers were not included in the study. The Pediatric Disability Inventory (PEDI) was used to assess self care, mobility skills, social skills, caregiver assistance and the use of modifications. Thirty-two children completed the two-year follow-up period of the study, 15 of them in the Olpadronate and 17 in the placebo group. The mean ages were 10.4 (SD 2.8) and 10.6 (SD 4.0) years, respectively, in both groups. In the complete study group, spinal BMD increased significantly during the two years of follow-up (p<.0001), but the level of BMD accretion per year in the Olpadronate group was higher than in the placebo group (p<.0155). No differences in changes in functional outcome (Bleck, PEDI) were observed. No side effects of the medication were noted during this study. The two children that did not complete the study were on Olpadronate. It can be concluded that Olpadronate proved to be effective in this first double-blind randomized placebo-controlled study on the effects of bisphosphonates in children with OI, as demonstrated by a greater annual increase in BMD, independent from the effects of increase of age and calcium and vitamin D supplementation. No favorable effects on functional outcome were noted during these two years of follow-up.

1106

Defining Candidate Genes for a Major IGF-I QTL that Affect Bone Mass: Use of In Silico and Micro-array Technology. C. L. Ackert-Bicknell*, K. L. Shultz*, W. G. Beamer, L. R. Donahue, G. Churchill*, J. D. Stockwell*, C. J. Rosen. The Jackson Laboratory, Bar Harbor, ME, USA.

Changes in serum and skeletal IGF-I, a key regulator of bone remodeling, can profoundly affect bone formation and mineralization. We found that differences in hepatic IGF-I expression between C3H/HeJ (C3H) and C57BL/6J (B6) mice are due to enhanced transcription from the P2 promoter. Using whole genome scanning to look for QTLs controlling serum IGF-1 levels, we found a strong QTL on Chr 6. A congenic strain for this locus, B6.C3H-6T (6T), has low serum IGF-I, plus markedly reduced trabecular and cortical BV/TV (Bouxsein, et al. JBMR, 2002). The QTL region is about 20cM in size and contains many genes. To find candidate genes in the Chr 6 QTL region, we performed a dye-flip microarray experiment using mouse 15K microarray chips from the Ontario Microarray Center. Total RNA was isolated from the livers of 6 wk old, fasted female B6 and 6T mice, then converted to cDNA. B6 cDNA was labelled with Cy3 and 6T cDNA with Cy5 for two arrays and then dye labeling reversed for two additional arrays. Gene chips were hybridized with labeled cDNA at 42º C overnight and scanned. Each EST was spotted on the chips twice, giving 8 data points/EST. We used ANOVA, (Kerr et al, JCB, 2000) and bootstrapping to identify genes that were significantly different in expression. Of the 15K EST's analyzed on these chips, 48 were down regulated and 8 were up regulated in 6T vs. B6 (p< 1.0 x10^{-7}). 23 differences were linked to known genes and the remaining additional differences were found for EST's not associated with characterized mouse genes. 22 additional differences were identified in the UniGene databases and by BLAST searching the Celera mouse genome, allowing putative transcripts for these genes to be predicted. In addition, by using domain, structure and human homology databases, putative protein function could be predicted for some of these genes. Three ESTs mapped to our region of interest on Chr 6. These genes were *p23,* human hypothetical protein FLJ22405*,* and *Lsm-3.* A fourth gene, *Gata-2*, located within the 6T region, was down regulated by 65%, but was only suggestively significant (p< 1.0X10^{-6}). Using the VISTA comparative alignment package, we found four regions of high nucleotide conservation between human and mouse in the P2 promoter of the IGF-I gene. These regions bind several transcription factors, including *GATA-2,* enhancing its potential as a candidate gene. In summary, by using the 6T congenic mouse, along with traditional bench top experimentation and in silico data-mining, we have been able to considerably narrow the list of candidate genes for this QTL and gained further insight into the biological differences embodied by this strain.

P2X7 Receptor Regulates Bone Formation and Bone Resorption. H. Z. Ke[1], H. Qi[1], D. T. Crawford*[1], Q. Zhang*[2], W. A. Grasser[1], V. M. Paralkar[1], M. Li[1], L. P. Audoly*[1], C. A. Gabel*[1], M. Su*[2], W. S. S. Jee[2], D. D. Thompson[1]. [1]Pfizer Global Research and Development, Groton, CT, USA, [2]Univ. of Utah, Salt Lake City, UT, USA.

The P2X7 receptor (P2X7R) is an ATP-gated ion channel expressed by monocytes, macrophages, osteoclasts and subpopulation of osteoblasts. However, the role of P2X7R in bone is not known. The purpose of this study was to elucidate the role of P2X7R in regulating bone formation and resorption by characterizing the bone phenotype of male and female mice that had been genetically modified to delete the P2X7R (KO). Femoral length did not differ between KO and wild-type (WT) littermates at 2, 5 and 9 months of age in either male or female mice, indicating that P2X7R does not regulate longitudinal bone growth. PQCT analysis of the distal femoral metaphysis (DFM) and femoral shafts showed that KO male or female mice had significantly lower total bone area (up to -39%), cortical content (up to -36%) and periosteal circumference (up to -20%) as compared with WT controls at 2, 5 and 9 months of age. Histomorphometric analysis of tibial shafts showed that KO mice had significantly lower periosteal bone formation at all ages. These results demonstrated that P2X7R deficiency decreases periosteal bone formation, radial bone growth and cortical bone mass. In cancellous bone, PQCT analysis of DFM showed that trabecular content was significantly lower at 2- and 5-month-old KO male mice as compared with WT controls. Histomorphometric analysis of proximal tibial metaphysis indicated that a lower cancellous bone mass and bone formation and a higher bone resorption was found at 2-month-old KO male mice as compared with WT. Cancellous bone resorption remained higher in KO than in WT at 5 and 9 months of age. A significant decrease in serum osteocalcin was found in both male and female KO mice at 2, 5 and 9 months of age as compared with WT controls. Results from the bone marrow culture study showed that cells derived from either male or female KO mice expressed a significant decrease in alkaline phosphatase activity compared with WT controls. Number of TRAP-positive multinuclear cells in bone marrow culture was no difference in either male or female KO mice. These results demonstrate that P2X7R deficiency decreases cancellous bone formation and increases bone resorption. Increased osteoclast number in vivo but unchanged number of TRAP-positive multinuclear cells in bone marrow culture in KO mice suggests a possible role of P2X7R in osteoclast apoptosis. Our data reveal that P2X7R plays a stimulating role in periosteal and cancellous bone formation, and an inhibiting role in cancellous bone resorption. Thus activation of the P2X7R provides a therapeutic potential for prevention and treatment of osteoporosis.

Elevated Fibroblast Growth Factor 23 Concentrations in Humoral Hypercalcemia of Malignancy and Primary Hyperparathyroidism. C. M. Preissner*[1], R. Singh*[1], R. Kumar[2]. [1]Pathology and Laboratory Medicine, Internal Medicine, Mayo Clinic, Rochester, MN, USA, [2]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA.

Fibroblast growth factor 23 (FGF 23) causes hypophosphatemia and rickets. Both humoral hypercalcemia of malignancy (HHM) due to excessive amounts of parathyroid hormone-related peptide and primary hyperparathyroidism (1º HPT) are also associated with decreases in the serum inorganic phosphorus concentrations. To ascertain whether increases in circulating FGF 23 might contribute to the hypophosphatemia seen in these disorders, we measured FGF 23 in the serum of patients with HHM and 1º HPT. FGF 23 levels were measured in an ELISA kit from Immutopics, Inc. The 2-day assay utilizes two affinity-purified goat antibodies, one coated onto a microtiter plate and the other biotinylated, and a horseradish peroxidase-avidin conjugate. Twenty-one patients with HHM diagnosed on the basis of increased parathyroid hormone related peptide concentrations (PTHrP > 2 pmol/L) and a concomitant malignancy, 13 patients with 1º HPT diagnosed on the basis of hypercalcemia and increased parathyroid hormone concentrations (PTH > 5 pmol/L) and twenty-one normal subjects were examined. All patients had normal renal function as assessed by the measurement of serum creatinine concentrations. In normal subjects FGF 23 concentrations were 48.5+/-7.3 RU/ml. In patients with 1º HPT FGF 23 concentrations were 90.4+/-19.3 eq/ml (p < 0.027 vs normal). In patients with HHM the concentrations of FGF 23 were 677.4+/-149.5 RU/ml (p < 0.001 vs normal and p < 0.004

vs, 1° HPT). These data show that FGF 23 concentrations are elevated in both 1° HPT and HHM and could contribute to the hypophosphatemia seen in these disorders. Additionally, the higher FGF 23 concentrations in HHM relative to 1° HPT, could explain the smaller increases in 1,25-dihydroxyvitamin D concentrations in HHM compared to 1° HPT. The precise reason for elevated FGF 23 concentrations in these disorders remains to be determined but causes include stimulation of FGF 23 synthesis by PTHrP or PTH, or the mobilization of FGF 23 from bone by PTHrP and PTH. In conclusion, FGF 23 levels are elevated in patients with 1° HPT and HHM; however, the increases are of much greater magnitude in HHM compared to 1° HPT. These findings are of relevance in the clinical interpretation of FGF 23 assays and in the pathophysiology of hypophosphatemia in both 1° HPT and HHM.

LIP, a Natural Truncated Isoform of the Transcription Factor C/EBPβ, Promotes Osteoblastogenesis and Inhibits Adipogenesis in the Mesenchymal Stem Cells. K. Hata*[1], F. Ikeda[1], K. Yamashita*[1], F. Ichida*[1], T. Matsubara*[1], T. Nokubi*[1], A. Yamaguchi[2], R. Nishimura[1], T. Yoneda[1]. [1]Department of Biochemistry, Osaka University Graduate School of Dentistry, Osaka, Japan, [2]Department of Oral Pathology, Nagasaki University School of Dentistry, Nagasaki, Japan.

C/EBPβ belongs to a large family of basic leucine zipper transcription factors. Recently several natural truncated isoforms of the C/EBPβ have been identified and one of them named LIP which lacks the transactivation domain is found to function as a dominant-negative repressor of C/EBPβ activity. Since C/EBPβ is known to play an important role in adipogenesis in the mesenchymal stem cells which also give rise to osteoblasts, we hypothesized that LIP was involved in osteoblastogenesis and adipogenesis. Consistent with this hypothesis, we found distinctive LIP expression in primary mouse calvarial osteoblasts. To define the role of LIP in osteoblastogenesis, we overexpressed LIP in the C3H10T1/2 mouse pluripotent mesenchymal cells using an adenovirus system. Since the C3H10T1/2 cells did not express Cbfa1 which is an essential transcription factor for osteoblastic differentiation in non-stimulated condition, overexpression of LIP alone did not cause osteoblastogenesis. However, when LIP and Cbfa1 were co-introduced, LIP significantly enhanced Cbfa1-induced osteoblastic differentiation. Co-immunoprecipitation experiments demonstrated that LIP physically associated with Cbfa1. Furthermore, we found that LIP directly bound to the osteocalcin gene promoter and transactivated the osteocalcin gene in cooperation with Cbfa1 despite that LIP lacked the transactivation domain. Consistent with these results, LIP together with Cbfa1 promoted osteoblastic differentiation in the C2 mouse mesenchymal cells that were deficient in Cbfa1 gene. Of note, LIP inhibited adipogenesis and suppressed the transcriptional activity of the PPARγ gene promoter in C3H10T1/2 cells. In contrast to LIP, C/EBPβ itself promoted osteoblastic differentiation and also adipocytic differentiation with an up-regulation of PPARγ expression in C3H10T1/2 cells. In summary, our results show that LIP enhances Cbfa1-induced osteoblastogenesis, suggesting that LIP is a co-activator of Cbfa1. On the other hand, LIP can inhibit adipogenesis in dominat negative fashion. These results suggest that LIP has different roles in osteoblastogenesis and adipogenesis from C/EBPβ and may direct the differentiation of the mesenchymal stem cells toward osteoblasts in collaboration with Cbfa1.

Runx1(Cbfa2/AML1) Is Expressed in Tissues Supporting Osteogenesis and Temporally Regulated During Chondrocyte and Osteoblast Differentiation. E. Balint[1], A. Javed[1], H. Drissi*[1], R. Vitti*[1], E. Quinlan*[1], L. Zhang*[2], T. North*[2], A. J. van Wijnen[1], J. L. Stein*[1], G. S. Stein[1], N. A. Speck*[2], J. B. Lian[1]. [1]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Biochemistry, Dartmouth Medical School, Hanover, NH, USA.

Runx2/Cbfa1 has an essential role in formation of a mineralized skeleton. Here we provide evidence that the hematopoietic transcription factor Runx1/AML1 contributes to early events in formation of the skeleton. Expression of Runx1 during embryonic development was characterized in a $Runx1^{+/lz}$ mouse model in which the LacZ gene was inserted in the C terminus. Thus the resulting Runx1-LacZ fusion protein allowed detection of Runx1 gene expression in its native context by monitoring β-gal activity. Although homozygous mice die at 10.5 dpc due to a lack of definitive hematopoiesis, heterozygous mice develop normally. We find that Runx1 expression in the skeleton is initiated at 12.5 dpc predominantly in mesenchymal condensations that will form bone and in dorsal root ganglia. Runx1 expression continues in all periosteal and perichondrial membranes of bone in the axial and appendicular skeleton. In perichondrium contributing to appositional growth of the epiphysis, Runx1 expression is observed in chondroblasts, but is downregulated in mature hyaline cartilage of the skeleton. By 15.5 dpc Runx1 expression was observed in the suture lines of the calvarium. Runx1 is expressed in osteoblasts at sites of new bone formation, but not in osteocytes of mature bone. In post-natal mice and in adults (up to 1 yr), Runx1 expression is retained in the calvarial sutures and periosteum and in hyaline cartilage of the trachea, but not in the vertebrae or limbs. Ex vivo cultures of cells from suture lines, periosteum, or marrow stroma show Runx1 positive colonies distinct from alkaline phosphatase positive colonies, as well as cells expressing both markers. In osteoblasts from the central bone of calvariae, an induction of Runx1 expression was observed during differentiation. These findings indicate a spatial and temporal role of Runx1 in the early events of osteochondroprogenitor cell maturation and in supporting the properties of periosteal and sutural membranes. We propose that Runx1 has functions beyond hematopoiesis and contributes to early skeletal development.

Loss of a Half Cbfa1 Gene Dosage Sharply Blocks Cancellous Bone Regeneration after Bone Marrow Ablation in Aged Adult Mice Due to the Reduction in Osteoblastic Cell Population in the Stromal Cells. K. Tsuji[1], T. Komori[2], M. Noda[1]. [1]Mol. Pharmacol., Med. Res. Inst., Tokyo Med. and Dent. Univ., Tokyo, Japan, [2]Osaka Univ., Osaka, Japan.

Cbfa1/Runx2, a transcription factor which belongs to Drosophila runt family, is required for bone development as shown by the knockout experiments. Retinoblastoma protein(pRb) induces G1 phase arrest during cell cycle by negatively regulating the transcriptional activity of E2F and also binds to Cbfa1 to co-operatively enhance osteocalcin promoter activity. Therefore, Cbfa1 interaction with pRb may play a pivotal role, and in this regard the dosage levels of Cbfa1 gene product to interact with pRb could influence the maintenance of the population of differentiated osteoblasts in bone. However, heterozygote Cbfa1 mutation ($Cbfa1^{+/-}$) has only been reported to exhibit cleidocranial dysplasia. Thus, the aim of this paper is to examine the effects of Cbfa1 gene dosage on osteoblastic differentiation in vivo and in vitro. First, we conducted bone marrow ablation experiments. In wild type mice, new bone formation to fill the ablated bone marrow space was observed within the first seven days and after that bone resorption followed during the next seven days in the bone marrow either in young(8 week old) or aged(over 20 week old) mice. In young $Cbfa1^{+/-}$ mutant mice, the amounts of regenerated cancellous bone formed within the first seven days in the bone marrow cavity in tibia were similar to those in wild type mice. In contrast, in the aged $Cbfa1^{+/-}$ mutant mice, regeneration of cancellous bone in femora after operation was sharply blocked(80% reduction compared to wild type). Bone volume levels in the non-operated femora were similar between aged wild type and $Cbfa1^{+/-}$ mutant mice. This block of cancellous bone regeneration in the $Cbfa1^{+/-}$ mutant mice was not simply due to delay in bone formation since new bone formation was not observed even fourteen days after bone marrow ablation in the $Cbfa1^{+/-}$ mutant mice. To examine cellular mechanisms underlying this observation in the aged $Cbfa1^{+/-}$ mutant mice, bone marrow cells were cultured in the presence of beta-glycerophosphate and L-ascorbic acid. The development of alkaline phosphatase positive cells in bone marrow cells after culture (7 days) was significantly reduced when cells were prepared from aged $Cbfa1^{+/-}$ mutant mice compared to wild type. Furthermore, mineralized nodule formation was completely blocked even after longer period of culture (21 days) in $Cbfa1^{+/-}$ mutant cells while abundant nodule formation was observed in wild type. These results indicate that full Cbfa1 gene dosage is required for osteoblastic differentiation in bone marrow cells in vitro and cancellous bone regeneration in vivo in aged mice.

Cell Growth Regulatory Role of Runx2 During Proliferative Expansion of Pre-osteoblasts. J. Pratap[1], M. Galindo*[1], S. K. Zaidi[1], D. Vradii*[1], J. A. Robinson[2], B. M. Bhat[2], J. Choi*[3], T. Komori[4], J. L. Stein*[1], J. B. Lian[1], G. S. Stein[1], A. J. van Wijnen[1]. [1]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA, [2]Bone Metabolism/ Osteoporosis, Wyeth Research, Collegeville, PA, USA, [3]Department of Biochemistry, School of Medicine, Kyungpook National University, Daegu, Republic of Korea, [4]Department of Molecular Medicine, Osaka University Medical School, Suita, Osaka, Japan.

The Runx2 (CBFA1/AML3/PEBP2αA) transcription factor promotes skeletal cell differentiation by activating bone phenotypic genes in post-proliferative osteoblasts. The presence of Runx2 in actively dividing osteoprogenitor cells indicates a dual regulatory role in control of osteoblast growth and differentiation. The genetic contribution of Runx2 to bone cell proliferation was directly addressed analyzed by monitoring ex vivo growth of calvarial osteoblasts. Cells were derived from wild type mice, Runx2 null (-/-) mice or Runx2 ΔC/ΔC mice which contain a mutation in the Runx2 gene that eliminates the normal C-terminus of the protein. The data show that calvarial cells from Runx2 -/- and ΔC/ΔC mice exhibit significantly higher cell growth rates. In contrast, mouse embryonic fibroblasts that do not express Runx2 protein did not display genotype-dependent alterations in cell growth. Therefore, Runx2 is essential for normal proliferation of osteoblasts and the C-terminal region, that integrates several cell proliferation related signaling pathways (e.g., Smad, Yes/Src, MAPK, pRB), is required for the cell growth regulatory functions of Runx2. Western blot analysis reveals that Runx2 (-/-) calvarial cells contain elevated levels of G1/S phase related regulatory factors (e.g., cyclin E and pRB/p105). Thus, increased cell growth rates of Runx2 (-/-) cells may be mechanistically linked to changes in cell cycle markers. Treatment of wild type osteoblasts with cell cycle inhibitors that block cells in G1 or S phase reveals that Runx2 levels are elevated when cells stop dividing. Hence, Runx2 acutely responds to cessation of cell growth. Calvarial cells from wild type but not Runx2 (-/-) or ΔC/ΔC mice are capable of differentiating into mature osteoblasts. Re-introduction of Runx2 into Runx2 -/- cells using an adenoviral vector does not restore the defect in osteoblast differentiation unless BMP2 is also present at early stages. These data show that cessation of proliferation and/or onset of differentiation in osteoblasts are both BMP2 and Runx2 dependent. We propose that Runx2 promotes osteoblast maturation at a key developmental transition by simultaneously supporting exit from the cell cycle and activating genes that promote skeletogenesis.

1113

Regulation of *TWIST* Gene Expression by *Wnt* 11 in Human Osteoblasts: *Wnt* Signaling Pathway in Osteoblast Differentation. T. Yan*[1], S. D. Flanagan*[2], A. Kudo[3], C. A. Glackin[1]. [1]Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, CA, USA, [2]Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA, USA, [3]Tokyo Institute of Technology, Yokohama, Japan.

The purpose of this study is to examine the role of the *Wnt* signaling pathway in osteoblast differentiation. *Wnt* is a family of secreted cysteine-rich glycoproteins that are expressed in a wide variety of organ systems in developing embryos. They are thought to play an important role in cell proliferation and differentiation. Recently, a newly isolated human *Wnt* gene, *Wnt*-11, has been shown to be highly expressed in perichondrium of developing human skeleton; however, its role in the human skeletal system is largely unknown. *TWIST* is a basic helix-loop-helix (b-HLH) transcription factor that is important for cell type determination and differentiation. We have shown that *TWIST* is an important regulator in osteoblast differentiation. In order to find the target genes that are regulated by *TWIST*, microarray studies were performed using RNA from stable osteoblast cells that over (TS) or under (TAS) expresses *TWIST*. We found that periostin, a known target of Wnt signaling, was up-regulated 23 fold in HSaOS-2 cells that overexpress *TWIST* as compared with controls. Furthermore, LM-PCR *in vivo* footprinting, gel-shift and super-shift analyses indicate that *TWIST* binds specifically to the "E-box" of the periostin promoter. Transient transfection studies further demonstrated that *TWIST* overexpression *trans*-activates the periostin promoter. These studies showed that *TWIST* binds specifically to the periostin promoter and is an important activator of periostin gene expression. Since *Wnt*-11 is highly expressed in the developing human skeletal system, and periostin is known to be a target of the *Wnt* signaling pathway, we have undertaken studies to examine the role of *Wnt*-11 in the regulation of periostin and *TWIST* expression. RT-*PCR* studies show that HSaOS-2 cells express *Wnt*-11. TS cells treated with *Wnt*-11 conditioned medium show a significant reduction of *TWIST* expression (74%). Interestingly, a dramatic decrease of periostin expression after *Wnt*-11 treatment (93%) was also observed. These results demonstrate that the *Wnt* signaling pathway is important for regulating genes critical for osteoblast differentiation. We propose that *Wnt*-11 reduces *TWIST* expression leading to the down-regulation of periostin expression. Our studies, for the first time, demonstrate that *Wnt* signaling is important for regulating genes critical to osteoblast differentiation. Future studies will explore the paracrine/autocrine effects of *Wnt* signaling on osteoblast differentiation.

1114

Msx2 Suppresses Osteocalcin Gene Expression via Interactions with a Novel Ku Antigen Complex and Runx2/Cbfa1/Osf2. D. M. Willis*, S. L. Cheng, N. Charlton-Kachigian*, A. P. Loewy*, J. S. Shao*, D. A. Towler. Division of Bone and Mineral Diseases, Washington University, Saint Louis, MO, USA.

The homeoprotein Msx2 exerts a minimum of two distinct actions in MC3T3E1 calvarial osteoblasts: (1) Cell-autonomous enhancement of cellular proliferation/DNA synthesis; (2) Inhibition of terminal differentiation, including suppression of osteocalcin (OC) gene expression. The rat OC promoter fragment –154 to –113 confers both basal and FGF responsiveness to the OC gene, and is a target for Msx2-dependent transcriptional suppression. Two elements, the OC FGF response element (OCFRE) and osteoblast specific element 2 (OSE2) are encoded in this region and recognized by the heterotrimeric OCFRE binding complex (Ku70, Ku80, and Tbdn100) and Osf2, respectively. We wished to study the functional interactions between these proteins supporting OC promoter activity via this region. In co-transfection assays, Osf2 upregulates 7-fold the transcription driven by multimerized OC[-154/-113] placed upstream of the unresponsive RSV minimal promoter. Co–expression of Ku70 and Ku80, the DNA binding constituents of the OCFRE complex, enhance Osf2-dependent transcription an additional 2 to 4-fold. Under basal conditions, the transcriptional adapter molecule Tbdn100 marginally enhances Ku–dependent transcription, with no effect on basal Runx2-dependent activity. Remarkably, in the presence of activated FGF receptor 2 signaling, Tbdn100 triples Osf2-dependent transcription. By contrast, Msx2 completely abrogates transcription activated by Osf2 and the Ku complex via this element in MC3T3E1 cells. Suppression is not reversed by the histone deacetylase (HDAC) inhibitor trichostatin A, indicating that suppression is not HDAC dependent. Chromatin immunoprecipitation (ChIP) assays confirm the association of Osf2/Runx2, Ku, and Tdbn100 with the endogenous OC chromatin in MC3T3E1 cells. Stable expression of Msx2 in MC3T3E1 cells suppresses OC gene expression and diminishes the association of Osf2, and to a lesser extent Ku, with OC chromatin. In pull-down assays, Msx2 associates strongly with Ku70 and Ku80, but only weakly with Osf2, suggesting that the Ku complex represents a primary target of inhibition. In culture, Ku70 -/- calvarial osteoblasts exhibit profound deficiency in OC gene expression though Runx2 is readily detected, consistent with a role for Ku in facilitating osteoblast terminal differentiation. In toto, these data indicate that Osf2 and the Ku antigen transcriptional complex functionally interact to support OC transcription in calvarial osteoblasts. Msx2 inhibits OC transcription by antagonizing the assembly of specific protein-DNA interactions in the proximal OC promoter.

Difference of Bone Mineral Density Between Both Hips. Influence of Body Weight and Age. J. L. Mansur, M. C. Cianciosi*. Center of Endocrinology and Osteoporosis La Plata, La Plata, Argentina.

Although Bone Mineral Density (BMD) of both sides are highly correlated in same reports, it is not described how many people have significant differences. We prospectively study the BMD of both hips (Lunar Prodigy) of 150 postmenopausal women. The presence of scoliosis in the image of spine scans, and previous treatments with drugs that affect bone metabolism were exclusion criteria. We report the difference between both sides in 1) % and 2) T-Score, in four regions: A) Femoral neck (FN), B) Ward area (W), C) Trochanter (Troch), and D) Total Hip (TH). We study the group as a whole, and divided in tertils of age and weight. Results: n:150. Age: x: 58.6 (SD: 9.0) years. Weight: 68.9 (SD:14.0) Kg. Difference mean: 3.84 % in FN, 3.75 % in W, 4.11 % in Troch, and 3.08 % in T.H. I) % of patients with difference between both sides; II) Dividing them in tertils, women with more weight (> 71 Kg) have more difference between both sides in all regions , and there were no difference in tertils of age. Conclusions: although BMD of both hips are correlated, a significant number of postmenopausal women without scoliosis have difference between both sides. Bilateral DXA-measurements of hips are recommended, specially in obese women.

Difference of BMD between both hips

	Femoral N.	Ward	Troch	Total hip
> 3 %	44.6 %	44.6 %	48.7 %	34.0 %
> 5 %	23.3 %	20.0 %	26.0 %	12.7 %
>10 %	4.0 %	4.7 %	2.7 %	1.3 %
>0.5 SD	18.7 %	8.7 %	12.7 %	6.7 %
> 1 SD	1.3 %	0.7 %	0.7 %	0.7 %

Influence of Double Deficiency of Estrogen and Androgen in Bone Mass in Castrated Aromatase-knockout Mice. C. Miyaura[1], C. Matsumoto*[1], K. Toda*[2], A. Ito*[1]. [1]Department of Biochemistry, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [2]Kochi Medical School, Kochi, Japan.

Aromatase is the sole enzyme able to convert androgen to estrogen. We have reported that estrogen deficiency induces bone loss by increased bone resorption not only in female aromatase-knockout (ArKO) mice but also in male ArKO mice, suggesting the essential roles of estrogen in bone metabolism in both genders. However, the possible role of androgen in bone mass in males, and the relationship between estrogen and androgen in bone metabolism remain unclear. To clarify these issues, we induced the double deficiency of estrogen and androgen by orchidectomy in ArKO male mice. ArKO mice were born phenotypically normal, and the growth of ArKO mice after birth was similar to that of wild-type siblings. At 7 weeks of age, male ArKO and wild-type mice underwent sham-operation or orchidectomy (ORX). At 4 weeks after operation, in ORX mice, the weight of seminal vesicles decreased in both ArKO and wild-type mice, indicating that the mice were deficient in androgen. Femoral bone mass was measured by DEXA, and trabecular bone of femoral metaphysis and cortical bone in the middle position of the femur was analyzed by pQCT and histological analysis. Sham-operated ArKO mice showed a significant loss of cancellous bone in femoral metaphysis due to increased bone resorption in comparison with that in sham-operated wild-type mice. ORX/wild-type mice showed significant bone loss compared with that in sham/wild-type mice. The bone mass in sham-operated ArKO mice was similar to that in ORX/wild-type mice. In ORX/ArKO mice, femoral bone mass was further decreased compared with that in sham/ArKO mice not only in cancellous bone but also in cortical bone due to the deficiency of both estrogen and androgen. Most of metaphysial cancellous bone disappeared, and the cross-sectional area of cortical bone at the midshaft of the femur was severely decreased in ORX/ArKO mice. Deficiency of both sex steroids may induce bone resorption and suppress bone formation, resulting in a scant skeletal structure. To examine the anabolic function of androgen, we used weaning wild-type mice in the next experiment. When 3-week-old wild-type mice underwent ORX, periosteal bone formation was severely suppressed in cortical bone and bone resorption was elevated in the metaphysial trabecular bone. At puberty, the cortical thickness and BMD in both cortical and trabecular bone were markedly decreased by ORX. These results suggest that estrogen maintains cancellous bone mass and androgen stimulates cortical bone formation. Sex steroids may share the work of regulating bone metabolism in males.

Increased Wnt-Frizzled Gene Expression in Cortical Bone from Transgenic Mice with Elevated Osteoblastic VDR Expression. W. Zhu*, G P. Thomas*, L. E. Worton*, P. A. Baldock*, R. F. Enriquez*, S. U. K. Baker*, C. M. Alles*, Y. Shi*, J. A. Eisman, E. M. Gardiner. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

Wnt secreted glycoproteins, signaling through frizzled (Fzd) transmembrane receptors, regulate cell growth and polarity, and have been shown to be involved in osteoblastic differentiation and bone formation. We have found that OSVDR transgenic mice, overexpressing vitamin D receptor (VDR) in mature osteoblastic cells, exhibit elevated periosteal bone formation on long bone diaphyses. Transcript profiling was conducted to identify changes in gene expression associated with this anabolic bone phentoype. Long bones

were collected from OSVDR and FVB wildtype mice 6 hours after treatment with 1,25-dihydroxyvitamin D3 (1,25-D) or vehicle. Wnt-Fzd gene expression changes were detected in whole tibial midshafts using Atlas cDNA filter arrays (Clontech). These changes were corroborated by real time RT-PCR analysis of femoral diaphyses with periosteum intact but marrow removed. Cellular localization of Wnt-Fzd gene expression and osteoblast differentiation markers (osteocalcin and alkaline phosphatase) was examined in femurs by in situ hybridization (ISH). In cluster analysis of Atlas array data, several genes of the Wnt-Fzd regulatory cascade were changed in OSVDR bone. In real time RT-PCR, there were OSVDR-associated increases in expression of Wnt5b, Fzd7 and Fzd8 genes (9-, 2- and 3-fold) but not Wnt4, in cortical bone from vehicle-treated mice. Interestingly, 1,25-D treatment reduced expression of Wnt5b, Fzd7 and Fzd8 genes by 90%, 47% and 60% in OSVDR but not FVB cortical bone. By contrast, Wnt4 expression was reduced by 1,25-D treatment in both OSVDR and FVB bones (68% and 56%). Cell-specific Fzd8 expression was confirmed to be abundant in mature osteoblasts on OSVDR and FVB periosteal surfaces (ISH), consistent with the observed differences between OSVDR and wild-type mice. However, Wnt4 expression was only observed in a few immature osteoblasts in the periosteum on the posterior aspect of the distal metaphysis and in mature trabecular osteoblasts of the secondary spongiosa. These findings indicate that expression of Wnt5b, Fzd7 and Fzd8 is up-regulated in association with elevated VDR in mature osteoblastic cells of OSVDR mice, but acute 1,25-D treatment reduced expression of these genes as well as Wnt4. The acute negative 1,25-D response may relate to direct effects on gene transcription, whereas the Wnt-Fzd differences in vehicle-treated mice could relate to effects of OSVDR at late stages of differentiation in the osteoblastic lineage. These data support a role for the Wnt-Fzd pathway in vitamin D regulation of cortical bone formation.

Gene Repression Mediated by the Liganded VDR Is Exerted by the Concomitant and Vitamin D-dependent Recruitment of DNA-PK, HDAC2 and VDR. T. Okazaki[1], E. Ogata[2], T. Fujita*[1]. [1]Endocrine Unit, Internal Medicine, University of Tokyo School of Medicine, Tokyo, Japan, [2]Cancer Institute Hospital of Japan, Tokyo, Japan.

(Background) By using chromatin immunoprecipitation (ChIP) assay, we previously demonstrated that vitamin D-dependent recruitment of VDR and HDAC2 (histone deacetylase 2) to the nVDREm, the half site of DR-3 DNA element originally found in the human PTHrP gene, was necessary for hypoacetylation of the nVDREm-containing chromatin region. Further, this assay revealed a vitamin D-dependent interaction between HDAC2 and VDR. On the other hand, we had suggested that the VDR phosphorylated by DNA-dependent protein kinase (DNA-PK) in the presence of vitamin D led to a weaker interaction with the nVDREm. We postulated that both HDAC2 and DNA-PK were crucially involved in this type of gene repression by vitamin D. (Purpose and methods) To clarify the effect of vitamin D on the recruitment of DNA-PK and its regulatory subunit, Ku antigen, to the chromatinized nVDREm, we performed ChIP assay. MCF7 cells and human lymphocyte MT2 cells, in which VDR and PTHrP genes are endogenously expressed, were transiently transfected with the nVDREm-TK reporter gene. Chromatin was immunoprecipitated from these cells treated with no or 10 nM of vitamin D for 40 hours. DNA-PK, Ku antigen, VDR and acetylated histone3 were immunoprecipitated with the respective antibody. These chromatin immunoprecipitates were then analyzed for the presence of the nVDREm in the introduced reporter or endogenous PTHrP gene by PCR. (RESULTS) We found that these two cell lines gave identical results and both types of PCR showed similar tendency. Vitamin D treatment decreased the degree of histone H3 acetylation, while it recruited VDR and DNA-PK to the nVDREm in the chromatin. However, Ku antigen was recruited to the nVDREm only in the absence of vitamin D. Therefore, Ku antigen as a DNA-binding protein constitutively recruited to the chromatinized nVDREm was replaced by its catalytic subunit, DNA-PK, after vitamin D treatment. To better define the manner of the interactive recruitment of DNA-PK and VDR, similar ChIP assay was carried out after introduction of the AF2-only domain of VDR, which by itself was not recruited to the nVDREm, along with the nVDREm-TK reporter into MCF7 cells. In these cells, we observed no recruitment of DNA-PK to the chromatinized nVDREm even in the presence of vitamin D, suggesting that DNA-PK interacts with the AF2 domain of VDR in the presence of vitamin. D. (Conclusion) Because the recruitment pattern of DNA-PK and VDR coincided well with that of HDAC2, we postulate that the concomitant recruitment of these three molecules is a prerequisite for this type of gene repression by vitamin D.

1119

MET, a Novel Stimulator of Estrogen-induced Transcription Isolated from Mouse Bone Marrow. S. M. Colley*[1], A. Flynn*[2], M. Norman*[2], D. Wynick*[2], J. H. Tobias[1]. [1]Rheumatology Unit, University of Bristol, Bristol, United Kingdom, [2]Urcn, University of Bristol, Bristol, United Kingdom.

High-dose estrogen is known to stimulate osteoblast activity in postmenopausal women and rodent models. To investigate the molecular mechanisms which mediate this action, subtractive hybridisation analysis was employed to compare the gene expression profiles of mRNA isolated from tibiae of adult mice treated with vehicle or high-dose estrogen for 4 days. A gene fragment showing no significant homology to previously characterised sequences was subsequently isolated and found to detect a single 3.8Kb transcript by northern analysis. A full length cDNA homologous to this gene, which we refer to as MET, was generated by EST directed Rt-PCR using bone marrow cDNA as the source of template. Sequence analysis of the cloned product revealed it coded for a 1031 amino acid protein. This peptide contains a SAF Box DNA binding motif, an RNA binding domain and shares an overall identity of 34% with the estrogen suppresser SAF-B/HET/HAP (HET). MET cDNA was subsequently expressed as a fusion product with enhanced yellow fluorescent protein and, consistent with a role as a regulator of transcription, found to localise to the nucleus of mammalian cells. To explore its cellular actions, we then compared the effects of MET and HET over expression on estrogen-induced ERE-luciferase reporter gene transcription in MCF-7 breast, HepG2 liver and a range of human and rodent bone cell lines. Consistent with previous reports, HET over expression was found to suppress the actions of estrogen on reporter gene expression. In contrast, MET co-transfection increased estrogen-induced reporter activity by 50-100% in all cell lines studied. Taken together, our results indicate that MET represents a novel SAF Box-containing nuclear protein which, in contrast to a related protein HET, serves to stimulate rather than suppress estrogen-induced gene transcription. Whether MET plays a significant role in regulating the response of the skeleton and other tissues to estrogen, and represents a useful target for novel therapies designed to manipulate these actions, is currently under study.

1120

A Novel Vitamin D Analogue Exhibits Selective Anabolic Actions in Osteoblasts that Result in Enhanced Bone Formation. N. K. Shevde, H. Yamamoto, M. Clagett-Dame*, L. Plum*, H. F. DeLuca, J. W. Pike. Biochemistry, University of Wisconsin- Madison, Madison, WI, USA.

Adult bone remodeling is achieved through the coordinated activity of bone-resorbing osteoclasts (OC) and bone-forming osteoblasts (OB). While many factors regulate the OB and the OC, the actions of 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) on OB proliferation, maturation, differentiation and function are well recognized. These actions are mediated by the vitamin D receptor (VDR), a transcription factor that regulates patterns of gene expression not only in the OB but in other tissues as well. High levels of $1,25(OH)_2D_3$, however, strongly induce the expression of RANKL by the OB, stimulating OC activity and recruitment in turn. This homeostatic imbalance leads to elevated bone resorption, hypercalcemia and weight loss. A novel series of $1,25(OH)_2D_3$ analogues was recently discovered that exhibit a 30 to 50 fold increase in calcium mobilizing activity in the rat, suggesting a selective activity on the OB. These analogues modified by either an alpha methyl or a methylene substitution on carbon 2, bind to the vitamin D receptor (VDR) with a affinity constant similar to that for $1,25(OH)_2D_3$. One of these analogues, 2-methylene-19-nor-(20S)-$1,25(OH)_2D_3$ (2MD), was evaluated further for its selective activity on osteoblasts in vitro. We explored the ability of 2MD to stimulate 1) OB-specific expression of RANKL, 2) OB-mediated OC formation in cocultures and 3) OB differentiation and mineralized nodule formation in vitro. 2MD was found to be 100x more potent than $1,25(OH)_2D_3$ in stimulating RANKL production and OC formation in cocultures in vitro. Surprisingly, 2MD markedly stimulated both mouse and human osteoblast cultures to form bone nodules at concentrations as low as 10^{-12} to 10^{-10} M. $1,25(OH)_2D_3$ showed little or no activity at the highest concentrations tested (10^{-7} M). This effect was absent in osteoblasts derived from VDR null mice, demonstrating that the molecular actions of 2MD are mediated by the VDR. Importantly, 2MD stimulated these potentially anabolic activities in OBs at concentrations well below those that favor OC formation in vitro. These results suggest that 2MD is a potent vitamin D analogue with VDR-selective bone forming anabolic actions in the OB in vitro. Moreover, our results are fully supported by current studies in ovariectomized rats that indicate that 2MD strongly induces bone formation in the absence of hypercalcemia. This analogue should prove therapeutically useful in bone diseases such as age- and sex steroid-related osteoporosis, cancer-induced osteolysis or perhaps to accelerate bone formation during fracture healing.

Fragmentation of Insulin-Like Growth Factor Binding Protein (IGFBP) 5 Is Required to Induce Osteoblastic Differentiation. D. Durant, R. M. R. Pereira*, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Insulin-like growth factors (IGF) have important anabolic effects in bone and their actions are modulated by IGFBPs. Of the six IGFBPs secreted by bone cells, IGFBP-5 has been reported to enhance the stimulatory effects of IGF-I in bone cells. However, the mechanisms of this effect and the specific molecules involved remain unclear. Transgenic mice overexpressing IGFBP-5 under the control of the osteocalcin promoter develop osteopenia due to decreased bone formation, suggesting that intact IGFBP-5 in excess is not anabolic and binds IGF-I, preventing its stimulatory actions on bone formation. However, IGFBP-5 secreted by osteoblasts is rapidly fragmented by the activity of metalloproteases, likely matrix metalloprotease (MMP) 13 or collagenase 3. We postulated that IGFBP-5 fragments have distinct activity. Initially, we used amino acid analysis and mass spectroscopy to determine the cleavage sites of IGFBP-5 by collagenase 3 and define the fragments formed. We demonstrated cleavage at glu162 - meth163, ala193 - val194, and glu235 - tyr236. Based on this information we created retroviral vector constructs to express intact IGFBP-5 1-252 and its fragments, IGFBP-5 1-162, IGFBP-5 1-193, IGFBP-5 1-235, and IGFBP-5 163-252. For this purpose, the indicated fragments, preceded by the signal peptide, were cloned into the retroviral vector pLPCX, transfected into PT67 or Phoenix packaging cells and the supernatant used to transduce MC3T3-E1 mouse osteoblastic cells. MC3T3-E1 cells were cultured for 0 to 4 weeks following confluence in alpha-MEM in the presence of 5mM beta-glycerophosphate and 100 ug/ml ascorbic acid. Overexpression of IGFBP-5 and each individual fragment was confirmed by reverse transcription polymerase chain reaction using specific primers to identify the recombinant transcript and by Northern blot analysis. Cells transduced with IGFBP-5 1-193 displayed accelerated maturation and enhanced mineralization, as determined by alizarin red staining, when compared to MC3T3 cells and to cells transduced with pLPCX vector. In contrast, intact IGFBP-5 1-252 impaired cell differentiation and the fragments IGFBP-5 1-162, 1-235, and 163-252 had little impact on cell maturation. In conclusion, intact IGFBP-5 impairs osteoblastic maturation, whereas the IGFBP-5 1-193 fragment induces the differentiation of cells of the osteoblastic lineage.

1122

Rescue of the Osteopetrotic Defect in op/op Mice by Osteoblast-specific Targeting of Membrane-bound CSF-1. S. L. Abboud, K. Woodruff*, N. Ghosh-Choudhury. Pathology, University of Texas Health Science Center at San Antonio and South Texas Veteran's Health Care System, San Antonio, TX, USA.

Soluble (s) and membrane-bound (m) forms of macrophage colony-stimulating factor (CSF)-1 are synthesized by osteoblasts in the bone microenvironment. In the op/op mouse, absence of osteoblast-derived CSF-1 leads to decreased osteoclasts and osteopetrosis. Systemic administration of recombinant sCSF-1 to op/op mice corrects the osteopetrotic defect. However, osteopetrosis relapses one month following cessation of CSF-1 therapy and it cannot be reversed if sCSF-1 is administered after 7 days of age, suggesting that early and sustained postnatal CSF-1 expression in the bone is required for complete remission. Our recent studies show that sCSF-1, selectively expressed in the bone of op/op mice, stimulates normal tooth eruption and rescues the osteopetrotic defect by 5 wks, with this effect persisting for over l2 mo. To determine if mCSF-1 alone can reverse the defect, transgenic mice harboring the human mCSF-1 cDNA under the control of the osteocalcin (OC) promoter were generated and crossbred with heterozygous op/wt mice to establish op/op mutants expressing the transgene (op/opT). The op/op genotype and transgene expression were confirmed by PCR and Southern blot analysis, respectively. mCSF-1 protein was detected in bone extracts (382 pg/mg protein), but not in other tissues or plasma. Op/opT mice showed tooth eruption of upper and lower incisors, albeit delayed, 25 days after birth. The abnormal body weight and skeletal abnormalities observed in op/op mice were significantly improved in 5-10 wk old op/opT mice. By x-ray, op/opT mice showed radiolucent marrow spaces in the iliac crest, caudal vertebrae, tibial and femoral diaphysis comparable to wt mice, although mild metaphyseal sclerosis persisted. Continuous resolution of osteopetrosis in op/opT mice is being evaluated at later time points using pQCT scanning and histomorphometry. These findings indicate that mCSF-1 is almost as effective as sCSF-1 in correcting the osteopetrotic defect, suggesting a redundant role of membrane-bound and soluble CSF-1 in regulating osteoclastogenesis and normalization of bone turnover. Moreover, the osteocalcin promoter provides an efficient tool for delivering CSF-1 and other cytokines to osteoblasts that, in turn, express these factors in a physiologic manner throughout development. Osteoblast-specific targeting of mCSF-1 may provide a useful therapeutic approach for regulating osteoclast development and function in a variety of bone disorders.

1123

gp130 Regulates Bone Turnover and Bone Size by Distinct Downstream Signaling Pathways. N. A. Sims[1], B. J. Jenkins*[2], J. M. W. Quinn[3], T. J. Martin[3], M. Glatt*[4], M. T. Gillespie[3], M. Ernst*[2]. [1]Department of Medicine at St. Vincent's Hospital, University of Melbourne, Fitzroy, Australia, [2]Ludwig Institute for Cancer Research, Melbourne, Australia, [3]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [4]Novartis Pharma, Basel, Switzerland.

IL-11, IL-6 and LIF are bone-active cytokines of the same family; their actions are transduced by interaction of their ligand-specific receptors with the gp130 signaling receptor subunit. gp130 signaling is itself mediated through at least two intracellular pathways including the SHP2/ras/Erk and STAT1/3 pathways. To further delineate the pathways through which gp130 regulates bone mass, we have analyzed the bone phenotypes of two gp130 knock-in mutant mice. The first mutant (gp130ΔSTAT) harbors a COOH-terminal truncation deleting all STAT signaling (Ernst et al, JEM 2001). The second mutant (gp130Y757F) contains a phenylalanine substitution of tyrosine 757 to abolish the SHP2/ras/Erk signaling pathway (Ernst et al, submitted). In male and female gp130Y757F mice, trabecular bone volume was reduced by approximately 50%, detected by histomorphometry and microCT. This reduction in bone volume was associated with high bone turnover. In male mice, osteoclast surface (OcS/BS) was 70% greater, osteoblast surface (ObS/BS) was doubled and osteoid volume (OV/BV) was three times that of control mice. Similarly, in vitro RANKL-driven osteoclastogenesis was elevated in cultures of bone marrow cells from gp130Y757F mice compared to wild type controls, indicating that this phenotype does not relate to alterations in systemic hormones. High bone turnover in these mice indicates that gp130 signaling through SHP2/ras/Erk is required for normal bone turnover. This result is comparable with elevated osteoclastogenesis in the gp130 knockout mouse previously described, and suggests that gp130-mediated effects on osteoclastogenesis and trabecular bone volume are mediated through the SHP2/ras/Erk pathway. In contrast, bone turnover and trabecular bone volume were normal in gp130ΔSTAT mice, suggesting that the STAT1/3 pathway is not required for gp130-mediated regulation of trabecular bone volume. However, in gp130ΔSTAT mice, longitudinal bone growth was reduced. Tibial and femoral length were significantly lower than in wild type mice, and growth plate closure was observed as early as 12 weeks of age, indicating that while gp130 signaling through STAT1/3 is not required for normal bone turnover, it is required for continued longitudinal bone growth. In conclusion, gp130 signaling is required for normal longitudinal bone growth and regulation of trabecular bone mass, but these two activities are mediated by distinct downstream signaling pathways.

1124

Protein Kinase D Induced Activation of the Stress-sensitive MAP kinases JNK and p38 is a New Signaling Pathway Involved in BMP-2 Induced Osteoblastic Cell Differentiation. J. Lemonnier*, C. Ghayor*, J. Caverzasio. Division of Bone Diseases, University Hospital of Geneva, Geneva, Switzerland.

BMP-2 is a critical morphogenetic protein for the development of osteoblastic cells. However, the cellular mechanisms by which BMP-2 induces this process remains uncompletely understood. Recent finding suggest that, in addition to the SMAD pathway, BMP-2 may also signal via protein kinase C (PKC) and/or the mitogen-activated protein kinases (MAPKs). In this study, we investigated the molecular mechanism by which BMP-2 activates JNK and p38 and the role of these pathways in the differentiation of osteoblastic cells. In MC3T3-E1 osteoblastic cells, the activation of JNK and p38 by BMP-2 (23-25 x at 3h) was not affected by overnight pretreatment of the cells with PMA suggesting that conventional PKC isoforms are not involved in this signaling response. In contrast, the PKC and protein kinase D (PKD) inhibitor Go6976 (10 μM) completely blocked BMP-2-induced activation of JNK and p38 without influencing SMAD1,5 phosphorylation. Interestingly, Go6976 also completely blunted the stimulation of alkaline phosphatase (ALP) activity (3-5x) induced by BMP-2. PKD, which is the mouse homologue of the human PKC mu, is a newly described diacylglycerol-sensitive protein kinase with homology to PKCs and unknown function. Among various PKCs expressed in MC3T3-E1 cells, BMP-2 only induced phosphorylation/activation of PKD with a maximal effect (3.3x) after 1 h incubation and this response was completely prevented by Go6976. To further determine the role of PKD in mediating activation of JNK and p38 by BMP-2, we constructed a MC3T3-E1 cell line stably expressing PKD antisens oligonucleotide (AS-PKD). In this cell line, PKD expression was lowered by 50-60% compared with vector transfected cells (V-PKD). Interestingly, activation of JNK and p38 as well as the stimulation of ALP induced by BMP-2 were markedly impaired in AS-PKD compared to V-PKD transfected cells suggesting a functional role of activation of JNK and p38 by PKD in osteoblast-like cells. In conclusion, our data describe a new signaling pathway activated by BMP-2 in osteoblastic cells. This pathway involves PKD-dependent activation of JNK and p38 which, in addition to SMADs, appears to be essential for the effect of BMP-2 on osteoblastic cell differentiation.

1125

Neuropeptide Y Y4 and Y2 Receptors Act Synergistically in Neuroregulation of Bone Mass. P. A. Baldock*[1], A. Sainsbury-Salis*[2], N. Ueno*[3], M. Couzens*[2], R. F. Enriquez*[1], A. Inui*[3], H. Herzog*[2], E. M. Gardiner[1]. [1]Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Neurobiology Program, Garvan Institute of Medical Research, Sydney, Australia, [3]Clinical Molecular Medicine, Kobe University Graduate School of Medicine, Kobe, Japan.

Neuropeptide Y (NPY) Y2 receptor has previously been shown to regulate bone mass, with knockout resulting in increased cancellous bone formation. Pancreatic polypeptide (PP) a member of the NPY family was elevated in these mice, suggesting a mechanism for this effect. Further, PP is the major ligand for NPY Y4 receptor, implicating Y4 in the Y2 KO bone phenotype. This study compared the effect of NPY Y2 KO with Y4 KO, Y2/Y4 double KO and PP transgenic overexpression in the regulation of bone mass. Bone structure was examined in the distal femoral metaphysis and mid-femoral diaphysis of 4 month old male knockout, transgenic and wild type mice. PP overexpression did not affect bone mass, as cancellous bone volume (BV/TV) in PP mice was not different from wild type mice (10.4 ±1.9 vs 9.0 ±1.2%), with no differences in trabecular number or thickness observed. Similarly, there was no difference in cortical area (0.81 ±0.04 vs 0.80 ±0.03 mm2). Unlike Y2 KO, deletion of the Y4 receptor did not affect bone mass. BV/TV in Y4 KO mice did not differ from wild type mice (8.2 ±1.2 vs 6.6 ±1.4%), and there were no microarchitectural differences. These values were significantly lower than in Y2 KO mice (12.4 ±1.7%). Cortical area was also unaffected by Y4 knockout (1.12 ±0.04 vs 1.17 ±0.14 mm2) and values did not differ from Y2 KO mice (1.09 ±0.5 mm2). Despite the lack of skeletal phenotype in Y4 KO mice, deletion of both receptors in Y2/Y4 KO mice had a synergistic effect on bone mass. BV/TV was elevated compared to Y4 KO (17.4 ±2.1 vs 8.2 ±1.2%) and Y2 KO (12.4 ±1.7%), although the latter 40% difference was not significant (p=0.055). Trabecular number was also elevated (4.9 ±0.4 vs 3.2 ±0.3 /mm) and (4.0 ±0.3 /mm). Trabecular thickness was elevated compared to Y4 KO (34.4 ±2.6 vs 24.7 ±1.9 um) but not Y2 KO (29.9 ±2.0 um). In contrast to cancellous increases, cortical area was reduced in Y2/Y4 KO compared to both Y4 KO (0.91 ±0.03 vs 1.12 ±0.04 mm2) and Y2 KO (1.09 ±0.05 mm2), associated with reduced cortical thickness (203 ±4 vs 239 ±5 and 237 ±6 um). These data suggest that PP is not involved in the Y2 KO bone phenotype. Furthermore, although the Y4 receptor pathway does not independently regulate bone mass, synergistic interaction between Y2 and Y4 elevates cancellous bone mass over Y2 KO levels, and produces a reduction in cortical bone not present in either KO. In conclusion, this study suggests neuroregulation by these two receptors to reduce cancellous and increase cortical bone.

1126

Mim-1, an Osteoclast Secreted Chemokine, Stimulates Differentiation, Matrix Mineralization and Increased Vitamin D Receptor Binding to the VDRE of Osteoblastic Precursor Cells. L. V. Ponomareva*, W. Wang*, N. J. Koszewski, J. P. Williams. Internal Medicine, University of Kentucky, Lexington, KY, USA.

Osteoclasts are terminally differentiated cells of hematopoietic origin. Mechanisms coordinating bone degradation by osteoclasts and new bone synthesis by osteoblasts are poorly defined. We have identified an osteoclast-secreted chemokine, mim-1, that stimulates concentration dependent increases in migration and differentiation of osteoblastic precursor cells. The signaling pathways mediating these effects have not been identified. We have reported that mim-1 stimulates concentration dependent changes in protein tyrosine phosphorylation and activation of ERK in human mesenchymal cells as determined by Western analysis with phospho-specific antibodies. In this study we demonstrate that mim-1 stimulates concentration dependent increases in differentiation and matrix mineralization of MC3T3 E1 cells and human mesenchymal cells as determined by total calcium measurements and VonKossa staining. The effects of mim-1 on early signaling events in osteoblast differentiation were examined. Mim-1 stimulates time and concentration-dependent increases in binding of the osteoblast-specific transcription factor, *cbfa1,* to the proximal transcription-factor binding site in the osteocalcin promoter. Increased *cbfa1* binding is evident at 30 minutes and maximal by 2 hours treatment with 15 nM mim-1. Binding is stimulated by as low as 0.3 nM mim-1. We examined the effect of mim-1 in vitamin D receptor (VDR) binding and demonstrate that mim-1 also stimulates increased VDR binding to the VDRE of osteocalcin with 10 minutes treatment in the absence of added hormone as determined by electrophoretic mobility shift assays and confirmed in supershift assays. VDR binding to the VDRE is maximal at 1 hour. These hormone-independent effects of mim-1 on VDR binding to the VDRE consistently preceded the *cbfa1* binding (n=3). In conclusion, the osteoclast derived chemokine stimulates migration, differentiation and matrix mineralization of osteoblastic precursors suggesting that mim-1 is an important signaling molecule regulating recruitment and differentiation of osteoblastic precursor cells to areas of recent bone resorption, and may represent an endogenous anabolic agent in bone.

The Effect of Monitoring on Adherence and Persistence with Raloxifene Therapy and the Impact on the Effectiveness of Treatment. J. A. Clowes, N. F. A. Peel, R. Eastell. Clinical Sciences (North), University of Sheffield, Sheffield, United Kingdom.

Long-term adherence and persistence with antiresorptive therapy is poor, this limits the effectiveness of treatment. Monitoring techniques may improve adherence or persistence and potentially increase the therapeutic response. The aims of the study were to determine if 1) monitoring by medical staff could enhance adherence and persistence with an antiresorptive agent, 2) providing information on biochemical response to therapy resulted in additional benefit and 3) different rates of adherence to therapy altered treatment efficacy. Seventy-five healthy postmenopausal women (age 50-80 years) with osteopenia (T score < -1 SD and > -2.5 SD), recruited from general practice surgeries, were treated with 60 mg raloxifene and 500 mg elemental calcium. Subjects were randomized in an open label study to one of three arms involving 1) marker monitoring, 2) nurse monitoring or 3) no monitoring. At each visit nursing staff followed a standard interview. Subjects in the monitoring (nurse and marker) protocols attended for visits at 12, 24 and 36 weeks. All subjects were evaluated at 1 year. In the marker protocol results of urine N-telopeptide of type I collagen (uNTX) measurements collected prior to each visit were given to subjects. Adherence was assessed using electronic event monitors, which record the date and frequency a prescription bottle is opened. Persistence with therapy was defined as continuing to take tablets for greater then 7 out of any 14 days prior to the 1-year visit. Cumulative adherence was the number of tablets actually taken divided by the number of expected tablets taken at each time point expressed as a percentage. The hazard ratio for persistence was 0.81 with a trend for monitored subjects to persist with therapy for longer (Log rank test; P = 0.07). This was seen for both nurse-monitored (Wilcoxon (Gehan) test; P = 0.06) and marker-monitored (P = 0.26) subjects. The hazard ratio for cumulative adherence to therapy (> 75%) was 0.64 with monitored subjects 36% more likely to adhere to > 75% therapy (Log rank test; P = 0.039) than non-monitored subjects. There was a trend for greater cumulative adherence to therapy (> 75%) in the nurse-monitored and marker-monitored subjects (P = 0.05 and P = 0.15). Adherence at 1 year was strongly correlated with % change in hip BMD (r = 0.34, P = 0.003) and % change in uNTX (r = - 0.46, P = 0.0001). We conclude that the monitoring of patients increases adherence to therapy by 36% over 1 year. Furthermore increased adherence to therapy increased the effectiveness of raloxifene therapy determined using surrogate end points.

Acute Androgen Deprivation Causes Early Rapid Bone Loss: A Longitudinal Study. P. S. Coates, J. Wagner, J. Ribich, D. L. Trump*, J. B. Nelson*, S. L. Greenspan. University of Pittsburgh Medical Center, Pittsburgh, PA, USA.

Androgen deprivation therapy, the most effective systemic therapy for prostate cancer, is a major risk factor for osteoporosis in men. To investigate the effects of androgen deprivation over time, we studied 120 men prospectively over 6 months. We compared men with prostate cancer; 1) not on androgen deprivation (No AnDep), N=27; 2) following acute (<6 months) androgen deprivation (Acute AnDep), N=23; and 3) following chronic (>6months) androgen deprivation (Chronic AnDep), N=32; with 4) healthy controls, N=38. The men did not differ in age, height, weight or BMI. Men with acute AnDep lost BMD at the radius, total hip and total body, gained body fat and had increased markers of bone turnover acutely over 6 months, compared to men on no AnDep, chronic AnDep or controls who remained stable (data shown in table, mean ± SD). Urine N-telopeptide (NTX) at 6 months was inversely related to the 6-month change in bone density at the radius (R=-0.43, p<0.01), total body (R=-0.54, p<0.001) and trochanter (R=-0.39, p=0.02), with a similar trend at the total hip. We conclude that AnDep causes an early rapid bone loss that slows over time. These longitudinal data suggest future studies are needed to target preventive strategies for this population.

% change in 6 months

	No AnDep	Acute AnDep	Chronic AnDep	Controls
Total radius BMD	0.63 ± 3	-1.46 ± 2[a]	-0.35 ± 3	0.04 ± 1

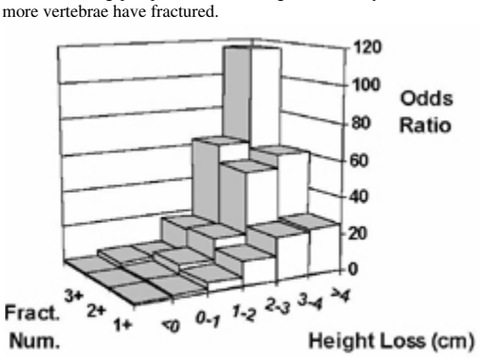
The Relationship Between Prospective Height Loss and Multiple Vertebral Fractures. K. Siminoski[1], J. D. Adachi[2], G. Cline*[3], C. B. M. B*[4], V. E. R. T Study Group*[3]. [1]Radiology, Univ of Alberta, Edmonton, AB, Canada, [2]Medicine, McMaster Univ, Hamilton, ON, Canada, [3]Procter & Gamble Pharm, Mason, OH, USA, [4]Bone Alliance, Toronto, ON, Canada.

We have analyzed the relationship between height loss during prospective monitoring and the occurrence of multiple new vertebral fractures. Subjects were women in the placebo arms of the VERT MN/NA risedronate studies (average age 69 yrs; range: 38-85 years) who had post-baseline data for both variables. Height loss was determined as the difference between the baseline measurement and the subsequent measurement using a stadiometer. Lateral vertebral radiographs were performed at the same times and were analyzed by digital morphometry from T4 to L4. Vertebral fractures were determined using both quantitative and semiquantitative methods. New fractures occurred in 18.1% of the 985 subjects over 3 years of observation. The odds ratios (OR) for detecting 1 or more fractures increased with the amount of height loss, as shown in the figure. In comparison to subjects with no height loss, height loss in the range of 0 to 1 cm produced an OR of 2.0; for height loss > 4 cm, OR was 25.1. For detecting two or more fractures, the OR increased from 2.0 for height loss in the range of 0 to 1 cm to 60 for height loss of > 4 cm. Odds increased further for detection of three or more fractures: OR was 3.9 when height loss was 0 to 1 cm, and rose to 117 for height loss > 4 cm. Two relationships are revealed by these analyses. First, for a specific number of vertebral fractures, the OR rises sharply as the amount of prospective height loss increases. Second, at a specific level of observed height loss, the OR increases for greater numbers of fractures. We conclude that (1) the greater the amount of height loss, the greater the likelihood that an incident vertebral fracture has occurred, and (2) the greater the height loss, the greater the likelihood of multiple fractures. Height loss > 2 cm during prospective monitoring substantially increases the probability that one or more vertebrae have fractured.



Disclosures: ***K. Siminoski****, Procter & Gamble 2, 5, 8.*

Comparison of 3 Bone Ultrasounds for Determining Osteoporotic Fracture Risk over 3.5 Years in 7487 Elderly Women: The SEMOF study. M. A. Krieg, J. Cornuz*, P. Burckhardt. Internal Medicine, University Hospital, Lausanne, Switzerland.

The SEMOF study group : Büche D, Dambacher MA, Hartl F, Häuselmann HJ, Kraenzlin M, Lippuner K, Neff M, Pancaldi P, Rizzoli R, Tanzi F, Theiler R, Tyndall A, Wimpfheimer K. The Swiss Evaluation of the Methods of Measurement of Osteoporotic Fracture Risk (SEMOF) study is a prospective multicenter study which compares 3 bone ultrasounds (QUS), Achilles+ (GE-Lunar), Sahara (Hologic), and DBM sonic 1200 (IGEA) for the assessment of osteoporotic fracture risk in elderly women, under strict quality control conditions. 7487 women aged 75.3 ± 3.1 years (mean±SD) were assessed using the following QUS parameters : "SI" for Achilles+, "QUI" for Sahara, and "ADSOS" for DBM Sonic 1200 (DBM). In addition, 80% of the measurements with DBM (n=6017) were analyzed in order to calculate the "UBPI". During the mean 3.5-year follow-up, 569 osteoporotic fractures (469 for UBPI) were reported. Age-adjusted relative risks (RR and 95% confidence intervals) were calculated for the QUS parameters, and expressed per decrease of 1 SD of the respective parameter (table). To compare the different devices, areas under the ROC curve (AUC) were calculated. Only Achilles+ and Sahara predicted hip fracture risk. However, all 3 QUS predicted other osteoporotic fracture risks, such as for vertebral or forearm fractures. For hip and forearm fractures, AUC (and by that prediction power) of Achilles+ and Sahara (AUC 0.59-0.70) were both higher ($p<0.01$) than AUC of ADSOS and UBPI (AUC 0.51-0.59). For clinical vertebral fractures, there was no significant difference between AUC of the 3 devices (AUC 0.57-0.64). These results of the SEMOF study show that QUS of the heel (Achilles+ and Sahara), and to a lesser degree QUS of the phalanges (DBM sonic 1200), are predictors of osteoporotic fractures in a cohort of elderly Swiss women.

Type of fracture	Hip	Clinical vertebral	Forearm
Nb of fractures	74	95	181
	RR (95%CI)	RR (95%CI)	RR (95%CI)
Achilles+ (SI)	1.8 (1.4 - 2.3)	1.5 (1.2 - 1.8)	1.4 (1.2 - 1.6)
Sahara (QUI)	2.1 (1.6 - 2.8)	1.7 (1.3 - 2.2)	1.8 (1.5 - 2.1)
DBM (ADSOS)	0.9 (0.8 - 1.2)	1.2 (1.0 - 1.5)	1.2 (1.0 - 1.3)
DBM (UBPI)	1.0 (0.8 - 1.3)	1.4 (1.1 - 1.9)	1.2 (1.0 - 1.5)

QCT Spine BMD, Hip BMD, and Risk of Fractures in Elderly Black and White Men and Women. S. R. Cummings[1], F. Harris[1], T. Lang[1], T. Harris[2], D. Taaffe[3], F. Tylavsky[4], J. A. Cauley[5], D. M. Black[1]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]National Institute on Aging, NIH, Bethesda, MD, USA, [3]University of Queensland, St. Lucia, Australia, [4]University of Tennessee, Memphis, TN, USA, [5]University of Pittsburgh, Pittsburgh, PA, USA.

The predictive accuracy of volumetric BMD (vBMD) of the spine has never been tested or compared with areal BMD (aBMD) of the hip by DXA. Additionally, the predictive accuracy of hip BMD has never been prospectively compared for women (W), men (M), African-Americans (AA) and Caucasians (C). We measured hip aBMD (Hologic 4500) in 846 CW, 929 CM, 724 AA W and 544 AA M age 70-80 years and trabecular vBMD by QCT in half of this cohort and then validated clinical fractures during a mean 3.7 years follow-up. All analyses are age-adjusted and exclude participants taking bone active drugs. Adjusting for gender and race, each SD decrease increased the risk of clinical fracture 1.8-fold (95% CI:1.2, 2.5) for spine vBMD and 2.1 (1.6 to 2.8) for total hip DXA. In the whole cohort, one SD decrease in total hip aBMD increased risk of clinical fractures in all race and gender groups: from 1.6 to 2.9 per SD. This was statistically significant for all groups except for black men who suffered only 4 fractures. We conclude that aBMD by hip DXA might be a somewhat stronger predictor of clinical fractures than vBMD of the spine. Hip DXA predicts clinical fractures in women of both races and in white men.

1132

Serum OPG and Bone Turnover in Human Pregnancy and Lactation. K. E. Naylor*[1], N. Wilde*[1], A. Rogers[1], C. Smith[1], R. B. Fraser*[2], R. Eastell[1], A. Blumsohn[1]. [1]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [2]Department of Obstetrics and Gynaecology, University of Sheffield, Sheffield, United Kingdom.

Osteoprotegerin (OPG) is an osteoblast derived decoy receptor, which inhibits osteoclastogenesis and bone resorption by neutralising RANKL. Animal studies have indicated that serum OPG is increased in pregnancy and might prevent excessive maternal bone resorption. The role of OPG in human pregnancy has not been studied. We assessed serum OPG in a longitudinal study of planned human pregnancy and lactation, and in human neonates. Fasting morning blood samples and 24 hour urine samples were collected before conception, at 16, 26 and 36 weeks gestation, and at 2 and 12 weeks postpartum in 17 Caucasian women (ages 20 to 36). Samples were also collected from 22 neonates. Reference data were obtained from an additional 35 healthy pre-menopausal women (ages 20 to 39). OPG was measured using an immunometric ELISA assay. Markers of bone turnover included serum βCTX (Roche Diagnostics), urine NTX (Ostex International), and bone ALP. Serum OPG increased to 151%±13SEM ($P < 0.001$) of pre-conception values at 26 weeks gestation, and to 251%±16 ($P< 0.001$) by 36 weeks gestation. By 2 weeks postpartum maternal OPG was not significantly higher than pre-conception values. Serum OPG was lower in neonates than in premenopausal women (289±91SD pg/mL vs. 420±167 pg/mL; $P<0.001$). Bone turnover was also markedly increased during pregnancy (increase vs pre-conception: βCTX 176%±17, UNTX 319%±41, bone ALP 206% ±18 by 36 weeks gestation; all $P<0.001$). There was however no correlation between the change in OPG and bone turnover. The tissue source of circulating OPG in pregnancy is uncertain, but the rapid postpartum decline in maternal OPG, and low levels of OPG in neonates suggest that the breast and fetus are unlikely sources. These findings may be consistent with a placental source.

1133

Preservation of Osteocyte Viability by Bisphosphonates Contributes to Bone Strength in Glucocorticoid-Treated Mice Independently of BMD: An Unappreciated Determinant of Bone Strength. R. S. Weinstein, C. C. Powers*, A. M. Parfitt, S. C. Manolagas. Div. of Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ of Ark for Med Sci, Little Rock, AR, USA.

Osteocyte viability and thereby integrity of their mechanosensory network, seems to be a critical determinant of bone strength. For example, glucocorticoid excess, in mice and humans, is known to increase osteoblast and osteocyte apoptosis and may alter the BMD threshold such that fractures may occur at higher lumbar BMD values than those found in sex steroid-deficiency or involutional osteoporosis. To investigate whether osteocyte viability contributes to bone strength independently of bone mineral density (BMD), we examined the relationship between spinal BMD and vertebral compression strength in adult Swiss-Webster mice receiving prednisolone pellets (n=47) compared to mice receiving placebo (n=153). We report that glucocorticoid administration significantly alters the correlation between vertebral strength, determined by compression of L5, and spinal BMD, determined by live DEXA. Specifically, the slope of the relationship between vertebral strength and spinal BMD found in the control animals was significantly different in the prednisolone group ($p<0.001$), indicating a glucocorticoid-induced deterioration in bone quality. In a second experiment with mice receiving prednisolone (2.1 mg/kg/d), placebo, alendronate (0.75 mg/kg/day) or prednisolone together with alendronate for 10 days (n=10 per group), the prevalence of osteocyte apoptosis was indirectly related to vertebral strength ($r = -0.38$, $p<0.03$). Moreover, preservation of cortical osteocyte viability in mice receiving both prednisolone and bisphosphonate ($p<0.01$) was associated with increased bone strength ($p<0.05$) as compared to mice receiving prednisolone alone, even though loss of BMD was similar between the two groups at this time point. These lines of evidence strongly suggest that osteocyte viability is a heretofore unappreciated determinant of bone strength.

1134

Systemic Lentiviral Delivery of Osteoprotegerin-Fc Fusion Protein Increases Bone Mass in Mice. P. Doran[1], S. J. Russell*[1], D. G. Fraser*[1], C. R. Dunstan[2], B. L. Riggs[1], S. Khosla[1]. [1]Mayo Clinic, Rochester, MN, USA, [2]Amgen, Inc., Thousand Oaks, CA, USA.

Osteoprotegerin (OPG) is a potent suppressor of osteoclast development and activity, but therapeutically must be administered subcutaneously, and has a relatively short half-life. With the availability of safe lentiviral vectors that provide sustained expression of proteins, we explored the possibility of delivering OPG systemically in mice over an extended period. To prolong the circulating half-life of the OPG protein, we engineered replication-incompetent lentiviral vectors expressing an OPG-Fc fusion protein. Since murine immune responses can neutralize human OPG, 10-week old female SCID mice (n = 12) were used. The mice (n = 6 per group) were injected with either a control lentivirus vector or with a similar vector expressing the OPG-Fc construct. Serial determinations of BMD (using a PIXImus densitometer) and serum levels of human OPG-Fc protein (by ELISA) at baseline and after 2, 10, and 16 weeks were obtained. The table shows the % changes from baseline BMD (mean ± SEM) at the tibia and vertebrae in the 2 groups.

	Tibia			Vertebrae		
	2 weeks	10 weeks	16 weeks	2 weeks	10 weeks	16 weeks
Control vector	+0.7 ± 0.4	+5.9 ± 2.1	+8.3 ± 2.0	+4.1 ± 2.3	+11.8 ± 2.6	+21.3 ± 3.8
OPG-Fc vector	+6.2 ± 1.2**	+13.6 ± 1.7*	+15.4 ± 2.0*	+16.2 ± 3.3*	+28.6 ± 5.2*	+36.0 ± 7.9

*, $P < 0.05$ and **, $P < 0.01$ versus control vector

The OPG-Fc lentivirus injected mice had 4 to 9-fold greater increases in BMD at 2 weeks than did the control mice. By 16 weeks, the differences between the increases in BMD in the 2 groups were less marked (~2-fold). Circulating OPG levels were undetectable (< 0.040 ng/ml) in all but one of the control mice. By contrast, the OPG-Fc lentivirus injected mice had serum OPG levels of 78.7 ± 10.7 ng/ml, 24.2 ± 3.3 ng/ml, and 17.6 ± 2.8 ng/ml at 2, 10, and 16 weeks, respectively (compared to normal circulating levels in humans of 0.1-0.2 ng/ml). This "proof of concept" study thus demonstrates that systemic lentiviral delivery of OPG results in increased BMD in mice. These data also indicate that with continued improvements in viral delivery systems, OPG (or other proteins with anti-resorptive or anabolic efficacy) could be delivered systemically or locally in bone, opening up novel therapeutic approaches to the treatment of osteoporosis and other metabolic bone diseases.

Gene Array Analysis of the Bone Effects of Raloxifene and Alendronate Show that Alendronate Strongly Inhibits the Expression of Bone Formation Marker Genes. J. E. Onyia, E. Dow*, C. Adams*, F. Lawrence*, K. Bemis*, D. L. Halladay*, R. R. Miles*, S. Huang*, P. Chen*, S. Chandrasekhar, C. A. Frolik, M. Sato, L. Ma, H. Bryant, L. Gelbert*. Eli Lilly and Company, Indianapolis, IN, USA.

The selective estrogen receptor modulator, raloxifene (Ral), and alendronate (ABP) are therapies currently used to treat osteoporosis. In an effort to ascertain the molecular/genomic events regulated by these agents in vivo, we characterized the pattern of bone gene expression in 6 months old ovariectomized rats treated with Ral or ABP. Rats were orally administered fully efficacious doses of Ral (1.0 mg/kg/day po) or ABP (8 µg/kg/day sc) starting from 5 days post-ovariectomy for 5 weeks. At study termination, total RNA was isolated from the proximal femoral metaphysis, labeled by in vitro transcription, and hybridized to a Affymetrix microarrays containing 8500 rat genes. To enable statistical validation of data, total RNA from bones of biological replicates (n=5 animals/group) were not pooled and each sample was analyzed on duplicate chips. Gene expression analysis ($P < 0.05$) demonstrated that 850 genes (10%) changed following ovariectomy. Treatment with ABP and Ral regulated 954 (11.2%) and 930 (10.9%) genes, respectively, indicating regulation of a comparable number of genes. Of the 850 genes induced by ovariectomy, approximately 23 % (195 genes) were regulated by ABP, while 30% (252) were regulated by Ral. A comparison of genes regulated by ABP vs. Ral showed that 793 genes were unique to ABP and 769 genes were unique to Ral, while 161 were common to both treatments. An analysis of the bone formation and bone resorption pathway genes identified novel potential differences in ABP and Ral action. ABP strongly inhibited the expression of bone formation marker genes -osteocalcin, collagen type1, alkaline phosphatase, collagen binding protein, SPARC, biglycan, decorin, IGF-I & -II. By contrast, Ral had no effect on any of the bone formation markers except for reductions in expression of decorin and IGF-I. Of the resorption pathway genes on the chip, ABP inhibited carbonic anhydrase II & III but stimulated cathepsin K, calcitonin receptor C 1b, and cortactin isoform C. Ral inhibited colony stimulating factor-1 (CSF-1), but stimulated carbonic anhydrase IV, and cortactin isoform C. These results demonstrate both similarities and differences in the molecular fingerprint of ABP and Ral that may give insights into the mechanistic differences in their skeletal actions in vivo. The strong suppression of osteoblast genes shown for ABP is consistent with the strong suppression of bone formation activity observed for ABP by histomorphometry in vivo.

Early Response of Bone Turnover Markers and Bone Mineral Density to Teriparatide [Recombinant Human Parathyroid Hormone (1-34)] in Postmenopausal Women Previously Treated with an Antiresorptive Drug. B. Ettinger[1], J. A. San Martin[2], G. Crans*[2], I. Pavo*[2]. [1]Division of Research, Kaiser Permanenete Medical Care Program, Oakland, CA, USA, [2]Lilly Research Labs, Eli Lilly & Company, Indianapolis, IN, USA.

To determine if prior use of an antiresorptive affects the response to teriparatide (TPTD), we are measuring changes in bone mineral density (BMD) and bone markers in postmenopausal women who stopped long-term antiresorptive therapy and switched immediately to TPTD 20 ug/day. Eligible patients were identified from pharmacy and bone density databases of the Kaiser Permanente Medical Care Program in Northern California. Patients included women who had regularly used either alendronate (ALN) 10mg/day or raloxifene (RLX) 60mg/day for at least 18 months and whose prescription data indicated ≥ 70% compliance in the prior year. A prior spinal or total hip BMD T-score must have been < -2.5, and at study entry the T-score had to be < -2.0. At baseline, ALN and RLX were similar in age (71.5±7.1 vs 69.4±5.7 y, mean±SD, respectively) and treatment duration (27.8±5.0 vs 27.8±6.0 mo), while each bone marker was significantly lower in ALN. After one month of TPTD, markers of bone formation (OC, PINP, BSAP) and resorption (CTX, NTX) increased above baseline, but RLX had a 2-3 times greater increase in formation markers than ALN.

Bone markers	Previous therapy	Baseline (median)	1 month (median)	Change after 1 mo (median)
OC (µg/L)	RLX	18.7	42.0	21.2[a,b]
	ALN	10.2	20.2	7.5[a]
PINP (µg/L)	RLX	38.8	93.5	48.5[a,b]
	ALN	13.6	37.3	22.5[a]
BSAP (µg/L)	RLX	9.3	17.5	5.1[a,b]
	ALN	4.7	6.8	1.2[a]
NTX (nMBCE/L)	RLX	11.3	13.7	2.9[a]
	ALN	7.6	9.4	1.5[a]
CTX (pmol/L)	RLX	2424.0	2921.5	370.0[a]
	ALN	980.5	1880.5	854.0[a]

[a] P<.05 within group, [b]P<.05 vs ALN (controlling for baseline differences); n=33 (ALN), n=26 (RLX). OC=serum osteocalcin, PINP=serum procollagen type I N propeptide; BSAP=serum bone-specific alkaline phosphatase; CTX=serum C-telopeptide type I collagen; NTX= serum N telopeptide

Early bone marker changes indicate that patients previously treated with either ALN or RLX have an appropriate initial response to TPTD. The magnitude of the initial response for bone formation markers was greater in patients previously treated with RLX. We will present 3 and 6 month BMD and bone marker data from this open label, prospective study.

Disclosures: ***B. Ettinger****, Eli Lilly and Company 2, 5, 8.*

Vitamin D and Calcium Treatment and Environmental Adjustment in the Prevention of Falls and Osteoporotic Fractures among Elderly Danish Community Residents. E. R. Larsen*[1], L. Mosekilde*[1], A. Foldspang*[2]. [1]C, Aarhus Amtssygehus, Aarhus University Hospital, Aarhus, Denmark, [2]Institute of Epidemiology and Social Medicine, Aarhus University, Aarhus, Denmark.

Falls and fractures among elderly people living in the community constitute a major public health problem, as falls are the leading cause of mortality due to unintentional injury in elderly aged 65 and over. In January 1995, 9,605 community dwelling residents aged 66 and over (females 5,771, males 3,834; median age, 74.0 years; range, 66-103 years) in the municipality of Randers were identified in the Danish Central Population Registry. For the present purpose, the municipality was divided into four blocks each comprising 2-3 public social service centres, which took care of the data collection. The four blocks were randomly allocated to three different fall and fracture prevention programmes. Participants in the first block were offered a home safety inspection by a community nurse in order to identify and remedy possible hazards. Furthermore, they were offered identification and correction of potential health or dietary problems. Finally, their prescribed medication was evaluated by the nurse in order to identify eventual errors or needs for dose adjustment. Participants in the second block were offered a daily supplement of 1,000 mg of elemental calcium as calcium carbonate and 400 IU (10 µg) of vitamin-D_3 (Calcichew D®, Nycomed DAK). Furthermore, they were offered an evaluation of their prescribed medication, as mentioned above. Participants in the third block were offered a combination of the two programmes. Residents in the last block served as controls. Information was achieved on actual health problems, medication, falls and fractures, exercise habits, dietary supply of vitamin D and calcium, social background and environment. Information on falls and fractures in the study population was achieved by use of the Danish Hospital Registration Database. The overall acceptance of a home visit was 51%. When offered the calcium and vitamin D programme, elderly female residents seemed to fall more rarely (RR, 0.9, $p<0.05$), whereas both males and females had a reduced risk of osteoporotic fractures (RR, 0.8, $p<0.025$) during the 3½ years of follow-up. The present factorial intervention study support that vitamin D and calcium supplementation may prevent falling in elderly females and osteoporotic fractures in both genders in an European region known to be deficient in vitamin D.

Daily Oral Ibandronate Prevents Bone Loss in Postmenopausal Women Without Osteoporosis. M. McClung[1], R. D. Wasnich*[2], R. Recker[3], J. A. Cauley[4], K. Ensrud[5], A. Burdeska*[6], P. Mahoney*[6], C. Hughes*[6], C. Chesnut[7]. [1]Oregon Osteoporosis Center, Portland, OR, USA, [2]Radiant Research, Honolulu, HI, USA, [3]Creighton University School of Medicine, Omaha, NE, USA, [4]University of Pittsburgh, Pittsburgh, PA, USA, [5]V.A. Medical Center, Minneapolis, MN, USA, [6]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [7]Osteoporosis Research Center, University of Washington Medical Center, Seattle, WA, USA.

A previous phase III trial (Delmas P, et al. IOF World Congress on Osteoporosis 2002; abstract O37) demonstrated the effectiveness of oral ibandronate, a potent nitrogen-containing bisphosphonate, in preventing vertebral fractures in women with postmenopausal osteoporosis (PMO). The objectives of this phase II/III dose-finding study were to investigate the efficacy, tolerability and optimal dose of oral daily ibandronate in the prevention of bone loss. In this multicenter, double-blind, placebo-controlled study, 648 postmenopausal women were allocated to one of four strata based on time since menopause (TSM) and baseline lumbar spine (L1-L4) bone mineral density (BMD); stratum A, normal BMD, TSM up to 3 years; stratum B, osteopenic, TSM up to 3 years; stratum C, normal BMD, TSM >3 years; and stratum D, osteopenic, TSM >3 years. Women were randomized to receive placebo (n=159) or ibandronate 0.5mg (n=161), 1.0mg (n=165) or 2.5mg (n=163) as once-daily oral treatment for 2 years. The primary endpoint was the percent change in lumbar spine BMD with ibandronate compared with placebo. All women received calcium supplementation (500mg daily). Baseline characteristics were similarly distributed across the four treatment groups. After 2 years, oral daily ibandronate produced a dose-related and consistent increase in BMD at the lumbar spine and hip (total hip, femoral neck, trochanter), together with a dose-dependent decrease in bone turnover (as indicated by serum as well as urinary CTx and osteocalcin levels). The results were consistent across the four enrolment strata. The greatest increases in lumbar spine BMD were observed with the 2.5mg dose, which produced statistically significant BMD gains compared with placebo at 6 months and all subsequent time points (+1.9% vs baseline [$p \leq 0.0001$] after 24 months). Lumbar spine BMD in the placebo group decreased by -1.2%. The largest lumbar spine BMD gain with ibandronate relative to placebo was observed in stratum D, where the change from baseline in the 2.5mg ibandronate group was 3.5% greater than that with placebo after 2 years. Oral daily ibandronate was well tolerated and no safety concerns were identified. In summary, oral daily ibandronate dose-dependently increases BMD and reduces bone turnover in postmenopausal women without osteoporosis, with the 2.5mg dose being the most effective. Furthermore, daily oral ibandronate is well tolerated.

1139

FGF-23 Is a Circulating Factor that Is Elevated in Oncogenic Osteomalacia and X-linked Hypophosphatemic Rickets. K. B. Jonsson[1], R. Zahradnik*[2], T. Larsson*[1], K. E. White[3], G. Hampson[4], A. Miyauchi[5], Ö. Ljunggren[1], H. Koshiyama*[6], T. Sugimoto*[7], K. Oba*[8], T. Yamamoto*[9], Y. Imanishi*[9], M. Econs[3], J. Lavigne*[2], H. Jueppner[10]. [1]Dept of Medical Sciences, University of Uppsala, Uppsala, Sweden, [2]Immutopics, Inc, San Clemente, CA, USA, [3]Indiana University School of Medicine, Indianapolis, IN, USA, [4]St Thomas Hospital, London, United Kingdom, [5]Kobe University Graduate School of Medicine, Kobe, Japan, [6]Amagasaki Hospital, Hyogo, Japan, [7]Kobe University, Kobe, Japan, [8]Kyushu University, Fukuoka, Japan, [9]Osaka University, Osaka, Japan, [10]Endocrine Unit, Massachusettes General Hospital, Boston, MA, USA.

Mutations in FGF-23 are responsible for autosomal dominant hypophosphatemic rickets (ADHR). Furthermore, FGF-23 mRNA is abundantly expressed in tumors that cause oncogenic osteomalacia (OOM) and recombinant FGF-23 leads, when injected into mice, to urinary phosphate wasting and hypophosphatemia, indicating that this growth factor is directly or indirectly involved in regulating phosphate homeostasis. The clinical and laboratory findings in ADHR or OOM are similar to those in X-linked hypophosphatemic rickets (XLH), suggesting that all three disorders may have a common pathway possibly involving FGF-23. To determine whether FGF-23 is secreted by OOM tumors, and whether its secretion and/or metabolism is abnormally regulated in different phosphate-wasting disorders, an assay for human FGF-23 was developed. Affinity purified antibodies against [Tyr-223]FGF-23(206-222)amide and [Tyr-224]FGF23(225-244)amide were used to develop an enzyme-linked immunosorbant assay (ELISA), which detects equivalently recombinant human FGF-23(1-251) and [R179Q]FGF-23(1-251), and synthetic human FGF-23(207-244)amide. Healthy individuals revealed FGF-23 concentrations of 55.6±50.6 RU/mL (mean±SD). Four OOM patients had concentrations ranging from 426.1 to 7970.0 RU/mL, which returned to normal after successful surgical tumor removal; other patients with suspected OOM showed levels of 481.4±159.2 RU/mL (mean±SEM). FGF-23 concentrations were elevated in 9 of 14 patient with XLH (range: 169.5 to 2335.0 RU/ml). Since circulating FGF-23 is readily detectable in healthy individuals, it could have a physiological role in phosphate regulation. FGF-23 measurements are likely to gain importance for establishing the diagnosis of OOM, for localizing OOM tumor, and for long-term monitoring of affected patients. Our findings furthermore suggest that PHEX may be involved in FGF-23 degradation indicating that urinary phosphate wasting in XLH could also be caused by elevated circulating concentrations of this growth factor.

1140

Chronic Kidney Disease (CKD) Directly Produces an Adynamic Bone Disorder Which Can Be Successfully Treated With BMP-7. R. J. Lund*[1], M. R. Davies*[1], N. Huq*[1], K. A. Hruska[2]. [1]Medicine, Washington University, St. Louis, MO, USA, [2]Pediatrics & Medicine, Washington University, St. Louis, MO, USA.

An adynamic bone disorder (ABD) is an increasingly important complication of CKD that is associated with high rates of bone fractures and perhaps calcification of the vascular media. The ABD is produced in patients with end-stage CKD on dialysis when PTH levels are aggressively suppressed. This has lead to the hypothesis that CKD directly affects skeletal remodeling and perhaps is a state of inadequate bone anabolism. The ABD is characterized histomorphometrically by very reduced active osteoblast number and surfaces, and by very reduced bone formation and mineral apposition rates. Here we report successful production of an animal model of the ABD demonstrating direct production of an osteodystrophy by CKD in the absence of secondary hyperparathyroidism, and its successful treatment with BMP-7. Twelve week old C57Bl6 mice were subjected to electrocautery of the right kidney followed in two weeks by left nephrectomy to create CKD. Animals were randomized into 5 Groups: Sham operated fed normal mouse chow (0.6%Pi, 0.8%Ca) n=7; Sham operated fed low phosphate chow (0.2% Pi, 0.5% Ca) and calcitriol (20 ng/kg tiw sq) n=12; CKD mice fed normal mouse chow n=11; CKD mice fed low phosphate chow and treated with calcitriol n=8; CKD mice fed low phosphate chow and treated with calcitriol and BMP-7 (10 mcg/kg q week) n=12. All groups were maintained on their regimens for 12 wks prior to calcein labeling of mineralization fronts, sacrifice and histomorphometry of distal femurs and proximal tibial metaphyses. BUN levels were elevated equally in all of the CKD groups, iPTH levels were elevated only in the CKD/chow fed group. Ca and PO_4 levels were normal in all groups until 12 weeks when the sham/low Pi and Calcitriol and the CKD/low Pi, calcitriol and BMP-7 groups had reduced PO_4 levels compared to the other groups. Osteoblast number and perimeters, mineralizing surfaces, bone formation rates, mineral apposition rates and activation frequency were all significantly depressed in the CKD/low Pi and Calcitriol group (ABD group) ($p<.01$) compared to the sham/chow group (normal group). The changes were all reversed to normal or greater levels in the BMP-7/low Pi and Calcitriol group ($p<.01$ vs the ABD group). In addition, BMP-7 lowered serum PO_4 by increasing its deposition into the skeleton in the rapidly exchangeable pool of the mineralization fronts. We conclude that CKD in the absence of hyperparathyroidism directly produces an ABD which we have successfully reversed by BMP-7 therapy.

1141

Late Low Dose Steroid Withdrawal in Renal Transplant Recipients Increases Bone Formation and Bone Mineral Density Without Altering Renal Function: A Randomised Controlled Trial. C. K. T. Farmer*[1], G. Hampson*[2], S. Vaja*[2], I. C. Abbs*[1], R. M. Hilton*[1], G. Koffman*[1], J. Watkins*[1], S. H. Sacks*[1], I. Fogelman[3]. [1]Nephrology and Transplantation, Guy's and St. Thomas' Hospital, London, United Kingdom, [2]Chemical Pathology, Guy's and St. Thomas' Hospital, London, United Kingdom, [3]Nuclear Medicine, Guy's and St. Thomas' Hospital, London, United Kingdom.

Glucocorticoid-induced osteoporosis is a major cause of secondary osteoporosis. Over 70% of renal transplant recipients remain on long-term steroid therapy despite clinical evidence showing the safety of late steroid withdrawal. However data on the effects of steroid withdrawal on bone metabolism in renal transplant patients on long-term low dose glucocorticoids (5-7.5 mg/day) are lacking. The aim of this study was to assess the effect of late low dose corticosteroid withdrawal for 12 months on bone mineral density (BMD) at the spine and hip, and humoral markers of bone metabolism in stable renal transplant recipients. We studied 52 patients mean 9.5 (3.4 SD) years post renal transplantation. They were randomised to 2 groups. The control group remained on their maintenance dose of prednisolone. The prednisolone dose was reduced by 1 mg per month in the patients in the withdrawal group. BMD (DXA) and biochemical markers of bone formation (serum osteocalcin ng/ml) and resorption (serum C-terminal telopeptides of type 1 collagen, CTx, pM) were measured at baseline and at 12 months. The clinical data and results are shown below.

	Control	Withdrawal
Number of Patients	29	23
Males n (%)	20 (68%)	14 (61%)
Mean Age (SD)	47.2 (12.4)	44.6 (15.3)
Femoral Neck BMD % Change (p)	-0.1	3.1 (<0.02)
L1-L4 BMD % change	-0.7	1.7 (<0.01)
% change in osteoclacin (range) (p)	3.7 (-63-325)	131.3 (-30-499) (<0.01)*
% change in CTx (range) (p)	-5.7 (-67-143)	10.1 (-79-211) (ns)

*Significant difference between groups and within groups

There was no significant difference in renal function following steroid withdrawal, mean serum creatinine 124umol/l. Late steroid withdrawal, even at low dose, results in a significant increase in BMD in renal transplant recipients with no detrimental effects on renal function. This is attributable to a positive effect on bone formation without any change in bone resorption.

1142

Effect of the Acute Infusion of Frizzled Related Protein 4 (FRP-4), a Protein Highly Expressed in Tumors Associated with Osteomalacia, on Phosphate Excretion In Vivo. T. J. Berndt*[1], J. Vassiliadis*[2], D. Reczek*[2], S. C. Schiavi*[2], R. Kumar[1]. [1]Medicine, Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [2]Genzyme Corporation, Framingham, MA, USA.

Frizzled related protein-4 (FRP-4) is over expressed in human tumors associated with osteomalacia, hyperphosphaturia and hypophosphatemia. The present studies were performed to determine whether infusion of biosynthetic FRP-4 protein increases renal phosphate excretion *in vivo*. Phosphate and inulin clearance studies were performed in 10-12 week old mice with intact parathyroid glands. The mice were anesthetized with Inactin (150 mg/kg). Catheters were placed in the carotid artery for measuring blood pressure and for blood sampling, and in the jugular vein for infusions. Mice were infused with a solution of 1% inulin and 0.1% BSA in isotonic saline at a rate of 2% BW/hr. After a ninety-minute equilibration period, phosphate and inulin clearances were determined during a control 30-minute clearance period. Following the control clearance period, FRP-4 (0.05 µg/120 min, n=7) was infused. Control mice received vehicle alone (n=3). Following a 45-minute stabilization period, fractional excretion of phosphorus and glomerular filtration rate were determined during two consecutive 30-minute clearance periods.

Fractional Excretion of Phosphate (%)

Clearance period	C_1	C_2	C_3
Vehicle infusion	0.02 ± .02	8.1 ± 6.7	9.2 ± 3.2
FRP-4 infusion	3.0 ± 1.5	21.3 ± 6.6*	26.3 ± 6.6*

*Indicates a significant difference from C_1, $p < 0.05$ paired T test.

Infusion of FRP-4 (0.05 µg/120 min) significantly increased fractional excretion of phosphate (FE_P) and was associated with a decrease in blood pressure from 102 ± 4 to 84 ± 5 mm Hg. Glomerular filtration rate decreased from 0.28 ± .09 to 0.16 ± .04 ml/min, ($p < .05$). Despite this decrease in glomerular filtration rate, FE_P increased significantly. We conclude that FRP-4, decreases renal phosphate reabsorption in intact mice *in vivo* and that FRP-4 is a "phosphatonin' like molecule.

1143

FGF-23 Protein is Present in Normal Plasma and Is Increased in Patients with Tumor-Induced Osteomalacia. Y. Yamazaki*[1], M. Shibata*[2], R. Okazaki[2], Y. Takeuchi[3], T. Fujita*[3], T. Yamashita[1], S. Fukumoto[4]. [1]Pharmaceutical Research Labs, KIRIN Brewery Co., Ltd., Takasaki, Japan, [2]Department of Medicine, Teikyo University, Ichihara, Japan, [3]Department of Medicine, University of Tokyo School of Medicine, Tokyo, Japan, [4]Department of Laboratory Medicine, University of Tokyo Hospital, Tokyo, Japan.

Tumor-induced osteomalacia (TIO) is a paraneoplastic syndrome characterized by hypophosphatemia and osteomalacia. Recently FGF-23 was identified as a causative factor of TIO. Recombinant FGF-23 induced hypophosphatemia with increased renal phosphate excretion and overexpression of FGF-23 in experimental animal models reproduced osteomalacia. In addition, abundant expression of FGF-23 has commonly been demonstrated in responsible tumors for TIO. However, it has not been shown that circulatory level of FGF-23 is actually elevated in patients with TIO. In addition, it has been unclear whether FGF-23 has some physiological role in healthy people, either. Therefore, to further investigate physiological and pathophysiological role of FGF-23, we developed the quantitative sandwich ELISA for FGF-23. BALB/c mice were immunized with purified recombinant human FGF-23. Because the substantial amount of cleavage between Arg^{179} and Ser^{180} of FGF-23 protein occurs in cell culture systems and affects the biological activity, two monoclonal antibodies, NA1 and CA1, that recognize N-terminal (25-179) and C-terminal (180-251) polypeptide of FGF-23, respectively, were selected to construct the sandwich ELISA. The assay range was between 15 and 500 pg/ml of standard full-length FGF-23. Plasma concentrations of FGF-23 in 25 healthy adults were detectable but below 50 pg/ml. In contrast, plasma FGF-23 was clearly high in a patient with TIO (270 pg/ml). The presence of uncleaved FGF-23 in plasma of the TIO patient was also confirmed by immunoprecipitation followed by Western blotting. After the removal of the responsible tumor, the elevated plasma FGF-23 concentration rapidly decreased to the normal range within a few hours. This change of FGF-23 level preceded the increase of 1,25-dihydroxyvitamin D and phosphate, and decrease of 24,25-dihydroxyvitamin D, which were first detected at 3, 6 and 9 hours, respectively. Thus, we demonstrated the presence of FGF-23 in circulation of healthy subjects and the elevation of FGF-23 in a patient with TIO. These results support the notion that TIO is caused by overproduction of FGF-23 and also suggest that FGF-23 plays an important role in physiological phosphate metabolism.

1144

Endocrine Response to Escalating-Dose Phosphate Supplementation in Men: Is FGF-23 Phosphatonin? H. C. Allen, A. Whybro*, M. E. Barker*, R. Eastell, A. Blumsohn. Bone Metabolism, University of Sheffield, Sheffield, United Kingdom.

Recent studies have shown that fibroblast growth factor 23 (FGF-23) is the probable mediator of hypophosphatemia and hyperphosphaturia in oncogenic osteomalacia, X-linked hypophosphatemia and autosomal dominant hypophosphatemic rickets. It is uncertain whether FGF-23 is a physiologically relevant phosphate regulating hormone, 'phosphatonin'. The aim of this study was to examine the effect of escalating dose phosphate supplementation in healthy adults. Twelve healthy men (ages 19 – 38 years) were studied for 5 weeks. For the first week, participants were studied on their habitual diet. Participants were then studied for 4 weeks on a standardised diet containing 1000mg/d phosphate and 1000mg/d calcium. No supplement was given for one week, followed by 1000mg/d, 1500mg/d and 2000mg/d elemental phosphate on successive weeks (total dose 1000mg/d, 2000mg/d, 2500mg/d, 3000mg/d respectively). Blood and urine samples were collected before breakfast at the end of each week. Serum FGF-23 was measured by ELISA (Immutopics, Inc., San Clemente, CA). Renal phosphate excretion increased with escalating phosphate intake from 34.2±3.4mmol/d at 1000mg intake to 61.4±3.6mmol/d at 3000mg intake (repeated measures ANOVA, $P<0.001$). As expected, calcium excretion decreased from 4.9±0.5mmol/d to 2.5±0.4mmol/d ($P<0.001$). There was a small but non-significant increase in PTH and no significant change in fasting serum calcium or phosphate. Fasting FGF-23 increased significantly in response to phosphate loading (40.5±1.9U/mL to 53.6±6.7U/mL; repeated measures ANOVA P=0.015). We conclude that serum FGF-23 does respond to altered phosphate intake within the physiological range, and the direction of effect is consistent with its possible role as a phosphate regulating hormone.

1145

Development of a Novel Bone-Targeted Src Tyrosine Kinase Inhibitor AP23451 Having Potent In Vitro and In Vivo Anti-Resorptive Properties. B. F. Boyce[1], W. Shakespeare*[2], L. Xing[1], Y. Wang*[2], R. Sundaramoorthi*[2], T. Keenan*[2], C. Metcalf*[2], R. Bohacek*[2], M. R. van Schravendijk*[2], D. Dalgarno[2], J. Iuliucci*[2], T. Sawyer[2]. [1]Pathology, University of Rochester, Rochester, NY, USA, [2]ARIAD Pharmaceuticals, Cambridge, MA, USA.

Genetic knockout studies have shown src -/- mice develop a bone-specific phenotype known as osteopetrosis resulting from defective remodeling. At the cellular level, these activities have been correlated to osteoclast (ocl) mediated bone resorption and osteoblast (obl) mediated bone formation. Recently, Src tyrosine kinase has been implicated in several examples of tumor proliferation, angiogenesis and metastases to bone. We have developed a novel bone-targeted Src tyrosine kinase inhibitor AP23451 having potent in vitro and in vivo activities, including: 1) low nM inhibition of Src tyrosine kinase and demonstrating high selecitvty against a panel of >30 protein kinases; 2) dose-dependent inhibition of ocl resorption in vitro (pit area and number); 3) dose-dependent inhibition of PTH induced hypercalcemia in mice (1-10 mg/kg/d s.c.) and inhibition of in vivo bone resorption (osteoclast number/mm calvarial bone surface: 14.4 +/- 3.3 PTH alone vs 1.7 +/- 1.7 PTH + AP23451 at 10 mg/kg b.i.d.); and 4) prevention of Ovx-induced vertebral (DEXA: .070+/-.0011 vs .0572+/-.0016 g/cm2) and femoral metaphyseal (pQCT: 660+/-13 vs 455+/-17 g/cm3) bone loss, with associated decreased ocl activity determined histomorphometrically. Our findings provide evidence that AP23451 is a novel bone-targeted Src tyrosine kinase inhibitor having potent in vitro and in vivo anti-resorptive properties for use in treating bone metastases and malignant hypercalcemia.

CSF1, TNFα and RANKL Promote Osteoclast Survival by Signaling Through mTOR/S6 Kinase. H. Glantschnig*, G. A. Rodan, A. A. Reszka. Bone Biology and Osteoporosis Research, Merck & Co., Inc., West Point, PA, USA.

Survival signaling by growth factors and cytokines in osteoclasts (OCL) is known to involve at least two anti-apoptotic signaling pathways including the effector molecules PI3K/PDK1/PKB and IKK/IκB/NF-κB, most likely followed by the synthesis of anti-apoptotic proteins. We report here a third anti-apoptotic pathway involving mTOR/ S6 Kinase (S6K) that is activated by CSF1, TNFα and RANKL and is essential for osteoclast survival *in vitro*. This pathway was investigated since we observed that inhibition of translation rapidly induces caspase activation and apoptosis in the OCL. OCL were generated by coculture of mouse bone marrow cells and MB1.8 osteoblasts. MB1.8 cells were removed by collagenase and purified OCL were further cultured in the presence of 15 ng/ml CSF1. OCL were then treated either with CSF1 (40 ng/ml), TNFα (50ng/ml) or RANKL (100 ng/ml) for various times in 0.5% FBS. Thereafter cell lysates were analyzed by western blotting with phospho-specific antibodies, and caspase-activities were determined fluorometrically. We found that CSF1 strongly induced PKB activation in OCL by phosphorylation at T308 and S473, but did not induce IκB phosphorylation. TNFα and RANKL only marginally induced PKB phosphorylation but strongly stimulated phosphorylation of IκBα at S32/36 and activation of NFκB. Interestingly, two mTOR substrates, S6K (T389) and 4E-BP1 (S65) were highly phosphorylated in OCL after treatment with any of these three pro-survival cytokines. Consistent with this observation, cytokine treatment led to phosphorylation of ribosomal protein S6, which was inhibited by rapamycin, a PKB-inhibitor or a MEK inhibitor. To test if mTOR is essential for survival, we treated differentiated OCL with rapamycin (1-100 nM) for 20 hr. This dose dependently induced morphological changes consistent with apoptosis and increased caspase-3 and -9 activities and (consequently) 34 kDa Mst1 kinase activity up to ca. nine-fold. Rapamycin also significantly suppressed the generation of TRAP+ OCLs from mouse bone marrow in the coculture system or when induced by CSF1 and RANKL, pointing to a role of mTOR in OCL differentiation. In summary we show in OCL distinct signaling by CSF1 via PKB and by TNFα / RANKL via IκB. However, all three osteoclastogenic survival factors induce the mTOR/ S6K signaling cascade. Upstream activators of mTOR and S6K include but are not restricted to PDK1 and PKB, thus creating an intersection of CSF1/ TNFα /RANKL signaling pathways. This demonstrates for the first time the existence of a survival pathway, common to seemingly divergent pro-survival cytokines, involving mTOR/S6K activation.

PYK2 Regulation of Osteoclast Ruffled Border Formation During Bone Resorption. P. T. Lakkakorpi[1], G. A. Rodan[2], L. T. Duong[2]. [1]Inst. of Biomed., Dept. of Anatomy, Univ. of Turku, Turku, Finland, [2]Dept. of Bone Biology & Osteoporosis Res., Merck Res. Labs., West Point, PA, USA.

Osteoclast $\alpha_v\beta_3$ integrin engagement leads to PYK2 tyrosine phosphorylation, tyrosine kinase activation, association with c-Src and cytoskeletal reorganisation. PYK2 localises to podosomes during osteoclast (OC) attachment and to the sealing zone in bone resorbing OCs. Using adenovirus expressing PYK2 mutants, we have shown that the PYK2 autophosphorylation site Y402, but not its kinase activity, is necessary for adhesion-induced association with c-Src, which further leads to the phosphorylation of tyrosines Y579/Y580 and Y881 in the PYK2 C-terminal domain. In this study we examined the effects of the PYK2 kinase-dead mutant *(K457A)* and the mutant lacking the autophosphorylation site *(Y402F)* on osteoclastic bone resorption, determined by light and electron microscopy. Infection of osteoclast-forming co-cultures with HSV-tagged PYK2*(wt)* or its mutants for 3-days resulted in 3-4 fold higher expression in purified pre-fusion osteoclasts (pOCs) of the exogenous constructs, relative to endogenous PYK2. OCs expressing PYK2(*wt)* or the mutants produced the same number of resorption pits per bone slice as uninfected cells. However, relative to controls OCs expressing PYK2(*wt)* or PYK2*(K457A)* formed smaller F-actin rings and deep resorption pits, whereas cells expressing PYK2*(Y402F)* mutant formed large F-actin rings, but very shallow resorption pits (by SEM). Interestingly, both mutants as well as PYK2*(wt)* were recruited to the sealing zone, based on the co-localisation of HSV-tag and F-actin. However, while β_3 integrin and cathepsin K were abundant (by immunolocalization) in the ruffled border of OCs expressing PYK2(*wt*) or PYK2 kinase dead*(K457A)*, they were absent from this region in cells expressing PYK2*(Y402F).* These findings suggest that the latter could have defective ruffled borders and reduced secretion. TEM confirmed that ruffled borders were almost completely lacking in OCs expressing PYK2*(Y402F)*, while cells expressing PYK2(*wt*) or kinase dead PYK2*(K457A)* showed deep convoluted ruffled borders. Thus, while overexpression of PYK2 or kinase-dead PYK2*(K457A)* seems to alter the dynamics of cell polarisation, expression of PYK2*(Y402F)* resulted in severe disruption of ruffled border formation, without significantly affecting formation of the osteoclast sealing zone. Since Src(-/-) or β_3(-/-) osteoclasts were previously found to have reduced ability to form ruffled borders on bone, we suggest that the adhesion-induced recruitment of c-Src to PYK2 via its autophosphorylation site Y402, but not PYK2 kinase activity, is important for the formation of ruffled border in osteoclasts during bone resorption.

Osteoclast Differentiation by RANKL Is Mediated by Inhibition of Cyclin-dependent Kinase 6 as a Downstream Effector of NF-κB Pathway. T. Ogasawara[1], M. Katagiri[1], A. Yamamoto[1], S. Tanaka[1], D. Chikazu[1], T. Takato*[1], K. Nakamura[1], H. Okayama*[2], H. Kawaguchi[1]. [1]Sensory & Motor System Medicine, University of Tokyo, Tokyo, Japan, [2]Molecular Biochemistry, University of Tokyo, Tokyo, Japan.

Cell cycle arrest at the G1 phase is a prerequisite for cell differentiation, so that it is possible that cell cycle molecules such as cyclins, cyclin-dependent kinases (CDKs) and CDK inhibitors (CKIs) may possibly regulate not only proliferation but also differentiation of cells. The regulation of osteoclast differentiation by cell cycle molecules was studied by looking at the involvement of these molecules in the action of receptor activator of nuclear factor-κB ligand (RANKL) on a murine monocytic cell line RAW 264.7 (RAW cells), known as osteoclast progenitor cells. We initially investigated the regulation of cell cycle molecules known to affect the G1 phase: cyclin D1, D2, D3, E, CDK2, 4, 6, and CKIs (p18, p21 & p27). Western blot analysis revealed that only the CDK6 level was markedly decreased by soluble RANKL (sRANKL, 100 ng/ml) in advance of the appearance of TRAP-positive multinucleated osteoclasts, while those of other cell cycle molecules were not significantly affected by sRANKL throughout the culture period up to 7 days. When NF-κB pathway was inhibited by overexpression of a dominant negative mutant of IκB kinase 2 gene ($IKK2^{DN}$) in RAW cells using an adenovirus vector, neither the inhibition of CDK6 nor the induction of osteoclastogenesis by sRANKL was seen, while the control LacZ adenovirus infection did not affect the sRANKL actions. To further investigate the contribution of CDK6 to osteoclast differentiation, we established stable clones of RAW cells transfected with *cdk*6 cDNA, and selected several of them with high expression and low expression on Western blotting. sRANKL induced osteoclastogenesis in low expressing clones and parental cells, whereas these effects were markedly suppressed in high expressing clones. sRANKL inhibited DNA synthesis determined by BrdU uptake and decreased the cell population in the G2/M phase determined by FACS; however, these proliferation parameters were similar among high expressing clones, low expressing clones, and parental cells both in the presence and absence of sRANKL. This indicates that the inhibitory effect of CDK6 on osteoclast differentiation is independent of its effect on the proliferation. We therefore conclude that CDK6 is a key molecule determining the differentiation rate of osteoclasts as a downstream effector of NF-κB pathway. Since we previously reported that osteoblast differentiation is also associated with CDK6 inhibition, CDK6 might possibly play a role in the coupling of bone formation and resorption.

The Functions of c-Cbl and Cbl-b Are Different in Osteoclasts: Cbl-b Deletion Leads to Increased Osteoclast Activity and Osteopenia. R. Chiusaroli[1], H. Gu*[2], R. Baron[1], A. Sanjay[1]. [1]Orthopaedics and Cell Biology, Yale University School of Medicine, New Haven, CT, USA, [2]Immunology, NIH, Bethesda, MD, USA.

The mammalian members of Cbl family of proteins, c-Cbl and Cbl-b are predominantly expressed in hematopoietic cells and function as ubiquitin ligases mediating down-regulation of both receptor- and non-receptor tyrosine kinases. We have previously shown that c-Cbl lies downstream of the vitronectin receptor and Src and forms a trimolecular complex with Src and Pyk2 in a signaling pathway that regulates cell adhesion and motility. We have also shown that deletion of the c-Cbl gene altered the ability of osteoclasts (OCs) to migrate in vitro and in vivo during development, delaying resorption and ossification of cartilage in long bones. However, detailed histomorphometric analysis of long bones from c-Cbl-/- adult mice failed to demonstrate any change in bone volume or in bone resorption parameters. Even though c-Cbl and Cbl-b are highly homologous in their phosphotyrosine binding domain and RING finger, there are significant differences between the two proteins in their C-terminal proline rich and acidic regions. To further investigate the role of Cbl family of proteins in osteoclast function we undertook a detailed bone histomorphometric analysis on adult Cbl-b-/- mice. In contrast to c-Cbl-/- mice, 12 week old Cbl-b-/- mice had decreased trabecular bone volume (wt, 7.7 ± 1.1; c-Cbl-/-, 7.4 ± 2, p = n.s. vs. wt; Cbl-b-/-, 4.6 ± 1.6, p <0.01 vs. wt; BV/TV mean ± SD), while no changes in osteoblast as well as in osteoclast surface and number were observed. Dynamic parameters of bone formation were also unaffected. In vitro pit assay revealed that in contrast to OCs derived from c-Cbl-/-mice, or to c-Cbl antisense-treated OCs whose bone resorption ability was reduced, the pit area resorbed by Cbl-b-/- OCs was 2.5 fold higher than wt control OCs (wt, 0.044 ± 0.017; c-Cbl-/-, 0.039 ± 0.009, p = n.s. vs. wt; Cbl-b-/-, 0.110 ± 0.02, p<0.01 vs. wt; pit area/total area/number of OCs, mean ± SD). Furthermore stimulation of the wt and c-Cbl-/- OCLs with IL-1 (10 ng/ml), a potent stimulator of osteoclastic bone resorption, led to a substantial increase (1.5 fold) in pit resorption area, whereas Cbl-b-/- mice-derived OCLs did not exhibit any further increase in pit resorption area in response to IL-1 stimulation. Collectively these data suggest that Cbl-b-/- osteoclasts display a cell autonomous defect, which results in increased bone resorption activity, and consequently in an osteopenic phenotype observed in Cbl-b-/- mice.

The Small GTP-Binding Protein Rac1 Is Involved in Signal Transduction of Osteoclast Survival. A. Fukuda*, Y. Kadono, T. Akiyama, A. Yamamoto, H. Oda*, K. Nakamura, S. Tanaka. Department of Orthopaedic Surgery, Faculty of Medicine, The University of Tokyo, Tokyo, Japan.

Although recent findings suggest that osteoclast survival is regulated through interactions of various cytokines and molecules, the precise molecular mechanism is not fully understood. We previously reported that small GTP-binding protein (G-protein) Ras plays an important role in osteoclast survival by regulating ERK activation. Rac1 is a member of Rho family small G-proteins, which is known to be involved in the cytoskeletal organization. Recent studies, however, have revealed that Rac1 also mediates anti-apoptotic signals in some types of cells. In the present study, we examined the role of Rac1 in osteoclast survival using adenovirus vector expression system. We constructed the adenovirus vector carrying either cDNA of fusion protein of EGFP and dominant negative Rac1 ($Rac1^{DN}$) or constitutively active Rac1 ($Rac1^{CA}$) gene, and osteoclast-like cells (OCLs) generated in mouse co-culture system were infected with these viruses as well as the control virus (EGFP virus). Clear induction of these molecules in OCLs was demonstrated by green fluorescence and Western blot analysis. To examine the role of Rac1 in osteoclast survival, OCLs were purified by removing the osteoblasts 24 hrs after infection. After 24 hrs of osteoblast removal, almost 100% of control virus-infected OCLs became apoptotic in the absence of stimulatory cytokines such as macrophage colony-stimulating factor (M-CSF). M-CSF has strong anti-apoptotic effects on OCLs, which was suppressed by overexpression of $Rac1^{DN}$. Overexpression of $Rac1^{CA}$ dramatically enhanced OCL survival in the absence of survival cytokines, and more than 30% of the cells survived after 24 hrs. The pro-survival effect of $Rac1^{CA}$ was completely abrogated by the treatment with phosphatidylinositol 3-kinase (PI3-kinase) inhibitor, LY294002 or wortmannin. Rapamycin, mTOR inhibitor also had a potent inhibitory effect, while MEK inhibitor PD98059 showed only partial inhibition. These data suggest that Rac1 lies downstream of M-CSF receptor signaling, and mediates survival signal of OCLs mainly via PI3-kinase pathways. Further study will be required to elucidate the role of Rac1 in osteoclast survival.

Osteonectin Supports Osteoblast Maturation and Survival. A. M. Delany, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Osteoblasts synthesize osteonectin (SPARC, BM-40), a glycoprotein important for the maintenance of bone mass. Osteonectin-null mice develop osteopenia due to decreased osteoblast number and bone formation rate. We used primary cultures of osteoblasts and stromal cells from wild type (WT) and osteonectin-null mice, and osteoblast cell lines established from these mice, to determine how osteonectin regulates cell number and bone formation. Although osteonectin is suggested to regulate cell proliferation, osteoblasts from calvaria of osteonectin-null mice did not have altered cell replication. However, our data suggest increased apoptosis in stromal cells from osteonectin-null mice. To determine whether osteonectin-null cells are more susceptible to stress, the ability of osteoblastic cell lines from osteonectin-null and WT mice to survive serum deprivation was assessed. After 2 days of serum-deprivation, ~60% of osteonectin-null cells survived, compared to ~85% of WT cells. When cell lines were transduced with retrovirus expressing full length osteonectin under the control of the CMV promoter, the ability of the osteonectin-null osteoblasts to survive serum deprivation was identical to that of wild type cells. Thus, osteonectin regulates osteoblast number by enhancing tolerance to stress. Further, osteonectin-null osteoblasts do not achieve a fully mature phenotype. Osteoblast cultures from osteonectin-null mice form fewer mineralized nodules, however transduction of osteonectin-null osteoblast cell lines with retrovirus constitutively expressing full length osteonectin or a C-terminal fragment containing the EF hand domain of osteonectin appeared to rescue this differentiation/mineralization defect. WT and osteonectin-null osteoblast cultured for up to 3 weeks post-confluence had similar levels of transcripts for osteopontin, type I collagen and bone sialoprotein. In contrast, expression of osteocalcin RNA was delayed and attenuated in osteonectin-null osteoblasts. Surprisingly, osteonectin-null cultures contained increased numbers of adipocytic cells. While the osteonectin-null mutation did not affect RNA for PPAR gamma 2, an early adipocytic marker, transcripts for adipsin, a marker of mature adipocytes, were increased. The C/EBP family of transcription factors functions in the differentiation of adipocytes and osteoblasts; and osteonectin-null cells had increased RNA for C/EBP delta, a stimulator of adipogenesis. In conclusion, osteonectin functions to maintain bone mass by increasing cell survival and by contributing a matrix that enhances osteoblast maturation, possibly at the expense of adipogenesis, through mechanisms that could involve C/EBP delta.

The Tumor Suppressor Gene VHL Is a Critical Modulator of Cell Proliferation and Cell Growth in the Mammalian Growth Plate. E. Schipani[1], T. Kobayashi[1], H. E. MacLean[1], M. C. Knight*[1], R. S. Johnson*[2], V. Haase*[3]. [1]Endocrine Unit, MGH-Harvard Medical School, Boston, MA, USA, [2]Division of Biology, Molecular Biology Section, UCSD, San Diego, CA, USA, [3]Renal-Electrolyte and Hypertension Division, University of Pennsylvania, Philadelphia, PA, USA.

It has been previously reported that the transcription factor HIF-1alpha (or Hypoxia Inducible Factor-1alpha) plays an essential role in chondrocyte survival and growth arrest. The ubiquitously expressed tumor suppressor gene VHL (or Von Hippel Lindau) negatively regulates HIF-1alpha levels and transcriptional activity in various tissues. We therefore explored the possibility that VHL could be a modulator of growth plate development. Mice nullizygous for VHL die at about E9.5. In order to study the role of VHL in chondrocyte activity, we conditionally inactivated the VHL gene in the murine growth plate by using the Cre-loxP system. Mutant mice lacking VHL in chondrocytes were viable, but smaller than control littermates and with short limbs. Their growth plates were remarkably hypocellular both in the round proliferative and in the columnar layers. In addition, the round proliferative layer appeared to be mainly occupied by "atypical" chondrocytes that were larger than wild-type cells. These "atypical" chondrocytes expressed collagen type II but not collagen type X, as shown by in situ hybridization, and they were not Tunel-positive, excluding therefore the possibility that their presence would be due to ectopic and/or premature hypertrophy. Furthermore, BrdU incorporation revealed that, in comparison to control chondrocytes, proliferation was dramatically inhibited both in the round proliferative and in the columnar layers of the mutant growth plate. Tunel assay did not show any significant difference between mutant and wild-type growth plates. The mutant phenotype

was already evident at E15.5, and persisted in postnatal life. Interestingly, viable chondrocytes lacking HIF-1alpha display an increase in proliferation rate. Further investigations will be now necessary in order to determine whether the VHL mutant phenotype is, at least in part, HIF-1alpha-dependent. In summary, the tumor suppressor gene VHL is, paradoxically, a critical positive modulator of chondrocyte proliferation in vivo; furthermore our model suggests the lack of VHL has a different effect on cell proliferation and cell growth, respectively, in the mammalian growth plate.

1153

RANKL/RANK/NF-kB Signaling Regulates Chondrogenesis. L. Xing[1], T. Yamashita[1], L. Childs*[1], E. M. Schwarz[1], R. J. O'Keefe[1], W. C. Dougall[2], B. F. Boyce[1]. [1]University of Rochester, Rochester, NY, USA, [2]Immunex, Inc., Seattle, WA, USA.

Recent studies have indicated that RANKL-/- and RANK-/- mice are dwarfed and have thickened growth plates. We observed similar abnormalities in NF-kB p50;p52 double knockout (dKO) mice, which have disorganized growth plates and an extended hypertrophic chondrocyte zone, suggesting that RANK/NF-kB signaling may regulate chondrocyte function. To study this possibility further, we examined growth plates in wild-type (wt) and RANK-/- (KO) mice of different ages. Growth plate thickness is increased in young, and to a lesser extent in older RANK-/- mice (age 2w: 0.73+/-0.12 mm vs 0.35+/-0.04 in wt; 3w: 0.38+/-0.01 vs 0.35+/-0.03; 6w: 0.27+/-0.01 vs 0.2+/-0.03), due predominantly to an increase in the hypertrophic zone thickness. The number of BrdU+ve proliferating chondrocytes (assessed using BrdU-labeling) was significantly decreased in the KO mice (29+/-4 vs 64+/-21 in wt), while the number of TUNEL+ve apoptotic hypertrophic chondrocytes was reduced (2.3+/-1.5 vs 8.3+/-1.5 in wt), suggesting a role for RANK/NF-kB signaling in chondrocyte and proliferation. To further examine the role of RANK signaling in chondrogenesis, cells from wt embryonic mouse limb buds (E11.5) were treated in vitro to produce micromass cultures of chondrocytes, using established methods. RANKL increased chondrocyte nodule formation alone (nodule area: 0.42+/-0.06 vs 0.17+/-0.04 mm2) and synergistically increased BMP2-mediated chondrocyte nodule number and area (3.2+/-0.4 mm2 vs 1.5+/-0.2 in BMP2-treated cultures). RANKL+BMP2 also increased the expression of chondrocyte-related genes (sox9 by 4-fold and type II collagen by 13 fold), as assessed by Real Time PCR analysis. To assess the role of RANK signaling in cartilage formation during fracture repair, tibiae of RANK-/-, Op/Op (a control osteopetrotic mouse) and wt mice were fractured and stabilized with an intra-medullary pin, using a standard method. Fracture healing was impaired in the RANK-/- animals (75% non-union rate) and they had reduced cartilage formation compared with the Op/Op and wt control animals, all of which healed their fractures. Our findings indicate that RANKL/RANK/NF-kB signaling plays an important regulatory role in endochondral ossification during embryogenesis, and in cartilage formation during fracture repair.

1154

Influence of Gli2 Deficiency on Endochondral Bone Formation and the Indian Hedgehog Signaling Pathway. D. Miao[1], M. Niu*[1], R. Huo*[1], C. Hui*[2], D. Goltzman[1], J. E. Henderson[1]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada.

Signaling by hedgehog family members is mediated in part by members of the Gli family of transcriptional regulators. Mice homozygous for targeted disruption of the gene encoding Gli2 (Gli2-/-) die at birth with a variety of developmental defects, which include short-limbed dwarfism. The current studies were undertaken to characterise the defects in endochondral bone formation in the axial and appendicular skeleton of Gli2-/- mice. A delay in endochondral bone formation was evident at E16.5 and E18.5, which was associated with longer cartilaginous growth plates, reduced bone tissue, and failure to develop intervertebral disks and primary ossification centres in the vertebral bodies by E18.5. The growth plates of tibiae and vertebrae exhibited increased chondrocyte proliferation, as determined by immunostaining for proliferating cell nuclear antigen, with no change in chondrocyte apoptosis, as shown by TUNEL assay. The increased number of proliferating chondrocytes was also reflected by an increase in type II collagen staining and was associated with increased FGF2 production. The zone of hypertrophic cartilage was also expanded in Gli2-/- mice, as evidenced by an increase in type X collagen expression, but revealed no defect in mineralization when stained with silver nitrate (von Kossa). Immunostaining for the angiogenic factors vascular endothelial growth factor (VEGF) and angiopoietin-1 (Ang-1) were reduced in the upper hypertrophic zone of Gli2-/- growth plates compared with those of wild type mice. This was associated with a reduction in TRAP positive cells at the chondro-osseous junction and with decreased numbers of osteoclasts and osteoblasts in metaphyseal bone. Indian hedgehog (IHH), its receptor patched (PCT) and parathyroid hormone related peptide (PTHrP), which play central roles in chondrocyte proliferation and maturation, were down-regulated in the growth plates of Gli2-/- mice. In contrast, hedgehog interacting protein (HIP) and the receptor smoothened (SMO), which inhibit hedgehog action, were increased. Taken together our observations suggest that Gli2 regulates endochondral bone formation by inhibiting chondrocyte proliferation by a PTHrP-independent pathway, by enhancing neo-vascularisation of mature cartilage and by recruiting osteoblasts to bone. Furthermore, Gli2 regulates the expression of PTHrP and components of the hedgehog signaling pathway.

1155

NF-kB Mediates Inflammatory Bone Erosion in Autoimmune Rheumatoid Arthritis. C. Biondo*, Y. Abu-Amer. Washington University School of Medicine, St. Louis, MO, USA.

Rheumatoid arthritis (RA) is an immune-inflammatory response associated with a joint inflammation, which often leads to matrix degradation and focal bone erosion. In this study, we set out to investigate molecular events that contribute to exacerbation of bone lesions in RA. We utilized a mouse model of T-cell transgenic K/BxN mice, which develop spontaneous joint RA. Serum-transfer from these mice triggers a rapid autoreactive Ig response in host mice that results in a highly joint-specific inflammatory arthritis. The onset of joint arthritis in serum-induced mice was within 48 hours. Swelling and limb deformation progressed thereafter. Histological examination of joint and ankle sections revealed a dramatically eroded bone surfaces. Bone erosion was maximal as early as 7 days post-serum transfer and was sustained thereafter. Next we examined osteoclast recruitment in long bones, ankles and joints. The data indicate a striking increase of osteoclast number and size in cortical and trabecular bone of arthritic mice compared to controls, with osteoclasts present throughout the arthritic cartilage. Articular cartilage and subchondral bone thickness in arthritic mice was reduced to approximately third of that in controls. We next turned to examine molecular events that mediate this inflammatory osteolysis. Given that NF-kB and p38 MAP kinase are central to inflammatory processes and both are essential for osteoclast development, activity of these two factors was investigated. Nuclear extracts from healthy or diseased joint tissue were subjected to DNA binding assays using specific probes. The data indicate that DNA binding activity of NF-kB and p38 was significantly increased within 48 hours post serum-induction of arthritis and maximal at 7 days. Thus, we reasoned that inhibition of NF-kB and/or p38 may reduce severity of the disease. Indeed we find that administration of dominant-negative form of IkB significantly reduced NF-kB DNA-binding activity and recruitment of osteoclasts in vivo. We also observed reduced clinical signs such as joint swelling and ankle thickening in the presence of the inhibitor. P38 inhibition studies are under investigation. In summary, our study describes a rapid and sustained autoimmune RA confined to joints. Development and progression of the disease are rapid and highly reproducible. More importantly, we document that severe osteolysis and bone erosion in this model is mediated, at least in a major part, by NF-kB and p38 activities. This conclusion was based on the fact that in vivo blockade of NF-kB by a dominant-negative form of its inhibitory protein IkB diminished the severity of inflammation and bone erosion.

1156

Osteopontin-Deficiency Suppresses TNF-alpha-Mediated Cytotoxicity in Chondrocytes to Protect Joints Against Destruction in Anti-Type II Collagen Antibody-Induced Arthritis in Mice. K. Yumoto[1], M. Ishijima[1], S. R. Rittling*[2], K. Tsuji[1], Y. Tsuchiya*[3], S. Kon*[3], A. Nifuji[1], T. Uede*[4], M. Noda[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Rutgers University, Piscataway, NJ, USA, [3]IBL, Gumma, Japan, [4]Hokkaido University, Sapporo, Japan.

OPN is an extracellular matrix protein containing Arg-Gly-Asp (RGD) sequence which interacts with integrins, promotes cell attachment, cell migration and is expressed in synovia and joint cartilage in rheumatoid arthritis patients. We recently demonstrated that osteopontin-deficiency suppressed joint swelling, chondrocyte apoptosis and joint destruction in mice rheumatoid arthritis (RA) model induced by injection with a mixture of anti-type II collagen monoclonal antibodies and lipopolysaccharide (mAbs/LPS). (PNAS 99:4556, 2002). The levels of angiogenesis in synovia estimated by the presence of CD31-positive vessels and the levels of bone resorption based on urinary deoxypyridinoline (D-Pyr) in this RA model were also suppressed in the absence of OPN even after mAbs/LPS injection. To understand the mechanism of OPN-deficiency induced resistance against joint destruction in the arthritis model mice, we examined the cellular basis for such protection. We found that the release of lactate dehydrogenase (LDH), a cytotoxic marker, from wild-type chondrocytes in culture, was induced by the treatment with TNF-alpha, a cytokine responsible for the pathogenesis of RA and for cytotoxicity and apoptosis in chondrocytes. TNF-alpha-induced LDH release from chondrocytes was observed in a dose-dependent manner. In contrast, LDH release by TNF-alpha treatment was significantly suppressed in chondrocytes derived from OPN-deficient mice. To explore the systemic components underlying the OPN-deficiency-induced resistance to joint destruction in arthritis model mice, we examined the levels of serum TNF-alpha induced by LPS injection. Serum TNF-alpha levels was very low in saline-injected mice, but was elevated by LPS injection. In OPN-deficient mice, similar elevation of serum TNF-alpha levels was observed after LPS injection. Thus, TNF-alpha production as a response to LPS was normal in OPN-deficient mice. Finally, toluidine blue staining revealed that more than 60 % of proteoglycan-positive cartllage surface was lost in the joint of wild-type mice after mAbs/LPS injection. In contrast, OPN-deficient mice did not show such loss of proteoglycan even after mAbs/LPS injection. These data indicated that OPN plays a critical role in TNF-alpha-mediated cytotoxicity in chondrocytes and OPN-deficiency protects joint cartilage against destruction at least in part through this mechanism.

1157

Identification of Smurf1 as the E3 Ubiquitin Ligase Responsible for Degradation of the Bone-Specific Transcription Factor Runx2/Cbfa1. M. Zhao, M. Qiao*, G. R. Mundy, D. Chen. Molecular Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

The osteoblast-specific transcription factor Runx2/Cbfa1 plays a central role in osteoblast differentiation and bone formation. Regulation of its activity has not been fully characterized. Since Runx2/Cbfa1 turnover is controlled by the ubiquitin-proteasome pathway, we have identified the specific E3 ubiquitin ligase responsible for this process. Protein ubiquitination involves a sequential cascade of enzymatic reactions catalyzed by E1, E2 and E3 enzymes. Among these, E3 ubiquitin ligases play a specific and crucial role in defining substrate specificity and subsequent protein degradation by 26S proteasomes. It has been reported that Smad1, the downstream mediator of BMP receptor signaling, directly interacts with Runx2/Cbfa1 and Smad1 undergoes ubiquitin-proteasome degradation mediated by E3 ubiquitin ligase, Smurf1. In the present studies, we examined the effect of Smurf1 on Runx2/Cbfa1 degradation in myoblast/osteoblast precursor C2C12 cells. We found that Smurf1 interacted with Runx2/Cbfa1 and mediated Runx2/Cbfa1 degradation in a dose-dependent manner. In contrast, unrelated F-box E3 ligase FWD1 has no significant effect on Runx2/Cbfa1 degradation. The Smurf1-mediated degradation of Runx2/Cbfa1 is ubiquitin and proteasome-dependent. A ubiquitinated protein ladder of Runx2/Cbfa1 was observed when the Runx2/Cbfa1 protein was immunoprecipitated in the presence of Smurf1. Treatment with the proteasome inhibitors epoxomicin or PS-I completely abolished the effect of Smurf1 on Runx2/Cbfa1 degradation. The interaction domain of Runx2/Cbfa1 with Smurf1 has been mapped. Smurf1 lost its ability to degrade Runx2/Cbfa1 when the C-terminal 153 amino acid residues of Runx2/Cbfa1 is deleted. In this C-terminal domain, a PY motif, the potential binding site for Smurf1, was identified. Smurf1-mediated Runx2/Cbfa1 degradation caused functional changes in Runx2/Cbfa1. Transfection of Runx2/Cbfa1 significantly increased luciferase activity of a specific reporter gene, 6xOSE2-OC-luc. Co-transfection of Smurf1 with Runx2/Cbfa1 completely inhibited Runx2/Cbfa1-induced luciferase activity of this reporter gene. Consistent with these findings, transfection of Smurf1 in osteoblasts significantly decreased alkaline phosphatase (ALP) activity. In contrast, transfection of ΔSmurf1 (C710A), which lacks catalytic activity, increased ALP activity and osteocalcin production. Our findings show mechanisms by which Runx2/Cbfa1 is regulated in osteoblasts during bone formation, and provide a new potential molecular target for drug discovery.

Osteoblast Specific Connexin43 (Cx43) Gene Deletion in Mice Leads to Reduced Bone Mass and Osteoblast Dysfunction. C. Castro[1], S. Sheikh*[1], L. Halstead[1], V. Szejnfeld[2], R. Civitelli[1]. [1]Div. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA, [2]Div. Rheumatology, UNIFESP, Sao Paulo, Brazil.

Interference with Cx43 expression or function alters osteoblast gene expression, and genetic deficiency of Cx43 *in vivo* causes developmental defects of the craniofacial skeleton and impaired osteoblast differentiation and function. To determine the role of Cx43 in adult bone mass achievement and maintenance, we developed a mouse model of selective Cx43 gene deletion in osteoblasts using a Cre/*lox*P approach, thus overcoming the perinatal lethality of the conventional knock out strategy. In this model, Cre mediated recombination replaces the entire Cx43 reading frame with the *Lac*Z reporter cassette. Homozygous $Cx43^{fl/fl}$ mice were crossed with mice expressing Cre driven by the OG2 promoter in a heterozygous Cx43-null background (OG2-Cre;$Cx43^{+/-}$). The recombination event was demonstrated exclusively in osteoblasts by X-gal staining of sections of tibia as well as calvarial cell cultures from OG2-Cre;$Cx43^{-/fl}$ mice. Cx43 mRNA (by Real Time RT-PCR) and protein abundance progressively declined in OG2-Cre;$Cx43^{-/fl}$ calvaria cells with time in culture compared to $Cx43^{+/fl}$, OG2-Cre;$Cx43^{+/fl}$ and $Cx43^{-/fl}$ controls, and disappeared after 3 weeks, concomitant to an increase in X-gal staining. Alkaline phosphatase activity was reduced in cells isolated from calvaria of OG2-Cre;$Cx43^{-/fl}$ mice compared to control $Cx43^{+/fl}$, OG2-Cre;$Cx43^{+/fl}$ and $Cx43^{-/fl}$ littermates, and this reduction was inversely correlated with Cx43 mRNA abundance. Matrix mineralization was also lower in OG2-Cre;$Cx43^{-/fl}$ calvarial cells compared to controls after 2 and 3 weeks in the presence of ascorbic acid and β-glycerophosphate. Accordingly, OG2-Cre;$Cx43^{-/fl}$ calvarial cells also exhibited lower abundance of Cbfa1 and type I collagen mRNA compared to control cells. Total body bone mineral density, monitored monthly by DEXA (PIXImus™, GE-Lunar), was consistently lower in OG2-Cre;$Cx43^{-/fl}$ mice compared to all control littermates up to 6 months of life, with maximum difference of 8% (OG2-Cre;$Cx43^{-/fl}$: 59±1.6mg/cm^2, $Cx43^{+/fl}$: 64.3±3.6mg/cm^2, $Cx43^{-/fl}$: 63.3±4.1mg/cm^2, $p<0.05$, at 5 months) without gender differences. Weight and percent body fat were similar among all groups at all times. Thus, Cx43 gene deletion *in vivo* disrupts the normal function of differentiated osteoblasts, leading to reduced bone mass. These results support the notion that Cx43 gap junctional communication is critical for bone formation in adult animals, contributing to achievement of peak bone mass.

Gene Network Regulated by the Immediate Early BMP2 Responsive Gene, Dlx5, in Osteoblasts. S. E. Harris[1], D. Guo*[1], A. Krishnaswamy*[1], A. C. Lichtler[2], M. A. Harris[1]. [1]Oral Biology, UMKC, Kansas City, MO, USA, [2]Genetics and Developmental Biology, UCONN Health Center, Farmington CT 06030, CT, USA.

The Dlx5 homeobox gene has been shown to be important in osteoblast growth and differentiation by analysis of null mutations of the Dlx5 locus in mice (Acampora et al, 1999; Depew et al, 1999). Dlx5 plays a role in regulating Col1a1, Runx2, and Msx2 genes (Pan et al, 2002; Shibuya et al, 2001; Tadic et al, 2001). We have shown that Dlx family members are also important in regulating BMP2 transcription in primary rat calvarial osteoblasts and that Dlx5 is an immediate early BMP2 responsive gene in both primary osteoblasts and 2T3 mouse osteoblasts. Dlx 5 is induced at 30 min and stays elevated for 3-5 days after BMP2 addition. To better understand the genetic network of BMP2 regulated genes, we are using several genomic approaches to identify early and late genes that are directly regulated by Dlx5. Using microarray analysis of immediate early (30 min to 1hr) and early (1hr to 8hr) BMP2 responsive genes, we selected a set of 48 genes that are induced a minimum of 2.5 fold by 100ng/ml of BMP2 in the 2T3 osteoblast model. This data was derived from 2 independent culture experiments and analyzed by Significance Analysis of Microarrays (SAM) (Tuscher et al, PNAS, 2001) for significance. As expected, Dlx5 was a member of this set and this was confirmed by Northern analysis. Of the 48 genes, 30 are unknown or poorly annotated genes and the other 18 well annotated. To derive additional information, we searched the Celera mouse genome and obtained the coding region, exon/intron structure and 10 kb of 5' and 3' flanking region of all 48 genes. Next, the equivalent human genes were obtained and mouse/human homology studies initiated using VISTA and Family Relations programs which identify islands of conserved nucleotide sequences (CNS) in the cis-regulatory regions of the respective genes. Then, candidate Dlx response elements were mapped in all 48 genes which are co-induced by BMP2 in this model. A criteria was set that at least two TAAT or one TTAATG sequence(s) had to be in the CNS motif of a given gene. Using this analysis, a provisional virtual gene network of candidate early genes that are directly regulated by Dlx5 or similar family members was built. To test components of this network experimentally, we have designed a Dlx5 expression virus vector in which the strong repressor domain of engrailed is fused to Dlx5. Upon infection of 2T3 cells with this vector, we will be able to identify genes directly regulated by Dlx5 using several microarray approaches. Thus, by using both computational and experimental approaches, we can derive a provisional regulatory gene network of early BMP2-Dlx5 functions in osteoblasts.

Marked Synergistic Interaction Between the Homeodomain Protein Nkx 3.2 and the Serum Response Factor (SRF) Transcription Factors on the Human α2 Type I Procollagen (hCol1A2) Promoter: A Key Stimulatory Mechanism for Osteoblast Collagen Expression. W. Zimmer*[1], K. Moses*[1], T. Linkhart*[2], D. Dean*[3], C. Stivers*[2], D. D. Strong[2]. [1]Univ South Alabama, Mobile, AL, USA, [2]Musculoskeletal Disease Center, J.L. Pettis VAMC, Loma Linda, CA, USA, [3]Northwestern Univ, Chicago, IL, USA.

Our goal was to identify a minimal set of control elements in an osteoblast specific promoter that would drive high expression in osteoblasts for development of retroviral skeletal targeting vectors for gene therapy that would not adversely affect viral titer. We found that the minimal hCol1A2 promoter (-267 to +1) was highly expressed in osteoblasts comparable to the rat 2.3 rat Col1A1 promoter and not in fibroblasts, marrow stromal cells or chondrocytes. While many control elements in the rat and mouse Col1A1 promoter for high osteoblast expression have been identified, much less is known about the required elements in the hCol1A2 promoter. Using deletion and mutation analysis, the hCol1A2 promoter was mapped for elements conferring high basal activity in ROS 17/2.8 cells and mouse calvarial osteoblasts and a complex stimulatory element containing a serum response element (CArG Box) and Nkx binding sites was identified. A similar complex Nkx-CArG element in the γ-actin promoter bound Nkx 3.1, a homeodomain transcription factor, and SRF to synergistically activate this promoter in smooth muscle cells. Furthermore, mouse Nkx gene family deletion studies indicate that loss of Nkx 3.2 resulted in serious skeletal defects (loss of bones & reduction in bone and cartilage size). We found by RT-PCR that Nkx 3.2 was expressed in osteoblasts. These results prompted us to test the effect of Nkx 3.2 and SRF overexpression alone and in combination on hCol1A2 promoter activity. Both SRF and Nkx 3.2 increased (2-6 fold of control) hCol1A2 promoter activity. More importantly, the combination of Nkx 3.2 and SRF synergistically increased hCol1A2 promoter activity up to 47 fold of control. Mutation of the CArG-Nkx complex abrogated the synergism. Nkx 3.1 did not significantly stimulate promoter activity or synergise with SRF. Gel shift analysis was conducted and Nkx 3.2 and SRF bound to the complex CArG-Nkx element. Mutation of each site eliminated the gel shift using purified proteins. In conclusion, these studies have identified a novel 47 fold stimulatory mechanism for transcriptional activation of the type I collagen gene in osteoblasts. These studies also suggest that the skeletal phenotype of the Nkx 3.2 knock-out mouse may be caused, in fact, by a reduction in type I collagen expression. CRM1/Exportin1-Mediated Nuclear Export is Required for the Pro-Survival Effect of Bisphosphonates on Osteocytes: Evidence for Cytoplasmic-Restricted Signaling by ERKs. L. I. Plotkin, B. Laska*, S. C. Manolagas, T. Bellido. Div. Endo/Metab. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Prevention of osteocyte and osteoblast apoptosis by both bisphosphonates (BPs) and estrogens (E) requires activation of the extracellular signal regulated kinases (ERKs). However, whereas E activate ERKs via a non-nuclear function of the estrogen receptor, BPs induce ERK activation by a novel, gap junction-independent effect initiated by opening of connexin43 hemichannels followed by Src activation. Using MLO-Y4 osteocytic cells and specific inhibitors of ERKs (PD98059 and U0126), PI3K (wortmannin), or PKA (H-89), we now report that, unlike in the case of E, ERKs are the only survival kinases required for BP anti-apoptotic effect. ERKs could inhibit apoptosis by transcription-dependent or independent mechanisms. The anti-apoptotic effect of BPs was not blocked by inhibition of RNA or protein synthesis with actinomycin D or cycloheximide. Moreover, dominant negative (dn) forms of the ERK-activated transcription factors Elk1, Stat3, Runx2/Cbfa1, C/EBPβ/NF-IL6, fos, jun, or CREB did not affect BP-induced anti-apoptosis. In contrast (as shown elsewhere in this meeting), the anti-apoptotic effect of E required gene transcription, and it was abolished by dn forms of several ERK-activated transcription factors. Further, whereas E increased Elk1-driven luciferase transcription, BP did not. On the other hand, the anti-apoptotic effect of BPs was abolished by a catalytic inactive dn mutant of the known ERK cytoplasmic substrate $p90^{RSK}$ or by a dn Bad mutated at Ser^{112}, the site specifically phosphorylated by $p90^{RSK}$. Taken together, these results indicate that BP-induced anti-apoptosis depends on cytoplasmic but not nuclear substrates of ERKs. Because the ability of ERKs to activate particular targets depends on their subcellular localization, we examined whether exclusion of activated ERKs from the cytoplasm abolished BP-induced anti-apoptosis. We restricted ERKs to the nuclear compartment by inhibiting the nuclear exporter CRM1/Exportin1 with its specific ligand leptomycin B. When the nuclear export of proteins was inhibited, BPs did not prevent apoptosis and, as expected, did increase Elk1-dependent transcription. These results indicate that cytoplasmic localization of activated ERKs is required for the survival effect of BPs and that activation of ERK nuclear targets is not sufficient for survival. Our findings provide evidence for cytoplasmic-restricted ERK signals triggered by BPs and suggest that BPs and E inhibit apoptosis by activating distinct pools of ERKs.

Cell Autonomous Inhibition of Osteoblast Differentiation in Transgenic Mice with Targeted Overexpression of p20C/EBPß, a Truncated C/EBP Isoform. J. Y. Lee*[1], P. L. Kelly*[1], D. Harrison*[2], J. R. Harrison[1]. [1]Department of Orthodontics, University of Connecticut Health Center, Farmington, CT, USA, [2]Department of Medicine, University of Connecticut Health Center, Farmington, CT, USA.

We reported previously that Col1a1 promoter-targeted overexpression of p20C/EBPß in transgenic (TG) mice causes osteopenia. These mice, in which the 3.6 kb Col1a1 promoter/first intron directs expression of a p20C/EBPß transgene to bone, show decreased trabecular bone volume and cortical thickness. Dynamic histomorphometry showed a decrease in the mineral apposition and bone formation rates, consistent with an inhibition of bone formation in this model. Long bones and calvariae of TG mice showed reduced COL1A1 and osteocalcin (OC) mRNA levels in vivo. To test the hypothesis that p20C/EBPß inhibits osteoblast differentiation, we used an ex vivo bone marrow stromal cell culture model. In some experiments, heterozygous p20C/EBPß mice were crossed with a homozygous pOBCol2.3-GFP mouse so that all progeny were heterozygous for the GFP transgene, an established marker of the differentiated osteoblast. Both male and female mice were used, with the sex ratio held constant for WT and TG groups. Stromal cells were cultured in MEM containing 10% FCS; half the medium was replaced on day 3. On day 7 and alternate days thereafter, cells were fed with differentiation medium containing ß-glycerolphosphate (8 mM) and ascorbic acid (50 µg/ml). At various times, cultures were stained for alkaline phosphatase (AP) activity and mineralized colonies were visualized by transmitted light. GFP fluorescent colonies were imaged at the macroscopic level using a fluorimager and at the cellular level by fluorescence microscopy. RNA was extracted for determination of transgene and osteoblast marker gene expression by Northern analysis. Bone marrow stromal cells from WT and TG mice showed similar AP staining patterns at 14 and 21 days of culture. However, both the number of mineralized colonies and the degree of mineralization was reduced in TG cultures. In WT cultures, GFP fluorescence in the nodules became apparent by day 14, and nodules showed intense GFP fluorescence at 17 and 21 days. In contrast, TG cells showed a reduction in both the number and intensity of GFP fluorescent nodules. Levels of osteopontin and bone sialoprotein mRNA were reduced in TG cells in 2 of 3 experiments, whereas OC mRNA levels in TG cells were dramatically reduced in all experiments. These data indicate that osteopenia in pOBCol3.6-FLp20C/EBPß transgenic mice may result from a cell autonomous inhibition of osteoblast differentiation and suggest that C/EBP transcription factors might function as key regulators of osteoblast lineage progression and bone mass.

Decreased Postmenopausal Bone Strength due to Bone Loss Is Compensated by Increased Bone Size, and a Strength Index Including both Bone Mass and Size, Predict Future Fractures - A 19 Year Population Based Prospective Study in 108 Women. H. G. Ahlborg*[1], O. Johnell[1], C. H. Turner[2], M. K. Karlsson[1]. [1]Department of Orthopaedics, University Hospital MAS, Malmo, Sweden, [2]Departmentt of Orthopaedics, The Biomechanics and Biomaterial Research Center, Indiana University, Indianapolis, IN, USA.

Bone strength depends on material properties, as bone mass, and structural characteristics, as bone size. The bone loss at menopause (MP) reduce bone strength, but a compensatory mechanism may occur by improving the skeletal geometrical properties. Additional, if a Strength Index, taking both bone mass and skeletal geometry in account, better predict fragility fractures than a bone mass measurement, is unclear. This prospective study evaluated bone loss and geometrical changes following MP in 108 women, all premenopausal at age 47, during a 19 years period. Bone mineral content (BMC) and bone mineral density (BMD) was estimated by single-photon absorptiometry (SPA) of the distal radius every second year. Skeletal geometry, cross sectional moment of inertia (CSMI) and Strength Index was calculated from the graphical tracing of the scans. Data is presented as mean with 95 % confidence interval (95% CI). BMD decreased with 1.7 %/year (95% CI 1.5%-1.8%), medullary width increased with 1.0 %/year (95% CI 0.8%-1.2%) and periosteal width by 0.6 %/year (95% CI 0.5%-0.7%). CSMI increased as a result with 2.8 %/year (95% CI 2.3%-3.2%) while Strength Index decreased with 0.7 %/year (95% CI 0.5%-0.8%). The quartile of women with the largest medullary expansion had compared to the quartile of women with the least medullary expansion the greatest BMC loss [mean 1.6 %/year (95% CI 1.3-1.9) vs. 0.8 %/year (95% CI 0.5-1.1)] but a larger subperiosteal apposition [mean 0.9 %/year (95% CI 0.7-1.1) vs. 0.3 %/year (95% CI 0.2-0.5)]. Thus, the quartile of women who lost most bone also increased skeletal size most. Also, annual changes in medullary and subperiosteal width correlated ($r=0.5$, $p<0.001$). A -1 SD reduction in Strength Index at baseline conferred a risk ratio (RR) of 3.8 (95% CI 1.8-8.0) and a -1 SD reduction in BMD by 1.5 (95% CI 0.9-2.6), to sustain a distal radius fracture during the study period. The decreased bone strength due to demineralisation of the distal radius following MP is compensated by a subperiosteal apposition, partly preserving bone strength. A Strength Index, including both bone mass and skeletal geometry, is an important predictor of distal radius fractures.

Low Levels of Serum Estradiol Contribute to the Rate of Bone Loss in Postmenopausal Elderly Women. P. B. Rapuri[1], J. C. Gallagher[2], G. Haynatzki[3]. [1]Bone Metabolism, Creighton University, Omaha, NE, USA, [2]Bone Metabolism Unit, Creighton University, Omaha, NE, USA, [3]Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

There are conflicting data on the effect of low levels of endogenous estradiol on bone. In the Study of Osteoporotic Fractures, elderly women with serum estradiol levels of <5 pg/ml had increased bone loss at the hip and higher risk of hip and spine fractures. However, in the EPIDOS study of elderly women, no relationship was observed between serum estradiol and the occurence of hip fractures. In another study, administration of an aromatase inhibitor reduced serum estradiol levels from 5 to 1 pg/ml and caused a significant increase in bone resorption markers. To explore the relationship between low estradiol and bone further, we examined the relationship between the total/bioavailable estradiol and the rate of bone loss at the spine, total body and femoral neck. The study population consisted of 98 women (mean age 71±3 years) assigned to the placebo group of an osteoporosis intervention study for 3 years. Serum total estradiol was determined by RIA (DSL Inc) and the fraction of bioavailable estradiol was determined as the difference between the total and SHBG bound estradiol. The rate of change in BMD over 3 years was determined at multiple skeletal sites by DEXA. Statistical analysis was performed using Pearson's correlations and independent sample t test. There was a significant correlation between serum total estradiol and bioavailable estradiol ($r=0.89$, $p<0.001$) and between serum estradiol and body mass index ($r=0.31$, $p<0.001$). Women were divided into higher or lower serum estradiol groups using the median value. The median value for serum bioavailable estradiol was 3.3 pg/ml and for serum total estradiol it was 11.4 pg/ml. The group with serum bioavailable estradiol below 3.3 pg/ml had significantly faster bone loss at the spine ($p<0.01$) and total body ($p<0.01$) but not the hip. Similar results were obtained for serum estradiol above and below 11.4 pg/ml. In conclusion,these results show that very low levels of estradiol play a contributing role in the pathogenesis of bone loss in the elderly women.

Effect of endogenous estrogen levels on the rate of bone loss

	percent change over baseline		
estradiol levels (pg/ml)	spine (L1-L4)	femoral neck	total body
bioavailable estradiol			
<3.3 (47)	-2.58±0.75	-0.59±0.68	-2.75±0.34
>3.3 (49)	-0.23±0.55**	-0.40±0.76	-1.31±0.44**
Total estradiol			
<11.4 (49)	-2.43±0.73	-0.05±0.71	-2.47±0.38

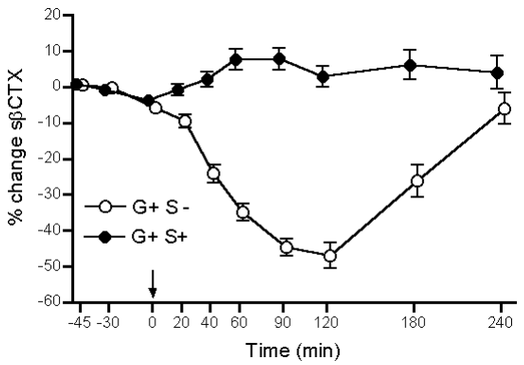
Effect of Octreotide on Bone Turnover and Parathyroid Hormone after Oral Glucose: Evidence for a Novel Endocrine Interaction between the Gastrointestinal Tract and Bone. J. A. Clowes, H. C. Allen, D. Prentis, R. Eastell, A. Blumsohn. Clinical Sciences (North), University of Sheffield, Sheffield, United Kingdom.

Feeding results in the acute suppression of bone turnover markers, an effect which is also seen with oral glucose. We have shown that insulin does not mediate this effect, but several other gastrointestinal hormones (e.g. glucose dependent insulinotropic peptide, GIP) appear to modulate bone turnover in vitro and may mediate the effect. The purpose of this study was to inhibit the production of gastrointestinal hormones using octreotide (a long acting analogue of somatostatin) to identify if the glucose-mediated suppression in bone turnover could be blocked. Fifteen volunteers (9M, 6F, age 27 ± 1.5 SEM) were each studied on 4 occasions in a randomised single blind crossover study to receive either 1) placebo (oral water, iv saline), 2) oral glucose (75g), 3) oral glucose + iv octreotide (50 µg/hr) and 4) iv octreotide alone. We measured serum C-terminal telopeptide of type I collagen (sβCTX), urine N-terminal telopeptide (uNTX), osteocalcin (OC), procollagen type I N-terminal propeptide (PINP), PTH, insulin, ionised calcium and glucose over 4 hours following the oral load. All bone turnover markers decreased significantly following oral glucose (repeated measures ANOVA; all $P < 0.001$). At 120 min sβCTX decreased by 45% ± 2, uNTX by 31% ±7, OC by 16% ± 1 and PINP by 6% ± 1. Octreotide completely abolished the bone turnover response to glucose for all markers (Figure sβCTX; legend glucose (G), octreotide (S); AUC analysis all $P < 0.01$ except uNTX (AUC; $P = 0.05$). Octreotide alone resulted in a significant increase in all bone turnover markers (AUC; $P < 0.05$) as well as an increase in PTH (AUC; $P < 0.01$), which was not explained by changes in ionized calcium. We conclude that octreotide completely abolishes the bone turnover response to glucose intake and increases PTH secretion. This suggests that the apparent bone turnover response to feeding is likely to be mediated by an octreotide-inhibitable endocrine factor.



1166

Bone Mass and Bone Loss at Trabecular and Cortical Sites are Differently Regulated by Sex Hormones in Elderly Men. L. Gennari[1], D. Merlotti*[2], S. Gonnelli[2], G. Martini[1], A. Montagnani*[2], M. B. Franci*[2], S. Campagna*[2], R. Nuti[1], C. Gennari[2]. [1]Metabolic Disease Unit, University of Siena, Siena, Italy, [2]Institute of Internal Medicine, University of Siena, Siena, Italy.

Sex steroid hormones play an important role in regulating bone turnover and bone mass in males, as well as in females. However, the exact mechanism of bone loss in men remains unknown. In this study 300 elderly men (age range 50-85 yrs) were recruited and followed for three years to evaluate the relationships between hormone levels, bone turnover, bone mineral density (BMD), and bone loss at different skeletal sites. Femoral and Lumbar BMD (DEXA), bone ultrasound parameters at the os calcis and phalanxes, serum dehydroepiandrosterone sulphate (DHEAS), serum testosterone (T), serum estradiol (E), sex hormone binding globulin (SHBG), gonadotropins (LH and FSH) and bone turnover markers (urinary CTX and bone alkaline phosphatase, BALP) were evaluated at the enrollment and after three years. The free androgen index (FAI) and free estrogen index (FEI) were calculated as the ratios between total hormone levels and SHBG. In the total population, T, DHEAS, FAI and FEI but not E decreased significantly with age while LH, FSH, and SHBG increased significantly. A significant effect of estrogen on bone was observed, particularly at trabecular sites. Subjects with FEI or E below the median showed lower baseline lumbar BMD values as well as higher rates of bone loss at the lumbar spine and Ward's triangle with respect to men with FEI or E above the median. Serum basal BALP was significantly higher and increased significantly after three years in men with FEI or E below the median than in men with FEI and E above the median. By contrast, androgens but not estrogen significantly affected ultrasound parameters at phalanxes. Subjects with FAI below the median showed lower AD-SOS values with respect to subjects with FAI above the median, with a difference in T-score of about 1SD (-2.8 vs –1.9). Moreover, the time frame, a graphic trace parameter related to the cortical thickness of the phalanxes, was significantly lower in subjects with FAI below the median than in subjects with FAI above the median. In conclusion, results from the present study indicate a different regulation of bone mass and loss by sex hormones at different skeletal sites, in males.

1167

Racial Differences in Hip Fracture Risk Are Established During Growth: Structural and Biomechanical Determinants of Strength at the Proximal Femur in Asians and Caucasians. X. F. Wang*[1], T. J. Beck[2], Y. Duan[1], E. Seeman[1]. [1]Department of Medicine, Austin & Repatriation Medical Centre, Melbourne, Australia, [2]Radiology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA.

The lower areal BMD (aBMD) in Asians than Caucasians is largely due to their smaller bone size so that the lower hip fracture rate in Asians is unlikely to be attributed to racial differences in aBMD. To determine the structural and biomechanical differences at the femoral neck at peak between Asians and Caucasians, we used DXA derived bone mass and dimensional data (width) to estimate endosteal diameter, mean cortical thickness, cross-sectional moment of inertia (CSMI) and section modulus at the mid-point of the femoral neck (FN) and calculated the buckling ratio, an estimate of the relative cortical thickness (subperiosteal radius/cortical thickness) in 42 healthy Asian men and 63 Asian women (Chinese ancestry), 101 healthy Caucasian men and 264 Caucasian premenopausal women aged 18 to 43 years. We hypothesized that Asians have a narrow bone with a thicker cortex at peak conferring a lower risk of hip fracture than Caucasians. FN width and cortical thickness were 11% and 10% narrower in Asian than Caucasian men, and 16% and 7% narrower in Asian women than Caucasian women. Section modulus was 29%-36% lower in Asians than Caucasians before, and after, adjusting for total body lean mass. There was no difference in buckling ratio between Asian and Caucasian men (8.0 ± 0.2 vs. 8.1 ± 0.2, NS), but buckling ratio was lower in Asian than Caucasian women (7.1 ± 0.2 vs. 7.8 ± 0.1, $p < 0.01$). Sex differences in FN width were greater than those in cortical thickness (Asians, 20% vs. 6%; Caucasians, 13% vs. 9%). Section modulus (an estimate of bending strength) was 57% higher in Asian men than women, and 43% higher in Caucasian men than women, but adjusting for sex differences in height and total body lean mass the difference disappear. We concluded that: (i) despite the larger bone size and greater bone strength in Caucasians than Asians, the relatively thicker cortices within the narrower FN in Asian women at peak may produce a more structurally stable femoral neck in old age. (ii) FN strength is greater in men than women in both racial groups due to the differences in lean body mass.

1168

Inhibin B is a Marker of Diminished Ovarian Function and Increased Bone Turnover in Peri-menopausal Women. D. Gaddy-Kurten[1], S. E. Bledsoe*[1], S. J. Achenbach*[2], S. Khosla[2]. [1]Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]Mayo Clinic and Foundation, Rochester, MN, USA.

Clinical indices of increased bone turnover are first detected in peri-menopausal women, and correlate best with elevated serum FSH levels, rather than decreases in estradiol. Other studies in peri-menopausal women have demonstrated that the mechanism responsible for the rise in FSH levels is a selective decrease in ovarian Inhibin B. These data led to our hypothesis that a selective loss of Inhibin B in peri-menopausal women, independent of changes in sex steroids, may have a direct effect on osteoblast and osteoclast development, thereby increasing bone turnover. In support of this hypothesis, our previous results in murine bone marrow cultures demonstrated that Inhibin B suppresses both osteoblast and osteoclast development. The current study was designed to determine if Inhibins could suppress human osteoblastogenesis, and if decreased serum Inhibin B in peri-menopausal women was associated with increases in markers of bone turnover. Human mesenchymal stem cells were grown for 21 days under osteoblastic conditions in the presence or absence of 50 ng/ml Inhibin A or Inhibin B. Mineralization of the developing osteoblasts was determined by alizarin red staining, normalized to total protein content per well. Both Inhibin A and Inhibin B suppressed osteoblastogenesis; Inhibin B was a more potent suppressor than Inhibin A. To determine if serum levels of Inhibin B were correlated with markers of bone turnover, a cohort of pre- and post-menopausal women (n = 188, age range 21-85 yrs) were analyzed by decade. Serum and urine samples were collected during the follicular phase of the cycle for pre-menopausal women. Samples were excluded if the women were obtaining estrogen through the use of oral contraceptives or hormone replacement therapy. Consistent with our hypothesis, in the cohort of women of peri-menopausal age (45-54 yrs) but not in any of the other age groups, Inhibin B was inversely correlated with Bone Alkaline Phosphatase (BAP; $R=-0.36$, $p<.05$), with a similar but non-significant trend for serum osteocalcin. These novel findings in human samples, along with our published suppressive effects of inhibins on both osteoblast and osteoclast development in murine cells, indicate that selective changes in Inhibin B alter human bone marrow cell differentiation in vitro and may also be doing so in vivo. Further studies and larger patient cohorts are required to validate the hypothesis that Inhibin B changes are significantly correlated with the increased bone turnover observed during the peri-menopausal transition.

A Double Blind Randomized Placebo Controlled Trial of Alendronate in Primary Hyperparathyroidism. A. A. Khan[1], J. P. Bilezikian[2], A. W. C. Kung*[3], M. M. Ahmed*[1], S. J. Dubois*[1], A. Y. Y. Ho*[3], Z. Motagally*[1], M. Rubin*[2], S. J. Silverberg*[2], T. I. Standish*[1], Z. A. Syed*[1]. [1]Medicine, McMaster University, Hamilton, ON, Canada, [2]Columbia University College of Physicians and Surgeons, New York, NY, USA, [3]University of Hong Kong, Hong Kong, China.

A randomized, double blind, placebo-controlled trial was conducted to determine if alendronate 10mg daily (ALN) maintains or improves bone mineral density (BMD) in patients with primary hyperparathyroidism (PHPT). Eligible patients were asymptomatic and did not meet surgical guidelines. Forty-four patients randomized to placebo or active treatment arms were stratified for gender. At 12 months, patients taking placebo crossed over to active treatment. All patients were on active treatment in year 2. Assessments were made at baseline, 3, 6, 9, 12, 15, 18, 21 and 24 months. The primary outcome index, BMD at the lumbar spine (LS), femoral neck, total hip and distal one-third radius, was measured at baseline, 6, 12, 18 and 24 months with dual energy X-ray absorptiometry (DEXA). Indices of bone metabolism - calcium, phosphate, PTH (IRMA), bone specific alkaline phosphatase, urinary calcium, urine N-telo peptides were obtained. Data are provided for 35 patients who completed 24 months of the protocol. Paired t-tests were conducted for groups A (active years 1 and 2) and B (placebo year 1, active year 2) second year mean differences for total hip, LS, and distal 1/3 radius BMDs; total and ionized calcium and phosphorus levels. Blinded analysis of year 1 data showed significant increases in the mean treatment group LS BMD by 5.4 % and total hip by 3.0% from baseline. Radial BMD showed no statistically significant change. Treatment with ALN over two years was associated with a significant increase in LS BMD by 6.85%(0.05 grams/cm2, 95% CI: 0.037,0.067, t=7.3, p< .001), a 2.9% increase in the BMD total hip (0.02 grams/cm2, 95% CI: -0.003,0.043,t=1.79,p= .09) and distal 1/3 radial sites remained stable (0.012 grams/cm2, 95% CI: -0.003,0.015, t=1.4, p= .19) compared to baseline. Group B mean LS and total hip BMD significantly increased from years 1 to 2 by 3.6% (0.87 grams/cm^2, 95% CI: 0.01, 0.05, t=3.4, p= .004) and 2% (0.73 grams/cm^2, 95% CI: 0.00,0.03,t=2.6,p=0.017) respectively. The distal 1/3 radial site remained stable (0.005 grams/cm2, 95% CI: -0.002,0.01, t=1.4, p= .17). Preliminary analyses of biochemical data demonstrated no significant change in total or ionized calcium, or phosphate. This is the first randomized placebo-controlled trial evaluating the effect of ALN on BMD in men and women with PHPT. ALN significantly increases BMD at the lumbar spine after 12 and 24 months of therapy from baseline. ALN may be an alternative to surgery in some patients with PHPT.

Effect of Anastrozole on Bone Density and Bone Turnover: Results of the 'Arimidex' (Anastrozole), Tamoxifen, Alone or in Combination (ATAC) Study. R. Eastell[1], R. A. Hannon[1], J. Cuzick*[2], G. Clack*[3], J. E. Adams[4]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Cancer Research UK, London, United Kingdom, [3]AstraZeneca, Macclesfield, United Kingdom, [4]University of Manchester, Manchester, United Kingdom.

The ATAC Study is a randomised, double blind trial of anastrozole (1 mg/day, A), tamoxifen (20 mg/day, T) or their combination (A+T) in 9366 postmenopausal women with early breast cancer (adjuvant therapy). The initial results from this study show that disease-free survival (DFS) was significantly improved in the A group compared with the T group (p=0.013), and the incidence of new (contralateral) primary breast tumours was reduced in the A group compared with the T group. After a median duration of 2.5 years, the fracture rate in the A group (5.8%) was higher than in the T group (3.7%). This could be a consequence of either the complete suppression of oestrogen levels by anastrozole or the partial oestrogen-agonist effect of tamoxifen on bone. We measured bone mineral density (BMD) by DXA at the lumbar spine (LS) and total hip (TH) in a subset of 308 women from the ATAC study, and 46 unrandomised control patients with breast cancer but receiving no hormone therapy. Bone resorption, by urinary N-telopeptide (NTX) and free deoxypyridinoline (DPD), and bone formation, by bone alkaline phosphatase (bone ALP), were also measured. The table shows the estimated percentage changes at one year in those patients completing the first year, following Analysis of Variance on log transformed data.

	A (n=80)	T (n=87)	A+T (n=82)	Controls (n=39)
LS-BMD	-2.59 (-3.41 to -1.77)	1.01 (0.15 to 1.88)	0.21 (-0.69 to 1.12)	-0.36 (-1.51 to 0.82)
TH-BMD	-1.68 (-2.36 to -0.98)	0.48 (-0.23 to 1.20)	0.78 (0.02 to 1.55)	-0.13 (-1.09 to 0.83)
NTX	12.2 (2.1 to 23.4)	-34.5 (-40.2 to -28.1)	-33.7 (-39.8 to -27.0)	-8.8 (-19.7 to 3.5)
DPD	-2.2 (-10.4 to 6.7)	-31.2 (-36.8 to -25.1)	-22.4 (-29.0 to -15.3)	-9.9 (-20.2 to 1.8)
Bone ALP	20.8 (13.3 to 28.6)	-14.0 (-19.3 to -8.2)	-9.6 (-15.4 to -3.5)	4.6 (-4.7 to 14.8)

Estimated Percentage Change (95% Confidence Interval).

Thus, at one year A therapy was associated with bone loss at the spine and hip and an increase in markers of bone resorption and formation, and T therapy with an increase in BMD and a decrease in markers of bone turnover; A+T had a similar effect on BMD and bone turnover as T alone. We conclude that the administration of A is probably associated with an increase in bone remodelling and that any consequent bone loss may be associated with a small increase in the risk of fractures. These data need be balanced against the overall efficacy and tolerability benefits observed in the main ATAC trial.
Submitted on behalf of the ATAC trialists

NSAIDs Impair Fracture Healing. M. Haberland*, M. Gesicki*, C. K. Nguyen*, J. Tibba*, F. T. Beil, M. Amling, J. M. Rueger*. Trauma Surgery, Hamburg University School of Medicine, Hamburg, Germany.

NSAIDs belong to the most widely used drugs in Europe and the USA. Their main action is to inhibit cyclooxygenase II and thereby reducing the synthesis of proinflammatory cytokines. Some of the most important inflammatory signals which are reduced by NSAIDs belong to the prostaglandin family, which has recently been shown to be important for skeletal homeostasis. We therefore hypothesized that NSAIDs might influence skeletal repair mechanisms, e. g. fracture healing. To test this hypothesis, fracture healing was studied in 100 mice treated with the NSAID diclofenac or placebo. Drugs or vehicle were administered via osmotic pumps or subcutaneously implanted pellets. Diclofenac was given in doses (per kg) similiar to the ones used in humans and for different periods of time to mimic chronic or acute use of these drugs. To make mouse models accessible to fracture modulation studies that also allow biomechanical analysis, we modified the Einhorn tibia fracture model and developed a standardized close femur fracture model. Analysis included biomechanics, contact-radiography, microCT analysis and undecalcified histology. In normal, control mice, the fractured femur reaches a biomechanical stability comparable to the contralateral intact femur after 20 days. Therefore the radiological, histological and biomechanical findings at 20 days in controls were defined as the physiologic reference. In sharp contrast, mice treated with diclofenac showed a significant delay in fracture healing. Callus size as assessed by contact-radiography and microCT was significantly reduced. Furthermore, not only radiological and histological data demonstrated a morphological interference of diclofenac with the fracture healing process, but also the functional competence of bone, as assessed by three-point-bending tests, was dramatically compromised at day 10 (Force to failure: 6,2 N in controls vs. 2,5 N in diclofenac treated mice, p< 0,05) and at day 20 (Force to failure: 15,2 N in controls vs. 9,1 N in diclofenac treated mice, p< 0,05). This study shows that NSAIDs impair the fracture healing process in vivo, leading to significantly reduced biomechanical stability. As these drugs are widely used in patients with fractures, it seems important that further experimental and clinical studies clarify the role of these drugs in fracture healing.

"Incipient" Primary Hyperparathyroidism: A "Forme Fruste" Of An Old Disease. S. J. Silverberg, J. P. Bilezikian. Medicine, Columbia University College of P&S, New York, NY, USA.

Recently, we have become increasingly aware of individuals with elevated levels of PTH in the absence of hypercalcemia. They have been carefully evaluated for other causes of elevated PTH. None have been found. These patients may represent the "forme fruste" of primary hyperparathyroidism (PHPT). The group includes 17 women (3 premenopausal, 14 postmenopausal; mean age: 60 ± 2 years), with normal renal function, no evidence for liver or gastrointestinal disease, no medications that could alter PTH or calcium levels. All have normal serum calcium levels (9.7 ± 0.1 mg/dl; nl: 8.4-10.4), with elevated PTH (118 ± 19 pg/ml; nl: 10-65). Urinary calcium is 182 ± 24 mg/24 hours (nl: 50-300), and bone density is normal compared to age and sex-matched controls at all sites (Z-Scores: spine: -0.4 ± .4; hip: -0.8 ± .2; radius: -0.3 ± .2). 25-hydroxyvitamin D levels are normal (34 ± 10 ng/dl; nl: 9-52), and well within the physiological range (>20 ng/dl). They do not have Familial Hypocalciuric Hypercalcemia (no family history of hypercalcemia; no hypocalciuria). They do not show evidence for the cortical demineralization that is characteristically seen when patients with hypercalcemia and PHPT are first evaluated. In one patient who fits this description, ^{99}Technetium-labeled Sestamibi imaging revealed a parathyroid adenoma that was removed and confirmed histologically. The existence of these patients satisfies many expectations about the disorder. Many of the clinical manifestations of PHPT are already present when the disorder is diagnosed; studies monitoring bone density and biochemical indices confirm that in most patients there is little evidence for disease progression. The pathophysiological construct calls for a biphasic disease course, in which the disorder is not clinically recognized when it begins (Phase 1) followed by the appearance of its biochemical hallmark, hypercalcemia (Phase 2). If one had insight into the earlier stage of the disorder, it would be characterized first by elevated PTH levels in the absence of hypercalcemia. Such patients would represent the earliest manifestation of PHPT, the elusive Phase 1 of the disease. The patients we describe have been referred for a screening evaluation of skeletal health. If our hypothesis is correct, hypercalcemia will develop as these patients are followed; we would then see the emergence of the typical pattern of bone loss as well as histomorphometric characteristics of PHPT. Information from the study of patients who represent this earliest form of PHPT could fill important gaps in our understanding of the development of the clinical features of modern PHPT.

Three Dimensional Assessment of Trabecular Architecture in Mild Primary Hyperparathyroidism (PHPT). D. W. Dempster[1], N. J. Caldwell*[2], S. A. Goldstein*[2], M. Parisien*[3], S. J. Silverberg[4], E. Shane[4], L. A. Fitzpatrick[5], R. Lindsay[6], J. P. Bilezikian*[7]. [1]Regional Bone Center, Helen Hayes Hopital, West Haverstraw, NY, USA, [2]Orthopaedic Research Laboratory, University of Michigan, Ann Arbor, MI, USA, [3]Department of Pathology, Columbia University, New York, NY, USA, [4]Department of Medicine, Columbia University, New York, NY, USA, [5]Department of Medicine, Mayo Clinic, Rochester, MN, USA, [6]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [7]Departments of Medicine and Pharmacology, Columbia University, New York, NY, USA.

We and others have previously reported maintenance of cancellous bone volume and trabecular number and connectivity in patients with mild PHPT. However, all studies to date have been performed in two dimensions. In the present study we have extended the analysis to the third dimension using microcomputed tomography. We studied biopsies from 10 premenopausal women and 15 men with primary hyperparathyroidism. The results were compared with biopsies from 14 normal women and 15 normal men. The average age of the men was the same in both groups (Normal, 48±3; PHPT, 49±3 years, p=NS). The women with PHPT were an average of five years older than their controls (Normal, 38±1; PHPT, 43±3 years, p<0.03). The results are given in the table.

	Men		Women	
	PHPT	Normal	PHPT	Normal
Cancellous bone volume (%)	23.3±1.7	21.4±1.8	30.8±2.2	30.2±2.1
Trabecular number (mm^{-1})	1.78±0.11	1.56±0.09	2.04±0.08	1.98±0.06
Trabecular thickness (μm)	131±6	135±8	151±8	152±7
Connectivity density (/mm^3)	4.17±0.69*	2.55±0.84	5.01±0.55	3.34±0.88

* p<0.05 by Wilcoxon's Rank Sum test

There were no significant differences between patients and controls in cancellous bone volume, trabecular thickness, and number. Trabecular connectivity density was significantly higher than controls in men with PHPT and there was a similar trend (p<0.06) in the women, especially noteworthy considering that the women with PHPT were significantly older by 5 years than their respective controls. This is the first study to analyze the three-dimensional structure of cancellous bone in patients with PHPT. The results confirm and extend our previous assessment, based on two-dimensional histomorphometric analysis, that cancellous bone volume is preserved in men and women with PHPT, and trabecular connectivity may be improved.

1174

Long-term Effects of Primary Hyperparathyroidism on Trabecular Bone Density. P. L. Selby[1], M. Davies[1], C. Alsop*[2], J. E. Adams[2]. [1]Musculoskeletal Research Group, University of Manchester, Manchester, United Kingdom, [2]Clinical Radiology, University of Manchester, Manchester, United Kingdom.

Primary hyperparathyroidism is a common disorder which is frequently asymptomatic. There remains controversy as to the long-term implications of the disease and the indications for surgical treatment. Recent evidence has indicated that parathyroidectomy leads to an increase in lumbar spine bone mineral density (BMD) which has led to suggestions that surgery should be offered to preserve bone density. However there are few data examining the long-term effects of primary hyperparathyroidism on trabecular bone density during conservative management and following parathyroidectomy. We studied 50 patients (16 male) aged 55 (SD 10) years with mild primary hyperparathyroidism (mean plasma calcium 2.76mmol/l, SD 0.11mmol/l). All had been followed with Quantitative Computed Tomography (QCT) bone densitometry of the lumbar spine for at least five years. Mean volumetric trabecular vBMD was measured in mg/cm^3 in 10mm slices in the mid-plane of four vertebrae (generally T12-L3) using K_2HPO_4 bone equivalent phantom. The median follow-up was 7.2 years and maximum 13.0 years. 16 patients underwent parathyroidectomy during follow-up. The effects of time and parathyroidectomy upon bone density were assessed using analysis of variance. Mean vBMD was 102.0 (SE 0.6) mg/cm^3 in those patients who did not undergo parathyroidectomy and 109.2 (SE 1.3) mg/cm^3 following surgery (mean difference 7.2 mg/cm^3 p<0.0001). Although there was a steady decline in vBMD with time (-2.3 mg/cm^3/y 95%CI -1.9 – -2.6), this was no greater than would be expected with age, and there was no change in Z score with time (mean change 0.00/y 95%CI -0.001 - +0.002). Furthermore, the relationship between bone loss and time was unchanged by parathyroidectomy. This study represents the longest follow-up of changes in trabecular bone density in patients with primary hyperparathyroidism. It indicates that parathyroidectomy does not alter the rate of trabecular bone loss in the long term, although surgery is associated with an initial quantal increase in bone density. We conclude that parathyroidectomy is of limited value in prevention of trabecular bone loss in patients with mild primary hyperparathyroidism..

Homozygous Deletion of the Murine Calcitonin Receptor Gene Is an Embryonic Lethal. C. Laplace*, X. Li*, S. R. Goldring, D. L. Galson. NEB Bone & Joint Institute, Dept. of Medicine, Beth Israel Deaconess Medical Center & Harvard Medical School, Boston, MA, USA.

The calcitonin receptor (CTR) has multiple ligands. It is the receptor for both calcitonin (CT) and amylin (requiring in the latter case, a RAMP accessory protein). CTR is expressed in a variety of tissues at different times during development from embryonic through adult, suggesting a role in morphogenesis. To study the consequences during development of a complete ablation of the murine CTR (mCTR) gene, we generated two ES cell lines that have a targeted deletion of exons E6 and E7 in one allele of the mCTR gene. Deletion of these exons should effectively disable all mCTR isoforms as splicing of exon E5 to exon E8a is out of phase. Therefore, any protein that could be generated would encode no more than a portion of the first extracellular domain. Although we have generated 17 chimeric mice from the two ES cell lines, only one male chimera has sired mCTR (–/+) heterozygous mice. Our heterozygous breeding pairs have produced 69 mCTR (+/+) wild type mice (29%), 170 mCTR (–/+) heterozygous mice (71%) and no mCTR (–/–) homozygous mice (0%). These results indicate that, although CTR is known to be expressed in sperm at various stages of differentiation, male heterozygous CTR knock-out mice are not sterile and do produce CTR-negative sperm. Therefore, expression of CTR is not necessary for sperm differentiation or function. However, the absence of CTR knock-out mice suggests that lack of CTR expression results in a lethal embryonic defect. Pregnant females from mCTR (–/+) heterozygous intercrosses were sacrificed at different times of gestation and the embryos genotyped by PCR. Analysis of 25 embryos at 9.5 days post coitum (dpc) shows that there is a concordance between the observed (7:12:6; +/+, –/+, –/– , respectively) and expected (1:2:1) distributions. These data indicate that there is no deleterious effect of the homozygous CTR deletion up to this point of development. Therefore, these data exclude the possible theory that blastocyst expression of CTR is necessary for implantation. This is a critical observation as uterine CT has been suggested to have a key regulatory role during blastocyst implantation and CTR has been demonstrated on mouse preimplantation embryos. The observed ratio of embryos at 10.5 dpc (11:38:5) suggests that some homozygous null embryos are dying between 9.5 and 10.5 dpc. We have not observed any homozygous null embryos after 10.5 dpc. The 66 embryos analyzed from 11.5 through 14.5 dpc have an observed ratio of 1:2.7:0. We have not observed any obvious differences in gross anatomy between the homozygous null and heterozygous or wildtype embryos. Further analysis of the lethal developmental defect due to ablation of the CTR gene is underway.

1176

Runx2/Cbfa1 Is Essential for the Anti-apoptotic Effect of PTH on Osteoblasts. L. I. Plotkin[1], T. Bellido[1], A. A. Ali[1], Q. Fu[1], I. Gubrij[1], L. K. McCauley[2], C. A. O'Brien[1], S. C. Manolagas[1], R. L. Jilka[1]. [1]Endo/Metab. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]School of Dentristy, University of Michigan, Ann Arbor, MI, USA.

PTH inhibits osteoblast apoptosis *in vivo* and *in vitro*, but the molecular mechanism of this effect has not been fully elucidated. It has been previously reported that activation of protein kinase A (PKA), but not protein kinase C or ERKs, is required for this action; and that PKA phosphorylates, and thereby inactivates, the pro-apoptotic protein Bad. Nonetheless, it is known that PKA also phosphorylates and activates the cAMP response element binding protein (CREB) and possibly Runx2/Cbfa1; and that CREB increases AP-1 activity by stimulating expression of AP-1 family members such as c-fos. To investigate whether CREB and/or Runx2/Cbfa1 play a role in the anti-apoptotic effect of PTH, we have utilized chemical transcription inhibitors as well as dominant negative (dn) mutants of these and other transcription factors. We report that actinomycin D abolished the survival effect of PTH on osteoblastic OB-6 cells, indicating the requirement for transcription. More specifically, dn CREB and dn Runx2/Cbfa1, completely abrogated the anti-apoptotic effect of PTH; but dn c-fos or dn c-jun were ineffective. The dispensability of c-fos was confirmed independently by the observation that osteoblastic cells obtained from *fos* null mice still exhibited the anti-apoptotic effect of PTH. We attempted to identify PTH-regulated genes involved in anti-apoptosis using an Affymetrix DNA microarray chip containing 12,000 genes (U74A). RNA was prepared from triplicate OB-6 cultures maintained under basal conditions, or treated with 50 nM PTH for 30, 60, or 120 minutes. Using Significance Analysis of Microarray software (Stanford University), we found that PTH caused statistically significant changes in the expression of several hundred genes, 8 of which have a known role in apoptosis. Of these, the best characterized is the anti-apoptotic protein Bcl-2, which was increased 2-fold at 1 hour following exposure of OB-6 cells to PTH. This response was confirmed by Western blot analysis using OB-6 and murine calvaria cells. Stimulation of Bcl-2 synthesis by PTH is consistent with the presence of one CREB binding site and several putative Runx2/Cbfa1 binding sites in the promoter region of the Bcl-2 gene. These findings demonstrate for the first time that, in addition to its essential function in osteoblast differentiation, Runx2/Cbfa1 is indispensable for the anti-apoptotic action of PTH on osteoblasts; and perhaps for osteoblast survival in general.

1177

Effects of PTH/PTHrP Receptor-Generated Signals on RANKL/RANK-Induced Osteoclastogenesis : Analyses I*n Vitro, In Vivo and Ex Vivo*. H. Kondo[1], J. Guo[2], U. Chung[2], S. Kasugai[1], H. M. Kronenberg[2], F. R. Bringhurst[2]. [1]Masticatory Function Control, Tokyo Medical and Dental University, Tokyo, Japan, [2]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

PTH is one of the major regulators for osteoclast formation and activation in bone metabolism. It has been previously reported that the PTH-supported osteoclastogenesis is also accompanied by reciprocal up- and down-regulation of RANKL and OPG, respectively. However, it is not yet clear how the downstream signals generated by PTH/PTHrP receptor - cAMP/PKA and PLC/PKC- are involved in osteoclastogenesis. To address this issue, we conducted the following experiments. Cyclic AMP accumulation, mRNAs expression of RANKL, OPG, and M-CSF, and osteoclast formation were examined in an established murine marrow stromal cell line (MS1) or in primary bone marrow stromal cells (BMSC). MS1 and BMSC supported osteoclast formation in response to PTH(1-34), stimulating RANKL and inhibiting OPG mRNA expression. Northern blot analysis dem-

onstrated expression of RANKL was stimulated by [G^1R^{19}]PTH(1-28), a PKA selective PTH analogue, which exerted similar effects to PTH(1-34) and other PKA stimulators on reciprocal regulation of RANKL and OPG, and on osteoclast formation. On the other hand, PMA, a direct PKC stimulator, did not stimulate RANKL, and up-regulated OPG rather than down-regulated it. Furthermore, PMA inhibited PTH(1-34)-dependent osteoclast formation. These results suggest that cAMP/PKA signaling controls RANKL-induced osteoclastogenesis, and that PLC/PKC may exert inhibitory effects on it. To further elucidate the mechanism whereby PTH promotes osteoclastogenesis, we generated PLC/PKC signaling defective PTH/PTHrP receptor knock-in mice. EKKY sequence, located in the second intracellular loop of the intact PTH/PTHrP receptor, was replaced by DSEL. As previously shown, this mutation selectively abolished PLC activation downstream of PTH/PTHrP receptor, preserving intact AC/cAMP signaling. Histological observation in tibiae of 8 week-old mice indicated that phenotype in PLC defective mutant mice was similar to wild type except larger marrow space in mutant mice, suggesting that PLC/PKC signaling is not required for osteoclasotgenesis. Moreover, primary bone marrow cells from both mutant and wild type mice support osteoclasts by PTH(1-34), and the number of osteoclasts from the mutant mice is greater than wild type. These *in vivo* and *ex vivo* findings, coupled with *in vitro* analysis, revealed that cAMP/PKA signaling plays a major role for osteoclastogenesis, and PLC/PKC is not required. Furthermore, PLC/PKC signaling may play a negative role for PTH-dependent osteoclastogenesis.

1178

Inhibition of Osteoclast Formation by Human PTH(7-84) Involves Direct Actions on Hematopoietic Cells. P. Divieti, O. Lotz*, A. Geller*, H. Jüppner, F. R. Bringhurst. Endocrine Unit, Mass General Hospital and Harvard Medical School, Boston, MA, USA.

Intact parathyroid hormone, PTH(1-84), regulates formation and activity of cells in bone via interaction of its amino-terminus with the G protein-coupled PTH/PTHrP receptor (PTHR). Osteoblasts and osteocytes derived from PTHR-null mice express additional receptors for PTH that specifically recognize the carboxyl(C)-terminal region of the hormone. These C-terminal PTH receptors (CPTHRs) are highly expressed on osteocytes, where they can induce cell death, an action opposite to that reported for PTHR activation in these cells. Recently, large carboxyl-terminal fragments of PTH, with chromatographic properties similar to synthetic hPTH(7-84), were detected in plasma of normal subjects and, at much higher levels, in plasma of patients with advanced renal failure. Synthetic hPTH(7-84) blocked the calcemic actions of PTH(1-84) and PTH(1-34) in parathyroidectomized rats in vivo. These actions appear to result from direct effects of hPTH(7-84) via CPTHRs in bone, as this peptide, which neither activates nor antagonizes PTHRs in vitro, inhibits both osteoclast formation in murine bone marrow cultures and resorption of intact murine calvarial bone in vitro. The cellular target(s) of these antiresorptive actions of hPTH(7-84) are unknown, although osteoblasts and marrow stromal cells are known to express CPTHRs. To determine if the antiresorptive actions of hPTH(7-84) might be mediated by activation of CPTHRs on cells of the hematopoietic lineage, we first sought effects of hPTH(7-84) on osteoclast formation induced by M-CSF and RANKL in murine whole bone marrow (WBM) and in purified bone marrow macrophage (BMM) cultures. As expected addition of RANKL(40ng/ml) and M-CSF (10ng/ml) induced osteoclast formation in both in vitro systems, as assessed by TRAP staining and TRAP solution assay. Addition of hPTH (7-84) (300nM), reduced osteoclast formation induced by combined RANKL and M-CSF treatment by about 40% in both systems, suggesting a direct effect of hPTH(7-84) on the hematopoietic compartment. We then performed CPTHR radioligand binding analysis using BMM and 125I- [Tyr34]hPTH(19-84) and observed that 1) BMM expressed specific CPTHRs and 2) the CPTHR expression in these cells was further reduced by treatment with RANKL, suggesting that CPTHR expression may decrease during osteoclast maturation. We conclude that CPTH fragments may act upon both the stromal/osteoblast and hematopoietic compartments, and that inhibition of bone resorption by hPTH(7-84) involves, at least in part, a direct effect of the hormone via CPTHRs expressed on osteoclasts or their precursors.

1179

Teriparatide (rhPTH (1-34)) Skeletal Efficacy Is not Affected by Longterm Pretreatment with Alendronate, Estrogen, or Raloxifene in Ovariectomized Rats. Y. L. Ma, Q. Q. Zeng*, A. Schmidt*, J. L. Hoover*, H. W. Cole*, H. U. Bryant*, M. Sato. Endocrine, Lilly Research Labs, Indianapolis, IN, USA.

Because of the ready availability of other therapies, teriparatide (rhPTH (1-34)) may be administered to osteoporotic women who have already been treated with other agents, such as alendronate (ABP), estrogen (EE2), or raloxifene (RA). The latter agents suppress bone turnover, by inhibiting resorption and secondarily reducing bone formation; and so, could interfere with the skeletal efficacy of teriparatide which increases bone turnover, as it stimulates mineral apposition. To probe this question, ovariectomized (Ovx) rats (3 months old) were pretreated with ABP (28µg/kg/2xwk sc), EE2 (0.1mg/kg/d po), or RA (1mg/kg/d po) for 10 months, before switching to PTH 30µg/kg/d sc for 2 months. All 3 agents prevented ovariectomy induced bone loss after 10 months, but were mechanistically distinct as shown by histomorphometry. For example, ABP preserved the primary spongiosa by preventing remodeling, because the primary spongiosa was considerably reduced compared to baselines for all other groups (13 months of age). ABP strongly suppressed activation frequency, eroded surface, and bone formation rate to below other treatment groups after 10 months, whereas these parameters were not different from Sham for EE2 and RA. Trabecular area for ABP, EE2 and RA were greater than Ovx controls, but trabecular number was greater for ABP compared to all other groups, while EE2 and RA had trabecular number that were between Ovx and Sham controls. RA tended to increase trabecular thickness, whereas ABP and EE2 had trabecular thickness that were not different from Sham. After 2 months of sequential teriparatide (PTH) treatment, trabecular area was increased by 105%, 113%, 36% and 48%, for vehicle/PTH, ABP/PTH, EE2/PTH and RA/PTH, respectively, compared to 10 month levels. The trabecular area of ABP/PTH resulted from the greater primary spongiosa which was preserved with the 10 month ABP treatment. PTH induced significant increases in mineralizing surface, mineral appositional rate, and bone formation rate in all the groups. Biomechanical testing of vertebra in compression showed that PTH improved peak load, stiffness and toughness in all groups to a proportionately similar extent compared to 10 month levels. These data showed a surprising ability of the rat skeleton to respond to PTH, despite extensive pretreatment with ABP, EE2, or RA and even when activation frequency was suppressed by more than 90% with ABP before switching to PTH. The mature skeleton of ovariectomized rats remained vigorously responsive to the appositional effects of PTH, regardless of pretreatment status in terms of bone turnover or trabecular bone area.

The Effect of Aging on the Skeletal Response to Intermittent Treatment with Parathyroid Hormone. E. A. Knopp*[1], B. Sun[1], N. Troiano*[1], K. Wilson*[1], C. Coady*[1], K. Lostritto*[1], C. M. Gundberg[1], M. L. Bouxsein[2], K. Insogna[1]. [1]Yale University, New Haven, CT, USA, [2]Beth Israel Medical Center, Boston, MA, USA.

Although proposed for therapeutic use in the elderly, little is known about the modifying effects of age on the skeletal response to intermittent treatment with PTH. We therefore compared the response to intermittent PTH treatment in aged and mature mice. In each of two identical experiments, 30 18-month old and 30 3-month old male C57BL/6 mice were randomly divided into PTH- or vehicle-treated groups. Treated mice received s.c. injections of h(1-34)PTH at 95 ng/g body weight once daily for 4 weeks. Serial bone density measurements by DEXA demonstrated a time- and PTH-dependent increase in bone density at all skeletal sites. The increase in total body density as compared to vehicle-treated animals was equivalent in aged and mature mice (+6.0% vs. +6.5%, combined data from both experiments). Surprisingly in each experiment, the aged animals demonstrated a greater increase in spinal BMD than their younger counterparts whether expressed as percent increase (+13.6% vs. +5.4%, $p<0.001$) or as an absolute increment in BMD (51×10^{-4} vs. 34×10^{-4} gms/cm^2, $p<0.045$). MicroCT analysis confirmed these findings and demonstrated a greater increase in L5 trabecular bone mass in the PTH-treated aged animals again whether measured by percent increase (+40.1% vs. +19.7%, BV/TV) or absolute increment. By contrast, the mature animals showed a significantly greater increase in femoral BMD when compared to the aged group (8.5% vs. 4.5%, combined DEXA data, $p<0.04$). This was confirmed by pQCT data from the two experiments which showed a 21% increase ($p<0.0002$) in mature adult tibial cortical content vs. a non-significant 5% increase in aged animals. Osteocalcin levels rose more significantly in the aged mice (157% vs. 83%), suggesting a greater sensitivity of osteoblasts to PTH in the aged group. Consistent with this latter finding, initial L-spine histomorphometric data demonstrated a significantly greater increase in NOb/TAR in the aged animals than in the mature ones (414% vs. 241%). The number of alkaline phosphatase positive and Von Kossa positive colonies in cultured marrow were unaffected by PTH treatment in either group. In summary, the trabecular-rich lumbar spine appears to be more responsive to PTH with aging while the response in the more cortically enriched femur declines. Differential effects on osteoblast progenitor recruitment do not seem to be the cellular mechanism underlying these changes. The occurrence of such effects on osteoblast apoptosis is being investigated currently. We conclude that aging differentially effects the regional skeletal response to PTH.

1181

Transfer of *CasR* Deficiency Onto the *GCM2* Null Background Rescues the Perinatal Lethality and Skeletal Abnormalities in *CasR*-Deficient Mice. Q. Tu*[1], M. Pi[1], G. Karsenty[2], L. D. Quarles[1]. [1]Center for Bone and Mineral Disorders, Duke University Medical Center, Durham, NC, USA, [2]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

The calicum sensing receptor *(CasR)* plays a predominant role in regulating parathyroid gland function, but its independent function in the skeleton is uncertain. Targeted deletion of *CasR* results in severe hyperparathyroidism resulting from the absence of CasR in the parathyroid glands and in an unexpected impairment of bone and cartilage mineralization resulting from excessive PTH levels and/or the absence of CasR in bone and cartilage. Ascertaining the contribution of excess PTH to the bone phenotype by surgical removal of the parathyroid gland has not been feasible, because of the high perinatal mortality in CasR deficient mice. *Glial cells missing2* (*Gcm2)*-deficient mice that lack parathyroid glands but produce auxiliary PTH in the thymus provide a genetic approach to achieve parathyroid gland ablation in *CasR* deficient mice. We crossed F2 double heterozygotic $Gcm2^{+/-}CasR^{+/-}$ mice to generate double knockout $Gcm2^{-/-}CasR^{-/-}$mice. We compared survival rates, serum calcium and PTH, and bone mineral density (BMD) in $Gcm2^{-/-}CasR^{-/-}$double knockouts, $Gcm2^{-/-}CasR^{+/+}$ double knockout, $Gcm2^{+/+}CasR^{-/-}$ single knockouts, and wild-type ($Gcm2^{+/+}CasR^{+/+}$) littermates. Consistent with previous reports, the mortality rates at 6-weeks in *CasR*-and *GCM2*-deficient mice were 100% and 30%, respectively. Serum calcium (mg/dl) and PTH (pg/ml) were 13.9± 0.8 and 456.98± 69 in 1 week-old *CasR*-deficient mice, compared to 6.3± 0.4 and 17.02± 3.0 in 6-week old *GCM2*-deficient mice, and 8.1± 0.2 and 23.6±4.0 in wild-type mice. The mortality rate (29%), calcium (6.1±0.3), and PTH (11.5+1.3) in $Gcm2^{-/-}CasR^{-/-}$ double knockout mice were not different from *Gcm2*-deficient littermates. Bone ashed weights (% dry wt) and BMD (g/cm^2) also were not different between $Gcm2^{-/-}CasR^{-/-}$, *Gcm2*-deficient, and wild-type mice. These findings indicate that genetic ablation of the parathyroid glands by intercrossing *CasR*- and *Gcm2*-deficient mice rescues the perinatal lethality of *CasR*-deficiency, and prevents the development of hypercalcemia, hyperparathyroidism, and low bone density in *CasR*-deficient mice. Further characterization of the phenotype of $Gcm2^{-/-}CasR^{-/-}$ should provide insights into the extra-parathyroid functions of *CasR*.

Targeted Ablation of FGF-23 Causes Hyperphosphatemia, Increased 1,25-dihydroxyvitamin D Level and Severe Growth Retardation. T. Shimada*[1], M. Kakitani*[1], H. Hasegawa*[1], Y. Yamazaki*[1], A. Ohguma*[1], Y. Takeuchi[2], T. Fujita*[2], S. Fukumoto[3], K. Tomizuka*[1], T. Yamashita[1]. [1]Pharmaceutical Research Labs, KIRIN Brewery Co., Ltd., Takasaki, Japan, [2]Department of Medicine, University of Tokyo School of Medicine, Tokyo, Japan, [3]Department of Laboratory Medicine, University of Tokyo Hospital, Tokyo, Japan.

Previous investigation revealed that transgenic mice for FGF-23 and mice carrying tumor expressing FGF-23 showed hypophosphatemia and low serum 1,25-dihydroxyvitamin [1,25$(OH)_2$D]. These results indicated that excess actions of FGF-23 decrease serum phosphate and 1,25$(OH)_2$D levels. However, it has been unclear whether FGF-23 has any physiological role in mineral metabolism. In the present study, we generated FGF-23 null (-/-) mice to address this issue. A 5.2 kb fragment containing 5'-untranslated region and 1.8 kb fragment encoding a part of exon 1 and the following intron of FGF-23 gene were isolated from C57BL/6 genomic BAC library and subcloned into 5' and 3' of a neomycin resistance gene, respectively, to construct a targeting vector. Using this targeting vector, ES clones carrying a targeted allele were selected and FGF-23 (+/-) mice were established from them. The phenotypes and biochemical parameters of FGF-23 (+/-) mice were indistinguishable from those of wild-type mice. When FGF-23 (+/-) mice were interbred, FGF-23 (-/-) mice were born according to Mendelian frequency, indicating that ablation of FGF-23 did not cause embryonic lethality. Body size of FGF-23 (-/-) mice was not different from that of wild-types or heterozygotes at birth. However, remarkable growth retardation in FGF-23 (-/-) mice was observed at 10 days and thereafter. Body weight of FGF-23 (-/-) mice was significantly less than that of heterozygotes both at 10 days and 9 weeks (10 days: 3.8 +/- 0.3 vs. 5.6 +/- 0.3 g, $p < 0.01$, 9 weeks: 6.5 +/- 0.5 vs. 20.7 +/- 0.4 g, $p < 0.001$). Life span of FGF-23 (-/-) mice was short and the survival of them more than 12 weeks has never been observed. Serum phosphate of FGF-23 (-/-) mice was significantly increased at 10 days compared to that of heterozygotes (16.9 +/- 2.6 vs. 10.8 +/- 0.2 mg/dL, $p < 0.001$), but serum calcium was not different (10.5 +/- 0.2 vs. 10.1 +/- 0.2 mg/dL). In contrast, serum phosphate, calcium and 1,25$(OH)_2$D of FGF-23 (-/-) mice were elevated at 9 weeks compared to those of heterozygotes (Pi: 14.7 +/- 0.5 vs. 8.58 +/- 0.42, $P<0.001$; Ca: 10.7 +/- 0.3 vs. 8.9 +/- 0.2, $p < 0.01$; 1,25$(OH)_2$D: 378 vs. 129 pg/ml). These results indicate that FGF-23 is not necessary during fetal development, but indispensable for normal growth after birth. Furthermore, FGF-23 plays physiological roles in maintaining serum phosphate, calcium and 1,25$(OH)_2$D levels.

Effects of Secreted Frizzled-Related Protein (sFRP)-3 on Osteoblasts In Vitro: sFRP-3 Is a Stimulator of Osteoblast Differentiation. Y. Chung, D. J. Baylink, A. K. Srivastava, Y. Amaar, Y. Kasukawa, S. Mohan. J.L. Pettis VAMC, Loma Linda, CA, USA.

The Wnt gene family represents a large and diverse group of signaling molecules involved in the proliferation and differentiation of a variety of cell types. The involvement of Wnt signaling in regulating bone formation is evident from recent studies demonstrating that mutations in LDL-receptor-related protein 5 gene influences bone accretion via alterations in Wnt-mediated signaling. Based on the findings that sFRP family members bind Wnt proteins and antagonize Wnt signaling, and that activation of Wnt signaling stimulates osteoblast differentiation, we proposed that sFRP is an inhibitor of osteoblast differentiation. To test this hypothesis, we evaluated the effect of sFRP-3 (Frzb1), originally identified in cartilage, on osteoblast proliferation and differentiation. Serum-free cultures of MC3T3-E1 mouse osteoblasts were incubated with various doses of recombinant sFRP-3 (1, 10, 100, 1000 pM) and cell number determined by alamarBlue assay. sFRP-3 inhibited cell number in a dose-dependent manner with a maximal inhibition of 53% ($P<0.001$) at 1 nM dose. At a dose of 10 pM, sFRP-3 caused a 33% inhibition ($P<0.001$). sFRP-3 inhibition of MC3T3-E1 cell proliferation is not specific to this cell type since sFRP-3 also decreased cell number significantly in mouse bone marrow stromal cells. To evaluate the effects of sFRP-3 on osteoblast differentiation, mouse bone marrow stromal cells or MC3T-3 E1 cells were incubated with varying doses of sFRP-3 for 6 days and its effect on ALP activity and osteocalcin production determined under serum-free conditions. Surprisingly, sFRP-3 caused a dose-dependent increase in ALP specific activity with a maximal increase of 2-fold over control (79.7±12 vs 38.1±6.6 mU/mg protein, $P<0.001$) at 100 pM dose. This increase in ALP activity was higher than that obtained with a combination of 1 ng/ml TGFβ and 10^{-8}M 1,25 D (62±11 mU/mg protein) under identical culture conditions. Consistent with the ALP data, osteocalcin level, which was undetectable in the culture media of control cultures (<1 ng/ml), was increased to 15±5 and 24±8 ng/ml respectively at 10 and 100 pM doses of sFRP-3. Summary: 1) sFRP-3 inhibits osteoblast cell proliferation. 2) sFRP-3 stimulates ALP activity and osteocalcin production in osteoblasts. 3) sFRP-3 is active at extremely low doses (1-10 pM). Conclusions: 1) Our findings demonstrate for the first time that sFRP-3 is a potent stimulator of osteoblast differentiation. 2) Based on these and other findings, the concept that sFRP acts exclusively to inhibit Wnt is probably oversimplified; instead, we propose that sFRP-3 may act as a novel ligand for an as-yet unidentified receptor in osteoblasts.

1184

In Vivo **Expression of a Dominant Negative Cadherin Increases Adipogenesis and Delays Achievement of Peak Bone Mass.** C. Castro[1], C. Shin[2], S. Sheikh*[1], S. Cheng[1], R. Civitelli[1]. [1]Div. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA, [2]Internal Medicine, Seoul National University, Seoul, Republic of Korea.

A null mutation of cadherin-11 or single allele deletion of Ncad cause mildly decreased bone mass, suggesting overlapping roles of these two cell adhesion molecules in skeletal development. To overcome the redundancy of cadherins and understand their biologic function in bone, we generated a mouse strain expressing a truncated Ncad mutant derived from an in-frame deletion of most of the extracellular domain of *Xenopus* Ncad, driven by the mouse OG2 promoter (OG2-NCadΔC), which functions as a dominant negative cadherin. The transgene was selectively expressed in calvarial and bone marrow stromal cells, its abundance increasing with osteoblast differentiation and upon BMP-2 stimulation. Alkaline phosphatase activity was reduced in cells isolated from newborn calvaria of transgenic mice compared to wild type controls, although matrix mineralization was similar after 4 weeks in the presence of ascorbic acid and β-glycerophosphate. Total body bone mineral density (BMD) and percent body fat (%BF) were monitored monthly by DEXA. During the first 3 months of life – when bone mass accumulates – BMD was reduced in transgenic animals compared to wild type littermates, with maximal difference of 10% at age 3 months (51.54±2.01mg/cm^2 vs. 57.3±2.45mg/cm^2; $p<0.001$; respectively). By contrast, %BF was 27% higher in OG2-NCadΔC than in wild type mice (29±5.7% vs. 22.8±2.3%, respectively; $p=0.011$). During this time, body weight and food intake were also higher in mutant vs. wild type animals. At age 4 months and higher, BMD, %BF, and body weights were no longer different between mutant and normal animals. There were no gender differences at any time. At the cellular level, the number of colony forming unit-adipocytes (CFU-AD) in bone marrow cells from OG2-NCadΔC mice was 3-fold higher compared to wild type cultures (7.9±1.5 vs. 1.6±0.6 CFU-AD/10^6 cells, respectively; $p<0.01$) after induction by hydrocortisone and indometacin. Accordingly, adipsin and PPAR-γ mRNA abundance – assessed by real-time RT-PCR - were increased in OG2-NCadΔC bone marrow cultures compared to wild type controls (2.3- and 10-fold, respectively), whereas cbfa1 mRNA was decreased 40%. These results suggest that *in vivo* disruption of cadherin function hinders full osteoblast differentiation, thus favoring, indirectly, bone marrow progenitor cell commitment to the alternative adipogenic lineage, and resulting in delayed acquisition of maximal bone mass. Since NcadΔC binds β-catenin, depletion of transcriptionally active β-catenin pools may cause a shift from osteogenesis to adipogenesis in these animals.

Use of GFP-Marked Primary Osteoblast Culture to Assess the Effect of PTH on the Osteoprogenitor Lineage. Y. H. Wang, K. M. Buhl*, D. W. Rowe. University of Connecticut Health Center, Farmington, CT, USA.

Transgenic mice harboring green fluorescent protein (GFP) marker genes driven by various promoter fragments can be used to identify the level of osteoblastic differentiation in real time in primary bone cell culture. This study was initiated to demonstrate the utility of these reagents for studying an agent that alters osteoblastic differentiation, in this case PTH. An inverted fluorescent microscopic workstation has been assembled that allows 63% of a 35 mm culture well to be reproducibly imaged over time from a series of 25 adjacent pictures that are tiled into a single image of the plate. Three fluorescent markers were used: pOBCol3.6GFP which is activated in preosteoblastic cells; pOBCol2.3GFP which is restricted to mineralized nodules; and xylenol orange (XO) which stains the mineralized nodules. The tempo and staining pattern was established at multiple time points in mouse calvarial osteoblast cultures. Preosteoblastic cells were evident at day 7 and markers of osteoblastic differentiation (accentuated expression of pOBCol3.6GFP, activation of pOBCol2.3GFP and XO staining) were evident by day 14 and became more intense by day 21. Continuous exposure to 25 nM PTH blocked expression of osteoblastic differentiation resulting in a cell population enriched for preosteoblastic cells. Addition of PTH for day 1-7 of culture delayed the appearance of osteoblastic markers but ultimately resulted in a culture with a greater number of osteoblastic nodules, while PTH given between day 7-14 delayed osteoblastic differentiation that had not fully recovered by day 21. In contrast, exposure of the culture to PTH between day 14-21 caused the pOBCol2.3GFP-positive cells to revert from a strongly fluorescent cuboidal cell to one with weaker fluorescence and more fibroblastic shape. pOBCol2.3 cells with these characteristic have not been previously appreciated and may represent dedifferentiated osteoblastic cells. Unlike pOBCol2.3, the high osteoblastic-associated expression in pOBCol3.6 cells was not lost while low fibroblastic-associated expression increased in the PTH treated cells. The analysis suggests that PTH acts on early progenitor cells to expand their number and maintain their ability to differentiate when PTH is removed, while the mature osteoblastic cells dedifferentiate into cells whose differentiation capacity is yet to be characterized. Thus the model has the sensitivity to reveal subtle alterations of the differentiation pathway, and when combined with FACS sorting, to define the molecular profile of a PTH directed cell subpopulation and their potential for subsequent osteoblastic differentiation.

1186

Use of a Col1a1-GFP Retroviral Marker System to Monitor In Vitro Differentiation of ES Cells into Osteoblastic Cells. U. Chung[1], M. Stover*[2], I. Kalajzic*[2], D. W. Rowe[2], A. C. Lichtler[2]. [1]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA, [2]Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Embryonic stem (ES) cells are pluripotent stem cells that can contribute to all cell types of the embryo. Recently, there has been intense research on development and tissue engineering of ES cells, since they have been shown to differentiate in vitro into many cell types, and they can proliferate almost indefinitely. Although they were shown to differentiate into osteoblastic cells in vitro, the efficiency and duration of the differentiation protocol is still not good enough to replace or substantially complement in vivo experiments or to be applied to clinical settings. To develop better protocols, it is necessary to have an easy and precise monitoring system for osteoblastic differentiation. For this purpose, a retroviral vector was constructed, which contains a 2.3 kb Col1a1 promoter driving green fluorescent protein (GFP) and the neomycin resistance gene. The 2.3 kb Col1a1 promoter was previously shown to confer specific expression in osteoblasts. The LTR of this retrovector was designed to self-inactivate upon integration, so that the viral promoter would not interfere with the inserted promoter. The vector was then packaged in a VSV-G pseudotyping sys-

tem. Wild-type ES cells were infected with the retrovirus containing the vector. Infected cells were selected, and single clones were isolated. Infected ES cells were then differentiated into osteoblastic cells by allowing formation of embryoid bodies, then culturing them in medium containing ascorbic acid, dexamethasone, and b-glycerophosphate. As bone nodules form, cuboidal cells in the nodules that accumulate calcium matrix start to show fluorescence. The nodules were positive by von Kossa stain as well as Alizarin Red S. Spindle-shaped cells surrounding the nodules show weaker fluorescence, suggesting that they may be osteoblastic precursors. On the other hand, fluorescence was not detected in other cell types such as trophoplastic, adipocytic and chondrocytic cells. Since it detects fluorescence, live cells can be monitored over time repeatedly, and a great number of samples can be tested easily and rapidly. We think that this method of monitoring differentiation is useful in developing and refining the differentiation protocol, and we are currently optimizing osteoblast differentiation by changing all parameters in the existent protocols. If successful, the establishment of the protocol may facilitate some aspects of in vitro studies of osteoblast differentiation as well as help open up possibilities for use of ES cells in tissue engineering of bone.

1187

A Novel Bone-specific Secreted Protein Which Regulates Osteoblast Differentiation. C. Lanctot, M. Bessette*, M. Gaumond*, R. Gingras*, É. Godin*, P. Moffatt*, P. Salois*, K. Sellin*, N. St-Amant*, G. Thomas. Phenogene Therapeutics, Montreal, PQ, Canada.

Screening of a mouse embryonic calvarial cDNA library using a signal trap strategy has identified a novel secreted protein referred to as PGTI0306. The protein is synthesized as a 130 amino acid precursor encoded by a 1280bp mRNA. The protein is well conserved across species (mouse to human 74.6%, mouse to rat 90.2%), but shares no homology with known genes. However, 2 conserved dibasic cleavage sites present the possibility that the protein is synthesized as a prohormone-like precursor and downstream proteolytic processing maybe necessary for activation. A cleavable signal peptide is located at the N-terminus of the molecule. Expression of this gene is highly specific. Northern blot analysis of 52 fetal and adult tissues revealed detectable expression only in bone tissues. A different sized mRNA species was evident in adult rat spleen, possibly arising through differential splicing. Interestingly, expression of PTGI0306 decreased with age in both long bones and calvaria. In situ hybridization on sections of developing embryos demonstrated expression in bones to be confined to the inner layer of the periosteum, co-localising with a subset of Cbfa1-positive cells that did not express osteocalcin. Expression of PGTI0306 was also demonstrated in primary rat osteoblastic cultures where the gene was down-regulated by 1,25 dihydroxyvitamin D3 treatment. The secretory nature of this protein was established via immunofluorescence and Western blotting utilising a specific antibody. Analysis was performed on HEK293 cells transiently transfected with an expression vector for PGTI0306. The bulk of the protein was found in the culture medium. Intracellularly, the protein was concentrated in the Golgi apparatus. Treatment of primary rat osteoblasts with conditioned media from transfected HEK293 cells resulted in an inhibition of osteoblast differentiation as indicated by reduced alkaline phosphatase levels and osteocalcin expression. The expression pattern and functional effects of PGTI0306 in vitro is suggestive of an autocrine/paracrine role for this prohormone-like molecule at an early stage in osteoblast differentiation, possibly to maintain the pool of osteoblast precursors.

1188

The Effects of Modulating Osteoactivin Function on Osteoblast Differentiation. A. Selim*[1], S. M. Abdelmagid*[1], S. L. Smock*[2], T. A. Owen[2], S. N. Popoff[1], F. F. Safadi[1]. [1]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA, [2]Cardiovascular and Metabolic Diseases, Pfizer Global R&D, Groton, CT, USA.

In a study examining differential gene expression in bone from normal and *osteopetrotic* (*op*) rats, we isolated a novel cDNA, termed osteoactivin (rOA), that was over-expressed in *op* when compared to normal bone. Subsequent *in situ* hybridization and immunohistochemical localization demonstrated that rOA mRNA and protein are expressed by osteoblasts. In primary osteoblast cultures, rOA mRNA levels exhibited a temporal pattern of expression being expressed at highest levels during the later stages of matrix maturation and mineralization. Furthermore, the protein is synthesized by osteoblasts and secreted into the medium. In this study we attempted to block rOA expression and function using an rOA anti-sense oligonucleotide or an anti-rOA antibody. Using an rOA anti-sense oligonucleotide, we were able to block rOA expression in primary osteoblast cultures resulting in decreased alkaline phosphatase activity, osteocalcin production, nodule formation and matrix mineralization. Using the Chariot protein transfection reagent as a vehicle to deliver the anti-rOA antibody inside the cells, we demonstrated that anti-rOA antibody treatment also showed a dose-dependent inhibition of alkaline phosphatase activity, osteocalcin production, nodule formation and mineralization. Conversely, a CMV-rOA construct was generated and used to examine the effect of rOA over-expression on osteoblast development and function in MC3T3-E1 osteoblast-like cells. rOA over-expression in cells transiently transfected with CMV-rOA increased nodule formation, alkaline phosphatase activity, osteocalcin production and matrix mineralization compared to cultures following transfection with an empty vector or treated with transfection reagent alone. These data suggest that rOA plays a major role in the regulation of osteoblast differentiation and function.

Molecular Mechanisms by which Osteoblast Differentiation Is Dependent on Microtubule Assembly. D. Chen, G. Rossini*, M. Zhao, M. Qiao*, G. Gutierrez, G. R. Mundy. Molecular Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

Osteoblast differentiation and bone formation are regulated by a number of important signaling molecules involved in BMP/Smad and wnt/β-catenin signal transduction pathways. Smad1 and β-catenin bind to and form a complex with microtubules and upon dissociation translocate from the cytoplasm to the nucleus where they are responsible for transactivation of genes involved in osteoblast differentiation. To determine if the state of microtubule assembly may regulate osteoblast differentiation by controlling nuclear translocation of these transactivating factors, we examined whether inhibition of microtubule assembly activates these signaling pathways and induces bone formation. A series of microtubule inhibitors were examined in BMP/Smad1 (12xSBE-OC-luc) and wnt/β-catenin (11xTCF-TATA-luc) reporter assays. Inhibitors of microtubule formation (depolymerization), namely nocodazole, colchicine, TN-16 and vincristine, stimulated luciferase activity of these reporters in myoblast/osteoblast precursor C2C12 cells and osteoblast precursor 2T3 cells. These compounds bind to both the colchicines and vinca sites on microtubules. In contrast, the microtubule stabilizers taxol and epothilone had no effects on these reporter genes. We then examined the effects of the microtubule inhibitor TN-16 on nuclear translocation of Smad1 and β-catenin by immunostaining. We found that TN-16 increased nuclear translocation of both proteins. To examine the effects of these microtubule inhibitors on bone formation *in vivo*, we injected 0.1-10 mg/kg/day for 2 days of these inhibitors into subcutaneous tissue over calvarie of mice and found that all microtubule depolymerizers, that stimulated luciferase activity in the reporter assays described above, also stimulated new bone formation in a dose-dependent manner. Also consistent with the reporter assays, microtubule stabilizers had no effects on bone formation. In separate experiments, systemic administration of TN-16 into 3-month old intact Sprague-Dawley rats (1-12 mg/kg/day for 5 days) or 2-month-old intact mice (2-8 mg/kg/day for only 2 days) substantially increased bone mineral density (6-12%), bone volume (26-46%) and bone formation rates (1.8-2.7 fold) in a dose-dependent manner when examined one month later. These results demonstrate that microtubule inhibitors have anabolic effect on bone formation and this effect is at least in part through activating BMP/Smad and wnt/β-catenin signaling pathways and facilitating nuclear translocation of critical signaling molecules.

Nongenotropic Regulation of CREB-, C/EBPβ-, as well as Elk-1- and AP-1 - Mediated Transcription by Estrogens: Downstream Effects of ERK and JNK Kinase Modulation Required for Anti-apoptosis. S. Kousteni, L. Han, L. I. Plotkin, T. Bellido, C. A. O'Brien, R. L. Jilka, S. C. Manolagas. Division of Endocrinology and Metabolism, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, U/sity of Arkansas for Medical Sciences, Little Rock, AR, USA.

Estrogens or androgens activate a Src/Shc/ERK signaling cascade via a non-genotropic action of their classical receptors. It was shown previously that this action leads to activation of the transcription factor Elk-1 which in turn binds to the serum response element (SRE) present in the promoter of many genes and rapidly induces their transcription; and that kinase-initiated transcriptional events are indispensable for the anti-apoptotic action of estrogen. In the studies reported here, we searched for the signaling pathway that leads to AP-1 downregulation and investigated the effects of AP-1-dependent transription, as well as the contribution of CREB or C/EBPβ, in the anti-apoptotic effects of sex steroids. To this end, HeLa cells were transiently transfected with either ERα or AR, together with a reporter construct in which binding of c-jun/c-fos to the AP-1 site drives the expression of secreted human alkaline phosphatase (SEAP) and with or without a dominant negative (dn) JNK1. Fifteen-minute exposure to 10^{-8} M 17β-estradiol (E_2) or dihydrotestosterone (DHT), followed by removal of the steroid from the culture media, downregulated AP-1-SEAP activity. This effect was blocked by the dn JNK1, indicating that sex steroids decrease AP-1-dependent transcription via the JNK signaling pathway. In agreement with this finding, in ERα transfected HeLa cells, expression of dn constructs for JNK1 or AP-1 abolished the anti-apoptotic effect of E_2. This effect was also abrogated by a dn CREB or a dn C/EBPβ but not dn mutants of STAT3, c-fos, or Cbfa-1/Runx2. The dn C/EBPβ selectively blocks the transcriptional activity of C/EBPβ without interfering with its phosphorylation by ERKs or its ability to form complexes with procaspases 1 and 8. The effects of the dn mutants were reproduced in osteocytic MLO-Y4 cells. Elucidation of the effect of estrogens or androgens on the regulation of not only Elk-1 but also CREB and C/EBPβ, through Src/Shc/ERK, raises the possibility that these are only few of probably several transcription factors regulated by the nongenotropic, sex nonspecific, mechanism of gene transcription described herein. Hence, the existence of kinase-initiated routes by which the ER or AR can exert transcriptional control provides the means of regulating a range of genes much wider than the ones that are regulated by the classical transcriptional mechanisms that depend on protein/DNA or protein/protein interactions.

The Anabolic, but Not Anti-Resorptive, Effect of Mevastatin In Vivo Is Dependent on Endothelial Nitric Oxide Synthase. R. J. van't Hof, K. J. Armour*, M. H. Helfrich, S. H. Ralston, K. E. Armour*, C. E. Clarkin*, M. J. Rogers. Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom.

Statins have both anti-resorptive and bone anabolic effects in vitro and in vivo. Statins inhibit resorption by preventing the prenylation of small GTPases in osteoclasts. The mechanisms underling the anabolic effect are less clear. However, the prenylated GTPase Rho can negatively regulate eNOS levels in endothelial cells, whilst eNOS itself is required for osteoblast differentiation and function. It is therefore possible that statins affect osteoblasts in vivo by enhancing eNOS function due to inhibition of Rho prenylation. We examined the importance of eNOS for the anti-resorptive and anabolic effects of mevastatin using mice with targeted inactivation of eNOS. 10mg/kg mevastatin or PBS was injected twice daily over the calvaria of four-day old wild-type or eNOS-null mice for 5 days. One day or 11 days after the final injection, (i.e. on day 6 or day 16) the mice were euthanised and the calvariae dissected for histomorphometric and pQCT analysis. In wild-type mice 1 day after the final injection of mevastatin, osteoclast number and erosion surface were decreased but calvarial width and bone volume were unchanged, suggesting anti-resorptive effects on osteoclasts. However, 11 days after the final injection we observed an increase in bone remodelling, associated with significantly increased osteoclast number, increased calvarial width and bone volume, and the presence of large medullary spaces. pQCT analysis also confirmed a significant increase in bone area and mineral content in the calvariae of wild-type mice. This apparent anabolic effect on day 16 was blunted in eNOS-null mice. Treatment with mevastatin did cause an increase in erosion surface and the appearance of medullary spaces, but calvarial width and bone volume were not significantly altered. Mevastatin treatment did not affect the number of calvarial osteoblasts in wild-type or eNOS-null mice. In calvarial organ cultures in vitro, 10nM or more mevastatin significantly inhibited resorption (45Ca release) in wild-type and eNOS-null calvariae. Histomorphometric analysis also demonstrated that 1μM mevastatin decreased osteoclast number and erosion surface in both wild-type and eNOS-null calvariae. Together, these observations demonstrate that the anti-resorptive effect of mevastatin is not dependent on eNOS. However, the apparent anabolic effect and increase in calvarial width in vivo is eNOS-dependent. It remains to be determined whether the anabolic effect is due to direct stimulatory effects of mevastatin on osteoblast activity or to an eNOS-dependent response following withdrawal of mevastatin treatment.

Id1/Id3 Double Gene Knockout Reasults in Defects in Angeogenesis in Fracture Callus and Suture Development. Y. Maeda*[1], R. Benezra*[2], M. Noda*[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Cell Biology, Memorial Sloan -Kettering Cancer Center, New York, NY, USA.

Angiogenesis plays an important role during bone development and regeneration. Id proteins belong to helix-loop-helix transcription factors and expression of Id genes in osteoblasts is under the control of calciotropic agents such as BMP and vitaminD. Recently, Id1 and Id3 were demonstrated to be required for tumor angiogenesis. However, the function of Id1 and Id3 during bone formation in vivo has not yet been elucidated. The purpose of this paper is to elucidate the role of Id1 and Id3 in regulation of bone metabolism. We first examined fracture healing which requires angiogenesis. Histological examination of the callus formed after the fractures maded in the ribs of wild type mice revealed abundant angiogenesis. In contrast, Id1-/+Id3-/- double knockout mice revealed suppression of such angiogenesis in the fracture callus. Quantification of CD31 positive vessels in the tissue sections revealed more than two-fold reduction in the number of vasculatures ($p<0.05$). This was associated with delayed remodeling process in the callus in the Id1-/+Id3-/- double knockout mice including new bone formation compared to the fractrue callus in wild type mice. We further examined calvarial bones to obtain insights into the Id function in bone cells. The calvarial sutures were clearly observed on the soft X-ray films in wild type mice. In contrast, such sutures in Id1-/+Id3-/-double knockout mice were unclear and almost fused in part compared with those in wild type mice. Quantification of the suture width revealed more than 50% reduction in Id1-/+Id3-/- double knockout mice compared to wild type. To obtain cellular basis for the mechanism of such defects, we examined proliferation and differentiation activities of the primary calvaria-derived osteoblasts. Proliferation was significantly reduced in Id1-/+Id3-/- double knockout osteoblasts compared to wild type cells. Alkaline phsphosphatase activity induced by BMP treatment was also significantly reduced in osteoblasts derived from Id1-/+Id3-/- double knockout mice compared to wild type cells. These results indicated that Id1 and Id3 are required for angiogenesis during fracture healing and the development of calvarial sutures.

1193

MyoD/Myf5 Null Mice Cannot Move actively *in utero* and Have Thin Weak Long Bones and No Rib Development. T. M. Skerry, N. M. Peet*. Veterinary Basic Sciences, Royal Veterinary College, London, United Kingdom.

Mechanical loading influences skeletal mass profoundly and is more effective in early than adult life. This suggests that modelling is more influenced by loading than is remodelling, and raises the question: how early in skeletal development do mechanical events influence bone development? To explore this question we bred mice lacking genes for muscle proteins MyoD and Myf5, hypothesising that the consequent demonstrated lack of functional skeletal muscle would prevent active movement in utero and affect bone development. While MyoD null mice are apparently normal, Myf5 nulls are poorly viable, so we bred double heterozygotes and crossed those to produce double knockouts (KOs). The predicted ratio of these offspring to heterozygotes and wild types should have been 1:4, but was ~1:40. There were striking differences between knockout and wild type (WT) pups. The long bones of the KOs were smooth, featureless and straight in contrast to the curved bones in the WT, which had recognisably adult proportion and shape. Specifically traction epiphyses where major muscles attached were absent or very much reduced. QCT analysis revealed that the shafts of the bones of KOs had cortices that were thinner (by 19%) than WT and less mineralized (by 24%)($p<0.001$). However, the most remarkable and striking difference between the KO and WT animals was that the KOs lacked ribs and the middle and medial parts of the clavicles. This was not due to a lack of thoracic contents, which were present. Osteoblasts isolated from both KO and WT calvariae were cultured on plastic strips and subjected to mechanical loading in vitro (1500 microstrain of bending at 1Hz) and showed identical responses as determined by NO release and proliferation. These data show that the KO animal's osteoblasts are not incapable of responding to mechanical stimuli, but that the absence of active movement in utero has profound consequences on the shape, mass and density and therefore strength of the bones. Since active movement in utero in humans can be affected by speech or music, there may be means by which it is possible to obtain high bone mass in babies at birth. The ratio of double null offspring of double heterozygote matings suggests that deletions in the KOs lead to a significant loss of viability, perhaps because of a problem with implantation or early embryonic mortality. The unexpected and remarkable lack of rib development of the KOs implies that some areas of the skeleton rely crucially on the expression of specific genes that have only lesser and indirect consequences on the rest of it. Should similar patterning be specified for vertebral trabeculae or the femoral neck, this would provide a means to target anabolic modalities in a radically new way.

1194

Biglycan Deficiency Interferes with Ovariectomy-induced Bone Loss. K. L. Nielsen*[1], M. R. Allen*[2], S. A. Bloomfield*[2], I. A. Timm*[3], X. D. Chen*[4], M. F. Young[4], A. Heegaard[1]. [1]Nordic Bioscience A/S, Herlev, Denmark, [2]Department of Health and Kinesiology, Texas A&M University, College Station, TX, USA, [3]CCBR, Ballerup, Denmark, [4]Craniofacial & Skeletal Disease Branch, NIDCR, Bethesda, MD, USA.

Biglycan is a small extracellular matrix proteoglycan enriched in skeletal tissues. Biglycan deficient mice suffer from osteopenia with decreased trabecular bone mass and bone strength as compared to wild type (wt) mice. The osteopenic phenotype has been shown to involve defects in the bone marrow stromal cells and in bone formation. The purpose of this study was to investigate the effect of estrogen depletion (ovariectomy) on the bone phenotype of the biglycan deficient mice. The ovx or sham operations were performed on 21 weeks old mice divided into four groups: wt sham (n=7), wt ovx (n= 9), biglycan deficient sham (n= 10) and biglycan deficient ovx (n=10). Six and two days prior to sacrifice the mice were injected with calcein and tetracyclin, respectively. The mice were sacrificed 4 weeks post surgery. Bone mass and bone turnover were analysed by periferal quantitative computed tomography (pQCT), biochemical markers, and histomorphometry. The results revealed that the biglycan deficient mice were resistant to the ovariectomy induced trabecular bone loss at the proximal tibia, and also did not show an increase in serum osteocalcin levels in response to ovx. The wild type mice responded as expected with an ovx induced bone loss and increased bone turnover. Similar, but less pronounced results were also found when using younger mice (6-8 weeks old). Analyses of the bone resorption marker deoxypyridinoline in the urine showed a delayed, but eventually equally strong induction in response to ovx for the biglycan deficient mice as compared to the wild type mice. These data support the previous findings indicating that biglycan deficiency leads to a defective bone formation, and show that even a strong stimulus such as estrogen deficiency cannot overcome this. Furthermore, we show that biglycan deficiency protects against increased bone turnover and bone loss in response to estrogen deficiency. Taken together these data support the concept that biglycan has dual roles in bone where it may modulate both formation and resorption ultimatively influencing the bone turnover process.

Absence of TACE, but not of ADAM-9 or 15, Prevents the Formation of the Primitive Marrow Cavity that Is Required for the Development of Long Bones. P. Boissy*[1], T. R. Lenhard*[1], T. Kirkegaard*[1], C. P. Blobel*[2], J. Peschon*[3], R. A. Black*[3], C. Christiansen[4], J. M. Delaisse[1], M. C. Ovejero*[1]. [1]Nordic Bioscience A/S, Herlev, Denmark, [2]Sloan-Kettering Institute, New-York, NY, USA, [3]Immunex Corp., Seattle, WA, USA, [4]CCBR, Ballerup, Denmark.

ADAMs (A Disintegrin And Metalloprotease domain) belong to a rapidly growing family of membrane-anchored cell surface proteinases, and they have been shown to modulate proteolysis, cell adhesion, cell fusion and signalling in a variety of tissues. Some ADAMs have been previously detected in bone cells. There is, however, little information on the actual function of ADAMs in bone physiology. In order to address this question, we investigated developing metatarsals of mouse embryos that were made deficient or not for a specific ADAM. We focused on the developmental stage where the primitive marrow cavity is about to be formed, because it is likely to give information on basic events of bone development like osteoclast (OC) differentiation, migration and resorption, as well as angiogenesis and ossification of cartilage. We found that the absence of ADAM 9 and 15 did not affect the metatarsal development, whereas in ADAM 17 (TACE) knockout bones, migration of OCs into the core of the diaphysis was impaired, thereby impeding the formation of the marrow cavity. Because TACE has been implicated in shedding of members of the TNF family including RANKL, and because RANKL is important for OC recruitment, we performed immunohistochemistry of RANKL in developing metatarsals. The signal was found at a very high concentration at the interface between the periosteum and the osteoid of the bone collar, i.e. exactly at the site of OC differentiation. We could however not relate this signal to TACE activity. Next, we investigated systematically in which bone cells

ADAM 9, 15, 17, and others are expressed by using northern blot (NB) and RT- PCR on both mouse and rabbit bone cells and tissues. NB was performed on 1-day rabbit long bones which permit a high purification of each bone cell type, and showed that ADAM 9 was expressed by both OCs and osteoblasts whereas ADAM 17 was restricted to the osteoblast population. By RT-PCR on OC progenitor and osteoblastic cell lines (MOCP-5 and MC-3T3, respectively) as well as on primary rabbit OCs, we have found ADAM 1, 6, 8, 9, 12, 15, 17, 19 and TS-1. NB was performed on RNA prepared from E18-mouse calvaria, which exhibit a strong remodeling activity at this stage. mRNAs of ADAM 8, 9, 12, 15, 17, 19 and TS-1 were found in this tissue. From this study we couldn't show any essential role of ADAM 9 and 15 in bone. In contrast, TACE proves to be indispensable for OC recruitment into the developing marrow cavity of long bones.

Transcriptional Regulation of Osteopontin Production by TGF-beta in Breast Cancer Cells: Implications in Metastasis and Tumorigenicity. N. Hashimoto, T. Yoneda. Div Endocrinol, Univ of Texas Hlth Sci Ctr, San Antonio, TX, USA.

Osteopontin (OPN), a secreted phosphoglycoprotein, is found to be expressed in many of human primary breast cancers, indicating that breast cancer cells produce OPN. Since OPN has been implicated in tumorigenesis and metastasis in a variety of cancers, elucidation of the mechanism by which OPN production is regulated in breast cancer cells is important. Here we studied this by examining the effects of TGFb, a well-known stimulator of OPN production, in the 4T1 mouse mammary cancer cells which constitutively produced large amounts of OPN. RT-PCR analysis and luciferase reporter assay showed that TGFb increased OPN mRNA expression and OPN gene promoter activity in 4T1 cells, respectively. Of note, Smad6 and Smad7, which are natural antagonists of the TGFb signaling molecule Smad, inhibited the TGFb-stimulated OPN promoter activity and TGFb failed to activate the OPN promoter lacking the Smad-binding element (SBE). Moreover, a homeobox gene Hoxa-9, which is known to bind to the Hox-binding element (HBE) in the OPN promoter and work as a repressor, inhibited TGFb-stimulated OPN promoter activity. In addition to 4T1 cells, we also found that TGFb stimulated OPN mRNA expression in the MDA-435, MCF-7 and MDA-231 human breast cancer cells. Since elevated plasma levels of OPN has been correlated with increased distant metastases in breast cancer patients, we next studied the role of OPN in the metastasis of 4T1 cells which spontaneously spread to bone and lung following orthotopic inoculation in the mammary fat pad in syngeneic female Balb/c mice. To approach this, 4T1 cells were stably transfected with a firefly luciferase gene for quantification of the tumor burden in lung and with an anti-sense OPN gene (4T1/luc.ASOPN cells). The 4T1/luc.ASOPN cells showed reduced OPN production and anchorage-independent growth in soft agar. These cells exhibited diminished frequency of bone metastases and histological examination showed reduced metastatic tumor burden in bone compared with empty vector-transfected 4T1/luc cells. Lung metastases determined by luciferase activity were also decreased. Tumor formation at the orthotopic site was also reduced. Consistent with these results, a neutralizing antibody to OPN inhibited the colony formation of 4T1/luc cells in soft agar and tumor formation at the orthotopic site. In conclusion, our results suggest that OPN production is regulated by TGFb at a transcriptional level in breast cancer cells and that OPN plays a critical role in controlling the distant metastasis and tumorigenicity of breast cancer. Thus, suppression of OPN production is a potential new adjuvant therapy for OPN-positive breast cancers.

1197

Loss of Function of Matrix Metalloproteinase-13 (MMP-13) Affects Collagen Accumulation and Bone Formation. M. Inada[1], Y. Wang[1], M. H. Byrne*[1], C. Miyaura[2], S. M. Krane[1]. [1]Department of Medicine, Harvard Medical School, Mass General Hospital, Boston, MA, USA, [2]Biochemistry, Tokyo University of Pharmacy and Life Science, Tokyo, Japan.

To determine possible roles of collagenases in bone development and remodeling and the specific role of MMP-13 (collagenase-3), we targeted a null mutation in mice in the MMP-13 gene splicing out Exon 5 which encodes the critical catalytic, Zn-binding domain. Previously we presented preliminary results indicating that homozygous mutant mice (MMP-13 -/-) had increased width and delayed maturation of the growth plates and increased bone mass. Here we show using histomorphometry (microCT) an increased bone vol/tissue vol ($p<0.001$), trabecular number ($p<0.001$) and trabecular thickness ($p<0.03$) but decreased trabecular separation ($p<0.001$) in 3 month-old MMP-13 -/- vs. MMP-13 +/+ mice. Evidence for increased bone formation in vivo in MMP-13 -/- mice includes increased osteocalcin-expressing cells(in situ hybridization) on bone surfaces and increased osteoblast proliferation (uptake of BrDU). To investigate further potential roles of type I collagen synthesis and degradation in the absence of MMP-13, we used bone marrow culture (BMC) with cells obtained from 1 month-old mice. In early phases of BMC (~ 1 week) osteoblast proliferation (MTT analysis, $p < 0.001$) and expression of alkaline phosphatase ($p < 0.01$) were increased in BMC from MMP-13 -/- vs. MMP-13 +/+ mice; differences were potentiated by addition of ascorbic acid (0.1mM) and/or parathyroid hormone (PTH), 0.1 microM. By Realtime PCR (Exon 5 primers), no MMP-13 mRNA was detected in MMP-13 -/- BMC but abundant MMP-13 was expressed in BMC from MMP-13 +/+ mice (2.6 x 106 molecules/50 ng RNA) and levels were increased ~ 6 fold in BMC treated with PTH. In longer term BMC (3 weeks), bone nodule formation (Alizarin red) and collagen accumulation (Sirius red) were evident and were increased in the BMC from MMP-13 -/- vs. MMP-13 +/+ mice. In the presence of the collagen synthesis inhibitor, dehydroproline (DHP) 0.01mM, bone nodule formation and collagen accumulation were abolished. Thus, type I collagen deposition continues as a result of osteoblast function in wild type BMC despite collagenase expression and is increased in MMP-13 -/- BMC suggesting that absence of MMP-13 and decreased collagenase-mediated collagen degradation are negative regulators of bone formation. This suggestion is consistent with other studies (Xiao et al., J Biol Chem 273:32988, 1998) indicating that an alpha2-integrin-collagen-interaction is required for activation of Osf2/Cbfa1 and induction of osteoblast-specific gene expression.

1198

Characterization of Collagenase-3 Binding to the Collagenase-3 Specific Receptor and LRP1. I. Choudhury*[1], S. Williams*[1], L. J. Raggatt*[1], M. H. Byrne*[2], S. M. Krane[2], N. C. Partridge[1]. [1]Department of Physiology and Biophysics, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ, USA, [2]Department of Medicine, Harvard Medical School and Arthritis Unit, Massaschusetts General Hospital, Boston, MA, USA.

Previously we have shown that in rat osteoblast-like cells and mouse embryo fibroblasts, a specific receptor for collagenase-3 (MMP-13) associates with the endocytotic receptor, the LDL receptor related-protein (LRP1) in binding, internalization and degradation of MMP-13. The purpose of this study was to investigate the nature of the interaction of MMP-13 with the specific collagenase-3 receptor and the LRP1. This has involved purification and sequencing of the specific collagenase-3 receptor in addition to whole cell and solid phase binding studies. Sequencing by LC-MS of the affinity-purified 170 kDa specific collagenase-3 receptor from primary rat osteoblastic cells showed that the molecule had no homology with any protein in the database. Solid phase binding assays showed that 125I-MMP-13 binds to the specific collagenase-3 receptor but not to LRP1 alone. However, in the presence of LRP1, there is enhanced binding of 125I-MMP-13 to the specific receptor. These results suggest one of two possibilities: that LRP1 associates with the specific receptor thus enhancing the latter's affinity for MMP-13. Alternatively, the binding of MMP-13 to the specific receptor induces a conformational change in the ligand which exposes the binding domain of MMP-13, allowing it to bind to LRP1. We have used a series of human MMP-1/MMP-13 chimeric proteins to identify the regions of MMP-13 that bind to the specific receptor and LRP1 (human MMP-1 does not compete). Binding experiments showed that the chimeric construct H(1-228)/M(229-472) does not bind to the specific receptor indicating that the MMP-13 binding site lies within the amino acid region 1-228. The chimera containing MMP-13 amino acid residues 141-228 did not compete as effectively, however the construct in which exon 5 (amino acid residues 213-267) was deleted competed almost as well as the wild-type form of MMP-13. These results indicate that the domain for MMP-13 binding lies within residues 1-228. The fact that residues 141-228 do not compete as well suggests that the receptor binding site lies more specifically within the region 1-141. However, it is possible that residues 141-228 are necessary to create the correct protein conformation for MMP-13 binding to its specific receptor. The data confirm and support our previous observations that binding and removal of MMP-13 from the extracellular milieu requires initial binding to a specific receptor and internalization by LRP1.

1199

Children and the Risk of Fractures due to Oral Corticosteroids. T. P. van Staa[1], C. Cooper[2], H. G. M. Leufkens*[1], N. Bishop[3]. [1]Pharmacoepidemiology and Pharmacotherapy, Utrecht Institute for Pharmaceutical Sciences, Utrecht, Netherlands, [2]Environmental Epidemiology Unit, Medical Research Council, Southampton, United Kingdom, [3]Sheffield University, Academic Child Health, Sheffield, United Kingdom.

Oral corticosteroids are known to increase the risk of fracture in adults. Whether the effects of oral corticosteroids are similar in children is unknown. The medical records of general practitioners in the UK (from the General Practice Research Database) were used to estimate the incidence rates of fracture of children aged 4 to 17 years taking oral corticosteroids and of control children. Within those cohorts, each child with a fracture was subsequently matched by age, sex, practice, and calendar time to one child without a fracture, in order to adjust for risk factors for fracture. There were 37 562 children taking oral corticosteroids. The average duration of treatment was 6.4 days (median 5 days). The figure shows the fracture incidence in children using oral corticosteroids (squares) and control children (diamonds). The risk of fracture was increased in children with a history of frequent use of oral corticosteroids: children who received four or more courses of oral corticosteroids had an adjusted OR for fracture of 1.32 (95% CI 1.03-1.69). There was also a trend towards higher fracture risks in children using high daily doses. The adjusted OR for fracture was 1.22 (CI 0.99-1.50) in children using 30 mg prednisolone or more per day. Children who stopped taking oral corticosteroids had a comparable risk of fracture to those in the control group. Frequent use of oral corticosteroids was associated with an increased risk of fracture. Our findings suggest that children who receive more than four short-term courses of oral corticosteroid have an increased risk of fracture.

Long Term Effect of Calcium Supplementation and Dairy Products on Bone Mass of Young Females. V. Matkovic[1], N. Badenhop-Stevens*[1], J. Landoll*[1], P. Goel*[2], B. Li*[2]. [1]Bone and Mineral Metabolism Laboratory, The Ohio State University, Columbus, OH, USA, [2]Statistics, The Ohio State University, Columbus, OH, USA.

The purpose of this investigation was to evaluate the long-term effect of Ca supplementation (Ca-s) and dairy product (DP) consumption on bone mass (BM) of young females (YF) through modeling (M-p) and consolidation phases (C-p) of skeletal development. The study was conducted among 456 healthy Caucasian YF (age 10.8±0.8 y) in pubertal stage 2 and with Ca intake (Ca-i) below/above threshold (T) level (1480 mg/d) at baseline. 354 YF with Ca-i below the T (mean 937±215 mg/d) were recruited and randomized into a double-blind, placebo-controlled clinical trial (CT) with Ca citrate-malate (Procter & Gamble Co.) at 1000 mg Ca/d. 102 YF with Ca-i above T (dairy group, DG) were followed as an observational study (OS). 179 YF completed the 7-y CT and 85 DG individuals finished 7-y OS. Anthropometry, BM of the forearm & total body (TB) by DXA (GE-Lunar, DPX-L), and nutritional and activity records were obtained every 6 months (m) (DG every 12 m); while blood and 24-hr urine for Ca, hormones, and biomarkers were collected every 12 m. Hand X-rays for bone age and radiogrammetry were obtained at ages 11, 15, 18 y. Hip and spine measurements were measured by DXA every 6 m (DG every 12m) after age 15 y. The results of the study show a positive influence of Ca-s and DP consumption on BMD of the TB and various skeletal regions. This influence is more pronounced during bone M-p (ages 11-15 y). The "catch-up" phenomenon in BM acquisition exists and proceeds in the control individuals (accustomed to Ca-i of ~850 mg/day/7 y) by the C-p of skeletal development when Ca requirement (Ca-r) declines. A permanent deficit in peak BM, as a result of inadequate Ca-i during M-p, is expected at the hip and metacarpals, and at other sites among certain subgroups of the population based on body size and activity. The DG subjects maintained their behavior with regard to DP intake and had higher BM throughout. The results of this research indicate that Ca-r are size dependant, however, understanding difficulties in predicting body size, current high dietary Ca-i standards for growth should be implemented to meet the demand of all young Americans. In addition, establishing healthy lifestyles (nutrition, activity) during early childhood should be initiated as a part of primary prevention programs for osteoporosis.

1201

Protein Intake Modulates the Effect of Calcium Supplementation on Bone Mass Gain in Prepubertal Boys. T. Chevalley[1], S. Ferrari[1], D. Hans[2], D. Slosman[2], M. Fueg*[1], J. P. Bonjour[1], R. Rizzoli[1]. [1]Division of Bone Diseases, Dept Internal Medicine, University Hospitals Geneva, Switzerland, [2]Division of Nuclear Medicine, Dept of Radiology, University Hospitals Geneva, Switzerland.

Calcium (Ca) and proteins are important nutritional determinants of bone growth. To what extent dietary protein intake can modulate the beneficial effect of calcium supplementation (Calsup) in healthy children is not known. In a one-year prospective double-blind placebo-controlled trial we examined in prepubertal boys whether the gains in areal bone mineral density (aBMD) in response to Calsup were modulated by protein intake at several skeletal sites. 235 healthy prepubertal boys aged 7.4±0.1 yrs (mean±SEM, range 6.5-8.5 yrs) were randomized into a group (Calsup, n=116) consuming 2 food products providing 850 mg of Ca daily, and into a placebo control group. The latter (Placebo, n=119) consumed similar products in terms of energy and protein but without added Ca. aBMD was determined by DXA using Hologic QDR 4500 at 6 skeletal sites: radius (distal metaphysis=Rmet; diaphysis=RDia); hip (femoral neck=FN; trochanter=FT); femoral diaphysis (FDia) and L2-L4 vertebrae (LS). Spontaneous Ca and protein intakes were assessed by frequency questionnaires at baseline, 6 and 12 months and the mean of the 3 records was taken into account. In an intention-to-treat analysis, the gain in aBMD (mg/cm2±SEM) was significantly higher at Fdia in the Calsup (n=114) as compared with the Placebo (n=117) group (76±3 vs 65±3, p=0.008). At the 5 other sites the Calsup effect was not statistically significant, even in the subgroup having spontaneous Ca intake below the median (727 mg/d). In these subjects with a relatively high spontaneous protein intake (1.8±0.1 g/kg/d), baseline BMD values at all sites were better positively correlated with protein than Ca intakes. Over the one year study, mean aBMD gain in the placebo group was higher with protein intake above than below the median (1.7 g/kg/d) (25±2 vs 17±1 mg/cm2, p<0.0012) at the 5 sites (Rmet, Rdia, FN, FT, LS). At these 5 sites, there was a significant (p=0.012) interaction between protein intake and Calsup effect on aBMD gain. Thus, in boys with a spontaneous protein intake below the median, mean gain in aBMD was significantly higher in the Calsup than in the Placebo group (24±2 vs 17±1 mg/cm2, p=0.007). In conclusion, our study strongly suggests a positive relationship between protein intakes and bone mass gain in prepubertal boys. In addition, the response to Ca supplementation appears to be modulated by protein intake.

1202

Interpretation of Whole Body DXA in the Assessment of Cortical Bone Health in Children: Validation with Peripheral QCT. M. B. Leonard[1], J. Shults*[2], V. A. Stallings[1], B. S. Zemel[1]. [1]Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, USA, [2]Center for Clinical Epidemiology and Biostatistics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA.

The confounding effects of bone size on traditional DXA measures of areal bone mineral density (areal-BMD, gm/cm2) are well-recognized. An alternative strategy has been proposed to determine if decreased whole body (WB) DXA bone mineral content (BMC) for age is due to short stature (decreased height for age), narrow bones (decreased bone area adjusted for height) or decreased density (decreased BMC adjusted for bone area). Although this approach has been adopted in studies of healthy and ill children, this approach has not been validated. The purpose of this study was to compare WB DXA results (which consist of predominantly cortical bone) with peripheral quantitative CT (pQCT) measures of cortical bone geometry and volumetric density (gm/cm3). WB DXA scans (Hologic QDR 4500) and pQCT scans of cortical bone at the 20% distal tibia (Stratec XCT-2000) were completed in 150 healthy children (75 female), 6 to 21 years of age. Bone results were log-transformed and standardized residuals (z-scores) were created for the following WB DXA measures: bone area for height and BMC for bone area; and for the following pQCT measures: cross sectional area (CSA) for tibia length, and bone strength (cross-sectional moment of inertia) for tibia length. Cortical volumetric BMD, as measured by pQCT, was not associated with tibia length. The correlations (R) between DXA and pQCT measures are summarized below. (NS = $p > 0.05$) These data demonstrate that decreased WB DXA bone area for height is significantly associated with decreased bone cross-sectional area for bone length, suggesting WB DXA bone area adjusted for height provides a valid measure of cortical bone geometry. Decreased breadth is associated with decreased strength since periosteal dimensions are a critical determinant of bone strength. However, WB DXA BMC adjusted for bone area is not significantly associated with cortical bone volumetric density, size or strength, suggesting this is not a valid measure of cortical bone mineralization. Decreased WB DXA BMC for bone area may give the false impression of decreased cortical bone density and strength.

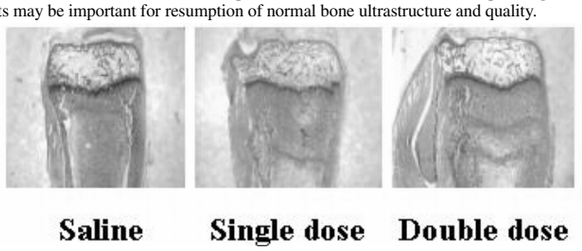
Correlations between DXA and pQCT Z-Scores

	WB DXA Bone Area for Height	WB DXA BMC for Bone Area
pQCT CSA for Tibia Length	R = 0.45, p < 0.0001	NS
pQCT Bone Strength for Tibia Length	R = 0.53, p < 0.0001	NS
pQCT Volumetric Density (gm/cm3)	NS	NS

1203

Removal of Unremodelled Growth Plate in the Metaphysis after Bolus Zoledronic Acid in Growing Rabbits. E. J. Smith[1], A. McEvoy*[2], R. A. Peat*[2], J. N. Briody[2], J. A. Eisman[1], D. G. Little*[2], E. M. Gardiner[1]. [1]Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Orthopaedic Research Unit, Childrens Hospital Westmead, Sydney, Australia.

Use of bisphosphonates in children suffering severe osteogenesis imperfecta or for prevention of fracture in patients undergoing distraction osteogenesis for correction of limb length discrepancy has major clinical benefits in terms of increased bone strength, leading to patient mobility and participation in normal childhood activities. However, there are concerns about the impact of bisphosphonates on the growth plate, metaphyseal modeling and consequent growth in long bones. This study examined bisphosphonate effects on metaphyseal histology and tibial length of 12 contralateral non-operated tibias in a growing male NZW rabbit model of distraction osteogenesis. At 8 weeks of age, 6 animals received IV saline, 6 received IV 0.1mg/kg zoledronic acid at 8 and 10 weeks. DXA scans and x-rays were taken at 10, 12, 14, 26, 40 and 52 weeks of age. For histology tibias were collected from other studies using the same model. X-rays of treated bones had radiolucent lines in the metaphysis that corresponded to number of doses. Histologically, lines contained chondrocytes in columnar formation from the hypertrophic zone surrounded by calcified matrix. Resorption of these lines at later times was evident in x-rays and histology. Tibial length in both groups increased by 14% from week 10 to 26 at a rate of 0.9mm/wk. Between 26 and 52 weeks there was no increase in length, consistent with normal cessation of rabbit growth at 25 weeks of age. Tibial length was 3-7% shorter at 14, 26, 34, 40 and 52 weeks in the treated groups ($p<0.05$) and a similar trend (2-5%) was seen at 12 weeks. The decrease in bone length at 14 weeks was still evident at 52 weeks. As shown with other bisphosphonates in animal models, zoledronic acid caused loss in tibial length but did not impact on growth rate. This study shows that zoledronic acid causes transient retention of growth plate remnants in the metaphysis, in association with transient inhibition of growth. It provides histological insights into the nature and persistence of growth inhibition by bisphosphonates, not otherwise seen with continuous dosing used in other studies. Removal of growth plate remnants may be important for resumption of normal bone ultrastructure and quality.



1204

Sprouty2 Induced by Constitutively Active FGF Receptor 3 Suppresses the Chondrocyte Proliferation through Inhibition of IGF-1 Signaling. Y. Yamanaka[1], H. Tanaka[1], K. Ueda*[1], E. Yamagami*[1], R. Nishimura[2], Y. Seino[1]. [1]Pediatrics, Okayama University Graduated School, Okayama city, Japan, [2]Biochemistry, Osaka University Faculty of Dentistry, Osaka, Japan.

Achondroplasia, the most common form of short-limb dwarfism, and its severe type, thanatophoric dysplasia (TD) are caused by constitutively activated mutations in FGFR3. The excessively activated FGFR3 appears to suppress the proliferation of chondrocytes, resulting in disturbing the growth of long bones. However, little is known how these mutations suppress proliferation of chondrocytes. To address this, we determined whether Sprouty2, which mediates FGFR3 signals, is involved in this process, using a chondrogenic cell line, ATDC5. BrdU incorporation assay demonstrated that the cells expressing TDII-mutated FGFR3 (TDII cells) showed the decreased DNA synthesis by 40%, compared with wild-type FGFR3 expressing cells (WT cells). In contrast, the expression of Sprouty2 mRNA is significantly increased in TDII cells. GH-IGF axis is an important system in bone growth. Especially, IGF-1 has a potent stimulator of chondrocyte proliferation. Of note, overexpression of Sprouty2 in WT cells markedly decreased IGF-1 dependent-DNA synthesis by 30% of WT cells. Furthermore, overexpression of dominant-negative Sprouty2 recovered DNA synthesis in TDII cells. These data suggest that Sprouty2 negatively regulates the mitogenic effects of IGF-1. To further investigate the mechanism, by which TDII FGFR3 mutation suppressed the IGF-1-dependent proliferation, we examined the effect of Sprouty2 on the MAP kinase since IGF-1 exhibits the mitogenic activity through MAP kinase pathway. In WT cells, IGF-1 increased MAP kinase activity as well as proliferation. Overexpression of Sprouty2 suppressed the IGF-1-induced MAP kinase activity. In conclusion, these results collectively suggest that excessive activation of FGFR3 by TDII mutation suppressed MAP kinase by up-regulating the Sprouty2 expression, consequently inhibiting the proliferation of chondrocytes. Our data suggest that excessive expression of Sprouty2 may account for the disturbance of endochondral bone formation in FGFR3-related skeletal dysplasia.

1205

The *Hyp* Mutation in Mice Reduces, but does not Eliminate, the Genomic Response of the Kidney to Low Phosphate Diet. M. H. Meyer, R. A. Meyer. Department of Orthopaedic Surgery, Carolinas Medical Center, Charlotte, NC, USA.

The genes active in the regulation of phosphate reabsorption in the kidney are not well understood. It is also not clear whether mutations of the *Phex* gene block renal adaptation to low phosphate diets. To investigate this, 5-week-old normal and *Hyp* mice were fed a control (1.0% P) or low phosphate (0.03% P) diet for five days. The kidneys were then collected, and the RNA was extracted and pooled between three animals to create each sample. Two microarrays were done for each diet for normal mice and three microarrays for each diet for the *Hyp* mice for a total of 10 arrays (30 mice). cRNA was prepared and hybridized to Affymetrix U74Av2 GeneChip microarrays with probes for 12,473 genes. Binomial tests were done to identify genes affected by diet or genotype. An average of 5,178 genes were scored as present. Of this number, 92 genes were scored as increased in both normal mouse samples on low P diet ($P < 0.001$). Of these, only 11 genes were also increased in the *Hyp* samples on low P diet, but this remained a significant overlap with the normal mice ($P < 0.001$). Three genes, calbindin-D9K, 25-hydroxyvitamin D-1alpha-hydroxylase, and glutathione reductase 1, were increased in normal mice on low P diet, but decreased in *Hyp* mice on low P diet. Diphor-1 (AW046638) was decreased in *Hyp* mice and not significantly affected by low P diet. The type IIb sodium/phosphate transporter was scored as absent in all samples. In contrast to the increased genes, 85 genes decreased in the two samples from normal mice on low P diet ($P < 0.001$). Of these, only 16 decreased in the *Hyp* mice ($P < 0.001$). On the control diet *Hyp* mice differed from normal mice by having 65 genes decreased ($P < 0.001$) and 53 genes increased ($P < 0.001$). In addition, we tested whether genes affected by low dietary P in normal mice were the same genes as those altered by the *Hyp* mutation under the control diet: No significant overlap was found between them. In conclusion, low phosphate diet led to significant alteration in mRNA expression of specific genes in the mouse kidney. The *Hyp* mutation reduced the number of affected genes, but did not totally eliminate this adaptation. The renal response to changes in dietary phosphate involves both *Phex*-dependent and *Phex*-independent mechanisms.

C-type Natriuretic Peptide Elongates the Dwarfing Bones in Mice Model of Achondroplasia by Increasing the Extracellular Matrix of Growth Plate Chondrocytes. A. Yasoda*, Y. Komatsu, H. Chusho*, A. Ozasa*, T. Miyazawa*, N. Tamura*, Y. Ogawa*, K. Nakao*. Medicine and Clinical Science, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Achondroplasia is the most common genetic form of dwarfism of which no efficient therapy has been established so far. Recently, we have demonstrated that C-type natriuretic peptide (CNP) is a novel skeletal growth factor regulating endochondral ossification. Here we report the therapeutic efficacy of CNP for achondroplasia using mice model of achondroplasia with targeted overexpression of the activated FGFR3 in cartilage ($FGFR3^{ach}$-Tg), which develop dwarfism with shortening of bones formed through endochondral ossification. To investigate the direct effect of CNP on longitudinal bone growth of $FGFR3^{ach}$-Tg mice, we performed organ culture experiments using tibiae from 16.5-G.D. fetal $FGFR3^{ach}$-Tg mice. Fetal $FGFR3^{ach}$-Tg tibiae were significantly shorter than non-Tg tibiae throughout the 4-day culture period, and 10^{-7}M CNP elongated the cultured $FGFR3^{ach}$-Tg tibiae to the level of vehicle treated non-Tg tibiae at the end of the culture period. Histological analysis revealed that CNP elongated the short cartilagenous primordia of $FGFR3^{ach}$-Tg tibiae, both in the proliferative and hypertrophic chondrocyte layers, with a characteristic picture of the enlarged extracellular space there. The decreased extracellular matrix synthesis of $FGFR3^{ach}$-Tg tibiae estimated by $^{35}SO_4$ incorporation was recovered by 10^{-7}M CNP up to just the same extent to that of non-Tg tibiae treated with vehicle. Then we achieved targeted overexpression of CNP using typeII collagen promoter in cartilage of $FGFR3^{ach}$-Tg mice to observe the effect of CNP for achondroplasia in vivo, and exhibited that CNP substantially rescued the shortening of bones formed through endochondral ossification. Histological analysis showed that CNP recovered the narrowed growth plate of $FGFR3^{ach}$-Tg mice with increased extracellular space, as was observed in organ culture experiments. On the other hand, decreased proliferation of the growth plate chondrocytes in $FGFR3^{ach}$-Tg mice shown by the BrdU staining was not recovered. CNP overexpressed in cartilage did not alter the intensity of type II and X collagens shown by in situ hybridization, or the delayed formation of the secondary ossification center in $FGFR3^{ach}$-Tg mice. These results exhibit that the mechanism by which CNP could rescue the shortening of bones of $FGFR3^{ach}$-Tg mice is to increase the extracellular matrix with little alteration in the proliferation and the differentiation of the growth plate chondrocytes, followed by the substantial recovery in the bone length, indicating the efficacy of CNP for the treatment of human achondroplasia.

1207

Differences in Measures of Femoral Neck Strength between Japanese-American and Caucasian-American Women. A. S. Karlamangla*, J. T. Young*, M. Huang*, G. A. Greendale. Division of Geriatrics, UCLA, Los Angeles, CA, USA.

Japanese women have fewer hip fractures than Caucasian women, despite having lower bone mineral density. Differences in hip geometry might be at the root of this difference in hip fracture risk. However, previous studies have not consistently found hip axis length (HAL) to be disproportionately longer in Caucasian women. The objective of this study is to compare structural measures of femoral neck strength in Japanese-American and Caucasian-American women, relative to the loads that they bear. Under the assumption that mineralization of the femoral neck is mostly in its cortical rim, the ability of the femoral neck to withstand compressive and bending forces proportional to body weight is given by Compressive Strength = BMD * FNW / Weight, and Bending Strength = BMD * $(FNW)^2$ / (HAL * Weight), where BMD refers to the projected (areal) bone mineral density of the femoral neck and FNW is the femoral neck width. Similarly, the ability of the neck to absorb the energy of impact in a fall from standing height is given by Impact Strength = BMD * FNW * HAL / (Height * Weight). We measured BMD, HAL, and FNW from dual energy x-ray absorptiometry scans and calculated the above 3 strength measures in 267 Japanese and 199 Caucasian women residing in the Los Angeles area, who participated in the Study of Women's Health across the Nation (SWAN) at the University of California at Los Angeles site. Though Caucasian women had higher mean BMD (p=.0003) than Japanese women, the means of each of the 3 strength measures was 12-13% higher in Japanese women than in Caucasian women (p<.0001 for each comparison).

Femoral Neck Strength Measures (in gm/ kg.meter)	**Mean**		**p value for t-test**
	Caucasian (N=199)	**Japanese** (N=267)	
Bending Strength	0.490	0.556	< .0001
Compressive Strength	2.49	2.78	< .0001
Impact Strength	0.161	0.180	< .0001

Relative to the forces that they have to withstand in weight bearing, and relative to the energy that they have to absorb in an impact from a fall from standing height, the femoral necks of Japanese American women are substantially stronger than those of Caucasian American women. This finding is consistent with the observed difference in hip fracture risk between Japanese and Caucasian women.

1208

Thoracic Kyphosis and Rate of Incident Vertebral Fracture. K. M. Shipp[1], H. A. Guess*[2], K. E. Ensrud[3], M. C. Nevitt[4], D. M. Kado[5], S. R. Cummings[4]. [1]Duke University, Durham, NC, USA, [2]Merck Research Laboratories, Blue Bell, PA, USA, [3]University of Minnesota, Minneapolis, MN, USA, [4]University of California, San Francisco, CA, USA, [5]University of California, Los Angeles, CA, USA.

Biomechanical evidence supports the theory that hyperkyphosis may increase the risk of new vertebral fractures (VFs). When the spine is in a flexed (kyphotic) position, the vertebral bodies sustain sufficiently high loads for usual daily activities potentially to result in a fracture in the osteoporotic spine. This cohort study examined whether baseline severity of thoracic kyphosis (TK) was associated with subsequent risk of new radiographically-detected VF, over 2 to 4 years of follow-up in 3,038 women, between 55 and 81 years of age with baseline femoral neck BMD $\leq$ 0.68 g/cm^2, enrolled in the placebo arms of the Fracture Intervention Trial. TK, measured by Debrunner kyphometer, was the primary exposure variable. VFs were assessed by quantitative morphometry using standard definitions. Our goal was to evaluate TK as an independent predictor of new VFs. Crude new VF rates follow:

TK (quartiles)	Person-years	#	Rate/1,000 p-yrs
7.0º -- 40.0º	3,150	45	14.3
40.1º -- 47.0º	2,701	43	15.9
47.1º -- 55.5º	2,854	54	19.0
55.6º -- 80.0º	2,680	79	29.5

Over 20 reported risk factors for osteoporotic fracture were evaluated as potential effect modifiers or confounders of the TK -- VF relationship. Controlling for age and BMD, TK > 36º was linearly related to incident VF, rate ratio [per 10º > 36 º] 1.22 (1.07, 1.39), giving the following predicted values:

TK	Rate Ratio	95% CI
60º vs. 36º	1.62	1.18, 2.22
70º vs. 36º	1.98	1.27, 3.09
80º vs. 36º	2.42	1.36, 4.32

With previous VFs added to this model, there was no independent effect of TK on risk of VF, rate ratio [per 10º > 36º] 1.03 (0.91, 1.18). Women with hyperkyphosis are at increased risk for new VFs, independent of age and BMD. This association is explained by a greater number of existing VFs among women with hyperkyphosis. Measurement of kyphosis may be useful for predicting vertebral fracture risk when spine radiographs are not available.

1209

Increased Risk of Falls, Increased Bone Resorption and Decreased Bone Mineral Density in Elderly Men with Hypogonadism. The MINOS Study. P. Szulc[1], F. Munoz*[1], B. Claustrat*[2], P. Garnero[1], F. Marchand*[3], P. D. Delmas[1]. [1]INSERM 403 Research Unit, Lyon, France, [2]Hôpital Cardiologique, Lyon, France, [3]SSMB, Montceau les Mines, France.

The goal of the study was to identify the clinical and biological pattern of hypogonadism in a large cohort of men. In that cohort of 1066 men aged 19 to 85 years, serum concentrations of free testosterone (fT) and of bioavailable testosterone (bioT) decreased with age (r = -0.39 and r = -0.43, respectively, p=0.0001). Hypogonadism was defined as concentration of fT more than 2 SDs below the mean in young healthy men. After adjustment for age and body weight, hypogonadal men had a lower bone mineral density (BMD) at the level of total hip (-5.8 %, p<0.005), ultradistal radius (-6.3 %, p<0.04), whole body (-3.9 %, p=0.002) and higher levels of the bone resorption markers (total deoxypyridinoline - +35 %, p=0.0001, urinary beta-isomerized C-terminal telopeptide of collagen type I [betaCTX–I] - +41 %, p=0.0001, serum betaCTX–I - +28 %, p=0.001). The same pattern was observed when hypogonadism was defined by the level of bioT. In contrast, serum concentrations of bone formation markers (osteocalcin, bone alkaline phosphatase, N-terminal extension propeptide of type I collagen) did not differ between groups. Hypogonadal men had a lower lean body mass (-3.1 %, p<0.002). In men aged more than 49 years, hypogonadism was associated (after adjustment for age and body weight) with an impairment of several clinical tests of muscle strength and balance such as standing up 5 times from a sitting position (O.R. = 5.0, p<0.005), maintaining equilibrium for 10 sec with open eyes (O.R. = 3.4, p<0.05) and for 5 sec with closed eyes (O.R. = 2.5, p<0.05), walking forwards 10 steps on a line drawn on the floor (O.R. = 4.1, p<0.001). In men aged more than 69 years, hypogonadism was a risk factor for falls (O.R. = 2.7, p<0.03). In conclusion, elderly men with hypogonadism have two groups of risk factors for osteoporotic fractures: decreased BMD and increased bone resorption on the one hand and, on the other hand, lower muscle strength, impaired balance, and increased risk for falls.

1210

Low Plasma Vitamin B12 Is Associated with Lower Bone Mineral Density: The Framingham Osteoporosis Study. K. L. Tucker[1], M. T. Hannan*[2], P. Jacques*[1], J. Selhub*[1], I. Rosenberg*[1], P. W. F. Wilson*[3], D. P. Kiel*[2]. [1]USDA Human Nutrition Research Center, Tufts University, Boston, MA, USA, [2]Hebrew Rehabilitation Center, Harvard Medical School, Boston, MA, USA, [3]Boston University, Boston, MA, USA.

Osteoporosis has been previously associated with pernicious anemia and vitamin B12 is thought to be important to osteoblast activity. In one case report, a man with pernicious anemia showed marked improvement in bone density over two years of vitamin B12 treatment. However, few studies have examined vitamin B12 and BMD. We therefore assessed the relationship between plasma vitamin B12 and BMD in 1144 men and 1487 women in the Framingham Offspring Study. In 1995-99, participants (30-87y) had BMD measured with Lunar DPX-L at hip (femoral neck, trochanter, Wards area, total hip) and lumbar spine. Plasma from the same examination was analyzed for vitamin B12 by radioassay, (Ciba-Corning). We divided subjects based on standard cutoffs for vitamin B12: 200-250, >250-350, and >350 pg/mL. BMD measures were each regressed onto this categorical variable by sex, adjusting for age, BMI, height, smoking, alcohol use, calcium intake, vitamin D intake, physical activity score and season of measurement and least squares means were obtained. We also regressed BMD onto each of the three higher categories relative to the lowest, separately for men and women. 5% of men and 4% of women had B12 <=200 pg/mL. These subjects had significantly (p<.05) lower BMD than at least two of the three higher categories as follows: Men: fermoral neck, Ward's area and total hip, but not spine or trochanter; Women: trochanter, Ward's area, spine and total hip, but not femoral neck. As an example, for men, the LS means for total hip BMD for the 4 categories were 0.98, 1.02, 1.03, 1.03 g/cm2, suggesting that vitamin B12 <=200 pg/mL was associated with BMD about 5% lower than those above this cut point (p< .05 with the 3rd and 4th). For women, corresponding total hip BMD LS means were 0.676, 0.705, 0.703, 0.700 g/cm2, p<.05 for 1st vs. 3rd and 4th. Patterns were similar for other BMD sites. These results support the hypothesized association between vitamin B12 deficiency and low BMD for both men and women in a population sample. Future studies should focus on B12 effects on bone biology, including the possibility that B12 effects are mediated directly or possibly through homocysteine metabolism.

1211

Long-Term Fracture Risk Following Renal Transplantation: A Population-Based Study. L. Vautour[1], L. J. Melton[1], B. L. Clarke[2], S. J. Achenbach*[1], A. L. Oberg*[1], J. T. McCarthy*[3]. [1]Health Sciences Research, Mayo Clinic, Rochester, MN, USA, [2]Endocrinology, Mayo Clinic, Rochester, MN, USA, [3]Nephrology, Mayo Clinic, Rochester, MN, USA.

While abnormalities in bone metabolism are well recognized in patients with end-stage renal disease, the overall risk of fracture following renal transplantation has not been well quantified. The 86 Olmsted County, MN residents who underwent a renal transplant between 1965 and 1995 were followed for 911 person-years in a retrospective cohort study. Risk factors and fracture outcomes were assessed through review of each subject's complete (inpatient and outpatient) medical records in the community. There were 59 men (69%) and 27 women, of whom 7 were postmenopausal. During follow-up extending to 33 years (mean 10.6±7.4 years), 117 fractures were observed. The cumulative incidence at 15 years of one or more fractures was 68% compared to 22% expected in the general population (p<0.001). Renal transplantation was associated with a significantly increased risk of any fracture (standardized incidence ratio [SIR] 4.8, 95% CI 3.6-6.4), but these patients had a particular risk of vertebral (SIR 23.1, 95% CI 12.3-39.6), rib (SIR 15.0, 95% CI 9.5-22.5), pelvic (SIR 17.1, 95% CI 4.7-43.8), and foot fractures (SIR 8.4, 95% CI 5.1-12.9). By univariate analysis, increasing age at transplantation, diabetes, peripheral neuropathy, peripheral vascular disease and blindness were significant predictors of fracture risk. In multivariate analysis, however, only age at first transplant and diabetic nephropathy were independent predictors of risk, while higher activity level had a protective effect. Diabetes was the only independent predictor of lower limb fractures, and duration of dialysis was the only predictor of vertebral fractures in multivariate analyses. An increase in cumulative glucocorticoid dosage was not correlated with increased fracture risk. Thus, renal transplantation among unselected patients in the community is associated with a significant increase in the risk of fractures (especially those of the vertebrae, ribs, pelvis and lower limbs) even up to 15 years post-transplant. Diabetics, in particular, seem to suffer a great number of lower limb fractures, possibly secondary to peripheral neuropathy, and perhaps should receive greater attention to ambulatory problems post-transplantation.

1212

Are Traumatic Fractures Osteoporotic? S. R. Cummings[1], K. L. Stone[1], L. L. Lui[1], T. A. Hillier[2], D. C. Bauer[1], H. K. Genant[1], S. T. Harris[1], J. A. Cauley[3]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]Kaiser Center for Health Research, Portland, OR, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA.

It is widely believed that fractures that occur during excessive trauma, such as motor vehicle accidents, are not related to osteoporosis. Traumatic fractures are ignored in assessment of risk and excluded as outcomes in trials. We tested two hypotheses: first, that there would be an inverse relationship between BMD and risk of subsequent traumatic fractures and second, that women with traumatic fractures would have an increased risk of subsequent non-trauma fractures. We tested these hypotheses in the prospective Study of Osteoporotic Fractures, a cohort of 9,704 women ≥ age 65 who had peripheral and central BMD measures and more than 15 years of subsequent follow-up for incident fractures. 218 women suffered fractures as a result of severe trauma (83% due to car crashes) during 11.6 years of follow-up after baseline measurement of calcaneal BMD. Of these, 144 occurred during the 10.0 years after measurement of total hip BMD (Hologic QDR 1000). Adjusting for age, the risk of traumatic fracture increased 1.3-fold with each SD decrease in calcaneal BMD (95% CI: 1.1 to 1.5) and 1.6-fold with each SD decrease in total hip BMD (1.3 to 2.0). This remained significant after adjustment for alcohol use. After age-adjustment, women with a traumatic fracture had a 1.7-fold (1.2 to 2.3) risk of suffering a future 'low trauma' fracture. We conclude that, as conventionally defined in SOF, traumatic fractures are osteoporotic fractures. Fractures that occur during trauma should be counted as risk factors for future fractures and as outcomes in trials.

1213

Oral Corticosteroids and the Relationship between Dose and Bone Mineral Density and Fracture: A Systematic Review of Literature. T. P. van Staa[1], H. G. M. Leufkens*[1], C. Cooper[2]. [1]Pharmacoepidemiology and Pharmacotherapy, Utrecht Institute for Pharmaceutical Sciences, Utrecht, Netherlands, [2]Environmental Epidemiology Unit, Medical Research Council, Southampton, United Kingdom.

We conducted a meta-analysis to examine the effects of oral corticosteroids (CS) on bone mineral density (BMD) and fracture risk. It included 66 BMD and 23 fracture studies (with 1 very large and 22 smaller fracture studies). Multiple linear regression analysis was used to estimate BMD change by cumulative CS dose (across-study range of 6.5 to 58.4 g). It was found that all BMD studies reported reduced lumbar spine and hip BMD in CS users (across-study average of 89.4% and 88.8% of normal, respectively). Cumulative dose was strongly correlated to BMD loss at the spine and hip (Pearson correlation coefficients p-values < 0.05). Using the regression analysis, the BMD loss was estimated to be 4.7% at the spine and 6.1% at the hip at a cumulative dose of 13.9 g (mean dose across the smaller fracture studies). This correlated to an expected RR of 1.48 for vertebral and 1.41 for hip fracture (based on published data on the relationship between BMD and fracture risk). The observed RRs of vertebral fractures at this cumulative dose were 3.05 in the largest fracture study and 2.86 in the other fracture studies. For hip fractures, the observed RRs were 2.34 and 2.01, respectively. Longitudinal BMD studies reported a rapid onset of bone loss after start of CS therapy. The risk of fracture was found to be correlated to daily dose and to rapidly increase after the start of CS therapy (within 3 to 6 months) and decrease after stopping therapy. We conclude that fractures may occur at much higher rates than expected on the basis of BMD changes.

Relationship between BMD changes and risk of fracture

Cumulative dose	Estimated BMD change as % normal	Expected fracture RR	Observed fracture RR (95% CI) -largest study	Observed fracture RR (95% CI) - smaller studies
1.5g	-0.5% Spine	1.04	2.40 (1.88-3.07)	-
13.9g	-4.7% Spine	1.48	3.05 (2.51-3.70)	2.86 (2.56-3.16)
1.5g	-0.7% Hip	1.04	1.54 (1.28-1.85)	-
13.9g	-6.1% Hip	1.41	2.34 (1.94-2.81)	2.01 (1.74-2.29)

Anticonvulsant Use in Elderly Women Increases the Rate of Hip Bone Loss. K. E. Ensrud[1], T. L. Blackwell*[2], P. J. Bowman*[1], T. S. Walczak*[3], E. R. Ensrud*[4], K. L. Stone[2]. [1]Medicine & Epidemiology, VA Medical Center & University of Minnesota, Minneapolis, MN, USA, [2]Medicine, Epidemiology & Biostatistics, University of California, San Francisco, San Francisco, CA, USA, [3]Minnesota Comprehensive Epilepsy Program, Minneapolis, MN, USA, [4]Noran Neurological Clinic, Minneapolis, MN, USA.

Anticonvulsant use may be directly detrimental to bone by resulting in osteomalacia or secondary hyperparathyroidism. To test the hypothesis that elderly women with continuous anticonvulsant use have increased rates of hip bone loss, we assessed current use of anticonvulsants using an interviewer-administered questionnaire at the 4th, 5th, and 6th exams in a cohort of 4202 elderly women participating in the Study of Osteoporotic Fractures. Hip bone mineral density (BMD) was measured at the 4th exam and an average of 4.4 yrs later at the 6th exam. We verified use from medication containers and classified type of medication from product brand or generic names obtained from containers using a computerized medication dictionary. We categorized women according to their reported anticonvulsant use as continuous users (use at all 3 exams), partial users (use at 1 or 2 exams), or non-users (no use at any exam). Individual drug use within the continuous user category included phenytoin, carbamazepine, valproic acid, divalproex sodium, and primidone. The mean annual percent change in total hip BMD (THBMD) and its 4 subregions was calculated by category of anticonvulsant use. All results were adjusted for the following characteristics measured at the 4th exam: age, health status, total calcium intake (dietary plus supplemental), vitamin D supplement use, estrogen use, body mass index, and THBMD. The average rate of decline in THBMD in the overall cohort steadily increased from -0.70%/yr in non-users to -0.94%/yr in partial users to -1.17%/yr in continuous users (p for trend =0.006). Findings were similar at subregions of the hip, though results reached significance only at the intertrochanteric region.

Category of Anticonvulsant Use	Mean Annual % Change in THBMD (95% CI)
Non-users (n=4094)	-0.70 (-0.74 to -0.66)
Partial users (n=68)	-0.94 (-1.25 to -0.63)
Continuous users (n=40)	-1.17 (-1.58 to -0.77)

Anticonvulsant use in elderly women is associated with increased rates of hip bone loss; continuous users have the highest rates of loss. Assessment of anticonvulsant use should be included in the clinical evaluation of osteoporosis risk in older women.

Spondyloepimetaphyseal Dysplasia, Missouri Variant, Is Located on Chromosome 11q22.3 and Is Caused by a Mutation of Matrix Metalloproteinase 13 (MMP13). A. M. Kennedy*[1], P. T. Christie[1], B. Harding*[1], A. A. J. Pannett*[1], A. Dearlove*[2], M. P. Whyte[3], R. V. Thakker[1]. [1]Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom, [2]MRC HGMP Resource Centre, Cambridge, United Kingdom, [3]Shriners Hospitals For Children, St. Louis, MO, USA.

Spondyloepimetaphyseal dysplasias (SEMDs) are a genetically heterogeneous group of skeletal disorders characterised by defective growth and modelling of the vertebrae and long bones. Genetic defects in two of the six autosomally inherited SEMDs have been identified, and involve abnormalities of the collagen type II gene, located on chromosome 12q12-q13.2, and an ATP sulfurylase/APS kinase gene, located on 10q23-34. These abnormalities are not the cause of the Missouri variant ($SEMD_{MO}$), which is an autosomal dominant trait in a four-generation kindred with 14 affected and 11 unaffected members. In order to identify the gene causing $SEMD_{MO}$ we first determined its chromosomal location by performing a genome wide search using chromosome-specific sets of fluorescently labelled microsatellite marker loci (400 primer pairs) at an average intermarker distance of 10 cM. Linkage was established between $SEMD_{MO}$ and loci from an approximate 30 cM region on chromosome 11q14.3-q23.2 (peak LOD score = 4.92, at 0% recombination, with D11S898). Analysis of this region using the ENSEMBL database revealed 234 genes including a cluster of 8 matrix metalloproteinase (MMP) genes (*MMP-1*, *-3*, *-7*, *-8* -*10*, *-12*, *-13* and *-20*) located in 11q22.3. We reasoned that MMP13, which is known to preferentially degrade collagen type II and is specifically expressed in fetal chondrocytes and osteoblasts, was the best candidate gene for $SEMD_{MO}$, and searched for mutations in the 1416 bp coding region, which is encompassed by 10 exons, in an affected family member. This revealed a T to C transition at residue 56 (TTC to TCC). This abnormality, which predicts an alteration of the wild type phenylalanine residue to a serine, co-segregated with $SEMD_{MO}$ and was absent in 110 unrelated normal individuals. This MMP13 missense mutation (Phe56Ser) resides in the pro-region domain and the alteration of a non-polar phenylalanine to a polar serine residue predicts a significant structural change in the enzyme that is likely to affect its processing and activity. Thus, our results have elucidated the molecular defect causing $SEMD_{MO}$ and an important role for MMP13 in skeletal development.

A Genome-wide Screening of N-Ethyl-N-nitrosourea (ENU) Mutagenized Mice for Musculoskeletal Phenotypes. A. Srivastava, S. Mohan, J. E. Wergedal, D. J. Baylink. Musculoskeletal Disease Center, Jerry L. Pettis Memorial VA Medical Center, Loma Linda, CA, USA.

We describe a mouse ENU mutagenesis program incorporating a genome-wide screen of dominant as well as recessive mutations affecting musculoskeletal disorders in C3H/HeJ mice. In a primary screen, progeny of one-generation dominant mutations (F1) and three generation recessive (F3) mutations were screened at ten weeks of age for abnormalities in total BMD, bone mineral content (BMC), bone area, muscle mass, and femoral bone density using DEXA. Biochemical markers, such as osteocalcin, C-telopeptide (type-I collagen), and skeletal ALP were evaluated to detect defects in bone turnover. Abnormal phenotypes were identified as ±2.5 SD different from baseline data collected from age and sex matched non-mutagenized control mice. A secondary screen at 16-week of age incorporating pQCT was used to confirm the abnormal phenotypes observed in the primary screen. Inheritability of mutations was tested in multiple litters and in at least two generation using wild type C3H/HeJ strain. We have screened about 600 mice (with dominant mode of inheritance) and were able to identify six mice with quantitative abnormalities in BMD, BMC, bone size, or bone turnover. 4 of the abnormal phenotypes are shown in the following table:

Mouse ID	BMC (DEXA)	BMD (DEXA)	Tibia Perimeter (pQCT)	Confirmed in Inheritance Test
5.37.5.C.F	-26%	-2%	-14%	Confirmed
6.5.5.A.M	-20%	-10%	-10%	Testing
6.9.5.B.M	+17%	+1%	+14%	Testing
6.5.3.B.M	-22%	-3%	-15%	Testing

Mutant 5.37.5.C.F showed statistically significant lower tetracycline labeled perimeter and decreased periosteal bone formation in the preliminary histological analysis. This mutant is ready for genotyping. In addition to the above phenotypes, two outliers were identified with abnormal C-telopeptide and skeletal ALP serum levels. In addition to quantitative phenotypes, several binary phenotypes were observed such as syndactyly, dominant spotting, albino, and kinky tail. In summary, we demonstrate feasibility of large scale screening of ENU-mutagenized progeny for musculoskeletal phenotypes. The precision of the screening procedures was an important factor in identifying quantitative skeletal phenotypes and less number of outliers was identified with low precision screens such as, bone turnover markers. In conclusion, this program has identified ENU mutants with genes contributing significant differences in BMD, BMC and bone size and will facilitate future discovery of major gene(s) that regulate BMD and other relevant skeletal phenotypes.

B6.C3H Congenic Mouse Strains Exhibit Site-Specific Alterations in Femoral and Vertebral Trabecular Bone Mass and Microarchitecture. M. L. Bouxsein[1], P. Solanki*[1], R. Müller[2], C. H. Turner[3], K. L. Schultz[4], C. Ackert-Bicknell[4], L. R. Donahue[4], C. J. Rosen[4], W. G. Beamer[4]. [1]Orthopedic Biomechanics, Beth Israel Deaconess Medical Center, Boston, MA, USA, [2]ETH, Zurich, Switzerland, [3]Indiana Medical School, Indianapolis, IN, USA, [4]the Jackson Laboratory, Bar Harbor, ME, USA.

We previously identified several quantitative trait loci (QTL's) for total femoral and vertebral BMD, assessed by pQCT, from the F2 intercross of female C57Bl/6J (B6) and C3H/HeJ (C3H) mice (Beamer et al, JBMR 2001). The strongest of these QTLs mapped to Chr 1, 4, 13 and 18 for femurs, and to Chr 1, 4 and 18 for vertebrae. Chr 1 and 4 were also identified as major regulators of vertebral trabecular architecture (Bouxsein et al, ASBMR 2001). To test the effect of these QTLs in vivo, we generated congenic strains by backcrossing the QTL chromosome regions from C3H onto the B6 background for 9 generations. We used high-resolution micro-computed tomography to assess bone volume fraction (BV/TV) and trabecular microarchitecture in the femur and 5th lumbar vertebrae (34 and 12 um resolution, respectively) from 4 mo. old female congenics, and compared them to B6 controls (n=7-10/group). Trabecular thickness (Tb.Th.), number (Tb.N.) and separation (Tb.Sp.) were computed using a direct 3-D approach (Hildebrand et al, JBMR 1999). For the intact femur, bone volume was similar in Chr 1, 4, and 18 congenics and B6 controls, but was 8% lower in Chr 13 congenics ($p=0.05$). In the distal femur, Chr 1, 4, 13 congenics had 2 to 4 fold higher trabecular BV/TV, and increased Tb.Th. (16-40%) and Tb.N. (27-54%) compared to B6 controls ($p<0.01$ for all). Chr 18 congenics also had increased femoral BV/TV (103%, $p<0.05$) and Tb.Th. (+16%, $p=0.01$), but had similar Tb.N. as B6 controls. Cortical thickness at the femoral mid-shaft was unaltered in Chr 4, 13 and 18 congenics, but was 7% higher in Chr 1 congenics ($p=0.05$) compared to B6 controls. In the vertebral body, Tb.Th. did not differ, but BV/TV and Tb.N. were 10-19% lower in Chr 1, 13 and 18 congenics ($p<0.06$ for all). In contrast, in Chr 4 congenics, vertebral trabecular BV/TV and Tb.Th. were higher (17% and 9%, respectively, $p<0.01$), while Tb.N. was similar to B6. Thus, interestingly, C3H alleles of the genes defined by the QTL regions from Chr 1, 13 and 18 were associated with increased femoral, but decreased vertebral trabecular BV/TV, whereas C3H alleles from Chr 4 were associated with increased trabecular BV/TV at both the femur and spine. Together these observations provide evidence that: 1) the BMD QTLs are indeed important regulators of trabecular bone mass and microarchitecture in both the femur and spine, and 2) genetic regulation of trabecular bone is skeletal site-specific.

1218

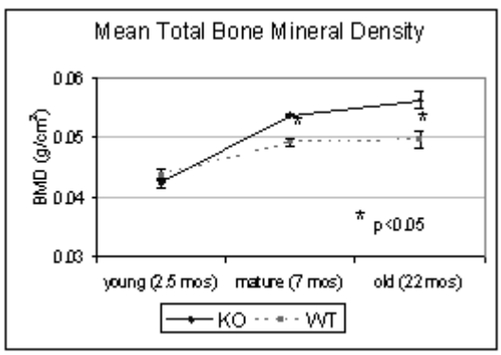
Hip Bone Mineral Density (BMD) Is Linked to Chromosomes 14 and 15. M. Peacock[1], D. L. Koller[2], S. L. Hui[1], C. C. Johnston[1], P. M. Conneally*[3], T. Foroud[1], M. J. Econs[1]. [1]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Medicine, Indiana School of Medicine, Indianapolis, IN, USA.

A major determinant of osteoporotic hip fracture risk is peak BMD. In an initial autosomal genome screen using 279 micro-satellite markers in 429 pre-menopausal white sister pairs, there was suggestive linkage of hip BMD to chromosome 14. The aim of this study was: to corroborate these findings in an independent sample of pre-menopausal white sister pairs; to examine the effect of utilizing these two samples to further localize the linkage finding; to test whether black sister pairs demonstrate linkage to the same chromosomal regions as white sister pairs. A second genome screen using 392 micro-satellite makers was performed in 570 white pre-menopausal sister pairs, of which 281 pairs overlapped with the initial sample, and in 204 black sister pairs. BMD at femoral neck, Wards and trochanter were measured by DXA. Non parametric quantitative trait sibling pair linkage analysis was performed using Map maker/SIB and chromosomal regions with evidence of linkage to the three hip BMD phenotypes identified. Chromosomal positions are reported using Marshfield map coordinates. At chromosome 14 the initial sample (n=429 pairs) had a LOD score of 2.0 (106cM) for trochanter BMD. In the second independent sample (n=289 pairs) LOD score was 1.8 (71 cM), 35cM centromeric to linkage in the initial sample. Analyses performed combining 281 pairs from the initial sample and 289 pairs from the second sample (n=570 pairs) yielded a LOD score of 1.8 (71cM). Analysis of the 204 black sister pairs yielded a LOD score of 1.6 (80cM). When these were analyzed with the 570 white sister pairs (n=774 pairs) the LOD score increased to 3.5 (72cM). At chromosome 15 the initial sample (n=429 pairs) had a LOD score of 1.8 (56cM) for neck BMD. In the second independent sample (n=289 pairs) the LOD increased to 2.2 (62cM). In the enlarged sample of white pairs (n=570 pairs) the LOD score increased to 3.2. Analysis of the 204 black sister pairs produced a LOD score of 1.5 (72cM). When the black sister pairs were analyzed with the enlarged sample of white sister pairs (n=570 pairs) the LOD score increased further to 4.2 (62cM). The study corroborates our initial finding that hip BMD is linked to a region on chromosome 14. It also shows significant linkage to a region on chromosome 15, which in the initial sample was below significance. The study provides strong evidence that regions on chromosome 14 and 15 harbor genes that affect peak BMD at the hip in both blacks and whites and illustrates the importance of replication of initial findings of linkage.

1219

Age-dependent Effect of Bax Deficiency on Bone Quality in Mice. L. M. Wise*[1], M. D. Grynpas[1], A. Jurisicova*[1], S. J. Korsmeyer*[2], G. I. Perez*[3], J. L. Tilly*[3]. [1]Mount Sinai Hospital & University of Toronto, Toronto, ON, Canada, [2]Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, USA, [3]Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA.

Bax is a pro-apoptotic member of the Bcl-2 gene family. Increased *Bax* expression has been correlated with ovarian cell death in both mice and humans. Moreover, young *Bax*-null female mice have 3 times as many primordial follicles in their ovarian reserves as do their wild-type (WT) sisters, and this follicle supply is maintained in advanced chronological age. Given that *Bax* deficiency thus prevents ovarian failure with age, these animals may serve as useful models to study menopause and its relation to the skeleton. Accordingly, *Bax*-null (knockout, KO) female mice and WT littermates were generated and euthanized after 2.5 months (young group), 7 months (mature group) and 22 months (old group). Dual energy x-ray absorptiometry (DEXA) using a PIXImus™ mouse densitometer was performed on all mice to determine bone mineral content (BMC), bone mineral density (BMD), and overall tissue lean and fat mass. To evaluate mechanical properties of the bones in these mice with age, unilateral compression was performed on the 6th lumbar vertebrae, while 3-point bending and torsion testing were performed on the femurs. The results were normalized to determine the elastic modulus, maximum stress, toughness, and post-yield behavior. Bone architecture and mineralization were evaluated using μCT, histomorphometry, backscattered electron imaging (BSE) and x-ray diffraction. The following figure displays the whole mouse BMD results among the 3 age groups.



For the 7- and 22-month age groups, the KO mice were found to have significantly higher BMD and BMC when compared to WT females. The 7-month old KO mice also had significantly higher values for total lean mass than the WT mice. When analysing the bones independently, the 22-month old KO mice had significantly higher vertebral BMD values than the WT mice, while the 7-month old KO mice had significantly higher femoral BMD

values when compared to WT mice. These findings suggest that *Bax* plays a significant role in preventing both age-related and post-menopausal bone loss. Current ovariectomy studies are now determining whether the effect of *Bax* gene disruption is due to indirect effects via a maintenance of ovarian function or a direct effect on the skeleton.

1220

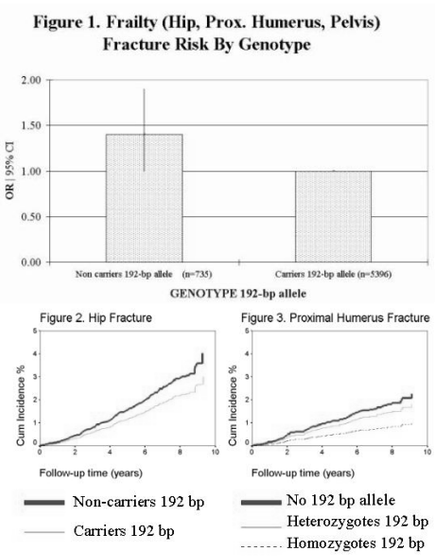
Femoral Response to Ovariectomy by C57BL/6J (B6), C3H/HeJ (C3H), and B6.C3H Congenic Strain Female Mice Carrying Quantitative Trait Loci (QTLs) for Volumetric BMD. K. L. Shultz*[1], A. B. Silva*[1], L. G Horton*[1], L. R. Donahue[1], M. L. Bouxsein[2], C. J. Rosen[1], W. G. Beamer[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Beth Israel Deconess Ctr., Boston, MA, USA.

Loss of bone mineral density (BMD) following withdrawal of gonadal steroid support is a well documented and mechanistically complex problem in skeletal biology. Unexpectedly, ovariectomy of 4 month old nulliparous and 8 month old retired breeder B6 and C3H mice showed that B6 lost bone after 6-8 wks, whereas C3H did not. Given that BMD is a polygenic trait with at least 10 independent regulatory loci in B6C3HF2 mice (Beamer et al. JBMR 2001), we hypothesized that c3h alleles at one or more BMD QTLs may block bone loss due to steroid-deficiency. To test this, we developed B6.C3H congenic strains of mice wherein B6 serves as the recipient background strain and C3H as the strain donating 1 of 5 different chromosomal segments. Each segment carries a BMD QTL accounting for 2 to 10% of the BMD variance identified in B6C3HF2 mice. Each congenic strain has significantly altered femoral BMD by pQCT: B6.C3H-1T, 4T, 13T, & 18T increased, whereas B6.C3H-6T decreased BMD. At 4 months of age, littermates from each congenic strain were assigned to control or treatment groups, then subjected to sham surgery or ovariectomy and held for 6 additional weeks. At necropsy, skeletal specimens were preserved in 95% EtOH, then femurs were assessed for changes in femoral density and cross-sectional phenotypes. A highly significant reduction in uterine wt/body wt confirmed completeness of ovariectomy. pQCT data showed that ovariectomized B6.C3H-1T, 4T, 6T, and 13T strain had significantly decreased femoral BMD (5 to 9%) and significantly decreased mid-diaphyseal cortical thickness (4 to 12%). Mid-diaphyseal periosteal circumfernces were unchanged. The B6.C3H-18T congenic strain was exceptional in that ovariectomy did not significantly decrease either femoral BMD or mid-shaft cortical thickness. These findings indicate: 1) genetic differences in response to ovariectomy exist among inbred mouse strains; and 2) c3h alleles for the Chr 18 BMD QTL may provide insight to why C3H female bone is resistant to loss of estrogen support.

1221

Insulin-Like-Growth-Factor I (IGF-I) Gene Promoter Polymorphism And The Risk Of Fracture In The Elderly: The Rotterdam Study. F. Rivadeneira*[1], J. Houwing-Duistermaat*[1], H. A. Pols[2], C. M. Van Duijn*[1], A. G. Uitterlinden[2]. [1]Epidemiology & Biostatistics, Erasmus Medical Center, Rotterdam, Netherlands, [2]Internal Medicine, Erasmus Medical Center, Rotterdam, Netherlands.

Previously, we have found a polymorphism in the promoter region of the IGF-I gene associated to bone mineral density (BMD) levels and rate of bone loss in post-menopausal women. We examined the role of this polymorphism in relation to frailty and site-specific risks of fracture within the Rotterdam Study, a population-based cohort study of determinants of chronic disabling diseases in the elderly. Genotyping was performed in 7012 (87.8%) of the 7983 respondent participants. Genotype relative risks were estimated as odds ratios from logistic regressions and as hazard ratios from Cox regressions, both adjusted for age, sex and body mass index. The mean follow-up period was 6.3 (*SD* 2.5) years. The distribution of incident fractures in genotyped individuals (n=905) was 26.6%, 10.3%, 4.3%, 25.9% and 32.9% for hip, proximal humerus, pelvis, wrist and other type of fracture, respectively. All genotype frequencies were in Hardy-Weinberg equilibrium proportions. When taking all frailty fractures into account (Figure 1), non-carriers of the wild type (*192-bp*) allele had a higher risk of fracture (*OR* 1.4 *95%CI* 1.0-1.9) than individuals carrying the allele, suggesting a recessive effect of the gene on the phenotype. This effect was consistent (although not significant) for the risk of hip fracture (*HR* 1.3 *95%CI* 0.9-1.9) evidencing a higher incidence in non-carriers of the allele (Figure 2). An allele dose effect was observed at the proximal humerus (Figure 3), where non-carriers (*HR* 2.2 *95%CI* 1.2-4.2) and heterozygotes (*HR* 1.8 *95%CI* 1.1-2.9) had a higher risk of fracture, as compared to homozygotes for the *192-bp* allele. None of these effects were observed at the pelvis, wrist or other type of fractures. When we adjusted for femoral neck BMD our point estimates did not essentially change. Our findings suggest that this promoter polymorphism or another polymorphism in linkage disequilibrium may be a genetic determinant of osteoporosis, including fractures. These results are consistent with our earlier findings on BMD and serum IGF-I levels. Based on this, we suggest that absence of the wild type allele (*192-bp*) has a deleterious effect on BMD and possibly on bone quality.



1222

Association of Polymorphisms in the Sclerosteosis/vanBuchem Gene Region with Bone Mineral Density in Elderly Subjects. A. G. Uitterlinden[1], P. P. Arp*[1], J. B. J. van Meurs[1], B. W. Paeper*[2], S. Proll*[2], P. Charmley*[2], T. B. Britschgi*[2], J. A. Latham*[2], R. C. Schatzman*[2], H. A. P. Pols[1], M. E. Brunkow*[2]. [1]Internal Medicine, Erasmus University Rotterdam, Rotterdam, Netherlands, [2]Celltech R&D, Bothell, WA, USA.

Osteoporosis has a strong genetic component but the genes involved are poorly defined. In this study we examine the association between the gene encoding sclerostin (SOST) and BMD in order to ascertain whether SOST can be considered an osteoporosis candidate gene. Sclerostin is an important regulator of bone density, and mutations in SOST result in sclerosteosis (MIM 269500), a rare recessive sclerosing bone dysplasia. We sequenced >90 kb of the SOST gene region in 90 ethnically diverse individuals, and used a set of 8 polymorphisms thus found to genotype 1927 men and women (55-80 years) from a large population-based prospective cohort study of elderly Dutch Caucasians. We analyzed genotype effects on BMD and on risk of vertebral and non-vertebral fractures (n=270) during 7 years of follow-up. We found no SOST gene coding polymorphisms but identified 3 variants within 8 kb upstream of the coding sequence, and 3 variants within a far downstream 52 kb interval recently found to be deleted in van Buchem disease, a monogenic bone disorder very similar to sclerosteosis. A 3 bp GGA-insertion in the SOST promoter region (SOST3; allele frequency 39%) was shown to be associated with decreased BMD in women at the femoral neck (p=0.05) and at the lumbar spine (p=0.01) with evidence for an allele-dose effect. We found genotype differences at the lumbar spine to strongly increase with age (Figure 1). In addition, we found a G-variant in the van Buchem deletion region (SOST9; allele frequency 41%) to be associated with increased BMD in men at femoral neck (p=0.006) and at lumbar spine (p=0.01) with evidence for an allele-dose effect. In both cases, overall differences between extreme genotypes amounted to 0.2 SD and we observed no genotype effects on fracture risk. In conclusion, 2 common variants in the SOST gene region were associated with BMD differences and the relations were found to be modified by gender (SOST 3 and 9) and by age (SOST3). The effect-size we observed on BMD was too small to be detected as genotype-dependent differences in fracture risk. The mechanism underlying the BMD differences is unclear but is likely to involve modulation of expression of sclerostin.

Bone Response to Maternal vs Therapist Administered Physical Activity in Premature Infants. L. J. Moyer-Mileur[1], S. D. Ball*[1], V. L. Brunstetter*[2]. [1]Pediatrics, University of Utah, Salt Lake City, UT, USA, [2]Occupational and Physical Therapy, University of Utah Hospital, Salt Lake City, UT, USA.

Background: Preterm infants are at risk of developing osteopenia due to limited in-utero bone accretion and increased ex-utero bone nutrient needs. We have previously reported greater bone mass and body weight gains in preterm infants who received daily physical activity (PA) from a trained occupational therapist (J Peds 1995 and Pediatr 2000). We wondered if a daily PA program administered by the infant's mother would elicit a similar response. Purpose: To compare bone and body weight changes in infants who received a maternal versus therapist-administered PA program. Design: Preterm infants (n=32) were randomized to the maternal (MT; n=16; 6M/10F) or therapist (OT; n=16; 10M/6F). PA consisted of range of motion against passive resistance to all extremities for 5-10 minutes each day for a 4-week period. The therapist provided PA training to mothers of MT infants at study entry. Infants were fed 24Kcal/oz mother's milk with fortification or preterm infant formula (Mead Johnson Nutritionals, Evansville, IN) to achieve an average daily intake of 120 Kcal/kg/day. Body weight and nutrient intake were recorded daily. Forearm measurements by pDEXA (Norland, Fort Atkinson, WI) and serum and urine markers of bone and anabolic activity were obtained at study entry and 4 weeks. MT and OT infant results were compared to age and weight-matched infant controls (n=16; 10M/6F) from the previous study. Body weight at entry and completion, energy intake, and study days were treated as covariants in the statisitical analyses. Results: The MT and OT groups experienced similar gains in bone mass and body weight. Despite similar nutrient intakes, bone mineral content (BMC; mg), area (BA; cm^2), and density (BMD, mg/cm^2) gains were greater for both MT and OT versus controls while OT infants had greater weight gain than controls ($p < 0.05$; Table). Bone alkaline phosphatase (BAP) levels increased ~15% in MT and OT infants and decreased ~20% in controls from baseline ($p < 0.05$). Urine calcium/creatinine excretion was similar and within normal limits for all groups. Conclusion: A daily PA program administered by the infant's mother or a trained therapist is equally effective in promoting greater bone mass in premature infants.

Forearm Bone Mass and Body Weight Changes During the 4-Week Study Period

Impact of Calcium Supplementation on Markers of Bone and Calcium Metabolism in 16-18 Year Old Boys. F. Ginty[1], S. J. Stear*[1], S. C. Jones*[1], D. Stirling*[1], J. Bennett*[1], A. Laidlaw*[1], T. J. Cole*[2], A. Prentice[1]. [1]MRC Human Nutrition Research, Cambridge, United Kingdom, [2]Department of Paediatric Epidemiology and Biostatistics, Institute of Child Health, London, United Kingdom.

The impact of increased Ca intake on markers of bone and Ca metabolism in older adolescent boys has not been previously investigated. To address this, we analysed samples from 143 boys, aged 16-18 years, who took part in a 12 month randomised, double-blind, placebo-controlled calcium intervention study (see Prentice et al, ASBMR Annual Meeting 2002). Randomisation was stratified according to physical activity level (less or greater than 9h of sport per week) and subjects were then assigned to either a Ca supplement (1000 mg of Ca/day (as CaCO3)) or matching placebo. Ca supplementation resulted in significant increases in skeletal size and bone mineral content (BMC). To identify the underlying mechanisms for these changes, first morning urine and non-fasting blood samples were collected at baseline and after 5 months (interim) and 12 months (final) supplementation. Urine was analysed for Ca, deoxypyridinoline (DPD) and N-terminal telopeptides of type I collagen (NTX-I), phosphate (P), and creatinine. Plasma was analysed for parathyroid hormone (PTH), intact osteocalcin (OC[1-49]), bone-specific alkaline phosphatase (Bone ALP), albumin-adjusted Ca (Ca-alb) and phosphate (Pi). In the Ca supplemented group at interim, there was a non-significant increase in urinary Ca excretion (+12%, p=0.26), a significant reduction in PTH (-16.2%, p=0.03) and DPD was reduced in the higher compliers (-11.5%, p=0.03). Non-significant reductions were also observed for NTX-I (-15%, p=0.08) and OC[1-49] (-10%, p=0.30), in the higher compliers. Only marginal changes were found for Bone ALP, Ca-alb, Pi and urinary P (ranging between -1 and +1%). By the end of the study, urinary Ca was 21% higher (p=0.04) in the Ca group and 34% higher (p=0.02) in the higher compliers. Both OC[1-49] and NTX-I were lower in the higher compliers (-11.4%, p=0.04 and -15.4%, p=0.08, respectively). Little effect of the supplement on PTH and DPD was observed (-4% and -2%, respectively, ns) and, again, the remaining markers only marginally changed. No interaction was found between the supplement and physical activity level. The results of this study suggest that the observed increases in BMC may have been due to a transient decrease in PTH, resulting in a lower rate of bone turnover. The varying responses of the markers demonstrates the importance of measuring more than one formation and resorption marker, at more than one timepoint, in order to fully elucidate mechanisms. Further analysis is underway to determine the mechanisms that led to increases in skeletal size.

Patterns and Pitfalls in pQCT Measurements of the Tibia in Children. B. S. Zemel, R. Ittenbach*, V. Stallings*, S. Kaup*, M. Gomelsky*, M. B. Leonard. Pediatrics, The Children's Hospital of Philadelphia, Phila, PA, USA.

Peripheral quantitative computed tomography(pQCT) measurements of the tibia have been proposed for assessment of bone density, dimensions and strength in children. Recommended measurement parameters were developed at a Pediatric User's Group Meeting in 2000. Following those guidelines, we assessed bone health in well children as part of a study to establish reference data on bone health and body composition in children. 152 (77 female) healthy children, ages 6 to 21 years enrolled. 35% of children were African-American ethnicity. All pQCT measurements were taken with a Norland-Stratec XCT2000 using a voxel size of 0.4mm and slice thickness of 2.3 mm. The medial aspect of tibia length (TL) was measured anthropometrically. The reference line was placed at the distal end of the epiphyses on the scout view scan. Measurements were obtained at the 4% (trabecular assessment), 20% (cortical assessment) and 66% (muscle assessment) sites. An additional region of interest (ROI) within the cortical bone envelope was defined at the 20% site to minimize partial volume effect. Cross-sectional moment of inertia (CSMI) was derived from the 20% site. Cross-sectional muscle area was derived from the 66% site(MA66%). All scans were reviewed for scan quality by two investigators. Results were evaluated in relation to age, gender, TL, ethnicity, and MA66%, by regression analysis. The major difficulty with scan quality occurred at the 4% site where variability in epiphyseal size resulted in glancing the metaphysis. This usually occurred on the bone periphery, so trabecular analysis was restricted to the inner 45%. There were no age or size trends in trabecular density. Girls had significantly greater trabecular density than boys, with a significant interaction between gender and ethnicity (r2=0.07). Overall cortical density was significantly associated with age, TL, gender, ethnicity (r2=0.63); however, cortical ROI density was associated with age and gender (r2=0.29). Cortical thickness was associated with MA66% and TL (r2=0.78). CSMI was associated with MA66%, TL and gender (r2=0.79). This measurement protocol had limitations due to variability in epiphyseal size and shape. Consequently, the interpretation of trabecular bone density is uncertain. There were no age trends in trabecular density, which may be related to the problems in the measurement protocol. Cortical density was strongly related to age, size and ethnicity, but the ROI analysis demonstrated weaker associations, which may be due to partial volume effect. New measurement strategies are necessary to further develop this tool for bone health research in children.

Intervertebral Disc Degeneration Increases Load-bearing by the Neural Arch and Reduces BMD in the Anterior Vertebral Body. P. Pollintine*[1], J. H. Tobias[1], D. S. McNally*[2], G. K. Wakley[1], P. Dolan*[1], M. A. Adams*[1]. [1]University of Bristol, Bristol, United Kingdom, [2]University of Nottingham, Nottingham, United Kingdom.

Introduction: Bone mineral density (BMD) of the whole vertebra is conventionally used to diagnose spinal osteoporosis. However, recent evidence suggests that bone loss can be more pronounced in the anterior vertebral body (1). We hypothesise that age-related degeneration of intervertebral discs increases neural arch compressive load-bearing, causing pronounced anterior vertebral body bone loss and weakening. Materials and Methods: Fifteen cadaveric thoraco-lumbar motion segments (aged 72-92 yrs), comprising 2 adjacent vertebral bodies and intervening disc and ligaments, were compressed to 1.5 kN while positioned to simulate the erect standing posture. The distribution of compressive stress was measured within the intervertebral disc by pulling a miniature pressure transducer along its mid-sagittal diameter. “Stress profiles” were integrated over area to give the compressive force acting on the anterior and posterior halves of the vertebral body (2). These were subtracted from the 1.5 kN to determine the force on the neural arch. Compressive strength of each motion segment was measured in flexion to simulate forwards stooping. DXA was used to measure bone mineral content (BMC) of the anterior vertebral body, and of the whole vertebra (including the neural arch). Volumetric BMD of the anterior vertebral body, and of the whole vertebra was then calculated from BMC. Results: In the simulated erect posture, the neural arch resisted 12-86% of the applied 1.5 kN, while the anterior vertebral body resisted only 4-32%. Compressive strength in flexion correlated negatively with load-bearing by the neural arch in erect posture ($r^2 = 0.51$, $p = 0.006$). Anterior vertebral body BMD was consistently lower than whole vertebra BMD ($p < 0.002$). Anterior vertebral body BMD was a better predictor of compressive strength than whole vertebral BMD ($r^2 = 0.82$ and $r^2 = 0.72$, respectively). Discussion: Age-related degenerative changes cause intervertebral discs to lose height, increasing neural arch compressive load-bearing in erect postures. This unloads the disc, particularly its anterior half, reducing the compressive force on the anterior vertebral body. Habitual unloading causes bone loss that is pronounced in the anterior vertebral body, making it vulnerable to fracture when the spine is loaded in flexion. Anterior vertebral body BMD measurement may be of greater diagnostic value in predicting vertebral fracture risk than whole vertebra BMD.

Young-old Differences in Vertebral and Proximal Femoral Bone Density and Size: The Mr Os Study. T. F. Lang*[1], J. Li*[1], A. Yu*[1], K. Ensrud[2], M. Nevitt[3], E. Orwoll*[4]. [1]Radiology, University of California, San Francisco, CA, USA, [2]VA Med Ctr, University of Minnesota, Minneapolis, MN, USA, [3]Epidemiology, University of California, San Francisco, CA, USA, [4]Medicine, Oregon Health Sciences University, Portland, OR, USA.

Bone size is thought to increase to compensate for the age-related decrease in bone mineral density. To address this issue we imaged the proximal femorae and L1-L2 vertebrae of 30 young Caucasian-American (mean age 39±3 years) and 800 elderly (mean age=75±7 years) men with volumetric quantitative computed tomography (vQCT). The young men were residents of the San Francisco Bay Area and had no known conditions affecting bone metabolism. The elderly subjects were healthy community-dwelling males recruited by the Pittsburgh and Minneapolis clinics of the Study of Osteoporotic Fracture in Men (Mr Os). VQCT images were processed to obtain measurements of integral (iBMD) and trabecular (tBMD) bone density and integral cross-sectional area (CSA) as well as indices of bending (BSi) and compressive strength (Csi) in the hip and spine respectively. Spine measures included tBMD, iBMD, CSA and CSi (CSi=iBMD2*CSA). Hip measures included iBMD and tBMD in the femoral neck. We also calculated the minimum CSA of the femoral neck and the polar moment of inertia (J) at this location. BSi was calculated by dividing J by sqrt(2*CSA/p). To adjust for differences in height and weight, we used ANACOVA to compare between young and elderly males. Elderly men had lower BMD but larger CSA than young men at both the spine and the hip. CSi was smaller in older men. BSi was also smaller in the elderly men, but the difference was not statistically significant. Results are tabulated below. Compared to younger men, older males have larger vertebral and femoral neck cross-sectional areas but lesser BMD. The increase in cross-sectional area appears to preserve BSi in the femoral neck. However, despite the increase in vertebral CSA in the elderly men, the CSi was significantly reduced in this group.

Assessment of Densitometric Criteria for the Diagnosis of Osteoporosis in Men and Women with Vertebral Fractures. L. del Rio[1], N. Guañabens[2], P. Bassa*[1], P. Peris[2], A. Monegal*[2], L. Jover*[3]. [1]Densitometria Osea, CETIR Centre Medic, Barcelona, Spain, [2]Servicio de Reumatologia, Hospital Clinico, Barcelona, Spain, [3]Departamento de Salud Publica, Facultad de Medicina, Barcelona, Spain.

The aim of this study was to investigate the relations between bone mineral density (BMD) and vertebral fractures in men and women who attended our facility for their osteoporosis work-up. BMD and anthropometric data of lumbar spine and proximal femur were obtained from a total of 71093 patients (68007 women, 3086 men). There were 2860 patients (2428 women and 432 men) with at least one vertebral fracture/deformity with no relationship with a significant trauma, and confirmed by conventional anterior and lateral X-ray of lumbar spine or vertebral morphometry using dual X-Ray absorptiometry (MXA). Mean age of women and men with vertebral fractures was 63.6 years (9.9 SD), and 61.1 (11.4 SD), respectively. BMD values in lumbar spine and proximal femur were obtained using LUNAR equipment (DPX-L and EXPERT), and results in spine were expressed as density by area (g/cm2) and apparent density (g/cm3), T-score and Z-score. Accumulated frequency for vertebral fracture was calculated for every parameter studied. Our results showed that BMD values in patients with spine fractures were significantly lower than in patients with no fracture, independently of sex. T-score in both regions was very similar for women and men with vertebral fractures (median value in lumbar spine, T, -2.2 vs 2.3). We found vertebral width differences (p<0.0001) between patients groups, with and without fractures, in both sexes. Vertebral height was not determinant for categorizing patients according to the fracture status, however, values were significantly lower in patients with fractures, irrespective of sex, in comparison with non-fractured patients. By using the WHO criteria, 50.92% of men and 51.02% of women with vertebral fractures were categorized within the osteoporotic range. Apparent BMD (g/cm^3) did not contribute with additional data in this study. These results suggest that WHO criteria for the identification of caucasian women with osteoporosis may also be applied to men, standing from the vertebral fracture strategy.

Specific Regulation of BMP-2 Gene Expression by NF-κB in Growth Plate Chondrocytes. D. Chen[1], J. Q. Feng[2], J. Zhang*[2], M. Zhao[1], D. Horn*[1], J. Chan*[1], S. E. Harris[2], G. R. Mundy[1], B. F. Boyce[3], L. Xing[3]. [1]Molecular Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]Oral Biology, University of Missouri, Kansas City, MO, USA, [3]Pathology, University of Rochester, Rochester, NY, USA.

It has been well documented in osteopetrotic null mice that NF-κB p50 and p52 proteins are essential for osteoclastogenesis. What has not been previously appreciated is that in two-week-old NF-κB p50/52 double knockout (dko) mice, the architecture of the endochondral growth plate is disorganized with a significantly expanded hypertrophic zone. Since this is not a feature of src-/- osteopetrosis, we hypothesized that NF-κB may play an important specific role in chondrogenesis. In *drosophila*, the dpp gene, a homologue of BMP-2, is regulated by *dorsal*, a homologue of mammalian NF-κB. BMP-2 has been shown to play important roles in chondrocyte proliferation and maturation. We hypothesized therefore that NF-κB regulates chondrogenesis via effects on BMP-2. We firstly examined BMP-2 mRNA expression in NF-κB p50/52 dko mice by in situ hybridization. BMP-2 mRNA was detected predominantly in hypertrophic and articular chondrocytes in wild-type and NF-κB p50/52 dko mice but its expression in hypertrophic chondrocytes in the dko mice was greatly reduced. We then investigated mechanisms by which NF-κB may regulate BMP-2 expression in chondrocytes. Two NF-κB response elements were found in the -2712/+165 region of the BMP-2 gene. Mutations in the NF-κB cis-DNA response elements of the BMP-2 gene or transfection of mutant I-κBα expression plasmids with the BMP-2 promoter into TMC-23 chondrocytes suppressed BMP-2 transcription. Gel shift assays demonstrated that TMC-23 cell nuclear preparations bind these two NF-κB response elements in the BMP-2 gene. The supershift assays revealed that the NF-κB proteins, which bound to NF-κB response elements in the BMP-2 gene, were NF-κB subunits p50 and p65. To determine if there are functional changes in growth plate chondrocytes of p50/p52 dko mice, cell proliferation following *in vivo* BrdU labeling and apoptosis with TUNEL staining were analyzed. In the NF-κB p50/52 dko mice, chondrocyte proliferation was dramatically reduced (BrdU+ve cells: 14.0 ± 2.1 in wt Vs 3.5 ± 2.4 in dko) and apoptosis of chondrocytes at chondrocyte/hypertrophic chondrocyte junction area of growth plate were also reduced in NF-κB p50/52 dko mice (apoptotic cells: 12.3 ± 0.5 in wt Vs 6.3 ± 1.9 in dko). Type X collagen mRNA expression was also reduced in the hypertrophic chondrocyte area in NF-κB p50/52 dko mice. These findings indicate that NF-κB regulates chondrocyte maturation in postnatal murine growth plates by directly activating BMP-2 gene expression.

Transplantation of Fibroblasts Expressing BMP-2 Promotes Bone Repair More Effectively Than That Expressing Cbfa-1. K. Hirata*[1], T. Tsukazaki[1], Y. Shibata*[1], A. Mizuno*[2], T. Komori[3], A. Yamaguchi[1]. [1]Oral Pathology, Nagasaki University School of Dentistry, Nagasaki, Japan, [2]Oral and Maxillofacial Surgery, Nagasaki University School of Dentistry, Nagasaki, Japan, [3]Osaka University, Osaka, Japan.

To explore new therapeutic approach to repair large bone defect, a new strategy, including cell transplantation and gene therapy, has to be established. Recently, an ex vivo gene therapy using adenoviral BMP-7 expression in fibroblast has been demonstrated to regenerate rat calvarial defect. However, it is so far unclear whether gene expression of bone-specific transcription factor also transduces nonosteogenic cells to osteoblastic lineage, and eventually forms bony tissue in vivo. In this study, we investigated the osteogenic potential of skin fibroblasts that transduced BMP-2 or Cbfa-1, an essential transcription factor for osteoblast, by transplantation into critical-sized bone defect. Skin fibroblasts isolated from newborn GFP transgenic mice (provided by Dr. Okabe) were transfected with adenovirus encoding hBMP-2 (provided by Dr. Bessyo) or mCbfa-1. These cells were trypsinized, immersed in a carrier of poly D,L lactic-co-glycolic acid gelatin sponge (PGS) and transplanted into bony defects with 4mm diameter that created on parietal bone of 8 weeks old mice with the identical genetic background. This calvarial defect was not repaired until at least 6 weeks when PGS was transplanted. Expression of BMP-2 and Cbfa-1 in vitro persisted at least 5days after transfection, as evaluated by ELISA and fused EGFP fluorescence color image analysis, respectively. Transfection of Cbfa-1 remarkably induced alkaline phosphatase (ALP) activity in vitro, but failed to stimulate bone formation even after 6 weeks of implantation. In contrast, BMP-2 transfected fibroblasts induced bone formation from 2 weeks in all cases, and more than 50% of PGS was replaced by newly formed bone at 4 weeks. This bone formation was initiated within PGS, and bone marrow tissue was also reconstructed. Immunofluorecence analysis of the regenerated tissue revealed that a part of the bony tissue contained EGFP-positive osteocytes and osteoblasts. These indicate that overexpression of BMP-2 in fibroblast promotes bone repair, and such fibroblasts have a potential to differentiate into osteoblastic lineage. In contrast, Cbfa-1 expression is insufficient to induce bone formation despite intense activity to induce osteoblast differentiation in vitro. Taken together, our results suggest that expressing several osteogenic growth factors is more suitable for fibroblast-based gene therapy to large bone defect than expressing osteogenic transcription factors.

F020

αv-Containing Integrins Colocalize with BMP-2 Receptors and Are Essential in BMP-2 Function. C. F. Lai, S. L. Cheng. Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

It is well established that integrins and BMP-2 regulate osteoblast growth and differentiation. Integrin-matrix interactions and BMP-2 also share overlapping signal transduction by activating MAPK cascade. Therefore, there appear to have intimate relationship between integrins and BMP-2 in osteoblast function. Indeed, collagen integrin receptors (α1β1 and α2β1), FAK, and Ras/Erk have all been implicated to play important roles in BMP-2 induction of osteoblast differentiation (JBMR14:1075, 1999; JBMR16:1772, 2001; JBMR17:101, 2002; and JBMR17:240, 2002). Conversely, BMP-2 has been shown to up or down regulate the expression of integrins depending on the cell types analyzed. In addition to collagen, osteoblasts also express several non-collagenous proteins such as osteopontin, bone sialoprotein, and fibronectin, which are important for matrix mineralization. These proteins can interact with the αv-containing integrins (αvβ) and their expression is upregulated by BMP-2. We examined the effects of BMP-2 on integrin expression and the role of αvβ integrins in BMP-2 regulation of normal human osteoblast function. BMP-2 elevated the levels of αvβ integrins, including αvβ3, αvβ5, αvβ6, and αvβ8, on osteoblast surface. The surface level of β1-containing integrins (αβ1) was also increased by BMP-2. Consistent with the increase in integrin levels, osteoblast adhesions to osteopontin and vitronectin, which were dependent on the αvβ integrins, were enhanced by BMP-2. Immunoprecipitation with specific integrin antibodies followed by Western blotting for BMP-2 receptors indicated that both type I and type II receptors of BMP-2 co-localized with αvβ integrins (αvβ3, αvβ5, αvβ6, and αvβ8) and αβ1 integrins. Immunostaining and confocal examination confirmed the co-localization of BMP-2 receptors with these integrins. To analyze the role of αvβ integrins in BMP-2 function, we employed the function-blocking anti-αv antibody, L230. BMP-2 reduced the proliferation of normal human osteoblasts and this inhibition was reversed by L230. L230 lessened the stimulation of alkaline phosphatase activity and abrogated the increase in osteopontin and bone sialoprotein levels by BMP-2. Incubation of osteoblasts with L230 prevented BMP-2 from inducing matrix mineralization. We conclude that BMP-2 and integrin share close relationship in their regulation of osteoblast function. BMP-2 increased the surface levels of αv- and β1-conatining integrins, resulting in an enhanced osteoblast adhesion to bone matrix proteins. Perturbation of αvβ integrin function inhibits BMP-2 regulation of osteoblast activity. Thus, the αv-containing integrins are essential in BMP-2 function.

Increased Root Cementum in ANK-Mutant Mice – Developmental and Regenerative Implications. F. H. Nociti, Jr.*[1], J. E. Berry*[1], B. L. Foster*[1], K. Gurley*[2], D. M. Kingsley*[2], M. J. Somerman[1]. [1]Periodontics, Prevention, Geriatrics, University of Michigan, Ann Arbor, MI, USA, [2]Developmental Biology, Stanford University, Stanford, CA, USA.

Ank is a multipass transmembrane protein that appears to control the transport of intracellular pyrophosphate (PPi) into extracellular matrix. Mice carrying a mutation in the *ank* gene exhibit an extracellular PPi deficiency and develop excess mineralization of articular surfaces and synovial fluid with eventual death due to joint immobilization. These mice have been used as a model for arthritic-like crystal deposition. We hypothesized that *ank/ank* mutant mice would develop ectopic hydroxyapatite crystals within the developing periodontium resulting in a compromised dentition. Studies designed to test this hypothesis were performed in compliance with guidelines of the University of Michigan Unit for Lab Animal Medicine and Stanford University Institutional Animal Care and Use Committee. In order to investigate the effects of this gene mutation on the periodontium, an initial *in situ* hybridization and immunohistochemical screen for ank expression in normal mice was performed. The results indicated that ank is highly expressed in cells involved in the developing tooth from day 21 to 33 (where day 19 is the date of birth), and that expression is weaker and relatively non-specific at later times. Subsequent experiments were done in which mandibular tissues in the first molar region of *ank/ank* mutant mice, at sequential stages of root development, were analyzed by routine H&E staining, *in situ* hybridization and immunohistochemical methods. H&E staining of the tooth root region of a fully developed molar revealed an enormous amount of cementum, predominantly cellular, on the root surface, approximately 10-fold greater than wild type littermates. No ectopic mineral formation was noted within the periodontal ligament region, and the surrounding alveolar bone appeared comparable to that observed in the wild type mice. Examination by H&E of mutant mice at earlier ages revealed that this striking overproduction of cementum is apparent from the onset of cementogenesis. Further investigations by *in situ* hybridization showed a 2-3 fold increase over wild type of mRNA levels of both type I collagen and also of osteopontin, a molecule consider to regulate crystal growth and whose expression has been shown to be sensitive to phosphate. These remarkable findings suggest that cementum production and cells within the periodontal region are highly responsive to changes in ANK activity and pyrophosphate metabolism. These results may have important clinical implications in the formulation of regenerative therapies for periodontal disease.

F026

A Functional Feedback Loop Comprising Stanniocalcin 1, the Type III NaPi Transporter (Pit1) and Pi Transport Regulates Bone Matrix Mineralization In Vitro and In Vivo. Y. Yoshiko[1], G. A. Candeliere[2], N. Maeda*[1], J. E. Aubin[2]. [1]Oral Growth and Developmental Biology, Hiroshima University, Hiroshima, Japan, [2]Anatomy and Cell Biology, University of Toronto, Toronto, ON, Canada.

In diseases such as X-linked hypophosphatemic rickets/osteomalacia, a dysfunction intrinsic to osteoblasts appears to be related to aberrant transport of inorganic phosphate (Pi), but little is known about how Pi transport is regulated and contributes to bone formation. To assess the role of the osteoblast sodium-dependent Pi (NaPi) transporter(s) in bone formation, we injected foscarnet, a selective inhibitor of NaPi transport, subcutaneously over the newborn rat calvaria. We observed a mineralization defect in the calvaria, without any detectable change in other bones or in serum levels of Pi, Ca, ALP and $1,25(OH)_2D_3$. The mineralization defect was also exhibited in the fetal rat calvaria (RC) cell culture model treated with foscarnet. To address the NaPi transporter(s) in osteoblasts, we analyzed RNA from discrete RC osteoblast colonies and Pit1 was found to be the predominant transporter expressed. To dissect the role of Pit1 in mineralization, we over- and underexpressed this transporter in RC cells using plasmid transfections and antisense (AS) oligonucleotides; mineralization positively correlated with Pit1 expression levels. To identify soluble proteins expressed in osteoblasts that may regulate their NaPi transport, we searched for genes responding to foscarnet in RC cells and identified stanniocalcin 1 (STC1). STC1 has been suggested not to be the putative phosphaturic substrate of PHEX (the phosphate-regulating gene with homologies to endopeptidases located on the X chromosome), because it is thought to stimulate renal NaPi transport and not to be cleaved by PHEX. However, to address further the role of STC1 and its relationship to NaPi transport and/or mineralization, we treated RC cells with STC1 AS oligonucleotides or recombinant STC1 (rSTC1) with or without Pit1 AS oligonucleotides. STC1 was found to stimulate NaPi uptake and mineralization and positively correlated with expression of Pit1 and osteopontin (OPN), a gene reported to be responsive to NaPi transport in an osteoblastic line. Concomitant with these findings in vitro, we confirmed that injections of rSTC1 over the neonatal rat calvaria hastened the mineralization process as indicated by decreased osteoid area and increased Pit1 and OPN expression in the calvaria without other systemic changes. Thus, we conclude that osteoblast-mediated NaPi transport is an essential process for bone matrix mineralization and have identified a new pathway regulating this process, which consists of a functional loop of STC1, Pit1 and Pi transport.

F029

Targeted Inactivation of the Integrin-Linked Kinase (ILK) in Mouse Chondrocytes Reduces PKB/Akt Phosphorylation, Diminishes Chondrocyte Proliferation and Adhesion, and Impairs Growth Plate Development. L. Terpstra*[1], J. Prud'homme*[1], A. Arabian*[1], S. Dedhar*[2], R. St-Arnaud[3]. [1]Genetics Unit, Shriners Hospital for Children, Montreal, PQ, Canada, [2]BC Cancer Research Centre, University of British Columbia, Vancouver, BC, Canada, [3]Genetics Unit, Shriners Hospital for Children and McGill University, Montreal, PQ, Canada.

Chondrocyte proliferation and differentiation requires their attachment to the collagen type II-rich matrix of developing bone. This interaction is mediated by the integrin family of transmembrane proteins and their cytoplasmic effectors, such as the integrin-linked kinase (ILK). To understand the role of integrin signaling in these processes, we have specifically inactivated the ILK gene in growth plate chondrocytes using the Cre-lox methodology. Mice carrying an ILK allele flanked by loxP sites (ILK-fl) were crossed to transgenic mice expressing the Cre recombinase under the control of the collagen type II promoter. Inactivation of both copies of the ILK-fl allele lead to a disorganization of growth plate architecture and to dwarfism. Chondrocyte proliferation, assessed by BrdU or PCNA labeling, was reduced. Apoptosis and differentiation of growth plate chondrocytes were not affected, however. Integrin-mediated adhesion of primary cultures of chondrocytes from mutant animals to collagen type II was severely impaired. At the molecular level, ILK inactivation in chondrocytes reduced phosphorylation of PKB/Akt on serine 473 and inhibited cyclin D1 expression. These results confirm that PKB/Akt is a physiologically relevant substrate of ILK and show that ILK inactivation in chondrocytes has dramatic consequences for chondrocyte proliferation and growth plate development.

F031

CTGF/Hcs24, a Hypertrophic Chondrocyte-Specific Gene Product, Stimulates Proliferation and Differentiation but Not Hypertrophy of Cultured Articular Chondrocytes. T. Nishida*[1], S. Kubota*[1], T. Nakanishi*[1], T. Kuboki*[2], G. Yosimichi*[1], S. Kondo*[1], M. Takigawa[1]. [1]Department of Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Department of Oral and Maxillofacial Rehabilitation, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan.

Connective tissue growth factor/hypertrophic chondrocyte-specific gene product 24 (CTGF/Hcs24), which is specifically expressed in hypertrophic zone of growth plate, plays a key role in the proliferation and differentiation of growth cartilage cells. Such effects on the cells suggest that CTGF/Hcs24 might also play a role in the function and maintenance of articular cartilage cells as well. However, the effects of CTGF/Hcs24 on articular cartilage cells have not been studied yet. In this study, we investigated the effects of CTGF/Hcs24 on the proliferation and differentiation of rabbit articular cartilage (RAC) cells in vitro. RAC cells transduced by recombinant adenoviruses generating mRNA for CTGF/

Hcs24 synthesized more proteoglycan than the control cells. Also, treatment of RAC cells with recombinant CTGF/Hcs24 (rCTGF/Hcs24) increased DNA and proteoglycan syntheses in a dose-dependent manner. Northern blot analysis revealed that the rCTGF/Hcs24 stimulated the gene expression of type II collagen and aggrecan core protein, which are markers of chondrocyte maturation, in both rabbit growth cartilage (RGC) and RAC cells. However, the gene expression of type X collagen, a marker of hypertrophic chondrocytes, was stimulated by rCTGF/Hcs24 only in RGC cells, but not in RAC cells. Oppositely, gene expression of tenascin-C, a marker of articular chondrocytes, was stimulated by rCTGF/Hcs24 in RAC cells, but not in RGC cells. Moreover, rCTGF/Hcs24 effectively increased both alkaline phosphatase (ALPase) activity and matrix calcification of RGC cells, but not of RAC cells. These results indicate that CTGF/Hcs24 promotes the proliferation and differentiation of articular chondrocytes, but does not promote their hypertrophy or calcification. Taken together, the data show that CTGF/Hcs24 is a direct growth- and differentiation factor for articular cartilage and suggest that it may be useful for the repair of articular cartilage.

F033

Regulation of Chondrogenesis by Nuclear Factor of Activated T Cells (NFAT) and p38 MAP Kinase. M. Tomita*, M. C. Naski. Pathology, University of Texas Heailth Science Center at San Antonio, San Antonio, TX, USA.

Elevation of intracellular calcium triggers cell growth and differentiation in many cell types. Calcium signals lead to the activation of the phosphatase calcineurin. Calcineurin, in turn, dephosphorylates the transcription factor family, nuclear factor of activated T cells (NFATs). Dephosphorylation of NFATs results in translocation from the cytoplasm to the nucleus and subsequently regulation of gene expression. We report here that the calcium/calmodulin-dependent phosphatase calcineurin and NFATs, contributes to early chondrogenesis using two different culture systems. In the chondroblast clone RCJ 3.1C5.18 (C5) the calcium ionophore, ionomycin, induced aggrecan gene expression. Additionally, induction of aggrecan expression was inhibited following the addition of the calcineurin inhibitor; cyclosporineA. A physiological inhibitor of calcineurin, CAIN, also inhibited the induction of aggrecan by ionomycin. Using the mouse limb bud culture assay, we showed that ionomycin augments chondrogenesis as demonstrated by increased numbers of alcian blue staining cartilage nodules. Furthermore, cyclosporine A blocked the differentiation of limb bud mesenchyme. These data indicate that ionomycin induces chondrogenesis and aggrecan expression through a calcineurin-dependent pathway. Because calcineurin can regulate NFAT activity, we hypothesized that NFATs may contribute to aggrecan gene expression. To test this we overexpressed NFATc3 and NFATc4 in C5 cells. We found that NFATc3, but not NFATc4, can induce aggrecan gene expression. NFATs frequently regulate gene expression cooperatively with other transcriptional regulators, such as AP1, GATA, etc. In addition, while an activated form of calcineurin A upregulated aggrecan gene expression, the magnitude of gene induction was not as great as that observed with ionomycin, suggesting that other calcium-dependent regulatory pathways, in addition to NFATs, may contribute to aggrecan expression. Consistent with this we observed that the p38 MAP kinase inhibitor, SB203850, inhibited ionomycin-induced aggrecan expression in C5 cells. Furthermore, SB203850 diminished the number of alcian blue staining cartilage nodules in the limb bud culture system. Taken together, we conclude that intracellular calcium activates both the calcineurin/NFAT and MAP kinase-signaling axis during chondrogenesis.

Increased Bone Mass in Proline-Rich Transcript of the Brain (prtb)-Deficient Mice. D. W. Sommerfeldt[1], M. Priemel[1], X. Wang*[2], M. Amling[1], T. Schinke[1], M. Hadjiargyrou[3], S. L. Mansour*[2], J. M. Rueger[1]. [1]Trauma and Reconstructive Surgery, Hamburg University Hospital, Hamburg, Germany, [2]Human Genetics, University of Utah, Salt Lake City, UT, USA, [3]Biomedical Engineering, State University of New York at Stony Brook, Stony Brook, NY, USA.

Prtb (Proline-rich transcript of the brain) is a recently discovered gene encoding a novel protein expressed in the brain of adult mice. Using differential display-PCR we found that prtb is also expressed in osteoblasts where its expression is upregulated during serum exposure and adhesion to various substrates. To determine whether prtb plays a physiologic role during bone remodeling in vivo, we analyzed the bones of prtb-deficient mice using static and dynamic histomorphometry. Initial contact radiography of 10 week-old prtb-/- mice, which have no gross pathological abnormalities, demonstrated an increase in bone density. Static histomorphometry confirmed a 41%-increase in bone mass within the spine of prtb-/- mice as compared to wildtype controls (17.85 ± 1.12 % vs. 12.7 ± 2.01 %, $p<0.001$). Surprisingly, bone cell number and bone cell surface indices were nearly identical between the two groups. In contrast, dynamic histomorphometry after fluorochrome labeling revealed a significant increase in bone formation rate in prtb-/- mice compared to wildtype littermates (223.79 ± 76.42 mm3/mm2/y vs. 144.61 ± 39.08 mm3/mm2/y, $p<0.05$). These findings suggest that the bone phenotype in prtb-deficient mice is due to a functional change of osteoblast activity and not due to an effect on bone cell differentiation and/or survival. Taken together, our data demonstrate that in adult mice the prtb gene is selectively expressed in brain and bone and that prtb-deficiency leads to an increased bone mass in mice due to increased bone formation.

F038

Temporospatial Expression of BIG-3 During Endochondral and Intramembranous Ossification. F. Gori, M. B. Demay. Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA.

Osteoblastic differentiation is a complex process controlled by a wide variety of factors including the family of the bone morphogenetic proteins (BMPs). We recently identified a novel BMP-2 induced gene, named BIG-3 (BMP-2 Induced Gene 3kb), that dramatically accelerates the program of osteoblastic differentiation in stably transfected MC3T3E1 cells. BIG-3 encodes a protein that belongs to the WD-40 family of proteins. The members of this family of proteins contain 4-17 WD repeats that form a characteristic beta-propeller structure that forms a scaffold for protein-protein interactions required for a wide variety of cellular functions including signal transduction, mRNA processing, gene regulation and the cell cycle. BIG-3 contains seven WD repeats, a C-terminal region of 3 amino acids, and a N-terminal domain of approximately 40 amino acids. We postulate that the N-terminal domain serves to determine the subcellular localization of the BIG-3 protein and thus regulates its function. Thus, we undertook studies to examine the subcellular localization of BIG-3 by immunohistochemistry and confocal microscopy. We have raised antibodies to an epitope that includes the sequences in the seventh WD repeat of BIG-3. Following affinity purification of serum on a peptide column, the purified anti-BIG-3 antibody recognized a single band of the correct size on Western analyses. Confocal microscopy using MLB13MYC clone 17 cells and MC3T3E1 cells showed that BIG-3 has a punctate cytoplasmic distribution. To further characterize this novel protein, we investigated the temporospatial expression of BIG-3 during endochondral and intramembranous bone formation from 13.5 to 18.5 days post coitus (dpc) embryos. In the developing tibia, BIG-3 was first detected at 13.5 dpc. By 16.6 dpc, BIG-3 was highly expressed in the proliferating and hypertrophic chondrocytes as well as in the cortical osteoblasts. BIG-3 was also present in osteoblasts of calvaria from embryonic day 14.5 to 18.5. Our data demonstrate that BIG-3 is a cytoplasmic protein and is developmentally expressed in cartilage and osteoblasts during endochondral and intramembranous ossification, suggesting that this novel WD-40 protein plays a developmental role in both endochondral and intramembranous bone.

F040

Haploinsufficiency of NF1 Tumor Suppressor Gene, Increases Osteopontin Expression snd Impairs Bone Strength, but Not Bone Mass in a Mouse Model of Neurofibromatosis Type 1. X. Yu*[1], O. Potter*[2], J. Milas[1], S. Murthy*[1], S. Chen*[3], D. W. Clapp*[3], J. M. Hock*[1]. [1]Anatomy & Cell Biology, Indiana University, Indianapolis, IN, USA, [2]Biology, Purdue University, West Lafayette, IN, USA, [3]Pediatrics, Indiana University, Indianapolis, IN, USA.

Impaired bone healing and osteoporosis occur in up to 50% of humans with Neurofibromatosis Type 1 (NF1). The loss of neurofibromin, which negatively regulates *p21*-ras, in NF1 results in constitutive activation of ras signal transduction in targeted cells. To better understand how NF1 affects bone homeostasis, we studied the skeletal biology of *Nf1* heterozygote mice (*Nf1* +/-), which model several features of human NF1. The skeletal phenotype was defined by bone mass, bone strength and bone histomorphometry. Cell biology was characterized as proliferation, apoptosis, osteoblast commitment (ALP+ CFU-f) of metaphyseal bone cells and diaphyseal bone marrow stromal cells, and ex vivo induction of osteoclasts (TRAP+ multinucleated cells) from spleen or bone marrow cells exposed to RANKL and M-CSF. Molecular characterization was based on RT-PCR of selected proteins in whole bone, metaphyseal bone cells and bone marrow stromal cells. Bone mass (BMD, BMC, XA and ash weight) and trabecular bone histomorphometry were equivalent in *Nf1*+/- and intact control mice. Biomechanical properties of strength (ultimate force and stiffness) were altered in female *Nf1*+/- mice; cortical bone formation was decreased in *Nf1*+/- males but with no detrimental effects on male bone strength. Osteoprogenitor proliferation, apoptosis and osteoblast commitment were all significantly impaired in *Nf1* +/- mice, while ex vivo induction of osteoclasts was increased and further enhanced by PTH and 1,25(OH)2D3. Osteopontin (OPN) expression increased in bone marrow stromal cells, but was equivalent to intact controls in whole bone, metaphyseal bone cells and osteoclasts. Immunohistochemistry showed OPN in bone marrow stromal cell cultures and increased OPN in epiphyseal bone of *Nf1*+/- mice. Expression of type I collagen, alkaline phosphatase, PTH1-receptor, RANKL and osteoprotegerin was equivalent in whole bones and primary bone cells from *Nf1* +/- mice and intact controls. In summary, haploinsufficiency of NF1 increased OPN expression in bone marrow cells, altered osteoprogenitor and osteoclast induction in vitro, and, in vivo, impaired biomechanical strength properties, in the absence of effects on bone mass. As bone marrow stromal cells support bone cell homeostasis, altered OPN may perturb bone cell functioning, resulting in detrimental effects on biomechanical properties of bone strength.

F042

β-Catenin Directly Activates Bone-Specific Genes in Osteoblasts and Chondrocytes. M. Zhao[1], J. Zhang*[2], J. Q. Feng[2], B. Oyajobi[1], S. E. Harris[2], G. R. Mundy[1], D. Chen[1]. [1]Molecular Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]Oral Biology, University of Missouri, Kansas City, MO, USA.

Recently, several lines of evidence have implicated the role of β-catenin in osteoblast differentiation and bone formation. Wnt/LRP5 signaling has been associated with bone mass and LRP5 activates downstream β-catenin, which is likely involved in this process. However, the precise molecular mechanism by which β-catenin stimulates osteoblast differentiation is unknown. Thus, we examined the effects of β-catenin (constitutively active form) on the transcription of bone-specific genes. The sequences of Runx2/Cbfa1, type I collagen, osteopontin, dentin matrix protein 1, BMP-2 and type X collagen promoters were analyzed and putative TCF response elements were found in these promoters. When these promoters were co-transfected with β-catenin and TCF-4 expression plasmids in pluripotent fibroblast C3H10T1/2 cells, myoblast/osteoblast precursor C2C12 cells, osteoblast precursor 2T3 cells and chondrocyte TMC-23 cells, β-catenin/TCF-4 stimulated transcription of all these genes 3-8 fold. Co-transfection of an expression plasmid of Inhibitor of β-catenin (ICAT) completely blocked promoter activity induced by β-catenin/TCF-4. Mutation of the TCF response element in the osteopontin promoter reduced basal promoter activity over 50% and β-catenin/TCF-4 failed to activate the osteopontin promoter with the mutated TCF response element. Co-transfection of an F-box deleted dominant-negative mutant of the murine E3 ligase FWD1, which protects the proteasome degradation of β-catenin, greatly enhanced the activity of wild-type β-catenin to activate these bone-specific genes. Transfection of β-catenin and TCF-4 increased ALP activity in C3H10T1/2 and TMC-23 cells. We also examined the expression pattern of β-catenin in bone tissues by in situ hybridization. Strong expression of β-catenin mRNA in growth plate chondrocytes and articular chondrocytes and expression in trabecular and cortical bones were observed in 2-week-old mice. Our findings demonstrate that β-catenin stimulates transcription of Runx2/Cbfa1, but in addition also directly stimulates the transcription of a number of other osteoblast and chondrocyte-specific genes.

COX-2 Dependent PGE2 Cooperates with BMP-2 to Enhance Osteoblast Differentiation Through the Induction of CBFA-1 and Osterix. X. Zhang, E. Schwarz, E. Puzas, R. Rosier, R. O'Keefe. Orthopaedics, University of Rochester Medical Center, Rochester, NY, USA.

We have previously demonstrated an important role of COX-2 in fracture repair and bone healing. To elucidate the mechanism we utilized bone marrow stromal cells from wild type and COX-2 -/- mice and examined the expression of CBFA-1 and Osterix, by real time PCR analysis. We found that CBFA-1 was slightly reduced in COX-2 -/- cells, whereas Osterix gene expression was reduced by about 49+12% ($p<0.05$). Accordingly, osteocalcin gene expression was reduced by about 72+15% ($p<0.05$). The COX-2 -/- cultures had a defect in nodule formation and this was completely restored by addition of PGE2. In these COX-2 -/- cultures with PGE2, CBFA-1 gene expression was increased 2.5 fold and Osterix gene expression was restored to the wild type levels. To examine whether BMP-2 is regulated by COX-2, we examined BMP-2 mRNA expression in these cultures. We found that BMP-2 expression in the knockout and wild type cells was similar, however, exogenous PGE2 stimulated BMP-2 mRNA expression in COX-2-/- cells by 2.1 fold. In comparison with wild type cells, COX-2 -/- cells also had an increased induction of CBFA-1 by BMP-2, indicating that a compensatory mechanism may have developed in the COX-2 -/- mice with increased BMP-2 responsiveness. Exogenous PGE2 has been reported to increase bone nodule formation in low density cultures of rat bone marrow cells. In our experiments with low density mouse marrow stromal cells culture (0.5-1X106/10cm2), we found that PGE2 increased the total cell number and the number of alkaline phosphatase positive colonies in both wild type and knockout cultures by about 2 fold on day 10. However, in these experiments, PGE2 induced CBFA-1 and Osterix expression only after 17 days of cultures. On day 13, no significant changes in CBFA-1 and Osterix gene expression were noted in both COX-2-/- and wild type cultures with PGE2. In contrast, if BMP-2 was added with PGE2, a 5-10 fold synergistic induction of CBFA-1,Osterix and Osteocalcin gene expression was observed. This result demonstrated that PGE2 can cooperate with BMP-2 to enhance osteoblast differentiation through the induction of CBFA-1 and Osteix. Taken together, we propose that PGE2 is capable of regulating osteoblastogenesis by regulating BMPs and/or by cooperating with BMP-2 in the local milieu. Our data support a model in which the role of COX-2 is limited in skeletalogenesis, but is required for mesenchymal stem cell differentiation in bone healing process in which COX-2 and its metabolites are highly expressed.

Chondromodulin-I Is a Positive Regulator of Bone Remodeling. Y. Nakamichi*[1], C. Shukunami*[2], T. Yamada[1], K. Aihara*[1], H. Kawano[3], Y. Nishizaki*[2], T. Sato*[1], Y. Yamamoto*[1], M. Shindo*[1], K. Yoshimura*[1], H. Kawaguchi[3], Y. Hiraki*[2], S. Kato[1]. [1]Laboratory of Nuclear Signaling, Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan, [2]Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Japan, [3]Orthopaedic Surgery, University of Tokyo, Tokyo, Japan.

Chondromodulin-I (ChM-I) is a 25 kDa glycoprotein generated from a larger typeII transmembrane precursor protein after post-translational modification and proteolytic cleavage at the processing signal site. ChM-I is mainly expressed in proliferating and prehypertrophic zone of cartilage and also ,to a lower extent, in eye and thymus. In vitro analyses of ChM-I have shown growth promoting activity of chondrocyte and inhibitory activity of angiogenesis. ChM-I also stimulated osteoblast proliferation and reduced ALPase activity of osteoblasts. ChM-I is a multifunctional growth regulator depending on the target cell type and seemed to be implicated in both cartilage growth and endochondral bone formation. To investigate the biological roles of ChM-I in vivo, we have generated ChM-I Knockout (KO) mice. ChM-I KO mice grew normally with no discernible physical defects and with normal fertility. ChM-I KO mice also exhibited no overt aberrations in cartilage development and endochondral bone formation at various pre- and post-natal stage. However, a significant increase (10%) in radiological bone mineral density was observed in 12-week-old ChM-I KO mice. Histomorphometric analysis showed trabecular bone volume (BV/TV) in ChM-I KO mice were 2.5-fold higher than in wild-type mice. Both bone formation (Ob.S/BS, MAR & BFR) and bone resorption indicators (Oc.N/B.Pm , Oc.S/BS & ES/BS) were reduced in ChM-I KO mice compared to wild-type mice. Reduced (20%) serum marker levels (ALPase activity and osteocalcin) and no alteration in serum minerals (Ca, P) in ChM-I KO mice supported the hypothesis that bone formation activity was reduced by ChM-I inactivation. The increased bone mineral density in ChM-I KO mice appeared to be due to lowered bone resorption with respect to bone formation. These results demonstrated that ChM-I is likely to be a positive regulator of bone remodeling through control of osteoclast and osteoblast functions rather than being involved in cartilage development.

F048

Functional Role of Acetylcholinesterase in Cranial Development. C. A. Inkson[1], T. Evron*[2], H. Soreq*[2], E. Duysen*[3], O. Lockridge*[3], P. Genever[1]. [1]Biology, University of York, York, United Kingdom, [2]Hebrew University of Jerusalem, Jerusalem, Israel, [3]University of Nebraska, Omaha, NE, USA.

Although best known for its role in cholinergic neurotransmission, Acetylcholinesterase (AChE) is a multifunctional protein that plays fundamental roles in cell differentiation, proliferation and adhesion in a variety of tissues including bone. The AChE gene undergoes complex translational and post translational modifications resulting in 3 different AChE isoforms, AChE-S (synaptic), AChE-E (erythrocytic) and AChE-R (readthrough). Previously we identified expression of all AChE isoforms in bone and demonstrated that AChE can function as a bone matrix protein and regulate osteoblast differentiation and adhesion. Here we provide evidence of a fundamental role for AChE in murine cranial development. By immunohistochemistry using a pan-specific antibody to AChE, we have shown that AChE is expressed in the condensing mesenchyme of developing calvaria during rat embryogenesis and is present in periosteal osteoblasts and throughout the midsutural mesenchyme in neonatal rat calvaria. Using ex-vivo cultures of primary osteoblasts extracted from neonatal rat calvaria, we demonstrated that application of bFGF and TGF-beta 1, key regulators of cranial development, caused marked increases in AChE expression. Four lines of transgenic mice were used to determine the functional role of AChE during skull development in vivo: mice overexpressing two different isoforms of AChE (AChE-S and AChE-R); mice expressing antisense for AChE (AChE-AS) and AChE knock out mice (AChE-KO). Whole mount skeletal staining with alizarin red and alcian blue on postnatal day 3 transgenics revealed delayed closure of sagittal and lambdoidal sutures in AChE-R, AChE-AS and AChE-KO mice compared to wild-type controls. Furthermore, histological analysis of calvariae from AChE-KO mice of various ages demonstrated reduced calvarial width compared to wild-type littermates. These observations were supported by radiographic analyses of AChE-KO mice, which indicated a reduced bone density throughout the skeleton but most significantly in the skull. Immunolocalisations for homeobox proteins involved in craniofacial patterning, Msx2 and Dlx5, using sections taken from AChE-KO mice calvariae indicated apparent normal expression patterns when compared to wild type mice. These data demonstrate a significant role for AChE in mammalian cranial development and may identify a previously unrecognised component of suture patterning and formation.

F052

Bone Sialoprotein (BSP) Promotes Invasion by Osteotropic Cancer Cells Through an RGD Dependant Mechanism. A. Karadag[1], A. Jain*[2], N. S. Fedarko[2], L. W. Fisher[1]. [1]Nidcr, National Institutes of Health, Bethesda, MD, USA, [2]Department of Medicine, Johns Hopkins University, Baltimore, MD, USA.

BSP is a member of the SIBLING (Small Integrin-Binding LIgand, N-linked Glycoproteins) family of proteins that also include, osteopontin, MEPE, DMP1 and DSPP. Each contains the integrin-binding tripeptide, Arg-Gly-Asp (RGD), as well as several conserved phosphorylation and N-glycosylation sites. We and others have previously reported that BSP levels are elevated in both the tissues of many tumors and in the serum of patients with breast, prostate, and thyroid cancers. In order to investigate whether the increased BSP levels are associated with metastatic ability of these cancer cells, we have modified the Boyden-chamber invasion assay and investigated the ability of a number of cancer lines to invade through Matrigel, an artificial basement membrane. The cells treated with BSP (4-20μg/ml), BSP with its RGD modified to KAE (Lys-Ala-Glu), or vehicle were placed on the upper chamber of transwell inserts and media conditioned by NIH-3T3 cells were placed at the lower chamber as a chemoattractant. After incubation for 6-24h, the cells that had migrated through the Matrigel layer were labeled with calcein and quantified using a fluorescence plate reader. Both prostate cancer cell lines treated with BSP, PC-3 and DU-145, showed a 3.5-fold increased invasion level over that of the untreated cells ($p<0.01$). Interestingly, the invasion level is 5.5-fold higher when compared to the cells treated with BSP-KAE ($p<0.01$). Breast cancer cell lines, MDA-MB-231, MDA-MB-435S, LCC-15, and MCF-7, showed a 12.6-, 3.1-, 17.6- and 31.6-fold increases respectively when compared to vehicle alone ($p<0.01$), and all of the values were higher when compared to the same cells treated with BSP-KAE ($p<0.01$). Similarly, a lung cancer cell line (NCI-H520) and a thyroid cancer cell line (SW-579) showed a 3.1- and 6-fold increase in invasive activity (over vehicle) with BSP ($p<0.01$) and 10.5- and 17.7-fold increase

respectively when compared to the BSP-KAE treated cells ($p<0.01$). In conclusion, many tumor cell lines are made more aggressive by the addition of recombinant BSP and less aggressive if the BSP has its RGD mutated to KAE. We have previously shown that BSP caused the release of proMMP-2 from marrow stromal fibroblasts and that it could bind and activate proMMP-2. Therefore, we propose that the BSP made in many types of tumors may be accentuating the invasive properties of the cells by releasing and activating MMP-2 through an RGD-dependent mechanism. Furthermore, this mechanism can be foiled by the addition of recombinant BSP-KAE that can bind proMMP-2 but not its integrin.

F054

Osteopontin-deficiency Not Only Suppresses Bone Destruction by the Invasion of Melanoma Cells But Also Preserves Newly Formed Marrow Bone After Ablation. Y. Ohyama*[1], Y. Nemoto[1], S. Rittling[2], K. Tuji[1], D. T. Denhardt[2], A. Nifuji[1], M. Noda[1]. [1]Molecular Pharmacology, Medical Resarch Institute, Tokyo Medical & Dental University, Tokyo, Japan, [2]Piscataway, Rutgers University, New Jersey, NJ, USA.

Osteopontin is an RGD-containing protein and is recognized by integrin family members. Osteopontin promotes cell attachment to bone, which is abundant in this protein. As osteopontin levels were reported to be elevated in patients bearing highly metastatic tumors, osteopontin has been implicated in the metastasis of tumors. However, the effect of osteopontin on the invasion of tumor cells in bone microenvironment has not been clear. The purpose of this paper is to elucidate the role of host osteopontin in the invasion of tumor cells in bone. Bone marrow ablation was conducted in the femora of mice and B16 melanoma cells were injected directly into the ablated bone marrow space of the osteopontin-deficient and wild type mice to examine the behavior of the tumor cells in bone. Invasion foci of B16 melanoma cells in the cortical bone were observed seven weeks after tumor cell implantation. The number of the foci was five-fold less in osteopontin-deficient mice compared to that in wild type. Trabecular bone was formed within a week of ablation. However, in wild type mice, tumor cells occupied the marrow and the remaining trabecular bone was destructed and not observed. In contrast, a significant amount of trabecular bone was remained in osteopontin-deficient mice as these trabecular bone was not resorbed compared to wild type mice. These observations indicated that the absence of osteopontin prevented tumor cell invasion after implantation of tumor cells into the bone marrow space. To examine cellular mechanisms of these observations, cocultures of bone marrow cells using B16 cells and bone marrow cells were conducted. While the presence of B16 cells promoted TRAP positive cell development in wild type bone marrow cells, varying levels in the enhancement of TRAP-positive cell formation by B16 cells were observed in the case of bone marrow cells from osteopontin-deficient mice. Thus, bone resorbing function of osteoclasts in response to tumor cell invasion in the local environment is impaired in osteopontin-deficient mice.

F056

Identification of Proteolytic Cleavage Sites in Latent TGFβ Binding Protein-1 that may be Responsible for Release of TGFβ During Bone Matrix Degradation. S. L. Dallas*[1], L. F. Bonewald[1], C. Barley*[2], Q. Chen*[1], J. Guthrie*[3]. [1]Oral Biology, University of Missouri, Kansas City, Kansas City, MO, USA, [2]Biochemistry, University of Manchester, Manchester, United Kingdom, [3]Midwest Research Institute, Kansas City, MO, USA.

Latent TGFß binding proteins (LTBPs) are large extracellular glycoproteins that bind to TGFßs and regulate their activity. We have previously shown that LTBP1 targets latent TGFß to bone extracellular matrix (ECM) for storage and that proteolytic cleavage of LTBP1 by osteoclasts and by osteolytic bone metastatic breast cancer cells provides a mechanism for release of latent TGFß from bone ECM. To determine the protease cleavage sites important for release of LTBP1 from bone ECM, a recombinant protein expression approach was used. LTBP1 fragments spanning the complete molecule were expressed using a modified pCEP4 episomal mammalian expression vector, engineered with a BM40 signal sequence and a 6 or 10 His epitope tag. Using this vector system, milligram amounts of recombinant fragments were obtained. Our previous studies suggested the involvement of serine proteases and matrix metalloproteinases in release of LTBP1 from bone matrix by osteoclasts and breast cancer cells. We therefore performed proteolytic cleavage studies using purified plasmin, MMP2 and MMP9. An LTBP1 fragment spanning 413 to 545 (termed the "hinge domain" due to its predicted flexibility) was cleaved by both plasmin and MMP2. A recombinant fragment spanning amino acids 526 to 1014, consisting of a long stretch of epidermal growth factor-like repeats, proved to be very resistant to cleavage with any of these proteases. A C-terminal fragment, 1008 to 1394, was cleaved by plasmin. Western blotting showed that the larger proteolytic fragment from this plasmin cleavage no longer expressed the His tag. By MALDI-TOF mass spectroscopy of a tryptic peptide mass map, it was determined that all peptides after residue 1285, including the His tag were missing. Edman sequencing confirmed that the N-terminus was still intact, suggesting that the cleavage site is located between 1285 and 1394. Edman sequencing of the smaller plasmin proteolytic fragment confirmed that plasmin cleavage occured on the carboxy side of Arg1285. These studies show that plasmin specifically cleaves the carboxy terminal fragment of LTBP1 at position 1285 and that amino acids 526 to 1014 of LTBP1 are protease resistant, which may protect latent TGFß from inappropriate activation. Specific cleavage of the hinge fragment 413 to 545 by plasmin and MMP2 may play a role in release of latent TGFß from bone ECM, potentially the first step in the pathway by which ECM-bound TGFß is rendered active.

Mechanism of Mechanical Stress-induced Activation of AP-1/IL-11 Transcriptional Cascades. D. Inoue, S. Kido, T. Matsumoto. Department of Medicine and Bioregulatory Science, University of Tokushima, Tokushima, Japan.

Mechanical stress to bone plays a critical role in maintaining bone mass and strength. We have shown that deltafosB, a fosB splicing variant, and an AP-1 target interleukin (IL)-11, both of which have been shown to stimulate bone formation in vivo when overexpressed in transgenic mice, are rapidly induced by reloading in tail-suspended mouse tibiae and femurs as well as by fluid shear stress (FSS) in cultured primary osteoblasts (POB). The induction of deltafosB and IL-11 expression was dependent on an intracellular calcium rise and ERK activation but independent of prostaglandin synthesis. In the present study, we further attempted to delineate the mechanism of AP-1/IL-11 induction. Pre-treatment with an transcriptional inhibitor, DRB, completely abolished the induction of deltafosB and IL-11 mRNA by FSS in POB, suggesting a requirement for ongoing transcription. We then cloned and analyzed the upstream regulatory region of the mouse fosB gene. Analysis with luciferase reporter assays revealed that FSS indeed increased transcriptional activity of a 1 kb fosB promoter fragment by two to three fold and that SRE at -428 and juxtaposed AP-1 like sequences are mainly responsible for the response to FSS. We also confirmed that IL-11 transcription is induced by FSS in both transient and stable transfection experiments using IL-11 promoter-luc constructs. The results indicated that the two tandem AP-1 sites, playing a critical role in both basal and TGF-beta-induced IL-11 transcription, conferred the response to FSS. Furthermore, although all the four fos family members were induced by FSS in vitro, we found that only c-fos and fosB/deltafosB preceded IL-11 in kinetic studies and that c-fos was dispensable for FSS-induced fosB/deltafosB and IL-11 mRNA expression using c-fos gene-deleted mouse osteoblasts, supporting a critical role for fosB/deltafosB in IL-11 induction. Interestingly, we observed that BMP increased IL-11 promoter activity in ST2 cells stably expressing luciferase under the control of 1.7 kb long IL-11 promoter fragment and endogenous IL-11 expression by C3H10T1/2 cells. Consistent with a cross-talk between Smads and AP-1, we found that FSS induced Smad1 phosphorylation and Smad4 nuclear translocation within 30 min in POB and that deltafosB, but much less (long)fosB, co-immunoprecipated with Smad1 when overexpressed in Cos cells. Collectively, our results suggest that mechanical stress activates an AP-1(deltafosB)/IL-11 transcriptional cascade contributing to enhanced bone formation, and participation of Smad signaling in this cascade may explain its bone specificity.

F061

Microcrack Matrix Strain Is 15 Times Greater than Average Global Strains; Implications for Osteocyte Signaling. D. P. Nicolella*[1], L. F. Bonewald[2], J. Lankford*[1]. [1]Materials Engineering, Southwest Research Institute, San Antonio, TX, USA, [2]Department of Oral Biology, University of Missouri at Kansas City, Kansas City, MO, USA.

Microdamage in bone occurs naturally as a result of normal functional in-vivo loading. In healthy bone, microdamage is repaired via the bone remodeling process, whereby osteoclasts specifically target regions of damaged bone matrix. Although the underlying mechanisms controlling this process are unknown, osteocytes are hypothesized to be essential in initiating and controlling this process. Several current theories link bone remodeling to biochemical signaling by the osteocyte in response to strain generated through deformation of the bone matrix or through fluid flow induced shear stresses. In-vivo bone matrix strains have been measured to be approximately 2,000 microstrain during rigorous physical activity. However, when applied in-vitro to osteoblastic cells via substrate stretching, this level of strain does not induce a significant biological response, whereas significantly higher levels of in-vitro substrate strain do. Alternatively osteoblastic and to a greater extent, osteocytic cells are more responsive to fluid flow induced shear stress than substrate strain in-vitro. However, fluid flow induced shear stress levels in bone in vivo have not been directly measured and are unknown. We hypothesize that compared to undamaged bone, microdamage results in a substantial increase in bone matrix strain in the surrounding area of the microcrack thus resulting in an altered mechanical signal to nearby osteocytes. We directly measured bone matrix strain in microdamaged bovine cortical bone at the microstructural level. The bone specimen was loaded in a specially designed microscopy load frame to specific levels of global mechanical strain while observed and imaged at high magnification using an optical microscope (Axioscope 2, Carl Zeiss Inc., NY). Strain fields associated with the microcrack and nearby osteocyte lacuna were measured by comparing loaded vs. unloaded image pairs using a custom image correlation system. Matrix strains at the tip of the microcrack reached 30,000 microstrain (3.0%) locally, up to 15 times greater than the average global strains measured in-vivo. Matrix strain in intact bone away from the microcrack was on the order of 2,000-3,000 microstrain. These results indicate that tissue strains acting on osteocyte lacunae associated with microdamage can be much greater than strain in undamaged bone and it is this high level of matrix strain that may cause osteocytes to initiate a remodeling response.

F064

A Novel Cathepsin K Inhibitor with Oral Activity in Rat and Monkey. M. Missbach[1], J. A. Gasser[1], K. Toriyama*[2], J. R. Green[1], T. Buhl*[1], H. Ishihara*[2], M. Kometani*[2], E. Altmann*[1], N. Teno*[2], R. Gamse[1], C. P. Jerome[3], R. Lattmann*[1], C. Betschart*[2]. [1]Novartis Pharma AG, Basel, Switzerland, [2]Novartis Pharma KK, Tsukuba, Japan, [3]SkeleTech Inc., Bothell, WA, USA.

The cysteine protease cathepsin K has been shown to be highly expressed in osteoclasts and to play an essential role in bone matrix degradation. The effects of a novel class of reversible inhibitors of cathepsin K on in vitro and in vivo assays of bone resorption have been examined. Inhibitors were identified based on a substrate analogue approach and further optimized to reveal potent compounds showing excellent specificity against cathepsins B, L and S. Compound 1 inhibits cathepsin K with Ki values of 3.3 nM (rabbit), 30 nM (rat) and 0.5 nM (human). It is highly specific with an IC50 of 2.5 nM for human cath K versus 4400 nM (cath B), 3700 nM (cath L) and >10,000 nM (cath. S). Cellular activity in vitro was demonstrated by the reduction of the total pit volume produced by rabbit osteoclasts on ivory slices (IC50 63±3.6 nM; mean±S.E., n=3). In vivo activity on bone resorption was tested in ovariectomised (OVX) rats treated orally with 50 mg/kg bid. Compound 1 reduced urinary deoxypyridinoline excretion by 85% after 2 weeks of treatment. In a separate experiment over 4 weeks, bone protection at the proximal tibia was 51% measured as cross-sectional BMD by pQCT. To confirm the ~60-fold higher potency on the human/monkey over the rat enzyme, compound 1 was evaluated in cynomolgus monkeys rendered estrogen deficient by a depot GnRH agonist. After administration of 5 mg/kg bid p.o. two serum markers of bone resorption, CTx and NTx, were reduced far below levels of the non-GnRH treated control group already at day 1. They remained depressed throughout treatment over 4 weeks and returned to normal within one day after the end of dosing. This is the first demonstration that an orally administered inhibitor of cathepsin K is able to potently and effectively reduce bone resorption markers in rats and monkeys and to partially protect BMD after ovariectomy in rats. Such compounds could represent a novel therapeutic approach for metabolic bone diseases like osteoporosis.

F066

Involvement of Collagenase-3 (MMP-13) in the Collagen Breakdown Required for the Excavation of the Cartilaginous Epiphysis of the Developing Rat Long Bone. E. R. Lee[1], L. Lamplugh*[1], B. Kluczyk*[1], J. S. Mort*[2], G. Murphy*[3], C. P. Leblond*[1]. [1]Electron Microscopy Unit, Shriners Hospital for Children, Montreal, PQ, Canada, [2]Joint Diseases Laboratory, Shriners Hospital for Children, Montreal, PQ, Canada, [3]School of Biological Sciences, University of East Anglia, Norwich, United Kingdom.

The formation of a secondary ossification center in the cartilaginous epiphysis of long bones requires the excavation of canals and marrow spaces and, therefore, the resorption of cartilage. On the assumption that the resorption requires the lysis of the major cartilage component, type II collagen, it was noted that this collagen was cleaved with high efficiency *in vitro* by collagenase-3. Such cleavage took place within the triple helix at the Gly^{775}- Leu^{776} bond to produce two fragments of itself at ¾ and ¼ the length of the original molecule. To find out if collagenase-3 produced the same cleavage in the epiphysis of the developing rat tibia, two affinity purified peptide antibodies were prepared; one against the amino acid sequence LAGQR… ending the N-terminus of the ¼ fragment of the cleaved collagen; the other against the sequence YNVFP…corresponding to the N-terminus of activated enzyme. With the aid of these antibodies we report here that the cleavage of type II collagen by collagenase-3 is localized to newly developed sites of cartilage erosion. Thus at 6 days of age, canals allowing the entry of capillaries are dug from the surface of the epiphysis (stage I), while immunostaining, indicative of the activated collagenase-3 enzyme or collagen cleavage fragments, appears at the blind end of each canal. By 8 days of age, the canal blind ends fuse to create a marrow space in the epiphysis (stage II), where the immunoreactivity produced by the two anti-peptide antibodies continues to coincide along the walls of the space. By 10 days of age, clusters of hypertrophic chondrocytes are scattered along the marrow space wall to initiate the formation of the secondary ossification center (stage III), where resorption sites are reactive to the anti-LAGQR but are unreactive to the anti-YNVFP antibodies. From 10-15 days the center keeps on enlarging and, as the secondary growth plate advances (stage IV), it is intensely immunostained with the anti-LAGQR but not the anti-YNVFP antibodies, indicating that the collagen has been cleaved, but not by collagenase-3. We conclude that collagenase-3 contributes to the lysis of collagen, but only at some sites and stages in the development of the tissue, particularly at early phases of excavation (stages I and II). This result implies that more than one collagenase is required to complete the excavation of a secondary center.

F069

Impaired In Vitro Osteogenesis and Defective Runx2 Activity in Multiple Myeloma Patients. J. J. Westendorf[1], K. Evenson*[2], R. A. Kahler*[3], X. Li*[1], A. M. Masellis*[2]. [1]Orthopaedic Surgery and Cancer Center, University of Minnesota, Minneapolis, MN, USA, [2]Virginia Piper Cancer Institute, Minneapolis, MN, USA, [3]Graduate Program in Cancer Biology, University of Minnesota, Minneapolis, MN, USA.

The bone marrow stroma contains a reservoir of mesenchymal progenitor cells (BMPCs) capable of osteogenesis in response to environmental cues such as growth factors/cytokines, cell to cell interactions and cell to extracellular matrix interactions. In individuals with the plasma cell malignancy multiple myeloma, there is evidence that bone formation rates are reduced and that increased ostoeclastic bone resorption is associated with impaired osteoblast function. The central hypothesis of our study is that impaired osteogenesis, resulting in defective mature osteoblast function, contributes to the formation of osteolytic bone lesions in multiple myeloma patients. Our data indicate that myeloma BMPCs exhibit decreased in vitro osteogeneic differentiation as compared to normal donors. BMPCs were cultured in osteogenic induction medium and assessed for bone alkaline phosphatase (ALP) expression and mineralization by immunohistochemistry, and for osteoblast specific markers by immunohistochemistry and Rt-PCR. Normal BMPCs showed a ten-fold increase in ALP levels, an induction of the osteocalcin transcript and a high degree of mineralization by day 21 in osteogenic induction medium. In contrast, myeloma BMPCs showed only a 1.3 fold increase in ALP and minimal mineralization at day 21. Because osteogenesis was impaired in myeloma-derived BMPCs, we analyzed Runx2 expression and activity in these cells. Runx2 (Cbfa1) is a transcription factor required for osteoblast formation. Immunoblot analysis indicated that Runx2 was expressed in both normal and myeloma-derived BMPCs. Runx2 DNA binding activity was easily detected in normal BMPCs; however it was significantly reduced in myeloma-derived BMPCs. Thus decreased Runx2 activity in BMPCs is directly correlated with decreased osteogenesis in myeloma patients. These data suggest that Runx2 activity is deregulated in BMPCs from myeloma patients. These studies provide novel cellular and molecular insights into the deregulation of bone formation in myeloma patients.

Molecular Mechanisms by which Proteasome Inhibition Reduces Myeloma Burden in Bone. B. O. Oyajobi, P. Williams*, A. Gupta*, A. Trauernicht*, M. Zhao, D. Chen, I. R. Garrett, G. R. Mundy. Molec Medicine, UTHSC, San Antonio, TX, USA.

Multiple myeloma (MM) is characterized by extensive tumor-induced osteoclastic bone destruction. Recently there have been reports that a proteasome inhibitor has striking therapeutic benefit in this disease and its bony complications. To determine mechanisms by which inhibition of the ubiquitin (Ub)-proteasome system reduces myeloma burden, we used the peptide aldehyde Z-Ile-Glu(OtBu)-Ala-Leu-CHO (Proteasome Inhibitor-1; PSI) as a tool. In syngeneic C57BL mice bearing subcutaneous 5TGM1 plasmacytomas, daily intratumoral injections of PSI (1mg/kg), after tumors were established significantly reduced tumor growth and induced dramatic regression of tumors in 50% of mice with marked apoptosis (assessed by standard morphological criteria) in PSI-treated tumors. In separate experiments, parenteral administration of PSI (5mg/kg/day; 28 days) prolonged time to onset of paraplegia in 5TGM1 MM-bearing mice inoculated via the tail vein. Flow cytometry of PSI-treated 5TGM1 and human RPMI 8226 MM cells revealed marked time- and dose-dependent induction of apoptosis (60-80%, Annexin V+/Propidium iodide-). In this regard, PSI was more potent (IC_{50} < 0.1μM) than other compounds with known proteasome inhibitory activity tested (MG132, epoxomicin, lactacystin, lovastatin) and was 2 log orders more potent than Risedronate. NF-κB activation promotes growth/survival of MM cells and since IκB degradation and consequently NF-κB activity, depends on proteasome function, we reasoned that proteasome inhibitors work through this transcription factor. Although parthenolide, an IκB kinase (IKK) inhibitor, also induced myeloma cell apoptosis it is unlikely that PSI acts by inhibiting IKK since TNFα (5ng/ml) still enhanced phospho-IκB levels in 5TGM1 and RPMI cells pretreated with 1μM PSI. Protein ubiquitination is mediated by an enzymatic cascade with substrate specificity due to E3 Ub protein ligases. As proteasome inhibitors have multiple potential targets, to directly assess the role of NF-κB blockade in myeloma apoptosis, the murine IκB-E3 ligase FWD1 and an F-box deleted dominant-negative mutant (FWD1ΔF), were transiently expressed in 5TGM1 cells. FWD1 expression in 5TGM1 cells reduced basal apoptosis levels compared to empty vector (EV) cells and there was no difference between them in response to TNFα. In contrast, apoptosis was increased in FWD1ΔF transfectants and TNFα further increased apoptosis (>30% vs untreated FWD1ΔF cells). Together, our data suggest that MM growth and behaviour in bone is dependent on nuclear translocation of NF-κB, and that inhibition of the Ub-proteasome pathway by PSI and other proteasome inhibitors works through this mechanism.

AML-1B Down-Regulates Macrophage Inflammatory Protein-1α (MIP-1α) Expression in Multiple Myeloma (MM) Cells. S. J. Choi*[1], T. Oba*[2], N. S. Callander*[3], D. Jelinek*[4], G. D. Roodman[2]. [1]Medicine/Hematology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [4]Mayo Clinic, Rochester, MN, USA.

High concentrations of MIP-1α are produced by MM cells in about 70% of patients and MIP-1α levels correlate with their disease activity and a poor prognosis. Furthermore, blocking MIP-1α expression in an in vivo model of human MM profoundly decreases both tumor burden and bone destruction, suggesting that MIP-1α is an important mediator of MM bone disease. To further analyze the regulation of MIP-1α production in MM, we cloned the hMIP-1α promoter and characterized its transcription factor (TF) motifs. The proximal region of hMIP-1α promoter was composed of two sets of identical transcription regulatory regions consisting of GATA-2+AML-1+C/EBPα sites. Since two alternatively spliced variants of the AML-1 class of TFs can bind the AML-1 region, AML-1A and AML-1B, we examined the relationship between the expression levels of AML-1A or AML-1B in MM cells with their capacity to express MIP-1α. AML-1A, AML-1B and MIP-1α mRNA expression levels were analyzed by RT-PCR using AML-1A, AML-1B, MIP-1α and GAPDH specific primers. AML-1A mRNA was relatively over-expressed compared to AML-1B in MM cell lines that produced high levels of MIP-1α (>1ng/ml / 10^6 cells / 72 hrs), but AML-1A was not increased in MM cell lines that expressed less than 200 pg/ml of MIP-1α. Furthermore, AML-1B mRNA levels were also decreased in marrow samples from MM patients that expressed increased amounts of MIP-1α. In contrast levels of AML-1A mRNA did not differ significantly between MM patients and normals. The average ratio of AML-1A to AML-1B mRNA in MM patients was 8-fold higher than in normals. To test the effects of AML-1A and AML-1B on MIP-1α expression in

MM cells, AML-1A and AML-1B cDNA constructs were transfected into ARH-77 MM cells. AML-1B totally blocked MIP-1α production by ARH cells, while AML-1A did not affect MIP-1α expression. Taken together, these data demonstrate that the relative levels of AML-1B are decreased in MM patients that produce increased concentrations of MIP-1α, and that transduction of AML-1B into MM cells totally blocks MIP-1α expression. These data further suggest that increasing AML-1B levels in MM cells may have beneficial effects on the bone destruction and tumor burden in MM patients.

Beta 3 Integrin -/- Mice are Protected From Osteolytic Bone Invasion. S. J. Bakewell*[1], N. R. Dowland*[2], K. N. Weilbaecher[2]. [1]Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]Medicine and Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Skeletal metastases are the cause of significant morbidity and mortality. Drugs that inhibit osteoclast (OC) function ameliorate both osteolytic and osteoblastic metastatic bone disease suggesting that OCs are involved in the pathogenesis of bone metastases. The beta 3 integrin subunit (β3) has been hypothesized to influence the development of metastases because of its critical role in osteoclastic bone resorption (αvβ3), tumor/platelet interactions (αIIbβ3 and αvβ3), and in tumor associated angiogenesis (αvβ3). To examine the role of the β3 integrin in skeletal metastases we utilized mice with a germline-targeted disruption of the β3 subunit gene ($\beta3^{-/-}$). The $\beta3^{-/-}$ mouse has diminished platelet aggregation mediated by αIIbβ3, and dysfunctional osteoclast resorption mediated by αvβ3. We established an in vivo model of bone metastasis using the B16 murine melanoma cell line (F10), which induces osteolytic bone metastases after tumor cell injection in the cardiac left ventricle (LV). After LV injection of B16 cells into β3 wild-type and heterozygous mice, extensive osteolytic bone lesions, pathologic bone fractures, spinal cord compression and histologic tumor invasion of the bone are observed in 87% of mice (n=46) after 14 days. However, after injecting $\beta3^{-/-}$ littermates (n=24), there is no evidence of osteolytic lesions or histologic evidence of tumor invasion in the bone. In fact, 23/24 $\beta3^{-/-}$ mice showed no histologic evidence of any tumor growth in the marrow cavity, and only 1/24 B16 injected $\beta3^{-/-}$ mice had a small focus of tumor cells growing in the marrow cavity. 18-fluorodeoxyglucose (18-FDG) Positron Emission Tomography (PET) of in vivo tumor activity/growth demonstrates extensive tumor activity in the spine of wild type mice at day 7 and 14 after B16 LV injection. In contrast, little 18-FDG tracer uptake was observed in saline injected wild type or tumor injected $\beta3^{-/-}$ littermates at days 7 and 14. In summary, osteolytic metastases are significantly impaired after LV injection of B16 tumor cells in $\beta3^{-/-}$ mouse compared to wild type littermate controls. Our data suggest that host cell β3 integrin expression facilitates the process of tumor cell metastasis to bone.

F079

Interleukin 8 Regulation of RANKL Is a Mechanism for the Metastatic Potential of Human Breast Cancer Cells. M. Bendre, T. Mon*, D. Gaddy-Kurten, L. J. Suva. Orthopaedics and Physiology and Biophysics, UAMS, Little Rock, AR, USA.

Metastasis is the process by which tumor cells spread from their site of origin to distant sites after gaining access to the circulatory system. An understanding of the factors contributing to the metastatic potential of breast cancer cells may enhance the prospect of developing new therapies. Using an in vivo selection scheme involving left cardiac ventricle injection into nude mice we previously identified a highly metastatic human breast cancer cell line (MDA-MET) from a less metastatic parental cell line (MDA-231). Complete microarray analysis identified the molecular fingerprint of gene expression in the metastatic (MDA-MET) versus non-metastatic (MDA-231) cells. An important molecular difference between MDA-MET and MDA-231 cells was the over expression by MDA-MET cells of the proangiogenic cytokine IL-8. Both RT-PCR and ELISA confirmed the increased expression of IL-8 in MDA-MET cells. The relevance of IL-8 expression in metastasis was demonstrated by its elevated expression in a variety of human cancer cell lines with an enhanced metastatic phenotype in vivo. Mining of the microarray data confirmed a lack of TGF-b-regulated PTHrP expression, no RANKL mRNA expression, and revealed the absence of IL-8 receptor (CXCR1 and 2) expression in MDA-MET cells. These experiments suggested that expression of other factors like IL-8 (and not PTHrP) by MDA-MET cells was related to their enhanced metastatic potential in vivo. As a result, we speculated that IL-8 expression by tumor cells in the bone marrow could directly regulate osteoclastogenesis by altering the RANKL:OPG ratio in osteoclast support cells. Testing this hypothesis, RT-PCR analysis of RANKL and OPG mRNA expression in murine osteoblastic MC3T3E1 cells showed that IL-8 markedly upregulated RANKL mRNA expression (within 6 hours), with no effect on OPG expression. Similarly, levels of RANKL protein were also increased after 24 hours of IL-8 treatment. These data suggest that in the early stages of the colonization of bone by breast cancer cells, the expression of cytokines such as IL-8 may be critical for tumor growth and the initial phase of tumor-activated bone resorption. Once osteoclastic bone resorption is increased, the normal products of bone resorption (such as TGF-b) would serve to further enhance osteoclast formation and bone resorption. These data implicate IL-8 (and potentially other unidentified factors) as important mediators of the process of breast cancer metastasis to bone.

F081

Over-expression of Native OPG by Breast Cancer Cells Enhances Tumor Growth in Bone. J. L. Fisher*[1], R. J. Thomas*[1], J. Elloitt*[1], C. R. Dunstan[2], P. F. M. Choong*[3], T. J. Martin[1], M. T. Gillespie[1]. [1]St. Vincent's Institute of Medical Research, Melbourne, Australia, [2]Amgen Corporation, Thousand Oaks, CA, USA, [3]Department of Orthopaedics, St. Vincent's Hospital, Melbourne, Australia.

Osteoprotegerin (OPG) acts as a decoy receptor for RANKL (receptor activator of NF-kB ligand), preventing it binding to its receptor, RANK, thereby inhibiting osteoclast formation and activation. We have previously demonstrated that OPG-Fc (22 – 194 aa) inhibits in vitro osteoclast formation stimulated by MCF-7 breast cancer-derived PTHrP. OPG-Fc also reduced the establishment of osteolytic lesions in a mouse model of tumor cell growth in bone following intratibial injection with MCF-7 cells over-expressing PTHrP. Since the local production of OPG may also be a means to limit tumor expansion in bone by preventing osteoclastogenesis, we transfected MCF-7 parental cells and MCF-7 cells overexpressing PTHrP with full-length cDNA for OPG (1 – 401 aa) in pCEP4. In vitro analysis demonstrated that over-expression of OPG in MCF-7 cells resulted in increased cell growth, in the presence or absence of PTHrP. Parental, vector control and MCF-7 cells over-expressing PTHrP, OPG or PTHrP plus OPG were injected into the proximal tibiae of athymic nude mice. The animals were monitored for 2.5 weeks, after which they were sacrificed and their limbs were assessed by radiology and histology. No osteolysis was observed radiologically following inoculation of the MCF-7 parental cells or the MCF-7 cells over-expressing OPG, although small intramedullary tumors were evident histologically in the latter group. Surprisingly, the MCF-7 cells over-expressing PTHrP and OPG developed larger tibial tumors than the MCF-7 cells over-expressing PTHrP alone (18.6 ± 3.1 % osteolysis as determined by radiology, compared with 9.0 ± 2.2 %, $p < 0.05$). The tumors overexpressing OPG also exhibited a change in histology, which was reflective of a less differentiated phenotype compared with MCF-7 cells over-expressing PTHrP. This increased tumor growth afforded by the over-expression of OPG was abrogated by treatment with OPG-Fc (2.5 mg/kg/day, subcutaneous) resulting in inhibition of tumor growth (2.5 ± 0.3 %, $p < 0.001$ compared with control). These results indicate that full-length native OPG exerts dramatically different actions on tumor behavior than OPG-Fc. These differences may relate to the death domains of native OPG or its intracellular expression.

F083

Clodronate Decreases the Incidence of Skeletal Metastases in Primary Breast Cancer - A Randomised, Placebo-Controlled Study. T. Powles*[1], E. McCloskey[2], A. Paterson*[3], J. Kanis[2], S. Ashley*[1], A. Tidy*[1], K. Rosenqvist*[4], I. Smith*[1], L. Ottestad*[5], S. Legault*[6], M. Pajunen*[7], A. Nevantaus*[1], S. Atula*[4], J. Nevalainen*[4], L. Pylkkänen*[4]. [1]Royal Marsden Hospital, London, United Kingdom, [2]Univ. of Sheffield, Sheffield, United Kingdom, [3]Tom Baker Cancer Centre, Calgary, AB, Canada, [4]Leiras, Helsinki, Finland, [5]Norwegian Radium Hospital, Oslo, Norway, [6]Montreal General Hospital, Montreal, PQ, Canada, [7]Central Hospital, Jyväskylä, Finland.

The development of bone metastases depends at least in part on tumour-induced osteoclastic resorption of bone. We wished to determine if the bisphosphonate, clodronate, could reduce the subsequent incidence of bone metastases when given to patients with primary breast cancer. This double blind, multicentre, trial accrued 1069 evaluable patients with primary operable breast cancer between 1989 and 1995. All patients received surgery, radiotherapy, chemotherapy and tamoxifen as required. Patients were randomised to receive oral clodronate 1600 mg/day or placebo for 2 years, starting within six months of primary treatment**.** The primary endpoint was relapse in bone, analysed on an intent-to-treat basis, during the medication period and during the total follow-up period (median follow-up 2007 days). Secondary endpoints were relapse in other sites, mortality and toxicity. During the total follow up period, there was a non-significant reduction in occurrence of bone metastases (63 clodronate, 80 placebo, HR 0.77, 95% CI 0.56 to 1.08, p=0.127). During the medication period there was a significant reduction in the occurrence of bone metastases (clodronate 12, placebo 28, HR 0.44, 95% CI 0.22 to 0.86, p=0.016). The occurrence of non-osseous metastases was similar (clodronate 112, placebo 128**,** p=0.257) but there was a significant reduction in mortality (clodronate 98, placebo 129, p=0.047) during the total follow up period. Clodronate, given to patients with primary operable breast cancer, reduces the occurrence of bone metastases, although this reduction was only significant during this medication period. There was a significant 23% reduction in mortality. The optimal duration of therapy needs to be addressed in future studies.

Prostate Cancer Cells Induce Osteoblastogenesis through Bone Morphogenetic Proteins (BMPs) and BMP-Mediated Autocrine Production of Vascular Endothelial Growth Factor (VEGF). J. Dai[1], J. Zhang[2], A. Mizokami*[3], E. T. Keller[2]. [1]Pathology/ULAM, University of Michigan, Ann Arbor,, MI, USA, [2]Pathology/ULAM, University of Michigan, Ann Arbor, MI, USA, [3]Department of Urology, University of Occupational & Environmental Health, Kitakyushu, Japan.

Advanced prostate carcinoma (CaP) is associated with osteoblastic bone metastases. Many factors are involved in osteoblast differentiation, including bone morphogenetic proteins (BMPs) and vascular endothelial growth factor (VEGF). The goal of this study was to determine if there is a relation between BMP and VEGF in prostate cancer-induced osteoblastogenesis. Using the C4-2B prostate cancer cell line, an androgen-independent bone metastatic cell line, we measured the effect of BMPs on VEGF expression. We first determined that C4-2B cells expressed BMP-2, BMP-6 and BMP-7 and VEGF. To determine if BMPs regulate VEGF expression in C4-2B cells, BMPs-2, -4, -6 and -7 were added to C4-2B cell cultures for 24 hours, all BMPs had increased VEGF in the culture supernatants as measured using ELISA. To determine if BMPs promote VEGF expression in C4-2B cells through an autocrine mechanism, the C4-2B cells were cultured in the serum-free medium plus Noggin, a BMP inhibitor. At 24 hours, Noggin had decreased VEGF expression in a dose-dependent manner. To determine if BMP controls VEGF expression through transcription, we transfected the VEGF promoter driving the luciferase reporter gene into the C4-2B cells then treated with BMPs and Noggin. BMP-2, -4, -6, and -7 induced promoter activity by 5-fold compared to basal levels. Noggin decreased basal luciferase activity by 70%. To determine if BMPs or VEGF could mediate prostate cancer-induced osteoblastogenesis, $SaOS_2$ cells and primary human osteoblast-like cells (HOB) were treated with C4-2B conditioned media (CM) plus Noggin or neutralizing anti-VEGF antibody. Alkaline phosphatase (ALPase) activity and osteocalcin (OCN) level in the supernatants was measured as indices of osteoblastogenesis. CM increased ALPase and OCN production by the $SaOS_2$ and HOB cells. Noggin decreased CM-induced ALPase and OCN levels by approximately 50-65% and 40-45%, respectively. Anti-VEGF antibody decreased CM-induced ALPase and OCN levels by approximately 27-32% and 26-39%, respectively. Combining Noggin and anti-VEGF antibody had no greater effect than Noggin alone. These findings indicate that C4-2B cells stimulate osteoblastogenesis through BMPs and VEGF secreted from C4-2B cells. Furthermore, the data demonstrate that VEGF expression is increased in C4-2B cells through autocrine activity of BMPs. These data suggest that BMPs play an important role in the development of prostate cancer osteoblastic metastases.

F087

NF-κB Mediates the Production of Osteoclastogenic Factors by Breast Cancer Cells. C. Menaa[1], J. Turbov*[1], C. J. Froelich*[1], M. Fujishiro*[2], T. Asano*[2], S. M. Sprague[1]. [1]Evanston Northwestern, Evanston, IL, USA, [2]Yamaguishi University, Yamaguishi, Japan.

Breast cancer cells are resistant to apoptosis and capable of migrating to bone, causing osteolysis. Tumor cells acquire this potential by expressing osteoclastogenic factors (OF). Osteoclast (OC) formation is identified as a key step in bone metastasis, however the mechanism is poorly understood. To determine how breast cancer cells support OC formation, MCF7 and MDA-231 were used. Both MCF7 and MDA-231 cells induced osteoclast formation when incubated with purified primary murine OC precursor cells, CFU-GM, or RAW 267.4 cell line. This effect did not require physical contact between tumor cells and OC precursors. Condition media (CM), harvested from tumor cell culture, dose dependently induced OC formation by a mechanism independent of RANKL and TNF-α production. Amounts of OPG and of neutralizing antibody against TNF-α that were sufficient to block, respectively 100 ng/ml of RANKL and 100 ng/ml of TNF-α were not able to block OC formation induced by CM. Utilizing MCF7 cells over-expressing the pro-apoptotic gene, caspase 3 (C3), not just abolished their resistance to apoptosis, but also totally blocked the breast cancer cells from supporting OC formation, suggesting that resistance of cancer cells to apoptosis and their osteolytic capacity are mechanistically linked. To analyze how C3 affects the production of OF, we examined NF-κB activity as this transcription factor is known to control protein expression and secretion. NF-κB has also been proposed to be directly linked to the pro-apoptotic effects of C3. Compared to wild type MCF7, Western blot showed that IκB, the inhibitory compound of NF-κB, was not degraded in MCF7-C3 cells. These results indicate expression of C3 blocks IκB degradation which, in turn, reduces NF-κB activation, an outcome crucial for OF production. To verify whether NF-κB mediates the control of OF by C3, we developed a MCF7 cell line over-expressing a mutated IκB that acts as a super repressor of NF-κB activation even upon stimulation with TNF-α (10 ng/ml). The super repressor IκB abolished the tumor cells' ability to support OC formation similar to the C3 effect, while the empty vector or the wild type IκB had no effect. These data suggest that NF-κB is the downstream signaling pathway of C3 effect that controls both cell resistance and OF production by breast cancer cells. In summary, we found that breast cancer cells regulate OC formation by a mechanism that is independent of RANKL and TNF-α. The production of OF is modulated by C3 expression through an NF-κB dependent pathway suggesting that apoptosis and OF production may converge at NF-κB. Thus, the NF-κB pathway could be an appropriate target for treatment of breast cancer.

F091

Digital X-ray Radiogrammetry Indices,Particularly MCI, Can Predict Vertebral Fracture Risk in Osteoporotic Women. S. Vasireddy*[1], C. Haigh*[2], L. Reaney*[1], J. Adams*[2], P. L. Selby*[2], S. K. Bal*[1], R. Ashford[1], D. Charlesworth*[1], J. A. Kanis[1], T. Jalava*[3], M. Beneton*[1], E. V. McCloskey[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]University of Manchester, Manchester, United Kingdom, [3]Leiras Oy, Helsinki, Finland.

It is not yet clear whether combined measures of skeletal strength are of more value in the prediction of fracture risk than a single measurement alone. We wished to determine the predictive ability of two new simple measurements, derived from hand radiographs, for future vertebral fractures in women with osteoporosis. We also wished to compare their performance with that of DXA measurements at the spine and hip. 538 women fulfilling the WHO criteria for osteoporosis (spine or hip T-score <-2.5) and/or with at least one prevalent vertebral fracture were recruited to a 3-year double-blind, controlled study. The women received either clodronate 800mg daily by mouth (Bonefos®) or an identical placebo and all patients received a calcium supplement of 500mg daily. Bone density (BMD) was measured at the spine and hip by DXA at baseline. Prevalent and incident vertebral fractures were identified by morphometric evaluation of lateral spine radiographs obtained at baseline and annually thereafter. Hand radiographs obtained at baseline were analysed using the Pronosco X-posure system^{TM} to derive DXR-BMD and metacarpal cortical index (MCI). The present analysis is blinded to the study treatment. 90 women (17%) experienced one or more incident vertebral fractures during the study. At baseline, these women were significantly older and had significantly lower mean values of BMD at the spine, hip, DXR-BMD and MCI (P≤0.001 for all). In univariate analysis, the gradients of risk per 1SD decrease (Odds Ratio, 95%CI) for incident vertebral fractures were identical for MCI and spine BMD (1.8, 1.4-2.4 for a 1SD decrease in either) and were slightly higher than that for DXR-BMD and total hip BMD (1.6, 1.2-2.0 and 1.5, 1.2-1.9 respectively). In a multivariate forward conditional regression model, the baseline presence of vertebral fracture, spine BMD and MCI were all significant independent predictors of future vertebral fracture with odds ratios of 6.8 (3.7-12.8) for prevalent vertebral fracture, 1.6 (1.2-2.1) for spine BMD and 1.5 (1.0-2.1) for MCI. We conclude that DXR-BMD and MCI are indicators of vertebral fracture risk in women with osteoporosis that are as good as that provided by spine or hip BMD. Moreover, MCI may capture a component of risk for incident vertebral fractures that is not accounted for by other measures of BMD. These simple measures may have wide applicability in the management of osteoporosis since hand radiographs are relatively inexpensive and involve low doses of radiation.

Fractures of the Distal Forearm, Humerus, Hip and Vertebrae: Association with Peripheral and Axial Densitometry Measurements. J. A. Clowes, N. F. A. Peel, R. Eastell. Clinical Sciences (North), University of Sheffield, Sheffield, United Kingdom.

We have examined whether the strength of association between different types of osteoporotic fracture and measurement of the peripheral skeleton are similar to those of the central skeleton. We consecutively recruited women (age 55 - 80 years) who had sustained a distal forearm (n = 78), humeral (75), hip (53) or vertebral (73) fracture. These were compared to a population-based sample of 500 women (age 55 - 80 years) from the Sheffield center of the osteoporosis and ultrasound study (OPUS study). All subjects had measurements of spine and total hip DXA (Hologic QDR4500A), distal forearm DXA (Osteometer DTX 200), distal forearm pQCT (Stratec XCT 2000) and QUS of the heel (Lunar Achilles+, Osteometer DTU One, Metra QUS 2, and DMS UBIS 5000). Measurements were made on the side contralateral to the site of fracture for the fracture cohorts. We examined the association of these measurements with fracture by calculating age adjusted standardized odds ratios per one SD decrease of population variance.

Age Adjusted sOdds Ratio (95% CI)

Parameter	Forearm #	Humeral #	Hip #	Vertebral #
DXA spine	1.74 (1.33-2.29)	1.96 (1.48-2.60)	2.25 (1.59-3.17)	4.67 (3.24-6.71)
DXA total hip	1.74 (1.32-2.30)	1.76 (1.32-2.36)	3.40 (2.30-5.04)	4.29 (2.99-6.15)
DXA forearm	2.05 (1.53-2.75)	1.62 (1.22-2.17)	1.81 (1.27-2.60)	2.91 (2.11-4.00)
pQCT forearm	2.02 (1.44-2.81)	1.85 (1.33-2.56)	1.93 (1.30-2.85)	3.51 (2.37-5.20)
Achilles BUA	1.77 (1.36-2.31)	1.82 (1.38-2.40)	2.89 (2.01-4.17)	3.08 (2.21-4.30)
DTU One BUA	1.81 (1.42-2.30)	1.75 (1.37-2.23)	2.46 (1.79-3.36)	3.23 (2.43-4.29)
QUS 2 BUA	2.01 (1.50-2.69)	1.85 (1.38-2.49)	3.44 (2.31-5.12)	3.67 (2.61-5.17)
UBIS 5000 BUA	1.65 (1.26-2.15)	1.67 (1.26-2.22)	2.70 (1.88-3.87)	4.03 (2.86-5.69)
Achilles SOS	1.54 (1.18-2.01)	1.46 (1.10-1.94)	2.41 (1.66-3.50)	2.68 (1.94-3.70)
DTU One SOS	2.01 (1.50-2.67)	1.66 (1.24-2.20)	3.17 (2.08-4.83)	3.20 (2.26-4.52)
UBIS 5000 SOS	1.36 (1.03-1.80)	1.33 (1.00-1.78)	2.28 (1.53-3.39)	2.73 (1.96-3.80)

The association of peripheral devices with fracture is site specific with hip and vertebral fractures more closely associated with BMD than upper limb fractures. This is consistent with the observation that prevalent vertebral fractures are stronger predictors of incident osteoporotic fractures than upper limb fractures. The performances of heel BUA, heel SOS and peripheral BMD are comparable with DXA in discriminating different types of osteoporotic fracture.

F099

In vivo Non-Invasive Monitoring of Changes in Structural Cancellous Bone Parameters with a Novel Prototype MicroCT in Rats. J. A. Gasser, J. Yam*. Arthritis & Bone Metabolism, Novartis Pharma AG, Basel, Switzerland.

At present, obtaining information on changes in structural parameters of cancellous bone is only possible after necrospy of animals followed by histomorpometric analysis or time intensive measurements on dedicated microCT systems ex vivo. In our study we tested a novel prototype micoCT scanner from SCANCO Medical (Bassersdorf, Switzerland) which allows for the first time to monitor such changes repeatedly in anaesthetised animals at 26µm resolution with an acquisition time of less than ten minutes for mapping of the entire proximal tibia metaphysis. Skeletally mature, 8 month old virgin Wistar rats (n:10 / group) were treated the following way to induce known specific changes in cancellous bone architecture: 1. Sham OP + placebo s.c., 2. hPTH(1-34) (25µg/kg/day s.c.), 3. OVX + placebo p.o., 4. OVX + zoledronic acid (5µg/kg s.c. 2.inj/week) or 5. OVX + 17-alpha ethinylestradiol (aEE, 0.3mg/kg/day p.o.). Cancellous bone structure was assessed by microCT at baseline as well as 1, 2, 4, 8, 12, and 16 weeks after surgery. Sham operated animals did not show any significant change in trabecular number (TbN), thickness (TbTh), bone volume/tissue volume (BV/TV), connectivity density (ConnD) or the Structure Model Index (SMI). As expected, administration of hPTH(1-34) increased BV/TV, TbTh significantly at 2 weeks with the effect starting to plateau at 4 weeks. TbN did not change significantly but tended to be lower than in Sham OP rats. The SMI dropped dramatically and even assumed negative values in the PTH group indicative of the development of a plate-like structure. In OVX-rats BV/TV, TbTh and TbN dropped to reach statistically significant differences from Sham OP animals at two weeks already. The increase in the SMI indicated development of rod-like characteristics. ConnD also decreased significantly at 8 and thereafter. Rats treated daily with aEE were not different from Sham OP rats at any time-point or parameter. A tendency towards an increase in TbTh and BV/TV was observed in rats treated with zoledronic acid. Our results demonstrate for the first time that this protoype micro-CT scanner has a great potential to investigate the effects of known and novel therapeutic agents on 3D-trabecular microarchitecture accurately, repeatedly, reliably and quickly in anaesthetised rats. Furthermore it is capable to pick up the structural changes induced by OVX, anabolic and antiresorptive treatment and to distinguish between them.

Optimizing the Biological Diagnostic Tools in Primary Hyperparathyroidism. C. Cormier[1], E. Lawson-Body*[2], C. Kindermans[2], B. Lacour*[3], E. Sarfati*[4], J. Souberbielle*[2], A. Kahan*[1]. [1]Rheumatology Cochin Hospital, APHP, Paris, France, [2]Physiology Necker Hospital, APHP, Paris, France, [3]Biochemistry Necker Hospital, APHP, Paris, France, [4]Surgery Saint Louis Hospital, APHP, Paris, France.

The diagnosis of primary hyperparathyroidism (PHP) may be difficult when serum calcium and / or serum PTH are within the normal range. We recently proposed (Souberbielle et al. J Clin Endocrinol Metab 2001, 86: 3086-90) that reference values for serum PTH should be established in healthy subjects without vitamin D insufficiency. By doing this, the reference range for serum PTH obtained with a widely used PTH assay, the Allegro Nichols assay, becomes 10-46 pg/mL instead of the usually accepted range (10-65 pg/mL). Furthermore, choosing to measure serum ionized calcium (iCa++) or total calcium corrected for albumin (alb corr tCa) is debated. We thus aimed to clarify 1) whether serum iCa++ may be more informative than alb corr tCa and 2) whether normative PTH values which take vitamin D status into account are more efficient than usual PTH reference values to diagnose PHP. We reviewed the charts of 42 consecutive patients with surgically proven PHP. These patients had been addressed to our calcium metabolism unit because of osteoporosis in order to eliminate secondary causes. Only one patient (2.4 %) had normal iCa++ (<1.31 mM), whereas 25 (61%) had normal alb corr tCa (<2.58 mM). Serum PTH was below 66 pg/mL in 17 patients (40.5%) and below 47 pg/mL in 5 patients (12%). It is noteworthy that 10 patients (24 %) had both normal alb corr tCa and serum PTH <66 pg/mL whereas only two (4.9 %) of them had PTH <47 pg/mL. For these 2 patients iCa++ was high. In conclusion, we found that using normative PTH data which take vitamin D status into account and iCa++ instead of alb corr tCa allowed to reduce the number of normal pre-surgery biological results in patients with surgically proven PHP.

Reduction in Bone Turnover Predicts Hip, Non-spine, and Vertebral Fracture in Alendronate Treated Women: The Fracture Intervention Trial. D. C. Bauer[1], D. M. Black[1], P. Garnero[2], M. Hochberg[3], S. Ott[4], D. L. Schneider[5], J. Orloff[6], D. Thompson[6], S. Ewing*[1], P. D. Delmas[2]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]INSERM, Lyon, France, [3]University of Maryland, Baltimore, MD, USA, [4]University of Washington, Seattle, WA, USA, [5]University of California, San Diego, San Diego, CA, USA, [6]Merck, Rahway, NJ, USA.

Short-term changes in biochemical markers of bone turnover with bisphosphonate therapy are weakly associated with subsequent changes in bone mass, but the relationship between change in markers and non-spine fracture is unknown. In the Fracture Intervention Trial (FIT), we measured BMD of the spine (BMDsp), and used stored serum (non-fasting) to measure bone specific alkaline phosphatase (BAP, Hybritech), C-terminal telopeptide (CTX, Crosslaps), and terminal propeptide (P1NP, Orion) at baseline and after 1 year of alendronate (ALN), 5 mg/d (n=3005), or placebo (PBO)(n=3081). During a mean follow-up of 3.6 years, 72 hip and 786 non-spine fractures were confirmed by central review of x-ray reports, and 336 women with incident vertebral fracture were identified from paired lateral spine x-rays. We used separate age-adjusted hazard models in the ALN and PBO groups to examine the relationship between percent change in marker or percent change in BMDsp and hip (n=45) or non-spine fracture (n=515) occurring after the 2nd marker or BMD measurement. Incident vertebral fractures were analyzed with logistic regression and odds ratios (OR) were calculated. We found no significant associations in the PBO group, but change in one or more biochemical marker was associated with the risk of hip, non-spine, and vertebral fracture in the ALN group (Table). Further adjustment for baseline BMD and prevalent vertebral fracture, or limiting the analysis to women with osteoporosis, had little effect on the results. We conclude that greater reductions in bone turnover with ALN therapy are associated with fewer hip, non-spine and vertebral fractures, and the effect is at least as strong as that observed with change in BMD.

Change in Marker (Per SD Reduction) or BMD (Per SD Increase) and Fracture Risk (*p<0.05)

	Mean % Change (SD)	Hip Fx RR (95% CI)	Non-spine Fx RR (95% CI)	Vertebral Fx OR (95% CI)

Diurnal Rhythm of Serum-based Markers of Bone Turnover: Impact on Monitoring Response to Risedronate in Osteoporosis. A. C. Eagleton[1], N. Hoyle*[2], A. Blumsohn[1], R. Eastell[1]. [1]Bone Metabolism Group, Division of Clinical Sciences (North), University of Sheffield, Sheffield, United Kingdom, [2]Roche Diagnostics GmbH, Penzberg, Germany.

Bone turnover markers show a diurnal rhythm with a peak in the early morning. This variability influences interpretation of marker measurement and requires defined sample collection procedures. The aims of this study were to assess the diurnal variability of serum-based markers of bone turnover in osteoporosis and after treatment with the bisphosphonate risedronate, and to determine an optimal sampling time for monitoring response to therapy. Measurements of procollagen type I N-terminal propeptide (PINP), osteocalcin (OC), and C-terminal telopeptide of type I collagen (CTX (β-Crosslaps™ assay)) were made using the Elecsys® 2010 (Roche Diagnostics GmbH) automated system. Diurnal profiles were determined at baseline and week one in postmenopausal women (n = 14, mean age 62 years, range 54,67) with osteoporosis (T<-2.5, Z<-1). Bisphosphonate therapy was begun and profiles re-determined at twelve and thirteen weeks. Diurnal profiles at a one week interval were determined in healthy controls (n = 15, mean age 62 years, range 53, 69). Study conditions were strictly controlled with meals at 10am, 11am, 1pm, and 4pm. Blood samples were taken at 8.30am, 9am, 9.30am, 11am, 12pm, 2pm, 3pm, 5pm, 6pm and 7pm. Time of measurement was significant for all the markers (ANOVA repeated measures P<0.05). CTX and OC measurements were significantly higher in the osteoporosis group pre-treatment compared to the controls (unpaired t test P<0.05). The shape of the profile was similar for all markers in the osteoporosis (pre- and post-treatment) and control groups with a peak in the morning before breakfast and nadir in the afternoon. The 'peak to trough' was minimal for PINP and OC (PINP 13%, OC 12%, CTX 129%). The post-treatment mean decrease in marker level varied between timepoints from 55% to 61% in PINP, 74% to 99% in CTX and 25% to 32% in OC. The least significant change (P<0.05) at each time-point was used to define response. The highest number of responders identified using PINP (n = 13) was at 8.30am and 6pm, at 8.30am for CTX (n = 12) and at 5pm, 6pm and 7pm for OC (n = 12). The signal to noise ratio was calculated at each timepoint. For PINP this was highest at 12pm (range 6.3, 12.7), for CTX at 9am (range 2.2, 6.8) and for OC at 6pm (range 3.2, 6.9). In conclusion, the serum markers of bone metabolism PINP, CTX, and OC have a diurnal rhythm. The rhythm has the greatest amplitude in CTX. The rhythm is not altered by osteoporosis or bisphosphonate therapy. PINP has the highest signal to noise ratio. The optimal sampling time for monitoring response to therapy would appear to vary according to the marker used.

F111

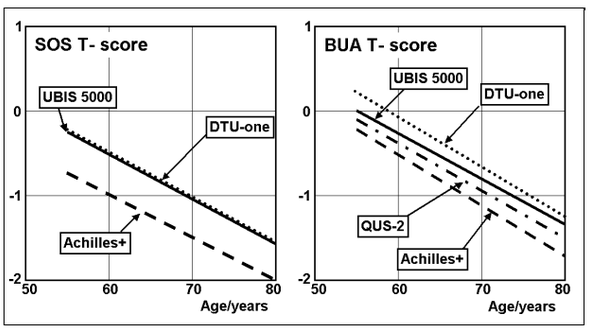
Prospective Evaluation of Hip-Fracture Risk in Institutionalized Elderly by Measurement of Ultrasonic Velocity at the Radius and Phalanx. H. Dobnig, A. Fahrleitner*, C. J. Piswanger-Sölkner*, B. Obermayer-Pietsch*, G. Leb*. Internal Medicine, Karl Franzens University, Graz, Austria.

Fractures constitute a major clinical problem in institutionalized elderly. Here, annual incidence rates for hip fractures usually range between 3% to 5%. Since bone mass or -density constitute an important factor of bone strength and DEXA measurements are limited in the majority of these patients (restricted mobility of patients and DEXA availability) we sought to investigate whether bone ultrasound measurements would help to characterize patients at very high risk for hip- and other non-vertebral fractures. A total of 1085 female patients above 70 years of age who lived in 95 homes for elderly in the southern and eastern part of Austria were followed for an average of 1 year. We excluded patients with hypercalcemia and renal or hepatic dysfunction. Speed of sound (SOS) was measured with a portable quantitative ultrasound device (Sunlight Omnisense Ultrasound Bone Sonometer) at the distal one-third of the radius (RAD) and at the proximal phalanx of the third finger (PLX). So far a total of 147 non-vertebral fractures have occurred, 78 of these being hip fractures. Correlations between age and PLX- or RAD-SOS measurements were comparable (r=-0.20 and -0.19, both p<0.0001). Over the 8th, 9th and 10th decade there was a significant decrease in mean SOS values of 0.84 SD (RAD) and 0.60 SD (PLX). RAD- and PLX-SOS values were correlated with each other (r=0.45, p<0.001). Using Cox-regression analysis and adjusting the data for age, body mass index and measurement device we found a significant increase in the relative risk of hip fracture for each standard deviation decrease in SOS: OR 1.51 (1.16-2.0) for the radial and OR 1.50 (1.16-1.93) for the phalangeal measurement. When all non-vertebral fractures were considered the odds ratios were 1.47 (1.22-1.8) for the radial and 1.19 (1.00-1.42) for the phalangeal measurements. Combining both radial and phalangeal measurements did not result in further improvement of fracture risk prediction. We conclude that measurements of both phalangeal and radial SOS in a large high-risk patient cohort significantly predicted hip-fractures and other non-vertebral fractures. Compared to published data on prediction of hip fractures (neck bone mineral density (OR 2.1/SD decrease); calcaneal SOS and BUA (OR 1.5-1.7/SD decrease) peripheral bone ultrasound measurements may present an attractive screening tool for identification of institutionalized individuals at very high risk of fractures.

F113

Population-Based Calcaneal Quantitative Ultrasound Reference Data: Results from the OPUS Study. R. Barkmann[1], R. John*[1], R. Eastell[2], D. Felsenberg[3], D. Reid[4], C. Roux[5], C. C. Glüer[1]. [1]University Hospital Kiel, Kiel, Germany, [2]University of Sheffield, Sheffield, United Kingdom, [3]Free University Berlin, Berlin, Germany, [4]University of Aberdeen, Aberdeen, United Kingdom, [5]René Descartes University, Paris, Germany.

Population-based reference data are essential for accurate assessment of bone status using quantitative ultrasound (QUS) approaches. We generated such data for four different QUS calcaneus devices and compared them to manufacturer-provided reference data. In the Osteoporosis & Ultrasound (OPUS) study a population-based sample of 2837 women (463 of ages 20 to 39, 2374 of ages 55 to 79 years) has been recruited in 5 European cities. QUS was obtained on the GE/Lunar Achilles+ (n=2246), OSI/Osteometer DTU-one (n=2769), Quidel/Metra QUS-2 (N=1858) and DMS UBIS 5000 (n=2503). We calculated mean values and standard deviations SD for age 20 to 39 years and in 5-year age groups for ages 55 to 79. Manufacturers' reference data for broadband ultrasound attenuation (BUA) and speed of sound (SOS) for DTU-one and UBIS 5000; for stiffness for Achilles+ and for BUA for QUS-2 were evaluated. Differences among devices are expressed as OPUS-based T-scores calculated from the 20-39 year group. Differences between OPUS and manufacturers' reference data are expressed in OPUS-based Z-scores (dZ-sc) and as percent difference for the standard deviation of population variance (%dSD). Comparing OPUS based T-scores among devices and QUS variables (see figures), postmenopausal age-related slopes are similar in all devices and variables, however SOS T-scores are slightly lower than BUA T-scores. The Achilles+ BUA and SOS decrease in each age-group and are lower in postmenopausal women compared to the other devices. Comparing OPUS and manufacturers data, differences in premenopausal women are small in mean (dZ-sc<0.25) and SD (%dSD<11%) except for BUA of UBIS 5000, where OPUS mean and SD values are higher (dZ-sc=0.35 and %dSD=31%). In postmenopausal subjects, differences for SOS of UBIS 5000 and BUA of QUS-2 are small (dZ-sc 0.2, %dSD<15%). For all other variables OPUS data are higher than manufacturer data (dZ-sc=0.17 - 0.75, %dSD=-19 to 31%). We propose that the OPUS reference data is used in place of the manufacturers' reference data. There are differences among devices and QUS variables even when a common population-based reference database is used.



F115

Fracture History and Other Factors Associated with Calcaneal QUS in Men: The MrOS Study. D. C. Bauer[1], D. L. Schneider[2], J. A. Cauley[3], S. Ewing*[1], E. S. Orwoll[4]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]University of California, San Diego, San Diego, CA, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]University of Oregon, Portland, OR, USA.

Quantitative ultrasound (QUS) has been widely studied in women, but there are few studies of older men. In this cross-sectional study we measured calcaneal QUS (Hologic Sahara) and femoral neck BMD (Hologic QDR 2000) in 5112 men age >65 (mean±SD, 73.7±5.9) recruited from 6 US centers. Duplicate QUS measurements with repositioning were obtained; if the first two BUA results differed by at least 10 dB/MHz, or if either were non-linear (defined as Chi square >50 when frequency is plotted against attenuation), a 3rd measurement was obtained. Medical history (including previous hip and other non-spine fractures), medication use, health habits and total calcium intake (food frequency) were collected by questionnaire. Factors associated with QUS were analyzed with linear regression; QUS and fracture history were analyzed with logistic regression (Table) and are presented as odds ratios (OR) and 95% confidence intervals per SD reduction in QUS or BMD. 16.2% of BUA measurements were non-linear and not analyzed, leaving 4738 men (93%) with at least one valid measurement. The mean BUA (±SD) was 79.0±16.8 dB/MHz and the mean BMDfn was 0.78±0.12 gm/cm2. 2458 men reported previous non-spine fracture, including 83 hip fractures. In multivariate analyses lower age, greater BMI, greater grip strength, and increased physical activity were independently associated with higher BUA (p<0.05), while previous fracture and smoking were associated with lower BUA. Calcium intake and use of medication were not associated with BUA (p>0.05). Results were similar for other QUS parameters (SOS and QUI). After adjustment for age and clinic, men were 39% more likely to report a history of hip fracture and 19% more likely to report non-spine fractures with each SD reduction in BUA (Table). Femoral neck BMD was also associated with fracture history. We conclude that non-linear BUA measurements are common in older men, but at least one valid measurement is obtained in a high proportion of subjects. QUS in men is influenced by body habitus, strength, and health habits. The association between QUS and non-spine fracture is similar to that observed with BMD.

QUS, BMD and Fracture History (OR and 95% CI)

Fracture	BUA	SOS	QUI	BMDfn
Hip	1.39 (1.12, 1.74)	1.46 (1.15, 1.85)	1.44 (1.15, 1.81)	1.85 (1.46, 2.35)
Non-spine	1.19 (1.12, 1.26)	1.21 (1.14, 1.29)	1.21 (1.14, 1.29)	1.22 (1.15, 1.29)

Skeletal Phenotype of Mice Expressing the Human High Bone Mass Gene. F. Bex[1], P. Babij*[2], W. Zhao[1], Y. Kharode[1], C. Small*[2], P. Reddy*[3], P. Yaworsky*[3], P. Bodine[1], B. Bhat[1], J. Robinson[1], M. Bouxsein[4], R. Moran*[1]. [1]Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA, [2]Genomics Division, Wyeth Research, Andover, MA, USA, [3]Genomics Division, Wyeth Research, Cambridge, MA, USA, [4]Musculoskeletal Sciences Division, Wyeth Research, Cambridge, MA, USA.

A mutation (G171V) in the low-density lipoprotein receptor related protein 5 (LRP5) has been shown to cause high bone mass (HBM) in an extended kindred. To validate and investigate the G171V substitution as being the cause of the HBM phenotype, we created transgenic mice expressing the human LRP5 G171V mutation in bone. Immunohistochemistry of calvaria and long bone revealed strong transgene expression in the pre-osteoblasts and osteoblastic cells lining the periosteum and in osteocytes present in mineralized bone. Measurement of volumetric BMD (vBMD) by pQCT analysis showed significant increases (p<0.01) in both total femoral vBMD (30-55%) and trabecular vBMD (103-250%) of the distal femoral metaphysis in male and female transgenics at 5, 9, 17, 26 and 52 weeks of age over their non-transgenic littermates. Diaphyseal cortical vBMD proximal to the metaphysis was slightly but not significantly increased (2-8%), whereas cortical thickness at the mid-diaphysis increased by 21-42% (p<0.01) due to an increase in periosteal circumference (7-17%; p<0.05). High resolution microCT analysis of the distal femorae from the transgenics revealed an increase (125-232%) in trabecular bone volume fraction due to both increased (41-53%) trabecular number and increased (43-46%) trabecular thickness resulting in greater (121-344%) connectivity density (p<0.01). There were no differences in osteoclast number at 17 weeks of age (controls: 21.41 ± 1.65 /mm2 vs. transgenics: 20.66 ± 1.07 /mm2). Fluorescent micrographs of calcein labeled bone revealed a 33% increase in actively mineralizing bone surface in the transgenic animals and an 11% increase in mineral apposition rate. There was enhanced alkaline phosphatase staining in osteoblasts and a significant reduction in the number of TUNEL positive osteoblasts and osteocytes. Taken together these results indicate that the increased BMD in the transgenics is due to increased osteoblast number and activity, which could in part be due to their increased functional lifespan. Importantly, increased bone density in the transgenics was associated with significant increases in vertebral compressive and femoral bending strength. The similarity of the bone density and architectural changes in the transgenic mice, together with the increased strength of the bone, suggest that the skeletal effects of LRP5 (G171V) transgene expression in the mouse closely mimic the human HBM phenotype.

Lumbar Spine BMD is Linked to Genetic Markers on Chromosome 1q. M. J. Econs[1], D. L. Koller[2], S. L. Hui*[1], P. M. Conneally*[2], C. C. Johnston[1], M. Peacock[1], T. Foroud[2]. [1]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA.

BMD of the spine is a major risk factor for fracture and has a high heritability. We previously performed an autosomal genome screen in 429 pre-menopausal Caucasian sister pairs and found significant evidence of linkage to markers on chromosome 1q (JCEM 85:3116, 2000). The maximum LOD score was attained at the 170 cM position of the Marshfield chromosome 1 map (Am J Human Genetics 63:861-689). The goal of the current study was to replicate this linkage finding in an independent sample of sister pairs. BMD for L2-4 was measured using a Lunar DPXL densitometer. A genome wide screen was performed using 392 microsatellite markers in 289 premenopausal, Caucasian sister pairs. Multipoint, nonparametric linkage analysis was performed using the maximum likelihood variance components method (Mapmaker/SIBS) yielding a LOD score of 3.2 approximately 18 cM distal to the previously reported linkage finding (at position 188 cM on the Marshfield map). We subsequently performed linkage analysis in an expanded sample of 570 white and 204 black sister pairs, which has partial overlap (281 white pairs) with the previously reported genome screen sample (JCEM 85:3116, 2000). The resulting maximum LOD score in this sample of 774 sibling pairs was 4.5 at position 188 cM. Due to the known racial differences in BMD, the sample of 204 black sister pairs was independently analyzed and yielded a maximum LOD score of 1.85 approximately 30 cM distal to the peak LOD score reported in the combined black/white analyses (at position 217 cM). Analyses of only the 570 white sister pairs demonstrated the strongest evidence for linkage to chromosome 1q with a maximum LOD score of 6.3 at position 188 cM. In summary, this study provides very strong evidence that a gene on chromosome 1q affects peak BMD of the lumbar spine in premenopausal white women. Further studies will be necessary to determine whether this gene also affects peak spine BMD among black premenopausal women.

F124

Large-Scale Genome-Wide Screen of Female Twin Pairs Confirms Presence of QTLs for BMD at 1p36 and 3p21. S. G. Wilson[1], P. W. Reed*[2], M. Chiano*[2], M. Shi*[2], J. Lichter*[2], M. Langdown*[2], T. D. Spector[3]. [1]Department of Endocrinology & Diabetes, Sir Charles Gairdner Hospital & PathCentre, Nedlands, Australia, [2]Sequenom Inc., San Diego, CA, USA, [3]Twin Research & Genetic Epidemiology Unit, St Thomas' Hospital, London, United Kingdom.

Low bone mineral density (BMD) is a major risk factor for osteoporotic fracture and studies of families and twins have shown that BMD is under strong genetic control. We performed a genome screen of a large cohort of unselected twin pairs to identify regions of the genome that contain quantitative trait loci (QTL) for BMD. Female twin pairs aged 18-80 years, were recruited from the St Thomas' Hospital, UK Twin Registry. Multiple phenotypes were assessed including BMD (Hologic DEXA) at lumbar spine (L1-4), hip (total, trochanter, intertrochanter, femoral neck, Ward's), forearm (1/3, mid and ultra distal) and whole body. Heritability estimates for BMD ranged between 0.66 and 0.82, which are consistent with published data. Genome scans were performed using the DNA extracted from the blood of 1098 twin pairs. Four-hundred highly polymorphic microsatellite markers from the ABI Prism linkage mapping set (ver. 2) and Genethon genetic linkage map were analyzed using PCR and electrophoresis on an ABI Prism 377 sequencer. Statistical analysis of the data was performed using MAPMAKER/SIBS and a non-parametric multipoint linkage (NPL) approach with BMD assessed as a quantitative trait. A nominal cut off of z=2.3 (LOD=1) was chosen for linkages that warranted further consideration. The maximum NPL score defined in this analysis was z=3.5 for spine BMD at 3p21. Fifteen additional regions were highlighted in the results using the $z \geq 2.3$ threshold. Among the results, linkage of hip BMD to 1p36 (z=3.0) was also of particular interest. These studies validate the use of large cohorts of unselected twins in linkage analysis and the search for QTLs that regulate BMD. Twins offer the advantage that they are age matched, have the same parents and generally have shared upbringing and environment. In contrast to the affected sib pair experimental design, multiple phenotypes can be analyzed simultaneously when genome scans are performed on unselected twins. Compelling regions identified in these studies are being validated by fine mapping and taken forward into Sequenom's gene discovery pipeline through large-scale high throughput SNP association analysis using the MassARRAY™ technology platform. This report provides substantial evidence for linkage of BMD to 1p36 and 3p21 and provides a replication of linkage to two regions highlighted from other linkage studies as well as defining numerous other regions that are likely to be important for the study of genes that regulate BMD.

Estrogen-metabolizing Gene Polymorphisms but not Estrogen Receptor Gene Polymorphisms Are Associated with the Onset of Menarche and Years of Menstruation in Healthy Postmenopausal Japanese Women. I. Gorai, K. Tanaka*, M. Inada*, H. Morinaga*, Y. Uchiyama*, R. Kikuchi, O. Chaki, F. Hirahara*. Obstetrics and Gynecology, Yokohama City University School of Medicine, Yokohama, Japan.

Both onset and cessation of menstruation have strong genetic inclination. An early onset of menopause is related with higher risks of cardiovascular diseases, osteoporosis and ovarian cancer, increasing the risks of mortality. Delayed menopause, however, increase the risk of endometrial and breast cancer. We aimed to identify genetic factors influencing the onset of menarche and natural menopause in a Japanese population by investigating the polymorphisms of estrogen receptor(ER) and estrogen-metabolizing enzyme genes. Three hundred and seventeen postmenopausal Japanese women aged 46 yr and over were enrolled in this study under informed consent. Genomic DNA was extracted from peripheral leukocytes and PCR-based restriction fragment length polymorphism(RFLP) assays were used to determine ER, *PvuII* and *XbaI*, and *CYP17*; estrogen biosynthesis, *CYP1A1*; hydroxylation and *COMT*; inactivation genotypes. There were no significant differences in ages at menarche and natural menopause, and years of menstruation among each *PvuII* or *XbaI* genotype and seven combinations of *PvuII* and *XbaI* genotypes. We could find ages at menarche in women with A1/A2 (higher activity of *CYP 17*) (13.6+/-1.2 yr) were significantly earlier than in those with A1/A1 (lower activity of *CYP 17*) (14.1+/-1.3 yr). There were no significant differences in ages at natural menopause and years of menstruation among each *CYP17*, *CYP1A1* or *COMT* genotypes. When three RFLPs of the estrogen metabolizing enzymes were classified together, ages at menarche were significantly earlier in women with A1/a2h/Lwt/vt (13.4+/-1.4 yr) genotypes as compared with those with A1/A1H/Hvt/vt (14.4+/-1.4 yr), A1/A1H/Hwt/wt (14.3+/-1.4 yr) and A2/A2H/Lwt/vt (14.7+/-1.5 yr) genotypes (P=0.0223, P=0.0252 and P=0.0155, respectively). Women with A2/A2H/Lwt/vt genotypes (34.0+/-1.8 years) had significantly shorter years of menstruation than those with A1/A1H/Lwt/wt (37.1+/-3.4 years), A1/A2H/Hwt/vt (36.8+/-3.0 years) and A1/A2H/Hwt/wt (37.3+/-3.4 years) genotypes (P=0.0391, P=0.0391 and P=0.0266, respectively). The results suggest that estrogen metabolizing *CYP17* genotype alone influences on ages at menarche and that combinations of three estrogen metabolizing genotypes, *CYP 17*, *CYP1A1* and *COMT*, interdependently have some consequences on the timing of onset of menarche and years of menstruation in healthy postmenopausal Japanese women.

F137

Fibroblast Growth Factor Receptor 2 (FGFR2) Interacts with FGF23 and Type IIa Na-Pi Cotransporter (NaPi Cotransporter) in OK Cells. H. Yokote*, X. Yan*, L. Yao*, S. Liang*, K. Fujita*, X. Jing*, E. Okuno*, K. Sakaguchi. Department of Molecular Medicine, Institute of Advanced Medicine, Wakayama Medical University, Wakayama, Japan.

Autosomal dominant hypophosphatemic rickets (ADHR) is caused by mutation of FGF23, that makes the molecule less susceptible to proteolytic cleavage, while overproduction of FGF23 is the cause of tumor-induced osteomalacia. FGF23 appears to be phosphatonin that is cleaved by PHEX, whose gene mutation is responsible for X-linked hypophosphatemic rickets. Then, how does FGF23 induce hypophosphatemia? To investigate which FGF receptor is involved in the signaling of FGF23 to NaPi cotransporter that is responsible for phosphate reabsorption in the proximal tubule, we examined the following: (1) mRNA expression of FGFRs 1-4 by RT-PCR in OK cells, (2) phosphorylation of FGFRs in OK cells in response to the exogenously added recombinant FGF23 with one of the ADHR mutations and an HA-His epitope at the C-terminus (FGF23[R176Q-HA-His]), (3) the interaction of FGF23[R176Q-HA-His] with extracellular domains of FGFRs, and (4) the interaction of FGFRs with NaPi cotransporter in OK cells. We found mRNA expression of FGFR2, FGFR3 and FGFR4 in OK cells. When all the 4 FGFRs with C-terminal myc-epitope (FGFRs-myc) were separately expressed in OK cells and exposed to FGF23[R176Q-HA-His], only FGFR2 was shown to be phosphorylated further by the immunoblotting study following immunoprecipitation by anti-myc antibody. Since FGFR2 can be divided into two isoforms containing IIIb or IIIc exon according to ligand binding specificity, we constructed the expression vectors for these extracellular domains fused to the IgG-Fc fragment (Ex-FGFR2-Fc), and examined the interaction of the recombinant receptors with FGF23[R176Q-HA-His] by immunoblotting with anti-HA antibody following precipitation of the receptor-ligand complex using GammaBind plus sepharose. Ex-FGFR2-Fc with either IIIb or IIIc exon interacted with the ligand. Finally, we cotransfected FGFRs-myc with NaPi cotransporter tagged with flag epitope (NaPi cotransporter-flag) into OK cells, and examined coimmunoprecipitation of the two molecules by immunoblotting with anti-FGFR antibody after immunoprecipitation by anti-flag antibody. Only FGFR2-myc coimmunoprecipitated with NaPi cotransporter-flag in OK cells. We conclude that FGF23 is likely to exert its effect on NaPi cotransporter through FGFR2 in OK cells representing the proximal tubular cells.

F139

FGF Signaling Regulates Dach1 Expression During Limb Skeletal Development. A. Horner, L. Shum*, J. A. Ayres*, G. H. Nuckolls*. Cartilage Biology and Orthopaedics Branch/NIAMS, National Institutes of Health, Bethesda, MD, USA.

Dach1 is a mouse homologue of the Drosophila dachshund gene, which is a key regulator of cell fate determination during eye, leg and brain development in the fly. Dach1 is expressed in the distal mesenchyme of the early embryonic mouse limb bud and subsequently becomes restricted to the tips of digital cartilages. Since signaling pathways that regulate skeletal patterning in the limb bud also regulate chondrocyte proliferation and maturation during endochondral bone development, we have investigated the expression and growth factor regulation of Dach1 during skeletal development in the mouse limb. Dach1 protein was localized to postmitotic, prehypertrophic and early hypertrophic chondrocytes of prenatal and early postnatal phalanges. Dach1 co-localized with Cbfa1 in chondrocytes but not in the forming bone collar or primary spongiosa. Dach1 also co-localized with cyclin dependent kinase inhibitors p27 (Kip1) and p57 (Kip2) in chondrocytes of the growth plate and in the epiphysis prior to formation of the secondary ossification center. Since fibroblast growth factors (FGF), bone morphogenetic proteins (BMP) and hedgehog molecules (Hh) regulate skeletal patterning of the limb bud and chondrocyte maturation in developing endochondral bones, we investigated the regulation of Dach1 by these growth and differentiation factors. Expression of Dach1 in 11 dpc mouse limb buds in organ culture was upregulated by implanting beads soaked in FGF2, 4, 8, or 9 but not FGF10. BMP4 soaked beads slightly down regulated Dach1 expression while Shh and BSA had no effect. Furthermore, FGF4 or 8 could substitute for the apical ectodermal ridge in maintaining Dach1 expression in the limb buds. Immunolocalization of FGFR2 and FGFR3 revealed overlap with Dach1 expression during skeletal patterning and chondrocyte maturation. We conclude that Dach1 is a target gene of FGF signaling during limb bud outgrowth and patterning, and is co-expressed with FGF receptors that regulate chondrocyte proliferation and maturation in developing endochondral bones. Genetic mutations that disrupt FGF signaling cause frequent, severe skeletal malformations. Therefore, further characterization of the function of Dach1 in FGF signaling during skeletal development will contribute to an understanding of the molecular mechanisms of skeletal morphogenesis and dysmorphogenesis.

F144

Flt-1 Tyrosine Kinase-Deficient Homozygous Mice Result in Decreased Trabecular Bone Turnover and Bone Strength. O. Hajime*[1], S. Uchida[1], M. Watanuki*[1], S. Tanaka*[1], A. Sakai[1], S. Niida*[2], T. Nakamura[1]. [1]Orthopedic Surgery, University of Occupational and Environmental Health, Kitakyushu, Japan, [2]Geriatric Research, National Institute for Longevity Sciences, Aichi, Japan.

Vascular endotherial growth factor (VEGF), a crucial modulator of angiogenesis, recently has been shown to affect directly on osteoblasts and osteoclasts through the expression of tyrosine kinase receptor Flt-1 (VEGFR1). Flt-1 displays higher affinity for VEGF but much lower kinase activity than Flk-1 (another tyrosine kinase receptor for VEGF, VEGFR2). Recent studies have suggested that Flt-1 plays a main role in angiogenesis as ligand-binding molecule, rather than as a signal transducting receptor. However the role of Flt-1 in osseous tissue has not been well characterized. The purpose of this study was to clarify whether the deficiency of Flt-1 tyrosine kinase domain causes abnormal bone metabolism. We examined C57BL/6J mice, aged 9 or 16 weeks, with disruption of the Flt-1 tyrosine kinase domain gene (Flt-1TK-/-) and compared with age matched wild type mice (WT). Dynamic histomorphometry confirmed significant decrease in the values of mineralising surface (MS/BS), mineral apposition rate (MAR), bone formation rate (BFR/BS) and osteoclast surface (Oc.S/BS) in the trabecular bone of the proximal tibiae. However there was no significant differences in the value of trabecular bone volume (BV/TV). Although the values of bone mineral content (BMC) and bone mineral density (BMD) of the femur showed no significant differences, the values of bending load of the femur significantly decrease in Flt-1TK-/- mice. In addition, serum osteocalcin significantly decreased in Flt-1TK-/- mice compared with those in WT mice. These findings demonstrate that Flt-1TK-/- mice show lower bone turnover and bone strength than WT mice, and suggest that VEGF signal pathway through the Flt-1 tyrosine kinase domain could be implicated in bone formation and resorption.

F146

IL-10 Knockout Mice Develop Reduced Bone Formation, Osteopenia and Mechanical Fragility. R. Dresner Pollak[1], N. Gelb*[2], D. Rachmilewitz*[3], F. Karmeli*[3], M. Weinreb[2]. [1]Hadassah University Hospital, Jerusalem, Israel, [2]Goldschleger School of Dental Medicine, Tel-Aviv University, Tel-Aviv, Israel, [3]Shaare Zedek Medical Center, Jerusalem, Israel.

Interleukin 10 (IL10), an anti-inflammatory cytokine, inhibits osteoclastogenesis and osteoblastic differentiation *in vitro*. To evaluate the role of IL10 in bone physiology *in vivo* we studied bone status in 8-12 week-old IL10 -/- mice and their age-matched, wild-type (WT) counterparts (C57BL/J6). IL10 -/- mice had lower body weight, lower femoral length and lower serum albumin, suggesting malnutrition. At 8 weeks of age, IL10 -/- mice exhibited osteopenia, evidenced by significantly reduced femoral ash weight (-9%) and tibial cancellous bone area (-25%). At 12 weeks, osteopenia was more pronounced (-22% and -55% respectively), and included reduced tibial cortical thickness (-25%), lower trabecular width (-30%) and number (-39%). Mid-femoral mechanical strength, tested at 12 weeks by 3-point bending, revealed reduced maximal load (-27%) and stiffness (-29%) in IL10 -/- mice. Using calcein-based histomorphometry, we found that 8-week old IL10 -/- mice had significantly reduced bone formation (35% and 19% reduction in cancellous % double labels and mineralizing surface, respectively, 20% reduction in cancellous mineral apposition rate (MAR), 37% reduction in cancellous bone formation rate and 16% reduction in endocortical MAR). In agreement, serum osteocalcin was reduced by 27% in IL10 -/- mice. There were no significant differences in serum PTH, $25(OH)D_3$ and DPD (deoxypyridinoline) levels. Since IL10 -/- mice develop progressive enterocolitis, we wished to examine whether their developing osteopenia is associated with the colitis. IL10 -/- mice with colitis (based on rectal prolapse and colon weight) had lower body weight, lower bone mass and lower osteocalcin levels compared to IL10 -/- mice with no gross evidence of colitis, suggesting that the two disorders may be associated. In summary, IL10 knockout mice develop a bone disease characterized by diminished bone formation, osteopenia and decreased mechanical bone strength, which may be caused by disregulated cytokine expression and/or malnutrition.

F149

Seven Quantitative Trait Loci (QTL) Contribute to Variation in Serum IGF Binding Protein-5 Levels in F2 Mice (MRL/MpJ X SJL/J): Evidence That Genetic Determinants of IGFBP-5 Are Involved in the Regulation of Peak BMD. S. Mohan[1], G. Masinde[1], X. Li[2], D. J. Baylink[1]. [1]J.L. Pettis VAMC, Loma Linda, CA, USA, [2]Univ of Chicago, Chicago, IL, USA.

Past findings that 1) IGFBP-5 is a growth factor that stimulates bone formation (BF) independent of IGFs, 2) IGFBP-5 production in osteoblasts is regulated by osteorgeulatory agents that regulate BF, and 3) serum IGFBP-5 levels are decreased in hip fracture patients and correlate with bone mineral density (BMD), provide evidence that IGFBP-5 could be an important physiological regulator of BF. Because serum IGFBP-5 levels correlate with BMD, a trait that is largely genetically determined, we proposed that serum IGFBP-5 level has a strong heritable component and that genetic determinants for serum IGFBP-5 levels are involved in the regulation of peak BMD. To evaluate this hypothesis, we intercrossed two inbred strains of mice, MRL/MpJ and SJL, which exhibit a 79% difference in serum IGFBP-5 levels (554±68 vs 309±51 ng/ml respectively, $P<0.001$). Genome wide scan was carried out using 119 polymorphic markers in 633 F2 female mice. Serum IGFBP-5 levels were measured using an RIA, which has been validated for mouse serum samples. Serum IGFBP-5 levels in the F2 progeny showed a normal distribution with an estimated heritability of 74%. Whole genome wide scans for co-segregation of genetic marker data with high or low serum IGFBP-5 levels revealed seven different QTL in chromosomes 1, 6, 9 (two), 10, 11 and X, which together explained 30% of F2 variance. Chromosome 11 QTL exhibited the highest LOD score (6.6). If IGFBP-5 is an important BF regulator, we predicted IGFBP-5 to contribute to BMD variation in F2 mice. Accordingly, we found three of the seven IGFBP-5 QTL (Chr 1, 9 and 11) identified for serum IGFBP-5 phenotype also showed significant association with total body BMD phenotype (DEXA) in the F2 mice. Summary: 1) MRL and SJL mice exhibit extreme differences in serum IGFBP-5 levels. 2) Serum IGFBP-5 level is a highly inherited polygenic trait in mice. 3) Seven genetic loci contribute to approximately 30% of phenotypic variance in serum IGFBP-5 levels in F2 mice (MRL X SJL). 4) IGFBP-5 and BMD phenotypes share three common genetic loci. Conclusions: Our study provides 1) the first identification of QTL regulating serum IGFBP-5 levels and 2) genetic evidence for a growth factor regulating BMD.

F150

Evidence that a Disintegrin and Metalloprotease (ADAM)-9 Is an IGF Binding Protein (BP-5) Protease that Binds to alpha2Macroglobulin (alpha2M) and Exists as a Complex in the Conditioned Medium (CM) of Human Osteoblasts (hOBs). S. Mohan[1], G. Thompson*[1], Y. Amaar[1], G. Hathway*[2], H. Tschesche*[3], D. J. Baylink[1]. [1]J.L. Pettis VAMC, Loma Linda, CA, USA, [2]Calif Inst of Tech, Pasadena, CA, USA, [3]Univ of Bielefeld, Bielefeld, Germany.

Previous studies have shown that BP-5 is a multifunctional protein that acts not only as a traditional binding protein but also as a growth factor independent of IGF to stimulate bone formation. The actions of BP-5 in local areas of bone are controlled in part by BP-5 protease produced by hOBs. Therefore, elucidation of the identity of BP-5 protease produced by hOBs is important for our understanding of the molecular pathways that control the actions of BP-5. In this regard, BP-5 protease purified by various chromatographic steps from a CM of U2 cells migrated as a single band, which comigrated with the protease activity in native PAGE and yielded multiple bands in SDS-PAGE under reducing conditions. N-terminal sequencing of these bands revealed that three of the bands yielded amino acid sequences that were identical to that of ∝2M. Although ∝2M is produced in large quantities by several hOB cell types, it was not found to be a BP-5 protease based on several criteria including failure of ∝2M antibodies to block BP-5 protease in hOB CM. Because ∝2M has been shown to complex with ADAM proteases and because ADAM-12 was found to cleave BP-3 and BP-5, we evaluated if one of the members of ADAM family is the BP-5 protease. The relative expression of various members of ADAMs (9, 10, 12, 17 and TS1) known to contain active proteolytic domain by Northern and Western immunoblot revealed that ADAM-9 is produced and secreted in high abundance by various hOB cell types. In addition, ADAM-9 but not other ADAMs was present in highly purified preparations of BP-5 protease. To determine if ADAM-9 could cleave BP-5, we expressed the metalloprotease domain of recombinant ADAM-9 and evaluated proteolysis of BP-5 and other BPs. Purified ADAM-9 cleaved BP-5 effectively while it did not cleave other BPs or did so with less potency. Because BP-5 protease existed as a complex by binding to ∝2M, we expected ADAM-9 to bind to ∝2M if it were the BP-5 protease. Accordingly, we found that purified ADAM-9 formed a complex with ∝2M. To determine if ∝2M alters the potency of ADAM-9 to cleave BP-5, ADAM-9 was incubated with or without purified native ∝2M prior to BP-5 proteolysis. It was found that addition of ∝2M did not prevent degradation of BP-5 by ADAM-9. Conclusions: Our findings demonstrate for the first time that 1) ADAM-9 is produced by hOBs and forms a complex with ∝2M which exhibits potent BP-5 protease activity, 2) ∝2M binding to ADAM-9 may protect ADAM-9 from degradation, and 3) ADAM-9 degrades BP-5 and thereby may regulate bone formation.

F151

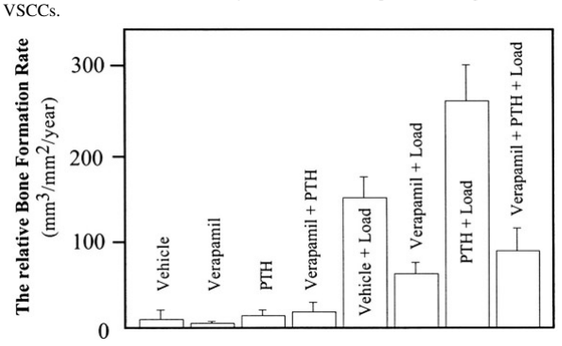
Impaired Adaptation to a Low Dietary Calcium Stress in IGF-I Knockout Mice. S. Mohan, Y. Kasukawa, J. E. Wergedal, Y. Amaar, R. Guo*, D. J. Baylink. J.L. Pettis VAMC, Loma Linda, CA, USA.

Human adaptation to decreased dietary calcium (Ca) intake is impaired with age, resulting in increased serum PTH levels. Based on prior findings that serum IGF-I levels decline with age and correlate with indices of calcium homeostasis, we proposed that a deficiency in IGF-I production contributes to impaired adaptation to low dietary Ca stress. Accordingly, serum PTH was elevated 7-fold (35±3 vs 4.9±2 pg/ml, P<0.001) in IGF-I knockout (KO) mice fed with normal Ca diet compared to wild type (WT) mice. To determine the molecular pathways contributing to increased PTH levels in IGF-I KO mice, we evaluated the effect of Ca deficiency on bone formation (BF) and resorption (BR) processes known to participate in Ca homoeostasis. At 4 weeks of age, IGF-I KO and WT mice were fed with low Ca (0.01%) or normal Ca (0.6%) for 2 weeks and labeled with tetracycline. Two weeks of Ca deficiency did not affect an increase in body wt. or femur length in either IGF-I KO or WT but increased PTH levels significantly in both. Low Ca diet caused a much greater increase in the bone resorbing surface in the tibia of IGF-I KO mice compared to WT (144% vs 46% increase, P<0.05). While resorbing surface was absent in the periosteum of WT mice, approximately 10% of the surface was covered with TRAP positive osteoclasts in IGF-I KO mice. Thus, the magnitude of increase in BR is greater in IGF-I KO mice compared to WT during Ca deficiency. Ca depletion also significantly decreased the endosteal BF parameters in IGF-I KO mice (60%, P<0.05) but not in WT mice (7%). Accordingly, femur BMC and bone area (DEXA) failed to increase significantly during active growth phase in IGF-I KO mice during Ca deficiency while they were increased in WT (40%, P<0.05). Furthermore, periosteal circ. (PQCT) increased in IGF-I KO mice fed with normal Ca but not low Ca while it increased similarly in WT mice fed with normal and low Ca. Serum Ca change due to Ca deficiency was greater in IGF-I KO mice compared to WT mice (11.5% vs 5.3%, p<.05). 1, 25 D was 25% less (P<0.05) in IGF-I KO mice fed with normal Ca compared to WT mice despite 7-fold higher PTH levels, thus suggesting that 1,25 D deficiency contributes to this impaired adaptation. Summary: 1) Serum PTH levels are elevated in IGF-I KO mice compared to WT mice in both normal and low Ca diet. 2) BF is severely compromised while BR is increased in IGF-I KO mice fed with low Ca, resulting in impaired bone growth. 3) Serum 1,25 D levels are significantly lower in IGF-I KO mice compared to WT mice fed with normal Ca diet. Conclusions: 1) Adaptation to low Ca stress is impaired during IGF-I deficiency. 2) IGF-I is a regulator of 1,25 D status, a finding which, together with published data, is strongly suggestive of a cross talk between the IGF and 1,25 D regulatory systems.

F155

Parathyroid Hormone Enhances Mechanically Induced Bone Formation Through Activation of L-type Voltage-Sensitive Calcium Channels. J. Li*[1], R. L. Duncan[2], D. B. Burr[1], C. H. Turner[2]. [1]Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Orthopedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA.

Intermittent administration of parathyroid hormone (PTH) stimulates bone formation. Cell culture studies show that PTH enhances the intracellular calcium concentration in osteoblastic cells subjected to fluid flow, and the synergistic effect between PTH and a mechanical stimulus can be attenuated by L-type calcium channel blockers, such as verapamil. These data suggest that PTH enhances fluid shear-induced calcium signaling in osteoblastic cells through activation of L-type voltage-sensitive calcium channels (VSCCs). We tested the in vivo effect of the L-type VSCC blocker verapamil on bone formation after PTH injection or mechanical loading using the rat ulnar loading system. Adult rats (6 months old) were divided into 8 groups (n=8 each group): vehicle, verapamil, PTH, or both verapamil and PTH treated groups with loading or without loading. Verapamil was given orally at 100 mg/kg using a gavage 90 minutes before loading, which gives maximal plasma levels of verapamil coincident with loading. PTH was injected subcutaneously at 80 microgram/kg 30 minutes before loading. The relative bone formation rate, indicated by bone formation rate from the left limb (nonloaded control) subtracted from the right limb (loaded ulna) value, is shown in the figure. One bout of loading at 360 loading cycles (2 Hz, 16 N peak force) significantly increased bone formation rate on the periosteal surface of the ulna (p<0.0001). Treatment with PTH increased load-induced bone formation by 76% (p<0.001). Treatment with verapamil decreased mechanically induced bone formation rate by 59% (p<0.01). Furthermore, treatment with verapamil suppressed bone formation in rats subjected to PTH+loading by 66% (p<0.0001). In the groups without loading, both verapamil and PTH treatment did not significantly change any bone parameters. This study indicates that L-type VSCCs mediate mechanically induced bone formation in vivo. It suggests that PTH enhances mechanically induced bone adaptation through activation of L-type VSCCs.



F157

Osteopontin: A Marker of Osteocyte Stress in Response to Loss of Mechanical Loading. T. S. Gross, N. A. Rabaia*, N. Y. Moy*, S. Srinivasan. Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA.

Osteopontin (OPN) is a glycoprotein expressed by cells in numerous tissues. Recently, it was observed that the OPN -/- mouse does not lose bone in response to tail suspension, suggesting an integral role for OPN in bone mechanotransduction. Here, we present data at the in vivo and in vitro levels that suggests a mechanism by which OPN expression may modulate disuse induced bone loss. The left ulna diaphysis of four adult turkeys was deprived of mechanical loading via parallel metaphyseal osteotomies. The left and intact right ulnae were recovered following 24 hr of disuse and decalcified sections were obtained from each mid-diaphysis. Sections were incubated with a mouse anti-OPN antibody and detected with a FITC secondary antibody. At 12 equal angle intervals around the cortex, osteocytes were imaged via confocal microscopy (x60) to determine the mean percentage of OPN positive osteocytes. For in vitro studies, MLO-Y4 osteocyte-like cells were plated at 25% confluence and grown for 24 hr in α-MEM supplemented with 2.5% fetal bovine serum (FBS) and 2.5% calf serum (CS). Osteocytes were then challenged by one of two conditions: 1) normal oxygen (19%) with a 90% reduction in serum levels, or 2) hypoxia (2%) and a 90% reduction in serum levels. For three separate experiments, Western blot analysis of OPN expression was performed on extracts at the following time points: 0, 4, 8, 12, 24, and 48 hr. Mean fold elevation of OPN band density was assessed via NIH ImageJ. One day of disuse resulted in a 90% increase in the mean (+S.E.) number of osteocytes staining positive for OPN (16.1 + 4.4% vs 30.6 + 9.9%, p=0.03). During the first 12 hours of serum reduction with normal oxygen, OPN was unchanged compared to zero-time control levels (5% increase). At 24 and 48 hr, OPN expression was substantially elevated (73% increase). In contrast, the OPN expression pattern in response to hypoxia and serum reduction was bimodal, with peaks near 8 to 12 hr (49% increase) and 48 hr (132% increase). At both peaks, OPN expression in hypoxic cells exceeded that observed in cells exposed to serum reduction alone (52% and 28%, respectively). The in vivo data presented here emphasize that loss of loading confers a 'stressful' environment upon the osteocyte, one by product of which is a rapid increase in OPN expression. In vitro, we found that osteocyte OPN expression was elevated by either oxygen and/or nutrient reduction, both of which occur when bone is deprived of loading. Given the known influence of OPN upon osteoclast recruitment, we speculate that this molecule, modulated by altered osteocyte oxygen and nutrient status, plays an important role in the mechanotransduction pathway resulting in disuse induced bone loss.

F159

Skeletal Unloading Induces Resistance to Insulin like Growth Factor-I (IGF-I) by Inhibiting Activation of the IGF-I Signal Pathways. T. Sakata, Y. Wang*, B. P. Halloran, H. Z. ElAlieh*, J. Cao*, D. D. Bikle. Endocrine Unit, Veterans Affairs Medical Center, San Francisco, CA, USA.

We have previously reported that skeletal unloading induces resistance to IGF-I with respect to bone formation. To investigate further the mechanisms underlying this resistance, we first determined the response of bone to IGF-I administration in vivo with respect to osteoblast proliferation and apoptosis during skeletal unloading (hindlimb elevation). We then evaluated the response of osteoprogenitor (BMOp) cells isolated from unloaded bones to IGF-I treatment in vitro with respect to activation (phosphorylation) of the IGF-I receptor and the MAPK (Erk1/2) and PI3K/Akt pathways as well as induction of genes marking osteoblast differentiation. To eliminate the variable of endogenous growth hormone during exogenous IGF-I treatment, we used growth hormone-deficient dwarf (dw-4) rats. For the in vivo experiments, 3 mo old rats were given IGF-I (2.5 mg/kg/day) or vehicle during the 2 week hindlimb elevation period. To evaluate cell proliferation, 5-bromo-2'-deoxyuridine (BrdU) was given to the rats during the first 7 days of the 14 day unloading period. IGF-I significantly increased the number of BrdU positive osteoblastic cells on the bone surface (BrdU(+)Ob./BS). Unloading markedly decreased the BrdU(+)Ob./BS in the vehicle treated rats, and blocked the ability of IGF-I to increase the BrdU(+)Ob. To evaluate apoptosis of the osteoblasts, the TUNEL procedure was used. Unloading for 7 days significantly increased apoptosis of the osteoblasts in both the vehicle-treated and IGF-I treated rats. IGF-I did not significantly alter apoptosis in either loaded or unloaded rats. Phosphorylation of the IGF-I receptor, Erk1/2 and Akt were measured in BMOp cells (8 day culture) isolated from unloaded (7 days) or normally loaded tibiae and femurs following IGF-I treatment (10 ng/ml, for 5 min). IGF-I stimulated the phosphorylation of the IGF-I receptor, Erk1/2 and Akt in the BMOp cells from loaded bones, but these effects were markedly diminished in the BMOp cells from unloaded bones. Furthermore, unloading decreased the protein levels of Erk1/2 and Akt, but not that of the IGF-I receptor. The mRNA levels of collagen (type1), alkaline phosphatase (ALP) and osteocalcin were measured in cultured BMOp cells treated with IGF-I (10 ng/ml, for 12 h) using quantitative real-time PCR. IGF-I increased the mRNA levels of collagen, ALP and osteocalcin in the BMOp cells from loaded bones, but BMOp cells from unloaded bone showed a blunted response. These results indicate that skeletal unloading induces resistance to IGF-I by inhibiting the activation of IGF-I signal pathways leading to altered rates of proliferation and differentiation.

Extracellular Signal-Regulated Kinase (ERK)-1 and ERK2 Are Both Essential in the Mediation of the Flow Shear Strain-Induced Human Osteoblast Proliferation. S. Kapur, S. T. Chen*, D. J. Baylink, K. H. W. Lau. Musculoskeletal Disease Center, Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA.

ERK1 and 2 are key mediators of mitogenic signaling pathways. There is now abundance of evidence that mechanical strain stimulates osteoblast proliferation through multiple signaling pathways, which may involve activation of ERK1 and/or 2. However, it remains unclear whether the activation of either ERK1 or 2 or both is required. Thus, this study sought to test whether the protein kinase activity of ERK1 and/or 2 is essential for the fluid flow shear strain-induced osteoblast proliferation. To test this hypothesis, we prepared MLV retroviral-based vectors that express either the wild type (wt) or kinase-dead (kd) ERK1 and 2. A HA tag was added to the N-terminus of each construct to help to distinguish the overexpressed enzyme from the endogenous enzyme. An MLV-red fluorescent protein (RFP) vector was also included as a control for comparison. Human TE85 osteosarcoma cells were transduced three times with each of the test retroviral vectors with a total MOI of 30. This treatment resulted in an apprxoimately 10-fold and 2-fold overexpression of ERK1 and 2, respectively, in TE85 cells based on Western analyses and protein kinase assays. To determine the effect of overexpression of ERK1 or 2 on fluid flow shear stress-induced cell proliferation, we measured the [^{3}H]thymidine incorporation in each MLV-transduced TE85 cells 24 hr after a 30 min constant flow shear stress at 20 dynes/cm^2. The RFP expressing control TE85 cells showed a 1.7-fold increase ($p<0.01$) in [^{3}H]thymidine incorporation in response to the flow strain. Cells overexpressing wt ERK1 or 2 also showed a mitogenic response to the flow strain with a 2- ($p<0.01$) and 2.7-fold ($p<0.01$) increase, respectively, in [^{3}H]thymidine incorporation, but the flow-induced increase in [^{3}H]thymidine incorporation in cells overexpressing wt ERK1 or 2 was not significantly different from that in control cells. That overexpression of either wt ERK1 or 2 had no further enhancing effect on the cellular mitogenic response to the flow strain suggests that the downstream substrates of ERKs rather than the levels of ERKs are the rate-limiting step of the flow-induced cell proliferation. In contrast, overexpression of an inactive form of either ERK1 or 2 completely abolished the fluid flow-induced bone cell proliferation, since the same flow strain failed to induce an increase in [^{3}H]thymidine incorporation in cells overexpressing either kd-ERK1 or ERK2. In summary, this study demonstrates for the first time that the protein kinase activity of ERK1 and that of ERK2 are both essential for the fluid flow strain-induced osteoblast proliferation

F165

Synergistic Effects of Exercise Plus Alendronate on Bone Mass and Structural Properties in Ovariectomized Rats. R. K. Fuchs[1], M. Shea[2], J. Widrick*[1], S. Stark*[1], B. Hansen*[2], C. M. Snow[1], [1]Oregon State University Bone Research Laboratory, Corvallis, OR, USA, [2]Oregon Health & Science University, Orthopaedic Biomechanics Laboratory, Portland, OR, USA.

We examined the effects of alendronate (Fosamax) therapy plus exercise on bone mass, geometry and biomechanical properties in 7-month old female rats (ovariectomized, n=46; sham-operated, n=13). Ovariectomized rats were randomly assigned to: placebo, n=10 (ovx); Fosamax-treated, n=12 (ovx+fos); exercise-trained, n=12 (ovx+run); and Fosamax-treated plus exercise-trained, n=12 (ovx+fos+run). The ovx+fos and ovx+fos+run groups received 1ml/kg body weight of Fosamax 2x/wk for 15 wks; sham, ovx and ovx+run groups received 1ml/kg body weight of placebo 2x/wk for 15 wks. All exercised rats were run on a motorized treadmill 60 min/day, 5 days/wk, for 15 wks. Total body mass (g) and BMC (g) were assessed by DXA at wks 1 and 15, and BMC of the excised left femur and L4 vertebral body were assessed by DXA at wk 15. The left femur and L4 vertebral body were scanned using μCT for geometric parameters. The left femur was tested to failure in 3-point bending and the L4 vertebral body was compressed to failure using an Instron system. At baseline there were no group differences for total body mass and whole body BMC. After 15-weeks the ovx and ovx+fos groups gained over 50% more body weight than the sham, while the sham, ovx+run and ovx+fos+run groups had similar gains in body weight. At sacrifice the sham had significantly higher BMC at the total femur and L4 vertebral body than the ovx group (+17% and +22%, respectively). Using multivariate analysis of variance for adjusted BMC (dependent variable: BMC/body weight), the ovx+run+fos group had significantly greater total femoral BMC than the ovx (+25%), ovx+fos (+16%), ovx+run (+17%) and sham (+8%) groups, and significantly greater L4 BMC than the ovx (+34%), ovx+fos (+22%), ovx+run (+21%) and sham (+13%) groups. In multivariate ANOVA, the ovx+fos+run group had significantly greater femoral failure load and stiffness compared to ovx (+16% and +19%, respectively) and ovx+run (+15% and +13%, respectively) groups. At L4, the ovx+fos+run group had significantly greater cross-sectional area than the ovx (+16%) and ovx+run (+12%) groups. Femoral and vertebral material properties (strength and modulus) did not differ between groups. Exercise plus Fosamax was synergistic for bone mass, as the combined effects were greater than those of each treatment independently. A synergy was also apparent for femoral failure load and vertebral cross-sectional area. Exercise plus Fosamax may provide the most effective strategy for reducing osteoporotic fractures and also prevent weight gains that may be associated with drug therapy alone.

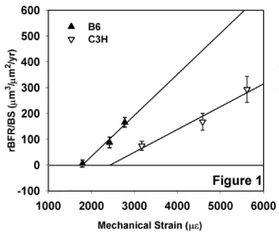
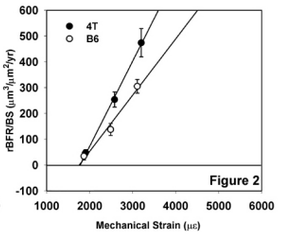
Evidence for a Skeletal Mechanosensitivity Gene on Mouse Chromosome 4. A. G. Robling[1], K. L. Shultz[2], W. G. Beamer[2], C. H. Turner[1]. [1]Indiana University School of Medicine, Indianapolis, IN, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Skeletal loading experiments conducted in different inbred strains of mice reveal that bone tissue's sensitivity to mechanical stimulation is partly under genetic control. For the same amount of mechanical strain, C57/BL6 (B6) mice form more bone in response to ulnar loading than do C3H/He (C3H) mice (Fig 1). The genes contributing to skeletal mechanosensitivity have yet to be identified, but the differences in mechanical adaptation observed among the C3H and B6 mice suggest that these two strains can be used to elucidate the genes involved in mechanosensitivity regulation. The C3H and B6 skeletons also differ in bone size. In particular, the femoral width is greater in B6 compared to C3H mice. Several quantitative trait loci (QTL) have been mapped for femoral width. We hypothesized that genes controlling bone size might exert their effect by influencing mechanosensitivity. The hypothesis was tested using the B6.C3H-4T (4T) congenic mouse strain that is 98.4% B6 and carries the C3H Chromosome 4 QTL genomic DNA donated to the B6 background strain by nine cycles of backcrosses. Using a noninvasive in vivo ulnar loading model adapted for the mouse forelimb, we applied 3 different load magnitudes to the right ulnae of the 4T congenic and B6 control strains. Load was applied for 3 consecutive days (60 cycles/day, 2 Hz), followed by calcein labeing on days 5 and 9. After sacrifice (day 18) bone formation rates (BFR/BS) were calculated from histomorphometric measurements collected from midshaft sections of the right (loaded) and left (nonloaded) ulnae. On a set of calibration animals from both 4T and B6 strains, mechanical strain was measured at midshaft using single element strain gauges. When expressed as a function of mechanical strain, the increase in relative (right minus left) BFR/BS was significantly greater in the 4T mice compared to the B6 controls (Fig. 2). These results might explain why 4T mice have wider femora and ulnae than do B6 control mice. In conclusion, mouse Chromosome 4 appears to contain a genetic locus that modulates the mechanosensitivity of bone tissue.





F173

Estrogens Induce Bad Phosphorylation via both ERK and PI3K Activation: A Two Pronged Signal Requirement for their Anti-apoptotic Effects. S. Kousteni, L. Han, T. Bellido, C. A. O'Brien, R. L. Jilka, S. C. Manolagas. Division of Endocrinology and Metabolism, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, U/sity of Arkansas for Medical Sciences, Little Rock, AR, USA.

Estrogens exert anti-apoptotic effects on osteoblasts via a nongenotropic mechanism of action of the estrogen receptor (ER) α or β, causing activation of the cytoplasmic kinases ERKs and PI3K. It has been reported that inactivation of the pro-apoptotic protein Bad is indispensable for the anti-apoptotic effects of estrogens. Based on evidence that either ERKs or PI3K may induce the phosphorylation, and thereby inactivation, of Bad we investigated here whether the anti-apoptotic effect of estrogens require convergence of these two signaling cascades on Bad. To this end, we employed HeLa cells transiently co-transfected with ERα and wild type Bad. Using Western blot analysis of immunoprecipitated Bad and antibodies specific for serines 112 (Ser-112), 136 (Ser-136) or 155 (Ser-155), we found that short exposure to 17β-estradiol (E_2) induced transient phosphorylation of Ser-136, wich peaked at 30 min. In addition, E_2 induced Bad phosphorylation at both Ser-112 and Ser-155, in a biphasic manner: a first peak occuring at 15 min and a second at 120 min. Pretreatment of the cells with either 50μM PD98059 or with 30nM wortmannin, specific inhibitors of ERKs and PI3K respectively, for 30 min, abrogated the E_2-induced phosphorylation of 112 and 155 serine residues at 15 and 120 minutes. Consistent with this, dominant negative (dn) Bad mutants lacking the ability to undergo phosphorylation at serines 136 or 155 abrogated the anti-apoptotic effect of E_2 in ERα- transfected cells. In contrast, a Ser-112 dn mutant did not. These findings, along with evidence that Ser-112 and Ser-136 are responsible for the recruitment of 14-3-3 proteins which when bound to Bad provoke the release of Bcl-2 from the Bad/Bcl-2 complex, suggests that phosphorylation of Ser-136 and Ser-155, but not Ser-112, is responsible for 14-3-3 recruitment in E_2-treated cells. Finally, a dn Rsk2 abolished phosphorylation of Bad at Ser-155 and blocked the anti-apoptotic effect of E_2 indicating that, at least part of, the estrogen-initiated survival signals that begin with the activation of ERKs and PI3K converge upstream of Bad, at the Rsk2 kinase. In support of this conclusion, Bad phosphorylation in response to simultaneous input from several kinases, like PI3K, PKA and ERKs, has been implicated in the pro-survival signals delivered by growth factors and cytokines in a variety of normal and transformed cells.

gp130-Mediated Signals Are Necessary for Full Activation of Both Osteoblasts and Osteoclasts. H. I. Shin[1], T. Kobayashi[2], U. Chung[2], P. Pajevic[2], N. A. Sims[3], R. Baron[4], F. R. Bringhurst[2], H. M. Kronenberg[2]. [1]Oral Pathology, Kyungpook National University, Daegu, Republic of Korea, [2]Endocrine Unit, MGH, Harvard,, Boston, MA, USA, [3]St. Vincent's Institute, Melbourne University, Melbourne, Australia, [4]Pathology, Yale University, New Haven, CT, USA.

Substantial evidence indicates that gp130-associated cytokines play a role in skeletal homeostasis by stimulating the development of osteoclasts and also by promoting the development of osteoblasts. However, in contrast to widely recognized effects of gp130-associated cytokines on osteoclasts, their roles in osteoblastic function are still incompletely characterized. To address this issue, we analyzed the effect of gp130-mediated signals on bone metabolism by using gp130 knockout mice [gp130 (-/-)] and primary calvarial cells harvested from them. gp130 (-/-) mice showed retarded skeletal development with reduced bone matrix formation and mineralization during embryonic development compared to wild type littermates. In histomorphometric analysis of tibia from wild type and gp130 (-/-) embryos at E18.5 the osteoblast number per total bone area and percentage of osteoblast surface per bone surface were significantly reduced in gp130 (-/-) mice. The osteoblasts in gp130 (-/-) tibiae revealed reduced alkaline phosphatase (ALP) activity and decreased expression of type I collagen and osteocalcin mRNA compared to wild type. In addition, the primary spongiosa was decreased, with markedly increased numbers of large multinucleated TRAP+ cells in that area. However, ultrastructurally, the TRAP+ cells showed poorly developed ruffled border, raising the possibility that these osteoclasts are dysfunctional. Primary calvarial osteoblastic cells from gp130(-/-) mice also showed reduced ALP activity and generated few bone nodules under osteogenic culture conditions, whereas calvarial cells from wild type littermates formed numerous bone nodules after 2 weeks in culture. Primary calvarial osteoblasts from gp130(-/-) mice did not support osteoclastogenesis in co-cultures with wild type spleen cells in the presence of 10^{-7} M hPTH(1-34). These findings suggest that gp130-mediated signals are necessary for full osteoblastic differentiation and function.

F180

Cap- and IRES-Dependent Translational Control of *Cbfa1/Runx2* Expression. Z. Xiao*, L. G. Simpson*, L. D. Quarles. Center for Bone and Mineral Disorders, Duke University Medical Center, Durham, NC, USA.

The *Cbfa1* (*Runx2*) gene has a complex organization giving rise to Type II and Type I isoforms that differ in their N-termini and 5'untranslated regions (UTRs). The 5'UTR (designated UTR1) for *Cbfa1* Type II is complex and contains a "mini-intron", several open reading frames, and sites for generating alternatively spliced products. The distinct 5'UTR for *Cbfa1* Type I (designated UTR2) also has a complex secondary structure. The complexity of the respective 5'UTRs suggests that translational control may play an important role in regulating *Cbfa1* isoform expression. To evaluate potential differences in cap-dependent translation imparted by the 5'UTRs of *Cbfa1*, we created monocistronic SV40-UTR1-Luc and SV40-UTR2-Luc constructs, in which the 5'UTR of Luc was replaced with the UTR1 or UTR2. These monocistronic constructs were tranfected into MC3T3-E1 osteoblasts and NIH3T3 fibroblasts and luciferase activity measured to estimate translational efficiency of the various UTRs. We found that UTR1 and UTR2 imparted 2 to 3 fold greater levels of translation in MC3T3-E1osteoblasts than NIH3T3 fibroblasts. In addition, the UTR2 was translated approximately twice as efficiently as UTR1 in MC3T3-E1osteoblasts. The inclusion of the "mini-intron" in UTR1 significantly suppressed its translation in these cells. More importantly, we observed a 2-fold decline in cap-dependent translation by both UTR1 and UTR2 during culture duration dependent maturation of MC3T3-E1osteoblasts. The complex secondary structures of the 5'UTRs of Type II and I *Cbfa1* also suggest a possible role of internal ribosome entry site (IRES)-dependent translational regulation. To investigate this possibility, we created bicistronic vectors SV40-Rluc-UTR1-Fluc, SV40-Rluc-UTR2-Fluc, and SV40-Rluc-IRES2-Fluc, in which transcription generates Rluc by cap-dependent translation and Fluc is produced only if the intercistronic UTR confers an IRES-dependent translation. These constructs were transfected into MC3T3-E1 osteoblasts and translational control was evaluated in response to cell stress and osteoblastic maturation. We found that both the UTR2 and the UTR1 possess IRES activity similar to the viral IRES2 and this activity increased with serum deprivation and genotoxic stress induced by mitomycin C. In addition, we observed an maturational stage dependent 3-fold increase in IRES-mediated translation by both UTR1and UTR2. These findings suggest that *Cbfa1* UTRs have dual cap-dependent and IRES-dependent translational activities. The alternative IRES translational mechanisms may permit continued *Cbfa1* expression under conditions that may not be optimal for cap-dependent translation.

F182

A CT-rich Element in the Proximal Osteocalcin Promoter Confers Sensitivity to Gap Junctional Communication. J. P. Stains[1], F. Lecanda[2], J. Screen[1], D. A. Towler[1], R. Civitelli[1]. [1]Div. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA, [2]Histology and Pathology, Univeristy of Navarra, Pamplona, Spain.

Disruption of gap junctional communication by overexpression of connexin45 (Cx45) in cells that endogenously express connexin43 (ROS 17/2.8, MC3T3-E1) alters osteoblast gene regulation, including downregulation of osteocalcin gene transcription. Accordingly, osteocalcin expression is markedly decreased in connexin43 null osteoblasts, which are not chemically coupled. To elucidate the molecular mechanisms of gap junction-mediated gene transcription regulation, we systematically analyzed the rat osteocalcin promoter to identify regions affected by changes in connexin expression profiles. Using 5' deletion analysis, we had previously mapped gap junction sensitivity to the -92 to +32 osteocalcin proximal promoter. We now report the identification of a minimal response element mediating this novel regulatory function of gap junctions. By electrophoretic mobility shift analysis (EMSA) of ROS 17/2.8 nuclear extracts, we identified a CT-rich stretch in the -67 to -57 promoter region that form DNA/protein complexes altered in response to Cx45 overexpression. Luciferase reporter assays demonstrated that this CT-rich element can confer gap junction sensitivity to a heterologous RSV minimal promoter, and that deletion of the CT element from the -92 to +32 osteocalcin promoter abrogates this sensitivity in the homologous promoter context. EMSA using radiolabeled CT element revealed two DNA/protein complexes whose binding activities are affected by gap junctional communication. The binding of a slow migrating complex was increased in nuclear extract from ROS 17/2.8 overexpressing Cx45, while the binding of faster migrating complex was decreased. Supershift and mutational analysis identified the low mobility complex as containing Sp1 and Sp3 transcription factors. In co-transfection experiments, we found that Sp1 stimulates transcription specifically via the CT element. Thus, an Sp1/Sp3 complex can bind and regulate the rat osteocalcin proximal promoter via a pyrimidine-rich CT element, a gap junction sensitive transcriptional unit. Since the Sp1/Sp3 ratio in the complex imparts either transcriptional activation or repression, respectively, we postulate that Cx45 overexpression increases the abundance of inhibitory Sp3 and Sp1/Sp3 heterodimers, leading to downregulation of osteocalcin gene expression.

F184

Locally Delivered Transcription Factor Cbfa1 Gene Enhances Periodontal Bone Repair and Regeneration. J. D. Dickson*[1], L. J. James*[1], J. Tang*[1], H. F. Thomas*[1], D. L. Cochran*[2], G. Karsenty*[3], C. A. G. McCulloch*[4], J. Chen[1]. [1]Pediatric Dentistry, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]Periodontics, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [3]Baylor College of Medicine, Houston, TX, USA, [4]University of Toronto, Toronto, ON, Canada.

The runt domain transcription factor, Cbfa1 (core binding factor, also called Runx2) has been identified as a "master gene" in osteogenesis. Bone formation is inhibited in Cbfa1-deficient mice and heterozygotic Cbfa1 deficient mice (Cbfa1+/-) survive but demonstrate many skeletal abnormalities. Using a bone wound healing model we found that bone repair was delayed in Cbfa1+/- mice (Tang et al., J Dent Res 81:A146, 2002). To determine in more depth the effects of Cbfa1 in enhancing bone wound healing and regeneration, we used a gene activated matrix (GAM) method to locally deliver Cbfa1 DNA into mouse periodontal bone wounds. Briefly, sterile and pure Cbfa1 DNA was prepared on a large scale from a CMV-Osf2/Cbfa1 plasmid. A biodegradable, absorbable bovine type I collagen sponge was mixed with the plasmid DNA. Periodontal wounds were created in three 7-week-old mice, and GAM was inserted and packed into the defect sites. Control sponges were collagen without plasmid DNA and were used in two mice. The animals were euthanized at 7 and 14 days, respectively, after transplantation. Tissues in the wound site were dissected, processed and subjected to histological analysis. Implantation of matrix containing Cbfa1 DNA promoted bone formation at the wound sites. We found that compared to controls, there was increased alveolar bone formation that almost filled the wound defect 14 days after surgery. The bone appeared more mature and was characterized by the formation of Haversian systems, compared to controls. In controls, bone formation was minimal and was scattered in the connective tissues. The newly formed bone in controls was poorly organized and weakly stained. In some samples of control tissues at 14 days, there were large amounts of granulation tissue in the wound site. The collagen sponge matrix did not seem to elicit significant foreign body reaction in either experimental or control groups. The results of this gain-of-function study suggest that Cbfa1 DNA, when incorporated into a collagen matrix, can induce tissue repair at osteogenic wound sites. Thus local application of Cbfa1 might promote osteogenic differentiation, trigger extracellular matrix gene expression, and subsequently enhance bone tissue regeneration.

F186

Regulation of Bone Collagenase-3 Gene Expression by the AP-1 and RD/Cbfa sites of the Collagenase-3 Promoter and by Overexpression of Cbfa1/Runx2 In Vivo. S. C. Jefcoat[1], N. Selvamurugan[1], Y. Yang*[1], R. Kowalewski*[1], O. Linton*[1], E. Karagrigoriou*[1], Z. Fung*[1], J. Ricci*[2], N. C. Partridge[1]. [1]Physiology and Biophysics, UMDNJ-RW Johnson Medical School, Piscataway, NJ, USA, [2]Prosthodontics and Biomaterials, UMDNJ-New Jersey Dental School, Newark, NJ, USA.

Previous work in our laboratory has determined that the activator protein-1 (AP-1) and runt domain binding (RD/Cbfa) sites and their respective binding proteins, c-Fos/c-Jun and Cbfa1/Runx2, regulate the collagenase-3 promoter in both parathyroid hormone (PTH)-treated and differentiating osteoblasts in culture. Furthermore, protein-protein interaction studies indicate that Cbfa1/Runx2 and the runt domain of Cbfa1/Runx2 alone interact with c-Fos and c-Jun. Also, co-transfection of Cbfa1/Runx2 in UMR 106-01 cells has been shown to enhance transactivation of the collagenase-3 promoter. In this study, we wished to show the importance of Cbfa1/Runx2 and the AP-1 and RD/Cbfa sites in the expression of collagenase-3 in vivo. To determine the regulatory elements of the collagenase-3 promoter in different tissues, transgenic mice containing either wild-type (-456 or -148) or AP-1 and RD/Cbfa mutated (-148A3R3) collagenase-3 promoters fused with the E. coli lacZ reporter were generated. Immunohistochemical studies show that wild-type transgenic lines express high beta-galactosidase expression in bone and teeth, some expression in skin, and none in heart, liver or lung, compared to the mutant and non-transgenic lines. Based on these data, we investigated if overexpression of Cbfa1/Runx2 regulates collagenase-3 expression in vivo, and whether this causes morphological changes in these animals. Five lines of mice were generated that carry a c-myc tagged rat collagenase-3 promoter (-148) driving expression of the Cbfa1/Runx2 gene. Samples of kidney, liver, stomach and calvariae were immunohistochemically analyzed for collagenase-3. Preliminary results show increased collagenase-3 staining in the calvariae of 14 day transgenic mice compared to wild-type mice, two transgenic lines were affected in their ability to breed, and x-ray analyses of 6 and 16 week old transgenic mice show that overexpression of Cbfa1/Runx2 causes a reduction in the length of the femur compared to the wild-type mice. These data provide evidence that Cbfa1/Runx2 and the RD/Cbfa and AP-1 sites are sufficient to regulate collagenase-3 gene expression in vivo, confirming our in vitro data as well as supporting the importance of the role of Cbfa1/Runx2 in normal bone development.

Colorful Transgenic Mice: New Autofluorescent Marker Genes of the Osteoblastic Lineage. I. Marijanovic, S. Dogan*, A. C. Lichtler, D. W. Rowe. Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Osteoblasts are generated from bone marrow osteoprogenitor cells by traversing through many maturational stages. We have demonstrated that promoter-GFP reporter constructs can visually discriminate some of these maturational stages in intact bone of transgenic mice as well as in cell cultures derived from those mice. We used 3.6 and 2.3 kb fragments of rat collagen promoter with 1.6 kb fragment of collagen first intron (pOB Col3.6 and pOB Col2.3). Activity of pOBCol3.6 was detected in early stages of osteoblast differentiation and activity of pOBCol2.3 was restricted to mature osteoblasts. These studies utilized either GFPtopaz or GFPemerald (Clontech) which cannot be visually discriminated. Both genes maintain their activity in histological section of bone after decalcification and paraffin embedding, a property that is not shared by the widely used eGFP (Clontech). Here we report generation of transgenic mice that express autofluoresent transgenes that can be distinguished with proper fluorescent filtering. GFPsaph (Clontech), GFPcyan (Clontech) and DsRed1 (Clontech) were placed under the control of Col2.3 promoter (no intron). Expression from all three transgenes was evident in freshly isolated tail biopsies as distinctly different colors than themselves and GFPtpz. In the cultures derived from the GFPsaph and GFPcyan, cells became GFP positive only in mineralized nodules at day 14 confirming our previous findings. Histology performed on bones derived from GFPsaph and GFPcyan transgenic mice showed GFPsaph does but GFPcyan does not survive paraffin embedding. Analysis of the DsRed1 expressing transgenic line in culture and histological sections is pending. In addition the utility of a dual reporter was assessed. Col2.3CATiresGFPcyan transgenic mice express two reporter proteins translated from same bicistronic mRNA. Expression of CAT was restricted to calvaria, teeth, long bones and tendon (cyan is lost during histological preparation) while both reporters were present during the differentiation phase of primary bone cultures. CAT activity preceded GFP expression in primary culture probably because it is a more sensitive reporter. In conclusion, these experiments demonstrate that it should be possible to develop multicolor (currently 4) and enzymatic (currently 3; CAT, Firefly and Renilla luciferase) reporters marking different stages of osteoblastic differentiation for the simultaneous visual and quantitative analysis of lineage progression in cell cultures.

F197

Fibroblast Growth Factor Receptor 2 with Apert Mutation (S252W) Increase Osteoblast Differentiation and Mineralization. Y. Tanimoto*, M. Yokozeki, K. Hiura*, K. Moriyama. Department of Orthodontics, School of Dentistry, University of Tokushima, Tokushima, Japan.

Apert syndrome characterized by craniosynostosis, hypertelorism, ocular proptosis and syndactyly, is reportedly associated with gain-of-functional mutations (S252W, P253R) in extra cellular domain of fibroblast growth factor receptor (FGFR) 2. This suggests that aberrant FGFR2 signaling might contribute to the establishment of the pathogenesis of this syndrome. Previously, we have reported the increased differentiation and mineralization of osteoblastic cells derived from two Apert syndrome patients with FGFR2S252W mutation. Therefore, in this study, in order to clarify the molecular mechanism of osteoblast heterogeneity caused by Apert FGFR2 signaling, we examined the effect of mesenchymaly expressed FGFR2IIIc with S252W (FGFR2IIIcS252W) on differentiation and mineralization of osteoblastic cells. The full length FGFR2IIIc and its soluble form with or without S252W which we previously isolated by RT-PCR, were subcloned into expression vectors driven by CMV promoter. When FGFR2IIIc and FGFR2IIIcS252W expressing vectors were transiently transfected in COS1 cells, highly autophospholylation were observed in FGFR2IIIcS252W as compared with FGFR2IIIc. For the assessment of dominant negative effects of FGFR2 soluble form, MG-63 osteoblastic cells were treated with conditioned media (IIIc-sup, IIIcAp-sup) from COS1 cells which were transiently transfected by FGFR2IIIc or FGFR2IIIcS252W expression vectors. IIIc-sup and IIIcAp-sup significantly inhibited the endogenous and FGF2 induced proliferation of MG-63 cells and the inhibitory effect were stronger in IIIcAp-sup than IIIc-sup. In order to evaluate the effect of the FGFR2IIIcS252W on osteoblast differentiation and mineralization, we established a stable MG-63 cell line (MG63-Ap) overexpressing the FGFR2IIIcS252W. MG63-Ap highly expressed RUNX2, osteopontin and osteocalcin mRNA as compared with MG-63 and MG-63-mock. MG63-Ap showed massive intensity of matrix mineralization within 6 days of culture and neither MG63 nor MG63-MOCK showed mineralization even in after 28 days of culture. Furthermore, administration of IIIcAp-sup dramatically inhibited the increased mineralization of MG63-Ap cells. These results suggest that FGFR2 signaling with Apert mutation have a critical role in controlling differentiation and mineralization of osteoblasts.

F199

Overexpression of the Notch 1 Receptor Intracellular Domain Inhibits Differentiation in Cells of the Osteoblast Lineage. M. P. Sciaudone*, A. M. Delany, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Notch receptors are important for communicating signals that determine the fate of cells in multiple systems. Following activation, Notch receptors are cleaved and the intracellular domain of the receptor translocates to the nucleus where it initiates a regulatory cascade involved in cellular differentiation. Notch signaling inhibits myogenesis and neurogenesis, but its role in osteoblastogenesis is unclear. Osteoblastic cells express the Notch 1 receptor, suggesting a possible function in osteoblast differentiation. Furthermore, cortisol induces Notch 1 mRNA, and it is possible that Notch 1 mediates selected effects of glucocorticoids on osteoblastic differentiation. Notch signaling might have different effects in osteoblastic precursors, such as stromal cells, and in committed osteoblasts. To examine Notch overexpression during osteoblast differentiation, we used a murine stromal cell line (ST-2) and a murine osteoblastic cell line (MC3T3-E1). Cells were transduced with the retroviral vector pLPCX containing the CMV promoter driving the Notch 1 intracellular domain, to generate cell lines constitutively overexpressing active Notch 1. Northern analysis was used to demonstrate expression of retroviral derived Notch 1 mRNA. Following confluence, ST-2 and MC3T3-E1 cells were cultured in the presence of 10% fetal bovine serum, 5 mM beta-glycerophosphate and 100 ug/mL ascorbic acid for up to 4 weeks. ST-2 cells were cultured with or without bone morphogenetic protein (BMP-2) at 1 nM, an inducer of osteoblast differentiation. ST-2 cells overexpressing Notch 1 had reduced levels of alkaline phosphatase activity and mineralized nodules when compared to ST-2 cells transduced with pLPCX alone. This effect was independent of BMP-2 addition and was maintained over the experimental period. Two independently derived ST-2 cell lines overexpressing Notch 1 were examined. Notch 1 inhibited osteoblast differentiation in both lines although the effect was more pronounced in a line expressing higher levels of Notch 1 mRNA, suggesting a dose dependent effect. MC3T3-E1 cells overexpressing Notch 1 had decreased alkaline phosphatase activity and did not form mineralized nodules, whereas MC3T3-E1 cells transduced with pLPCX alone formed mineralized nodules. In conclusion, Notch 1 overexpression inhibits osteoblastogenesis in both early and late stages of osteoblast differentiation and could mediate the inhibitory effects of glucocorticoids on the process.

F201

The Novel Membrane-bound Glycerophosphodiester Phosphodiesterase-like Protein, DD045, Dramatically Promotes Osteoblastic Differentiation. N. Sakurai[1], E. Kawai*[2], N. Yanaka*[2], Y. Imai*[2], H. Akatsuka*[1], T. Takagi*[2]. [1]Discovery Research Laboratory, Tanabe Seiyaku Co., Ltd., Saitama, Japan, [2]Discovery Research Laboratory, Tanabe Seiyaku Co. Ltd., Osaka, Japan.

The osteoblast is the bone-lining cell responsible for the biosynthesis, organization, and mineralization of the bone extracellular matrix. Osteoblast maturation is a multistep series of events characterized by an integrated cascade of gene expression that are accompanied by specific phenotypic alterations. To find new osteoblast-related genes we cloned differentially expressed cDNAs characteristic of specific differentiation stages in the mouse osteoblast-like MC3T3-E1 cells. By a differential display method, we have identified a novel gene, DD045, specifically expressed at the stage of matrix maturation. It encodes a protein of 593 amino acids with seven putative transmembrane regions. Interestingly, one of the extracellular loops is highly homologous to glycerophosphodiester phosphodiesterases (GlpQ). Northern blot analysis revealed that DD045 was also expressed in spleen as well as primary calvarial osteoblasts and femur. Immunofluorescence staining with DD045 antibody and phalloidin in MC3T3-E1 cells indicated that endogenous DD045 might be co-localized with the actin cytoskeleton. We next transfected HEK293T cells with DD045 with green fluorescent protein (GFP) fused to the C terminus (DD045-GFP). DD045-GFP accumulated at the cell periphery, and the transfected cells changed from a spread form to retracted or rounded form with disappearance of actin filaments. This dynamic morphological change seemed to mimic the rounding/retracting of the lining osteoblast involved in the coupling phenomenon of the bone remodeling. Replacement of amino acids of DD045 significantly conserved with GlpQs suppressed the morphological alteration, and the mutated proteins were not localized peripherally. This mutagenesis study suggested that the biological function of DD045 might depend on the putative enzy-

mic activity of the extracellular GlpQ-like motif to mediate the intercellular signal transduction. To identify a role for DD045 in osteoblast differentiation, MC3T3-E1 cells stably expressing the full-length protein were constructed. Pooled MC3T3-E1-DD045 clones showed alkaline phosphatase activity earlier and 10-30-fold higher than cells transfected with the empty vector. In conclusion, we have identified a novel seven transmembrane protein with a GlpQ-like extracellular motif expressed during the osteoblastic differentiation that dramatically accelerates the program of osteoblastic differentiation and involves in the morphological change of cells with the cytoskeletal disintegration.

F203

Androgen Inhibition of Elk-1 Transcription Factor Activity may Mediate Reduced Osteoblast Growth. K. M. Wiren, A. Evans*, X. W. Zhang. Oregon Health & Science University, VA Medical Center, Portland, OR, USA.

Clearly, non-aromatizable androgens have significant beneficial effects on skeletal homeostasis independent of conversion to estradiol, but the mechanisms are not established. The aim of this study is to elucidate the effects of non-aromatizable dihydrotestosterone (DHT) on committed osteoblast growth by characterizing specific signaling cascades using either normal rat calvarial osteoblastic (rOB) cultures, or immortalized clonal calvarial osteoblastic cells (MC3T3-E1 or Py1a). We show that in differentiating rOB cultures treatment with DHT (48h; 10^{-9}M - 10^{-7}M) dose-dependently inhibits osteoblast viability measured by colorimetric MTT assay. DHT treatment also inhibited DNA accumulation measured with Hoechst bisbenzimid H 33258. Since little is known about signaling cascades important in DHT control of osteoblast growth, we interrogated mitogenic pathway-specific cDNA microarrays. Results showed reduced expression of several genes important in MAP kinase-mediated signaling, implicating this pathway as a target of androgen regulation. In both rOB and MC3T3-E1 osteoblast models, DHT treatment (48h; 10^{-8}M) in the presence of charcoal-stripped serum inhibited both ERK-1 and -2 roughly 30% with the most dramatic effect an 80% reduction in Elk-1 expression. Further, MAP kinase activation of the Elk-1/GAL4 transactivator with GAL4/luciferase reporter was reduced nearly 30% by DHT treatment, with a similar reduction in phosphorylated Elk-1 abundance by Western analysis. Since Elk-1 belongs to the ETS-domain family of transcription factors and is a c-*fos* protooncogene regulator, we determined whether DHT treatment also influenced c-*fos* gene expression. Northern analysis revealed a modest reduction in c-*fos* gene expression in DHT-treated rOB cultures. DHT treatment also reduced activation of an AP-1/CAT reporter construct by IGF-I nearly 80%. These results suggest one of the mechanisms by which DHT modulates osteoblast viability is through inhibition of the expression of Elk-1 target genes like c-*fos*. Together these data provide the first evidence that androgen inhibition of the MAP kinase signaling pathway, particularly at the level of Elk-1, is an important mediator of committed osteoblast growth and may be a specific downstream target of DHT in its growth control pathway. Since the AP-1 transcription factor is also a significant regulator of osteoblast development, these findings may provide valuable insight into the molecular mechanisms of androgen action.

F206

Smad1C, a Hoxc-8 interacting Domain of Smad1, Augments Bone Mineral Density in Transgenic Mice. Z. Liu*[1], W. Shi[1], C. Sun*[1], T. Nagy*[1], C. Lu*[1], W. S. S. Jee*[2], X. Ji[3], Y. Wu*[1], X. Shi[1], Q. Li*[1], X. Cao[1]. [1]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]University of Utah, Salt Lake City, UT, USA, [3]P & G Pharmaceutics, Cincinnati, OH, USA.

Bone morphogenetic proteins (BMPs), members of the TGF-beta superfamily of secreted signaling molecules, bear an obligatory task in the induction of osteoblast differentiation and bone formation. Smads, a group of functional and structural related molecules, mediate signaling initiated by BMPs and regulate cell definite commitment. Previously, we showed that Smad1 activates osteopontin and OPG gene expression in response to BMP through dislodging Hoxc-8, which functions as a transcription repressor associating osteopontin promoter. Smad1C, a domain of Smad1 spanning from the COOH terminal of MH1 to linker region (145-278aa), was characterized as interacting with Hoxc-8 and disabling Hoxc-8 DNA binding ability. Ectopic expression of Smad1C with nuclear localization sequence mimics the Smad1 function in activation of osteopontin gene expression. Furthermore, overexpression of Smad1C in 2T3 osteoblast precursor cells induced osteoblast differentiation by upregulating bone mark gene expression and mineralized bone matrix formation. These data suggest that Smad1C is able to bypass BMP's signals in induction of osteoblast differentiation and bone formation in vitro cell culture. To test the function of Smad1C on osteogenesis in vivo, we generated transgenic mice which express Smad1C exclusively in bone and under control of exogenous induction by utilizing tetracycline inducible system (Tet-on) and bone specific type I collagen α promoter (α1p). We detected mRNA of Smad1C in the binary transgenic mice (α1p-rtTA/ Smad1C) under doxcycline induction. Double-transgenic α1p-rtTA/TRE-Smad1C mice in absence of doxcycline and any single-transgenic mice (either α1p-rtTA or Smad1C) fed with water containing doxcycline did not show any noticeable Smad1C expression. The mice expressing Smad1C showed higher bone density compared with their littermates, including non-transgenic and single-transgenic mice. As a control, double transgenic mice in absence of doxcycline did not display distinct differences in terms of bone density from their littermates. Culturing stromal cells isolated from transgenic mice in the medium supplemented with osteoblast induction reagent and doxcycline, we found that stromal cells isolated from dual transgenic mice displayed higher potential to differentiate osteoblasts than the others. Bone histomorphometric analyses showed that significant trabecular bone was induced. Taken together, the results of this study indicate that ectopic Smad1C mimics BMPs in induction of osteogenesis in vivo.

F208

Role of Hedgehog Signaling in KS483 Osteoblastic Differentiation. G. van der Horst*, H. Sips*, C. Lowik, M. Karperien. Endocrinology, Leiden University Medical Center, Leiden, Netherlands.

Indian hedgehog (Ihh) has been shown to control both chondrocyte and osteoblast differentiation. In the present study, we have analyzed the role of hedgehog signaling in osteoblast differentiation in greater detail using the pre-osteoblastic cell line KS483. This cell line differentiates into mature, mineralizing osteoblasts in a three-week culture period. First, we analyzed expression of hedgehog signaling components at various stages of differentiation, using semi-quantitative RT-PCR. Ihh, the receptors patched1 (ptc), ptc2 and smoothened, as well as the intracellular mediators Gli1, 2 and 3 were all present. Interestingly, Ihh mRNA expression increased during differentiation and peaked during matrix formation and maturation, decreasing thereafter. Furthermore, ISH demonstrated the presence of Ihh in osteoblasts in tissue sections of human prenatal bone. Continuous addition of sonic hedgehog (rShh) significantly increased osteoblastic differentiation of KS483 cells dose-dependently. Modest effects on alkaline phosphatase (ALP) activity were observed, whereas mineralization was strongly affected. In addition, mRNA expression of various markers of osteoblast differentiation, such as osteocalcin, cbfa1 and the PTH/PTHrP receptor, as well as Ihh, Gli1, Ptc1 and smoothened was upregulated. Addition of Shh during the first week of culture only, was sufficient for increasing osteoblastic differentiation. Addition during later phases, i.e. matrix maturation and mineralization, was not effective, suggesting that Hh predominantly affects less differentiated osteoblasts. The stimulatory effects of Hh were blocked by the antagonist cyclopamin, which by itself had no effect on differentiation. It has been suggested that Hh regulates osteoblast differentiation via BMPs. In KS483 cells, the stimulatory effects of Shh were synergistically enhanced by BMP-4. Furthermore, the effects of BMPs were not blocked by cyclopamin. In contrast, the effects of Hh were completely blocked by BMP antagonists. This is in line with the observation that KS483 osteoblastic differentiation strictly depends on autocrine BMP signaling. It has been shown that PTHrP is a negative regulator of Hh expression in chondrocytes. Also in KS483 osteoblasts, PTHrP downregulates Ihh mRNA expression and inhibits differentiation. In addition, immunohistochemistry demonstrated a dramatic increase in Ihh expression in osteoblasts in tissue sections of Blomstrand dysplasia (human PTH/PTHrP receptor knockout), compared to control. These data suggest that PTHrP might be a natural inhibitor of hedgehog expression in osteoblasts. In conclusion, our data suggest a role for osteoblast expressed Hh in bone formation.

CGI-135 Is Part of a New Chromatin Remodelling Protein Complex and It Regulates the Osteoprogenitor Proliferation-Differentiation Transition. G. A. Candeliere, Y. Yoshiko, J. E. Aubin. Anatomy and Cell Biology, University of Toronto, Toronto, ON, Canada.

We isolated CGI-135 based on its high and differential expression during the osteoprogenitor proliferation-differentiation transition and showed that it was part of a new higher-order chromatin remodelling complex. To address the in vivo function of CGI-135 in bone formation, we prepared adenoviral vectors designed to over- and underexpress the protein and injected them subcutaneously over the calvaria sagittal suture of newborn rat pups. Reducing CGI-135 levels for three days resulted in a statistically significant decrease in bone volume at the sagittal sutures, growth retardation at the osteogenic front, and reduced cell numbers over the ectocranial trabecular surface. In contrast, increasing CGI-135 levels for 3 days resulted in an increase in active osteoblasts over the ectocranial trabecular surface. Overexpression for 8 and 12 days resulted in a statistically significant and progressive increase in bone volume with time. These data suggest that CGI-135 is essential for rapid de novo bone formation and that it promotes appositional bone growth in vivo. To address the cellular mechanisms responsible, we infected primary rat calvaria (RC) cells during different proliferation-differentiation time windows. Reducing CGI-135 in confluent RC populations prior to bone nodule formation resulted in dose-dependent death of preosteoblastic cells surrounding bone nodules, while differentiated osteoblasts over mineralizing portions survived. Consistent with this, the number of nodules formed was not different from control-treated cultures, but a dose-dependent and statistically significant decrease in the mineralized area of nodules was seen in antisense virus-treated RC cells. Increasing CGI-135 levels in RC cells during log phase growth resulted in more rapid growth, an increase in the number of alkaline phosphatase-positive cells, and a statistically significant and dose-dependent increase in both mineralized nodule number and mineralized area. Increasing CGI-135 in rapidly proliferating MC3T3-E1 cells resulted in a cell cycle shift from G1 to S and G2 phase (24 hours post infection), but this did not occur in more mature cells. On the other hand, decreasing CGI-135 in rapidly proliferating MC3T3-E1 cells caused a cell cycle shift from S and G2 to G1 phase, followed by cell death and decreased bone formation, while decreasing it in more mature cells had no effect on bone formation or on cell death. These data show that CGI-135, which we had identified as being part of a new chromatin remodelling complex, regulates osteoprogenitor proliferation-differentiation in vivo and in vitro at a specific time during lineage progression.

F214

Constitutive Activation of Wnt signaling through Low-Density Lipoprotein-Related Protein-5 Elevates Expression of TGF-beta, Fibronectin and Osteocalcin in Primary Murine Osteoblasts. G. Yao, K. Yu*, M. Mitnick, K. Insogna. Yale University, New Haven, CT, USA.

Wnt signaling through the low-density lipoprotein receptor-related protein 5 (LRP-5) has been recently identified as an important pathway regulating bone mass. Loss of function mutations in LRP-5 cause the autosomal recessive disorder, osteoporosis-pseudoglioma syndrome. Recently, two families with very high bone density were found to have identical G to T transversions in exon 3 of the LRP-5 gene resulting in a glycine-to-valine change at amino acid 171. It is presumed, but not proven, that this is a gain of function mutation. One of these kindreds was noted to have marked elevations in circulating levels of osteocalcin, transforming growth factor-beta (TGF-beta) and fibronectin. LRP-5 is expressed by osteoblasts and is capable of functioning as a Wnt co-receptor in the canonical signaling pathway that employs beta-catenin as a downstream effector. A truncated version LRP-5, which includes the entire intracellular domain, the transmembrane domain, and a portion of the extracellular domain beginning with residue 1370, has been reported to constituitively activate the Wnt pathway. To examine the response of osteoblasts to activation of the Wnt signaling pathway we constructed a truncated murine LRP-5 beginning with residue 1305 and introduced it into the mammalian expression vector PcDNA4/His-Max. Transient transfection experiments were performed in primary cultures of murine osteoblasts. As compared to vector transfected cells, cells expressing the truncated form of LPR-5 secreted 2-3 fold greater amounts of fibronectin into the condition media. Since fibronectin is a known target of the Wnt signaling pathway in other cells, these data suggest that the increase in circulating levels of fibronectin observed in patients with the G-to-V LRP-5 variant may reflect activation of the Wnt pathway in osteoblasts. Levels of osteocalcin were about 25% higher and levels of TGF-beta were approximately 2-fold elevated in the conditioned media of cells expressing the truncated receptor. We conclude that activation of Wnt signaling in osteoblasts leads to increased expression of proteins consistent with the biochemical profile in one kindred with the G-to-V LRP-5 variant. These data support the conclusion that this variant results in a gain of function in the Wnt pathway in osteoblasts.

F218

Telomerase Accelerates Osteogenesis of Bone Marrow StromalStem Cells by Increasing Proliferation and by Up-regulation of CBFA1, Osterix, and Osteocalcin. S. Gronthos*[1], S. Chen*[2], C. Y. Wang*[2], P. G. Robey*[1], S. Shi*[1]. [1]Craniofacial and Skeletal Diseases Branch, NIDCR/NIH, Bethesda, MD, USA, [2]Department of Biologic and Material Sciences, University of Michigan, Ann Arbor, MI, USA.

Telomerase activity can prevent telomere shortening and replicative senescence in human somatic cells. We and others have demonstrated that forced expression of telomerase in human bone marrow stromal cells (BMSSC-Ts) is able to extend their lifespan. In this study, we found that telomerase was able to accelerate and enhance osteogenesis in vitro and in vivo by osteogenic inductive culture conditions and xenogeneic transplantation, respectively. Furthermore, there is no evidence of malignant transformation. Low density DNA array analysis revealed that telomerase activity increases the expression of genes that regulate progression through G1 of the cell cycle including cyclin D3, cyclin E1, E2F-4, and DP2. Hyperphosphorylation of retinoblastoma (pRb) appears to extend the proliferative capacity of BMSSC-Ts beyond 40 population doublings. Importantly, BMSSC-T transplants showed a higher number of human osteogenic cells surviving at eight weeks post transplantation when compared to the control BMSSCs transplants, coupled with a significantly increased osteogenic capacity. One possible mechanism leading to accelerated osteogenesis by BMSSC-Ts may be attributed, at least in part, to the up-regulation of the important osteogenic genes such as CBFA1, osterix, osteocalcin, and increasing population of STRO-1 positive progenitors. Taken together, these findings show that telomerase can accelerate and enhance osteogenic differentiation of BMSSCs, due to the progression from G1-to-S phase, as well as up-regulation of CBFA1, osterix, and osteocalcin.

F220

Clonal Tendon-derived Cell Lines Behave as Pluripotent Stem Cells to Differentiate into Multiple Cell Lineages Including Bone, Cartilage and Fat Cells. R. Salingcarnboriboon[1], H. Yoshitake*[2], K. Tsuji[1], A. Nifuji[1], T. Amagasa*[2], M. Noda[1]. [1]Dept.of Molecular Pharmacology, Tokyo Medical & Dental University, Tokyo, Japan, [2]First Dept.of Oral and Maxillofacial Surgery, Tokyo Medical & Dental University, Tokyo, Japan.

Ectopic bone formation in tendon under pathological or experimental conditions raises a possibility of the presence of pluripotential mesenchymal stem cells in tendon. However, this has not been directly demonstrated. The aim of this study was to establish and characterize tendon cell lines to be utilized as a model for further studies on tendon biology and also to understand the mechanism that differentiates these cells from the cells in osteoblastic and chondrocytic lineages. Transgenic mice harboring SV 40 large T antigen were used to establish tendon-derived cell clones (E4, G11, and D6). Tendon specific phenotype related genes including Scleraxis, Six1, EphA4, and COMP were expressed in the tendon cell clones. Proliferation of these cells was significantly increased by the treatment with bFGF ($p<0.01$) and TGF-b ($p<0.01$) but not BMP2. Interestingly, these cells expressed the genes of osteogenic (OC, OPN, Col-I, ALP, Osterix), chondrogenic (Sox9, Col-II, Col-X), and adipogenic (aP2, PPAR-g) lineages when examined by RT-PCR. Northern blot analysis indicated the constitutive expression of Scleraxis, OPN, Col-I, and Cbfa1 but not OC and ALP mRNAs. BMP2 treatment increased ALP activity and upregulated ALP and osterix mRNA levels while it downregulated Scleraxis gene expression. The cells differentiated into osteoblasts or adipocytes when they were cultured in respective differentiation medium. Formation of tendon-like connective tissue bands, stained strongly positive for mature collagen and anti-large T antigen antibody, was observed when tendon cell sheets detached from long-term culture were transferred to cultured on chorioallantoic membrane in ovo. Formation of fibrocartilagenous tissue was also observed in vivo when D6 cell sheets were implanted into patella tendon defects in adult mice. These observations indicated that the established tendon cell lines could serve as mesenchymal stem cells. This observation will be the first evidence indicating the existence of stem cells in tendon.

F223

Actin Related Protein (Arp)2/3 Complex in Osteoclasts. I. R. Hurst*, J. Zuo*, L. S. Holliday*. Orthodontics, University of Florida College of Dentistry, Gainesville, FL, USA.

Actin rings are dynamic cytoskeletal structures that are required for forming sealing zones, essential elements of the bone resorptive apparatus of osteoclasts. The Arp2/3 complex is a vital regulator of actin dynamics, suggesting a role for Arp2/3 in the formation of actin rings. Polyclonal anti-Arp2 and anti-Arp3 antibodies were shown to bind specifically to Arp2 and Arp3 from purified platelet Arp2/3 complex and to recognize single bands in mouse osteoclast and OPGL-stimulated RAW 264.7 osteoclast extracts. By confocal microscopy, Arp2/3 complex was most abundant in actin rings and was at highest concentrations where the cell contacted the substrate. Arp2/3 generally co-localized with microfilaments but sometimes sandwiched the zone of microfilaments near the plasma membrane. When osteoclasts were torn free from glass coverslips by shearing force, an actin ring remnant remained that was rich in Arp2/3. Somewhat surprisingly, because of the tremendous enrichment of F-actin in actin rings, the ratio of Arp2/3 to F-actin was lower there than in the network of actin filaments that underlies the ruffled border. Based on the presence of Arp2/3 in actin rings we propose that continuous Arp2/3 complex-triggered actin polymerization pushes the plasma membrane at the base of the actin ring into the bone surface, creating the sealing zone. Integrin-based adhesions between the osteoclast and bone outside of the actin ring-ruffled membrane area counter the force being applied by the polymerization motor at the sealing zone and keep the osteoclast in position on the bone. The enrichment of Arp2/3 in the sub-ruffled membrane actin network may provide a supply of Arp2/3 complex near the region of polymerization that could be mobilized by gelsolin. Such a supply would be necessary because, as Arp2/3 nucleates polymerization near the sealing zone, it would be expected to move basolaterally as the newly formed filaments treadmill. The idea that actin rings are Arp2/3 directed actin polymerization-depolymerization motors would explain the dynamic nature of the actin ring-sealing zone region and the inability to identify an adhesion molecule associated with the sealing zone.

F225

Pyk2-dependent Recruitment of Src to Adhesion Structures Is Important for Osteoclastic Bone Resorption. T. Miyazaki[1], A. Sanjay[1], L. Neff[1], S. Tanaka[2], W. C. Horne[1], R. Baron[1]. [1]Yale University, New Haven, CT, USA, [2]The University of Tokyo, Tokyo, Japan.

Pyk2 is a member of the focal adhesion kinase family, that like Src is highly expressed in osteoclast podosomes and is phosphorylated in response to integrin stimulation upon adhesion. We have previously established that Pyk2 autophosphorylation at Y402 is required for the formation of the Pyk2/Src /Cbl complex, which plays an important role in bone resorption. Osteoclasts derived from mice lacking any of these proteins exhibit decreased migration indicating that all three proteins participate in the regulation of osteoclast motility and, thereby, bone resorption. While Pyk2 autophosphorylation in osteoclasts is not Src-dependent, the two molecules associate by the interaction of Pyk2's phosphorylated tyrosine 402 and the Src SH2 domain. To further investigate the function of Pyk2 in osteoclasts and its relation to Src recruitment and activation, we have used adenovirus encoding Xpress-tagged wild type Pyk2, autophosphorylation site-mutated Pyk2 (Pyk2Y402F) or kinase-dead Pyk2 (Pyk2KD) to express these proteins in osteoclast-like cells (OCLs). Although Pyk2 and Pyk2KD were able to interact with endogenous Src, Pyk2Y402F was not, demonstrating that the Src/Pyk2 interaction requires the binding of Src SH2 to Pyk2 phosphotyrosine 402. Similarly, while Pyk2- and Pyk2 KD-OCLs exhibited the characteristic peripheral actin ring, Pyk2Y402F-OCLs exhibited actin patches and multiple small actin rings located in the center of the cell, a pattern also found in the Pyk2-/- osteoclasts. To investigate the functional consequence of overexpressing Pyk2 mutants, the bone resorbing activity of OCLs was quantified in the pit assay. The pit-forming activity of Pyk2Y402F-OCLs was strongly inhibited (85%), while overexpression of Pyk2 and Pyk2KD had no effect. The interaction between phosphorylated Y402 of Pyk2 and SrcSH2 increases Src kinase activity. To determine whether up-regulation of Src kinase activity is sufficient to rescue the decreased pit-forming activity of Pyk2Y402F-OCLs or whether recruitment of Src to adhesion structures is also required, we co-infected OCLs with Pyk2Y402F and CskKD. Src kinase activity was increased when CskKD was expressed alone or in combination with Pyk2Y402F, but the increased Src kinase activity was not sufficient to rescue the inhibitory effect of AxPyk2Y402F on bone resorption. Thus, high Src kinase activity alone is not sufficient to rescue the decreased bone-resorbing activity in Pyk2Y402F-OCLs. We conclude that Pyk2-dependent recruitment of Src to podosomes is necessary for osteoclastic bone resorption.

F227

Identification of the RGD-Binding Site in the Human Osteoclast alphaVbeta3 Integrin Receptor. A. Wittelsberger[1], D. Yahalom*[1], D. F. Mierke[2], M. Rosenblatt[1], J. M. Alexander[1], M. Chorev[1]. [1]Department of Bone and Mineral Metabolism, BIDMC-Harvard Medical School, Boston, MA, USA, [2]Division of Biology and Medicine, Departments of Chemistry and Molecular Pharmacology-Brown University, Providence, RI, USA.

By combining data obtained by photocross-linking RGD-containing ligands to the intact membrane-bound human $\alpha_V\beta_3$ integrin with the crystal structure of the ectopic domain of this receptor (Xiong et al. *Science*, 2001, 294, 339-345), we have modeled the bimolecular contact interface between the 49-amino acid RGD-containing disintegrin ligand echistatin and $\alpha_V\beta_3$. We synthesized three novel analogs, [Bpa^{21},Leu^{28}]-, [Bpa^{23},Leu^{28}]-, and [Bpa^{28}]echistatin, each of which contains a photoreactive *p*-benzoylphenylalanyl (Bpa) residue in close proximity to the RGD motif present at positions 24-26. The analogs bind with high affinity to the purified recombinant $\alpha_V\beta_3$ integrin, but very poorly to the closely related human $\alpha_{IIb}\beta_3$ platelet integrin. While the echistatin analogs containing Bpa in either position 23 or 28 cross-link specifically and almost exclusively to the β_3 subunit of $\alpha_V\beta_3$, [Bpa^{21},Leu^{28}]echistatin cross-links to both α_V and β_3 subunits, with cross-linking to the former favored. [Bpa^{23},Leu^{28}]echistatin cross-links 10-30 times more effectively than the other two analogs. We identified β_3[109-118] as the domain that encompasses the contact site for [Bpa^{28}]echistatin. This domain is included in β_3[99-118], a contact domain previously identified by our group (Bitan et al. *Biochemistry*, 2000, 39, 11014-11023) for a cyclic RGD-containing heptapeptide with a benzophenone moiety in a position that is similar to the placement of the benzophenone in [Bpa^{28}]echistatin relative to the RGD triad. Recently, we identified β_3[209-220] as the contact site for an echistatin analog with a photoreactive group near the C-terminus of echistatin (Scheibler et al. *Biochemistry*, 2001, 40, 15117-14126). These experimentally identified contact sites where used as constraints when docking echistatin, based on its NMR structure, onto the crystal structure of the ectopic receptor domain. The model obtained after relaxation and molecular dynamics simulations is consistent with the very recently published crystal structure of a cyclic RGD-containing pentapeptide in complex with the extracellular segment of $\alpha_V\beta_3$ (Xiong et al. *Science*, 2002, 296, 151-156) and allows for the first time to gain insights on the bimolecular interface between a large disintegrin ligand and the $\alpha_V\beta_3$ integrin.

F230

WASp Deficiency in Mice Results in Abnormal Assembly of Podosomes in Osteoclasts and Defects in Bone Resorption. Y. Calle*[1], C. Jagger*[2], T. Chambers[2], K. Fuller[2], M. P. Blundell*[3], J. Chow[2], G. E. Jones[1], A. Thrasher*[3]. [1]The Randall Center for Molecular Mechanisms of Cell Function, King's College London, London, United Kingdom, [2]Department of Cellular Pathology, St. George's Hospital Medical School, London, United Kingdom, [3]Molecular Immunology Unit, Institute of Child Health, University College London, London, United Kingdom.

The Wiskott Aldrich Syndrome protein (WASp) is a protein specifically expressed in haematopoietic cells. It belongs to a larger family of more widely expressed proteins that mediate actin polymerisation. In humans, mutation in the gene coding for WASp is the basis of the Wiskott Aldrich Syndrome (WAS), an immune disorder characterised by eczema, thrombocytopenia and severe immunodeficiency. Leukocytes and platelets from WAS patients show abnormal cytoskeletal organisation including lack of podosomes in macrophages and dendritic cells. Podosomes are highly dynamic conical adhesion structures only observed in cells of the monocytic lineage and also in certain tumour cells. They consist of a core of actin filaments and other structural and adaptor proteins, which are linked to adhesion molecules of the integrin family. Podosomes are involved in osteoclast adhesion, migration and in the formation of the actin ring around the osteoclast periphery that defines the resorbing area during bone resorption. WASp is a structural component and plays a key role in the dynamics of podosomes in macrophages and dendritic cells. To our knowledge, no evidence has been provided showing that WASp is a structural component of podosomes in osteoclasts. In addition, no obvious abnormalities in bone development and/or structure have been reported as part of the clinical manifestations in WAS patients. In the present work we aimed to investigate whether WASp was involved in assembly of osteoclast podosomes and if expression of WASp was necessary for bone resorption. Using cultures of bone marrow derived osteoclasts from normal and WASp deficient mice, our results showed that: a) In cultures on glass, WAS osteoclasts failed to assemble migratory podosomes (podosomes not inserted in actin rings) and assembled actin plaques co-localising with vinculin instead. Some punctate actin structures were observed inserted in ring frames although they were significantly fewer than in normal cells and they did not appear evenly arranged in the ring. b) In cultures on bone slices, WAS osteoclasts performing resorption presented a dense plaque of actin surrounded by incomplete and thin actin rings, which were absent in many instances. In contrast, normal cells assembled well-defined actin rings. Migratory osteoclasts with podosomes were absent in WAS cultures whereas they could be detected in normal cells; c) Transduction of WASp deficient osteoclasts with eGFP-WASp rescued the normal phenotype on glass and on bone. In addition, WASp localised to the core of podosomes. Our results provide evidence that WASp is a structural component of podosomes in osteoclasts and suggest an important role of WASp in the dynamics of these actin structures during bone resorption. The differences in bone resorption will be discussed at the conference.

F234

RANKL Renders Pre-osteoclasts Resistant to Interferon-gamma While Preserving JAK-STAT1 Signaling. W. Huang*[1], R. O' Keefe[2], R. Rosier[2], J. E. Puzas[2], E. Schwarz[1]. [1]Orthopedics, University of Rochester, Rochester, NY, USA, [2]University of Rochester, Rochester, NY, USA.

While a number of studies have identified IFN-γ to be a potent inhibitor of osteoclastogenesis *in vitro* and *in vivo*, these findings are inconsistent with the inflammatory bone loss that occurs in patients with psoriatic arthritis and bone infections, which are known to occur in the presence of high levels of IFN-γ. To understand the mechanism of this resistance to IFN-γ we hypothesized that IFN-γ has different effects on early-stage versus late-stage osteoclast precursors. In cultures of RAW264 cells and primary murine splenocytes, pretreatment with RANKL ($\geq$ 50ng/ml) for 48hrs rendered these cells resistant to the anti-osteoclastogenic effect of IFN-γ in a dose dependent manner. Interestingly, these cells were also resistant to the effects of IFN-γ on macrophage activation. Nitric oxide production was completely inhibited by pretreatment with $\geq$ 50ng/ml RANKL ($p<0.01$). Additionally, IFN-γ induced upregulation of Mac-1 (mean fluorescence intensity from 1285 to 1912) was inhibited MFI = 547) by RANKL pretreatment. These data indicate that early administration of RANKL causes a broad inhibition of the cellular effects mediated by IFN-γ. To examine whether RANKL disrupts the JAK-STAT1 pathway used by IFN-γ signaling, western blot analysis of nuclear extracts with antibodies specific for STAT1 and its active-phosphorylated isoform revealed that both phosphorylation and translocation of this transcription factor following IFN-γ stimulation were not inhibited by RANKL pretreatment. This phosphorylated STAT1 was capable of DNA binding, as measured by gel-shift, confirming that RANK signaling does not inhibit IFN-γ signaling upstream of the STAT1 transcription factor. STAT1 inhibitors SOCS1 and SOCS3 were undetectable in cytoplasmic extracts. These results lead us to propose a model of osteoclastic bone resorption at sites of Th1 mediated immune responses in which osteoclast precursors are exposed to RANKL before they reach the site of erosion. In support of this model, immunohistochemistry revealed that monocytes/preosteoclasts from patients with psoriatic arthritis must migrate through the RANKL rich enviroment of the synovial lining before they can be exposed to Th1-produced IFN-γ in the synovial fluid. Thus, these preosteoclasts may be resistant to the anti-osteoclastogenic effects of IFN-γ in the joint and capable of the extensive bone erosion seen in this disease.

F236

Osteopontin-Dependent CD44 Surface Expression Is Stimulated by Association With ROK-α and Is Required for Normal Bone Resorption. M. A. Chellaiah[1], R. S. Biswas[1], D. S. Yuen[1], S. R. Rittling[2], D. T. Denhardt[2], K. A. Hruska[3]. [1]Dept. of OCBS, University of Maryland, Baltimore, MD, USA, [2]Dept. Cell Biology and Neuroscience, Rutger's University Nelsons Labs, Piscataway, NJ, USA, [3]Department of Pediatrics, Washington University, School of Medicine, St. Louis, MO, USA.

Osteopontin (OPN) deficiency reduces plasma membrane CD44 surface expression leading to osteoclast hypomotility and decreased bone resorption both *in vitro* and *in vivo*. OPN stimulates podosome assembly dependent on Rho-A GTPase activation as a key step in osteoclast motility. We demonstrate that Rho kinase (ROK-α) is a critical down stream effector of CD44 bound Rho, and plays a critical role in CD44 phosphorylation and its interaction with the ERM/actin complex. Osteoclasts were transduced with Tat-HA fusion proteins containing constitutively active Rho^{Val-14} and dominant negative Rho^{Asn-19}. A dramatic translocation of ROK-α from cytoplasm to membrane was observed in OPN and Rho^{Val-14} -treated osteoclasts that required ROK-α phosphorylation. Increased phosphorylation of ROK-α enhances its association with CD44 resulting in an increase in the CD44 phosphorylation and its surface expression. Y-27632, a specific ROK-α inhibitor, blocked OPN and Rho^{Val-14} stimulated bone resorption thereby indicating a critical role for ROK-α in the osteoclast function. CD44 surface expression as well as CD44/ROK- α association was markedly diminished in the osteoclasts isolated from OPN-/- mice. Transduction of Rho^{Val-14} rescued the OPN-/- phenotype. Exogenous addition of OPN to OPN-/- osteoclasts augments the association of ROK- α with CD44. Although antibodies against α_v, β_3, or CD44 inhibited osteoclast migration and bone resorption, only antibody to α_v or β_3 blocked OPN- induced phosphorylation of ROK-α, CD44 and ERM proteins. Taken together, these results demonstrate that OPN-dependent $\alpha_v\beta_3$ outside-in signaling pathway is required for the Rho-dependent phosphorylation of CD44 associated proteins, and CD44 surface expression. In the absence of OPN or surface CD44 expression activation of bone resorption by estrogen deficiency, parathyroid hormone or RANKL is incomplete.

F239

AlphavBeta5 Integrin Modulates Osteoclast Generation and Activity–Results from Ovariectomized avb5-Null Mice. N. Lane[1], W. Yao[1], D. Sheppard*[1], X. Huang*[1], G. Wesolowski[2], T. Howard*[3], D. Kimmel[2], F. P. Ross*[4]. [1]Department of Medicine, University of California at San Francisco, San Francisco, CA, USA, [2]Merck Research Laboratory, West Point, PA, USA, [3]Creighton University, Omaha, NE, USA, [4]Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Alphavbeta5 ($\alpha V\beta 5$) is highly expressed in the osteoblasts and osteoclast precursors. The purpose of this study was to examine the role of $\alpha v\beta 5$ in bone remodeling using an $\alpha v\beta 5$ knockout mouse model. Six-weeks-old 129/SvEm wide-type (WT) or $\alpha v\beta 5$-knock-out (KO) mice were either sham-operated or underwent bilateral ovariectomy (OVX) and maintained for 6 weeks. In-life double calcein labeling was completed. At sacrifice, bone histomorphometry was performed on the right proximal tibial metaphysis to determine cancellous bone mass, structure and bone turnover. Bone marrow aspiration of the femur was performed and aspirates were co-cultured with mouse osteoblast cells for 7 days in the presence of vitamin D and then stained for tartrate resistant acid phosphatase (TRAP) activity to determine the number of multinucleated cells. Biochemical assessment of bone resorption (DPD) was evaluated at 0, 3 and 6 weeks by ELISA. Statistical analysis of histomorphometric variables and bone turnover was done within groups as means and standard deviations, and between groups and treatments with a 2-factor ANOVA (genotype and estrogen). Results: BV/TV, BFR/BV, Oc.S., Oc.N, and osteoclast activity are influenced only by estrogen status, and TRAP(+) is influenced by both genotype and estrogen. These findings suggest that this integrin has a role in controlling osteoclast generation following estrogen depletion. Additional studies are now in progress to further evaluate the role of this integrin in regulating osteoclast generation in other conditions of high bone turnover.

Groups	N	BV/TV (%)	BFR/BV (%/yr)	Oc.S (%)	Oc.N (%)	TRAP(+) (#/0.72 cm^2)	DPD/Cr (nM/mM)
WT-Sham	5	11±3	312±85	5±1	2±0.2	11±6	10±1
WT-OVX	5	4±1	367±92	8.±1	3±1	22±6	18±2

Cholesterol and Lipoproteins Regulate Osteoclast Formation and Survival. E. B. Luegmayr*, G. A. Rodan, A. A. Reszka. Bone Biology and Osteoporosis Research, Merck & Co., Inc., West Point, PA, USA.

Osteoporosis is associated with both atherosclerosis and vascular calcification. No mechanism yet explains the parallel progression of these diseases. While lipids and lipid-lowering agents are known to affect osteoblast differentiation, little is known about lipid effects on osteoclasts (OCL). We previously observed that OCL synthesize very little sterol, suggesting that internal stores of cholesterol may depend on exogenous sources. In the present study we demonstrate that lipoproteins (i.e. exogenous cholesterol regulation) modulate osteoclast formation and survival. OCL were generated by coculture of mouse bone marrow and MB1.8 osteoblasts in FBS. OCL were purified and then cultured in the presence of M-CSF, RANKL and lipoprotein-deficient FBS (LPDS), containing 90% less cholesterol than FBS. Exogenous lipoproteins were then used to modulate cholesterol levels in OCL. Low-density lipoprotein (LDL), used to deliver cholesterol, increased OCL viability up to 3- fold (vs. controls) at 48 hr. High-density lipoprotein (HDL), used as a cholesterol acceptor, removed dose-dependently up to 70% of labeled cholesterol over 24 hr and increased OCL apoptosis up to 3-fold by 48 hr, as measured by formation of pyknotic nuclei, actin disruption and caspase-3 activation. More rapid effects were observed with methyl-β-cyclodextrin (MBCD), which removed 80% of labeled cholesterol from OCL within one hr and induced massive apoptosis within 6-12 hr. Similar but delayed apoptotic responses to MBCD (over 24 hr) were observed in macrophages (J774, Raw264.7) but not cells derived from mesenchyme (osteoblasts, NIH/3T3). The LDL receptor null mouse (LDLR -/-) was used to further investigate the role of cholesterol delivery in OCL formation and survival. OCL were formed in vitro using bone marrow from LDLR-/- or background (+/+) C57BL6 mice. The OCL from LDLR-/- mice were substantially smaller by comparison to +/+. In males, there was an 8-fold reduction in the proportion of large (i.e. >340 μm) OCL, while in females there was a 2.5-fold reduction. This was accompanied by a significant increase in the number of smaller multinucleated cells, suggesting a defect in spreading rather than in fusion. OCL formation in +/+ could be suppressed by replacing FBS with LPDS during differentiation. Indeed, in LPDS, the size distribution of LDLR-/- and +/+ OCL was identical. In summary these observations show that exogenous cholesterol delivery via the LDL receptor plays an essential role for OCL formation and survival *in vitro*. Conversely, cholesterol removal leads to apoptosis. These effects might contribute to the link between osteoporosis and hyperlipidemia observed epidemiologically.

F243

Localization of a Sequence in TRAP Promoter Mediating RANKL-Induced Transcription of TRAP Gene. Y. Liu*, Z. Shi*, H. Yang, X. Feng. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Osteoclasts (OC), the major bone-resorbing cells, derived from cells of monocyte/macrophage lineage. RANKL is an essential and potent activator of OC differentiation. Despite the critical role of RANKL in OC differentiation has been established, the molecular mechanisms underlying RANKL-induced OC differentiation remain largely unknown. During RANKL-induced OC differentiation, a variety of genes are activated, including the gene for Tartrate-Resistant Acid Phosphatase (TRAP). In this study, we investigated the molecular mechanisms by which RANKL activates TRAP gene. We subcloned 1.8-kb mouse TRAP promoter (-1284 to +552), amplified by PCR based on published sequence, into pGL3-basic to generate a reporter construct named RL(-1284)Luc. RL(-1284)Luc was transiently transfected into RAW264.7 cells and transfected cells were then either untreated or treated with RANKL. The transfection results indicated RANKL up-regulates the TRAP promoter activity about 2-fold. Thus, the 1.8-kb TRAP promoter contains a sequence(s) mediating RANKL-dependent activation of TRAP gene transcription. To locate the sequence(s), we generated 5 deletion mutants of the TRAF promoter: TRAP(-684)Luc, TRAP(-484)Luc, TRAP(-484)Luc, TRAP(-284)Luc, TRAP(+116)Luc. These mutants contain RANKL promoter regions starting from different 5' positions (the numbers in parentheses) and ending at the same 3' site (+552). Transfection data with these mutants demonstrated that a 200-bp promoter region (-684 to -484) contain the sequence(s). To further locate the sequence(s), we prepared 4 more mutants: TRAP(-644)Luc, TRAP(-604)Luc, TRAP(-564)Luc, TRAP(-524)Luc. Transfection assays with these mutants further located the sequence(s) in a 40-bp region (-684 to -644). Gel shift/competition assays showed that 40-bp oligos derived from the 40-bp region specifically binds nuclear proteins from untreated RAW264.7 cells. Consistent with the transfection data, the banding was significantly enhanced in gel shift assays using nuclear extracts from RANKL-treated RAW264.7 cells, suggesting that RANKL activates TRAP transcription through the nuclear proteins binding to the 40-bp sequence. Given that RANKL activates NF-kB or AP1, we determined whether the nuclear proteins binding to this 40-bp sequence are NF-kB or AP1. Super shift assays with antibody against p50, P65, c-fos and c-jun confirmed that the 40-bp sequence binds transcription factors other than NF-kB and AP1. Taken together, we have located a 40-bp sequence in TRAP promoter regulating RANKL-induced TRAP gene transcription. More interestingly, this sequence may regulate TRAP transcription by binding novel transcription factors induced by RANKL.

F246

A Potent Antagonist of $\alpha_v\beta_3$ Integrin Is a Powerful Inhibitor of Bone Resorption In Vivo. S. B. Rodan[1], L. T. Duong[1], M. E. Duggan*[2], J. E. Fisher[1], M. A. Gentile[1], C. Fernandez-Metzler*[3], W. Halczenko*[2], G. D. Hartman*[2], J. H. Hutchinson*[2], C. Leu[1], L. Lipfert*[1], R. M. Nagy*[1], B. Pennypacker[1], T. Prueksaritanont*[3], J. G. Seedor*[1], G. Wesolowski[1], D. B. Kimmel[1], G. A. Rodan[1]. [1]Bone Biology & Osteoporosis Research, Merck Research Laboratories, West Point, PA, USA, [2]Medicinal Chemistry, Merck Research Laboratories, West Point, PA, USA, [3]Drug Metabolism, Merck Research Laboratories, West Point, PA, USA.

The $\alpha_v\beta_3$ integrin was shown to play a major role in bone resorption *in vitro* and *in vivo*. $\alpha_v\beta_3$ is highly expressed in osteoclasts and binds to the RGD sequence in extracellular matrix proteins. We report here the pharmacological properties of a low molecular weight RGD mimetic (compound A) and its *in vivo* activity in several models of bone resorption. ^{3}H-compound A binds with high affinity (Kd 0.33 nM) to purified human $\alpha_v\beta_3$. In cell assays *in vitro* compound A: (i) is a potent inhibitor of osteoclast formation and bone resorption with IC50s of ~ 10 nM; (ii) inhibits attachment to vitronectin of HEK 293 cells, transfected with either $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrin, with IC_{50}s of 0.6 and 25 nM, respectively; and (iii) inhibits $\alpha_{IIb}\beta_3$-dependent human platelet aggregation with an IC_{50} of 35 μM. In pharmacological assays of *in vivo* bone resorption compound A: (i) increases bone mineral density (BMD) significantly in growing male rats, when administered at 10 and 30 mg/kg P.O., b.i.d. for 10 days; (ii) increases BMD dose dependently in growing male rats by 4.7 to 32%, at increasing steady state concentrations between ~70 and 1550 nM, respectively, obtained by administering the drug S.C. with minipumps; (iii) in 6 month old ovariectomized (ovx) rats (a) increases BMD of distal femur; (b) increases bone volume of proximal tibial cancellous bone determined by histomorphometry; and (c) reduces bone turnover rate, when administered orally at 10 and 30 mg/kg, b.i.d. for 4 weeks, all relative to ovx rats receiving vehicle; and (iv) suppresses urinary N-telopeptide (uNTx) in ovx rhesus monkeys, when administered orally at 5, 15 and 40 mg/kg/day. In conclusion, compound A, a potent and selective $\alpha_v\beta_3$ integrin ligand, is a powerful inhibitor of bone resorption; it prevents bone loss in several animal models when given orally, without eliciting detectable changes in other tissues examined.

Generation and Characterisation of Bisphosphonate-Resistant J774 Cells. K. Thompson*, M. J. Rogers. Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom.

Different cell types exhibit different sensitivities to bisphosphonates (BPs) *in vitro*. To identify possible routes by which cells could become resistant to BPs, we sought to isolate a BP-resistant strain of J774 macrophages. J774 cells were cultured in increasing concentrations of ibandronate (IBA), from 0.1μM to 5μM, which caused extensive (>95%) apoptosis. The surviving cells were further cultured in IBA (5μM) for 3 weeks, until recovery occurred. The resulting cells (J774-RES) were resistant to the cytotoxic effects of BPs in

an MTT assay (IC_{50} >100μM for IBA, vs 59μM in wild-type cells) but grew at a comparable rate to the parental cells, although the protein content of the resistant cells was significantly lower than in the parental strain. J774-RES cells were also found to be cross-resistant to the cytotoxic effects of zoledronic acid (ZOL) (IC_{50} 69μM in J774-RES vs 18μM in parental cells). The resistance of J774-RES cells to BPs was not due to differences in cellular uptake since J774-RES cells did not differ from parental cells in the ability to internalise [^{14}C]IBA or [^{14}C]ZOL. Western blotting for unprenylated Rap1A and metabolic labelling with [^{14}C]mevalonolactone were used to determine the effect of IBA and ZOL on protein prenylation in the resistant cells. IBA and ZOL were markedly less effective at inhibiting protein prenylation in J774-RES cells compared to the parental cells. To determine the mechanism for the resistance of J774-RES cells, we examined the activity of FPP synthase, the molecular target of IBA and ZOL. FPP synthase activity in lysates of the resistant cells was not significantly different to the activity in parental cells and there was no difference in the degree of inhibition by IBA or ZOL. J774-RES cells did not differ from the parental cells in the cytotoxic response to mevastatin, suggesting that changes in HMG-CoA reductase activity do not account for the mechanism of resistance. Western blot analysis also suggested that the level of HMG-CoA reductase did not differ between resistant and parental cells, and IBA and ZOL treatment upregulated the level of HMG-CoA reductase in both strains. This study supports the notion that cells can become resistant to BPs, although the exact molecular basis for this resistance remains to be determined.

N-Bisphosphonates Stimulate Proliferation of γ/δ-T Cells in Human PBMC Cultures by Inhibiting the Mevalonate Pathway: Clarification of the Acute Phase Response. K. Thompson*, S. A. Gordon*, M. J. Rogers. Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom.

Several recent studies have suggested that bisphosphonates (BPs) can stimulate proliferation of γ,δ-T cells by acting as non-peptide antigens (such as isopentenyl diphosphate/IPP) that can be presented to the γ,δ-TCR. However, since nitrogen-containing BPs (N-BPs) can disrupt the mevalonate pathway by inhibiting farnesyl diphosphate (FPP) synthase, it is also possible that N-BPs affect γ,δ-T cells by altering the intracellular synthesis of isoprenoid lipids or by preventing protein isoprenylation. We examined the effect of a range of BPs on the proliferation of γ,δ-T cells, using flow cytometry to quantitate the number of CD3+/γ,δ-TCR+ cells after 7 days' culture of human PBMCs in the presence of rhIL-2. 1μM zoledronic acid, ibandronate, alendronate and pamidronate, or 1μM IPP, consistently increased the proportion of γ,δ-T cells in the CD3+ population (from 3-6% in controls to 20-65%). The order of effectiveness of N-BPs was similar to the order of potency for inhibiting FPP synthase (ZOL>ALN~IBA>PAM). Furthermore, minor changes in N-BP structure that affect the potency for inhibiting FPP synthase also affected the ability to stimulate γ,δ-T cell proliferation. Clodronate, which does not inhibit FPP synthase, had no effect. The stimulatory effect of N-BPs on γ,δ-T cell proliferation was abrogated by co-incubation with 1μM mevastatin, but was not affected by 10μM geranylgeraniol. Furthermore, mevastatin alone did not affect the proportion of γ,δ-T cells, suggesting that the stimulatory effect of N-BPs on T cells was not due to inhibition of protein isoprenylation but was related to the accumulation of isoprenoid lipids (eg IPP) upstream of FPP but downstream of mevalonate. Treatment of purified γ,δ-T cells (isolated from PBMCs by negative selection) with N-BPs or IPP in the presence of rhIL-2 did not stimulate T cell proliferation, indicating that accessory cells are required for the stimulatory effect of N-BPs on γ,δ-T cells. Together, these observations demonstrate that N-BPs indirectly stimulate the proliferation of human γ,δ-T cells *in vitro*. This effect is dependent on the ability of N-BPs to inhibit the intracellular enzyme FPP synthase, either in γ,δ-T cells or in other PBMCs. Inhibition of FPP synthase causes the accumulation of isoprenoid lipids (eg IPP) upstream of FPP in the mevalonate pathway. It is likely that the release of isoprenoid lipids can cause activation of γ,δ-T cells via presentation of isoprenoid lipid on antigen-presenting cells. These studies finally shed new light on the mechanism underlying the acute phase response observed in patients treated with N-BPs.

A New Class of Anti-Resorptives: Inhibitors of Type IIa Sodium/Phosphate Cotransporter. E. Chan*, A. deRosier*, S. Sankuratri*. Roche Bioscience, Palo Alto, CA, USA.

The type IIa sodium/phosphate co-transporter (Npt IIa) is a key player in overall phosphate homeostasis and bone remodeling. In addition to its expression in kidney, previous studies showed that the protein was expressed in osteoclasts and the plasma membrane expression and activity of Npt IIa protein in osteoclasts increased in presence of bone particles. A non-specific inhibitor of Pi transport, PFA reduced Pi uptake in isolated osteoclasts and inhibited pit formation in a dose-dependent manner. Npt IIa-/- mice exhibited reduction in osteoclast number and higher trabecullar volume in 115d or older mice relative to wild-type mice. Hence, it makes Npt IIa an attractive target for developing anti-resorptive agents. We established a stable Npt IIa expressing mammalian cell line, which was then subjected to high throughput screening with Roche's collection of compounds. Several inhibitors have been identified with an IC_{50} as low as 2 μM in Pi transport assays. Specificity and selectivity of the identified inhibitors have been confirmed using a variety of assays. None of the inhibitors showed cytotoxic effects (>100 μM) and were at least 5-fold selective over sodium/sulfate co-transporter. Many of these compounds also showed selectivity over two other related sodium/phosphate cotransporters Npt IIb and a type III transporter. The most potent compounds were tested for their ability to inhibit bone resorption by mouse osteoclasts. The compounds inhibited osteoclast-mediated bone resorption by over 80% at 10 μM. These compounds could be potential leads to develop a more potent anti-resorptive drug.

F254

Non-peptide Small Molecule Compound that Selectively Inhibits RANK-RANKL Interaction. N. Sakurai, H. Akatsuka*, J. Mizukami*, N. Sato*, M. Tsuda*, S. Hashimoto*, E. Koitabashi*, K. Kawano*, J. Kohno*, M. Nishio*. Discovery Research Laboratory, Tanabe Seiyaku Co., Ltd., Saitama, Japan.

Receptor activator of NF-κB (RANK) and its ligand RANKL play crucial roles in osteoclast differentiation and activation. A secreted soluble TNF receptor family member, osteoprotegerin (OPG), a natural decoy receptor for RANKL, has been found to be a potent inhibitor of osteoclast differentiation and activation *in vitro* and *in vivo*. The administration of OPG has been reported to be effective on several animal models for bone diseases characterized by excessive bone resorption including osteoporosis, suggesting that inhibition of RANK-RANKL interaction is a promising avenue to the prevention of bone loss. In this study, we identify a novel non-peptide small molecule compound that blocks the RANK-RANKL interaction. We isolated TMC-315s from a fungal culture extract composed of at least four homologs of molecular weight of about 600 as inhibitors of RANKL function. TMC-315B2, the best of these components inhibited the RANKL-induced NF-κB activation at submicromolar concentrations while it failed to block the TNF-induced activation. TMC-315B2 also inhibited the RANK-RANKL interaction in enzyme-linked immunosorbent assay using soluble forms of RANKL and RANK proteins (IC50=2.1 μM), whereas it did not antagonize the TNF-TNFR1 binding. Biospecific interaction analysis using surface plasmon resonance detection (BIAcore) revealed that TMC-315B2 bound to RANKL but did not bind to RANK. Moreover, the binding of TMC-315B2 to TNF or TRAIL was not detected. We next tested TMC-315B2 for its effect on osteoclastogenesis using the coculture system. Osteoclast formation was inhibited dose-dependently by TMC-315B2. We further examined the effect of TMC-315B2 on bone resorption *in vivo*. TMC-315B2 significantly prevented parathyroid hormone-related peptide (PTHrP)-induced hypercalcemia in thyroparathyroidectomized (TPTX) rats when administered intravenously at 10 mg/kg. In conclusion, we have identified a non-peptide small molecule TMC-315B2 that antagonizes osteoclastogenesis by blocking RANK-RANKL interaction and exerts this effect both *in vivo* and *in vitro*. Derivatives of this compound may have a therapeutic advantage over OPG as they may be orally available.

F256

Zoledronic Acid Modulates Bone Repair through Transiently Delayed Remodelling. E. J. Smith[1], R. A. Peat*[2], A. McEvoy*[2], J. N. Briody[2], P. A. Baldock*[1], J. A. Eisman[1], D. G. Little*[2], E. M. Gardiner[1]. [1]Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Orthopaedic Research Unit, Childrens Hospital Westmead, Sydney, Australia.

Distraction osteogenesis for correcting limb length discrepancy can be clinically difficult due to fractures through poorly mineralised regenerate bone in the distraction gap. Bisphosphonates increase regenerate mineral content, size and strength but the mode by which this occurs is unclear. Inhibition of osteoclastic resorption may lead to regenerate retention, but bisphosphonates also stimulate bone formation in vitro. To investigate these possibilities 8 week old male NZW rabbits underwent right tibial osteotomy, 14 days of distraction and consolidation until sacrifice at 2, 4, 6, 18 and 44 weeks post surgery. The intact left tibia was used as internal control. Animals received saline, single dose zoledronic acid (0.1mg/kg at surgery), or double dose zoledronic acid (at surgery and 2 weeks later). X-rays were taken at 6, 18 and 44 weeks. In some animals, BMD and BMC were measured by DXA at 2, 4, 6, 12, 18 and 44 weeks. In others histomorphometry was carried out after sacrifice. Although BMD and BMC increased in all animals between 2 and 4 weeks, this was greater in single and double dose animals (33% and 53%, $p<0.01$). Saline animals lost regenerate bone between 4 and 6 weeks (34%, $p<0.01$) but treated animals did not. Between 6 and 44 weeks BMD and BMC gradually decreased in treated animals and increased in saline group, such that at 18 and 44 weeks there was no difference between groups. Trabeculae and cortical bone ends were still apparent in x-rays of treated groups at 18 and 44 weeks. Trabecular BV/TV was greater in the double dose group at 4, 6 and 18 weeks ($p<0.05$). Similar increases in single dose group were not significant. Trabecular number increased by 26% and 53% in single and double dose groups at 4 weeks and by 28% and 60% at 6 weeks ($p<0.01$). There was no difference in trabecular thickness at 2, 4 or 6 weeks and no change in mineral apposition rate at later times. Osteoblast surface tended to be lower in treated animals (15% at 2 weeks and 11% and 50% in single and double dose groups at 4 weeks, $p<0.05$). There was a decrease in osteoclast surface (63% at 2 weeks in single dose and 20% and 60% at 4 weeks in treated groups, $p<0.05$). Thus these data do not support a bisphosphonate-induced increase in bone formation. Rather, the increase in new bone in the distraction gap appears due to retention as a result of decreased resorption. In this study, the clinically valuable increase in regenerate volume and strength can be explained by bisphosphonate suppression of osteoclastic resorption of bone produced in the exuberant osteoblastic response to fracture and distraction.

F259

Possible Role for TGF-Beta-Induced SOCS Expression in Osteoclast/ Macrophage Lineage Commitment In-Vitro. S. W. Fox*, T. J. Chambers. Dept of Cellular Pathology, St George's Hospital Medical School, London, United Kingdom.

The ligand that induces osteoclast (oc) differentiation has been identified as RANKL, a member of the TNF superfamily. However, only some precursors form oc when incubated with RANKL, suggesting that RANKL alone might not be sufficient to ensure that precursors become oc at sites of resorption. Responses to stimuli from the TNF superfamily are characteristically associated with inputs from other factors such as TGF-beta. Previously, we have shown that TGF-beta augments oc formation. Furthermore, oc formation is abolished by anti-TGF-beta antibodies, suggesting that oc that form without the addition of exogenous TGF-beta are dependent on TGF-beta in the medium or produced by precursors themselves. The mechanism by which TGF-beta facilitates oc formation is unknown. One possibility is that the environment in-vitro is essentially pro-inflammatory, due to the presence of agents such as interferons, and TGF-beta opposes this. Interferons signal via the JAK-STAT pathway, and TGF-beta might therefore block these signals. Recently, a group of STAT-induced factors, termed SOCS (suppressors of cytokine stimulation), have been isolated which form part of the negative-feedback mechanisms that switch off JAK-STAT signalling after cytokine stimulation. Therefore, we proposed to identify those SOCS expressed in oc, and establish if SOCS expression plays a role in the mechanisms by which TGF-beta enables oc formation. To assess the pattern of SOCS1-4 expression in oc and their precursors we performed Northern analysis and quantitative PCR on RNA extracted from macrophages, oc and precursor cells incubated with or without TGF-beta-1. Interestingly, we found that while SOCS1-4 mRNA is not detectable in macrophages, oc express SOCS3 mRNA, and TGF-beta further upregulates this expression. Furthermore, TGF-beta induces SOCS3 expression in uncommitted precursors within 1 hour. To determine if SOCS3 plays a role in the mechanisms by which TGF-beta facilitates oc formation we examined the effect of overexpressing SOCS3 in precursors using retrovirus. We found that oc formation and bone resorption were significantly enhanced in SOCS3-infected cells. This suggests that TGF-beta-induced expression of SOCS3 mRNA may represent a mechanism by which TGF-beta suppresses inhibitory cytokine signalling, priming precursors for oc differentiation.

F261

Cell Swelling Mediates Activation of a Cl^- Channel by Extracellular Ca^{2+} in Murine Osteoclasts. K. Sakuta*[1], H. Sakai[2], H. Mori[1], H. Morihata*[3], M. Kuno[1]. [1]Physiology, Osaka City University Graduate School of Medicine, Osaka, Japan, [2]Orthopedic Surgery, Osaka City University Graduate School of Medicine, Osaka, Japan, [3]Neurology, Osaka City University Graduate School of Medicine, Osaka, Japan.

Bone resorbing activity of osteoclasts is inhibited by high concentrations of extracellular Ca^{2+} ($[Ca^{2+}]_o$) released from the degraded bone matrix in the resorption pit. Osteoclasts possess Ca^{2+}-sensing cellular machineries to regulate their own activity. We have previously shown that exposure to high $[Ca^{2+}]_o$ (≥20 mM) activates a volume-sensitive, outwardly-rectifying Cl^- (OR_{Cl}) channel (Shibata et al., 1997; Sakai et al., 1999). In this study, the Ca^{2+}-sensing mechanisms leading to activation of the OR_{Cl} channel were examined using whole cell current recordings of murine osteoclasts developed from bone marrow cells in the co-culture with ST-2 cells in the presence of vitamin D. The OR_{Cl} current was also activated by Gd^{3+}, Zn^{2+} and a polycation, neomycin, suggesting that osteoclasts respond to di-, tri-, and polycations. Activation of the OR_{Cl} channel by these cations was accompanied by increases in the planar cell area of the cell body, suggesting that swelling is involved in the Ca^{2+}-sensing response. There was a positive correlation between the current density and increment in the cell area. The $[Ca^{2+}]_o$-induced swelling was confirmed in intact (unclamped) cells by three-dimensional analysis using confocal scanning microscopy with a fluorescent dye (BCECF) in the extracellular medium, although the extent of swelling was smaller than that in clamped cells. Either removal of extracellular Na^+ or a blocker for the Na^+-Ca^{2+} exchanger (2'4'-dichlorobenzamil hydrochloride) inhibited both the $[Ca^{2+}]_o$-activated OR_{Cl} current and the accompanying cell swelling. Decreasing intracellular pH from 7.3 to 6.6 enhanced the sensitivity of the OR_{Cl} channel to cations. Amiloride (1 mM), a blocker for the Na^+-H^+ exchanger, prevented the activation and decreased the current once activated at pH 6.6. Intracellular dialysis with an ATP-free pipette solution or application of an actin-destabilizer (cytochalasin D, 0.1 μM) inhibited the $[Ca^{2+}]_o$-activated OR_{Cl} current and the accompanying cell swelling. These results propose a new Ca^{2+}-sensing mechanism in osteoclasts: exposure to high $[Ca^{2+}]_o$ may induce cell swelling by Na^+ influx via Na^+-dependent transporters, such as the Na^+-Ca^{2+} exchanger and the Na^+-H^+ exchanger, which leads to activation of the OR_{Cl} channel. Cell volume may be a second-message in the regulation of osteoclast function.

F263

Association of the Cytoplasmatic Tail of the Calcitonin Receptor with Filamin Prevents its Degradation in Lysosomes. T. Seck, L. Neff, W. C. Horne, R. Baron. Cell Biology and Orthopedics, Yale University, New Haven, CT, USA.

The interactions of G-protein coupled receptors (GPCR) with a variety of intracellular proteins regulate receptor signaling, internalization and recycling. To identify proteins that might interact with intracellular domains of the calcitonin receptor (CTR), we used the carboxy-terminal tail of the receptor as bait to screen a yeast two hybrid library. We isolated a clone encoding filamin, an actin binding protein. The interaction of the CTR and filamin was confirmed by co-immunoprecipitation. However, a CTR mutant lacking the C-terminal tail did not bind to filamin. Confocal microscopy showed partial colocalization of filamin and the CTR at the surface of mouse osteoclast-like cells. Using the directed yeast two-hybrid assay, the binding site on filamin was mapped to amino acids (aa) 2129-2330, and the interacting site on the CTR was mapped to the C-terminal half of the tail (aa 447-474). Overexpression of fragments spanning the interacting site of filamin or the C-terminal tail inhibited the interaction. The functional relevance of the association of the CTR with filamin was tested in M2 melanoma cells that lack filamin and a control cell line (A7) stably transfected with filamin. The production of cyclic AMP and elevation of cytosolic free calcium in response to Calcitonin (CT) were identical in both cell lines. CT-induced Erk1/2 phosphorylation was also intact in filamin-free cells. Thus, filamin is not directly involved in signal transduction from the CTR. However, there was markedly less of the CTR in the filamin-free M2 cells, as determined by Western blots. Moreover, surface expression of the CTR, determined by FACS analysis, was significantly lower in the filamin-free cells. Pulse chase experiments, comparing the rates of degradation of the CTR in the two cell lines, showed a significantly faster ligand-independent degradation of the receptor in the absence of filamin. In contrast, the degradation of another GPCR, the beta2-adrenergic receptor, was identical in both cell lines. The degradation of the CTR was partly inhibited by chloroquine and ammonium chloride, agents which inhibit lysosomal degradation. Thus, the interaction of the cytoplasmatic tail of the CTR with the actin binding protein filamin regulates the level of expression of the CTR at the cell surface by preventing its degradation.

F269

The Effect of Socioeconomic Deprivation on Primary Care Referral to a Direct Access DXA Scanning Service. S. J. Gallacher[1], A. R. McLellan[2], I. Baxter*[3], P. McGill*[4], R. Dargie*[5], C. Morrison*[3]. [1]Medical Unit B, Southern General Hospital, Glasgow, United Kingdom, [2]Western Infirmary, Glasgow, United Kingdom, [3]Greater Glasgow NHS Board, Glasgow, United Kingdom, [4]Stobhill Hospital, Glasgow, United Kingdom, [5]Royal Infirmary, Glasgow, United Kingdom.

Osteoporosis and increased fracture risk is recognised to be a major public health problem. Strategies are required to identify individuals at highest risk in order that interventions can be targeted to this group. Bone densitometry, in particular axial DXA scanning, has been shown to predict individuals both at increased risk of fracture and those who are likely to derive benefit from bisphosphonate therapy. This work describes the outcome of collaboration amongst four hospitals serving the population of the City of Glasgow (population 960,000) to provide Direct Access DXA Scanning to primary care physicians for patients with clear osteoporosis risk factors. These risk factors include history of low trauma fracture over age 50, long term (>3 months) oral corticosteroids, early menopause (<45 years) and radiological osteopenia. Over the past 3 years 3985 patients have been seen through this service. There are 216 primary care practices in Glasgow all of whom were advised of this service. Of these 190 (88%) have used the service. The modal number of referrals per practice was between 2 and 9 but 4 practices have referred over 100 patients. The reason behind this disparity is not clear. One factor might relate to patients' socioeconomic status. To investigate this further all referred patients had their appropriate Deprivation Category (Depcat) (Carstairs 1991) allocated. Depcat is a 7 point score with category 1 being most affluent and category 7 least affluent. The proportion of the total population in each Depcat was related to the proportion of DXA referrals in each Depcat. 17.5% of the population of Glasgow are in Depcat 1 & 2 but this population accounted for 27.6% of referrals. At the other extreme 52.6% of the population are in deprivation categories 6 & 7 and this population accounted for only 38.5% of patients scanned. This variation remained present in each of the age bands 50-59, 60-69 and greater than 70 years and remained constant by year of referral. Overall patients resident in the most deprived area of the city are approximately 8 times less likely to be referred for DXA than those from the most affluent area. As some osteoporosis risk factors (such as cigarette smoking) are more prevalent in populations of lower socioeconomic status, it is reasonable to expect a higher prevalence of osteoporosis in this population. This is another example of the inverse care law where the population most at risk is least likely to receive appropriate medical care.

F275

Low Vitamin K Status Is Associated with Low Bone Mineral Density and Quantitative Ultrasound in Men. S. L. Booth[1], K. E. Broe[2], R. R. McLean[2], D. R. Gagnon*[3], J. W. Peterson*[1], M. T. Hannan[2], L. A. Cupples*[3], D. M. Cheng*[3], P. W. F. Wilson*[3], B. Dawson-Hughes[1], D. P. Kiel[2]. [1]USDA HNRCA at Tufts University, Boston, MA, USA, [2]Hebrew Rehab Ctr & Harvard Med Sch, Boston, MA, USA, [3]BU Sch Public Health, Boston, MA, USA.

Low vitamin K (VK) status, as indicated by low fasting plasma phylloquinone (VK1) and high serum % undercarboxylated osteocalcin (%ucOC), is a potential risk factor for bone loss and hip fracture. Few data exist on the association between VK and bone mineral density (BMD) in men. We examined associations between fasting plasma VK1, serum %ucOC, BMD and quantitative ultrasound (QUS) of the calcaneus. BMD of the hip (femoral neck and trochanter) and spine (L2-4) was measured by Lunar DPX-L in 734 men participating in the Framingham Study Offspring cohort. Broadband ultrasound attenuation (BUA) and speed of sound (SOS) were also measured in 576 of these men using the Sahara bone sonometer (Hologic). Participants had a mean (SD) age of 59 (9) years, with a mean (SD) VK1 of 1.5 (2.0) nmol/L and a mean (SD) %ucOC of 15.8 (16.1). The mean (SD) BMD of the femoral neck, trochanter and spine were 0.982 (0.142), 0.894 (0.144) and 1.328 (0.221) g/cm^2, respectively. The mean (SD) BUA and SOS were 80.6 (17.2) dB/MHz and 1555 (31) m/s, respectively. The associations between VK status, BMD and QUS were evaluated using regression models that adjusted for age, BMI, current smoking, caffeine, alcohol and total calcium intakes, physical activity, and plasma 25(OH)D and triglycerides. Plasma VK1 was positively associated with femoral neck BMD (p=0.03), BUA (p=0.009) and SOS (p=0.03). There was also a non-significant (NS) trend between plasma VK1 and BMD of the trochanter (p=0.07) and spine (p=0.16). Whereas %ucOC was negatively associated with BMD of the femoral neck (p=0.02) and trochanter (p=0.004), with a NS trend at the spine site (p=0.18), %ucOC was not associated with either QUS measure. In conclusion, low vitamin K status is associated with low QUS and low BMD of the femoral neck and trochanter in men. VK supplementation trials are needed to evaluate the role of vitamin K in reducing bone loss.

F277

Prevalence of Vitamin D Depletion Among Subjects Seeking Advice on Osteoporosis: A Five-Year Cross Sectional Study with Therapeutic and Public Health Implications. N. Parikh*, T. Eskridge*, J. Hill*, E. Phillips*, D. Rao. Bone & Mineral Research Laboratory, Henry Ford Hospital, Detroit, MI, USA.

There is continued concern about vitamin D depletion in the U.S. population. We previously reported that a significant proportion of patients seeking advice for osteoporosis are vitamin D depleted. Since then concerted public health education efforts about calcium (Ca) and vitamin D nutrition have occurred. We therefore assessed the impact of such efforts on the prevalence of vitamin D depletion among individuals attending our osteoporosis clinic. The computerized database of all patients seen between January 1997 & December 2001 was reviewed for the prevalence of vitamin D depletion (defined as serum 25-OHD of ≤15 ng/ml). We excluded patients with obvious known causes for vitamin D, and all Hispanics and Asians (n=201). Serum Ca, creatinine (Cr), PTH and 25-OHD were measured in all patients. Three thousand, seven hundred, and ninety new patients were seen during the 5 years; 3343 (88%) were women and 3195 (84%) were whites. The mean age was 65 ± 13 years. For the entire study cohort the prevalence of vitamin D depletion was 20% (748/3790) and remained constant during the 5 years (17%, 21%, 18%, 18%, and 24% respectively). Vitamin D depletion was higher in blacks than in whites (43% vs 16%; p<0.001). Serum 25-OHD correlated with PTH (r= -0.22; p<0.001) but not with age, Ca, or Cr. Age and serum 25-OHD, Ca and Cr all predicted PTH level, but serum 25-OHD and Cr were the strongest predictors (t statistic -13.7 & +17.7 respectively). Based on the differences in slopes of PTH on 25-OHD, black women had a greater increase in PTH than white women (-1.23 vs. -0.79) This is the largest study of its kind in the U.S. and confirms the preliminary findings of our 2-year study. Indeed, we observed a disturbing upward trend (about 2%-5%) in vitamin D depletion over the 5 years despite an explosion of public education efforts. This implies that either these efforts are ineffective, or that foods and supplements contain inadequate amounts of vitamin D, or both. Conclusions: Vitamin D depletion is prevalent among ambulatory patients seeking advice about osteoporosis. Since poor vitamin D nutrition may adversely affect response to specific osteoporotic therapy, greater attention to vitamin D nutrition in addition to Ca is essential. The lack of decline in the prevalence of vitamin D depletion over 5 years implies that current efforts are ineffective and need reexamination.

F279

Dietary Phytoestrogen Intake Is Not Associated With Low Bone Mineral Density in Healthy Caucasian Premenopausal Women. M. R. French*[1], A. C. Blakely*[1], C. C. Chase*[1], L. U. Thompson*[2], G. A. Hawker[1]. [1]Osteoporosis Research Program, Sunnybrook and Women's College Health Sciences Centre, Toronto, ON, Canada, [2]Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, ON, Canada.

The consumption of soy products and other dietary phytoestrogens has increased, likely due to perceived potential benefits on menopausal symptoms, postmenopausal bone health and cancer risk. The bone effects of these compounds in premenopausal women is unclear. We evaluated the association between dietary intake of the two major classes of phytoestrogens, isoflavones and lignans, and bone mineral density (BMD) in 557 healthy, Caucasian, premenopausal women aged 21-40 years. Intake of lignans and isoflavones were assessed by quantitative food frequency questionnaire during a detailed standardised interview. Total phytoestrogen intake was a composite value of dietary lignan and isoflavone intakes. BMD was measured at the lumbar spine (L2-L4) and femoral neck using dual energy Xray absorptometry (DXA). Bone mass was classified as low if BMD values (g/cm^2) were in the lowest quintile as measured by DXA. Using multiple logistic regression modelling, independent correlates of low BMD were identified. Variables considered included age, weight, height, dietary factors including phytoestrogen intake (daily lignan, isoflavone and total phytoestrogen intake by quartiles), menstrual and reproductive history, body composition, physical activity and smoking. The mean age of the cohort was 31.9 ± 4.7 years. Mean intake of isoflavones, lignans and total phytoestrogens were 21.6 µmol/day (0-404.9 µmol/day), 4.6 µmol/day (0.1-22.7 µmol/day) and 26.3 µmol/day (0.2-420.4 µmol/day), respectively. At the femoral neck, low BMD was associated with low body weight, lower percent lean body mass and physical inactivity as an adolescent. Younger age, low body weight and lower percent lean body mass were associated with low BMD at the lumbar spine. Low BMD at the femoral neck was not associated with daily intake of isoflavones (OR 1.176, 95% CI 0.952 – 1.453), lignans (OR 1.120, 95% CI 0.901 – 1.393) or total phytoestrogens (OR 1.217, 95% CI 0.995 – 1.490). Nor was there an association between phytoestrogen intake and low BMD at the lumbar spine. In this sample of healthy Caucasian premenopausal women, dietary phytoestrogen intake was not associated with BMD. A prospective study is ongoing to determine whether dietary phytoestrogen intake affects changes in BMD over time.

F282

Inflammatory Bowel Disease and the Risk of Fracture. T. P. van Staa[1], L. S. Brusse*[2], M. K. Javaid[1], H. G. M. Leufkens*[2], C. Cooper[1], N. K. Arden*[1]. [1]Medical Research Council Environmental Epidemiology Unit, Southampton, United Kingdom, [2]Pharmacoepidemiology and Pharmacotherapy, Utrecht Institute for Pharmaceutical Sciences, Utrecht, Netherlands.

Patients with inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC), have an increased risk of low bone mass, the pathogenesis of which is multifactorial. There are limited data on fracture prevalence in patients with IBD, with conflicting results. We therefore conducted a primary care based case-control study to determine the risk and major risk factors of fracture in IBD patients. 231,778 patients with a fracture and 231,778 age and sex matched controls were recruited from the General Practice Research Database. The database has been previously demonstrated to be a representative sample of the general population of England and Wales. The IBD diagnosis and risk factors were collected from electronic medical records. Adjusted odds ratios (OR) were estimated from conditional logistic regression. The mean age of cases and controls was 51 years and 52.5% were women. A history of IBD was found in 1134 fracture cases, compared to 896 of the controls (adjusted OR 1.21; 95% CI 1.10-1.32 p<0.001). The risk of fracture was significantly related to disease severity, as assessed by the number of symptoms [OR in IBD patients without symptoms, 1.02 (0.90-1.17); 1 symptom, 1.66 (1.41-1.96); and 2 or more symptoms, 1.74 (1.43-12.12)]. Similarly, severity assessed by medication demonstrated inceasing fracture risks compared to untreated patients:Aminosalicylates use: 1.32 (1.14,1.54), oral corticosteroids 1.46 (1.18-1.82) and disease modifying agents 1.86 (1.15,3.02). IBD patients with a history of small bowel surgery did not have an increased risk of fracture [OR 1.03 (0.84-1.28)]. Use of oral corticosteroids increased with disease severity. The OR in IBD patients was 1.10 (1.00-1.20) after adjustment for oral corticosteroids. For hip fracture, this OR was 1.46 (1.04-2.04). In conclusion, IBD patients have a significantly higher risk of fractures, especially in patients with more severe disease. This increased risk is partially explained by oral corticosteroid usage.

Table 1. Risk of fracture in CD and UC

Disease	All fracture	Hip fracture	Vertebral fracture	Distal forearm fracture
CD	1.32 (1.13,1.53)	1.86 (1.08,3.21)	2.25 (1.13,4.47)	1.38 (0.99,1.93)
UC	1.13 (1.02,1.27)	1.40 (0.92,2.13)	1.42 (0.84,2.40)	1.17 (0.93,1.47)

OR with 95% CI adjusted for age, sex, disease and medication history and body mass index and smoking.

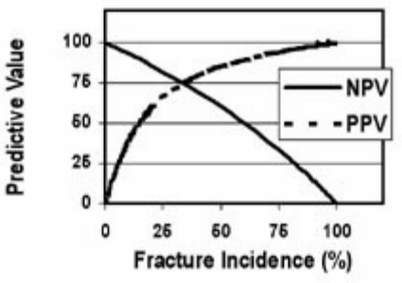
F284

The Utility of Prospective Height Loss for Detecting Vertebral Fracture Depends on Fracture Incidence. K. Siminoski[1], J. D. Adachi[2], G. Cline*[3], C. B. M. B*[4], V. E. R. T Study Group*[3]. [1]Radiology, Univ of Alberta, Edmonton, AB, Canada, [2]Medicine, McMaster Univ, Hamilton, ON, Canada, [3]Procter & Gamble Pharm, Mason, OH, USA, [4]Bone Alliance, Toronto, ON, Canada.

Our previous analysis of the VERT MN/NA risedronate studies indicated that prospective height loss could not be used to rule in the development of an incident vertebral fracture in that population. Height loss < 2 cm could effectively rule out a new fracture in the VERT population. We have examined the performance of height loss as a clinical test across a range of fracture incidence to determine (1) whether there is any clinically relevant fracture incidence range for ruling in a fracture, (2) the useful incidence range for ruling out a fracture. Sensitivity and specificity were derived from the placebo arms of the risedronate VERT MN/NA trials. Post-baseline height and vertebral radiographs were available in 985 postmenopausal female subjects (average age 69 years, range: 38-85 years). Height loss was determined as the difference between the baseline measurement and the subsequent measurement using a stadiometer. Lateral vertebral radiographs were performed at the same times and were analyzed by digital morphometry from T4 to L4. Vertebral fractures were determined using both quantitative and semiquantitative methods. New vertebral fractures occurred in 18.1% of study subjects. At a cut-off point of 2 cm height loss over 3 years, sensitivity was 38% and specificity was 93%. These parameters were applied over a range of theoretical vertebral fracture incidence to determine positive predictive value (PPV) and negative predictive value (NPV). Fracture can be ruled in when PPV is high. As shown in the figure, PPV is relatively low over much of the incidence range. PPV only rises > 80% at a fracture incidence of 41%, and only becomes greater than 90% when incidence is 61%. Fractures can be effectively ruled out when NPV is high. The negative predictive value is > 90% when fracture incidence is < 14%. NPV is above 80% up to fracture incidence of 27%. This analysis demonstrates that a 2 cm cut-off for height loss during prospective monitoring could only rule in a fracture with high accuracy at extremely high fracture incidence rates (>61%). A 2 cm cut-off can rule out the development of a fracture with high accuracy over the range of vertebral fracture incidence that would be observed in clinical practice (< 14%).

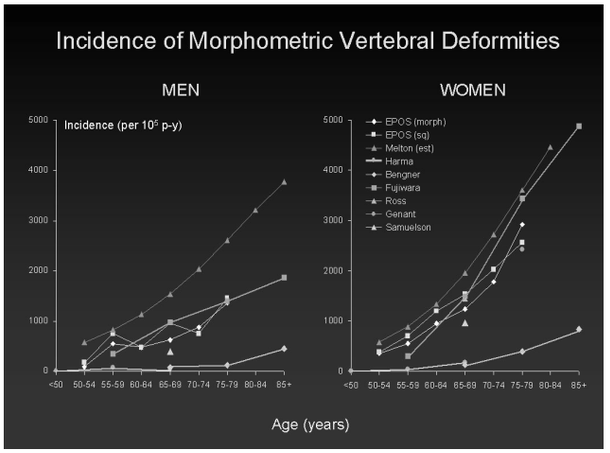


Disclosures: ***K. Siminoski****, Procter and Gamble Pharmaceuticals 2, 5, 8.*

F286

The Global Burden of Vertebral Fracture. C. Cooper[1], O. Johnell[2], P. Lips[3], L. J. Melton[4], J. A. Kanis[5]. [1]MRC Environmental Epidemiology Unit, University of Southampton, Southampton, United Kingdom, [2]Malmo General Hospital, Malmo, Sweden, [3]Vrije Universiteit Medical Center, Amsterdam, Netherlands, [4]The Mayo Clinic, Rochester, MN, USA, [5]Sheffield University Medical School, Sheffield, United Kingdom.

Vertebral fractures are recognised as a hallmark of osteoporosis, yet their global burden has not been characterised. A large number of epidemiological studies have now been performed that use consistent methods for the definition of incident morphometric deformities. We have performed a systematic review of these studies which permit characterisation of the global burden of morphometric vertebral deformity; the proportion of these deformities that come to clinical attention; and estimates of the global cost. The figure illustrates age and sex-specific incidence rates of morphometric vertebral deformities among men and women aged ≥ 50 years from various studies around the world. The application of these incidence rates to the global population suggests that around 4.67 million incident vertebral deformities occur worldwide among men and women aged ≥ 65 years each year; 1.34 million among elderly men, and 3.33 million among elderly women. The rate at which incident vertebral deformities come to clinical attention varies in the literature. Sensitivity analyses suggests that as many as 1.4 million of these deformities may come to clinical attention each year; however, ascertainment levels in some populations vary, such that this number may be as low as 373,000 annually. The minimum annual cost of vertebral fracture worldwide is estimated at $2.4 billion.



F288

Reducing Risk of Vertebral Fracture Through Specific Back Exercises: A Long Term Follow-up. M. Sinaki[1], E. Itoi*[2], H. W. Wahner*[3], P. Wollan*[4], R. Gelczer*[5], B. P. Mullan*[3], D. A. Collins*[3]. [1]Physical Medicine and Rehabilitation, Mayo Clinic, Rochester, MN, USA, [2]Department of Orthopedic Surgery, Akita University School of Medicine, Akita, Japan, [3]Nuclear Medicine, Mayo Clinic, Rochester, MN, USA, [4]Biostatistics, Mayo Clinic, Rochester, MN, USA, [5]Diagnostic Radiology, Mayo Clinic, Rochester, MN, USA.

The long-term protective effect of strong back muscles on reducing the risk of vertebral fractures in healthy Caucasian postmenopausal women was assessed. Fifty women, aged 58 to 75 years, who had completed a 2-year, randomized controlled trial 10 years earlier, were reassed. Of these, 27 had previously performed progressive, resistive back strengthening exercises for 2 years and 23 had served as controls. Bone mineral density (BMD), spine radiographs, back extensor strength (BES), biochemical marker values, and level of physical activity (PA) were obtained on all subjects at baseline, 2 years, and 10 years. Mean BES in the back exercise (BE) group was 39.4 kg at baseline, 66.8 kg at 2 years (after 2 years of prescribed exercises), and 32.9 kg at 10 years (8 years after cessation of the prescribed exercises). Mean BES in the control (C) group was 36.9 kg at baseline, 49.0 kg at 2 years, and 26.9 kg at 10 years. The difference between the 2 groups was still statistically significant at 10-year follow-up (P = 0.001). PA was not significantly different between the 2 groups at baseline. At 10-year follow-up PA was lower in both groups but still significantly higher in the former BE group (P = 0.0106). The difference in BMD, which was not significant between the 2 groups at baseline and 2-year follow-up, was significant at 10-year follow-up (P=0.0004). The incidence of vertebral compression fracture at 10-year follow-up was 14 fractures in 322 vertebral bodies examined (4.3%) in the C group and 6 fractures in 378 vertebral bodies examined (1.6%) in the BE group (Chi square test, P = 0.0290). The relative risk for compression fracture was 2.7 times greater in the C group than in the BE group. We conclude that strong back muscles can reduce the risk of vertebral fractures in estrogen-deficient women.

F290

Sleep and Nap Habits Predict Falls, Fractures and Mortality in Older Women. K. L. Stone[1], S. K. Ewing*[1], D. C. Bauer[1], J. C. Cauley[2], S. Redline*[3], S. Ancoli-Israel*[4], K. E. Ensrud[5], T. A. Hillier[6], S. R. Cummings[1]. [1]Univ of California, San Francisco, CA, USA, [2]Univ of Pittsburgh, Pittsburgh, PA, USA, [3]Case Western Reserve Univ, Cleveland, OH, USA, [4]Univ of California, San Diego, CA, USA, [5]Univ of Minnesota, Minneapolis, MN, USA, [6]Kaiser Ctr for Health Research, Portland, OR, USA.

Sleep disturbances are very common in the elderly. Insomnia and other sleep disorders have been associated with poor cognitive function and other risk factors for falls, fractures and mortality. Napping is a marker of sleep disorders, such as sleep apnea, that cause daytime sleepiness. Disturbed sleep alters circadian rhythms and hormone levels and may increase the risk of age-related diseases, such as osteoporosis. During the fourth exam (1993-4) of the Study of Osteoporotic Fractures (SOF), we administered a brief questionnaire to assess sleep and nap habits in 8,101 women aged 69 and older. We examined the relationship of self-reported sleep and nap habits with subsequent risk of falls, fractures and mortality. During 6.7 years of follow-up we observed 553 hip fractures and 1,922 deaths. 913 women (11%) reported suffering 2 or more falls during the year after the fourth exam. Daily napping (DN) was reported in 11% of participants, while insufficient sleep (IS) was reported among 26%. Short (< 6 hours) and long (> 8 hours) night-time sleep were reported in 13% and 10% of women, respectively. In multivariable models adjusting for age, BMI, health status, depression, cognitive function, selected medication use, and personal health habits, those who reported DN were 40% more likely to report two or more falls during the year after Exam 4 (Relative Risk=1.4; 95% CI= 1.1 - 1.7), had a 30% increase in risk of hip fracture (RR=1.3; 1.0 - 1.8) and 50% higher mortality risk during follow-up (RR=1.5; 1.3 - 1.7) than others. IS was associated with subsequent risk of falls (RR=1.2; 1.0 - 1.4) but did not predict mortality or fracture risk. Self-reported duration of sleep was not independently associated with any of the outcomes studied. Impaired sleep, marked by daily napping, is a common and often treatable risk factor for falls, hip fracture, and mortality. More objective and comprehensive assessments of sleep patterns are underway in SOF, so that we may further examine the associations of sleep disorders and these outcomes.

F292

Women with Incident Hip Fracture and Baseline BMD T-score >-2.5 Have Fewer Risk Factors than those with Fracture and Lower BMD. S. A. Wainwright*[1], L. M. Marshall*[1], M. T. Vogt[2], T. A. Hillier[3], J. A. Cauley[2], D. M. Black[4], M. C. Hochberg[5], E. S. Orwoll[1]. [1]Oregon Health & Science University, Portland, OR, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Kaiser Permanente Center for Health Research, Portland, OR, USA, [4]University of California, San Francisco, CA, USA, [5]University of Maryland, Baltimore, MD, USA.

Many older women who experience hip fracture have baseline BMD T-scores > -2.5. For instance, 54% of women (age 65 and over) with incident hip fracture over 5 years in the Study of Osteoporotic Fractures (SOF) had baseline total hip BMD T-score > -2.5. To establish the characteristics of these women and to test the hypothesis that they have other important risk factors for fracture, we analyzed data from SOF. Baseline demographics, medical history, activity, fall frequency, strength, and vision were assessed and total hip BMD was measured using DXA. Ascertainment of incident, nontraumatic hip fractures began at the time of BMD measurement and continued for five years. Hip fracture cases were divided into a higher BMD group (total hip BMD T-score >-2.5) and a lower BMD group (BMD T-score ≤ -2.5). We compared case characteristics in the higher versus lower BMD groups, using appropriate statistical tests for difference. In 5 years of follow-up, 131 hip fractures occurred in 6667 participants in the higher BMD group and 111 occurred in 1398 participants in the lower BMD group, yielding incidence rates of 4.1/1000 person-years and 17.5/1000 person-years respectively. Hip fracture cases in the higher BMD group were younger (mean 76.3 vs 78.1 yrs); had greater weight (mean 67.3 vs 58.0 kg), knee height, and BMI; better distance depth perception, contrast sensitivity, mental status, grip strength, and knee extension force; and lower frequency of weight loss since age 25 (yes/no) than those in the lower BMD group. There was a tendency toward lower frequency of previous fracture in the higher BMD group. The groups were not different with regard to history of maternal hip fracture, weekly activity, weighted lifetime activity, being on one's feet less than 4 hours each day, inability to rise from a chair without using one's arms for support, and any falls in the last year. In summary, many elderly women with hip fracture have baseline BMD T-scores > -2.5. While we postulated that women with higher BMD and fracture are older, more frail, more likely to fall, and more likely to have a family history of fracture, our results do not support these hypotheses. In fact, many of these risk factors are more common in women with lower BMD (T-scores ≤ -2.5). The pathophysiology of fracture in women with higher BMD is obscure. Understanding more about this group is essential to direct appropriate prevention and treatment strategies.

F295

The Use of Magnetic Resonance Imaging to Diagnose Occult Fractures of the Femoral Neck. K. M. Sanders*. Clinical & Biomedical Sciences, The University of Melbourne, Geelong, Australia.

While increased awareness and treatment of people with osteoporosis will help reduce the occurrence of hip fractures, prompt comprehensive treatment at the time of fracture will help maximise functional recovery. It can be difficult to diagnose a femoral neck fracture on plain radiograph in the elderly due to low bone density or the technique used to take the radiograph. In the acute setting a nuclear bone scan may involve a delay of up to 72 hours. If an occult hip fracture is not detected, displacement can occur with an associated increased risk of prolonged incapacity, avascular necrosis and non-union resulting in escalated health costs and morbidity. Magnetic resonance imaging (MRI) was performed on 76 patients (mean age (years), range; 83.6 {45.1, 101.5}) who presented with clinical features suggestive of a hip fracture but had negative plain radiographs (anterior-posterior and cross-table lateral). Patients were imaged in a flexible phased-array body coil wrapped around the pelvis, with images showing the pelvic girdle, both hips and the proximal femur. Twenty-seven patients (36%) presenting with suspected hip fracture but with negative plain radiographs were subsequently found to have a fractured neck of femur with MRI. This represents 5.6% of all hip fracture cases treated at our acute hospital between July 1997 and February 2000. None of the 49 patients in whom a hip fracture was not detected subsequently presented with this type of fracture within two months of the MRI scan. There was minimal delay in establishing a diagnosis through the use of MRI as 52 patients (68%) had their scan performed within 24 hours of their presentation. Failure to detect an occult hip fracture can lead to disastrous results with subsequent displacement. MRI is an effective means of detecting these fractures allowing early and accurate diagnosis.

F297

Spine, Hip, Wrist and Rib Fractures are Strongly associated with Stiffness Index measurement both in Early and in Late Postmenopausal Women. G. Crepaldi*[1], D. Maugeri*[2], G. Gandolini*[3], B. Frediani*[4], G. D'Avola*[5], G. Iolascon*[6], S. Gatto*[6], R. Giorgino[7]. [1]Internal Medicine, University of Padova, Padua, Italy, [2]Geriatrics, Ospedale Cannizzaro, Catania, Italy, [3]Fondazione Don Gnocchi, Milano, Italy, [4]Rheumatology, University of Siena, Siena, Italy, [5]ASL Catania 3, Catania, Italy, [6]Orthopaedics, Primo Policlinico, Naples, Italy, [7]Procter&Gamble Health Care, Rome, Italy.

A multicenter population based study was conducted in order to relate the prevalence of osteopenia and osteoporosis with personal fracture history in the Italian general female population. Eighty-three University and Hospital centers located over 18 out of 21 Italian peninsular and insular regions participated to the study. Subjects were randomly invited to participate from 1,536 General Practitioners through their own Patients Directory by a specific randomization protocol: reasons of decline were accurately recorded. . Eleven thousands-eleven females aged 40-79 were enrolled for the study: each woman underwent a bone quantitative ultrasound measurement on a Lunar Achilles Express. Personal history for clinical vertebral, hip, rib, wrist and other low-trauma fractures (occurred after the age of 50) was recorded. The table below shows the proportion of 7,441 postmenopausal women who reported an history of fractures according to age and Stiffness T-score categories.

Decade	50-59 years			60-69 years			70-79 years		
T-score	>-1	<-1, >-2.5	<-2.5	>-1	<-1, >-2.5	<-2.5	>-1	<-1, >-2.5	<-2.5
Cases	**1206**	**1366**	**480**	**711**	**1414**	**993**	**176**	**519**	**576**
All Fx	4.4%	9%	13.8%	13.9%	21.1%	28.9%	22.7%	29.1%	34.7%
Spine Fx	0.4%	0.7%	1%	1.4%	2.1%	3.8%	1.1%	3.1%	5.4%
Hip Fx	0.1%	0.1%	0.4%	0.1%	0.9%	1.8%	0.1%	1.7%	4.2%
Rib Fx	0.5%	1.1%	1.5%	1.7%	2.2%	2.8%	2.3%	2.7%	5.7%
Wrist Fx	0.8%	2.5%	3.8%	3.0%	6.0%	9.2%	8.0%	8.9%	12.2%
Other Fx	2.5%	5.3%	8.5%	8.7%	12.8%	16.8%	14.8%	17%	17.4%

The association between Stiffness Index and Fractures history was significant at all sites and in each decade. In particular the proportion of subjects with an history of hip fractures was about 4 times higher in 50-59 years aged osteoporotic subjects (T-score <-2.5) vs normals (T-score>-1), 18 times higher in the 60-69 decade, and 42 times higher in the 70-79 years aged osteoporotic group. This large population-based study establishes that Stiffness Index ultrasound measurements are strongly and significantly related to spine, hip, wrist and rib fractures either in early and in late postmenopausal women.

F300

Racial Differences in Bone Mineral Density in Older Men. A. George*[1], J. K. Tracy*[1], P. D. Wilson*[2], R. H. Flores*[1], M. C. Hochberg[1]. [1]Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Epidemiology & Preventive Medicine, University of Maryland School of Medicine, Baltimore, MD, USA.

While several studies have examined factors associated with bone mineral density (BMD) in older white men, none have had sufficient numbers of older black men to allow for meaningful comparisons by race. The Baltimore Men's Osteoporosis Study (MOST) is a prospective cohort study designed to identify factors associated with low bone mass and bone loss in older men. 503 white and 191 black men aged 65 and above (mean [SD] 75.1 [5.8] and 72.2 [5.7] years, respectively) were recruited through mass mailings to holders of Maryland drivers licenses; 85% were veterans. All men completed a battery of self-administered questionnaires, underwent a standardized examination, and had BMD measured at the femoral neck (FN), lumbar spine (LS) and total body (TB) using a Hologic QDR-2000 and quantitative ultrasound (QUS) performed at the heel using a Hologic Sahara. Results (mean [SD]) by racial group are shown in the Table; all comparisons by race were significantly different with $P < 0.001$. Forty-three (8.6%) white and only 2 (1.0%) black men had osteoporosis at the FN as defined by WHO criteria. FNBMD was significantly correlated with LSBMD (R = 0.51), TBBMD (R = 0.62) and QUS Index (R = 0.34) when data from both groups of men were combined; correlations did not differ between racial groups. In multiple variable linear regression models, adjusted for age, height, weight, mean quadriceps strength, total calcium and vitamin D intake, alcohol consumption, smoking, physical activity in the past year and use of seizure medications, as well as all potential interactions, black men had significantly higher adjusted FNBMD than white men: mean adjusted difference (95% confidence interval) = 0.09 (0.07, 0.12) g/cm^2. This difference, corresponding to about 0.7 SD, may explain in part the reduced risk of hip fracture in older black compared to white men. Longitudinal measurememt of BMD as well as vertebral radiographs are currently being collected during the first annual followup visit.

BMD and QUS Index by Race in Older Men

Racial Group	Femoral Neck BMD	LumbarSpine BMD	Total Body BMD	QUS Index
White	0.75 (0.13)	1.09 (0.19)	1.18 (0.13)	94.0 (19.7)
Black	0.86 (0.15)	1.16 (0.20)	1.25 (0.13)	101.9 (23.7)

F302

Height Loss and Increased Risk of Osteoporosis in Men. E. A. Krall[1], J. J. Anderson*[1], D. R. Miller[2], R. Ferguson*[2], S. E. Rich*[1]. [1]Boston University, Boston, MA, USA, [2]Massachusetts Veterans Epidemiology Resource & Information Center, Boston, MA, USA.

Height loss is a risk factor for fracture, particularly of the spine. Height loss is usually inferred from self-reported height in young adulthood, which may be prone to recall error. We examined height loss in men in relation to osteoporosis status using heights recorded over 4 decades as part of a research study. The subjects are 353 participants in the VA Longitudinal Osteoporosis Research (VALOR) study who also participated in the VA Normative Aging Study (NAS) since 1962 and had >10 years of serial height measurements. Standing height was measured and recorded in tenths of an inch every three years between 1962 and 1998 (mean±SD time period=30±3 years, range=12 to 36) in the NAS. At the NAS baseline, mean age was 40±7 years, range 25 to 57. In 1998-2001, femoral neck, total femur, total radius and total body bone mineral density (BMD) were measured using DXA (model DPX-IQ, Lunar Corp., Madison, WI). Osteoporosis was defined as BMD 2.5 SD or more below the mean value of males age 20-29 years. Mean height loss by BMD status and odds ratios (OR) of osteoporosis were evaluated by analysis of covariance and logistic regression. Odds ratios were adjusted for age, current weight, smoking history, and years of follow-up. Current age of the men was 56 to 89 years (mean ±SD=72±7). Average height declined from 69.4±2.5 inches to 68.4±2.6 inches over the time period, for a mean individual loss of 1.0±0.7 inches. Fourteen percent of men were osteoporotic at any skeletal site, 53% osteopenic, and 33% normal. Prior height loss in men who were osteoporotic was 67% greater than in men who were normal or osteopenic (Table). Per one inch lost, the odds of osteoporosis at any site doubled (OR=2.0, 95% confidence interval, CI=1.2-3.3). Odds of osteoporosis at individual sites were similar: femoral neck, OR=1.9 (CI=1.1-3.4); total femur, OR=2.2 (CI=1.0-4.8); total radius, OR=2.0 (CI=1.1-3.6); and total body, OR=3.1 (CI=1.2-8.1). These results suggest that a relatively small amount of height loss is an indicator of increased risk of osteoporosis in men. Table 1.

Bone status at worst site	N	Mean ± SD Total height loss (inches)
Osteoporotic	49	1.5±0.9*†
Osteopenic	186	0.9±0.6†
Normal	118	0.8±0.5*

*† Means with matching symbols differ, p<0.001.

Bone Mass in Men of African Heritage: Relative Contribution of Serum Androgens and Estrogens. J. M. Zmuda[1], J. A. Cauley[1], A. L. Patrick*[2], V. W. Wheeler*[2], C. H. Bunker*[1]. [1]Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, [2]The Tobago Regional Hospital, Scarborough, Trinidad and Tobago.

Recent population studies in older Caucasian men suggest that endogenous estrogens may be more strongly correlated with bone mass than androgens. However, the relative importance of sex steroid hormones for bone health among non-white men is less well defined. Thus, we evaluated associations among bioavailable testosterone (BT), bioavailable estradiol (BE) and bone mineral density (BMD) in 367 Afro-Caribbean men (age 40-91 yr; mean±SD, 57±12 yr) who were participants in the Tobago Bone Health Study. Hip and whole body BMD was measured with a Hologic QDR 4500 densitometer. BT and BE were measured in fasting morning serum samples by radioimmunoassay (Esoterix Endocrinology). BT and BE decreased 56% and 41%, respectively, between ages 40 and 80 yrs ($P<0.01$). Total hip BMD increased with increasing BT and was 0.5 standard deviations or 7% greater among men in the highest compared with lowest quartile independent of age, body weight and height (Table). In contrast, we found no significant association between BE and hip BMD. Similar results were observed for the sub-regions of the hip and whole body BMD. We conclude that in contrast to studies in Caucasians, bioavailable testosterone, but not bioavailable estradiol, is correlated with bone density among middle-aged and elderly Afro-Caribbean men. Table.Quartile of Serum Biovailable Sex Hormones and Total Hip BMD (g/cm^2) in Afro-Caribbean Men.

BT(ng/dl)	Hip BMD*	BE (pg/ml)	Hip BMD*
≤ 128	1.09 (.16)	≤ 16	1.13 (.17)
129-168	1.13 (.15)	17-22	1.12 (.15)
169-219	1.13 (.14)	23-28	1.13 (.14)
≥220	1.17 (.15)	≥ 29	1.14 (.14)
P (ANOVA)	0.02		0.62

*Values are mean (SD) and adjusted forage, weight, height.

A Potentially Deleterious Role of IGFBP-2 on Bone Mineral Density in Aging Men and Women. S. Amin, E. J. Atkinson*, L. J. Melton, S. Khosla, A. L. Oberg*, B. L. Riggs. Mayo Clinic and Foundation, Rochester, MN, USA.

Insulin-like growth factors (IGFs) and their binding proteins (IGFBPs) are important regulators of tissue growth and metabolism, but their association with bone mineral density (BMD) is controversial. In an age-stratified, random sample of the adult community population, we assessed serum levels of IGF-I, IGF-II, IGFBP-1, -2 and -3, bioavailable estradiol (Bio E2) and testosterone (Bio T), and sex hormone binding globulin (SHBG); and measured total fat and skeletal muscle mass, and total hip BMD by DXA. The associations between the IGF/IGFBP system and hip BMD were assessed using regression models, before and after adjustment for age, sex steroids, SHBG, muscle and fat mass. Analyses were stratified by sex and by menopausal status in women. We studied 348 men (age range 23-90) and 276 women not on oral contraceptives or hormone replacement (age range 21-93; 166 postmenopausal). In men, lower IGF-I, IGF-II and IGFBP-3 were associated with lower hip BMD (r=0.21, 0.14, 0.12, respectively; $p < 0.04$). In postmenopausal women alone, similar associations were seen with IGF-1 and IGFBP-3 (r=0.23, 0.22; $p < 0.01$). In all men and women, higher IGFBP-2 correlated with lower hip BMD (r=-0.36, r=-0.53, respectively; $p < 0.001$) and was the strongest predictor of hip BMD among the IGFs and IGFBPs studied. In men and women, IGFBP-2 was correlated with age (r=0.55, r=0.45) and SHBG (r=0.60, r=0.53) but inversely correlated with all other covariates (r=-0.24 to -0.53; r=-0.29 to -0.39). IGFBP-2 remained an independent predictor of hip BMD after adjustment for age, Bio E2 and Bio T in both sexes. Both SHBG and muscle mass attenuated the association between IGFBP-2 and hip BMD in men and women, with the association being lost in men following adjustment for muscle mass. In women, but not men, adjustment for fat mass attenuated the effect of IGFBP-2 on hip BMD, particularly in premenopausal women where the association was lost. Associations of other IGFs and IGFBPs with hip BMD in men and postmenopausal women were similarly attenuated or lost with adjustments for age, SHBG, or muscle mass. Thus, among the IGFs and IGFBPs studied, we found IGFBP-2 to be a key negative predictor of total hip BMD in both men and women. Our findings suggest a potential role of the IGF/IGFBP system in regulating bone loss in aging men and women, and identify a previously unrecognized, potentially deleterious role for IGFBP-2, a known inhibitor of IGF action, which increases with age in both sexes. Whether the action of the IGF/IGFBP system on bone is mediated through its effects on fat and muscle mass, or SHBG, deserves further study.

Primary Care Resident Evaluations for Chronic Health Conditions: A Failure to Assess for Osteoporosis. A. Chhabra*[1], T. McNearney*[1], A. J. Shepherd*[1], N. Hussain*[1], N. Goel[2]. [1]University of Texas Medical Branch, Galveston, TX, USA, [2]University of Texas Medical Branch, Procter & Gamble Pharmaceuticals, Galveston, TX, USA.

Primary care residents routinely screen for hypercholesterolemia, hypertension, diabetes, and breast cancer in the at-risk population and institute therapy where appropriate. This prospective, single-blind, longitudinal, observational study tests the hypothesis that primary care residents at a university teaching hospital outpatient clinic evaluate their patients for osteoporosis at a rate less than that for other common diseases in the at-risk female population. The medical records of 122 new female outpatients 45 years or older seen by an internal or family medicine resident in their continuity clinics between 9/01 and 3/02 were reviewed. Data were collected on 1) risk factor assessment, 2) physical findings, 3) diagnostic tests ordered, and 4) treatment initiated for multiple common chronic health conditions. Additional data were obtained regarding the availability of information to the resident at the time of their evaluation which would identify patients for bone density screening by the Osteoporosis Risk Assessment Instrument (ORAI). Data analysis was performed by Fisher's exact test. A p value of < 0.05 was considered significant. Most of the outpatients were evaluated by a first or second year resident (32% and 54%, respectively). The median age of the patients was 58 years with an interquartile range of 14 years. Documented rates of screening, diagnosis, and therapy were 68% for hypercholesterolemia, 67% for breast cancer, 51% for hypertension, and 49% for diabetes mellitus. In marked contrast, screening or evaluation for osteoporosis was documented in only 5% of patients ($p < 0.001$ compared to hypertension or hypercholesterolemia). Risk factors widely considered contributory to osteoporosis were addressed or documented as part of the general work-up with variable frequency: estrogen use 47.2%, postmenopausal 50%, supplemental calcium 22%, prior fracture 5%, smoking 85%, ethanol use 78%, thyroid disease 30%. ORAI scores of 9 or above were obtained in 34.1% (n=41) of the 120 patients with sufficient information for ORAI scoring by an independent evaluator. Among those at-risk patients, only 24.4% (n=10) had a BMD ordered. In conclusion, primary care residents at a university teaching hospital outpatient clinic assess at-risk female patients for osteoporosis at a rate far below the rates for other common health conditions. The impact of specific interventions to increase primary care resident awareness of the diagnosis and treatment of osteoporosis will be determined next.

The Impact of Cyclooxygenase Selectivity on Bone Loss: The Health ABC Study. L. D. Carbone[1], F. A. Tylavsky[2], J. A. Cauley[3], T. B. Harris*[4], D. C. Bauer*[5], K. D. Barrow*[2], S. B. Kritchevsky*[2]. [1]Medicine, University of TN, Memphis, TN, USA, [2]Preventive Medicine, University of TN, Memphis, TN, USA, [3]Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, [4]National Institute of Aging, Bethesda, MD, USA, [5]Prevention Sciences Group, UCSF, San Francisco, CA, USA.

Nonsteroidal Anti-Inflammatory Drugs (NSAID) could potentially influence BMD by affecting the production of prostaglandins involved in the bone remodeling cycle. Cross-sectional evidence suggests that the relative selectivity of cyclooxygenase (COX) 1 and 2 of NSAIDs may have an impact on BMD, and the use of aspirin (ASA) may blunt the effect of COX-2 selective NSAIDs. The objective of this study was to examine the effects by relative COX selectivity both with and without concomitant aspirin (ASA) use on changes in BMD of the total hip over two years. Participants enrolled in the Health, Aging and Body Composition Study (Health ABC) who consistently reported using NSAIDS, ASA or no use of NSAIDS or ASA at baseline, year 1 and year 2 follow-up visits were included in this analyses. 1134 individuals (40% African- American, 56% Male, Mean age at baseline=73.6 years) were grouped for analysis according the COX selectivity of NSAID used, with or without the use of aspirin. BMD of the total hip by DXA was assessed at baseline and after 2 years of follow-up. After adjustment for potential confounders, those with consistent use of COX-2 showed an increase in BMD compared to little or no change in the other groups. (Table I, Mean +/-SEM).

Analysis Group	Baseline BMD (g/cm2)	Year 3 BMD (g/cm2)	Percent Change (%)
Nonuser (N=658)	0.890 +/- 0.006	0.888 +/- 0.006	-0.28 +/- 0.12*
Relative COX-1 Selective NSAID only user (N=55)	0.902 +/- 0.019	0.902 +/- 0.020	0.14 +/- 0.42
Relative COX-2 Selective NSAID only user (N=14)	0.873 +/- 0.038	0.885 +/- 0.039	1.43 +/- 0.82
Aspirin only user (N=37)	0.901 +/- 0.007	0.899 +/- 0.008	-0.27 +/- 0.16*
Relative COX-1 and Aspirin user (N=21)	0.945 +/- 0.031	0.939 +/- 0.032	-0.57 +/- 0.67
Relative COX-2 and Aspirin user (N=9)	0.914 +/- 0.048	0.916 +/- 0.049	0.28 +/- 1.04

* P<0.05 compared to relative COX-2 selective NSAID only users **Adjusted for gender, race, age at baseline, study site, History of rheumatoid arthritis,

History of osteoarthritis, Womac score at baseline, Vitamin D supplementation, Calcium supplementation, oral estrogen use, and weight change from baseline to year 3 Our results suggest that the consistent use of COX-2 selective NSAIDS may have a small but potential benefit on BMD of the hip. In addition, there is insufficient power to evaluate whether ASA blunts this benefit. These preliminary results will need to be replicated in a larger sample with a longer duration of follow-up.

Decreased Osteocyte Density Is Relevant to Fragility Fracture. S. Qiu*[1], D. Rao[2], S. Palnitkar*[2], A. Parfitt[3]. [1]Bone and Mineral, Henry Ford hospital, Detroit, MI, USA, [2]Bone and Mineral, Henry Ford Hospital, Detroit, MI, USA, [3]Division of Endocrinology and Center for Osteoporosis and Metabolic Bone Disease, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

The objective of this study was to test the hypothesis that the decreased osteocyte density is a factor in the etiology of fragility fracture. Iliac bone biopsies were performed in 144 postmenopausal white women, aged 50 to 73 years. Of them, 66 were healthy subjects and 78 suffered from nontraumatic vertebral fracture not just deformity. Conventional bone histomorphometry was conducted for all the subjects. Osteocyte density was measured in 56 of healthy and 44 of fracture subjects due to the fair quality of cell stain in these sections. Receiver operating characteristic (ROC) curve was used to discriminate fractured patients from healthy subjects by cancellous bone volume fraction (BV/TV), trabecular thickness (Tb.Th) and osteocyte density in superficial bone (Ot.N/B.Ar(s)) (<25µm from the bone surface), deep bone (Ot.N/B.Ar(d)) (>45µm from the bone surface) and whole trabecula (Ot.N/B.Ar(w)). The results are shown in table 1 (in p* column: p values are for area comparison with indicated variable numbers; all p values < 0.001). Conclusion: The results suggest that the risk of fragility fracture may be increased in the subjects with deteriorated bone architecture and osteocyte network. According to the area under the ROC curve, a decrease in cancellous osteocytes has a closer relationship with vertebral fragility fracture than decreased cancellous bone volume and trabecular thickness, although both of them have been regarded as major insults to bone strength. Our data indicate that the decrease in osteocyte density contribute to bone fragility independent of bone volume. Moreover, the decrease in osteocytes in superficial cancellous bone may play important role in producing fragility fracture.

Table 1. Data from ROC analysis

Variables	Sensitivity (%)	Specificity(%)	Area (%)	p*
1) BVTV (%)	85.5	56.1	76.9	1 vs 2, 3 & 4

Tumor Necrosis Factor Alpha but not Interleukine-1 Is involved in Protein Undernutrition-Induced Bone Resorption. P. Ammann[1], C. Gabay*[2], G. Palmer*[2], I. Garcia*[3], R. Rizzoli[1]. [1]Department of Internal Medicin, Division of Bone Diseases, Geneva-14, Switzerland, [2]Department of Internal Medicin, Division of Rheumatology, Geneva-14, Switzerland, [3]Department of Pathology, Geneva-14, Switzerland.

Bone loss resulting from protein undernutrition is related to an uncoupling in bone turnover with increased bone resorption and decreased bone formation. Tumor Necrosis Factor Alpha (TNF) and Interleukine-1 (IL-1) could be involved in the increased bone resorption. We studied the effects of isocaloric low (2.5%) or normal (15%) protein diets in 6-month old female transgenic mice (Tg), either expressing high levels of soluble tumor necrosis factor receptor-1 fusion protein (TNFR1) which blocks the actions of TNF or IL-1 receptor antagonist (IL-1Ra) which blocks IL-1. Respective negative littermates TNFR1 and IL-IRa (NegLit) were used as controls. We measured bone strength (integrating all the modifications of bone structures) at skeletal sites containing cortical and trabecular bone (proximal tibia) or mainly cortical bone (midshaft tibia), and bone mineral density (BMD) before and after 12 or 16 weeks of low/normal protein diets, in IL-1Ra or TNFR1 Tg and their Neglit, respectively. Isocaloric low protein diet was associated with similar decreases in IGF-I (-47 to -57%) and osteocalcin (-37 to -51%) in all animals. Whereas proximal tibia bone strength was significantly decreased in NegLit (13.1±1.8* vs 23.3±2.8N) but not in TNFR1 Tg (19.0±3.0 vs 22.2±1.3), it was significantly decreased in both NegLit (8.5±1.0* vs 19.6±0.9N) and IL-1Ra Tg (7.3±1.0* vs 20.1±0.9). Similar trend was observed at the midshaft tibia. BMD decrease (in % of pretreatment values) was less pronounced in TNFR1 Tg (-6.4±3.1* vs +7.9±5.4) than in their NegLit (-19.6±2.6*# vs +7.0±3.6%) (*p<0.05 vs 15%; # vs 2.5% NegLit by ANOVA, x±SEM), but of similar magnitude in IL-IRa Tg (-27.5±3.9* vs -10.9±3.6) and in their NegLit (-20.9±3.2* vs –6.0±1.6). Midshaft diameter was lower in protein-undernourished TNFR1 and IL-1Ra Tg suggesting a reduced periosteal apposition. Thus, blocking TNF attenuated the increase in bone loss and the decrease in bone strength induced by protein undernutrition. In contrast, blocking IL-1 did not modify this response. Decrease IGF-I and osteocalcin, and possible depressed periosteal apposition were observed in TNFR1 and IL-1Ra Tg suggesting a reduced bone formation. This suggests that TNF but not IL-1 might play a role in increased bone resorption caused by an isocaloric low protein diet but not in the depressed bone formation. This underlines the bone catabolic role of TNF during protein undernutrition.

F325

Trial to Predict the Risk of Vertebral Compression Fractures in Patients Treated with Glucocorticoid. M. Yamauchi*, T. Makino*, H. Sowa*, T. Yamaguchi, T. Sugimoto, K. Chihara*. Division of Endocrinology/Metabolism, Neurology and Hematology/Oncology, Kobe University Graduate School of Medicine, Kobe, Japan.

Since vertebral compression fractures associated with glucocorticoid (GC)-induced osteoporosis is one of major problems in patients treated with GC, it would be clinically useful if fracture risk could be predicted. In the present study, anthropometric indices, bone mineral density (BMD) as well as biochemical bone markers were compared between patients with (Fx+) and without vertebral compression fractures (Fx-) and we further tried to predict the fracture risk in patients treated with relatively high dose of GC for the long duration. Subjects were 62 women aged 24 to 74 (mean 48 years) who were treated with predonisolone (PSL) [means of average daily dose and total dose: 13.6mg and 27.3g, respectively] for more than 6 months (mean 87.2 months), because of collagen diseases except rheumatoid arthritis as well as myasthenia gravis disease. 15 patients had more than one vertebral compression fractures. Regional BMD values of lumbar spine (L2-4), femoral neck (FN) and distal one-third of radius (R1/3) were measured by DXA. Mean BMD values (mean Z-scores) of L2-4, FN and R1/3 were 0.827 (-0.7), 0.640 (-0.6) and 0.600g/cm^2(+0.5), respectively, indicating preferential loss of trabecular bone. Z-score of FN was negatively correlated with total PSL dose and positively correlated with serum osteocalcin (BGP) level. Age, serum ALP and urinary deoxypyridinoline levels were significantly higher in Fx+ group, compared with Fx- group, while body height, body weight, handgrip strength as well as Z-score of FN and BGP level were significantly lower. Receiver Operating Characteristic (ROC) and logistic regression analyze were performed to select indices which discriminated Fx+ from Fx- most effectively. In these analyze, handgrip strength, FN BMD and BGP level were selected [sensitivity-specificity and odds ratio (95%CI): 75%, 73%, 65% and 0.37(0.16-0.90, p=0.03), 0.31(0.13-0.75, p=0.009), 0.21(0.07-0.61, p=0.004), respectively]. ROC analysis revealed that cut-off values of BMD that discriminated Fx+ from Fx- were 0.783, 0.599 and 0.592 g/cm^2 for L2-4, FN and R1/3, respectively. These values were all higher, compared with cut-off values obtained from 205 postmenopausal healthy women [48~84 years (mean 64), numbers of Fx+ subjects: 66] (0.691, 0.570 and 0.444g/cm^2). In conclusion, FN BMD, handgrip strength and BGP level are clinically useful to predict the risk of vertebral compression fractures in women treated with GC and bone of GC-treated patients would have severer fragility than estimated from BMD value.

F327

Prevalence of Sex Steroid Deficiency in Men Receiving Systemic Glucocorticoids. S. J. A. Goemaere[1], K. Toye*[1], M. Daems*[1], D. De Bacquer*[2], J. M. Kaufman[1]. [1]Unit for Osteoporosis, Ghent University Hospital, Gent, Belgium, [2]Dpt of Public Health, Ghent University Hospital, Gent, Belgium.

Glucocorticoid excess in men can result in sex steroid deficiency, however also in lower serum sex hormone binding globulin (SHBG) levels, with better preservation of biological active hormone fractions. There have been few systematic evaluations of the prevalence and severity of sex steroid deficiency in men under glucocorticoid therapy. We analysed the sex steroid status of 174 men (median age: 59y; P25-P75:47-68y) receiving long-term glucocorticoid (GC) treatment (prednisolone equivalent dose ≥ 7.5 mg/day) for dermatologic (12%), rheumatologic (54%), pulmonary (18%), gastrointestinal (9%) or other (7%) diseases and participating in a clinical trial on prevention and treatment of glucocorticoid induced osteoporosis (GIOS) with alendronate* (Saag et al, N Engl J Med 339: 292, 1998). Testosterone (T), estradiol (E2) and SHBG were determined by immunoassay in serum obtained at the base-line visit. Free T (FT) and E2 (FE2) were calculated using a validated equation. For comparison we examined a healthy young (n=107, age 20-39y) and an age-matched (n=174) male reference group. The proportion of patients with serum levels below the 5th percentile for young controls was 71 and 68% for T and FT, 19% for SHBG, 25 and 21% for E2 and FE2. Compared to age-matched controls, the median decrease in patients was 34%, 22%, 31%, 19% and 5% , respectively for T, FT, SHBG, E2 and FE2. The prevalence of values below the 2.5 percentile for matched controls was 25%, 14%, 9%,19% and 12%, respectively. The difference between patients and controls increased by increasing actual GC dose for T, FT and E2 (p=0.04 to 0.004; p=0.06 for FE2) and was not significantly affected by the cumulative dose or duration of the GC treatment. Alcohol use and disease category significantly affected the (F)E2 levels. After adjustment for age, BMI, albumin and creatinine the actual dose remained significantly negatively correlated with absolute hormone levels and deviations of patients from controls (r ranging from -.14 to -.34). The observed difference in sex steroid levels did not correlate with biochemical indices of bone turnover, as assessed by urinary NTX and serum BAP. In conclusion, a considerable proportion of patients receiving systemic GC therapy have sex steroid levels ((F)T and (F)E2) below the reference for young men, but the prevalence is lower compared to age-matched controls. The observed effects are dose dependent. These findings constitute the background for the need of prospective data (re)evaluating the contribution of sex steroid deficiency in the pathogenesis of GIOS in men.*Manufactured by Merck & Co., Inc., Whitehouse Station, NJ

Increased T Cell Proliferation and Lifespan through Enhanced Expression of Interferon Gamma and Class II Transactivator Mediate Ovariectomy Induced Bone Loss. S. Cenci, C. Roggia, G. Toraldo, M. N. Weitzmann, Y. Gao, O. Sierra, W. Qian, R. Pacifici. Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Expansion of the pool of TNF-producing T cells in the bone marrow (BM) is critical for the bone wasting effect of estrogen deficiency, but the responsible mechanism is unknown. In vivo BrdU incorporation studies in mice revealed that ovariectomy (ovx) increases T cell number by upregulating T cell proliferation and by decreasing T cell apoptosis. Increased T cell proliferation results from enhanced activation induced by an increase in the activity of macrophages as antigen-presenting cells (APC), due to augmented MHCII expression. We also found that ovx decreases T cell apoptosis by suppressing Fas ligand (FasL) expression in response to activation. Class II transactivator (CIITA) is the master regulator of MHCII expression and APC activity in macrophages and of activation-induced FasL expression in T cells. By RT-PCR, CIITA mRNA was found to be increased threefold by ovx both in macrophages and in T cells, thus identifying a key mediator of the control of T cell activity exerted by estrogen in vivo. Production of interferon-gamma (IFN-gamma), the physiologic inducer of CIITA, by T helper cells was found to be higher in ovx mice, as assessed by ELISA and FACS, thus providing a mechanism for increased CIITA expression in target cells. Increased T cell secretion of IFN-gamma was repressed in vitro by a selective inhibitor of the MAP kinase p38, indicating that induction of IFN-gamma by ovx is cytokine-driven. Indeed, ovx was found to stimulate macrophagic production of IL-12 and IL-18, the physiologic inducers of T cell IFN-gamma production, thus defining a mechanism whereby estrogen regulates IFN-gamma in vivo. To assess if enhanced IFN-gamma and CIITA mediate the effects of ovx on T cell and bone homeostasis in vivo, we sought to block both IL-12/18-induced IFN-gamma production, and IFN-gamma induced CIITA expression. As CIITA, IL-12 and IL-18 are all specifically induced by IFN-gamma via IFN-gamma receptor (R) signaling, we utilized IFN-gamma R deficient (-/-) mice. In vivo blockade of IL-12/18 signaling and CIITA induction through silencing of IFN-gamma R resulted in failure of ovx to upregulate CIITA in macrophages and T cells, and to modulate T cell proliferation and apoptosis. As a result, ovx failed to increase the number of TNF producing T cells in the BM and to induce bone loss, as assessed by DEXA and histology, in IFN-gamma R -/- mice. Thus, upregulation of T cell proliferation and lifespan through increased IFN-gamma signaling and CIITA expression is critical for the bone wasting effect of estrogen deficiency.

HIV Protease Inhibitor Indinavir Impairs Osteoblastic Bone Formation, in vivo and in vitro. M. W. H. Wang, S. Wei, S. L. Teitelbaum, F. P. Ross. Pathology, Washington University School of Medicine, St. Louis, MO, USA.

We and others have demonstrated previously that HIV protease inhibitor usage is associated with osteopenia in HIV infected individuals. To investigate the underlying mechanism for this observation, we tested the hypothesis that one or more HIV protease inhibitors block osteoblast differentiation and/or function. Two HIV protease inhibitors, nelfinavir and ritonavir, have no effect on bone nodule formation in vitro. In contrast, we find that indinavir, at a pharmacologically relevant concentration (5 μg/ml), arrests osteoblast bone nodule formation, decreases alkaline phosphatase activity, and impairs type I collagen synthesis. Congruent with the observation of impaired osteoblast maturation, alkaline phosphatase, PTH/PTHrP receptor, and osteocalcin gene expressions are dose dependently decreased with indinavir (1 and 5 μg/ml), while osteopontin, a matrix protein not specific to osteoblasts, is not affected. Confirming that the inhibition is not due to cell toxicity, the drug has no effect on the number, proliferation, or apoptosis of osteoblasts. Furthermore, systemic indinavir administration to mice leads to a ten fold decrease in osteoblast colony forming units ex vivo, indicating that the drug affects early osteoblast differentiation. Consistent with an early differentiation arrest, indinavir downregulates the gene expression of Cbfa1 and Osterix, both critical osteoblast transcription factors. To extend the effect of indinavir to bone in vivo, we administered the drug to 4 week old mice for 5 weeks and analyzed the skeleton. We find that indinavir treatment leads to a 17-20% decrease in bone mineral density by DEXA, a 50% decrease in proximal tibial trabecular bone volume, as assessed by bone histomorphometry, and a decrease in cortical and trabecular bone, as seen by Faxitron radiography. Furthermore, consistent with osteopenia resulting from an osteoblast defect, indinavir treatment dampens the mineral appositional rate (1.05 +/- 0.22 vs. 0.41 +/- 0.09; $P < 0.01$) and bone formation rate (571.9 +/- 60.8 vs. 179.3 +/- 42.3; $P < 0.01$) as determined by double fluorochrome labeling. Consistent with a cell type specific inhibitory effect, indinavir has no effect on osteoclast formation or function in vitro and in vivo. In sum, these findings indicate that the HIV protease inhibitor indinavir can lead to osteopenia by selectively impairing osteoblast maturation.

F337

Maintenance of Increased Bone Mass After Recombinant Human Parathyroid Hormone(1-84) with Sequential Zoledronate Treatment in Ovariectomized Rats. Y. Rhee*[1], S. Kim*[1], R. Namgung[2], R. Hwang*[3], S. Lim[1]. [1]Internal Medicine, College of Medicine, Yonsei University, Seoul, Republic of Korea, [2]Pediatrics, College of Medicine, Yonsei University, Seoul, Republic of Korea, [3]Internal Medicine, College of Medicine, Brain Korea 21 Project, Yonsei University, Seoul, Republic of Korea.

Anti-resorptive agents against osteoporosis have quite a limitation in the aspect of increasing bone mass to only with these agents. Strong anabolic agent such as human parathyroid hormone(PTH) is expected to be helpful. However, as PTH is only injectable, it would be practical to use both anti-resorptives and anabolic agents sequentially. To determine the effectiveness of the respective anti-resorptive agents after anabolic phase with the PTH to prevent the loss of bone mass, the maintenance therapy with estrogen or zoledronate was tested. Thirty 16 weeks-old virgin female Sprague-Dawley rats were used. Ovariectomy was done at 16 weeks of age then 5 weeks were given to have the osteopenic changes in the bones. Then each treatment was started at the age of 21 weeks for 5 weeks of recombinant human PTH(1-84) [rhPTH(1-84)] 100 mcg/kg/d*5 days/wk, then respective sequential therapy for 5 weeks. Groups were as follows ; 1) Ovariectomized rats (OVX) (n=6), 2) Sham operated rats (SHAM) (n=6), 3) PTH treated then withdrawn OVX rats (PTH-Veh) (n=6), 4) PTH maintained OVX rats (PTH-PTH) (n=6), 5) PTH treated OVX rats then treated with 17b-estradiol(E2) [10 mcg/d, SQ *5 days/wk] (PTH-E2) (n=6), 6) PTH treated OVX rats then treated with zoledronate(PTH-ZOL) [12.5 mcg/kg, SQ weekly] (n=6). Bone mineral density(BMD) of rt femurs were measured with dual x-ray absorptiometry(Hologic QDR 4500A, Waltham, MA). The μCT and software used for structural parameter of 2nd lumbar vertebrae are from Skyscan (Antwerpen, Belgium). Three-point bending test was done with material testing machine (Instron LTD, Buckinghamshire, England). The BMD of right femur and bone volume and trabecular thickness of L2 vertebrae were highest in the PTH-PTH and PTH-ZOL groups compared with OVX rats($p<0.05$). There was no significant differences in circumferential diameter, but the significant cortical thickening was observed in PTH-PTH group($p<0.05$). Maximal load at 3-point bending test was highest in PTH-PTH group($p<0.05$). In conclusion, PTH withdrawal resulted in loss of acquired BMD and sequential therapy with zoledronate prevented further loss as much as continuous PTH-treated rats. Therefore, it would be practical and beneficial to administer bisphosphonate after the gaining bone mass with PTH.

F339

Efficacy and Safety of Oral Weekly Ibandronate in the Treatment of Postmenopausal Osteoporosis (PMO). C. Cooper*[1], G. Hawker*[2], R. Emkey[3], R. McDonald*[4], R. Schimmer*[5], P. Mahoney*[5], K. Wilson*[5]. [1]Southampton General Hospital, Southampton, United Kingdom, [2]Sunnybrook and Women's College, Toronto, ON, Canada, [3]Radiant Research, Wyomissing, PA, USA, [4]University of Pittsburgh, Pittsburgh, PA, USA, [5]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Bisphosphonates are well established in PMO. However, these agents are currently associated with relatively stringent dosing guidelines that may be inconvenient to some patients and potentially result in reduced compliance. Reducing dosing frequency is predicted to increase convenience. The highly potent, nitrogen-containing bisphosphonate, ibandronate, has demonstrated strong reduction (62%) in vertebral fracture risk when administered once daily (Delmas P, et al. IOF World Congress on Osteoporosis 2002; abstract O37). Ibandronate has strong potential for intermittent administration: significant and lasting antifracture efficacy was observed when ibandronate was given with a dosing interval of >9 weeks. A multicenter, double-blind, randomized, non-inferiority study was initiated in 235 women (age 55-80 years; time since menopause at least 3 years) with PMO (lumbar spine bone mineral density [BMD] T-score <-2.0) to compare oral daily 2.5mg and once-weekly 20mg ibandronate. All patients received daily calcium (500mg) and vitamin D (400IU). The primary endpoint was the relative change in lumbar spine BMD after 48 weeks. Baseline characteristics were similar across both treatment arms. The daily and weekly dosing regimens produced similar increases in BMD and reductions in bone turnover. The mean increases in lumbar spine BMD at 48 weeks were 3.47% and 3.54% in the 2.5mg daily and 20mg once-weekly groups, respectively. The mean spine BMD difference (95% CI) between daily and weekly dosing was 0.07% (-0.96, 1.10). The boundary of the one-sided 97.5% confidence interval (-0.96%) of the observed differences in mean spine BMD between the two dosing regimens lay well above the pre-specified margin for non-inferiority (-1.65%) and met also more stringent non-inferiority criteria as subsequently set by Health Authorities (-1.1%). These results indicate that weekly dosing of ibandronate provides the same efficacy as daily dosing in women with PMO based on non-inferiority criteria. In addition, both regimens had similar safety profiles: the incidence of clinical adverse events (AEs), including upper gastrointestinal AEs, was comparable and no drug-related serious AEs were observed. In summary, once-weekly dosing of oral ibandronate is equally efficacious and tolerable as daily dosing, but provides the advantage of greater convenience. This added benefit may enhance compliance and, thus, improve therapeutic outcomes in women with PMO.

F341

Efficacy of Oral Ibandronate in Postmenopausal Osteoporosis: Incidence of Vertebral Fractures by Subgroup. M. Ettinger[1], R. Emkey[2], R. Schimmer*[3], P. Mahoney*[3], J. Kilbride*[3]. [1]Regional Osteoporosis Center of South Florida and Radiant Research, Stuart, FL, USA, [2]Radiant Research, Wyomissing, PA, USA, [3]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

A multinational, randomized, double-blind, placebo-controlled phase III pivotal fracture study (BONE: Bonviva® Osteoporosis Trial in North America and Europe) recently compared daily and intermittent oral ibandronate regimens, which provide similar cumulative doses every 3 months (Delmas P, et al. IOF World Congress on Osteoporosis 2002; abstract O37). A total of 2,946 women with postmenopausal osteoporosis (PMO; at least 1 vertebral fracture [VF] at entry) were enrolled. Baseline characteristics were comparable across the three study arms. After 3 years, treatment with oral daily ibandronate 2.5mg resulted in a significant 62% reduction in the incidence of new VFs in the ITT population ($p=0.0001$). Even when administered intermittently with a dose-free interval of 9-10 weeks (20mg every other day for 12 doses at the start of each 3-month cycle), oral ibandronate significantly reduced the risk of VFs by 50% after 3 years ($p=0.0006$). Similar reductions in VF risk were observed after 2 years (daily, 61% [$p=0.0006$]; intermittent, 56% [$p=0.0017$]), indicating a robust and consistent efficacy without waning of effect over time. Ibandronate is the first oral bisphosphonate that has proven - prospectively, in a full ITT population - to offer antifracture efficacy from a regimen with a dose-free interval of 9-10

weeks. Highly significant risk reduction was consistently demonstrated in subgroups of patients who were at varying fracture risk, based on the number of prevalent VFs at baseline and the history of a previous clinical fracture (see Table). Both regimens of oral ibandronate were well tolerated and there were similar incidences of adverse events across all treatment groups. Thus, oral ibandronate provides clinically significant and lasting reductions in the incidence of new VFs for patients at low and high risk for new VFs, whether given daily or intermittently.

Subgroup	Placebo fracture rate (%) [n=975]	New VF risk reduction (%) 2.5mg (daily) [n=977]	CI	20mg (intermittent) [n=977]	CI
All patients	9.6	62		50	
Zero or 1 baseline VF	7.5	66	(27–84)	42	(–8–69)
≥2 baseline VFs	16.7	61	(34–77)	55	(24–73)
History of clinical fracture within 5 years of study	13.1	67	(24–85)	52	(–3–78)
No history of clinical fracture within 5 years of study	11	60	(33–76)	49	(19–68)

F343

Risedronate Significantly Reduces Moderate and Severe Vertebral Fractures by 70% in One Year. D. Felsenberg[1], D. A. Hanley[2], T. D. Johnson*[3], M. D. Manhart[3], H. K. Genant[4]. [1]Department of Radiology, University Hospital Benjamin, Berlin, Germany, [2]University of Calgary, Calgary, AB, Canada, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [4]University of California San Francisco, San Francisco, CA, USA.

We have analyzed data from the VERT studies to determine the vertebral fracture risk reduction with risedronate treatment on moderate or severe fractures in 1 year using the semi-quantitative assessment method of Genant et al (JBMR 1993; 8: 1137). In the VERT studies both quantitative and semi-quantitative methods were used to determine fractures. If these methods disagreed on the fracture status, adjudication was utilized to determine if a fracture was present. Overall efficacy results with this adjudicated method agreed with the results of semi-quantitative analysis alone. In the present analysis, the semi-quantitative method was used to determine fracture status and only moderate (a change from grade 0 to grade 2) or severe (a change from grade 0 to grade 3) fractures were used. The VERT studies enrolled patients with either low BMD (T-score < -2) and one prevalent vertebral fracture (VERT-NA) or patients with at least two prevalent vertebral fractures (VERT-MN). Patients were randomized to receive either placebo or risedronate 5 mg daily. All patients received 1 g/day calcium supplementation, and up to 500 I.U. vitamin D/day if serum 25-OH vitamin was low at baseline. Kaplan-Meier estimates were used to determine new fracture incidence. During the first year, 46 out of 992 (4.6%) patients experienced a new moderate to severe vertebral fracture in the placebo group compared to 14 out of 1002 (1.4%) in the risedronate-treated group. The risk reduction in moderate and severe vertebral fractures at 1 year was 70.7% (p<0.001). If all incident fractures, i.e., mild, moderate and severe were included in the analysis, there is a vertebral fracture risk reduction of 63.9% (p<0.01) at 1 year. The reductions in vertebral fracture risk were sustained over three years. Treatment with risedronate 5 mg daily results in significant vertebral fracture risk reduction, especially for moderate and severe vertebral fractures.

F345

Alendronate in the Prevention of Osteoporosis. P. N. Sambrook[1], J. P. Rodriguez[2], R. D. Wasnich*[3], M. M. Luckey[4], A. Kaur*[5], A. Lombardi[5]. [1]University of Sydney, Sydney, Australia, [2]Dept. Biologia Celular, Universidad de Chile, Santiago, Chile, [3]Hawaii Osteoporosis Center, Honolulu, HI, USA, [4]St. Barnabas Ambulatory Care Center, Livingston, NJ, USA, [5]Merck Research Laboratories, Rahway, NJ, USA.

In a 3-year study followed by a 2-year open-label extension, alendronate sodium (ALN)* maintained or increased bone mineral density (BMD) in 445 recently postmenopausal women with a spine BMD T-score > -2. In a second 2-year extension, 84 women previously treated with either 5 or 10 mg ALN daily during the first 3 years and 5 mg ALN during the first extension (Group A) were randomized to either 5 mg ALN or placebo (PBO). Another group of 59 women (Group B) received 20 mg ALN during the first 2 years, PBO during Year 3, and were then followed up without treatment during Years 4-7.

Group	Triple-Blind		Open-Label Extension	Triple-Blind Extension
	Years 1 and 2	Year 3	Years 4 and 5	Years 6 and 7 (N = 143)
A	ALN 5 mg	ALN 5 mg	ALN 5 mg	ALN 5 mg (N = 26) or PBO (N = 15)
	ALN 10 mg	ALN 10 mg	ALN 5 mg	ALN 5 mg (N = 29) or PBO (N = 14)
B	ALN 20 mg	PBO	Follow-up without treatment	Follow-up without treatment (N = 59)

Continuous ALN treatment for 7 years increased spine and trochanter BMD by 2.7-4.1% and 3.3-4.2%, respectively, while femoral neck and total body BMD were maintained. Patients switched to PBO during the last 2 years lost femoral neck and total body BMD, while spine and trochanter BMD remained stable. Among women who received ALN 5 mg during Years 4-7, those who had been treated with 10 mg ALN in the first 3 years had slightly greater increases in BMD at all sites at the end of the study, compared with women who received 5 mg ALN during the first 3 years. Women in Group B showed significant loss in BMD at all skeletal sites during Year 4-7, when they received no treatment. In conclusion, ALN 5 or 10 mg daily for up to 7 years prevents bone loss in recently postmenopausal women. Early postmenopausal women who discontinue ALN after 2 years of treatment experience significant bone loss at all skeletal sites. Patients initially started on 10 mg ALN appear to gain more BMD than those initially treated with 5 mg ALN. *Manufactured by Merck & Co., Inc, Whitehouse Station, NJ

Effectiveness of External Hip Protectors in Preventing Hip Fractures: A Randomized Clinical Trial. N. M. van Schoor*[1], J. H. Smit*[2], G. Asma*[3], L. M. Bouter*[1], P. Lips[3]. [1]Institute for Research in Extramural Medicine, VU University Medical Center, Amsterdam, Netherlands, [2]Department of Sociology and Social Gerontology, VU University, Amsterdam, Netherlands, [3]Department of Endocrinology, VU University Medical Center, Amsterdam, Netherlands.

The incidence of hip fractures is very high in institutionalized elderly. Hip protectors have been shown to be an effective preventive treatment option, but compliance remains a problem. A randomized clinical trial was performed to examine the effectiveness and compliance of external hip protectors (Safehip, Denmark) in preventing hip fractures. The participants were residents from nursing homes, homes for the elderly or apartment houses for the elderly, aged 70 years and over, with a low bone density and /or high fall risk. The inclusion criteria were: (1) broadband ultrasound attenuation 'BUA' ≤ 40; or (2) 40 < BUA ≤ 60 and two risk factors for falls; or (3) 60 < BUA ≤ 70 and three risk factors for falls. Based on previous research of our institute, we used the following risk factors for falls: fall in the previous half year, dizziness while standing up, stroke with consequences, urinary incontinence, cognitive impairment, low activity, low mobility. A member of the research team performed unexpected visits to assess the compliance at 1, 6 and 12 months after inclusion in the study. During these visits, it was checked whether the participant was wearing the hip protector and whether the hip protector was worn correctly (placed over the greater trochanter and protectors in good state). Furthermore, all participants and /or nurses were interviewed to assess the determinants of compliance. Of the 830 persons that were screened for risk of hip fracture, 561 persons had a high risk. These persons were assigned to the hip protector group (n=276) or control group (n=285) by individual randomization. After exclusion of the persons who died and other persons who could not be visited, the compliance was 61% after 1 month (n=217), 55% after 6 months (n=201) and 61% after 12 months (n=140). About 92% of the participants was wearing the hip protector correctly. By intention to treat, 18 persons from the hip protector group fractured a hip during the study period versus 20 persons from the control group. Only 4 persons from the hip protector group were actually wearing the hip protector while fracturing a hip. Per-protocol and subgroup analysis will be performed. To our knowledge, this is the first large trial, which has used individual randomization to assign persons to the intervention or control group. In this study, hip protectors were not effective in reducing the incidence of hip fractures.

Interactive Effects of Hormone Replacement Therapy and Abdominal Fat on Bone Mineral Density: A Twin Study. L. M. Paton*[1], C. Margerison*[1], C. Nowson*[2], L. Lan*[1], S. Kantor*[1], B. Kaymakci*[1], J. D. Wark[1]. [1]Medicine, University of Melbourne, Melbourne, Australia, [2]Deakin University, Melbourne, Australia.

Hormone replacement therapy (HRT) maintains or increases bone mineral density (BMD) in postmenopausal women. In our studies of adult female twins, within-pair differences in BMD were associated with fat mass (FM) and lean mass (LM). Since soft tissue composition may influence the response to HRT, we used a co-twin design to examine interactive effects of HRT use and soft tissue composition as determinants of BMD. Lumbar spine (LS) and femoral neck (FN) BMD, total LM, total FM and abdominal fat mass (AFM) were measured by dual-energy X-ray absorptiometry in 127 pairs of healthy female twins aged 30-65 years (Group 1) and in 39 pairs, aged 42-88 years, reporting within-pair discordance for HRT use (Group 2). The strongest interaction was with total abdominal fat mass: for the FN, the within-pair difference (SE) in BMD increased from 4.7(1.9)%, P = 0.01, per kg of AFM in Group 1 to 14.1(3.1)%, P <0.001, per kg of AFM associated with HRT discordance in Group 2. Similarly, for the LS the within-pair BMD difference increased from 6.2(1.6)%, P <0.001, per kg of AFM in Group 1 to 11.6(3.2)%, P = 0.001, per kg of AFM in Group 2 twins. There was no within-pair difference in FM, AFM or LM in either group. In a multivariate model including age, FM and AFM in Group 2, AFM predicted the within-pair difference in LS BMD (16.7(5.9)%, P = 0.008, per kg) while FM was not associated significantly with BMD. This model explained 37% of the within-pair difference in BMD for Group 2. In Group 1, FM was predictive of the within-pair difference in LS BMD (0.7 (0.3)%, P = 0.035, per kg), while AFM was not associated with the within-pair difference in LS BMD. Further modeling including age, height, LM, FM and AFM supported these findings. Similar results were found for the FN. These finding demonstrate that the association between fat mass and BMD is enhanced in HRT-discordant twin pairs. Abdominal fat mass was identified as a powerful determinant of FN and LS BMD associated with HRT use. These effects suggest novel mechanisms by which HRT may influence bone mass.

The Association between Changes in Bone Mineral Density (BMD) and Biochemical Markers of Bone Turnover at 1 Year with Vertebral Fracture Risk at 3 Years: Results from the Multiple Outcomes of Raloxifene Evaluation (MORE) Trial. S. Sarkar*, G. G. Crans*, M. Wong, K. D. Harper. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA.

Although the association between baseline BMD and new fracture risk is well understood, the relationship between BMD change and fracture risk is less clear. We have previously demonstrated that BMD change was a poor predictor of vertebral fracture risk in raloxifene-treated women, explaining only a small proportion of the drug's efficacy [JBMR 17 (2002): 1-10]. Recently, Bjarnason et al., have shown that changes in bone turnover markers during raloxifene therapy were significantly associated with future fracture risk [Osteopor Int 12 (2001): 922-30]. In the current analysis, we consider prediction of vertebral fracture risk using changes in both BMD and bone turnover simultaneously, while controlling for important baseline variables. MORE was a randomized, placebo-controlled trial of 7705 women with osteoporosis treated with raloxifene 60 or 120 mg/d for 3 years [JAMA 282 (1999): 637-45]. Since markers of bone turnover were measured in one-third of the study population, the present analyses involve only these women. Logistic regression models were constructed utilizing one-year percentage changes in BMD and bone turnover, and relevant baseline demographics to predict the risk of vertebral fracture with pooled raloxifene therapy at 3 years. All covariates were standardized before modeling, to facilitate direct comparisons between changes in BMD and changes in bone turnover. Prevalent vertebral fracture status ($p<0.0001$), baseline lumbar spine BMD ($p<0.0001$), and number of years postmenopausal ($p=0.0005$) were significant. Therapy-by-change in femoral neck BMD interaction ($p=0.02$) and therapy-by-change in osteocalcin (OC) interaction ($p=0.01$) were also significant. These interactions indicate that changes in BMD and OC have different effects on fracture risk for the placebo and pooled raloxifene groups. To further investigate these interactions, models for pooled raloxifene and placebo were fit separately, using the above baseline variables and changes in BMD and OC. The final raloxifene model included each baseline variable and change in OC ($p=0.01$), while change in femoral neck BMD was not significant. In summary, baseline lumbar spine BMD, prevalent vertebral fracture status, and number of years postmenopausal were the most important baseline variables to predict vertebral fracture risk at 3 years. After adjustment of these baseline variables, the percentage change in OC appears to be a better predictor of fracture risk reduction with raloxifene therapy than the percentage change in femoral neck BMD.

Endogenous Levels of Estrogen Determine the Response to Treatment with Hormone Replacement Therapy in Elderly Women. P. B. Rapuri*[1], J. C. Gallagher[2], G. Haynatzki*[3]. [1]Bone Metabolism, Creighton University, Omaha,, NE, USA, [2]Bone Metabolism, Creighton University, Omaha, NE, USA, [3]Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

Age related bone loss in elderly women has been attributed to age-related factors such as malabsorption of calcium, vitamin D nutritional status and secondary hyperparathyroidism. There is some evidence to suggest that low levels of endogenous estradiol may influence the age related bone loss. However, it is not known whether endogenous estradiol can influence the response to treatment with estrogen in elderly women. In the present study, we investigated the association between the baseline estradiol levels and the treatment response to estrogen. The study population included 489 elderly women aged 65-77 years randomized to 4 treatment groups, placebo, calcitriol (0.5 mcg/d), estrogen (conjugated equine estrogen (CEE), 0.625mg/MPA2.5 mg) and calcitriol+CEE. Baseline total and bioavailable estradiol, and the percent change in bone mineral density (BMD) after 3 years at spine, femoral neck and total body were determined in 337 women who were adherent to treatment. The rate of bone loss across the tertiles of bioavailable estradiol and total estradiol in the 4 treatment groups was compared by analysis of variance (ANOVA). In the placebo group, women in the lowest tertile for baseline bioavailable estradiol showed significantly higher bone loss at spine ($p<0.05$) and total body ($p=0.08$) compared to that of the highest tertile. No such significant changes were noted in the calcitriol group. In the hormone treatment groups (analyzed by combining both the estrogen groups), women in the lowest tertile for baseline bioavailable estradiol gained a significantly higher BMD at the spine ($p<0.01$) and femoral neck ($p<0.01$) compared to women in the highest tertile. Similar results were observed when the data was analyzed for total estradiol. This is the first observation to show that estrogen therapy causes a larger increase in BMD in elderly women with the lowest serum estradiol, probably because they have higher bone resorption and a larger remodeling space. In conclusion, endogenous estradiol level is an important determinant of bone loss and affects the response to treatment with estrogen, in elderly women.

Longitudinal Changes in Three-Dimensional Trabecular Microarchitecture of Paired Iliac Crest Bone Biopsies before and after Estrogen Replacement Therapy in Postmenopausal Women. J. Zhao[1], Y. Jiang[1], S. Vedi*[2], J. E. Compston[2], H. K. Genant[1]. [1]Oarg, University of California, San Francisco, CA, USA, [2]Department of Medicine, University of Cambridge, Cambridge, United Kingdom.

Postmenopausal bone loss is associated with deterioration of trabecular bone microarchitecture, which has adverse biomechanical effects. Estrogen replacement therapy (ERT) has been shown to prevent menopausal bone loss and reduce fracture risk, but its effects on three-dimensional (3D) trabecular microarchitecture have not been characterized. This study was designed to capture true longitudinal changes in 3D trabecular architecture before and after ERT, which may improve our ability to estimate bone biomechanical properties in terms of fracture resistance, as the mechanical competence of trabecular bone is a function of its apparent density and 3D distribution. During aging and in diseases such as osteoporosis, trabecular plates are perforated and connecting rods dissolved, with a continuous shift from one structural type to the other. These changes can not be evaluated by 2D histological sections in bone histomorphometry based on the parallel plate model assumption. We examined paired bone biopsies from the iliac crest (not a primary weight bearing anatomical site) from 20 postmenopausal women with osteopenia or osteoporosis. Bone biopsies were obtained from one side of the iliac crest before treatment and from the other side after treatment (mean 2 years). The specimens were blindly scanned and evaluated using a micro computed tomography scanner ($\propto$CT 40, Scanco) with isotropic resolution of 15 $\propto m^3$. 3D trabecular structural parameters were directly measured without stereological model assumptions as in 2D histomorphometry. Values of 0 and 3 for the structure model index represent an ideal plate structure and a perfect cylindrical rod structure, respectively, while values between 0 and 3 indicate a structure with both plates and rods of equal thickness, depending on the volume ratio of rods and plates. Compared with pre-treatment, post-treatment biopsies showed significant change in structure model index (-13.7%). Post-treatment changes in 3D trabecular bone volume fraction (+0.3%), trabecular thickness (+2.4%), trabecular number (-13.2%), trabecular separation (+9.0%), connectivity density (-0.4%), and degree of anisotropy (-4.4%) were statistically non-significant. The results indicated that ERT not only preserves existing 3D trabecular bone microarchitecture and connectivity but also is able to reverse the change from rod-like structure to plate-like pattern, which may improve trabecular biomechanical competence in terms of resistance to osteoporotic fragility fractures.

Teriparatide (rhPTH(1-34) Improves the Structural Geometry of the Hip. K. Uusi-Rasi*[1], T. J. Beck[1], T. L. Oreskovic*[1], M. Sato*[2], C. E. Bogado*[3], J. R. Zanchetta*[3]. [1]Department of Radiology, Johns Hopkins University, Baltimore, MD, USA, [2]Eli Lilly and Company, Indianapolis, IL, USA, [3]Fundación de Investigaciones Metabólicas, Buenos Aires, Argentina.

Postmenopausal women administered teriparatide (rhPTH (1-34) showed increased BMD with lower fracture rates, suggesting that bone strength properties were improved. We used the hip structure analysis (HSA) program to clarify possible effects of teriparatide on the hip structural geometry. This program measures BMD and geometric properties within narrow regions across the femoral neck, intertrochanter and femoral shaft from images acquired by DXA. Subjects were participants in a multi-center placebo-controlled clinical trial of teriparatide (Lilly). Data for this pilot study were obtained from the Buenos Aires cohort of patients and included 84 postmenopausal women (mean age 67.6 ± 6.4 years) randomized into those receiving daily injections of placebo (n=26), 20 (n=32) or 40µg (n=26) teriparatide, respectively. Hip DXA scans (Lunar-GE, Madison WI) were performed at baseline and repeated on average at 20.1 months. General linear models were used to assess the effects of teriparatide treatment on bone structure using baseline values as covariates. Adjusted % mean differences (95% CI) from baseline at termination are listed for treatment groups in the table with significant differences ($p<0.05$) noted with asterisks. While not all points reached significance, BMD, cross-sectional area (CSA), and section modulus (Z) an index of bending strength, were higher in 20 or 40 mg groups. Reduction in buckling ratio (BR), an index of cortical instability, may be particularly important since fracture cases in other studies have high BRs and the ability to reduce this parameter may help to explain teriparatide efficacy in reducing non-vertebral fractures. Results of this pilot study are encouraging and should be verified with a larger sample size to further clarify the structural effects of teriparatide treatment.

Percent Mean Difference (95% Confidence Interval) from Placebo Controls

Variable	Narrow Neck		Shaft	
	20 ug	40 ug	20 ug	40 ug

The Association of Serum RANKL and OPG Levels with Other Biochemical Markers of Bone Turnover in Glucocorticoid Induced Osteoporosis Patients treated with hPTH (1-34). N. Lane, W. Yao, C. D. Arnaud. Department of Medicine, University of California at San Francisco, San Francisco, CA, USA.

Daily injections with hPTH (1-34) is associated with increase in both biochemical markers of bone formation and bone resorption. In addition, changes in levels of biochemical markers predicted increases in bone mass associated with hPTH (1-34) treatment (Lane, Osteo Inter, 2000). Since osteoclast maturation and activity are influenced by RANKL and OPG, we determined the changes in the serum levels of RANKL and OPG and compared these changes to other biochemical markers of bone turnover in patients treated with hPTH (1-34) for 1 year. All studied subjects (n=51) had post-menopausal osteoporosis, were treated chronically with glucocorticoid + HRT and were randomized to hPTH (1-34) 40 ug/d (n=28) or a control group (n=23). In addition, all study subjects were also treated with 1000mg/d calcium + diet and 800IU/d vitamin D3. Biochemical markers of bone formation (osteocalcin) and bone resorption (Deoxypyridinoline/Cr = DPD), sRANKL and OPG were monitored at the baseline, 1 month and every 3 months for 1 year. Results: In the hPTH (1-34) group, osteocalcin increased by 150% above baseline at 1 month ($p<0.01$ from time 0) and was maintained at this level throughout the treatment period. sRANKL increased > 250% over the baseline level at 3 months and was maintained at 150% above baseline for the next 9 months ($p<0.05$). The ratio of sRANKL/OPG did not significantly change until 3 months of treatment, when it increased > 100% over the baseline level and was maintained at > 60% above baseline throughout the treatment period ($p<0.05$). DPD levels increased at a slower rate than sRANKL and osteocalcin, with an increase of only 70% by 1 month and an increase of 150% above baseline by 6 months ($p<0.01$). In the control group, no significant changes were observed in any of the biochemical markers of bone turnover or sRANKL/OPG ratio evaluated. In summary, we found that daily hPTH (1-34) injections increase sRANKL levels earlier and to a greater degree than DPD levels. These results support the hypothesis that hPTH (1-34) daily injections increases osteoclast activity by stimulating osteoblast production of RANKL. Additional studies are now underway to determine if changes in RANKL/OPG levels are correlated with or predict bone mineral density changes with hPTH (1-34) treatment.

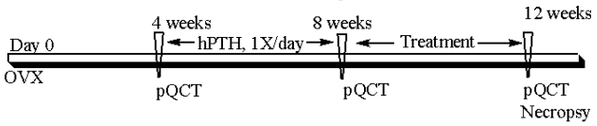
OPG Prevents Relative Osteopenia and Deficits in Skeletal Strength in Mice During a 12 Day Spaceflight. P. J. Kostenuik[1], T. A. Bateman[2], S. Morony[1], K. S. Warmington*[1], Z. Geng[1], S. J. Simske[2], V. L. Ferguson*[2], C. R. Dunstan[1], D. L. Lacey[1]. [1]Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA, [2]University of Colorado, BioServe Space Technologies, Boulder, CO, USA.

Bone loss poses a barrier to long-term spaceflight that could be alleviated with a safe and convenient bone-sparing agent. OPG is a protein that causes sustained inhibition of bone resorption after a single injection. We tested the ability of OPG to preserve bone during spaceflight (SF) in mice, a species whose skeletal response to microgravity has not been previously described. 10 week old female C57/B6 mice (n=12/group) were injected once (SC) with OPG (20 mg/kg) or with vehicle (VEH), 24 h prior to launch. Ground control (GC) mice (VEH or 20 mg/kg OPG) were maintained under environmental conditions that mimicked those in the shuttle middeck. A group of age-matched mice was sacrificed at launch to serve as baseline (BL) controls. SF mice were launched into orbit for 12 days on the shuttle Endeavor (STS-108), and were sacrificed within 4 hours of their return. pQCT analysis of the proximal tibial metaphysis revealed that GC/VEH, but not SF/VEH mice, gained BMD during the mission ($p<0.05$ vs. BL). After landing, SF/VEH mice had lower BMD vs. GC/VEH mice ($p<0.05$), while SF/OPG mice had greater BMD than SF/VEH or GC/VEH groups ($p<0.05$). OPG increased tibial cancellous bone volume and BMD in all groups ($p<0.05$ vs. VEH). SF reduced elastic strength at the femoral midshaft in VEH mice ($p<0.05$), while OPG increased elastic strength in SF mice ($p<0.05$). Serum TRAP was elevated in VEH/SF mice vs. VEH/GC mice (p95% in all groups ($p<0.05$). This OPG effect provides a plausible mechanism for the preservation of bone during SF. However, inhibited bone formation appeared a more significant mechanism for SF-induced osteopenia. SF reduced periosteal bone formation rate in the femoral diaphysis ($p<0.05$ vs. GC mice). SF/VEH mice also had lower serum alkaline phosphatase ($p<0.05$ vs. GC/VEH mice), suggesting the suppression of osteoblast activity during SF. OPG did not cause any reversal of the SF-related changes in these bone formation parameters. These observations suggest that the beneficial effects of OPG on mouse bone during SF are due to dramatic and sustained suppression of bone resorption. In growing mice, this effect appears to compensate for the SF-related inhibition of bone formation, while preventing any potential SF-related increase in bone resorption. We have demonstrated that the young mouse is an appropriate model for SF-induced osteopenia. A single pre-flight treatment with OPG effectively prevented the deleterious effects of SF on mouse bone.

F371

Maintenance of Therapeutic Effects of hPTH in Ovariectomized Rats with Established Osteopenia: Evaluation of Bazedoxifene, Raloxifene and Ethinyl Estradiol. Y. P. Kharode, J. T. Marzolf*, P. V. N. Bodine, B. S. Komm, F. J. Bex. Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA.

Intermittent administration of hPTH produces osteogenic effects in both normal and ovariectomized (ovx) rats. The osteogenic effects observed in ovx rats with hPTH regress upon discontinuation of the treatment resulting in a very rapid bone loss and recurrence of osteopenia. The present study was conducted to evaluate the effects of the SERMs bazedoxifene (BZA), and raloxifene (RAL), as well as ethinyl estradiol (EE) on maintenance of the hPTH effects in ovx rats with established osteopenia as outlined below.



48 female rats were ovx at 12 weeks of age and were found to have developed significant osteopenia compared to eight age matched sham ovx rats after four weeks as judged by proximal tibial (PT) bone mineral density (BMD) using pQCT (total BMD 542 ±4 mg/gm^3 for ovx vs. 709 ± 8 mg/cm^3 for sham, $p<0.01$ and trabecular BMD 353 ± 6 mg/cm^3 for ovx vs. 533 ± 15 mg/cm^3 for sham, $p<0.01$). The ovx rats were then treated daily with hPTH (1-34), 10 µg/kg, sc (n=40) or vehicle (n=8) for four weeks. BMD measurements taken after hPTH treatment, eight weeks after ovx, confirmed a significant hPTH osteogenic effect (total BMD 564 ± 15 mg/cm^3 for ovx + vehicle vs. 686±6 mg/cm^3 for ovx +hPTH, $p<0.01$; and trabecular BMD 256±15 mg/cm^3 for ovx vs. 431 ± 10 mg/cm^3 for ovx + hPTH, $p<0.01$). After stopping PTH treatment the rats were divided in five groups of eight and received daily oral treatment for four weeks as follows: (1) Vehicle (2) BZA, 0.1mg/kg (3) BZA, 0.3 mg/kg (4) RAL, 3 mg/kg and (5) EE, 0.3 mg/kg. After four weeks of treatment, twelve weeks after ovx, the total and trabecular BMD (621±12 mg/cm^3 and 307± 5 mg/cm^3 respectively) decreased significantly in the vehicle group compared to the immediate post-PTH eight week observation but remained significantly higher than the ovx group not receiving PTH. At the twelve week time point, total and trabecular densities between the treatment groups were not statistically different and were not significantly different from the immediate post-PTH eight week time period. We conclude that BZA, RAL and EE were all effective in maintaining the effects of hPTH in the ovx rat with established osteopenia, although potential differences in potency were observed.

F373

Different Effects of Anti-resorptive Agents on Fracture Repair of Ovariectomized Rats. Y. Cao*[1], S. Mori[1], T. Mashiba[1], M. S. Westmore[2], L. Ma[2], M. Sato[2], T. Akiyama*[1], L. Shi*[1], S. Komatsubara*[1], K. Miyamoto*[1], H. Norimatsu[1]. [1]Orthopedic Surgery, Kagawa Medical University, Takamastu, Japan, [2]Lilly Bone Research Laboratories, Indianapolis, IN, USA.

The effects of anti-resorptive agents-estrogen, raloxifene, and alendronate- on the processes of fracture repair were studied in ovariectomized rats. 140 female SD rats were either ovariectomized or sham-operated and divided into five groups: Sham (vehicle), OVX (vehicle), EE2 (0.1mg/kg, estrogen), Rlx (1.0mg/kg, raloxifene) and Aln (0.01mg/kg alendronate) groups. Treatment started from the day of surgery. Four weeks later, pre-fracture controls were euthanized, while bilateral osteotomies were performed on femoral midshafts and fixed with intramedullary wires for all remained animals. Treatment was continued and the rats were sacrificed at 6 and 16 weeks post-fracture for evaluation by x-ray radiography, QCT, biomechanical testing, and histomorphometry. At 6 weeks post-fracture, Aln and OVX had significantly larger callus than other groups. Sham and OVX had significantly higher ultimate load than EE2 and Rlx, while Aln no different from either control. Aln callus contained more mineral (BMC) than all other groups. By 16 weeks post-fracture, OVX callus was significantly smaller than at 6 weeks, while the callus volume for Aln had not changed. Aln had significantly higher BMC and ultimate load than OVX, EE2 and Rlx. EE2 and Rlx had similar biomechanical properties with Sham. Ultimate load normalized by body weight showed no significant difference in strength of the whole callus among the groups at either 6 or 16 weeks post-fracture. However, Aln strongly suppressed the remodeling of callus, resulting in the highest content of woven bone, persistent visibility of the original fracture line, and lowest content of lamellar bone, compared to the other groups. OVX-stimulated bone turnover resulted in the fastest progression of fracture repair that was most delayed with alendronate treatment, consistent with marked suppression of bone resorption and formation activity. Estrogen and raloxifene had similar effects that were generally similar to Sham, indicating that mild suppression of bone turnover with these agents has insignificant effects on the progression of fracture repair.

F381

Effect of Estrogen, Calcitriol or the Combination of Both on Falls and Non Vertebral Fractures in Elderly Women. J. C. Gallagher[1], G. Haynatzki*[2], S. Fowler*[3]. [1]Bone Metabolism, Creighton University, Omaha,, NE, USA, [2]Osteoporosis Research Center, Creighton University, Omaha, NE, USA, [3]Biostatistics, George Washington University, Washington D.C, MD, USA.

Nonvertebral fractures represent 50 percent of total fractures, the majority of which are due to falls. Therefore, reducing falls is a very effective way to reduce fractures. In a prospective study, 489 women were randomized in a double blind placebo trial to treatment with placebo, calcitriol 0.25mcg bid, conjugated equine estrogens (CEE)0 .625mg (ERT or HRT), and a combination of CEE and calcitriol. Women were followed for 3 years and data collected prospectively on falls, non-vertebral fractures due to falls and changes in bone density. Only the data on falls and fractures will be presented. To compare the effect of treatment on falls the cumulative number of falls over 3 years and the incidence rate of falls was performed by recurrent events analysis using a homogeneous Poisson regression model.(SAS GENMOD)Allresults were corrected for body mass index and age . Results: The cumulative number of falls in each group over 3 years was 63 percent on placebo, 56 percent on estrogen, 56 percent on the combination of estrogen and calcitriol and 48 percent on calcitriol; there was a significant decrease in the number of falls in the calcitriol treated group ($p<0.001$). The three-year incidence rate for falls was 0.43 on placebo, 0.39 on ERT/HRT, 0.35 on the combination, and significantly lower on calcitriol 0.29 ($p<0.001$). There was no significant relationship between serum 25 hydroxyvitamin D or serum PTH on fall incidence,caffeine($p<0.09$),but there was a highly significant decrease in the incidence of falls in women who smoked ($p=0.00006$). Overall, 10 percent of women suffered non-vertebral fractures due to falls. There was a significant reduction in fall related fractures in the two groups treated with calcitriol compared to the non calcitriol groups($p<0.052$).There was no significant effect of estrogen on fractures. In conclusion, calcitriol reduces the incidence of falls and fall related fractures.Because falls are one of the most important cause of non-vertebral fractures,this therapeutic approach to preventing fall related fractures may be a useful adjunctive effect to that on bone density.

Regulation of PHEX Gene Expression in Bone by Chronic Renal Insufficiency and 1,25-Dihydroxyvitamin D_3. A. J. Brewer*, L. Canaff*, G. N. Hendy, H. S. Tenenhouse. McGill University, Montreal, PQ, Canada.

The PHEX gene (Pi-regulating gene with homologies to endopeptidases on the X chromosome), which is mutated in patients with X-linked hypophosphatemia, is predominantly expressed in bones and teeth. However, little is known about the regulation of PHEX expression. The present study was undertaken to examine the effects of hyperparathyroidism, secondary to chronic renal insufficiency (CRI), and hypoparathyroidism, in response to 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2$D) administration, on PHEX mRNA and protein expression in rat bone. Rats underwent 5/6 nephrectomy (Nx) or sham operation (control) and were maintained on a high Pi (1.4%) diet for five weeks. In addition, normal rats were injected 48 and 24 hours before sacrifice with either vehicle or 1,25-$(OH)_2$D (10 pmol/gBW). PHEX mRNA abundance, relative to β-actin, was measured by ribonuclease protection assay and PHEX protein abundance, relative to actin, was quantitated by analysis of western blots. When compared to controls, Nx rats exhibited increased serum creatinine (Cr) and urea concentrations, increased serum Pi and urinary Pi excretion, and increased serum PTH (38 ± 2 vs 102 ± 7 pg/ml, $p<0.001$) and urinary cAMP/Cr (23 ± 5 vs 35 ± 5, $p<0.05$). These results indicate that the conditions for CRI and hyperparathyroidism are evident in Nx rats. PHEX mRNA (100 ± 7 vs 168 ± 26, $p<0.05$) and protein (100 ± 11 vs 157 ± 23, $p<0.05$) abundance were significantly increased in tibia of Nx rats when compared to controls. Administration of 1,25-$(OH)_2$D to normal rats had no effect on serum Cr or urea but significantly increased serum Ca and Pi concentrations, and urinary Ca and Pi excretion. Furthermore, both serum PTH (35 ± 2 vs 7 ± 0.5 pg/ml, $p<0.001$) and urine cAMP/Cr (19 ± 2 vs 12 ± 1, $p<0.05$) were significantly decreased in response to 1,25-$(OH)_2$D, indicating that the pharmacological dose was effective in generating hypoparathyroidism. PHEX mRNA (100 ± 12 vs 63 ± 10, $p<0.05$) and protein (100 ± 13 vs 56 ± 11, $p<0.05$) abundance in tibia of 1,25-$(OH)_2$D-treated rats were significantly decreased when compared to vehicle-treated rats. In contrast, tibial mRNA expression of the homologous neutral endopeptidase (NEP) was unchanged in Nx rats and increased in 1,25-$(OH)_2$D rats. The serum concentration of PTH was positively correlated with tibial PHEX mRNA ($p<0.001$) and protein ($p<0.001$) abundance. In summary, we demonstrate that PHEX mRNA and protein expression in rat tibia are significantly increased by Nx, decreased by 1,25-$(OH)_2$D and correlate with the serum concentration of PTH. We also show that PHEX and NEP expression are differentially regulated in rat tibia. Our data suggest that PTH status plays an important role in the regulation of PHEX expression in bone.

F387

Expression of mRNA and Protein for the Stimulatory G Protein Alpha Subunit (Gsα) of Adenylyl Cyclase in Progressive Osseous Heteroplasia (POH) Patients with Inactivating *GNAS1* Mutations. M. Xu*[1], S. M. Jan de Beur[2], C. Li*[1], N. Hebela*[1], S. Fitzgerald*[1], M. A. Levine[2], F. S. Kaplan[1], E. M. Shore[1]. [1]Orthopaedic Surgery, University of Pennsylvania School of Medicine, Philadelphia, PA, USA, [2]Medicine and Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Progressive osseous heteroplasia (POH) is an autosomal dominant disorder of extensive dermal ossification during childhood followed by disabling ossification of skeletal muscle and deep connective tissue. POH is caused by heterozygous inactivating *GNAS1* mutations. Although most identified cases of POH appear to be due to spontaneous mutations, all known examples of genetic transmission occur by a paternal inheritance pattern. To date, we have identified *GNAS1* mutations in 18 of 27 POH families with one or more affected members. These mutations include small (1-4 nucleotide) insertions and deletions, tandem duplications, and a single nucleotide substitution that disrupts a splice site junction. Each of these mutations predicts a protein reading frame shift. The *GNAS1* gene consists of 12 common exons plus 4 alternative first exons and generates transcripts for XLαs, NESP55, 1A, and Gsα. Although the *GNAS1* gene is reciprocally imprinted, the most well-characterized product, the Gsα protein, is biallelically expressed in most cell types. Examination of Gsα mRNA expression by RT-PCR in cultured lymphoblasts from POH patients with *GNAS1* mutations revealed expression of only normal transcripts if the mutation occurred prior to exon 13, but both normal and mutant transcripts were detected if the mutation affected the last exon. This result was confirmed by RNA blot analyses that detected reduced or normal amounts of hybridizing Gsα mRNA for patients with pre or post exon 13 mutations, respectively. No Gsα transcripts of altered sizes were identified. Immunoblot analysis showed reduced Gsα protein in cultured lymphoblast membranes from POH patients as compared to controls. These data suggest that haploinsufficiency of Gsα protein may be important in directing the clinical phenotype of POH. However, paternal inheritance of *GNAS1* mutations in POH is similar to that observed in pseudopseudohypoparathyroidism, a form of Albright hereditary osteodystrophy (AHO) that is clinically distinct from POH but which is also caused by paternally inherited mutations of the *GNAS1* gene. We conclude that the explanation for differences between these two disorders may not be solely dependent on the level of Gsα expression but may be influenced by the tissue-specific expression of the additional *GNAS1* transcript forms (Nesp55, XLαs, 1A) and/or by involvement of other genes.

F389

Paternal Imprinting of $G\alpha_s$ in the Thyroid as the Basis for TSH Resistance in Pseudohypoparathyroidism type IA. E. L. Germain-Lee*[1], C. Ding[1], J. L. Crane*[1], W. F. Schwindinger*[2], M. Ringel*[3], M. Saji*[3], M. A. Levine[1]. [1]Pediatric Endocrinology, Johns Hopkins University School of Medicine, Baltimore, MD, USA, [2]Weiss Center for Research, Geisinger Clinic, Danville, PA, USA, [3]Medstar Research Institute, Washington, DC, USA.

Albright hereditary osteodystrophy (AHO) is characterized by somatic defects that include brachydactyly, short stature, and obesity and heterozygous mutations in the *GNAS1* gene that lead to reduced expression or function of the alpha chain of G_s, the heterotrimeric protein that couples heptahelical receptors to stimulation of adenylyl cylase. AHO patients with *GNAS1* mutations on maternally inherited alleles also manifest resistance to multiple hormones (*e.g.* PTH, TSH), a variant termed pseudohypoparathyroidism (PHP) Ia, due to presumed tissue-specific paternal imprinting of $G\alpha_s$. Studies of transgenic mice in which one *Gnas* allele has been inactivated by homologous recombination have confirmed these clinical predictions and have demonstrated tissue-specific paternal imprinting of $G\alpha_s$ in renal proximal tubule cells, as well as in fat cells. Similar studies in humans have failed to demonstrate imprinting of $G\alpha_s$, although recent experimental evidence suggests that $G\alpha_s$ may be imprinted in the human pituitary. Because mild hypothyroidism due to TSH resistance occurs in AHO patients and *Gnas* +/- mice that inherit the mutant allele maternally, we sought to determine whether there is imprinting of $G\alpha_s$ in the thyroid. We isolated RNA from normal regions of thyroids that had been removed at surgery from subjects with thyroid nodules. Eight of 12 patients were heterozygous for a known T/C polymorphism in exon 5 of *GNAS1* that allowed us to distinguish between parental alleles. RT-PCR was performed using a common primer in exon 6 and exon-specific upstream primers and demonstrated expected uniallelic expression of NESP55 (maternal), XLαs (paternal), and 1A (paternal). Relative expression of $G\alpha_s$ mRNA was significantly greater from the maternal allele of *GNAS1* than the paternal allele in all 8 cases (0.83 ± 0.03 vs 0.40 ± 0.06). The proportion of paternal $G\alpha_s$ transcripts in these samples ranged from 25-40%. Immunohistochemical analyses of $G\alpha_s$ expression in thyroid tissue showed little or no apparent staining in *Gnas* +/- mice that had inherited the mutant allele maternally and reduced staining in mice that had inherited the mutant allele paternally compared to normal mice. We conclude that $G\alpha_s$ is incompletely paternally imprinted in the thyroid both in humans and in mice. The partial imprinting of the paternal $G\alpha_s$ allele is could explain the development of mild TSH resistance in both patients with AHO and *Gnas* +/- knock-out mice that inherit the mutant allele maternally .

Partial Rescue of the Hyp Phenotype by Osteoblast-Targeted PHEX Expression. X. Bai*[1], D. Miao[1], D. Panda[1], M. D. McKee[2], D. Goltzman[1], A. C. Karaplis[1]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Dentistry, McGill University, Montreal, PQ, Canada.

Inactivating mutations and/or deletions of PHEX/Phex are responsible for X-linked hypophosphatemic rickets in humans and in the murine homologue, Hyp. The predominant osteoblastic expression of Phex has implicated a primary metabolic osteoblast defect in the pathophysiology of this disorder. By targeting PHEX expression to osteoblasts in the Hyp genetic background, we aimed to correct the corresponding biochemical and morphological abnormalities and obtain information on their pathogenetic mechanism. When transgene Phex expression, driven by a mouse pro-α1(I) collagen gene promoter, was crossed into the Hyp background, it improved the defective mineralization of bone and teeth but failed to correct the hypophosphatemia and altered vitamin D metabolism associated with the disorder. Ex-vivo bone marrow cultures confirmed the amelioration in the Hyp-associated matrix mineralization defect following Phex expression. These findings suggest that while the Hyp bone and teeth abnormalities partially correct upon PHEX gene transfer, additional factors and/or sites of PHEX expression may be critical for the elaboration of the appropriate molecular signals that alter renal phosphate handling and vitamin D metabolism in this disorder.

F395

Expression of *FGF23* mRNA in Human Cell Lines and Tissues. M. Mirams*[1], B. G. Robinson*[2], R. S. Mason[1], A. E. Nelson[2]. [1]Dept of Physiology, Institute of Biomedical Research, University of Sydney, Sydney, Australia, [2]Cancer Genetics Dept, Kolling Institute of Medical Research, Royal North Shore Hospital, University of Sydney, Sydney, Australia.

The inherited phosphate wasting condition autosomal dominant hypophosphatemic rickets (ADHR) has been found to be associated with missense mutations in *Fibroblast Growth Factor 23* (*FGF23*) (1). Tumors associated with oncogenic osteomalacia (OOM), a tumor-induced phosphate wasting condition with similar features to ADHR, express FGF23 (2). The pathogenesis of OOM is unknown, but FGF23 may be involved. The purpose of this study was to investigate *FGF23* in cell lines established from OOM tumors, other human cell lines and normal human tissue. Sequencing of *FGF23* exons, amplified from genomic DNA, from OOM tumor cell lines revealed no mutations, and specifically not at the RXXR site that is affected by mutation in ADHR. Some evidence of a direct effect of expressed FGF23 on renal OK cell phosphate uptake was detected. Expression of *FGF23* mRNA was detected in OOM cell lines by RT-PCR. A number of other cell lines, including HEK293 and HUH7 cells, were found to express *FGF23* mRNA, and the identity of the product was confirmed by sequencing. In human tissue samples, *FGF23* mRNA expression was detected by RT-PCR in both renal and bone tissues, as well as in liver tissue. Results with human bone cultures suggest that *FGF23* mRNA expression is increased with mineralisation in the presence of beta-glycerophosphate. The lack of mutations in *FGF23* from OOM cell lines indicates that the mechanism of the disease differs from ADHR, and gives weight to the suggestion that overproduction of FGF23, rather than a mutated protein, plays a part in OOM. The expression of *FGF23* mRNA in bone and renal tissues is consistent with a role of FGF23 in regulation of mineral metabolism. This is also indicated by the increased expression of *FGF23* mRNA in mineralised, compared to non-mineralised, bone cells. The significance of *FGF23* mRNA expression in liver is as yet unknown. We conclude that *FGF23* may be a regulator of phosphate metabolism, and that overproduction of FGF23 by OOM tumors contributes to this disorder. (1) ADHR Consortium (2000) Nat. Gen. 26:345-348. Circulating FGF-23 Concentrations in Oncogenic Hypophosphatemic Osteomalacia (OHO) Patients Pre- and Post-surgery. K. E. White[1], W. E. Evans*[1], D. I. Shulman*[2], G. Colussi*[3], S. M. Moe*[1], M. Peacock[1], M. J. Econs[1]. [1]Indiana Univ. Sch. of Med., Indianapolis, IN, USA, [2]Univ. of So. Fl. Coll. Med., Tampa, FL, USA, [3]Niguarda-Ca' Granda Hospital, Milan, Italy.

We determined that FGF-23 is the secreted factor mutated in the heritable renal phosphate wasting disorder autosomal dominant hypophosphatemic rickets (ADHR) and demonstrated that FGF-23 is over expressed by tumors causing the acquired phosphate wasting syndrome oncogenic hypophosphatemic osteomalacia (OHO). ADHR and OHO share similar clinical profiles, and OHO is rapidly resolved upon surgical removal of the tumor, thus we hypothesize that FGF-23 is the factor responsible for the renal phosphate leak present in these disorders. The serum concentrations and clearance mechanisms of FGF-23 in OHO patients are, however, unknown. Therefore, our present goals were: 1) to test whether FGF-23 concentrations are elevated in OHO patients prior to tumor resection; and 2) to assess whether FGF-23 is cleared through the kidneys. Using an ELISA-based serum assay that recognizes C-terminal portions of FGF-23, the mean pre-operative serum concentrations of seven OHO patients was 786.1 RU (Relative Units)/ml ±SE 224.3 compared to 67.9 RU/ml ± 7.9 for normal controls (n=30), P<0.02. In a subset of OHO patients, FGF-23 was assessed pre- and post-tumor resection. For patient 1, FGF-23 was originally 1873.8 RU/ml and fell 91% to 161.0 RU/ml 24 h post-surgery, and 99% to 43.1 RU/ml after 48 h. Serum phosphorus concomitantly rose from 1.7 mg/dl to 2.6 mg/dl. For patient 2, FGF-23 was initially 1248.8 RU/ml, and fell to 91.1 RU/ml; serum phosphorus increased from 1.4 mg/dl to 3.0 mg/dl. Patient 3 had an FGF-23 value of 250.7 RU/ml that decreased to 38.7 RU/ml after surgery. FGF-23 mRNA was readily detectable in available tumors from patients 1 and 2. To test if FGF-23 is cleared by the kidney, pre-operation urine from patient 1 was assayed, and had a 5.8 FGF-23/creatinine ratio vs. 0.4± 0.076 for controls (n=26). In addition, pooled serum from renal failure patients had an FGF-23 level of 25,654.5 RU/ml. In summary, the elevated FGF-23 concentrations in OHO patients rapidly normalize following tumor removal. The presence of FGF-23 in OHO urine indicates that FGF-23 or C-terminal portions may be cleared through the kidneys. This is supported by the high serum levels of FGF-23 in renal failure patients. Our studies indicate that renal function is necessary for FGF-23 and/or C-terminal fragment clearance, or that FGF-23 is secreted in response to hyperphosphatemia. The fact that OHO patient serum phosphorus and FGF-23 concentrations rapidly return to normal after tumor removal further implicates FGF-23 as the phosphate wasting factor responsible for OHO.

F400

CHO-cells Expressing MEPE, PHEX and Co-expressing MEPE/PHEX Cause Major Changes in BMD, Pi and Serum Alkaline Phosphatase in Nude Mice. P. S. N. Rowe*[1], Y. Kumagai[2], R. Garrett[3], R. Blacher*[2], A. Escobada*[3], G. R. Mundy[1]. [1]Molecular Medicine, University of Texas HSC San Antonio IDDW/CTRC, San Antonio, TX, USA, [2]Acologix Inc, Emeryville, CA, USA, [3]Osteoscreen, San Antonio, TX, USA.

MEPE is secreted by tumors causing oncogenic hypophosphatemic osteomalacia (OHO) and increased expression occurs in murine X-linked hypophosphatemic rickets (Hyp). PHEX is a Zn metalloendopeptidase that is mutated in patients with HYP/hyp. Both proteins are developmentally co-expressed in osteoblasts. The effects of MEPE and PHEX over-expression and MEPE/PHEX co-expression *in-vivo* using CHO-cell nude-mouse models were investigated. Measurements were made on BMD, serum alkaline phosphatase (SAP), and serum inorganic phosphate (Pi), over a 21-day period in mice (3 week old female) injected (subcutaneously) with CHO cells. 60 animals divided into 6 experimental and control groups (10 animals per group) were used. The groups consisted of saline control (N), blank CHO cells (CHO-B), CHO cells transfected with empty vector (CHO-V), CHO cells expressing MEPE (CHO-M), CHO-cells expressing PHEX (CHO-P) and CHO cells co-expressing MEPE and PHEX (CHO-MP). BMD measured from days 13 to 21 decreased significantly (-5% to -11%) at the distal-femur in all groups except group CHO-MP and the saline control group-N. Group CHO-MP and N exhibited a significant increase in distal-femur BMD of +5.4% and +2.8% respectively over this period. SAP levels as expected declined steadily in the saline control group N over the 21 days. Surprisingly, all tumor groups except CHO-MP showed a marked and significant decrease (50%) in SAP levels on days 13 and 21 relative to group-N saline control animals. SAP levels in MP tumor-animals were not significantly different to the saline controls on day 13 but did decrease significantly relative to non-tumor controls by day 21 (Group-N; 39.9 IU/l SEM=2.9, group CHO-MP; 17.3 IU/l SEM=3.9). Groups CHO-M and CHO-MP exhibited decreased serum Pi relative to the other groups (including saline control) with group CHO-MP showing a more marked decrease on day 13 (group-N; 10.5 mg/dl SEM=0.3 and CHO-MP; 7.1 mg/dl SEM=0.5). In contrast, all tumor-groups exhibited a marked and significant increase in serum Pi by day 21 including groups CHO-M and CHO-MP relative to the saline controls (group-N; 9.9 mg/dl SEM=0.5 and group-CHO-B; 14.2 mg/dl SEM=2.6)). Finally, addition of purified recombinant MEPE protein (<1 ng/ml) to rat calvaria in bone-organ culture stimulated bone-resorption in a dose dependent manner. Thus confirming a direct *in-vitro* effect of MEPE on bone. In conclusion these studies demonstrate that MEPE and MEPE/PHEX interactions play major roles in bone-renal homeostasis in disease and health.

SHIP Deficient Mice Are Severely Osteoporotic Due to Accelerated Bone Resorption by Pagetic-like Osteoclasts. S. Takeshita[1], N. Namba[1], J. J. Zhao[2], Y. Jiang[2], H. K. Genant[2], M. J. Silva[3], M. D. Brodt*[3], C. D. Helgason*[4], R. K. Humphries*[4], G. Krystal*[4], S. L. Teitelbaum[1], F. P. Ross[1]. [1]Pathology, Washington University, St. Louis, MO, USA, [2]Radiology, University of California, San Francisco, CA, USA, [3]Orthopedic Surgery, Washington University, St. Louis, MO, USA, [4]Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, Canada.

SHIP is an SH2-containing inositol-5-phosphatase, preferentially expressed in hematopoietic cells. By dephosphorylating its major substrate, phosphatidylinositol-3,4,5-trisphosphate (PIP_3), SHIP blunts phosphatidylinositol-3-kinase (PI3-K) initiated signal transduction. $SHIP^{-/-}$ mice are known to be rich in bone marrow macrophages (BMMs) and we find osteoclasts (OCs), which are derived from these cells, are increased two fold in these mutants. Consistent with the increased number of OCs in $SHIP^{-/-}$ mice, osteoclastogenesis induced by RANKL or M-CSF, occurs at substantially lower concentrations of either cytokine, than WT. Furthermore, the number of apoptotic nuclei and the level of cytoplasmic histones/DNA, the latter measured by ELISA, were decreased 75% in $SHIP^{-/-}$ OCs. Thus, the increased OC number characterizing $SHIP^{-/-}$ mice arises from a combination of an enhanced response to the osteoclastogenic cytokines M-CSF and RANKL and a prolonged lifespan. More strikingly, $SHIP^{-/-}$ OCs are greatly enlarged (2.6 fold), contain upwards of 100 nuclei, and are indistinguishable from those characterizing Paget's disease of bone. Like Pagetic osteoclasts, the capacity of those generated from $SHIP^{-/-}$ mice to generate resorptive pits on dentin slices is enhanced. In contrast to resorption, the rates of bone formation, assessed by calcein double labeling, are indistinguishable in $SHIP^{-/-}$ and WT mice. Consistent with accelerated resorptive activity, 3D trabecular volume fraction, trabecular thickness and trabecular number and connectivity density of $SHIP^{-/-}$ long bones, determined by micro-computed tomography, are all dramatically reduced, resulting in a 22% loss of bone mineral density (BMD) and a 49% decrease in fracture energy, measured by DEXA and three point bending, respectively. Since the SHIP gene co-segregates with a site of loss of heterozygosity for familial Paget's disease, and $SHIP^{-/-}$ and pagetic osteoclasts are indistinguishable, it is possible that SHIP is mechanistically important in some Pagetic patients. Thus, SHIP negatively regulates osteoclast formation and function and absence of the enzyme results in severe osteoporosis, with a pathological state mimicking the resorptive phase of Paget's disease.

F405

Juvenile Paget Disease Caused By Homozygous Deletion Of *TNFRSF11B* Encoding Osteoprotegerin. M. P. Whyte[1], S. E. Obrecht*[2], P. M. Finnegan*[2], J. L. Jones*[2], M. N. Podgornik*[1], W. H. McAlister*[3], S. Mumm[1]. [1]Cntr Metab Bone Dis & Mol Res, Shriners Hosp Child, St. Louis, MO, USA, [2]Div Bone & Min Dis, Wash Univ Sch Med, St. Louis, MO, USA, [3]Mallinckrodt Inst Radiol, Wash Univ Sch Med, St. Louis, MO, USA.

Juvenile Paget disease (JPD), an autosomal recessive osteopathy, features rapidly remodeling woven bone, osteopenia, fractures, and progressive skeletal deformity. If untreated, JPD can be lethal. The molecular basis is not known. *Osteoprotegerin* (OPG) deficiency could explain JPD because OPG suppresses bone turnover, functioning as a decoy receptor for *osteoclast differentiation factor* (ODF). ODF, also called *RANK ligand*, promotes skeletal resorption when it binds on osteoclasts to *receptor activator of nuclear factor-κB* (RANK). Two Navajos with JPD in separate families were studied for defects in the *TNFRSF11B* gene, encoding OPG, by: i) polymerase chain reaction (PCR) with direct sequencing, and ii) Southern blotting. Genetic loci adjacent to *TNFRSF11B* were investigated by PCR. Delineation of the breakpoints of a deletion removing *TNFRSF11B* involved sequence tagged site (STS) content mapping and PCR across the deletion breakpoints. Selective, homozygous deletion of *TNFRSF11B*, with identical chromosomal 8q24.2 breakpoints, affects both JPD patients. The defect spans ~ 100 kb but leaves genes neighboring *TNFRSF11B* intact. Serum levels of OPG and uncomplexed ODF are undetectable and markedly raised, respectively. JPD results from OPG deficiency due to homozygous deletion of *TNFRSF11B*. Consequently, circulating levels of unbound ODF are elevated. OPG importantly suppresses bone remodeling in humans. OPG knockout mice manifest JPD rather than osteoporosis. The JPD literature suggests that OPG protects against arterial calcification. Both "bottleneck" and "founder" effects involving *TNFRSF11B* deletion seem to be emerging in the Navajo population. Prenatal and carrier detection is now possible. OPG administration could be a particularly effective treatment for JPD.

F408

Significance of 7-84 PTH in Primary Hyperparathyroidism: Its Production and Metabolism. H. Yamashita[1], P. Gao[2], T. Cantor[2], S. Noguchi*[1], S. Uchino*[1], S. Watanabe*[1], M. Fukagawa*[3]. [1]Surgery, Noguchi Thyroid Clinic, Beppu, Japan, [2]Scantibodies Laboratory Inc, Santee, CA, USA, [3]Dialysis and Metabolism, Kobe University School of Medicine, Kobe, Japan.

Most current commercial 2nd generation intact PTH (iPTH) assays cross-react with 7-84 PTH and this interference accounts for up to 90% of immunoreactivity in samples obtained from uremic patients. It is reported that 7-84 PTH has an antagonistic action to 1-84 PTH, however, very little is known about the production and metabolism of 7-84 PTH. A new 3rd generation cyclase activating PTH (CAP) novel immunoradiometric assay, was shown to specifically measure 1-84 PTH without any cross reactivity to 7-84 PTH. Using this CAP assay, we studied the production and metabolism of 7-84 PTH in primary hyperparathyroidism (pHPT). This study comprised 63 patients with pHPT caused by a single adenoma who underwent parathyroidectomy. Preoperatively, blood samples were drawn from the bilateral internal jugular vein by ultrasonographic guidance and from the peripheral vein. During surgery, blood samples were drawn after anesthesia (basal level), before excision (pre-excision level) of one enlarged parathyroid gland, and at 5, 10, and 15 minutes post excision. The 7-84 PTH level was calculated by subtraction of the 3rd generation CAP assay value from the 2nd generation iPTH assay value. There were 34 patients whose iPTH assay levels differed by more than 10% between the right and left internal jugular. In those 34 patients, the level of 7-84 PTH levels obtained from the adenoma side was significantly higher than those from the contralateral side (124±18 vs. 44±18 pg/ml, $p<0.05$).The plasma CAP and iPTH value had dropped to 25±10 and 32±11% at 5min, 14±7 and 21±7% at 10 min, and 10±5 and 17±7% 15 min after removal of an enlarged gland of pre-excision value, respectively ($p<0.001$). Interestingly, the 7-84 PTH level after 5 min was higher than that at pre-excision in seven of 63 patients (11%). Further, the level at 10 min was higher than that at 5 min 1n 10 (16%) and the level at 15 min was higher than that at 10 min 1n 15 (24%). Our results suggest that 7-84 PTH may not only be produced by parathyroid adenomas but also may be produced by the metabolism of 1-84 PTH during circulation and the new 3rd generation CAP assay may be a more useful adjunct to parathyroidectomy than the currently used 2nd generation iPTH assay.

F410

The Calcimimetic Compound KRN1493 Suppresses Parathyroid Hyperplasia in Rats with Chronic Renal Insufficiency. M. Wada*, T. Kawata*, Y. Furuya*, N. Kobayashi*, M. Ozai*, S. Miyata*, S. Obana*, N. Nagano. Pharmaceutical Development Laboratories, Kirin Brewery Co., Ltd., Takasaki-shi, Japan.

Secondary hyperparathyroidism is characterized by the elevation of circulating parathyroid hormone (PTH) levels and parathyroid hyperplasia. In this study, we evaluated the effects of the calcimimetic compound KRN1493 on secondary hyperparathyroidism progression using 5/6 nephrectomized rats. Exp.1 Rats were subjected to 5/6 nephrectomy and treated with KRN1493 (1 or 5 mg/kg) for 5 consecutive days. During the treatment, rats were infused with 5'-bromo-2'-deoxyuridine (BrdU) to label S-phase cells. After sacrifice, the parathyroid glands were dissected and subjected to immunohistochemical analysis for BrdU. The number of BrdU-positive parathyroid cells in rats with chronic renal insufficiency (CRI) was about 5-fold larger than that in sham-operated controls. Treatment with KRN1493 (5 mg/kg) reduced the number of BrdU-positive parathyroid cells by 40% compared to the vehicle-treated controls. Exp.2 We evaluated the long-term effect of KRN1493 on the progression of parathyroid cell hyperplasia. Rats were subjected to 5/6 nephrectomy and KRN1493 (3 or 15 mg/kg) was orally given for about 5 weeks daily. Serum PTH levels were measured before and after the last administration. Parathyroid glands were dissected and subjected to quantitative stereologic analyses, unbiased estimations of parathyroid cell number and size. Serum PTH levels in rats with CRI were about 9-fold higher than those in sham-operated controls before the last administration. KRN1493 (15 mg/kg) reduced serum PTH levels significantly 90 min after the last administration. Both the number of parathyroid cells and parathyroid grand volumes in rats with CRI were about 2.5-fold larger than those in sham-operated controls. KRN1493 (15 mg/kg) reduced the number of parathyroid cells by 47% and parathyroid grand volumes by 40%, respectively. The parathyroid cell volumes in rats with CRI were 1.3-fold larger than those in sham-operated controls and were not affected by KRN1493 (15 mg/kg). Serum PTH levels before the last administration positively correlated with the number of parathyroid cells ($r=0.85$, $P<0.01$) and the parathyroid grand volumes ($r=0.83$, $p<0.01$). We conclude that treatment with KRN1493 inhibits the progression of parathyroid hyperplasia by suppressing parathyroid cell proliferation. The present data suggest that KRN1493 would be a useful therapeutic agent for the treatment of secondary hyperparathyroidism.

F412

Elevated expression of RANK in osteoblasts from Pagetic Lesions. D. G. Ammerman*[1], A. M. Desphande*[1], D. Pathmanathan*[1], P. Bhatia[1], K. K. Unni*[2], M. Seton[3], R. J. Leach[4], M. F. Hansen[1]. [1]Molecular Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Pathology, Mayo Clinic, Rochester, MN, USA, [3]Rheumatology, Massachusetts General Hospital, Boston, MA, USA, [4]Cellular and Structural Biology, UT-Health Science Center, San Antonio, TX, USA.

Paget's disease of bone (PDB) is a focal disorder of bone metabolism characterized by accelerated bone resorption coupled to bone formation in affected sites. PDB is thought to be driven primarily by osteoclasts (OC), as the initial lesion is lytic, the phenotypic and biochemical abnormalities have been demonstrated in the OC, and it is sufficient to treat the OC to restore normal parameters of bone turnover. Noting both previously reported elevated expression of Receptor Activator of NFkB (RANK) in OC from Pagetic lesions, and recent data suggesting that RANK may play a role in osteoblast growth, we were interested to see if RANK expression was also elevated in Pagetic osteoblasts. We therefore examined osteoblasts for expression of RANK and its' ligand RANKL. We found that while RANKL expression levels remained comparable to those of normal bone, RANK expression was increased in osteoblasts in both the Pagetic bone and osteosarcomas that arose in Pagetic patients. To rule out the possibility that the increased expression was due to infiltrating osteoclasts (or their precursors), we immunostained the samples with Cathepsin K, a marker of osteoclast lineage. This confirmed that the cells examined were not osteoclasts. Elevated expression of RANK in the osteoblasts may induce these cells to proliferate inappropriately, possibly contributing to both PDB and Pagetic osteosarcoma tumorigenesis. Our study is the first to show primary biochemical abnormalities in the Pagetic osteoblasts.

F414

Decrease in Parathyroid Hormone Serum Levels with Age and with Correction of Extracellular Calcium Is Not Associated with a Reduction in Parathyroid Gland Size in Mice with a Nonfunctioning Vitamin D Receptor. K. Weber*[1], U. Zeitz*[1], C. Bergow*[1], D. W. Soegiarto*[2], R. Balling*[2], R. G. Erben[1]. [1]University of Munich, Institute of Animal Physiology, Munich, Germany, [2]GSF National Research Center for Environment and Health, Institute of Mammalian Genetics, Neuherberg, Germany.

Cell proliferation and parathyroid hormone (PTH) secretion in the parathyroid gland is known to be regulated by the vitamin D hormone via the vitamin D receptor (VDR) and by extracellular calcium via the calcium-sensing receptor. In this study, we sought to separate the effects of extracellular calcium from the effects of vitamin D on parathyroid gland function and size using mice with a nonfunctioning VDR. By 10 weeks of age, homozygous VDR mutant mice developed profound hypocalcemia and severe secondary hyperparathyroidism with PTH serum levels beyond 1,000 pg/ml in all animals. The parathyroid glands of 10-week-old VDR mutants were grossly enlarged, as measured by about a 3-fold higher maximum area in serial histological sections. After the rapid growth phase, when calcium demands of the growing skeleton decrease, hypocalcemia was less pronounced, and PTH serum levels declined from 1290 ± 418 in 10-week-old mutants to 45 ± 45 pg/ml in 1-year-old mutants (means ± SD). Northern analysis of total RNA extracted from the larynx region and in situ hybridization with a PTH-specific probe showed variations in PTH gene expression that paralleled those of PTH serum levels. However, the age-related decline in PTH mRNA levels and PTH secretion was not associated with a reduction in parathyroid gland size. In mice fed a rescue diet enriched with calcium, phosphorus, and lactose, beginning from 16 days of age, blood ionized calcium, PTH mRNA levels, PTH serum levels and parathyroid gland size were normal, showing that the absence of vitamin D signaling is not associated with increased chief cell proliferation or increased PTH secretion. When 6-month-old VDR mutants where switched to the rescue diet, PTH serum and mRNA levels declined over the 3-month experimental period. However, the rescue diet was not able to induce a decrease in parathyroid gland size. Also, there was no evidence of an increase in chief cell apoptosis in the parathyroid glands of animals on the rescue diet, as measured by TUNEL staining. We conclude that 1) vitamin D has no essential function in the control of PTH secretion and of cell proliferation in the parathyroid gland, and 2) that normalization of extracellular calcium reduces PTH gene expression and PTH secretion but does not reduce parathyroid gland hyperplasia in the absence of a functioning VDR. Our findings suggest that signaling via the calcium-sensing receptor is not able to reverse parathyroid gland enlargement.

F417

Lymphocytes from FOP Patients Induce Early FOP-like Lesions in Nude Mice. P. C. Billings*[1], Y. Wu*[1], R. Caron*[1], L. Serrano de la Pena*[1], F. H. Gannon[2], B. Young*[3], M. Pacifici[3], F. S. Kaplan[1], E. M. Shore[1]. [1]Orthopaedic Surgery, University of Pennsylvania School of Medicine, Philadelphia, PA, USA, [2]Orthopedic Pathology, Armed Forces Institute of Pathology, Washington, DC, USA, [3]Anatomy and Histology, University of Pennsylvania School of Dental Medicine, Philadelphia, PA, USA.

Fibrodysplasia ossificans progessiva (FOP) is a devastating genetic disease of progressive hetrotopic ossification leading to joint ankylosis throughout the body. While FOP was first described ~300 years ago, the precise genetic defect(s) and pathophysiology remain enigmatic. Progress in understanding FOP has been hampered by the lack of an animal model to study FOP lesion formation. To address this problem, we subcutaneously implanted lymphoblastoid cell lines obtained from FOP patients or unaffected family members into nude mice. As positive controls, upper and lower sternal chick chondrocytes were also implanted. Both types of sternal chondrocytes grow as a solid mass in mice, laying down a cartilage matrix. Cells from unaffected individuals either did not grow or formed small masses with little evidence of a fibrotic or angiogenic response. In contrast, cells from FOP patients gave rise to solid tumor-like masses in the animals. Histopathological evaluation of these lesions indicated that FOP cells induced angiogenesis and a fibrotic response in the host, similar in appearance to early FOP patient lesions (stage 1A-2B). FOP cell-induced lesions were probed for human-specific Alu sequences, confirming that the cellular masses contained human as well as host cells. These results suggest that cells of FOP patient origin produce stimulatory factors that induce changes in cell growth and/or differentiation, and mimic events in early FOP lesions. Hence, implantation of FOP-derived cells in nude mice will provide a useful model for examining the early stages of the disease and ultimately, a better understanding of this catastrophic condition.

F419

Osteoporosis and Fractures in Children with Duchenne Muscular Dystrophy Treated with Glucocorticoids: A Longitudinal Study. G. Chabot[1], N. Alos*[1], Y. Brousseau*[2], J. Dubé*[2], E. Delvin*[1], M. Filiatreault*[2], M. Vanasse*[1]. [1]Hopital Ste Justine, Montreal, PQ, Canada, [2]Hopital Marie Enfant, Montreal, PQ, Canada.

Oral glucocorticoids (OG) are increasingly used to treat Duchenne Muscular Dystrophy (DMD) to preserve muscle function and mobility. Concerns of skeletal complications associated with chronic administration of OG led us to follow at the neuro-muscular diseases clinic a group of 46 boys with DMD treated with deflazacort. Treatment was started between 4 and 11 years of age (mean: 7y 5m) and extended from 4 months to 9 years (mean: 5y 9m). Every patient received vitamin D (400 IU/day) and calcium supplements (750 mg/day). Growth was recorded at regular intervals. Bone mineral content (BMC) of the lower spine was measured and areal bone mineral density (aBMD) was calculated with a Hologic QDR 4500 DXA scanner, and repeated over a period of 4 years. Fractures were recorded and documented by X-ray. During the treatment period, 26 of the 46 patients (52%) suffered from 37 fracture events. Of these, 18 (39%) presented crush fractures of the vertebrae, and 19 episodes of long bone fractures occurred in 17 patients. Delay between treatment onset and the first fracture ranged between 22 months and 71/2 years (Mean 4 1/ 2 years). A total of 106 BMC measurements were performed in 46 patients between the ages of 5 years 11 months and 17 years and 5 months. Over this age span, the aBMD did not increase. The aBMD Z score decreased from a mean of –2 SD at 5 years to reach –5 SD at 17 years of age. Repeated measurements in 37 patients at a mean interval of 2 years allowed us to assess the longitudinal changes of the aBMD. In this subgroup, the aBMD Z score decreased from a mean of –2,59 SD to –3,27 SD ($P < 0,001$, paired T test) and the mean aBMD remained essentially unchanged at 0,480 g/cm2. The mean BMC increased slightly from 15,71 to 16,12 gm but the difference was not statistically significant. Our data allow us to conclude that skeletal complications in patients with DMD treated with OG are frequent and are associated with very low aBMD as calculated with DXA. If glucocorticoids are to be given to these patients, treatment to prevent bone loss should be started early. A study to evaluate the effectiveness and safety of such a preventive treatment should be initiated.

F422

Kaliotoxin Decreases Receptor Activator of NFκB Ligand (RANKL) Expression in Activated T Cells *In Vitro* and Ameliorates Local Inflammatory Bone Resorption in Experimental Periodontal Disease. P. Valverde*[1], T. Kawai*[2], M. A. Taubman*[2]. [1]Oral Biology, The Forsyth Institute, Boston, MA, USA, [2]Immunology, The Forsyth Institute, Boston, MA, USA.

It has been reported that the alveolar bone destruction observed in periodontal infections is partly mediated by microorganism-triggered induction of receptor activator of NFκB ligand (RANKL) expression on T cells and the subsequent activation of osteoclasts. The activation of RANKL in T cells is calcium-dependent and hence can be blocked by the calcineurin-dependent inhibitor cyclosporin A. Therefore, it might be expected that blocking Kv1.3, a T cell-expressing voltage-gated potassium channel that regulates the membrane potential and therefore the driving force for calcium entry through calcium release-activated calcium channels, will decrease the expression of RANKL and hence ameliorate T-cell mediated bone resorption. To test this hypothesis, we first analyzed whether kaliotoxin, a specific blocker of Kv1.3 can decrease the expression of RANKL in human peripheral blood T cells activated *in vitro* with anti-CD3 alone or anti-CD3 and anti-CD28 antibodies. RT-PCR and flow-cytometric analyses indicated that RANKL expression was decreased by more than 50% on T cells activated in the presence of kaliotoxin as compared to the absence of kaliotoxin. Secondly, we tested whether the inflammatory alveolar bone resorption induced by Th1 clone cells in an experimental model of periodontal disease could also be decreased by kaliotoxin. In this rat model, gingival injection of *Actinobacillus actinomycetemcomitans* 29-kDa outer membrane protein (Omp29) and LPS induces bone resorption on the palatal surface of the maxillary molars 10 days after transfer of antigen-specific Th1 clone cells. Subcutaneous injections of 10 μg of kaliotoxin twice a day for 4 days (days 0 to 3), resulted in a decrease of 84% ($p<0.01$, n=7) of the bone loss induced in the control group, injected with saline as placebo. The kaliotoxin group of rats also exhibited 74% lower levels of serum IgG2a antibody levels to Omp29 than the control group as determined by ELISA ($p<0.01$, n=7). Furthermore, the antigen-specific-stimulation index of T cells isolated from the spleens of kaliotoxin-treated animals was 65% lower than that of the control group ($p<0.01$, n=7). Taken together, these data suggest that selective blocking of Kv1.3 by kaliotoxin may decrease local T cell-mediated inflammatory bone resorption and therefore might be a novel therapeutic approach for intervention with periodontal disease and other inflammatory bone resorptive disorders.

F424

Zoledronic Acid Improves Short-Term Outcome in Traumatic Osteonecrosis in Young Wistar Rats. R. A. Peat*[1], A. McEvoy*[1], P. R. Williams*[1], P. A. Baldock[2], E. J. Smith[1], D. G. Little*[1]. [1]Orthopaedic Research Unit, Children's Hospital at Westmead, Sydney, NSW, Australia, [2]Garvan Institute of Medical Research, Sydney, NSW, Australia.

Currently there is no reliable medical therapy for the prevention of femoral head collapse and deformity in patients suffering from osteonecrosis. We hypothesized that the bisphophonate zoledronic acid could preserve femoral head structure while allowing revascularization and new bone formation. To model traumatic osteonecrosis, 24 female Wistar rats had the right femoral head dislocated, ligamentum teres divided, and femoral neck denuded of all soft tissue. Rats were randomized into 3 treatment groups: saline, zoledronic acid (0.1 mg/kg) at 1 and 4 weeks post-operation (post), and zoledronic acid (0.1 mg/kg) given 2 weeks pre-operation and 1 and 4 weeks post-operation (pre-post). Bone scintigraphy revealed revascularization at 6 weeks in all groups, with an observed increase in uptake on the operated side. Radiographs showed collapse of the femoral head in the saline group, with considerable preservation in both treated groups, such that femoral head size was increased 31% and 49% in post and pre-post groups, respectively ($P<0.01$), whereas only 13% and 0% of operated heads in treated groups were aspherical ($P<0.05$). DXA generated BMD was increased by 52% and 73% in the treated groups over saline, and BMC by 111% and 160% ($P<0.01$). Undecalcified histomorphometry showed preservation of femoral head architecture in treated groups, whereas the saline group had collapsed (Fig 1). There were increases of 14% and 20% in BV/TV in treated groups, as well as an increase in trabecular number of 22% and 16% ($P<0.05$). MAR was increased by 51% in the operated limb as compared to the non-operated limb of saline animals ($P<0.05$). MAR was similar in the operated femoral heads of saline and post animals, but reduced to the values of non-operative saline animals in the pre-post group. BFR increased in saline operated femoral heads over treated groups but this was not sufficient to prevent collapse. Zoledronic acid treatment prevented collapse of the femoral head following traumatic osteonecrosis in this rat model at 6 weeks. Pre-treatment with zoledronic acid provided protection from the avascular insult. These data indicate that by retaining femoral head architecture, revascularization can occur, preventing collapse.

F433

Parathyroid Gland Responsiveness to Hypo- and Hypercalcaemic Stimuli in Adult Growth Hormone Deficiency Before and During Growth Hormone Replacement. A. M. Ahmad*[1], J. Thomas*[1], H. White*[1], M. Hopkins*[1], B. Durham*[1], W. D. Fraser[2], J. P. Vora*[1]. [1]Diabetes & Endocrinology, Royal Liverpool University Hospital, Liverpool, United Kingdom, [2]Clinical Chemistry, Royal Liverpool University Hospital, Liverpool, United Kingdom.

Adult GH deficiency (AGHD) is associated with osteoporosis. Alterations in parathyroid gland responsiveness to changes in calcium concentration play a role in the genesis of osteoporosis. We investigated PTH response to hypo- and hypercalcaemic stimuli in AGHD. 12 patients with severe AGHD were hospitalised, prior to GH replacement (GHR), at 0800 h after an overnight fast. Venous cannulae were inserted in each arm and ½ hourly blood sampling commenced at 0900 h. After 5 basal samples, sodium EDTA infusion (50 mg/kg, in 500 ml 5% dextrose with 7 ml 2% lignocaine) was commenced at 1100 h for 2 h to induce hypocalcaemia in 6 patients (group 1). Hypercalcaemia was induced in 6 patients (group 2) by calcium gluconate (6 mg/kg in 500 ml of 5% dextrose) over 2 h. Sampling continued at ½ hourly intervals during the infusions up to 1800 h. PTH, calcium and albumin were measured on all samples. GHR was commenced after baseline visit. The protocol was repeated at 3/12 and 12/12 on GHR. The 5 basal samples (0900-1100 h) were averaged and showed a significant increase in adjusted-calcium (ACa) concentration (mmol/L) at 3/12 and 12/12 ($p<0.001$). PTH concentration (pmol/L) decreased significantly at 12/12 ($p<0.001$), compared to baseline in both groups. In group 1, maximum PTH stimulation occurred at an ACa concentration (percentage drop) of 1.79 (23.8%) at 0/12 . Following GHR, maximum PTH stimulation occurred at an ACa concentration of 1.92 (17.2%) at 3/12 and 2.16 (12.9%) at 12/12 ($p<0.05$). The maximum PTH response was a 365% rise before and 326% rise after 12/12 (p=ns). In group 2, maximum PTH suppression occurred at an ACa concentration (percentage rise) of 2.79 (18.9%) at 0/12 compared to 2.92 (16.7%) at 3/12 (p=ns) and 2.84 (14.7%) at 12/12 ($p<0.01$). The maximum PTH suppression was 75% before and 82% after 12/12 (p=ns). The calcium set point (the calcium concentration at which the rate of PTH secretion is one half of its maximal value) progressively increased from 2.08 ± 0.04 (SEM) at 0/12 to 2.20 ± 0.04 at 3/12 ($p<0.01$) and 2.35 ± 0.04 at 12/12 ($p<0.001$) in group 1, and increased from 2.39 ± 0.04 at 0/12 to 2.59 ± 0.04 at 3/12 ($p<0.05$) and 2.61 ± 0.04 at 12/12 ($p<0.001$) on GHR in group 2. These results suggest increased parathyroid gland sensitivity to significantly smaller changes in serum calcium following GHR. Together with the increase in calcium set-point this may explain the increase in basal calcium and decrease in PTH concentration. Our findings may help explain the genesis of osteoporosis in AGHD patients.

The PTH mRNA 3'-Untranslated Region (UTR) Calcium and Phosphate Responsive Element – Structure and Function. R. Kilav*, O. Bell*, J. Silver, T. Naveh-Many. Nephrology, Hadassah Hospital, Jerusalem, Israel.

Ca^{2+} and Pi regulate PTH gene expression post-transcriptionally by affecting PTH mRNA stability. This is due to binding of *trans* acting factors to a *cis* acting instability element in the 3'-UTR. In hypocalcemia there is increased binding to the element that protects the PTH mRNA from degradation by cytosolic ribonucleases resulting in higher levels of PTH mRNA In hypophosphatemia there is decreased binding, with a subsequent increased degradation of the PTH mRNA resulting in low levels of PTH mRNA. We have identified the sequence of a minimal protein-binding element and have now studied its functionality and structure. The cDNA coding for the 63 nt *cis* element of the PTH mRNA 3'-UTR was inserted into two reporter cDNAs, GFP and growth hormone (GH). The constructs were transiently transfected into HEK293 cells. mRNA levels were measured by Northern blot, and protein levels of GFP by immunofluorescence, and secreted GH by radioimmunoassay. There was a dramatic reduction in the expression of the chimeric genes containing the 63 nt, but not with a truncated PTH 40 nt element, compared to wt genes. The 63 nt transcript, like the full-length PTH RNA, bound PT proteins by REMSA, but the truncated element did not bind PT proteins. These results are consistent with the destabilizing effect of the *cis* element in the PTH mRNA. RNA utilizes sequence and structure for its regulatory functions. To study the structure of the *cis* element, we performed RNase H analysis, and computer modeling of the PTH mRNA. The secondary structure was substantiated by primer extension analysis using a PTH transcript that was partially cleaved by structure specific RNases and the resulting cDNAs analyzed on sequencing gels. Our results indicate that there is a defined loop-stem-loop structure in the 63 nt. This structure is preserved when the full-length PTH mRNA and smaller transcripts including the functional 63 element of the 3'-UTR were studied. This structure was disrupted in a transcript of the truncated element that was not functional in reporter RNAs and in PT protein binding. In addition, point mutations in the PTH element that disrupted structure did not bind cytosolic PT proteins in binding assays. The results demonstrate an important role of the defined structure of the *cis* element. In summary, we have demonstrated a functional instability *cis* element in the PTH mRNA 3'-UTR that also confers instability to reporter genes. The element has a defined structure that is important for its function. Protein-RNA interactions at the element determine PTH mRNA stability. Calcium and phosphate regulate mRNA levels by altering the binding of the *trans* acting parathyroid cytosolic proteins to the *cis* acting PTH mRNA 3'-UTR element.

F437

Role of Cyclooxygenase-2 in the Calvarial Response to Parathyroid Hormone. M. Xu*, G. A. Gronowicz, O. S. Voznesensky, L. G. Raisz, C. C. Pilbeam. Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Cyclooxygenase-2 (COX-2) is necessary for the maximal osteoclastogenic response to parathyroid hormone (PTH) in marrow stromal cell cultures. We injected PTH above the calvariae in 4 month old male COX-2 wild type (+/+) and knockout (-/-) mice to examine the role of COX-2 in osteoclastic responses in vivo. COX-2+/+ and -/- were bred for experiments by mating C57Bl/6x129 COX-2 heterozygote (+/-) mice. Mice were injected once daily for 14 days over one half of the calvaria with vehicle (7 COX-2+/+, 5 COX-2-/-) or with 30 μg/kg of rhPTH 1-34 (7 COX-2+/+, 6 COX-2-/-). Histomorphometric analyses were performed on the injected half of the calvaria. There were no differences in body weights between COX-2+/+ and COX-2-/- mice at the beginning or the end of the experimental protocol. Serum creatinine (Cr) and calcium were measured at time of sacrifice. Cr tended to be higher (although not statistically significantly different) in COX-2-/- mice relative to COX-2+/+ mice. Serum calcium was not elevated in any group at the end of treatment. Calvarial width was significantly increased ($P < 0.05$) in COX-2+/+ mice treated with PTH (212 ± 23 μm) relative to COX-2+/+ mice treated with vehicle (155 ± 9.5 μm). Bone marrow area was increased 18-fold ($P < 0.05$) in PTH-treated COX-2+/+ mice, reflecting a marked increase in porosity of the calvariae after PTH treatment. As a result, the percent bone area relative to total tissue area (TA/TTA) was decreased in COX-2+/+ mice from 98.0 ± 0.8% in vehicle-treated mice to 74.8 ± 9.1% in PTH-treated mice ($P < 0.05$). In COX-2-/- mice, PTH treatment did not increase calvarial width, bone marrow area or TA/TTA. Osteoclast number and osteoclast number per bone marrow perimeter were both significantly increased in PTH-treated COX-2+/+ mice: 17.0 ± 2.9 vs. 1.6 ± 0.9 ($P < 0.01$) and 26.0 ± 2.1 per mm vs. 1.0 ± 0.6 per mm ($P < 0.05$), respectively. Neither parameter was increased by PTH in COX-2-/- mice. We conclude that the absence of COX-2 expression results in resistance to PTH-stimulated resorption in calvariae *in vivo*.

F439

Effect of Low Calcium Diet on Calcium and Skeletal Homeostasis in PTH-Deficient Mice. X. K. Tong*, D. Miao, R. Huo*, A. C. Karaplis, D. Goltzman. Medicine, McGill University, Montreal, PQ, Canada.

We previously reported that targeted disruption of the PTH gene leads postnatally to abnormalities in skeletal development and calcium homeostasis. $PTH^{-/-}$ mice on normal (1.0%) calcium diet developed hypocalcemia, hyperphosphatemia and decreased serum 1,25-dihydroxy vitamin D_3 ($1,25(OH)_2D_3$) levels and exhibited increased trabecular and cortical bone volume compared to wild type littermates. To further investigate the regulation of calcium and skeletal homeostasis in the absence of PTH, 2-month-old PTH deficient mice and wild type littermates were fed either a normal (1.0%) or low calcium (0.005-0.01%) diet for 8 weeks. When placed on a low calcium diet, normocalcemia and hypocalcemia persisted in the wild type and $PTH^{-/-}$ mice, respectively, but serum phosphate rose from 17.9±1.4 to 20.2±1.6 mg/dl in the $PTH^{-/-}$ mice. Serum $1,25(OH)_2D_3$ levels increased from 120 to 587 pmol/L in wild type and from 51 to 305 p mol/L in $PTH^{-/-}$ mice during the transition from a normal to a low calcium diet. Low calcium intake caused marked decreases in trabecular bone volume in both wild type (56%) and $PTH^{-/-}$ (78%) mice. Only in $PTH^{-/-}$ mice, however, did a low calcium diet cause a marked decrease (44%) in cortical bone volume. On a normal calcium diet, the number of TRAP positive osteoclasts was decreased (28.5%) in $PTH^{-/-}$ mice compared to the wild type animals. However, when the animals were changed to a low calcium diet for 3 days, the number of osteoclasts was increased 2-fold in the wild type mice and 6-fold in the $PTH^{-/-}$ mice. These studies show that although $PTH^{-/-}$ mice on a normal calcium intake have hypocalcemia, low $1,25(OH)_2D_3$ levels, low bone turnover and elevated bone mass, on a low calcium intake, $1,25(OH)_2D_3$ increases, accelerates bone resorption and has a negative impact on trabecular and cortical bone. Consequently a low calcium diet can stimulate $1,25(OH)_2D_3$ production even in the absence of PTH.

F440

Monitoring the Skeletal Response to PTH by Analysis of Peripheral Leukocyte Gene Expression. T. E. Hefferan[1], Q. Rehman*[2], N. E. Lane[2], R. T. Turner[1]. [1]Orthopedic Research, Mayo Clinic, Rochester, MN, USA, [2]Rheumatology, University of California - San Francisco, San Francisco, CA, USA.

Rheumatic disease is often treated with low-dose glucocorticoids , which is a risk factor for bone loss and fractures. Presently, several therapies are used to reverse this bone loss, including antiresorptive agents, calcium and vitamin D supplementation. These therapies are able to suppress resorption, but are unable to stimulate bone formation. Parathyroid hormone (hPTH 1-34) has been shown to increase spine trabecular bone density in postmenopausal women undergoing low-dose glucocorticoid therapy. Current methods to evaluate safety and efficacy are highly invasive (histomorphometry), insensitive (densitometry), or nonspecific (conventional biochemical markers). Therefore we wanted to determine a method of monitoring bone changes that was less invasive. We hypothesized that RNA extracted from leukocytes could be analyzed by microarray to examine genes related to bone metabolism that were being regulated with hPTH treatment. To test this hypothesis, RNA was isolated from leukocytes of control subjects and subjects receiving hPTH, 400U subcutaneously per day. One microgram RNA was hybridized to a microarray filter from ResGen that contains approximately 4,000 named genes. The microarrays from the hPTH treated subjects were compared to the microarrays from the control subjects. Many genes involved with bone metabolism were detected in the RNA isolated from the leukocytes, including growth factors, cytokines, bone matrix proteins, and bone morphogenetic proteins (BMPs). Bone matrix proteins including, type I collagen,

alkaline phosphatase, and biglycan were upregulated with PTH treatment. TGF-beta, as well as selective BMPs, -2,-4,-6, were upregulated in leukocytes with PTH treatment. Interestingly, both IGF–I and IGF-II, as well as IGF-binding proteins (IGFBP) –1, -2, and –3 were detected in leukocyte RNA. The microarray analysis showed IGF-I, the most potent IGF in bone, and IGFBP-3 to be upregulated by PTH treatment. Similar gene changes were observed in RNA isolated from the proximal tibial metaphysis of rats treated with hPTH (1-34). Thus, the regulation by PTH of selected genes in leukocytes that are related to bone metabolism reflects a similar regulation seen in bone. Therefore, analysis of gene expression in leukocytes could be utilized as a less invasive technique to assess expression of bone-related genes during disease and treatment.

F442

Osteopontin-Deficiency Augments Parathyroid Hormone Activation of Bone Formation (BFR/MAR) and Mineralized Nodule Formation without Altering PTH Enhancement of Deoxypyridinoline Excretion, in Vitro Osteoclastogenesis and Osterix Gene Expression. K. Kitahara[1], M. Ishijima[1], S. R. Rittling[2], K. Tsuji[1], H. Kurosawa*[3], A. Nifuji[1], D. T. Denhardt[2], M. Noda[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Rutgers University, Piscataway, NJ, USA, [3]Juntendo University, Tokyo, Japan.

Treatment of osteoporosis patients at high risk requires not only inhibitors for bone resorption but also stimulators for bone formation. Intermittent parathyroid hormone (PTH) treatment enhances bone volume in osteoporosis patients and thus it is considered to be one of the promising treatments. However, underlying molecular mechanisms are largely unknown. Since PTH regulates expression of osteopontin (OPN) in osteoblasts, OPN could play a certain role in PTH actions in bone. We observed that OPN-deficiency enhanced PTH-dependent increase in bone mass based on micro-CT analyses of trabecular bone volume. To examine cellular and molecular basis for the OPN-deficiency effects on PTH-induced bone gain, we injected 80μg/kg PTH (1-34) daily for 5 days a week for 4 weeks into mice. PTH treatment increased mineral apposition rate (MAR) (by about 30%) as well as bone formation rate (BFR) (by about 30%) in wild type mice. In the OPN-deficient mice, basal levels of the two bone formation parameters were similar to those basal levels in wild type mice. However, OPN-deficiency significantly augmented PTH enhancement in MAR (by about 40%, $p<0.05$) and BFR (by about 100%, $p<0.05$). In vitro cell culture experiments using bone marrow cells obtained from PTH-treated mice indicated that OPN-deficiency clearly enhanced bone nodule formation (by 30%, $p<0.05$) while such augmentation was not significant in the bone marrow cell cultures taken from PTH treated wild type mice. PTH enhanced expression of osterix gene about 3-fold in the wild type long bone and a similar PTH effect on the expression levels of osterix m-RNA expression (3-fold) was observed in the long bone of OPN-deficient mice. In contrast to the OPN-deficiency enhancement of the PTH effects on bone formation parameters in vivo as well as in vitro, the levels of PTH-enhancement on the osteoclast number per area in vivo, TRAP positive cell development in culture, and excretion of deoxypyridinoline in urine were similar in wild type and OPN-deficient mice. These data indicated that OPN deficiency specifically augments the effect of PTH on bone formation in vivo as well as in vitro.

Genetic Rescue of Cardiac Defects in Mice Lacking the PTH/PTHrP Receptor. M. C. Colbert*[1], J. Qian*[2], W. D. Stuart*[2], D. Witte*[3], E. Gruenstein*[4], H. Osinska*[5], B. Lanske[6], H. M. Kronenberg[7], T. L. Clemens[2]. [1]Department of Pediatrics, Children's Hospital Medical Center, Cincinnati, OH, USA, [2]Department of Medicine, University of Cincinnati, Cincinnati, OH, USA, [3]Pathology, Children's Hospital Medical Center, Cincinnati, OH, USA, [4]Department of Molecular Genetics, University of Cincinnati, Cincinnati, OH, USA, [5]Division of Molecular Cardiovascular Biology, Children's Hospital Medical Center, Cincinnati, OH, USA, [6]Department of Oral Pathology, The Forsythe Institute and Harvard Dental School, Boston, MA, USA, [7]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

Parathyroid hormone-related protein (PTHrP) is a key developmental regulatory protein and a potent vasoactive agent. Previous studies have shown that mice lacking either the *Pthrp* or the PTH type 1 receptor (*Pth1r*) gene exhibit severe chondrodysplasia, but in most genetic backgrounds, the receptor null mice die prenatally at mid gestation. We have previously reported that a functional PTH1R is expressed throughout the developing wild type mouse heart at E11 and that mice lacking the *Pth1r* gene die abruptly with massive cardiomyocyte death at gestational day E12. In the present study we further investigated the mechanisms for the heart defects in the PTH1R null mice. Histological and ultrastructural analysis revealed precipitous cardiomyocyte death and striking mitochondrial abnormalities at E11.5 followed by degenerative changes in the liver and massive necrosis of other tissues 24 hr later. No abnormalities were observed in the yolk sac or placenta implicating heart degeneration as the primary cause of death. To further examine the cause of cardiomyocyte death, sections of wildtype and null hearts were examined at E11.5, E12, and E12.5 and processed for TUNEL and caspase 3 staining. Our results suggest that apoptotic rates were not significantly elevated in nulls over those observed in wild-type mice. In order to verify that the lack of the receptor caused cardiomyocyte death, we intercrossed the PTH1R knockout mice with mice carrying a smooth muscle alpha actin PTH1R transgene (SMP-8-PTH1R). These transgenics, which express the receptor in the heart by E9.5, had been backcrossed onto the C57BL/6 background for 9 generations. PTH1R transgenic mice carrying both null *PTH1R* alleles survived until birth with skeletal dysplasia and other phenotypic abnormalities indistinguishable from the PTHrP null mice. Taken together, these findings demonstrate that the PTH1R is required for the development of normal cardiomyocyte function.

Parathyroid Hormone-mediated Activation of MAPK Is Dependent upon NHERF2 in PS120 Cells. M. J. Mahon*[1], G. V. Segre[2]. [1]Endocine Unit, Massachusetts General Hospital, Boston, MA, USA, [2]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

The receptor for parathyroid hormone (PTH1R) binds to the Na+/H+-exchanger regulatory factor 2 (NHERF2) via a PDZ-domain-specific interaction in vitro, in glomerular extracts and when they are expressed in PS120 cells. The purpose of this research was to investigate the downstream actions of PTH1R when bound to NHERF2. NHERF2 contains two PDZ domains and a C-terminal region that interacts with ERM (ezrin, radixin, and moesin) actin-binding proteins. In vitro, PDZ1 and PDZ2 bind PLCbeta1 and PTH1R, respectively, to form a multiprotein complex. PTH treatment of PS120 cells that express both NHERF2 and PTH1R activate Gi/o protein(s) and thus inhibit adenylyl cyclase (AC) and markedly activate phospholipase C (PLC). Introduction of a M591A point mutation at the C-terminus of the PTH1R disrupts the NHERF2 interaction. PTH treatment of PS120 cells expressing NHERF2 and PTH1R, but not PTH1R(M591A), transiently activates extracellular regulated kinases (ERK) 1 and 2. Peak activation occurs after 5 minutes of PTH treatment as demonstrated by ERK1/2-mediated phosphorylation of myelin basic protein (MBP). Importantly, PTH treatment of PS120 cells expressing PTH1R(M591A) and NHERF2 fails to elicit a significant increase in ERK1/2 activation, indicating that signaling via the MAPK pathway is dependent upon the PTH1R-NHERF2 interaction. Neither AC/PKA nor PLC/PKC pathways, however, appear to be involved. Acute treatment of PS120 cells that express PTH1R and NHERF2 with forskolin (10 mM) fails to activate ERK1/2 and treatment with the PKA inhibitor, H89, fails to block the PTH-mediated activation of MAPK. These data suggest that PTH-mediated activation of MAPK is AC-independent. Whereas acute treatment of PS120 cells with phorbol esters (10 nM) activates ERK1/2, 24-hour treatment of PS120 cells with phorbol esters or an acute treatment with calphostin C, a PKC inhibitor, fail to block the PTH-mediated activation of ERK1/2, suggesting that PTH-induced MAPK is not dependent upon PKC activation. Furthermore, herbimycin A, a src-kinase inhibitor, genistein, a non-specific tyrosine kinase inhibitor and wortmannin, a PI-3 kinase inhibitor, fail to block PTH-mediated activation of MAPK. We conclude that PTH stimulation of the NHERF2-PTH1R complex activates the MAPK pathway by a novel mechanism(s).

F451

Arrestin Is Translocated by PTH but not Required for PTH1 Receptor Internalization. W. B. Sneddon*[1], A. Bisello[2], P. A. Friedman[1]. [1]Pharmacology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

Arrestins are adapter proteins that target activated G protein-coupled receptors (GPCRs) for endocytosis in clathrin-coated vesicles. Arrestin-dependent endocytosis of GPCRs has been implicated in receptor desensitization, downregulation, and recycling. The type I PTH receptor (PTH1R) is a class B GPCR that desensitizes and internalizes in response to ligand binding. In distal tubules (DT), the nephron site of PTH's calcium sparing action, both the agonist PTH(1-34) and the antagonist PTH(7-34) stimulate PTH1R endocytosis. In contrast, PTH(1-34), but not PTH(7-34), desensitizes the PTH1R in DT cells. PTH(1-34)-induced PTH1R internalization has an associated latency of 10 min, whereas PTH(7-34) internalizes the PTH1R promptly and 50% more extensively. This suggests that the two ligands employ different mechanisms of PTH1R internalization in DT cells. Ligand activated PTH1R internalization and arrestin3 movement were examined in DT cells by real-time confocal fluorescence microscopy. PTH(1-34) induced clustering and endocytosis of a green fluorescent protein (GFP)-tagged PTH1R. Internalization was not inhibited by a dominant negative (319-418) arrestin2, which competitively blocks arrestin's interaction with clathrin. However, this dominant negative arrestin blocked endocytosis of the same PTH1R in HEK293 cells. Internalization of the ß-adrenergic receptor by isoproterenol in DT cells was abolished by the dominant negative arrestin. In normal DT cells co-transfected with the wild-type human PTH1R and an arrestin3-GFP fusion protein, PTH(1-34) mobilized arrestin3 to the plasma membrane within 5 min. Clusters of arrestin3-GFP appeared in the cytoplasm after 15 min. In contrast, PTH(7-34) did not induce arrestin3 mobilization. Co-expression of PTH1R-GFP and an arrestin3-DsRed fusion protein indicated that the PTH1R and arrestin3 traffic together in response to PTH(1-34) but not PTH(7-34). Clathrin depolymerization prevented PTH1R internalization in response to both PTH(1-34) and PTH(7-34). We conclude that the interaction and trafficking of the PTH1R and arrestin3 is opportunistic but not required for PTH1R endocytosis in clathrin-coated vesicles. This interaction may, however, be required for PTH1R desensitization. The differential ability of different PTH peptides to desensitize and internalize the PTH1R underscores the presence of structural determinants within the PTH peptide that direct these processes. Carboxy-terminal PTH fragments that accumulate in renal insufficiency may contribute to PTH resistance through arrestin-independent PTH1R internalization.

F452

PTH Receptor Desensitization Accompanies Receptor Activation and not Internalization. W. B. Sneddon*[1], A. Bisello[2], P. A. Friedman[1]. [1]Pharmacology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

The physiological activity of G protein-coupled receptors (GPCRs) is a function of the balance between signal activation and termination. Receptor desensitization and downregulation are two mechanisms that terminate GPCR action. The parathyroid hormone type 1 receptor (PTH1R), a class B GPCR, is activated by the agonists PTH(1-34) and PTH(1-31), but not by the antagonist PTH(7-34). In contrast to their differential effects on receptor activation, both PTH(1-34) and PTH(7-34) internalize the PTH1R by 50% and 80%, respectively, after 15 min in mouse distal tubule (DT) cells, the site of the calcium sparing action of PTH. PTH(1-31), which stimulates cAMP, does not internalize the PTH1R. The present experiments were directed at determining if the separation of PTH1R activation and internalization was associated with a concomitant dissociation of PTH1R desensitization. Mouse DT cells stably expressing the PTH1R fused to enhanced green fluorescent protein (PTH1R-EGFP) were pre-treated with PTH(1-34), 7-34, 1-31, or vehicle at 37C. Cells were rinsed with ice-cold PBS, acid washed, and rinsed again with ice-cold PBS. The cells were loaded with ^{3}H-adenine at 4C and then challenged for 15 min at 37C with PTH(1-34) in the presence of IBMX. cAMP accumulation was measured after the second peptide treatment. Pre-treatment with PTH(1-34) or PTH(1-31) reduced subsequent PTH(1-34)-stimulated cAMP formation by 35% and 30%, respectively. In contrast, PTH(7-34), which robustly internalized the PTH1R did not desensitize the PTH1R. The inverse relation between receptor activation (RA) versus endocytosis (VE) of PTH peptides was analyzed. RA and VE were normalized to the effects of PTH(1-34), which has a value of 1. PTH(1-31) and PTH(7-34) have RAVE values of 6.6 and 0.02, respectively. We conclude that PTH1R desensitization follows the pattern of receptor activation but not the profile of endocytosis, and occurs with peptides having RAVEs >1. Therefore, PTH1R desensitization and internalization proceed by different mechanisms. Both phenomena employ similar structural determinants within the C-terminus of the PTH1R. However, uncoupling of the PTH1R from its cognate G protein may desensitize the PTH1R without necessarily targeting the receptor for internalization.

F456

A Novel Mutation in Helix 12 of the VDR Impairs Coactivator Interaction and Causes Hereditary 1,25-Dihydroxyvitamin D-Resistant Rickets Without Alopecia. P. J. Malloy*[1], R. Xu*[1], L. Peng*[1], P. A. Clark*[2], D. Feldman[1]. [1]Department of Medicine, Stanford University, Stanford, CA, USA, [2]Department of Pediatrics, University of Louisville, Louisville, KY, USA.

Hereditary vitamin D resistant rickets (HVDRR) is a genetic disorder most often caused by mutations in the vitamin D receptor (VDR). The patient in this study exhibited the typical clinical features of HVDRR with early onset rickets, hypocalcemia, secondary hyperparathyroidism, and elevated serum concentrations of alkaline phosphatase and 1,25-dihydroxyvitamin D, [1,25(OH)2D3]. Interestingly, the patient did not have alopecia. Assays of the VDR showed normal high affinity low capacity binding for [3H]1,25(OH)2D3 in extracts from the patient's fibroblasts. However, the cells were resistant to 1,25-dihydroxyvitamin D action as demonstrated by the failure of the patient's cultured fibroblasts to induce the 24-hydroxylase gene when treated with either high doses of 1,25(OH)2D3 or vitamin D analogs. This finding is unique since all other reported cases with complete resistance to 1,25(OH)2D3 action have had alopecia. A novel point mutation was identified in helix 12 in the ligand-binding domain of the VDR that changed a highly conserved glutamic acid at amino acid 420 to lysine (E420K). The patient was homozygous for the mutation. The E420K mutant receptor recreated by site-directed mutagenesis exhibited many normal properties including ligand binding, dimerization with the retinoid X receptor (RXR) and binding to vitamin D response elements (VDREs). However, the mutant VDR was unable to elicit 1,25(OH)2D3-dependent transactivation. Subsequent studies demonstrated that the mutant VDR had a marked impairment in binding the coactivators SRC-1 and DRIP205. Taken together, our data indicate that the mutation in helix 12 alters the coactivator binding site preventing coactivator binding and transactivation. In conclusion, we have identified the first case of a naturally occurring mutation in the VDR (E420K) that disrupts coactivator binding to the VDR and causes HVDRR.

F458

Enhanced Transactivation Activity of Vitamin D Receptor B1 Associated with Focal Nuclear Accumulation and Cofactor Binding. J. L. Flanagan*, K. L. Sunn*, G. M. Leong, C. Fong*, A. P. Kouzmenko*, J. A. Eisman, E. M. Gardiner. Bone and Mineral, Garvan Institute of Medical Research, Sydney, Australia.

Biological responses to 1,25 dihydroxyvitamin D3 are mediated by the vitamin D receptor (VDR), of which there are two protein isoforms. The A/B region of the recently identified VDRB1 isoform is extended at the N-terminus by 50 amino acids producing a 73 amino acid A/B region, compared with the 23 amino acids of the conventional VDRA receptor. As A/B regions of nuclear receptors often contain ligand-independent activation function (AF-1) domains, the functional properties of this region of VDRB1 might differ from those of VDRA. The VDRB1 isoform exhibited greater (144% ± 17%) transactivation of a rat 1,25-dihydroxvitamin D-24-hydroxylase reporter construct than VDRA in transiently transfected COS-1 cells 6 hr post treatment with 10nM 1,25-dihydroxyvitamin D3. This difference was not apparent at 16 hr post treatment. Evidence for AF-1 activity in the VDRB1 N-terminal A/B region was observed in yeast and mammalian one-hybrid experiments. The VDRB1 A/B region exhibited strong AF-1 activity (8-fold ligand-independent activation), compared to the VDRA A/B region (3-fold activation). Similarly, there was stronger interaction between the A/B region of VDRB1 and the VDR ligand binding domain (LBD) in mammalian two-hybrid and GST pull-down assays (3-fold in the presence of ligand, whereas interaction between the VDRA A/B domain and the LBD was weak. Introduction of an E420Q mutation into the LBD, which inactivates C-terminal ligand-dependent transactivation (AF-2) activity by abolishing recruitment of coactivators, markedly reduced but did not abolish ligand-dependent interaction with the VDRB1 A/B domain. This suggests that, as well as cofactor mediated interaction between the VDRB1 A/B domain and the LBD, there may be a direct AF-1/AF-2 interaction. In the absence of ligand, GFP-tagged VDRB1 accumulated in discrete nuclear foci whereas VDRA exhibited a diffuse nuclear signal. VDRB1 foci were not observed with the E420Q mutation, suggesting that speckle formation may be mediated at least in part by A/B domain-LBD interaction or by cofactor recruitment in the absence of ligand. Ligand-independent interaction of p160 co-activator proteins with full-length wildtype VDRB1, but not with the E420Q mutant VDRB1 or wildtype VDRA in GST-pull-down assays, supports the latter concept. Thus, accumulation of VDRB1 in nuclear foci may relate to its differential binding to transcriptional co-activators in the absence of ligand and the physical association of cofactors in the absence of ligand may allow for a more rapid response to ligand leading to the more effective transactivation observed.

F460

Persistent Reduction in Bone Resorption Despite Prolonged Dietary Calcium Restriction in Transgenic Mice with Elevated Osteoblastic Vitamin D Receptor. P. A. Baldock*, J. A. Eisman, G. P. Thomas, E. M. Gardiner. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

1,25-Dihydroxyvitamin D3 stimulates both osteoblast and osteoclast activity. In order to amplify its osteoblastic actions, vitamin D receptor (VDR) levels were elevated exclusively in mature cells of the osteoblastic lineage in a transgenic mouse model (OSVDR). As previously reported, bone loss after 1 month of calcium restriction was reduced in OSVDR mice. These observations have now been extended to examine the long-term kinetics of this protective effect. Three month old OSVDR and wild type (FVB/N) mice were divided into 2 dietary groups consuming semi-synthetic High Ca (1% Ca) and Low Ca (0.1%) diets. Groups were collected at baseline (3 months old) and after 1 and 3 months of calcium restriction (4 and 6 months old). The 4th caudal vertebrae were analysed for trabecular architecture and turnover. Cancellous bone volume was greater in OSVDR than FVB/N across the study ($P<0.0001$). This difference (OSVDR vs FVB/N) was evident in High Ca fed groups at both 4 months (27.1 ±1.5% vs 21.5± 2.3%; $p<0.05$) and 6 months (21.1 ±0.9% vs 16.9 ±1.0%; $p<0.05$). In Low Ca groups, OSVDR was greater at 4 months (24.9 ±1.6% vs 17.5 ±1.5%; $p<0.05$) but had returned to FVB/N levels at 6 months (17.6 ±1.7% vs 16.6 ±1.4%). Trabecular thickness changes paralleled those of bone volume. Trabecular number was not different between genetic groups. The decline of OSVDR bone volume to FVB/N levels in the Low Ca group at 6 months was not the result of bone resorption. Osteoclast surface was significantly reduced in OSVDR across the study ($P<0.005$), but this was significant only in the Low Ca groups: 4 months (8.6 ±1.1% vs 13.3 ±0.6%; $p<0.05$) and 6 months (12.8 ±1.8% vs 19.7 ±2.3%; $p<0.01$). The decline in bone volume in the older Low Ca OSVDR group was, however, consistent with changes in bone formation. Bone formation rate was initially higher in OSVDR at 3 months (0.19 ±0.02 um2/um/d vs 0.12 ±0.02 um2/um/d; $p<0.05$) but was reduced in the 6 month groups to be lower than FVB/N ($p<0.005$) on both High Ca (0.09±0.01 vs 0.69±0.01) and Low Ca (0.21±0.01 vs 0.95±0.04) diets. These data suggest that elevation of VDR protein in mature osteoblastic cells results in a permanent reduction in bone resorption that persists despite extended calcium restriction. Furthermore, reduction in bone formation can contribute significantly to net bone loss during calcium restriction.

F463

Functional Characterization of the Intracellular Estradiol Binding Protein in Estrogen Resistant New World Primates. H. Chen[1], B. Hu*[2], M. Sharma*[3], Z. Sun*[3], J. S. Adams[1]. [1]Endocrinology/ Medicine, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA, USA, [2]Pathology, Cears-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA, USA, [3]Surgery and Molecular Pharmacology, Stanford University School of Medicine, Stanford, CA, USA.

New World primates (NWP) exhibit a compensated form of resistance to gonadal steroid hormones. We recently demonstrated that estrogen resistance in NWP cells was associated with the overexpression of two proteins, one a non-receptor–related, dominant-negative acting-estrogen response element binding protein (ERE-BP) and the other an intracellular estradiol binding protein (IEBP). In order to study the function of IEBP, a 17ß-estradiol (E2) affinity column was used to purify IEBP from the estrogen-resistant NWP cell line, B95-8. N-terminal sequence analysis of tryptic peptides from E2-affinity-purified protein disclosed IEBP to be in the hsp27 family. The full-length cDNA of IEBP was successfully cloned and demonstrated 81% nucleotide homology with human hsp27. When hormone-responsive, wild type Old World primate (OWP) cells were transiently transfected with IEBP cDNA, E2-directed estrogen response element (ERE) reporter luciferase activity was reduced 50% compared to vector alone-transfected OWP cells. When IEBP and ERE-BP were co-transfected, the ERE luciferase reporter activity was further reduced by 60%. Gel shift analysis showed that IEBP neither bound to ERE nor competed with the estrogen receptor (ER) for binding to ERE. However, there was evidence of protein-protein interaction of IEBP and ER alpha; IEBP was coimmunoprecipitated with anti-ER alpha antibody in wild type cells stably transfected with IEBP. Specific interaction between the ER alpha and IEBP was confirmed in GST-pull down assays. Extracts from estrogen–responsive wild type and IEBP-overexpressing cells were incubated with a panel of GST-hormone receptor ligand binding domain fusion proteins representing the ER alpha, VDR

and GR. The GST-ER alpha fusion protein only reacted specifically with the hsp27-related IEBP but not with hsp70 or hsp90. The interaction of ER alpha and hsp27 in IEBP-overexpressing cells was 2-fold greater than in wild type cells. In summary, we have cloned and purified an intracellular estradiol binding protein (IEBP). IEBP is an hsp27-related protein which binds to the ligand domain of the ER alpha and acts to squelch ER alpha-directed ERE transactivation. We conclude that IEBP may collaborate with ERE-BP to cause estrogen resistance.

F465

Estrogen Receptor-β Reduces Estrogen Receptor-α Regulated Gene Transcription in Mice. C. Ohlsson[1], M. K. Lindberg*[1], S. Movérare[1], S. Skrtic*[1], H. Gao*[2], K. Dahlman-Wright*[2], J. Å. Gustafsson*[2]. [1]Div. Endocrinology, Dept. Internal Medicine, Gothenburg, Sweden, [2]Dept. Medical Nutrition and Dept. BioScience, Karolinska Institute, Novum, Huddinge, Sweden.

Estrogen is of importance for the regulation of adult bone metabolism. The aim of the present study was to determine the role of estrogen receptor-β (ERβ) *in vivo* on global estrogen-regulated transcriptional activity in bone. The effect of estrogen in bone of ovariectomized (ovx) mice was determined using microarray analysis including 9400 genes. Most of the genes (89%=289 genes) that were increased by estrogen in wild type (WT) mice were also increased by estrogen in ERβ inactivated ($ER\beta^{-/-}$) mice. The relative magnitude of the effect of estrogen in WT and $ER\beta^{-/-}$ mice was compared for these genes. Interestingly, the average stimulatory effect of estrogen on the mRNA levels of these genes was 82% ($p<0.0001$) higher in $ER\beta^{-/-}$ (472±25% over vehicle) than in WT (260±12% over vehicle) mice, clearly demonstrating that ERβ reduces ERα regulated gene transcription in bone. A similar inhibitory role of ERβ on ERα regulated gene transcription was also seen in liver ($p<0.0001$). The average stimulatory effect of estrogen on estrogen-regulated bone genes in ERα inactivated mice ($ER\alpha^{-/-}$; 169±9% over vehicle) was intermediate between that seen in WT (260±12% over vehicle) and ERαβ double inactivated mice ($ER\alpha^{-/-}\beta^{-/-}$; -7±3% over vehicle), demonstrating that ERβ, in the absence of ERα, is partially able to mediate the effect of estrogen on gene transcription. Thus, ERβ inhibits ERα mediated gene transcription in the presence of ERα, while, in the absence of ERα, it can partially replace ERα. In conclusion, our *in vivo* data indicate that an important physiological role of ERβ is to modulate ERα mediated gene transcription and we propose that ERβ may act as a transdominant repressor of ERα activity in mice.

F468

Real-time Non-Invasive *In vivo* Imaging of Estrogen Receptor Activity in Transgenic Mice. P. Ciana*[1], C. Lowik[2], E. Vegeto*[1], A. Brusadelli*[1], S. Belcredito*[1], I. Que*[2], A. Maggi*[1]. [1]Dept. of Pharmacological Sciences, Center MPL, Milan, Italy, [2]Endocrinology, LUMC, Leiden, Netherlands.

Estrogens exert complex physiological functions extending far beyond the control of reproductive functions. Several reports point to a beneficial role of estrogens with respect to diseases related to bone, mental and cardiovascular systems. Thus an increased understanding of the modalities of estrogen action and estrogen receptor (ER) activation in different tissues, might have relevant implications also from the therapeutic point of view. To date this has been hampered by the lack of suitable model systems. We recently generated transgenic mice expressing a ER reporter gene ubiquitously for direct evaluation of ER state of activation in physiological conditions as well as after treatments with compounds active through ERs. Preliminary results, showed that the luciferase reporter gene is expressed in all the tissues taken under consideration and is significantly induced by ER agonist only in tissues expressing ERs. Pharmacological studies carried out in male and female mice show that in the estrogen target organs the transcriptional activation of ER is regulated by estrogens in a dose- and time-dependent manner. In addition, the ER antagonists ICI 182,780 and Tamoxifen block estradiol action and have partial agonist functions in selected tissues. By the use of a CCD camera we here show that the activity of luciferase can be directly measured in living animals. The CCD camera was mounted on a light-tight specimen box and the bioluminescence emission from the anesthetized transgenic mice previously injected with luciferine was acquired and analyzed by the aid of specialized software. The *in vivo* analysis was initially carried out in adult cycling mice. We show that at at proestrus, when circulating estrogens are highest, lucifease activity is maximal in mammary gland, uterus, ovaries and liver, but not in bone, brain and intestine where luciferase peaks three days later at diestrus. In the absence of detectable levels of circulating estrogens like in ovariectomized and two-week old mice we document that estrogen receptor is transcriptionally active. Theses results demonstrate that the levels of circulating estradiol are not predictive of the state of estrogen receptor activity in each target. This is not the case with exogenous administration of estradiol to ovariectomized mice which induces a synchronous increase of luciferase activity in all the organs tested. The results of the present study underline a so far unsought complexity in the regulation of estrogen receptor activity partly independent from estradiol blood levels and which is not reproduced in hormone replacement therapy.

F473

Tumor Suppressor Smad4/DPC4 as a Differentially Ligand-Regulated Estrogen Receptor Corepressor. L. Wu*[1], S. Bai[1], X. Li*[1], Z. Liu*[1], B. Gathings*[2], C. Lu*[1], X. Cao*[1]. [1]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]University of Alabama at Huntsville, Birmingham, AL, USA.

Estrogens regulate differentiation and maintenance of reproductive, skeletal, cardiovascular and neural tissues by activating their estrogen receptors (ER). Antiestrogen compounds exhibit a variety of different effects in different tissues, and are widely used for the treatment of osteoporosis, breast cancer and other diseases. Tamoxifen is an ER antagonist in breast tissue but an ER agonist in bone and uterine tissue. Raloxifene is also an ER antagonist in breast tissue and agonist for bone yet without estrogenic effect in uterine tissue. To examine their molecular mechanisms, we have identified that Smad4, a common signal transducer in BMP/TGF-β signaling pathway, functions as a transcription corepressor for human ERα. Smad4 plasmid was cotransfected with human ERα and estrogen response reporter plasmids in MCF-7 cells. Ectopic expression of Smad4 inhibited both estrogen and antiestrogen induced luciferase activity dose-dependently. In comparison with ERα, Smad4 only partially inhibited estrogen induced luciferase activity when human ERβ was coexpressed with Smad4 and the reporter plasmids, and it did not affect antiestrogen-mediated transcription inhibition like in ERα signaling. Yeast two-hybrid assay demonstrated the interaction between Smad4 and ERα. Furthermore, immunoprecipitation showed that endogenous ERα was co-immunoprecipitated with Smad4 and the interaction was only induced by antiestrogen ligands, not by β-estradiol. In addition, Smad4 and ERα formed a complex in gel-shift assays. The complex was further confirmed by super shifts with antibodies against Smad4 or ERα, respectively. As expected, Smad4 was demonstrated to interact with HDAC-3. By using TUNEL assay, we detected that retrovirus-mediated Smad4 expression enhanced antiestrogen-mediated apoptosis of MCF-7 cells. In a similar experiment, Smad4 enhanced antiestrogen-induced cell growth arrest. In summary, we found Smad4 functioned as a human ERα transcription repressor, and Smad4 repression activity was differentially regulated by antiestrogens. Thus, TGF-β may regulate breast cancer cell fate through Smad4-mediated cross-talk with estrogen signaling.

F478

Characterization of Glucorticoid Receptor (GR) Function in Osteoblast Differentiation using GR Deficient Mice. J. P. Tuckermann, B. Stride*, F. Tronche*, M. Kirilov*, G. Schütz*. Division of Molecular Biology of the Cell I, German Cancer Research Centre (DKFZ), Heidelberg, Germany.

An excess of glucocorticoids (GC) leads to net bone loss (osteoporosis) which is a major problem in therapeutic applications of GC. GC exert their effects by binding to the glucocorticoid receptor (GR) which in turn, causes positive or negative regulation of gene expression by binding to GC responsible elements (GRE) in the promoter region of target genes or by interacting with and thus interfering with other transcription factors such as AP-1 and NFkB. In addition GC have also been shown to act via non genomic effects interfering with signal transduction pathways. The role of the GR during differentiation of osteoblasts is at present unknown. Therefore, we analyzed the proliferation and differentiation capacity of primary calvarial osteoblasts derived from mice with abrogated glucocorticoid receptor by gene targeting (GRnull). The synthetic glucocorticoid dexamethasone inhibits the past confluency growth of calvarial osteoblastic cells. This inhibition is abolished in GRnull cells. The differentiation of GR deficient osteoblasts is accelerated in the presence of dexamethasone. The number of alkaline phosphatase positive cells are increased after one week of differentiation in GRnull cultures which results in an earlier onset of mineralized nodule formation. These results demonstrate that the GR is essential for mediating the inhibitory effects of GC in osteoblastic cell differentiation. In order to determine the mechanism by which the GR regulates osteoblastic differentiation we are currently extending our analysis to calvarial osteoblasts derived from GRdim mice. These mice carry a DNA binding defective GR, which is not able to activate GRE regulated gene expression. However, the mutated receptor is still able to interact with AP1 and NFkB to regulate gene expression. Finally, in order to more specifically address the role of GR in osteoblast function we are currently generating mice with an osteoblast specific deletion of the GR using the cre-lox P system. The precize characterization of these mice GR will allow an extended understanding of glucocorticoid induced osteoporosis on the molecular level.

Serum 25 Hydroxyvitamin D Level Required to Minimise Bone Resorption in Postmenopausal Women. A. G. Need[1], P. D. O'Loughlin*[2], D. R. Jesudason*[3], B. E. C. Nordin*[4]. [1]Clinical Biochemistry, Institute of Med and Vet Science, Adelaide, Australia, [2]Clinical Biochemistry, Institute of Medical and Veterinary Science, Adelaide, Australia, [3]Clinical Biochemistry, Instituite of Medical and Veterinary Science, Adelaide, Australia, [4]Institute of Medical and Veterinary Science, Adelaide, Australia.

We have previously reported that serum parathyroid hormone (PTH) is increased in postmenopausal women with serum 25 hydroxyvitamin D (25(OH)D) below 40 nmol/L and that serum PTH becomes critical for maintenance of serum 1,25 dihydroxyvitamin D at these low levels [1]. Elderly patients with vitamin D insufficiency have elevated levels of PTH (which normalise when vitamin D is given), as well as a raised serum alkaline phosphatase (ALP) [2] and increased urinary excretion of c-termninal telopeptide [3] suggesting an increase in bone resorption. There is, however, controversy over the level of 25(OH)D necessary for bone health. We have therefore examined the relationships between serum 25(OH)D, serum ionised calcium, PTH, the formation marker ALP and resorption markers fasting urinary hydroxyproline, pyridinoline and deoxypyridinoline, corrected for creatinine (OHPr/Cr, PYD/CR and DPD/CR) in 486 postmenopausal women of mean age 63 (SD9.5) years attending our osteoporosis and menopause clinics. PTH, OHPr/CR, PYD/CR and ALP were inversely related to serum 25(OH)D. PTH was inversely related to serum ionised calcium. When the patients were divided into two groups with 25(OH)D above or below 20, 30, 40, 50, 60 or 70 nmol/L, we found the most significant differences between groups for all markers at a serum 25(OH)D of 60 nmol/L ($P<0.001$ for all). The most significant difference between groups for serum PTH was found when the patients were divided at a serum 25(OH)D of 50 nmol/L. When the patients with and without vertebral fractures were studied separately, a cut-off of 60 nmol/L of 25(OH)D was again found to give the most significant difference in both groups for all measures of bone turnover. We conclude that rises in PTH, three bone resorption markers and ALP can be detected in postmenopausal women when the serum 25(OH)D level falls below 60 nmol/L. Levels above this may be required for optimal bone health.

Identification of Oncogenic Nucleoporin CAN/Nup214 as a Regulator of Vitamin D Receptor -Mediated Transcription. Y. Miyauchi*[1], T. Michigami[1], K. Ozono[2]. [1]Department of Environmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan, [2]Department of Pediatrics, Osaka University Graduate School of Medicine, Osaka, Japan.

Vitamin D receptor (VDR) is one of the ligand-dependent transcription factors and must be localized in nuclei to exert its function. We have previously shown that VDR is located predominantly in nuclei even in the absence of ligand, and that the presence of ligand induces the accumulation of more VDRs in nuclei. In the present study, in an attempt to explore the molecules that can interact with VDR and modulate its function, we screened human kidney cDNA library by yeast two-hybrid system, and have found that VDR can bind to the C-terminal region of an oncogenic nucleoporin, CAN/Nup214. CAN/Nup214 was originally identified through its involvement in two types of acute myeloid or undifferentiated leukemia, and is a component of nuclear pore complex (NPC) that mediates the bidirectional traffic of macromolecules across the nuclear envelope. The binding of VDR with the C-terminal region of CAN/Nup214 was further confirmed by co-immunoprecipitation experiments in mammalian cells. In the region, CAN/Nup214 possess a FG repeat motif, which has been reported to play important roles in the nucleocytoplasmic traffic. We then examined the effect of overexpression of the FG repeat region of CAN/Nup214 on the 24-hydroxylase-gene promoter activity in osteoblastic SaOS-2 cells that possess the endogenous VDR. Treatment with 1,25(OH)2D3 increased the 24-hydroxylase-gene promoter activity, and the overexpression of the FG repeat region of CAN/Nup214 suppressed the 1,25(OH)2D3-induced transactivation in a dose-dependent manner. Similar results were obtained when COS7 cells were utilized with the exogenously expressed VDR. These results suggest that CAN/Nup214 regulate the VDR-mediated gene transcription probably by modulating the nuclear transport of VDR. It is reported that overexpression of CAN/Nup214 induces growth arrest in monocytic cell line U937, and 1,25(OH)2D3 is known as an inducer of differentiation in the cells of macrophage-monocyte lineage. Interaction between VDR and CAN/Nup214 might be involved in 1,25(OH)2D3-induced monocytic differentiation.

F488

Liganded VDR Induces CYP3A4 via DR3 and ER6 VDREs: A Potential Mechanism for Vitamin D-mediated Cellular Detoxification. P. W. Jurutka, P. D. Thompson, G. K. Whitfield, S. M. Myskowski*, K. R. Eichhorst*, C. Encinas Dominguez*, C. A. Haussler*, M. R. Haussler. Biochemistry and Molecular Biophysics, University of Arizona College of Medicine, Tucson, AZ, USA.

The nuclear vitamin D receptor (VDR) mediates the effects of 1,25-dihydroxyvitamin D_3 ($1,25D_3$) to alter gene transcription and achieve bone mineral homeostasis. Additionally, extraosseous actions of $1,25D_3$ are observed in several epithelial cell types, as well as in the immune and central nervous systems. $1,25D_3$ also triggers vitamin D catabolism through induction of 25-hydroxyvitamin D_3 24-hydroxylase (24-OHase), a cytochrome P450-containing (CYP) enzyme encoded by a gene possessing two (proximal and distal) vitamin D responsive elements (VDREs). In the present study, we examined the efficacy of $1,25D_3$ to induce other CYP enzymes. The human CYP3A subfamily consists of four homologous proteins (CYP3A4, -3A5, -3A7 and -3A43) that are collectively expressed in many tissues, including the gastrointestinal tract, liver, kidney and prostate. Exposure of human colorectal adenocarcinoma cells (HT-29) to 10^{-8} M $1,25D_3$ resulted in a 3-fold induction of CYP3A4 mRNA as assessed by quantitative RT-PCR. The effect was specific for VDR since treatment with dexamethasone (a GR and PXR agonist), that normally upregulates CYP3A4 in liver, did not affect expression in HT-29 cells. Examination of HT-29 cell extracts by Western blotting with anti-CYP3A4 mAb confirmed a stimulatory action of $1,25D_3$ at the protein level. Analysis of the promoter region of human CYP3A4 (10.5 kb) revealed the presence of six VDRE-like sequences that were then tested in hormone-dependent gel mobility shift assays using purified human VDR and RXRα along with HT-29 cellular extracts. Each VDRE was also examined for its ability to drive the transcription of a reporter gene in response to 10^{-8} M $1,25D_3$ in HT-29 and Intestine 407 cells. These experiments identified two candidate VDREs that support both significant $1,25D_3$-dependent VDR/RXR binding and marked stimulation of reporter gene expression. The first VDRE is a canonical DR3-type element located in the distal region of the promoter (-7719-GGGTCA gca AGTTCA-7733), and the second is a more proximal, non-classical everted repeat with a spacer of 6 bases (ER6; -169-TGAACT caaagg AGGTCA-152). A similar analysis of the rat CYP3A23 (the kidney-expressed homolog of human CYP3A5) promoter led to the identification of an active DR3-type VDRE (-120-AGTTCA tga AGTTCA-134). These data suggest that $1,25D_3$-dependent, VDR-mediated induction of CYP enzymes may be an important mechanism not only in vitamin D catabolism via upregulation of 24-OHase, but also of more general significance in the cellular detoxification of xenobiotics.

Changes in Bone Geometry and Body Composition during Adolescence: The Penn State Young Women's Health Study. T. L. Oreskovic*[1], K. Uusi-Rasi*[1], M. A. Petit[2], C. Bentley*[2], M. Tulchinsky*[3], T. J. Beck[1], T. Lloyd[2]. [1]Department of Radiology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, [2]Department of Health Evaluation Sciences, Penn State University, College of Medicine, Hershey, PA, USA, [3]Department of Radiology, Penn State University, College of Medicine, Hershey, PA, USA.

Skeletal bone mass is known to accumulate during growth and reaches a peak in early adulthood. Whether this accumulation of mass corresponds to an increase in mechanical strength has not been established and was the objective of this study. Longitudinal hip scans acquired on a Hologic QDR2000 DXA in the Penn State Young Women's health study were analyzed using the Hip Structure Analysis (HSA) program. The program analyzes narrow regions traversing the femoral neck and proximal shaft to derive BMD, cross-sectional area (CSA), subperiosteal width (W) section modulus (Z) and estimated mean cortical thickness (CT). Changes in BMD and bone structural variables from 16.5y (range 16-17y) to 21.5y (range 21-22y) were compared in 56 participants at the neck and 53 at the shaft (reduced due to shaft cut-off on 3 images). Body composition (lean and fat mass) was taken from DXA total body scans. Paired t-tests were used to assess change in body composition, BMD and bone structural variables over 5 years. On average, weight, total fat mass, total body bone mass (tbBMC) increased from ages 17 to 22, while total lean mass declined ($p < 0.001$). BMD increased at the shaft but remained unchanged at the neck. CSA, W and Z increased ($p < 0.03$) but CT remained unchanged at both regions. After adjusting for change in lean and fat masses, BMD and CT changes were non significant at both regions, but Z, CSA and width all increased significantly ($p< 0.03$). Over the late adolescent period, proximal femur BMD remained unchanged in these young, healthy Caucasian women. The lack of change in BMD was due to an increase in the amount of bone (CSA) as well as in its size, because these changes have opposing effects on BMD. The increases in CSA and Z suggests that axial and bending strength is increasing during this period of life, independent of changing body mass and composition.

Generalised Osteopenia Associated with Higher Calcium Intake in Adolescent Idiopathic Scoliosis. W. T. K. Lee*[1], C. S. K. Cheung*[1], X. Guo[2], J. C. Y. Cheng*[1]. [1]Orthopaedics & Traumatology, The Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region of China, [2]Rehab. Sciences, Hong Kong Polytechnic University, Kln., Hong Kong Special Administrative Region of China.

Adolescent Idiopathic Scoliosis (AIS) is a serious deformity of the spine affecting mostly adolescent girls. Generalised low bone mineral density (BMD) has been observed in AIS patients. Whether low BMD is due to low calcium (Ca) intake is not certain. This study aimed to correlate the habitual Ca intake and BMD in AIS patients and to compare with age-matched normal controls. 788 girls aged 11-16-y (582 AIS patients & 206 healthy control girls) entered the study. Areal BMD (aBMD) of the lumbar spine (L2-L4), femoral neck, Ward's triangle and trochanter were measured by DXA (Norland XR-36). Volumetric BMD (vBMD) of the distal radius and distal tibiae were measured by pQCT (Densiscan 1000). Ca intake was assessed by a food frequency method. Pubertal status was physically examined. Osteopenia and osteoporosis were defined as BMD based Z scores -(1 to 2) SD of, and -2 SD of normal mean BMD values respectively. 20.33% & 22.45% AIS patients were found osteopenic while 2.03% & 2.35% were osteoporotic based on aBMD and vBMD based Z scores respectively. At pre-puberty, no significant differences in aBMD & vBMD were found between AIS and controls. However, as the girls grew from Tanner's stage (breast) 2 to 5, the differentials of aBMD at various sites between the AIS and control group increased from -4.3% to -9.4 % ($P = 0.0033$ to <0.001), whereas those of vBMD between the AIS and control group increased from -5.0% to -9.3 % ($P = 0.09$ to <0.001). Mean Ca intakes of both groups were <500 mg/d. However, mean Ca intake of AIS patients was significantly higher than that of controls (442.6 ± 349.1 mg/d vs. 349.3 ± 224.5 mg/d, $P<0.001$). Furthermore, Ca intake was significantly correlated with BMD at most skeletal sites in AIS from Tanner's stage 3-5 ($P = 0.048$ to < 0.0001). In addition, multiple regression models showed that Ca intake was an independent predictor to predict the variations of aBMD ($P<0.05$) and vBMD ($P<0.05$) at various sites of the girls. To conclude, a large proportion of AIS girls were found osteopenic and even osteoporotic at the critical phase of pubertal bone growth, the disparity of BMD between AIS girls and controls increased when they were becoming sexually matured. Ca intake was positively correlated with BMD in AIS. Despite a relatively higher Ca intake, BMD of AIS was still significantly lower than that of controls suggesting an abnormal Ca homeostasis and bone turnover exists in AIS patients. Further study on the etiology of osteopenia in AIS patients would provide novel approach in the monitoring, prognostication and treatment of AIS.

SA005

Abnormal Bone Turnover in Adolescent Girls with Idiopathic Scoliosis. C. S. K. Cheung*[1], W. T. K. Lee*[1], X. Guo[2], S. P. Tang*[1], S. K. M. Lee*[1], J. C. Y. Cheng*[1]. [1]Orthopaedics & Traumatology, The Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region of China, [2]Rehab. Sciences, Hong Kong Polytechnic University, Kln., Hong Kong Special Administrative Region of China.

Declines in axial and peripheral bone mineral density (BMD) during pubertal growth have been observed in adolescent idiopathic scoliosis (AIS). In our ongoing study more than 20% and 2% of AIS girls at age 11-16-y were found osteopenic and osteoporotic respectively based on BMD Z-scores. Bone deposition in growing children is a net result of bone formation and bone remodeling process. Thus, low systemic BMD in growing AIS girls could well be related to disturbance of bone turnover. We attempted in this study to evaluate the bone turnover in AIS patients and compared the results with normal age matched controls. 538 girls aged 11-15-y (AIS, n = 396; normal controls, n=142) entered the study. Serum bone-alkaline phosphatase (bALP) reflecting bone formation activity and urinary deoxypyridinoline (Dpd) reflecting bone resorption activity were assayed by spectrophotometry and ELISA method (Metra Biosystems, USA) respectively. AIS girls had markedly higher serum bALP level at age 11, 13 & 14 year, whereas urinary Dpd level of AIS was marginally lower at age 13-y and were significantly lower than those of controls at age 14-y (P=0.022) and 15-y (P=0.043) (Fig. 1). In conclusion, AIS patients from age 11-15-y had uncoupled bone turnover rates: higher bone formation and lower bone resorption rate during pubertal growth. The significant reduction in BMD in growing AIS as evident in our ongoing research was not a direct result of enhanced bone resorption as reflected in the Dpd level in the present study. This observation is drastically different from that of age related osteoporosis. Further metabolic bone studies are warranted to understand the etiopathogensis of fast linear growth rate and systemic low BMD in growing AIS patients.

Fig.1. Median Levels of bALP and Dpd of AIS *vs.*Control Girls Aged 11-15-y

Seasonal Gains in Bone Mineral Content of the Spine during Puberty in Girls. S. S. Sullivan*[1], C. J. Rosen*[2]. [1]Food Science and Human Nutrition, University of Maine, Orono, ME, USA, [2]Maine Center for Osteoporosis Research and Education, St. Joseph Hospital, Bangor, ME, USA.

Puberty is a time of rapid bone mineralization and a critical time for interventions to maximize the peak bone mass acquired. The purpose of this study was to compare gains in bone mineral content (BMC) at the end of summer with those at the end of winter to see if a seasonal pattern in bone mineralization could be detected. We measured BMC of the spine using dual x-ray absorptiometry in 23 girls, age 10 to 13 years, each September and March for two years. The subjects self-assessed their Tanner stage of puberty using photographs. The ratings for breast and pubic hair stages were averaged together. Heights and weights were measured with each bone density measurement. Gains in BMC were stratified according to Tanner stage: Tanner 1.5 to 2 (n=10 measurements), Tanner 2.5-3 (n=28 measurements), and Tanner 3.5-4 (n=26 measurements). The mean ± standard deviation 6-month gain in BMC for girls in Tanner stage 1.5 to 2 was 1.91 ± 0.86 g, in stage 2.5-3 was 2.52 ± 1.59 g, and in stage 3.5-4 was 4.4 ± 1.99 g. Within each Tanner category, there was no significant difference between gains in BMC after summer versus winter seasons. The greatest mean 6-month gain in height (3.56 ± 0.95 cm) occurred in Tanner stage 2.5 to 3 while the greatest mean 6-month gain in weight (3 ± 3.19 kg) occurred in Tanner 3.5-4. A seasonal difference in the rate of gain in BMC or in rate of growth was not apparent.

SA008

In vivo Three-Dimensional Analysis of Trabecular Structure of Human Vertebra Using Image Data from Multi-Detector Computed Tomography-Its Precision Study. M. Takada[1], S. Imai*[2], K. Kikuchi*[2], K. Murata*[1]. [1]Radiology, Shiga Univ. of Med. Sci., Otsu, Japan, [2]Orthopaedic Surgery, Shiga Univ. of Med. Sci., Otsu, Japan.

We developed a system to perform in vivo three-dimensional (3D) analysis of trabecular structure of human vertebra using image data from multi-detector computed tomography (MDCT). Image data of MDCT, which is used clinically, was imported into the software specialized for 3D analysis of trabecular bone architecture. This allowed us to evaluate human vertebra in vivo. The purpose of this study was to evaluate reproducibility of those parameters. The lumbar vertebra of a cadaver (male, 84 years old) was used for this precision study. The L1-5 vertebra with the surrounding soft tissue was scanned by MDCT, Somatom Plus 4 (Siemens, Erlangen, Germany), at 140Kv and 170mAs, by a slice thickness of 0.5mm, and the CT images were reconstructed using a field of volume of 50mm x 50mm with 0.2mm interval, resulting a spatial resolution of 0.097mm x 0.097mm with a thickness of 0.2mm. The image data of the 165 slices was imported into the software of 3D analysis for trabecular structure, TriBON (Ratoc System Engineering, Tokyo, Japan) and a 3D image was constructed. A cubic region of interest (ROI) for analysis was extracted by the following way. The base was the maximum size of a square on the transverse image at the middle portion of the vertebra. Along z-axis, the images containing the upper and lower endoplates were excluded. Finally the size of the ROI for the vertebra was 19 x19 x 17.3 mm3. 3D analysis was performed for the cube, and bone volume (BV), bone surface (BS), trabecular bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), trabecular bone pattern factor (TBPf), structure model index (SMI), and number of nodes (N.Nd) were calculated. In order to evaluate reproducibility, the vertebra was scanned 5 times with repositioning, and coefficient variations (CVs) of those parameters were calculated. The CVs for BV, BS, BV/TV, Tb.Th, Tb.Sp, TBPf, SMI, N.Nd were 1.8%, 0.91%, 1.8%, 1.4%, 1.5%, 7.7%, 0.81%, 2.5%, respectively. The results were comparable to those of bone densitometry by dual x-ray absorptiometry except TBPf. This suggests that our method to set ROI would be reproducible, and also a possibility of in vivo 3D analysis of trabecular bone structure of human vertebra.

Aging Increases the Propensity of Osteoblasts to Induce Osteoclastogenesis by Increasing Expression of RANKL and Decreasing Expression of OPG. J. Cao, L. L. Venton*, B. P. Halloran*. Department of Medicine and Physiology, University of California at San Francisco, San Francisco, CA, USA.

With advancing age, the osteoprogenitor pool diminishes, while the osteoclast progenitor pool increases and the balance between formation and resorption necessary to maintain bone mass is lost. Osteoblasts regulate the recruitment and activity of osteoclasts through expression of receptor activator of nuclear factor κB ligand (RANKL) and osteoprotegerin (OPG). To determine whether osteoblasts from marrow stromal cultures of aged animals have a greater tendency to induce osteoclastogenesis than osteoblasts from younger animals we measured: 1) induction of osteoclastogenesis (tartrate resistant acid phosphatase staining) by osteoblasts in a donor-age-mixed cross-over co-culture system, and 2) expression of RANKL and OPG by real-time PCR in whole bone and bone cells in 6 week (young), 6 month (adult) and 24 month (old) old mice. Co-culture of equal numbers of osteoblasts (OB) from young (Y), adult (A) and old (O) mice with equal numbers of osteoclast (OC) precursor cells from young, adult and old mice produced 56±16, 63±12 and 135±31 (Y, A, O-OB x y-OC, respectively); 66±5, 71±18, and 202±38 (Y, A, O-OB x A-OC, respectively); 69±11, 96±17, and 246±77 (Y, A, O-OB x O-OC, respectively) tartrate-resistant acid phosphase-positive osteoclast-like cells. RANKL mRNA levels in whole bone were 2.1- fold and 4.4-fold higher in adult and old mice, respectively, compared to young mice, whereas OPG mRNA levels in whole bone decreased with age. Expression of RANKL was higher and expression of OPG lower in cells from older animals early in culture (day 7). With cell maturation in culture, RANKL mRNA levels in cells from young and adult mice increased significantly while levels in cells from old animals decreased. By 21 and 28 days of culture, no differences were found in RANKL mRNA in osteoblasts among different age groups. These data demonstrate that: 1) osteoblasts from older animals have a greater propensity to induce osteoclastogenesis than oseoblasts from younger animals, and 2) these changes are associated with increased RANKL and decreased OPG expression.

Osteoprotegrin, COLIA1 and VDR Gene Polymorphisms and the Rate of Bone Loss in Postmenopausal Irish Women. F. J. Drummond*, F. Wynne*, M. G. Molloy*, K. A. Quane*. Rheumatology and Medicine, National University of Ireland, Cork, Cork, Ireland.

Genetic factors are known to influence peak bone mass and there is increasing evidence to suggest that they also affect the rate of change in bone density. We investigated the role of polymorphisms in the Osteoprotegrin (OPG), COLIA1 and VDR genes with change in bone mineral density (BMD) by association in a longitudinal study in 134 postmenopausal Irish women (mean age 58.19 ± 7.67 years) over a mean follow-up time of 2.70 ± 1.15 years. Rate of change in bone mineral density (BMD) at the lumbar spine (LS) and femoral neck (FN) was calculated from baseline and follow-up DEXA measurements and expressed as annualised percentage (%/yr) rate of change from initial BMD values. Significant covariates with rate of change of BMD were identified from stepwise linear regression analysis and were used to adjust annualised bone loss. The Fok1 VDR, Hpa1 OPG T950C, Alwn1 OPG G1181C and Sp1 COLIA1 polymorphisms were investigated by RFLP analysis. Association of genotype with change in BMD was analysed in terms of three possible genetic models: the effect of a (A) dominant or (B) recessive allele, tested using an unpaired 2-tailed t-test and (C) allele-dose effect of a "risk/protective" allele, tested by looking for a linear trend going from 0 alleles to 1 to 2 by linear regression analysis. Bonferroni correction factor was used to correct for multiple hypothesis testing ($p<0.01$). Genotype frequencies for each polymorphism were in Hardy-Weinberg equilibrium. Bone loss at the FN was adjusted for weight, age and baseline BMD. There was a relationship between bone loss at the FN and OPG G1181C genotype ($p = 0.03$) such that the CC group lost more bone than the GG group (22.41 %/yr and 17.85 %/yr, respectively). This was not significant following the Bonferroni correction. A significant interaction between age and OPG G1181C genotype ($p = 0.01$) was observed, where women above 60 years with the CC genotype had 25% greater bone loss than women with the GG genotype and heterozygotes had intermediate rates of bone loss. There was a linear allele dose effect ($p = 0.03$). An interaction was also observed between age and VDR genotype, where women older than 60 years with the FF genotype lost more bone than the other two genotypes ($p=0.03$). No association was observed between rate of bone loss and either of these alleles in women below 60 years. Annualised bone loss at the LS was adjusted for weight and baseline BMD. No association was observed between OPG T950C or COLIA1 and rate of bone loss at the FN or between polymorphisms in these three genes and the rate of bone loss at the LS. This data supports the involvement of OPG G1181C and Fok1 VDR polymorphisms in the regulation of postmenopausal change in bone density at the FN.

Long-term Bone Loss in Elderly Women: A 10-year Epidemiological Study. T. V. Nguyen*, J. R. Center*, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

Femoral neck bone mineral density (BMD) is known to decline with aging, but the magnitude of decline has been inadequately documented as short-term studies are often confounded by few measurements and relatively small sample size. The present epidemiological, population-based study was designed to assess the long-term changes in BMD in a group of 1030 Caucasian women of Caucasian background, whose age was 70 ± 6.6 years (mean ± SD). The women had been followed for an average of 8.6 years (range: 1.3 to 12.6 years). BMD at the femoral neck and lumbar spine were measured dual energy X-ray absorptiometry using a LUNAR DPX-L densitometer (LUNAR Corporation, Madison, Wisconsin, USA). The median number of measurements per subjects was 4 (range: 2-6). The annual rate of change in femoral neck and lumbar spine BMD, measured by DXA, was -0.6 ± 1.8% and +0.2 ± 1.4% (mean ± SD), respectively. The increase in lumbar spine BMD was presumably confounded by osteoarthritis and degenerative change. At the femoral neck, although there was a wide range of loss, there were no evidence of a distinct "fast loss" group as the rates were normally distributed. During the the entire study period, approximately 54% of women experienced a decrease of at least 1% per year, 14% of women experienced an increase of at least 1% per year, and 32% of women experienced no change in BMD. The rate of loss in femoral neck BMD accelerated with advancing age. There was no significant correlation between baseline BMD and its rate of change. Subjects with only 2 measurements had a significantly higher rate of femoral neck bone loss (-1.1 ± 3.0%; $p < 0.01$) than those with higher frequency of measurements (-0.5 ± 1.4%). However, among subjects with the same number of measurements, those who had been followed for a longer duration had a significantly lower rate of loss than those who had been followed for a shorter duration. While both weight and age were significantly associated with change in femoral neck BMD, they accounted for only 3% of the variance of rates of change in femoral neck BMD. However, the changes in bone mineral content and cross-sectional area explained almost 94% of the variance of femoral neck bone loss. It is concluded that bone loss at the femoral neck in elderly women is highly heterogeous, and increased with advancing age but at a slower rate than previously documented. These results also suggest that a two-measurement method of estimation of bone loss is not reliable, and that an increase in the duration of follow-up (more than 2 years) could yield a more accurate estimate of change in bone mineral density for individual subjects.

Identification of Placental Growth Factor as a New Early BMP-2 Target Gene in Bone Cells. S. Marrony*, F. Bassilana*, K. Seuwen*, H. J. Keller. Bone Metabolism Research, Novartis Pharma AG, Basel, Switzerland.

The bone morphogenetic proteins (BMPs), and in particular BMP-2, are well known inducers of bone formation both in vitro and in vivo. BMPs are even capable of inducing ectopic bone formation when injected subcutaneously into rodents through a process that resembles endochondral bone formation and fracture repair. Although BMP-2 has been shown to stimulate in vitro osteoblast differentiation and concomitant induction of osteoblastic gene expression, the early gene regulatory events by which these complex effects are induced are unclear. Thus, we have used high-density cDNA microarrays to identify new BMP-2-regulated genes in primary human trabecular bone cells (HTBs). Placental growth factor (PlGF) was found to be an early regulated gene whose induction was already detected after 2h treatment with BMP-2. Microarray tissue distribution analysis of PlGF mRNA in several tissues and cell lines showed a very restricted expression only in BMP-2 treated HTBs and in placenta, as previously described. Induction of PlGF by BMP-2 in HTBs was confirmed by ribonuclease protection assay (RPA). In addition, RPA was used to measure PlGF isoform expression. Two PlGF isoforms (PlGF1 and 2) have been described that differ in a 21 amino acid insert near the C terminus. PlGF-1 was twice as much expressed in HTBs than PlGF-2, whereas placenta showed the reverse ratio as described. Next, we analyzed PlGF expression in two commonly used osteosarcoma cell lines, MG63 and U-2 OS. Interestingly, BMP-2 induced PlGF expression in MG63 but not in U-2 OS cells. PlGF induction appears highly specific as neither vitamin D3, tumor growth factor beta, nor basic fibroblast growth factor were able to stimulate PlGF expression. BMP-2 induced PlGF mRNA expression in MG63 with an ED50 of about 50 ng/ml and expression peaked between 24 and 32 h after treatment. Finally, strong stimulation of PlGF protein release by BMP-2 from MG63 and HTBs was detected by immunoassay. In summary, we have identified PlGF, which is a member of the vascular endothelial growth factor (VEGF) family, as a new BMP-2-regulated early gene in bone cells. This suggests that PlGF may play a role in osteoblast differentiation and bone formation.

OP-1 Induces Bone Formation in the Presence of Bacterial Infection. L. S. Kidder, X. Chen*, A. H. Schmidt*, W. D. Lew*. Midwest Orthopaedic Research Foundation, Minneapolis, MN, USA.

Infection is a common complication of open fractures. Since infection directly hinders the bone healing cascade, it is necessary to effectively treat the infection before significant healing can be appreciated. Treatment usually requires the removal of the fixation device, surgical débridement, and antibiotic therapy, followed by re-fixation. An intervention that accelerates fracture healing without exacerbating the infection would improve the clinical management of these difficult cases. To address this, we have examined whether Osteogenic Protein-1 (OP-1/BMP-7), can be used to stimulate bone formation in the presence of Staphylococcus aureus. In one series of experiments, we assessed BMP-mediated osteoinduction in a mechanically isolated setting with and without the presence of metal. Lyophilized allogenic collagen carrier was combined with 0 or 25 ug OP-1 +/- 5x10E5 CFUs of S. aureus. This bolus was implanted in surgically created pockets in rats thoracic erector spinae muscle. A 1x1mm stainless steel rod was sutured into some pockets, in order to provide a metallic surface for bacterial proliferation. Quantitative radiographic examination and calcium measurements of the intramuscular ossicles revealed that OP-1 induced the formation of mineralized bone by 2 weeks ($p=0.002$). While infection significantly diminished the osteoinductive response ($p<0.01$), 25ug OP-1 initiated significant mineralized bone formation compared with carrier alone ($p=0.015$). The presence of metal did not significantly influence the outcomes. In order to assess osteoinduction in an intraosseus setting, a 6mm mid-diaphyseal segmental defect was surgically created and internally stabilized in the rat femur. These critical defects received implants of either 0, 11, or 50ug of OP-1 mixed with collagen carrier +/- 10E5 CFUs of Staphylococcus aureus. Untreated infection in this model resulted in loss of fixation by 9 weeks. OP-1 (50ug) healed the infected defect, significantly maintaining construct stability. We demonstrate here that OP-1/BMP-7 maintains its osteoinductive capacity in the presence of a clinically significant infection. The controlled application of an osteo-anabolic cytokine (such as a BMP) may permit the earlier removal of stabilizing hardware, thereby allowing more efficacious treatment of osteomyelitis Resources for this project were generously provided by the (US) Orthopaedic Trauma Association and Stryker Biotech Corp.

Effects of Osteogenic Protein-1 (OP-1, BMP-7) on Medial Collateral Ligament Cells in Culture. A. D. Tsai*[1], L. C. C. Yeh*[1], J. C. Lee[2]. [1]Biochemistry (MC7760), University of Texas Health Science Center, San Antonio, TX, USA, [2]Biochemistry (Mail Code 7760), The University of Texas Health Science Center, San Antonio, TX, USA.

The medial collateral ligament (MCL) is a commonly injured area of the knee joint. Healing of the ligament is a complicated process consisting of cellular proliferation and migration, as well as synthesis and deposition of ligament components. The healing process seems to be affected by growth factors, such as basic FGF, PDGF-B, and TGF-beta. Limited data is currently available on the effects of bone morphogenetic proteins (BMPs) on ligaments. BMPs are members of the transforming growth factor-β superfamily. Osteogenic Protein-1 (OP-1), a member of the BMP family, induces formation of new bone and cartilage. In the present study, we wished to use primary cultures of rat MCL cells as a model to study the effects of Osteogenic Protein-1 (OP-1, BMP-7) on cell proliferation and gene expression. MCLs from young adult male rats were surgically excised from the surrounding connective tissues at the knee joints and cultured in DMEM/F12 with 10% FBS. Treatment with OP-1 resulted in dose-dependent increases in alkaline phosphatase activity and cell proliferation. Northern blot analysis revealed that control cells expressed a high level of type I collagen mRNA. OP-1-treated MCL cells expressed an elevated steady-state mRNA expression level, in a dose- and time-dependent manner. OP-1 stimulated the activity of the cloned promoter of type I collagen. The mRNA expression levels of several BMP receptors as a function of time in culture, in both control and OP-1-treated cells, were also measured by Northern blot analysis. Control cells expressed a significant level of mRNA coding for ActR-I, BMPR-IA, BMPR-IB, and BMPR-II at the beginning of culture. The levels remained relatively constant throughout the 16 days in culture. OP-1 appeared to stimulate mRNA expression of all four receptors examined, though to varying extents. In summary, the present study indicates that the primary culture of MCL cells might be an appropriate cell culture model to study the effects of growth factors on ligament growth and repair. We showed that OP-1 stimulated cell proliferation and mRNA expression of several biochemical markers in this culture model.

Prefabrication of Vascularized Bone Flap Transformed from Fat Vascularized Pedicle Using rhBMP-2 in Rat Femur. M. Hosoya*[1], Y. Maruoka*[1], M. Oda*[2], I. Asahina[1], S. Ichinose*[3], H. Kimura*[2], K. Omura*[1]. [1]Oral Surgery, Department of Oral Restitution, Division of Oral Health Sciences, Graduate School, Tokyo Medical and Dental University, Tokyo, Japan, [2]Dentistry and Oral Surgery, Hirosaki University School of Medicine, Aomori, Japan, [3]Instrumental Analysis Research Center, Tokyo Medical and Dental University, Tokyo, Japan.

In the field of not only oral surgery but also clinical medicines, it is significant to restore bone defect as a result of trauma or tumor. We described a vascularized bone flap transformed from a fat vascularized pedicle (FVP) raised on host using recombinant human bone morphogenetic protein-2 (rhBMP-2). It is enable to increase the survival rate of the subsequently grafted bone, and to form it into the desired shape. Collagen sheet was applied inside of the cylinder shaped silicone mold to deliver impregnated with rhBMP-2. FVP, the same size as lumen of the mold, was raised on the superficial inferior epigastric neurovascular bundle in Wistar rat, and then it was sandwiched between two halves of silicone mold. In the experimental group, 20 ug of rhBMP-2 was used; diluting material alone, in addition, ligation of the neurovascular bundle upstream to the molds for control groups. At 2, 4, and 8 weeks after surgery, bone formation were confirmed radiologically, histologically, and electronmicroscopically. Macroscopically, compared to the control group, new bone was formed with the identical shape as the lumen. In the control groups, bone was not observed. Here, we found out that FVP applied with rhBMP-2 induced a vascularized bone. It was indicated that our model could be a potential approach therapeutically for bone reconstruction effectively.

Bone Morphogenetic Protein-1 Expression During Rat Tibia Bone Formation. P. Manduca, S. Zanotti*, C. Volta*, F. Galmozzi*. Dobig, University of Genova, Genova, Italy.

BMP-1 (procollagenase I) processes trimeric pro-collagens I, II and III and produces carboxyl trimer pro-collagen fragments (C3). The C3 I production occurs in developmentally regulated fashion in osteoblasts cultures differentiating in vitro. C3 I is a powerful chemoattractant for endothelial and breast carcinoma cells, suggesting that it might drive bone vascular invasion and tumor homing to bone. We investigated the expression of BMP-1 in ossifying rats tibiae (from fetal to 10 days after birth) by in situ hybridization and by immunoperoxidase staining with antisera to the C3 I, and levels of BMP-1 mRNA by PCR in rat tibia osteoblasts differentiating in vitro. Expression of BMP-1 mRNA is first detected in limbs in the newly formed bone collar and thereafter increasing with animal age in osteoblasts in trabecular bone under the growth plate and in the diaphyseal collar. Osteocytes are usually negative, occasionally less positive that the osteoblasts. Osteoblasts differentiating in vitro express BMP-1 mRNA, detected by PCR, in a developmentally regulated fashion, with maximal expression in mature osteoblasts. Periosteum and adjacent perichondrium, and osteoclasts are strongly positive. Peroxidase staining with antiserum either to the a1 or to the a2 chains of the C3 I, decorate mostly ECM, in locations consistent with the expression of mRNA by the cells. Bone marrow positive both for mRNA and protein expression is found in patches. In the cartilage, differences in intensity of in situ hybridization in the pre- and hypertrophic chondrocytes are observed between the proximal and distal epiphyses, as if, during growth, a defined pattern of expression in the chondroblast department of tibial epiphyses evolved, expressed differently in the two extremities of the bone. Peroxidase staining with the antiserum to the a1 chain of the C3 I, detected the corresponding fragment from type II pro-collagen in cartilage. In summary, expression of BMP-1 in the cells of the bone compartment suggests that the production of C3 I could enhance endothelial cells mobility towards and within the forming bone. BMP-1 expression is also modulated during osteogenesis in vitro and is a developmental feature of the osteogenic phenotype. The modalities of the expression of BMP-1 in the cartilage department of the forming tibia suggest that both spatial and developmental control of its expression could be acting during chondroblast differentiation. No informations are presently available on a biological role of the C3 II, the BMP-1 product in cartilage. The expression of BMP-1 limited to areas (clones ?) in the bone marrow is a new finding and the nature of the producing cells is presently under investigation.

Comparison of Aortic Calcification in Hemodialysis Patients between with and without Diabetes Mellitus. H. Taniwaki*[1], T. Tabata*[1], S. Shoji*[1], A. Shioi[2], E. Ishimura*[3], T. Inoue*[1], Y. NIshizawa[4]. [1]Internal Medicine, Inoue Hospital, Suita, Japan, [2]Cardiovascular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan, [3]Nephrology, Osaka City University Graduate School of Medicine, Osaka, Japan, [4]Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan.

Vascular calcification is frequently seen in patients with diabetes and also in patients with chronic renal failure who are undergoing hemodialysis (HD). It is unknown, however, whether there are different factors associated with vascular calcification between diabetic HD patients and non-diabetic HD patients. Thirty-three HD patients were enrolled in the present study. The patients ranged in age from 40 to 85years (19 men and 14 women). They were divided into two groups according to the presence of diabetes mellitus (DM). DM group consisted of 14 patients, and non-DM group of 19 patients. Using computerized tomography (CT), calcification of the abdominal aorta above the bifurcation was evaluated in 10 slices of 1 cm interval, and aortic calcification index (ACI %) was calculated by division of calcified aortic area by total aortic areas (expressed in percent). Blood was drawn for routine analysis before a session of HD. There were no significant differences in age, mean blood pressure (mean BP), total cholesterol, serum calcium, serum phosphrus, and intact parathyroid hormone (i-PTH) between DM and non-DM groups. There was significant difference in the duration of HD between the two groups. The ACI % did not significantly differ between the two groups. Although there was significant correlation between ACI % and age, and between ACI % and mean blood pressure in non-DM group, there were no significant correlation between ACI % and these parameters in DM group. The results suggest that factors affecting calcification of abdominal aorta are different between DM and non-DM hemodialysis patients.

Mineralization and Nano-mechanical Properties of Human Femoral Articular Calcified Cartilage and Subchondral Bone. V. L. Ferguson[1], A. J. Bushby*[1], A. Boyde[2]. [1]Department of Materials, Queen Mary, University of London, London, United Kingdom, [2]Department of Anatomy and Developmental Biology, University College London, London, United Kingdom.

The levels of mineralization and the micromechanical properties of normal and arthritic human femoral head articular calcified cartilage (ACC) are unknown, as is any correlation. We studied the former using quantitative backscattered electron imaging (qBSE) and the latter using nanoindentation. The novel technical combination gave means to study relationships in the thin, complex structure of intact, undecalcified ACC and immediately underlying subchondral bone (SCB). Thick slices of human normal reference post-mortem (PM) and osteoarthritic (OA) femoral heads (n=7/group) were embedded in PMMA, micro-milled, carbon coated, and studied using qBSE, quantified via halogenated dimethacrylate standards. Nanoindentation (3µm diameter, spherical tip diamond indenter; UMIS 2000, CSIRO, Australia) was performed in selected superior (more highly loaded) and medial regions of the joint surface. A partial unloading method gave Young's modulus (E) as a function of indenter penetration depth (40 increments/indent). Each test used an array (5*24 at 20 micron spacing) spanning SCB, ACC and hyaline articular cartilage. Mineralization at each indent site was derived from qBSE data. Elastic modulus and mineralization levels of ACC tended to be higher in superior regions in both PM and OA cases. In keeping with its more recent replacement, OA SCB had greater ductility and lower mineralization than in PM reference cases. In superior regions, elastic modulus in ACC was 16.9% greater than SCB in OA, cf. 2% greater in the PM group. There was no relationship between superior vs. medial sites (loading history) and elastic modulus and mineralization in ACC or SCB in normal PM tissue. However, there was a profound difference in OA, where mean values for elastic modulus and mineralization in superior ACC were both 11% greater than in medial ACC. One extreme case contained superior ACC that was 51% more highly mineralized than medial regions on the same sample. Such hypermineralization occurs as water space, comprising ~70% of normal cartilage, is filled with mineral. This hypermineralization of ACC, which occurred primarily in superior regions of OA samples, implies altered tissue microstructure, where more mineral per unit volume may be present as more or larger crystals. We surmise that the very highly mineralized cartilage component will function as a hard grinding abrasive, thus accelerating wear rates, and whether attached to or fragmented from the eburnated (‘bone‘ to ‘bone‘ contacting) surfaces of OA ACC.

Temporal and Spatial Development of Cholesterol-Induced Atherosclerotic Calcification in Juvenile Rabbits. H. H. T. Hsu, O. Tawfik*, F. Sun*. University of Kansas Medical Center, Kansas City, KS, USA.

Accumulating epidemiological evidence indicates that atherosclerotic calcification can occur in young age of human population, suggesting that the dietary influence is as important as the aging process in the development of atherosclerotic calcification. However, there is a lack of detailed knowledge on morphological and biochemical changes that eventually lead to calcification in the affected aortas responding to high lipid diets in youth. We selected 4-month-old young rabbits as an animal model to study some of these changes during the course of mineral deposition in aortas. Rabbits were fed 0.25% cholesterol and 2% peanut oil for up to 6 months. Several histochemical stains were utilized in the study. These included H & E for morphology, Verhoeff’s van Gieson (VVG) stain for elastin, Masson Trichrome stain for collagen, and Alizarin red stain for calcification. At the end of 3 months of atherogenic diet, rabbits developed the earliest lesions with partial thickening of the intima. VVG staining revealed a focal rupture of the internal elastic laminae. Collagen deposition was noted to accumulate at the same location of elastic disruption. Calcification was barely detected at the same site as well. When animal were sacrificed at 4, 5, or 6 months of high lipid intervention, progressive worsening of the above-mentioned changes was noted. The intima was progressively circumferentially thickened and fibrotic. The media became partially fibrotic. Collagen deposition became more prominent while elastic fibers completely disintegrated at this stage of atherosclerosis. At the 6th month, calcification was predominantly present in the intimal area adjacent to the media. The fatty streaks and calcification areas were frequent in the proximal regions of the aorta and were gradually decreased in the distal part of aortas. The structural irregularity of the proximal aorta as a result of the high lipid dieting may cause earlier occurrence of calcification, since this portion of aortas is subjected to more turbulence and less shearing force of blood flow than the distal part of aortas. Coincidentally, calcifiability of vesicles isolated from proximal aortas was higher than from the distal regions. Likewise, vesicle calcifiability was higher at the 6th month of cholesterol intervention than that at the 3rd month. Thus, it is concluded that atherosclerotic calcification is closely related to the direct effect of cholesterol dieting on aortas besides the expected outcome of the aging process. The correlation of vesicle ability to calcify to the extent of mineralization in aortas further strengthens the role of calcifying vesicles in atherosclerotic calcification.

CTGF/Hcs24 Induces Chondrocyte Differentiation Through p38 Mitogen-activated Protein Kinase (p38MAPK), and Proliferation Through p44/42 MAPK/Extracellular-signal Regulated Kinase (ERK). G. Yosimichi*[1], T. Nakanishi*[2], T. Nishida[2], T. Hattori*[2], T. Takano-Yamamoto*[3], M. Takigawa[2]. [1]Biodental Research Center, Okayama University Graduate School of Medicine and Detistry, Okayama, Japan, [2]Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [3]Orthodontics, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan.

Connective tissue growth factor/hypertrohic chondrocyte specific gene product 24 (CTGF/Hcs24) promotes proliferation and differentiation of chondrocytes in culture. We investigated the roles of two major types of mitogen activated protein kinase (MAPK) in the promotion of proliferation and differentiation by CTGF/Hcs24. Here we report the effects of the MAPKK/MEK 1/2 inhibitor, PD098059, and p38 MAPK inhibitor, SB203580, in a human chondrosarcoma-derived chondrocytic cell line (HCS-2/8) and rab-

bit growth cartilage cells (RGC) treated with CTGF/Hcs24. In the proliferation phase, CTGF/Hcs24 induced about a 5-fold increase in the phosphorylation of p44/42 MAPK/ERK and about a 2-fold increase in that of p38 MAPK in an in vivo kinase assay. These inhibitors of MAPKK and MAPK suppressed phosphorylation of ets-like gene-1 (Elk-1) and nuclear activating transcription factor-2 (Atf-2) induced by CTGF/Hcs24 in a dose-dependent manner, respectively. Western blot analysis showed that phosphorylation of ERK was induced from 10 to 30 min and phosphorylation of p38 MAPK from 3 to 30 min after the addition of CTGF/Hcs24 in confluence HCS-2/8 cells. PD098059 suppressed the DNA synthesis of HCS-2/8 cells and RGC cells, while SB203580 did not. On the other hand, the p38 MAPK inhibitor, SB203580, completely inhibited the CTGF/Hcs24-induced synthesis of proteoglycans in HCS-2/8 cells and RGC cells but the MEK1/2 inhibitor, PD098059, did not. These results suggest that ERK mediates the CTGF/Hcs24-induced proliferation of chondrocytes, and that p38 MAPK mediates the CTGF/Hcs24-induced differentiation of chondrocytes.

Differentiation of Chondrocytes Sensitizes Them to Apoptosis. P. Bruna*. Orthopaedic Research, Thomas Jefferson University, Philadelphia, PA, USA.

Endochondral bone formation is a key pathway in the development of long bones in the vertebrate skeleton. During this process chondrocytes proliferate and exit the cell cycle to mature into hypertrophic chondrocytes. These chondrocytes then undergo apoptosis leaving mineralized cartilage and empty lacunae for blood vessel and osteoblast invasion. The objectives of this study test the hypothesis that the mature chondrocyte exhibits a high sensitivity for matrix apoptogens. Chick cephalic sternal chondrocytes were matured by treatment with 35 nM retinoic acid (RA). Chondrocyte maturation was determined by the expression of collagen type X and by activation of alkaline phosphatase. Chondrocytes were treated with Pi and Ca^{2+} ions. Ion pair treatment of maturing chondrocytes induced cell death in a dose-dependent manner. Chondrocytes maintained in the absence of RA showed a reduced sensitivity to ion pair-induced apoptosis. To probe the mechanism of cell death, Bcl-2 family member expression was measured by western blot analysis. During chondrocyte maturation, protein levels of Bcl-2- and Bcl-xl, both anti-apoptotic proteins, were decreased. In contrast, the protein levels of several pro-apoptotic proteins, including Bax, remained elevated. These results indicate that during chondrocyte maturation there is a significant downregulation of anti-apoptotic factors. This observation suggest that the process of chondrocyte hypertrophy and the ultimate cell death of those chondrocytes may be linked and may share molecular pathways.

Characterization of Collagenase-3 Binding and Internalization by Rabbit Chondrocytes. L. J. Raggatt[1], I. Choudhury*[1], S. Williams*[1], M. L. Tiku*[2], N. C. Partridge[1]. [1]Physiology and Biophysics, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ, USA, [2]Rheumatology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ, USA.

Collagenase-3 (MMP-13) is an extracellular matrix metalloproteinase that cleaves type II collagen, the major protein component of cartilage, with high specificity. Several studies have identified increased levels of MMP-13 in arthritic synovial fluid where it may contribute to matrix destruction in this disease. Our laboratory has previously documented a process whereby osteoblastic cells remove MMP-13 from the surrounding milieu by binding the enzyme to a specific receptor. The enzyme is then internalized and degraded through the actions of the endocytotic receptor, the low-density lipoprotein receptor-related protein (LRP). Such a mechanism provides for a controlled elimination of a potentially destructive enzyme from the extracellular environment. The process of MMP-13 internalization also occurs in chondrocytes and is significantly reduced in osteoarthritic (OA) chondrocytes. We are currently characterizing the internalization of MMP-13 in normal rabbit chondrocytes. Primary rabbit chondrocytes were harvested and cultured in monolayers for three passages. RT-PCR was used to assess the cell phenotype during the culture period and the rabbit chondrocytes were found to express the cartilage specific genes aggrecan and type II collagen throughout this time. 125I-MMP-13 was used to determine the ability of the rabbit chondrocytes to bind MMP-13. Appreciable specific cell-association of MMP-13 was detected after 10 min of exposure to the ligand and equilibrium was obtained after 2 h. After identifying the time to equilibrium we determined whether binding was saturable by incubating the chondrocytes with increasing concentrations of 125I-MMP-13 ranging from 0 to 50 nM at 4°C for 2 h. The amount of specifically associated MMP-13 approached saturation at 50 nM, allowing assessment of the receptor kinetics. Finally, we have investigated the ability of rabbit chondrocytes to internalize a single cohort of 125I-MMP-13 over time at 36°C. Internalization of MMP-13 accumulation was evident after 20 min, reached a maximum at 30 min and had returned to baseline by 90 min. Subsequent to internalization the enzyme is released to the cell surface or into the extracellular media as trichloroacetic acid-soluble degradation products. The internalization of MMP-13 by rabbit chondrocytes correlates with that of normal human cartilage cells. We are currently using this accessible rabbit chondrocyte model to explore the receptors involved in the internalization of MMP-13 by chondrocytes as a first step in identifying how this system is impaired in OA cartilage.

The Function of p21 Cip-1/SDI-1/WAF-1 in Chondrogenic Differentiation. Y. Negishi*, N. Ui*, M. Nakajima*, K. Kawashima*. Pharmaceutical Sciences, Teikyo University, Kanagawa, Japan.

Development of skeletal cartilage is characterized with coupling growth arrest and cell differentiation. Here, to know the cyclin-dependent kinase inhibitors involved in the progression of chondrogenic differentiation, we examined changes in the expression levels of CKI members using mouse ATDC5 prechondrocytes as a widely used in vitro model of cartilage differentiation. By a semiquantitative reverse transcriptase-polymerase chain reaction analysis, up-regulation of p21 mRNA and p27 mRNA was observed following a decrease in growth rate of prechondrocytes, and both transcripts subsequently accumulated during chondrogenic differentiation; p15, p18, and p19 mRNA, in contrast, did not change during the differentiation. The increase of p21 and p27 gene expression preceded the up-regulation of gene marker, type(II)collagen, in early chondrogenic differentiation. Only the up-regulation of p21 mRNA during the differentiation was prevented by the continuous treatment of early chondrogenic inhibitor, parathyroid hormone, indicating a close correlation between the differentiation and p21 induction in ATDC5 cells. Furthermore, by immunoprecipitation analysis, we observed that the level of p21 and p21/CDK2 complexes transiently increased during the differentiation, but not in undifferentiated cells, leading to a decrease in CDK2-associated kinase. This down-regulation of CDK2-associated kinase correlated with a reduction in DNA synthesis during the differentiation. Finally, to examine the role of endogenous p21 during chondrogenesis, we established stable-cell lines overexpressing full-length p21 antisense RNA in ATDC5. The reduction of endogenous p21 in these cell lines caused inhibition of the early chondrogenic differentiation in ATDC5.

SA035

Establishing Immortalized Periodontal Ligament Cells from Oncogene Transgenic Rat and Gene Expression of Bone Metabolic Markers. M. Chiba[1], M. Kubota*[1], M. Obinata*[2], H. Mitani*[1]. [1]Division of Orthodontics, Tohoku University, Graduate School of Dentistry, Sendai, Japan, [2]Department of Cell Biology, Institute of Development, Ageing and Cancer, Tohoku University, Sendai, Japan.

It is well known that there are multiple populations of periodontal ligament (PDL) cells and that these maintain PDL homeostasis. Various cell types in the PDL control orthodontic tooth movement. When the PDL is stimulated, cell differentiation is prompted and the cell-component ratios change to suit the new environment. The stimulus of mechanical stress is thought to cause osteoblasts, cementoblasts, and fibroblasts to differentiate from undifferentiated mesenchymal stem cells. However, the process of differentiation is unknown. The purposes of this study were to establish immortalized PDL cell lines derived from the PDL of transgenic rats harboring the temperature-sensitive simian virus 40 T-antigen gene (TG rats), and to compare the characteristics of these cell lines. The PDL was removed from the molar roots of TG-rats and incubated in alpha-MEM supplemented with 10% FBS and antibiotics in a humidified atmosphere of 5% CO_2 in air at the permissive temperature (33ºC). Cells that grew from the PDL were passaged and cloned depending on the shape of colony formation. RT-PCR analysis of the cell lines established was used to examine the expression of genes for Type-I collagen, osteopontin, fibronectin, alkaline phosphatase (bone type), bone sialoprotein, the receptor-activator of NF-kB Ligand, and osteoprotegerin. Furthermore, to examine the capacity of differentiation into mineralized-tissue-forming cells, cells were treated with 1,25 (OH) $_2D_3(10^{-8}M)$(D3) and incubated at 37º C. The formation of mineralized nodules was examined in a mineralized medium. Fifteen cell lines were established. These cell lines could be classified into six groups based on their pattern of gene expression at 33ºC. Calcified nodule formation occurred in two clones. The gene expression patterns also changed when the cell lines were treated with D3 and incubated at 37ºC, enabling the subclassification of the cell lines. In conclusion, differential gene expression in established cell lines was demonstrated in PDL-cell subpopulations. There were cells that had the potential for differentiating into cells found in mineralized tissues, like osteoblasts and cementoblasts, and cells that expressed the molecules that regulate osteoclast differentiation.

Analysis of Gene Expression in Osteoblastic Cell Stimulated by Connective Tissue Growth Factor/Hypertrophic Chondrocyte-Specific Gene Product 24 (CTGF/Hcs24). E. Nakata*[1], T. Nakanishi*[1], T. Nishida*[1], A. Kawai*[2], H. Doi*[1], H. Inoue*[2], M. Takigawa*[1]. [1]Department of Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Department of Orthopaedic Surgery, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan.

Connective tissue growth factor (CTGF/Hcs24) belongs to the CCN family which is believed to regulate many biological processes. We reported that recombinant CTGF/Hcs24 (rCTGF/Hcs24) promoted the proliferation and differentiation of osteoblastic cells (Saos2) in culture and increased the expression levels of collagen type I, alkaline phosphatase, osteopontin, and osteocalcin. To investigate the effect of rCTGF/Hcs24 on gene expression levels in Saos2, we used DNA microarrays. Saos2 cells cultured in DMEM containing 10% FBS for 48hs was incubated in DMEM containing 0.5% FBS for 12 hrs. Then, DMEM containing 0.5% FBS or DMEM containing 0.5% FBS and 50 ng rCTGF/Hcs24 was added to the culture. DNA microarrays containing 1091 human genes were used to compare mRNA levels between cultures with or without rCTGF/Hcs24 at 6 and 24 hrs after the addition of rCTGF/Hcs24. Total RNA was isolated from cells cultures with or without rCTGF/Hcs24, and purified mRNA was labeled with Cy3 or Cy5, respectively. These cDNA probes were hybridized to DNA microarrrays. We compared the resulting expression patterns between Cy3 and Cy5, and identified some genes in each time point using a criteria of over 1.5-fold change in expression. After 6hr incubation with rCTGF/Hcs24, several genes such as calcium-activated potassium channel beta, PLC-beta-1, camp response element binding protein, and MCM5 DNA replication licensing factor were up-regulated, and several genes such as hint protein, and IL-10 were down-regulated. After 24hr incubation, several genes such as transforming growth factor beta receptor, Smad4, and integrin beta 7 were up-regulated, and several genes such as phospholipase A2, and cadherin 3 were down-regulated. These results suggest the utility of DNA microarrays to identify the expression patterns of mRNA involved in the cellular response to rCTGF/Hcs24.

Role of the Calcium-Binding Domain in Cartilage Oligomeric Matrix Protein (COMP) on Its Synthesis and Secretion. H. Yusuke*. Dept. of Orthop. Surg., Osaka City University Medical School, Osaka, Japan.

Cartilage oligomeric matrix protein (COMP) is a large pentameric glycoprotein in the territorial matrix surrounding chondrocytes and the fifth member of the thrombospondin (TSP) family and the causal molecule of an autosomal dominantly inherited chondrodysplasia such as Pseudoachondroplasia (PSACH) and multiple epiphseal dysplasia (MED). Beside pentamer-formation and EGF domains, the calcium-binding repeat domain was widely believed to be important because many mutations occurred in this small region. The function of COMP has remained unknown although genetic analyses provided important clues. With the goal of establishing a model to study the mechanisms by which COMP mutations cause these disease, a COMP cDNA was isolated from human synovial cells and a mutation (G1414T) was introduced into the calcium-binding domain that was previously reported for a severe PSACH patient. Both COMP cDNA were transfected in synovial cells or COS cells and their biochemical and morphological changes were examined with an aid of newly prepared antibodies against the bacterial recombinant peptides corresponding the amino-terminal and carboxyl-terminal COMP fragment. A considerable amount of wild COMP but not mutant COMP was detected in the culture medium of transfected cells while mutant COMP was found to accumulate as a full-sized form in cells. This observation indicates that mutant COMP was synthesized as wild COMP but failed to take outside due to reduced secretion process but not increased degradation. A confocal view showed that both COMPS were associated with the rough endoplasmic reticulum (rER) marker molecule such as Bip or Grp78, indicating that COMP is an ER retention or membrane/secretion protein. Increased immunofluorescence was detected in cells transfected with mutant COMP as compared with wild COMP. Moreover such immunofluorescent structures of mutant COMP were strikingly swollen. This was in good agreement with the previous in vivo observation that the characteristic enlarged lamellar appearing rER cisternae were observed in PSACH and MED. The possible occurrence of ER stress as the main mechanism for this mutation was examined. However, little difference in eIF2-a, ER stress marker, was observed between cells tranafected with wild and mutant COMPs. In contrast, we observed a significant TUNEL-reactivity in cells with mutant COMP, suggesting that a secretion process is important for COMP function and secreted COMP itself also plays a surviving role on chondrocyte.

Transcriptional Regulation of Cartilage gene expression by SRF. M. I. Reinhold, M. C. Naski. Pathology, University of Texas Health Science Center, San Antonio, TX, USA.

The differentiation of mesenchymal cells into chondrocytes is a multistep pathway. These steps include the condensation of mesenchymal chondroprogenitor cells into aggregates assembled by intercellular cadherin dependent contacts. Continued differentiation of the condensed mesenchyme into chondrocytes results in the dissociation of the condensed cells, which at this stage surround themselves with an abundant layer of extracellular matrix that is characteristic of cartilage. The actin cytoskeleton is required for intercellular adhesion and its remodeling coincides with the loss of cell-cell contacts during differentiation. Recent studies showed that alterations in actin dynamics activate serum response factor (SRF). We hypothesized that SRF is activated during the dissociation of chondrogenic mesenchyme and that this contributes to chondrocyte differentiation. To investigate SRF during chondrogenisis, we examined i) activation of SRF following dissociation of cadherin-mediated intercellular contacts and ii) SRF-dependent transcription of genes that are key regulators of chondrocyte differentiation. We found that SRF is potently activated following dissociation of calcium-dependent intercellular contacts in the mesenchymal chondrocytic cell-line RCJ3.1C5.18. Activation of SRF was evidenced by the up-regulation of a SRF-dependent reporter gene and coincided with the loss of N-cadherin mediated intercellular contacts. Activation of SRF correlated with increased expression of chondrocyte specific genes, such as aggrecan. Conversely, a dominant-negative form of SRF suppressed aggrecan gene expression. The fibroblast growth factor receptor (FGFR) 3 gene was also specifically regulated by SRF and promoter mapping studies identified a 50 bp sequence element in the FGFR 3 gene that contains a SRE. The transcriptional activity of the 50 bp element is strictly dependent on the SRE and SRF. We conclude i) that SRF is activated following the dissociation of condensed-chondrogenic mesenchyme and ii) that SRF contributes to chondrocytic differentiation by regulating chondrocyte specific gene expression.

Novel *cis*-element TRENDIC that Enhance Connective Tissue Growth Factor (ctgf) Gene Expression in Chondrocytic HCS-2/8. T. Eguchi*[1], S. Kubota*[1], S. Kondo*[1], Y. Mukudai*[1], T. Kuboki*[2], H. Yatani*[2], M. Takigawa[1]. [1]Biochemistry&Molecular Dentistry, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Oral and Maxillofacial Rehabilitation, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan.

CTGF, which is a multi-functional growth factor, is specifically expressed in hypertrophic zone of endochondral growth plate. HCS-2/8 chondrocytic cells also highly express CTGF. In the previous study, we demonstrated that TGF-β signaling pathway was working through the TGF-β response element (TbRE) in the CTGF promoter in HCS-2/8 cells, and it was thought to be one of the cause of the high expression level of CTGF in HCS-2/8 cells. While continuing to analyze the chondrocyte-specific regulatory mechanism of CTGF gene expression, we subsequently identified a novel *cis*-element in the promoter region, which acts in the HCS-2/8-specific transcriptional enhancement of CTGF gene expression. For functional evaluation, plasmids containing firefly luciferase gene under the control of CTGF promoter, and its deletion/point mutants were constructed to be used in transfection experiment into HCS-2/8 and fibroblasts (NIH3T3 and HeLa cells). On the basis of the results of the luciferase assay, several DNA sequences in the critical region in the promoter were selected for the preparation of the probes for the gel shift assay, and it was performed with nuclear extracts of HCS-2/8 and other types of cells as controls. Comparative luciferase assay of the *ctgf* promoter deletion mutants among HCS-2/8 chondrocytic cells and fibroblastic cells revealed that a110 bp region in the promoter was critical in the HCS-2/8-specific transcriptional enhancement. Subsequent competitive gel shift assay revealed that transcription factors in HCS-2/8 nuclei bound to a 60 bp portion in the corresponding region. Relative luciferase activity from a CTGF promoter with mutant TbRE was 16.9% lower than that from the intact promoter. On the other hand, relative luciferase activity from a CTGF promoter with 4 bp point mutations in the 30 bp upstream of the TbRE was 47.7% lower than that from the intact one. The binding activity of HCS-2/8 nuclear factor(s) to the sequence over the 4 bp was especially higher than any nuclear extract form other cells. Therefore, we entitled the sequence 'TRENDIC', a transcription enhancer dominant in chondrocytes. Further investigation on the TRENDIC-binding transcription factor and the mechanism of its action is currently in progress.

Insight Into the Molecular Complexity of Fracture Repair. F. Lombardo*[1], D. White*[2], J. Joo*[3], H. Ahn*[3], C. T. Rubin[4], M. Hadjiargyrou[5]. [1]Biomedical Engineering, SUNY, Stony Brook, Stony Brook, NY, USA, [2]Metabolic Disease, Millennium Pharmaceuticals, Cambridge, MA, USA, [3]Applied Mathematics and Statistics, SUNY, Stony Brook, NY, USA, [4]Biomedical Engineering, SUNY, Stony Brook, NY, USA, [5]Biomedical Engineering, State University of New York, Stony Brook, NY, USA.

The healing of a fractured bone is, in essence, a recapitulation of embryonic development that involves chondrogenesis, ossification and remodeling. These processes are characterized by an intricate series of events that requires temporal and spatial orchestration of numerous cell types and the expression of thousands of genes. Despite detailed understanding of skeletal repair at the tissue and cellular level, there is surprisingly little known of the scale or complexity of the process at the molecular level. This study was designed to address this issue, by characterizing the global increases in gene expression that occur during the critical phases of bone fracture repair. Previously we reported the construction and analysis of a cDNA library that consisted of transcriptionally induced genes (pooled from RNA isolated from post fracture (PF) 3, 5, 7 and 10 day callus) that were subtracted following hybridization with RNA derived from intact bone. This cDNA library included thousands of known genes that reflected a variety of families with diverse functions in cell cycle regulation, cell-matrix and cell adhesion, ECM construction, inflammation, general metabolism, mitochondria signaling, transcriptional regulation, protein transport, etc. In addition, hundreds of cDNAs showed homology to expressed sequenced tags (EST's). Further, custom microarrays containing all isolated cDNA clones were constructed and screened using RNA derived from intact bone (control) as well as PF day 3, 5, 7, 10, 14 and 21 callus. These experiments confirmed the temporal expression (PF day 3-21) of all genes and also indicated that ~93% of the subtracted cDNAs are upregulated during the repair process. Finally, clustering analysis revealed subsets of genes, both known and unknown, that exhibited distinct expression patterns over 21 days PF, indicating distinct roles in the healing process. In summary, the data demonstrate that the healing process is exceedingly complex, involves thousands of activated genes and indicates that groups of genes rather than individual molecules should be considered if the regeneration of bone is to be accelerated exogenously. Given the strong parallels of mammalian bone regeneration, skeletal development, and wound repair, this information will surely provide great insight towards some of the critical molecular mechanisms involved in a wide array of skeletal processes and dysfunctions.

Phase-Contrast X-Ray Imaging in Investigation of Osseointegration of Craniofacial Implants and Other Hard Tissue Applications. S. L. O'Connell*[1], S. Watson*[1], J. Courtney*[2], J. G. Clement*[1]. [1]School of Dental Science, University of Melbourne, Melbourne, Australia, [2]X-Ray Technologies Pty. Ltd., Melbourne, Australia.

Phase-Contrast X-ray Imaging (PCI) radiographs contain both absorption and phase contrast and thus display enhanced edge definition of objects and their structural features. We compared PCI images with conventional contact radiographs during investigation of the osseointegration of surgical implants in growing pigs. Six 3-week old male piglets were implanted with 'Epitek' craniofacial fixtures. One fixture (12.5 x 12.5mm), anchored by 3mm screws, was placed beneath the periosteum on the left parietal bone. Another (12.5 x 24.5mm) was placed over the left coronal suture, with an extra dummy screw head in each long side. The pigs were sacrificed 9 weeks after surgery. A single section was cut along the coronal plane, spanning both sides of the skull and bisecting one end of the square fixture. Another section dissected one long end of the rectangular fixture in the sagittal plane, with a parallel control section cut from the untreated side. Radiographs were taken using a conventional X-ray unit (Faxitron Series 43805N, Hewlett-Packard, USA) (40kV, 54 mAs) and high resolution film (Agfa Structurix D2), scanned using a UMAX Powerlook 2000 Flatbed scanner (2000dpi/8.5um pixels). Digitised radiographs were obtained for comparison using a phase-contrast unit (X-Ray Technologies Pty. Ltd., Australia) (30um molybdenum filter, 30kV, 2.1 mAs) and Fuji phosphor imaging plates scanned with a BAS-5000 scanner (25um pixels). The anterior ends of the sagittal implants were overgrown with bone, whereas posterior ends were partially overgrown or remained exposed. The control slices were thicker, with more trabecular and cortical tissue. In the coronal sections, the implants were overgrown so as to be effectively translocated to deep within the calvarial bone. Again, bone around the implants was thinner than on the control side. Osseointegration was observed around the attachment screws but not the dummy heads or immediately beneath the connecting bars. In these areas, fibrous connective tissue and granulation tissue were observed, indicating an inflammatory response, later confirmed by histology. Craniofacial implants reduced the amount of new bone formed in the calvarium, probably a response to their force-bearing properties. This was readily observed in the PCI images, which provided greater detail than conventional radiographs. The variable inherent magnification of PCI also permitted closer examination of areas of interest, in addition to digital manipulation. Phase-contrast X-ray imaging appears to have potential for a wide variety of hard tissue research applications.

The Primer Metabolic Processes on the Bone after Xenobiotics Treatment. Z. Valkusz[1], M. Gálfi[2], A. Juhász[3], O. Vetró[2], A. Farkas[2], A. Petri[4]. [1]Dept. of Endocrinology, University of Szeged, Szeged, Hungary, [2]Faculty of Juhász Gyula Teacher Training College, Department of Biology, Environmental Sciences Team, University of Szeged, Szeged, Hungary, [3]Dept. of Psychiatry, University of Szeged, Szeged, Hungary, [4]Dept. of Surgery, University of Szeged, Szeged, Hungary.

From **earlier studies** is known, that on the cellular and higher organization levels the normal neuronal, hormonal, and immune regulation determine the synthesis of bone matrix. The xenobiotics disturb these processes, by the systemic endocrine-immune intra- and extracellular effects of these agents. The xenobiotics change the function of osteoblasts, and osteoclasts, the mineral content, and the fundamental structure of the bone matrix. Our **aim** was investigate the effects of halogenic-hydrocarbones on the changes of bone formation. The hormone levels and calcium level in serum, and calcium content in the bone were measured. Wistar rats (100-120 g b w.; female, male/exp. group) treated with chlorobenzene by stomach-bougie, for10-30 days (hexachlorobenzene: 2,4,6-trichlorobenzene; one-to-one rate each 25µg/bw.kg.) were used in this experiment. **Control system:** normal control (untreated); positive control (1,5% ethanol treated); negativ-1 control (only stomach-bougie); negative-2 control (water treated). After the treatment the steroid hormone levels, the calcium content in the serum and in the bone were measured. The structure of the bone was studied after different histological stains for morphological analysis. **Our results**: The bone structure showed strong morphological deformation in fundamental bone matrix. This destruction in the bone matrix correlates with the changes of the hormone- and calcium levels in the serum and in the bone. (This work was supported by: ETT 06402/2000)

Bone Parameters In Remnant Kidney Osteopontin Knockout Versus Wildtype Mice. A. R. J. Bervoets*, V. P. Persy*, G. J. S. Behets*, M. E. De Broe, P. C. D'Haese*. Nephrology-Hypertension, University of Antwerp, Antwerp, Belgium.

To further unravel the role of osteopontin in bone remodeling, we induced chronic renal failure in osteopontin knockout and wild type mice. Bone histomorphometric analysis was performed in the "remnant kidney" mouse model (3/4 nephrectomy) of both the osteopontin knockouts (n=13) and wild types (n=18). Four knockout and 6 wildtype mice were sham operated and served as controls for the effect of renal function on bone metabolism. Animals were sacrificed at 12 weeks after installation of the chronic renal failure and tibiae and femora of all animals were transferred and fixed in either Burkhardt or ethanol. Bone was embedded in methylmetacrylate. Bone histomorphometry was performed on Goldner stained sections. We found a lower ($p<0.05$) (mean ± SD) osteoid surface (1.5 ± 1.3% vs 3.3 ± 2.4%) and perimeter (13.0 ± 9.1% vs 25.6 ± 15.1%) in remnant kidney osteopontin knockout mice as was the case for the number of active osteoblasts (3.3 ± 8.4 vs 7.2 ± 7.1) and the number of osteoclasts (0.3 ± 0.9 vs 1.8 ± 1.9) per unit of osteoid perimeter lining the resorption lacunae. There was no statistical difference in sham operated knockout versus wildtype mice. These findings indicate that osteopontin plays a role in the development of renal osteodystrophy. Further experiments and dynamic histomorphometry are needed for a better understanding of the exact role of osteopontin in bone remodelling.

Immunohistochemical Localization of Lysyl Oxidase and Its 18kDa Pro-Peptide in Endochondral Bone Development and in Differentiating MC3T3 Cells. N. R. Pischon*, A. H. Palamakumbura*, Y. Guo*, R. B. Santana*, P. C. Trackman. Oral Biology, Boston University, Boston, MA, USA.

Endochondral bone formation is a suitable model to study the sequential events of mesenchymal cell differentiation. Limited data suggest that the lysyl oxidase pro-peptide has modulating effects on differentiating bone forming cells. The 18 kDa pro-peptide, is a cationic, arginine-rich protein which is spliced from the 50 kDa pro-lysyl oxidase by procollagen-C-proteinase, a Bmp1 gene product. We investigated the spatial distribution of the pro-peptide and the mature enzyme in the process of endochondral ossification. Upper tibial growth plates, metaphyseal and epiphyseal bone as well as articular cartilage were obtained from 2 week old male mice (CD1). Dissected tissues were fixed in 4% paraformaldehyde and decalcified (7% EDTA, pH 7.4) for 16 days at 4 °C. Serial sections were cut at 6 µm thickness utilizing a cryostat. In addition, in order to determine forms of lysyl oxidase protein expression in osteoblasts, murine calvarial cell cultures (MC3T3) were plated in 4-well chamber slides at a density of 40,000 cells/well. Confluent cell monolayer where treated with differentiation media (10 % FCS, ascorbate, ß-GP) for 6 days and then processed for immunohistochemistry. Primary pro-peptide antibody (Ab), and anti-mature 30 kDa lysyl oxidase Ab, were produced as described earlier[Uzel 2001; Palamakumbura 2002]. Non-immune antisera was used as control. Microscopic images were captured using the Image Processing Solution (IPS) System (Media Cybernetics). Results show strong lysyl oxidase pro-peptide staining in the resting as well as the late hypertrophic cartilage zone. Different from type II collagen, which is expressed in the extracellular matrix, a cell associated accumulation of the lysyl oxidase pro-peptide was detected in vivo. This observation can be confirmed by a discrete cell associated pro-peptide expression in MC3T3 cells. Calcified bone matrix in the primary and secondary ossification zone was highly immunoreactive for the pro-peptide as well as for the mature lysyl oxidase. Little staining for mature 30 kDa lysyl oxidase was seen in resting cartilage, suggesting that the released lysyl oxidase pro-peptide may accumulate preferentially in this area. The observed staining patterns for the lysyl oxidase pro-peptide in vivo and in vitro suggest that it could have a role in chondrocyte and osteoblast differentiation.

The Matrix Extracellular Phosphoglycoprotein OF45 Is Down-Regulated by Growth Factors and Osteotropic Hormones. D. N. Petersen, A. Mansolf*, T. A. Brown. Osteoporosis, Pfizer Global Research and Development, Groton, CT, USA.

OF45, also known as MEPE, is a bone-specific extracellular matrix protein that has been implicated in the process of mineralization. Targeted disruption of MEPE in the mouse was previously reported to increase bone mass. In order to gain further understanding of the role of OF45 in the normal physiology of bone, in this report we determined the regulation of OF45 mRNA by various growth factors, steroid and osteotropic hormones. UMR106 cells were treated with and without 10 nM dexamethasone (DEX) with the following compounds for 7 days: PGE2, PTH(1-34), IGF-I, 1,25 dihydroxyvitamin D3 (VD), retinoic acid, estradiol, dihydroxytestosterone, and progesterone. DEX induced the expression of OF45 mRNA in these cultures. No OF45 mRNA was detected in the absence of DEX treatment under any of the conditions. Therefore, all subsequent determinations were in the presence of DEX treatment. Under these conditions, PGE2, PTH, and VD markedly reduced the expression of OF45. Other treatments had no effect on OF45 expression. In order to further define the time course of expression, UMR106 cells were treated with PGE2, PTH or VD for 4 h, 8 h, 24 h, 72 h, or 7 days. VD reduced OF45 mRNA expression at 24 h and 72 h and no OF45 mRNA could be detected after 7 days of VD treatment. OF45 mRNA expression was reduced with PGE2 treatment at 72 h and completely eliminated with 7 days of treatment. PTH reduced OF45 mRNA expression even more rapidly with a slight reduction by 4 h, marked reduction by 72 h; and complete elimination after 7 days of treatment. Since both PTH and PGE2 can act by increasing cAMP activated pathways, we determined that activation of these pathways with forskolin also had a pronounced effect on OF45 mRNA expression; ~50% reduction by 8 h and total abrogation by 24 h. To further delineate the mechanisms of regulation, the protein synthesis inhibitor cyclohexamide (CHX) was added for 24 h to cultures that had been pretreated for 6 days with 10 nM DEX. CHX dramatically reduced the expression of OF45 mRNA, suggesting that sustained new protein synthesis was necessary for the elevation of OF45 mRNA expression by DEX. In the absence of protein synthesis, neither VD, PTH, PGE2 nor forskolin further reduced OF45 mRNA expression, suggesting that down-regulation by these agents also requires new protein synthesis. In summary, OF45 mRNA expression is markedly reduced by VD, PTH and PGE2, agents known to be important in the regulation of bone formation and bone resorption. These data, combined with the increase in bone mass reported in OF45 knockout mice, suggest that OF45 has a role in the physiological processes regulating bone homeostasis.

Osteocalcin Response to Stress in Lewis and Fischer 344 Rats. P. E. Buckendahl[1], G. Blakley*[1], L. Pohorecky*[1], S. Rao*[2], B. Martin*[2], R. Kvetnansky*[3]. [1]Center of Alcohol Studies, Rutgers University, Piscataway, NJ, USA, [2]University of California, Davis, CA, USA, [3]Institute of Experimental Endocrinology, Bratislava, Slovakia.

Lewis (Lew) and Fischer 344 (F344) rats are histocompatible inbred strains derived from Sprague-Dawley rats selected for the response of the hypothalamic-pituitary-adrenal (HPA) axis to stressful psychosocial and environmental stimuli. Lew are hyporesponsive and have a defective hypothalamic production of corticotropin releasing hormone, while F344 are hyperresponsive. Because of the importance of the HPA axis to bone metabolism we investigated bone and osteocalcin (OC) in male Lew and F344 rats. OC is highly responsive to stressful stimuli, acutely elevated by foot restraint immobilization (IMMO), and slowly decreased by anxiety inducing stimuli. IMMO of 4 mo old and 24 mo old male F344 rats (n=8 each) induced significant elevation of OC ($p < 0.01$) which was greater in old (120%) than young (34%) rats compared with non-IMMO controls after 2 hr. Second, we obtained timed samples via tail cannulae during IMMO of 3 mo old F344 (n=7) and Lew (n=5) rats. Lew rats were higher than F344 at baseline and did not change significantly during 120 min, while F344 increased 43% after 5 min IMMO and remained elevated for at least 60 min ($p< 0.01$). Corticosterone (cort) levels for these rats (previously published Moncek et al, 2001) were elevated in both strains, but lower in Lew than F344 verifying the divergent stress response. Third, we evaluated growth, bone strength, and OC response to social interaction in 6 Lew and 8 F344 rats, beginning at age 2 mo. Intra-strain diad pairs were formed to evaluate dominant and submissive behaviors previously shown to elicit strong cort response. Blood was obtained from tail cuts to establish basal levels of OC and cort. On the following day, rats were paired for 15 minutes and social behaviors recorded, followed by a second tail blood sampling. OC in Lew did not change in spite of clear evidence of dominance or submission, but was decreased by 25% in F344 ($p < 0.01$). Basal cort in F344 was nearly 3 times higher than Lew (243 ± 35 vs 89 ± 18 ng/ml) and was further elevated by social interaction in both strains (666 ± 30 and 370 ± 30 ng/ml, F344 and Lew respectively, $p << 0.001$). At time of arrival in the laboratory, Lew were significantly heavier than F344 (210 ± 2 vs 177 ± 2). This relative difference was maintained until sacrifice at 5 mo (362 ± 10 vs 336 ± 7, $p < 0.05$). F344 femurs were shorter ($p < 0.01$), diaphysis thinner ($p < 0.05$), and bones more fragile ($p < 0.05$) than Lew, consistent with published findings in females of the same strains. We believe these two rat strains will be an excellent model in which to study relationships between the HPA axis and bone in response to stressful stimuli.

Tensile Stress-inducible α-adaptin C Enhances Endocytosis and Osteoblast Differentiation in Calvarial Sutures. J. Shimomura*[1], O. Ishibashi[2], M. Ikegame[3], T. Yoshizawa*[2], S. Ejiri[3], T. Noda*[1], H. Kawashima[2]. [1]Division of Pediatric Dentistry, Course for Oral Life Science, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [2]Division of Cell Biology and Molecular Pharmacology, Course for Oral Life Science, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [3]Division of Anatomy and Cell Biology of the Hard Tissue, Course for Oral Life Science, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan.

We previously demonstrated that tensile stress- (TS) induced osteoblast differentiation with the increased expression of several genes including bone morphogenetic protein-4 (BMP-4)[1] and tetranectin[2], which eventually led to osteogenesis in an organ culture of mouse calvarial sutures. In the present study, we employed RNA-fingerprinting arbitrary primed polymerase chain reaction to identify α-adaptin C, a component of the endocytosis machinery AP2, as a TS-inducible gene in the sutures. Western blotting revealed that protein production, as well as gene expression, of α-adaptin C was induced by TS as early as 3 hr following the initiation of loading. By *in situ* hybridization we demonstrated that the induction of α-adaptin C occurred not only in (pre)oteoblasts but also in alkaline phosphatase (ALP)-negative fibroblastic cells in the sutures, suggesting that it precedes TS-induced osteoblast differentiation. Overexpression of α-adaptin C in A431 epithelial cells resulted in the enhanced internalization of fluoroscein-labeled epidermal growth factor (EGF), thereby indicating that increased α-adaptin C expression eventually stimulates receptor-mediated endocytosis. Several proteins in TS-loaded and control sutures were differentially tyrosine-phoshorylated by EGF. Among the proteins, extracellular signal-regulated kinases (ERKs) were hyperphosphorylated in the TS-loaded sutures relative to control sutures after EGF stimulation. Since EGF receptor (EGFR) endocytosis has previously been reported to positively rather than negatively regulate EGF-induced ERK phosphorylation, our data raise a possibility that TS activates the endocytosis of growth factor/hormone receptors represented by EGFR. Further, TS-induced ALP activity in the sutures was significantly suppressed when endocytosis was inhibited by potassium depletion. These results, taken together, suggest that TS accelerates osteoblast differentiation and subsequent osteogenesis, at least in part by the induction of α-adaptin C protein and consequent activation of endocytosis.

Effect of Long-term Skeletal Unloading on Articular Cartilage and Bone of Growing Rats. M. Tomiya*, S. Ichimura*, T. Kikuchi*, Y. Yoshihara*, T. Kobayashi*, K. Fujikawa*. Orthopaedic Surgery, National Defense Medical College, Tokorozawa, Japan.

We investigated the effects of skeletal unloading on articular cartilage. Sixty-four 9-week-old male F344/N rats were randomly divided into two groups: caged control (C) and tail suspended (TS). Hind limbs of the TS rats were subjected to unloading for up to 12 weeks. Animals were injected twice with calcein to label the site of the mineralization front (tidemark) in the articular cartilage. The sequential changes of the patellar cartilage and bone were analysed by pathological findings with hematoxylin-eosin stain and alkaline phosphatase (ALP) stain. Total cartilage area (TCA), calcified cartilage area (CCA)/TCA, and bone volume (BV)/total volume (TV) both in medial and lateral facets and the tidemark mineral apposition rate (tidemark MAR) were analysed in the section of the distal one-third of the patella. The values of cross-linked C-telopeptide of type II collagen (Col2CTx) in 24 h urine were also measured by ELISA. A partial defect of patellar cartilage at the medial facet margin was found in 94% of the TS animals after 9 weeks or more of tail suspension, but no fibrillation was observed in the remaining articular surface. In the medial facet of the patella at 3 and 6 weeks, most of the subchondral bone marrow was in direct contact with the calcified cartilage. TCA in the medial facet was significantly decreased after the first 3 weeks, but no such significant differences were found in the lateral facet. In contrast, CCA/TCA significantly increased after 3 weeks. Bone atrophy was also observed, with significant decreases in BV/TV after 3 weeks, and was more marked in the medial facet than in the lateral at 3 weeks. Tidemark MAR was sequentially reduced in both groups. In the TS group, it was highest at the first 3 weeks and had a tendency to be elevated compared with the C group. The number of ALP-stained chondrocytes in the deep zone in the TS group was greater than in the C group. Urinary Col2CTx excretion in the C group slowly decreased during the experimental period; however, the excretion in the TS group was highest at the first week and was significantly elevated until 9 weeks compared with the C group. This study indicated that skeletal unloading accelerated advancement of not only the tidemark, which was preceded by a high level of ALP expression in chrondrocytes in the deep zone but also the subchondral ossification front. Also, revealed was a full-thickness cartilage defect in the medial margin of the patella without any fibrillation of the remaining articular surface. These results suggested that long-term skeletal unloadings could cause the destruction of the articular cartilage in the different way from that induced by overloading.

SA060

Development of a Model of the Regulation of Bone Strength Based on Data from 29 Genetically Inbred Strains of Mice. J. E. Wergedal[1], M. H. C. Sheng*[1], C. L. Ackert-Bicknell*[2], W. G. Beamer*[2], D. J. Baylink[1]. [1]Musculoskeletal Disease Center, J.L. Pettis VAMC, Loma Linda, CA, USA, [2]The Jackson Laboratory, Bar Harbour, ME, USA.

In order to develop a model of the regulation of bone strength that is based on universal relationships among various parameters contributing to bone strength, we undertook a study of 29 genetically different inbred strains of mice. Each strain was evaluated at 10 weeks of age for femoral volumetric bone density and size by the Norlan pQCT, bending bone strength of the femur by the DynaMite instrument, as well as femoral bone length and body weight. All animals were reared and housed under identical environmental conditions. We selected maximum load as our strength parameter for model development. There was a 26% CV in bone strength in the strains studied, which was only slightly reduced to 21% by dividing by body weight. In our model, bone strength was determined 38% by bone density, 42% by architecture (moment of inertia), and 20% was due to measurement error, plus other unknown factors. Accordingly, the multiple correlation coefficient for bone density and moment of inertia, versus bone strength, was r=.91, p<.001. In the moment of inertia component, 22% of variation was accounted for by growth in femur length, 12% by adaptation (body weight), and 8% was unaccounted for. We next sought to evaluate bone quality. Sigma max is strength corrected for size, is an estimate of bone quality (which includes material bone density) and showed a 19% variation among these inbred strains of mice, suggesting that some of the material properties of bone are variable and genetically determined. By regression analysis, material bone density accounted for 48% of the variation in sigma max. This is surprising and may indicate that material density contributes to the variance in bone strength. We next sought to determine the relationship of two major determinants of bone strength, bone density and bone size (ie moment of inertia), with body weight, since, to some extent, body weight reflects the amount of mechanical stress imposed upon the femur. For bone density, there was only a low correlation with body weight (r=.23), whereas for moment of inertia (even after adjustment for length) there was a stronger correlation, (r=0.56, p<.01). Summary and conclusions: 1) bone size (ie moment of inertia) and bone density are the major determinants of bone strength and both are genetically regulated. 2) Mechanical stress may have more influence on bone size than bone density. 3) Sigma max (bone quality) is genetically regulated.

Interlaminar Discectomy and Selective Foraminotomy in Degenerated Lumbar Lesions. S. Singh*, M. Garg*. Orthopaedics, B.P.Koirala Institute Of Health Sciences, Dharan, Nepal.

Objective: To assess the clinical outcome of interlaminar discectomy in patients suffering with degenerated lumbar disc lesions. **Methods:** We made a prospective study of 50 consecutive patients who underwent limited lumbar discectomy, based on specific objective patient selection criteria. The clinico-radiological parameters, type of surgery performed and the post-operative follow up were assessed. **Results:** Interlaminar discectomy without laminotomy was adequate in 33 cases (66%). Most patients requiring laminotomy (17 cases –34%) for discectomy had associated lumbar canal stenosis, herniation at proximal levels (L3-4) and/or sacralization of L5 vertebra. Selective foraminotomy in addition to discectomy was performed in 28 cases (56%). The post-operative results were good in 43 (86%) fair in 6 (12%) and poor subjective in 1 case (2%). No patient was classified as poor objective. **Conclusion :** Interlaminar discectomy without laminotomy is a safe, effective and reliable surgical technique for treating properly selected patients with herniated lumbar disc at L4-5 and L5-S1 levels.

Inhibition of Proteolytic Cleavage of MEPE by *Phex*. R. Guo*[1], P. S. N. Rowe[2], S. Liu[1], L. D. Quarles[1]. [1]Center for Bone and Mineral Disorders, Duke University Medical Center, Durham, NC, USA, [2]Institute for Drug Development and Molecular Therapies, The University of Texas Health Science Center, San Antonio, TX, USA.

X-linked hypophosphatemia (XLH) is caused by inactivating mutations of *Phex*, a phosphate regulating endopeptidase predominantly expressed in osteoblasts. Abnormal *Phex* in osteoblasts derived from the *Hyp*-mouse homologue of XLH results in the accumulation of an unknown factor that inhibits mineralization of extracellular matrix *in vitro*. We investigated whether the matrix extracellular phosphoglycoprotein MEPE, which is also increased in *Hyp*-osteoblasts, is a *Phex* substrate using recombinant *Phex* produced in *Sf9* cells. We found that *Phex* did not directly hydrolyze MEPE, but that endogenous cathepsin-like enzyme activity present in *Sf9* cells cleaved recombinant human MEPE into two major fragments of ~50 and ~42 kDA. The expression of mouse recombinant wild-type *Phex* protein (r*Phex*WT) in *Sf9* membrane fractions or pretreatment of *Sf9* membranes with leupeptin prevented the hydrolysis of MEPE by *Sf9* membranes. Moreover, purified Cathepsin B mimicked the effects of *Sf9* membranes to degrade MEPE. In addition, Cathepsin B-mediated MEPE cleavage was blocked by r*Phex*. *Phex* enzymatic activity, however, was not required to inhibit *Sf9* membrane cleavage of MEPE, since EDTA, which inhibited *Phex*WT activity against a chromagenic peptide Z-Ala-Ala-Leu-pNA, failed to prevent *Phex*WT inhibition of MEPE cleavage by *Sf9* membranes. The C-terminal domain of *Phex* was required, since r*Phex*(1-433)3'M, a C-terminal deletion mutant, did not block *Sf9* cleavage of MEPE. These findings suggest that non-ezymatic actions of the *Phex* interfere with the metabolism of MEPE *in vitro*. Whether non-enzymatic actions of *Phex* are involved in the physiologic regulation of MEPE degradation and control of mineralization *in vivo* remain to be established.

Temporal Expression of Metalloproteinases and Angiogenic Factors during Murine Fracture Healing and their Dependence on TNF-alpha. W. Lehmann[1], C. C. Edgar*[2], T. Cho[3], A. W. Tsay*[2], J. M. Rueger*[1], L. C. Gerstenfeld[2], T. A. Einhorn[2]. [1]Department for Trauma and Reconstructive Surgery, University Clinic Hamburg-Eppendorf, Hamburg, Germany, [2]Department of Orthopaedic Surgery, Musculoskeletal Research Laboratory, Boston, MA, USA, [3]Department of Orthopaedic Surgery, Seoul National University College of Medicine, Seoul, Republic of Korea.

The progression of endochondral ossification during fracture healing is dependent on the concurrent processes of proteolytic degradation and ingrowth of new blood vessels that allow osteogenic and osteoclastic cells to facilitate the primary resorption of the calcified cartilage. Thus the expression and activation of selective metalloproteinases (MMP´s) that cleave the extracellular matrix and the expression of specific angiogenic factors are essential for both the remodelling and induction of new bone formation. Our previous investigations have shown that TNF-alpha is a key mediator at multiple steps during fracture healing. The aims of this study were to identify metalloproteinases and important angiogenic factors that are temporally expressed during fracture healing and determine if TNF-alpha functionally affects these processes. RNA expression was examined over a 28-day period following the generation of simple transverse fractures in mouse tibiae of TNF-alpha receptor null (p55-/- p75-/-) and strain matched control mice. The effects of TNF-alpha on the expression of specific MMPs and angiogenic factors was also examined ex vivo in cultures of cells prepared from eight day post fracture callus tissues. Using microarray analysis we examined the expression of 20 MMPs, their associated inhibitors and 23 different angiogenic factors during murine fracture healing. These data identify those MMPs and angiogenic factors that are expressed uniquely during both the period of endochondral resorption and later times during osteogenic tissue formation. Two of the unique findings of these data were the identification of pleiotrophin (OSF) as the quantitatively the highest angiogenic associated gene that showed peak expression during the endochondral phase and MMP8 which was restricted during the osteogenic phase. Both these genes were uniquely expressed by osteogenic lining cells and periosteal cells based on in situ hybridization. However MMP8 was also highly expressed by osteogenic cells infiltrating the areas of cartilage resorption. Multiple members of these two families of factors were delayed and showed altered levels of expression in the absence of TNF-alpha signaling. In summary the pattern of MMP and angiogenic factor expression during fracture repair shows unique temporal spatial and quantitative variations in the expression.

Matrix Metalloproteinase-9 Antisense Oligodeoxynucleotide Inhibits Osteoclastic Pit Formation on MATRIGEL-coated Dentin Slices. S. Niwa*[1], O. Ishibashi[2], T. Inui*[3]. [1]Tsukuba Research Institute, Novartis Pharma K.K., Tsukuba, Japan, [2]Cell Biology and Molecular Pharmacology, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [3]Tsu City College, Tsu, Japan.

We have previously demonstrated that the inhibitor of matrix metalloproteinases (MMPs), BB-94, inhibited osteoclastic pit formation on dentin slices coated with reconstituted basement membrane, MATRIGEL. On the other hand, the inhibitor had no effect on osteoclastic pit formation on naked dentin slices, indicating that MMPs are necessary for the migration of preosteoclasts and/or immature osteoclasts to bone surfaces through basement membranes, but not for direct bone resorption. However, it still remains to be demonstrated that which MMP in osteoclasts plays the most crucial role in the degradation of basement membranes. Since MMP-9 is a most abundant MMP in osteoclasts, we have investigated the effect of MMP-9 antisense phosphothiorate oligodeoxynucleotide (S-ODN) on the osteoclast-mediated degradation of MATRIGEL-coated dentin slices in the present study. Rabbit osteoclasts were cultured on the dentin slices for 24 h in the presence or absence of the antisense S-ODN in a medium containing 100 nM TfxTM-50, polycationic liposome, as a carrier of the S-ODN. The antisense S-ODN inhibited the osteoclastic pit formation in a concentration-dependent fashion. At 10 microM the antisense S-ODN reduced the total pit volume by approximately 40%. The sense S-ODN of MMP-9, which was used as negative controls, had no effect on the pit formation. The inhibitory effect of the antisense S-ODN similar to that of BB-94 demonstrates that MMP-9 is an MMP playing a major role in the migration of preosteoclasts and/or immature osteoclasts through basement membrane.

An Altered Bone Microenvironment Can Select a More Aggressive Multiple Myeloma Cell Line. H. Libouban*[1], M. Moreau*[1], M. Baslé*[1], R. Bataille*[2], D. Chappard[1]. [1]LHEA-GEROM, Angers, France, [2]INSERM U463, Nantes, France.

Bone destruction is the main clinical consequence of multiple myeloma (MM). Several cytokines implied in the bone remodeling can promote the tumor growth. Plasma cells are also secreting cytokines that activate bone remodeling leading to a "vicious circle" between bone and MM cells. The graft of 5T2MM mouse plasma cells in the C57BL/KaLwRij mouse mimics bone lesions observed in human. We recently showed that a pre-existing high bone turnover dramatically increases the growth of MM cells in a combined model 5T2MM+OVX (Ovariectomy). The 5THL cell line was naturally selected by the microenvironment in a 5T2MM-OVX mouse. Cells were propagated unchanged in normal C57BL/KaLwRij mice during 5 generations. This study characterized a new plasma cell line 5THL in terms of its morphology, expression of paraprotein, osteolytic activity and proliferative activity. Two groups of mice were injected intravenously with 1.5 106 of 5T2MM or 5THL cells. The development of the disease was monitored from 6 weeks post injection by serum electrophoresis to detect the presence of the paraprotein. Paraproteinemia was detected 6 weeks post injection in 5THL group and after 8 weeks in the 5T2MM group. At 8 weeks, the concentration of the paraprotein was 5 fold higher in the 5THL than in the 5T2MM group. All 5THL mice developed a hind-limb paralysis after 9-10 weeks and were euthanazied due to ethical consideration. Control mice were euthanazied at 16 weeks. Osteolytic lesions were analyzed by numeric radiography and X-ray microtomography. At 10 weeks, we observed the presence of numerous bone lacunae in the long bones of the 5THL mice. No extra osseous lesions were observed. We have euthanazied 3 animals in each group at 6 and 8 weeks post injection. Histological examination of the femur revealed infiltration of MM cells into the marrow cavity at 6 weeks in the 5THL group. Radiological lesions were observed at 8 weeks post injection in the 5THL group and at 10-11 weeks post injection in the 5T2MM group. The proliferative activity was assed by nucleolar organizer regions (AgNOR). Texture analysis of the nuclear DNA revealed marked differences between the 2 cells lines ($p<0.001$). The 5THL MM model closely mimics the human disease with higher and faster bone aggressiveness. This new aggressive cell line, with a preserved phenotype, was selected by an altered microenvironment due to an increased bone remodeling.

2-Methoxyestradiol Inhibits the Osteosarcoma Cell Growth by Inducing a Blockade in Cell Cycle. A. M. Kennedy*, R. T. Turner, A. Maran. Orthopedic Research, Mayo Clinic, Rochester, MN, USA.

Osteosarcoma occurs most frequently in childhood and adolescence. Although the combination of surgery and chemotherapy has led to improved survival rate, the mortality rate remains high and a definite therapy is not yet available. 2-Methoxyestradiol (2-ME), a naturally occurring mammalian metabolite of 17beta-estradiol has been implicated as a physiological inhibitor of tumor cell proliferation. 2-ME did not affect the growth of normal osteoblasts in rats or in cell culture but inhibited the proliferation of osteosarcoma cells and induced programmed cell death. To explore the beneficial effects of 2-ME in controlling osteosarcoma, we have investigated further the molecular mechanisms associated with its growth inhibitory actions. Flow cytometric analysis of 2-ME treated MG63 human osteosarcoma cells showed a 50% increase in the Go/G1 phase population and a 68% decrease in S phase population in the cell cycle compared to the vehicle control. Whereas the parent compound, 17beta-estradiol and other metabolites of estrogen (4 and 16-alpha hydroxyestradiol) did not have any effect on MG63 cell growth. These results demonstrate that 2-ME inhibits osteosarcoma cell proliferation by progression of cells from Go/G1 to S-phase. Thus, a reduction in cell proliferation as well as induction of cell death by apoptosis is responsible for the reduction in osteosarcoma cell number following treatment with 2-ME.

Molecular Characterization of Head and Neck Osteosarcoma Suggests a Distinct Disease Entity. D. Krishnadasan*[1], A. M. Deshpande*[1], D. G. Ammerman*[1], P. Bhatia[1], G. Pringle*[2], M. M. Sanders*[3], K. K. Unni*[4], M. F. Hansen[1]. [1]Molecular Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Department of Pathology, Temple University, Philadelphia, PA, USA, [3]Department of Pathology, University of Connecticut School of Medicine, Farmington, CT, USA, [4]Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, USA.

Osteosarcoma is the most common primary tumor of bone and the third most common malignancy in adolescents. Osteosarcoma of all sites accounts for approximately 20% of all malignant tumors of bone and approximately 7, 500 new cases annually in the United States. Although a majority of osteosarcomas occur in the long bones of the skeleton, 6-13% of all osteosarcomas occur in the head and neck. Evidence, such as the differences in the degree of cellular atypia, the frequency of local versus distant metastases, the time until metastases, and the median age of onset, suggests that primary osteosarcoma of the appendicular skeleton and primary osteosarcoma of the head and neck represent biologically discrete diseases. To demonstrate this hypothesis we chose to analyze expression patterns of genes implicated in appendicular osteosarcoma tumorigenesis. The expression patterns of these genes differed in head and neck osteosarcomas from those observed in the appendicular osteosarcomas. These results suggest that the mechanism of tumorigenesis in these two forms of osteosarcoma may also be distinct and that primary head and neck osteosarcoma may be a separate disease from appendicular skeletal osteosarcoma.

Inhibition of Renal Cell Carcinoma Growth in Bone by the Receptor Tyrosine Kinase Inhibitor, PKI166. K. Weber*[1], M. Doucet*[2], J. Price*[2], I. J. Fidler*[2]. [1]Surgical Oncology and Cancer Biology, University of Texas M.D. Anderson Cancer Center, Houston, TX, USA, [2]Cancer Biology, M.D. Anderson Cancer Center, Houston, TX, USA.

Purpose: The purpose of this study is to determine the effect of epidermal growth factor receptor (EGF-R) blockade on growth of renal cell carcinoma (RCC) in the bones of nude mice. Methods: Standard proliferation assays, Western blotting, and ELISA assays were used to characterize RBM1-IT4, a novel RCC cell line derived from a human bone metastasis. An experimental animal model was developed where intratibial injection of RBM1-IT4 cells produces lytic destructive lesions similar to those seen in patients with metastatic RCC. Faxitron analysis and immunohistochemical techniques were used to study the bone lesions. A double staining technique for CD31 and TUNEL was used to evaluate the presence of apoptotic endothelial cells. Results: RBM1-IT4 cells express high levels of EGF-R. Proliferation of these cells is increased 2.0-2.3-fold when stimulated with EGF or TGF-alpha. There is inhibition of proliferation from 12-63% when TGF-alpha and PKI166, a novel receptor tyrosine kinase inhibitor in increasing doses from 0.1-3.2 uM/ml, is added compared to TGF-alpha alone ($p<0.05$). Western blot analysis reveals an 11-fold increase in tyrosine autophosphorylation when RBM1-IT4 cells are stimulated with EGF and an 87% decrease when PKI166 (2.5 uM/ml) and EGF are added compared to EGF alone. Murine-derived bone endothelial cells also express EGF-R. They respond similarly to the addition of EGF or PKI166. Mice treated with PKI166 alone or in combination with Taxol show a marked decrease in radiographic bone destruction after 9 weeks. The mean tumor weights were 156 mg in the Control group, 24 mg in the Taxol group, 20 mg in the PKI166 group, and 8 mg in the PKI166/Taxol group ($p<0.05$). There is a decreased incidence of tumors in the PKI166 +/- Taxol groups. No drug toxicity was noted and the effect is maintained at 20 weeks. Immunohistochemical analysis reveals no difference in the presence of EGF, TGF-alpha, and EGF-R in the 4 groups. There is a marked decrease in activated EGF-R in the PKI166 and PKI166/Taxol groups. There is a decrease in tumor cell proliferation and an increase in tumor cell apoptosis as evidenced by PCNA and TUNEL staining in these groups, respectively. There is also an increase in apoptotic endothelial cells in the same groups. Microvessel density (CD31 staining) is decreased in the Taxol and Taxol/PKI166 groups. Conclusions: Blockade of EGF-R signaling with PKI166 causes a decrease in bone destruction and tumor growth in the bones of nude mice. This is due to a direct effect on the tumor cells and an indirect effect on the surrounding endothelial cells.

Bisphosphonate Induce Apoptosis in Stromal Tumor Cells of Giant Cell Tumor of Bone. Y. Y. Cheng*[1], L. Huang*[2], F. M. Lai*[3], M. H. Zheng[4], S. M. Kumta*[5]. [1]Department of Orthopaedics and Tramatology, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [2]Department of Orthopaedic and Tramatology, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [3]Department of Anatomical and cellular pathology, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [4]Department of orthopaedic surgery, University of Western Australia, Perth, Australia, [5]Department of Orthopaedics and Traumatology, Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China.

Giant cell tumor of bone (GCT) is a benign primary neoplasm of bone, but is locally aggressive and produces expansible and lytic lesions. Bisphosphonate has been known to prevent osteoclastic bone resorption by inhibiting osteoclast activity and promoting osteoclast apoptosis. Recent evidence also emerged that bisphosphonate has potent anti-tumor effect by inducing tumor cell apoptosis. Indeed there is level I clinical evidence that bisphosphonate therapy has beneficial effects in preventing the development of skeletal lesions in patients with giant cell tumor of bone. However the molecular mechanism involved remained unclear. We have therefore investigated whether bisphosphonate induce cell death in giant cell tumor of bone. Surgical specimens were collected from patients with GCT before and after clinical treatment with pamidronate. Electron micrographs and TUNEL assay were used to study the morphological changes associated with apoptosis. We demonstrated that pamidronate induce apoptosis in both stromal tumor cells and multinucleated giant cells in GCT. The percentage of apoptotic cells in specimens after pam-

idroate treatment was significantly increased compared with those before pamidronate treatment. Our observation suggests that bisphosphonate may inhibit tumor progression of GCT by inducing cell death in both stromal tumor cells and multinucleated giant cells.

SA077

Cellular Interplays Between Myeloma and Bone Cells Enhance Myeloma Expansion and Bone Resorption While Suppressing Bone Formation. M. Abe[1], T. Hashimoto*[1], T. Oshima*[1], H. Shibata*[1], S. Ozaki*[1], A. Shioyasono*[2], Y. Tanimoto*[2], K. Hiura[2], K. Moriyama[2], S. Kido*[1], D. Inoue[1], T. Matsumoto[1]. [1]Dpt of Medicine and Bioregulatory Science, University of Tokushima, Tokushima, Japan, [2]Dpt of Orthodontics, University of Tokushima, Tokushima, Japan.

We and others have identified and reported that CC chemokines macrophage inflammatory protein (MIP)-1 alpha and beta are among major osteoclast activating factors secreted by multiple myeloma (MM). Since MM cells almost exclusively expand in the bone marrow, close interactions with bone cells may be critical to the develoment of myeloma bone disease. We therefore investigated a role of such cellular interplays in the present study. First, MIP-1 stimulated adhesion of MM cells to stromal cells via VLA-4/VCAM-1, and to OCs as well. The MM cell interactions with stromal cells enhanced MIP-1 secretion. The MIP-1-induced adhesion also promoted IL-6 secretion by stromal cells and to lesser extent by OCs. IL-6 in turn enhanced both MIP-1alpha and beta secretion by MM cells. These results suggest that MIP-1 secretion by MM cells form a positive feedback loop with MM adhesion to stromal cells and OCs, and IL-6 production by these bone cells. As we previously reported, PBMC-derived OCs enhanced survival and growth of MM cells in a partially IL-6-dependent but strongly contact-dependent manner. Even though stromal cells also supported MM cell expansion, the effect was much weaker than that of OCs on the per cell basis. We found that in the presence of IL-6 and osteopontin (OPN) significantly increased the number of MM cells. This effect was blocked by neutralizing antibodies against OPN and IL-6 in combination. We also confirmed abundant expression of OPN receptors including CD44, VLA-4 and vitronectin receptor by MM cells. Importance of OPN was further supported by our observations that OCs secreted a much higher amount of OPN but much lesser IL-6 than stromal cells. Finally, we examined if MM cells affect osteoblast function in long-term primary osteoblast cultures. The results indicated that MM cell-conditioned media, but not MIP-1 itself, suppressed bone nodule formation either in the presence or absence of BMP-2, suggesting MM cells suppress bone formation through unknown mechanism. Consistently, measurements of metabolic bone markers in MM patients revealed that serum osteocalcin levels were relatively suppresed compared to urinary deoxypyridinoline excretion. We therefore conclude that the cellular interplays between MM cells and bone cells result in efficient activation of osteoclastic bone resorption and myeloma expansion as well as impaired bone formation, leading to an uncoupling status of bone turnover which causes rapid and profound loss of bone mass.

SA078

Vitamin D Enhances Caspase Dependent and Independent TNF- Induced Breast Cancer Cell Death - the Role of Reactive Oxygen Species and Mitochondria. R. Koren*[1], G. Weitsman*[2], U. A. Liberman[2], A. Ravid*[2]. [1]FMRC Physiology&Pharmacology, Tel Aviv University, Tel Aviv, Israel, [2]Tel Aviv University, Tel Aviv, Israel.

The in-vivo anti cancer activity of calcitriol (1,25(OH)2D3) may be partially due to potentiation of the activity of immune agents including the major cytotoxic cytokine, TNF. TNF can cause cell death by activating caspase dependent (apoptotic) and independent pathways, and reactive oxygen species (ROS) are thought to play a mediatory role in its action. Our aim was to investigate the role of caspases and the involvement of ROS in the interaction between calcitriol and TNF using MCF-7 human breast cancer cells as the experimental model. Caspase 3-like activity, implicated in the execution phase of apoptosis, was increased 6 hours following exposure of the cells to TNF. This activity was monitored by cleavage of the fluorogenic substrate DEVD-AMC and of the endogenous substrate Poly-(ADP-Ribose)-Polymerase. TNF-induced caspase activation was markedly enhanced by a 24-hour treatment with calcitriol in a dose dependent manner. Under these conditions calcitriol on its own had no effect on caspase 3-like activity or on cell viability. Co-treatment of cells with TNF and the pan-caspase inhibitor zD-cho, at a concentration that abrogated caspase 3-like activity, reduced the cytotoxic effect of the cytokine. However, calcitriol enhanced TNF cytotoxicity by the same extent, in the presence or absence of zD-cho. Pretreatment of MCF-7 cells with the antioxidants N-acetylcysteine, GSH, ascorbic acid and lipoic acid only slightly reduced TNF-induced caspase activity, but markedly inhibited caspase activation in cells co-treated with calcitriol. Antioxidants also inhibited caspase independent TNF-induced cytotoxicity in the presence or absence of calcitriol. These findings indicate that calcitriol enhances both caspase dependent and independent TNF-induced cell death by affecting ROS dependent event(s) in both pathways. Mitochondria are one of the major sites for ROS production in the course of TNF-induced cell death. Thus, we examined the effect of TNF on mitochondrial membrane potential (Dp) using the specific potential sensitive fluorescent probe JC-1. We found a transient increase in Dp, peaking about 9 hours after addition of TNF, which was followed by a marked decrease in Dp to about 80% of control levels after 24 hours. At all time points Dp was lower in cells treated with calcitriol for 24 hours, whereas the hormone on its own did not affect Dp. We conclude that the interaction between TNF and calcitriol at the level of the mitochondria can account for the ROS dependent enhancement of caspase dependent and independent TNF-induced cell death.

The Genotype of Metastatic and Non-metastatic Breast Cancer Cells Provides Insight into Their Phenotype. M. Bendre, T. Mon*, D. Gaddy-Kurten, L. J. Suva. Orthopaedics and Physiology and Biophysics, UAMS, Little Rock, AR, USA.

In order to understand the mechanism(s) that permit human breast tumors to metastasize specifically to the skeleton, a population of human breast cancer cells (MDA-MET) with an enhanced metastatic potential in vivo was isolated from an initial population of poorly metastatic tumor cells MDA-MB-231 (MDA-231). We reasoned that genetically related cell lines with distinct metastatic phenotypes would be useful for the identification of genes involved in the metastasis of breast cancer cells to bone. Having identified the distinct phenotypes of MDA-231 and MDA-MET, the role of PTHrP in the metastatic phenotype of MDA-MET cells was evaluated. Basal PTHrP protein secretion was low in both cell lines, and not increased by the addition of 10 ng/ml TGF-b in MDA-MET. Gene expression profiling validated this specific phenotypic characteristic of MDA-MET cells and revealed a lack of TGF-b type II receptor mRNA. Array comparison between MDA-MET and MDA-231 defined the pattern of genes differentially expressed (greater than 2-fold up- or down regulated). Using a simple reductionist approach to focus attention on the process of bone metastasis, which is significantly different in the two related cell types, all differentially expressed genes was assigned to non-mutually exclusive metastasis-related process categories. A total of (7) process categories: proliferation, transcription and translation, signaling, motility invasion and cytoskeleton, immune surveillance, adhesion, angiogenesis were developed. This rationale assumed that if a gene was represented in multiple metastasis process categories, then that gene was more likely to play a significant role in the aggressive phenotype of the MDA-MET cells. The high rate of assignment of the candidate genes is presumably related to the design of the comparison (using cells with a similar genotype, but distinct metastatic potential) and the bias of the method used to assign the genes (PubMed search). Mining of the array data identified many genes whose expression was altered (e.g.: IL-8, tie-2) or absent (e.g.: CXCR1; RANKL) in MDA-MET cells. On the basis of this metastasis-related characterization, IL-8 was considered a candidate to be associated with the aggressive behavior of MDA-MET compared with MDA-231 cells. The elevated expression of IL-8 by MDA-MET cells was confirmed by RT-PCR. These data suggest that the genotype of MDA-MET cells may explain the functional metastatic phenotype in vivo. An understanding of the factors contributing to the metastatic potential of breast cancer cells will enhance the prospect of developing new therapies that impede the metastasis of breast cancer to bone.

Characterization of C4-2 Bone Metastasis and Its Response to Castration. E. Corey[1], J. E. Quinn*[1], A. M. Odman*[1], J. Zhang[2], E. T. Keller[2], R. L. Vessella*[1]. [1]Urology, University of Washington, Seattle, WA, USA, [2]University of Michigan, Ann Arbor, MI, USA.

Prostate cancer metastasizes with high frequency to bone. Well-characterized pre-clinical models of CaP bone metastases are needed in order to improve our understanding of the nature and development of CaP bone lesions in patients. Moreover, almost all patients with CaP bone metastases undergo hormone ablation, and it is therefore important to characterize models of bone metastasis under hormone-ablated conditions. The objective of this study was to characterize C4-2 bone metastases and their response to castration in a murine model. C4-2 cells were injected directly into tibiae of intact SCID male mice. Group-1 animals were sacrificed 8 weeks after injection of C4-2 cells. In group 2 animals were castrated three weeks after injection of C4-2 cells, and tumors were monitored for an additional 5 weeks. Blood samples were drawn for PSA determination to monitor tumor growth. Bone mineral density (BMD) was determined for all tibiae by Dual X-ray absorptiometry. Bone histomorphometric analysis was performed on un-decalcified tibiae stained with Goldner's stain. Our data showed that C4-2 cells cause a decrease of ~36% in BMD (p=0.0005) and ~74% in BV/TV (p=0.0131) *vs.* contralateral normal tibiae. The numbers of both osteoblasts and osteoclasts were significantly higher in C4-2 tibiae *vs.* normal tibiae (p=0.0370 and p=0.0089, respectively). When animals underwent castration we detected a drop in serum PSA levels in all animals, with a nadir at 14 days post-castration (67.7% of the starting PSA level, p=0.0059), after which PSA levels started to rise again. Tumor volume (TuV) in castrated animals was lower than in intact animals (p=0.0220). Castration decreased the bone destruction associated with C4-2 bone lesions: BMD of tibiae with tumor in castrated animals was ~18% higher than in intact animals but the difference did not reach significance (p=0.0899). However, C4-2 tumors after castration still caused bone destruction: BMD of tibiae with tumor in castrated animals was lower than BMD of normal tibiae (p=0.0006). In three of five castrated animals, %BV/TV was higher in tibiae with tumors than in intact animals, but the other two castrated animals exhibited %BV/TV in the same range as the intact animals. We also detected decreases in BMD and %BV/TV in tibiae without tumor in castrated *vs.* intact animals (p=0.0406 and p=0.0545, respectively). Based on our data, the C4-2 model of bone metastasis recapitulates the response to androgen-deprivation observed in CaP patients with mixed and lytic bone lesions. We conclude that this model is suitable for studying mechanisms associated with CaP bone metastasis and for evaluation of new therapeutic modalities.

Role of Estrogen Receptor Alpha in Aggressiveness and Osteoclastogenic Potential of Human Breast Carcinoma Cells. N. Rucci*[1], M. Brama*[1], E. Ricevuto*[1], A. Teti[1], S. Migliaccio[2]. [1]Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [2]Medical Physiopathology, University La Sapienza, Rome, Italy.

Since a correlation between breast cancer aggressiveness and estrogen receptor alpha (ER) expression has been hypothesized, we chose ER+ and ER- human breast cancer cell lines to address this issue in a culture system. MCF7(ER+) cells and an adriamycin-selected MCF7 clone failing to express ER (ADR) showed no difference in proliferation rate. However, a higher ability to migrate and invade gelatine and matrigel substrates was observed in ADR(ER-) cells. Enhanced invasiveness might result from increased MMP-9 activity and cytoskeletal re-arrangement, since ADR(ER-) cells expressed higher levels of tyrosine kinases involved in cell adhesion and motility, such as c-Src, PYK2 and FAK. In these cells, we also observed significantly higher levels of the alpha and beta2 PKC isoforms and a selective activation of the epsilon PKC isoenzyme. This was at variance with MCF7(ER+) cells, where the most abundant isoforms were beta1 and delta. Given the involvement of PKC alpha, beta and epsilon in cell motility, we believe that the pattern observed in ADR(ER-) cells may further account for their greater aggressiveness. To investigate the ability of the two breast cancer cell lines to induce osteoclastogenesis, mouse bone marrow cultures were treated with MCF7(ER+) or ADR(ER-)-conditioned media (CM). MFC7(ER+)-CM stimulated osteoclast formation and bone resorption. In contrast, ADR(ER-)-CM had no effect. Paracrine factors stimulating (IL-6, IL-1β, TNF-α) or inhibiting (IL-12, IL-18, GM-CSF) osteoclastogenesis were significantly increased in ADR(ER-) relative to MCF7(ER+) cells, raising the hypothesis that the inhibitory cytokines could selectively overwhelm the effects of the stimulatory ones in ER+ cells. Interestingly, treatment of osteoblast primary cultures with MCF7(ER+)-CM induced a selective up-regulation of IL-6 expression, suggesting an indirect stimulation of osteoclastogenesis and bone resorption via the osteoblast lineage. This occurrence was confirmed in vitro by treatment of mouse bone marrow cells with IL-6, which was found to increase both osteoclast numbers and pit formation. In conclusion, we have demonstrated that, despite a more invasive phenotype of ADR(ER-) cells relative to MCF7(ER+), these ER- cells failed to stimulate osteoclastogenesis and osteoclast activity. Therefore, we believe that ER might reduce aggressiveness of breast carcinoma cells but might enhance their osteotropism and consequently facilitate the development of osteolytic metastases.

Tyrosine Kinase Src Inhibitors: Cellular Mechanisms for Potential Therapeutic Applications in Bone Disease. I. Recchia*[1], N. Rucci[1], S. Migliaccio[2], A. R. MacKay*[1], C. Festuccia*[1], M. Bologna*[1], D. Fabbro*[3], M. Susa[3], A. Teti[1]. [1]Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [2]Medical Physiopathology, University La Sapienza, Rome, Italy, [3]Novartis Pharma, Basel, Switzerland.

A variety of cancers are associated with bone. Not only primary tumours can arise in this tissue but also common cancers, such as those of breast and prostate origin, metastasize to bone. The interaction of tumour cells with bone cells, either osteoblasts and osteoclasts, and with the bone local environment is a promising target for the development of new drugs against tumour bone diseases. c-Src proto-oncogene plays a critical role in osteoclast mediated bone resorption and osteoblast differentiation. Moreover, it is known that several tumours show high levels of c-Src expression. On this basis we tested the effects of pyrrolopyrimidine Src inhibitors on bone cell and tumour cell function. Src inhibitors, CGP77675 and CGP76030, exhibited a potent concentration-dependent inhibition of osteoclast maturation and mature osteoclast bone resorption ability. Moreover, they impaired osteoclast adherence and spreading, with a greater effect on mature vs immature cells. Src inhibitors triggered apoptosis, with apoptotic osteoclasts showing marked ERK1/2 activation and reduced expression of $p21^{WAF1/CIP1}$. They also dramatically reduced, concentration- and time-dependently, proliferation, adhesion and spreading of the human, bone metastasis-derived, prostate cancer cell line, PC3. However, the Src inhibitors were scarcely active in promoting cell detachment. When PC3 cells were left to attach to substrate prior to treatment with the inhibitors, cell adherence showed only 15% reduction at the highest concentration (20microM). Nevertheless, cells rounded up, confirming a role of Src in cell spreading. To evaluate the effect of Src inhibitors on the invasive potential, we plated PC3 cells in porous membrane transwells, coated with reconstituted Matrigel or gelatine. Adherent cells were treated with Src inhibitors and allowed to migrate vs chemoattractant (NIH3T3 cell conditioned medium). Results showed a dramatic concentration-dependent inhibition of PC3 cell ability to invade these substrates. These effects appeared merely due to block of cell motility, since changes in secretion and activity of MMP-2, MMP-9, uPA and their inhibitors TIMP1 and 2 were unremarkable. In conclusion, these data demonstrated not only a role for Src activity in the regulation of osteoclast and PC3 behavior, but also highlighted the cellular mechanisms through which Src kinase inhibitors could find an application as therapeutics, particularly in the field of bone and cancer-induced bone metastases.

The Effect of Osteoprotegerin Administration on the Intra-tibial Growth of the Osteoblastic LuCaP 23.1 Prostate Cancer Xenograft. J. A. Kiefer[1], R. L. Vessella*[1], J. E. Quinn*[1], A. M. Odman*[1], J. Zhang*[2], E. T. Keller*[2], E. Corey[1]. [1]Department of Urology, University of Washington, Seattle, WA, USA, [2]Department of Pathology, University of Michigan, Ann Arbor, MI, USA.

Skeletal deposits of metastatic prostate cancer (CaP) frequently cause an increase in bone remodeling which is predominately osteoblastic in nature. Associated with the osteoblastic lesions is a significant resorptive component, which may facilitate CaP growth in bone. Osteoprotegerin (OPG) is a soluble member of the TNF Receptor family, which functions as a decoy receptor for the pro-resorptive cytokine RANKL. Elevated levels of OPG are associated with a decrease in bone resorption. The objective of our study was to investigate the effects of exogenous administration of OPG on CaP growth in the bone, using the osteoblastic LuCaP 23.1 osseous CaP model. LuCaP 23.1 cells were injected intra-tibially and Fc-OPG (6.0 mg/kg) was administered subcutaneously three times a week either starting at the time of cell injection (prevention regimen) or at 4 weeks post-injection (treatment regimen). Administration of Fc-OPG resulted in an increase in bone mineral density (BMD) at tumor site as determined by dual x-ray absorptiometry (DXA). The BMDs of LuCaP 23.1 tibia from the control group (n=8) were 0.102 ± 0.026 g/cm^2, treatment group (n=8) 0.101 ± 0.022 g/cm^2, and prevention group (n=7) 0.130 ± 0.023 g/cm^2 ($p<0.05$ *vs.* control). The increase in bone density was confirmed histologically. In the animals receiving Fc-OPG, serum PSA levels decreased by 80% ($p<0.05$) and 74% ($p<0.05$) in the prevention and treatment regimens, respectively, compared to the untreated animals. Lower levels of PSA are often associated with decreased tumor growth, indicating that OPG may interfere with CaP growth in the bone. Our results suggest a potential role for OPG in the treatment of CaP bone metastases.

SA089

Validation of the ORAI, OST and Body Weight to Aid in the Identification of Women Aged 45 or More Years with Osteoporosis. S. M. Cadarette, S. B. Jaglal, W. J. McIsaac*, G. A. Hawker, L. Jaakkimainen*, A. Culbert*, G. Zarifa*, E. Ola*. University of Toronto, Toronto, ON, Canada.

The purpose of this study was to assess criterion validity of the Osteoporosis Risk Assessment Instrument (ORAI), the Osteoporosis Self-Assessment Tool (OST) and body weight to identify women with osteoporosis. The ORAI is an additive scoring tool based on age, body weight and current estrogen use. The OST is a mathematical equation based on age and body weight (OST=integer(0.2*weight)-integer(0.2*age)). Both tools target the identification of women with primary osteoporosis and recommend that decisions for testing among women at high risk for secondary osteoporosis or with prior fragility fracture be made independently. Body weight of at least 70 kg has also been suggested as a method to selectively exclude women for testing. Chart abstractions from family practices of 3 University affiliated hospitals were completed for women aged 45 years or more with baseline bone mineral density (BMD) testing results by dual energy X-ray absorptiometry. Participants taking bone active medication other than ovarian hormones, or at high risk for secondary osteoporosis were excluded. Receiver operating characteristic (ROC) curve analyses were used to evaluate the identification of women with osteoporosis defined as a BMD t-score ≤-2.5 SD at either the femoral neck or lumbar spine (L1-L4), N=691. Exact binomial 95% confidence intervals (CI) were calculated. At the thresholds of ≥9 (ORAI) and ≤1 (OST), and selecting body weight <70 kg, the sensitivity to identify women with osteoporosis was 92% (95%CI=85.0-95.9) for the ORAI, 91% (95%CI=83.9-95.3) for the OST and 93% (95%CI=87.1-97.0) using the weight criterion. The tools also selected 41% (ORAI, 95%CI=35.2-47.4), 30% (OST, 95%CI=24.5-35.9) and 52% (weight criterion, 95%CI=45.5-57.8) of women with normal BMD (t-score ≥-1.0 SD). Area under the ROC curves to identify women with osteoporosis were significantly better for both the ORAI (0.805, SE=0.02) and the OST (0.819, SE=0.02) compared with body weight (0.749, SE=0.02). Overall, all three methods proved to be good tools to aid the identification of women with osteoporosis. Each identified over 90% of women with osteoporosis yet selected fewer than 48% of women with normal BMD. Our results validate the efficacy of the ORAI and OST at the thresholds of 9 and 1 respectfully, and body weight <70 kg to identify women with primary osteoporosis. The practical application (clinical utility) of the OST equation compared with the additive ORAI or simple body weight to assist the identification of women with osteoporosis should be explored.

SA090

Ultrasound and DXA Bone Mineral Density in Patients with Ankylosing Spondylitis. H. Franck*, T. Meurer*. Center of Rheumatology, Oberammergau, Germany.

Introduction: Patients with ankylosing spondylitis well-known to have osteoporosis / osteopenia dependend on the inflammatory acitivity and immobilisation of the spine. Consequently controll measurements of bone densitometry has to be done more frequently than in the normal population. The aim of our study was to compare the ultrasound densitometry and DXA-measurements in patients with ankylosing spondylitis. Methods: We have incuded 184 patients with ankylosing spondylitis, all fulfilled the modified New York cirtria. We measured the bone mineral density with DXA (QDR 4500) in the right hip and lumbar spine and with ultrasound (UBIS 5000) in the calcaneum. Results: The best correlation was found between DXA of the right hip and ultrasound (tab.) Discussion: The hip total measured by DXA present with significant (p > 0,005) correlations with ultrasound measurements of the calcaneum. In contrast BMD of the lumbar spine did not show significant correlations with the ultrasound measurements. As measurements of BMD of the lumbar spine in patients with ankylosing spondylitis has limitations caused to disease specific changes of the lumbar vertebra, also sound measurement should be considered as an alternative.

Correlation Bmd hip total (BMD LS total) with				
	N =	mean value	r =	p =
Ultrasound BUA	184 (184)	65,32 (65,32)	0,235 (0,135)	0,001 (0,067)
Ultrasound T-Score	184 (184)	0,80 (0,80)	0,205 (0,119)	0,005 (0,108)
Ultrasound Z-Score	184 (184)	0,07 (0,07)	0,203 (0,133)	0,006 (0,072)

Digital X-ray Radiogrammetry Indices are Sensitive to Clodronate Treatment In Women With Osteoporosis. C. Haigh*[1], L. Reaney*[2], J. Adams[1], M. Davies*[1], P. L. Selby[1], J. Robinson[3], R. Francis[4], A. Dey[2], J. A. Kanis[2], J. Bostock*[2], C. Horvath*[5], J. Kenrali*[6], T. Jalava*[6], E. McCloskey[2]. [1]University of Manchester, Manchester, United Kingdom, [2]University of Sheffield, Sheffield, United Kingdom, [3]Crosby Clinical Research Centre, Liverpool, United Kingdom, [4]University of Newcastle, Newcastle, United Kingdom, [5]Simmelweis University, Budapest, Hungary, [6]Leiras Oy, Helsinki, Finland.

A number of new techniques have been developed for skeletal assessment that are more convenient than DXA, but require biological validation. The aim of this study was to determine the utility of DXR-BMD and metacarpal cortical index (MCI), estimated by the Pronosco X-posure system™, to assess responsivity to treatment with the bisphosphonate, clodronate, in a prospective clinical trial in osteoporosis. Women fulfilling the WHO criteria for osteoporosis (spine or hip T-score <-2.5) and/or with at least one prevalent vertebral fracture were recruited to a 3-year double-blind, controlled study. Hand radiographs on standard film were obtained at baseline in 538 women (91% of all participants) and were repeated annually during follow-up. The women received either clodronate 800mg daily by mouth (Bonefos®) or an identical placebo and all patients received a calcium supplement of 500mg daily. Bone density (BMD) was measured at the spine and total hip at 6, 12, 24 and 36 months by DXA. Prevalent and incident vertebral fractures were identified by morphometric evaluation of lateral spine radiographs obtained at baseline and annually thereafter. At entry, no significant differences in DXR-BMD and MCI were observed between the women randomised to clodronate or placebo. Treatment with clodronate was associated with highly significant differences in changes of DXR-BMD and MCI and other skeletal measures over 3 years compared to placebo (Table). The mean changes in DXR-BMD and MCI were of similar magnitude to those observed at the spine when expressed relative to precision errors (CV% for spine BMD, hip BMD, DXR-BMD and MCI of 1.3%, 1.6%, 0.6% and 0.7% respectively.)

% Change from Baseline (±SE)				
	Clodronate	Placebo	P-value*	Mean Diff./CV%
DXR-BMD	-0.68±0.17	-2.80±0.24	<0.0001	3.5
MCI	-0.86±0.17	-3.55±0.27	<0.0001	3.8
Spine BMD	5.14±0.48	0.60±0.46	<0.0001	3.5
Hip BMD	1.03±0.43	-3.33±0.45	<0.0001	2.7

* Using absolute changes

We conclude that DXR-BMD and MCI are sensitive to changes induced by anti-resorptive therapies. These measures have potential applicability in multi-centre clinical trials in osteoporosis and may be of similar utility to spine BMD for monitoring treatment in osteoporosis.

Disclosures: ***E. McCloskey****, Pronosco A/S, Vadbaek, Denmark 2; Leiras Oy, Helsinki, Finland 2.*

SA093

A Comparison of pQCT and DXA for Bone Density Measurements in the Mouse. G. Toraldo*, C. Roggia*, M. N. Weitzmann, Y. Gao, S. Cenci, R. Pacifici. Division of Bone and Mineral Diseases, Washington University and Barnes Jewish Hospital, St. Louis, MO, USA.

In studies with mice, bone densitometry is an established technique for the detection of the bone loss induced by ovariectomy (ovx). Today two different techniques are available for this purpose, peripheral quantitative computerized tomography (pQCT) and dual-energy x-ray absorptiometry (DXA). However, there is no consensus on which is the preferable method for studies in mice. Although used interchangeably, measurements by these methods differ quite considerably as only pQCT measures a true volumetric density and provides selective measurements of both trabecular and cortical bone. To test the diagnostic sensitivity of these methods, we measured BMD 4 weeks after either ovx or sham operation in mature C57BL/6 mice. pQCT measurements were obtained from isolated tibias using an XCT-960M Nordland instrument. Peripheral and central DXA measurements (total body, spine, femurs, limbs) were obtained in vivo using a PIXImus2, Lunar scanner and a Hologic QDR 2000, respectively. All three methods were able to discriminate between the two groups, but the greatest bone loss was detected by pQCT (-16%). Peripheral DXA was less sensitive (-14%) than pQCT but superior to central DXA which detected only a 9% difference between ovx and sham mice. pQCT measurements were highly correlated with peripheral DXA measurements (r = 0.74-0.80), depending on the anatomical site, while no significant correlations were found between pQCT and central DXA measurements. When peripheral DXA was compared to central DXA, significant correlations were found between each site measured using the peripheral device and total body and limbs measured with the central device. The remaining central sites did not correlate with any peripheral measurement. The coefficients of correlation for within-instrumental comparisons with peripheral DXA were >0.9 for all the sites analyzed, with the best correlation between total body and spine (r = 0.98). For central DXA, the best correlation was found between total body and spine (r = 0.81) and the poorest between spine and limbs (r = 0.04). The short term in vivo precision (CV) was 1.7% for peripheral DXA and 2% for both central DXA and pQCT. The precision of pQCT for repeated measures in vivo was ~ 5%. In conclusion, pQCT is the most sensitive method for ex-vivo cross-sectional studies and is the technique of choice when selective measurements of either trabecular or cortical bone are required. However, because of the higher precision, especially for repeated in vivo measurements, peripheral DXA measurements is the technique of choice for prospective in vivo studies.

Validation of a Risk Index to Identify Men with an Increased Likelihood of Osteoporosis. M. C. Hochberg[1], J. K. Tracy*[1], M. van der Klift*[2], H. Pols[2]. [1]Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Epidemiology, Erasmus University School of Medicine, Erasmus, Netherlands.

The Osteoporosis Self-assessment Tool (OST) was originally developed to classify the risk of osteoporosis (OP), as defined by low bone mineral density (BMD), in postmenopausal Asian women (Koh et al: Osteoporos Int 2001;12:699-705). The OST is easily calculated from just the patient's weight and age: OST = 0.2 (weight [in kg] - age [in years]); the result is truncated to the integer. We previously validated the OST in Caucasian women who were screened for eligibility for the Fracture Intervention Trial and those enrolled in the Rotterdam Study (Geusens et al: Mayo Clin Proc: accepted for publication). In the present analysis, we calculated sensitivity, specificity, positive and negative predictive values, likelihood ratios and post-test odds for the OST using data from two cohorts of older Caucasian men: the Rotterdam study (2445 men aged 55 and over) and the Baltimore Men's Osteoporosis Study (503 men aged 65 and over). BMD was measured in Rotterdam men using a Lunar DPX-L, and in Baltimore men using a Hologic QDR-2000. OP was defined as a BMD T-score of -2.5 or less at the femoral neck using young white male reference data from NHANES III. The OST risk groups were defined using the cutpoints of >2 (low risk), 2 to -2 (moderate risk), and <-2 (high risk). Results are shown in the table. Results were generally similar when OP was defined as a BMD T-score of -2.0 or less, although prevalence and proportions in all risk groups were higher. While there are presently no published guidelines for the assessment and treatment of OP in men, we conclude that this free and simple risk assessment tool could help increase awareness of and encourage the appropriate use of BMD measurements to diagnose OP in men.

Prevalence of OP in Older Men by Risk Group

Cohort	Baltimore	Rotterdam
Overall Prevalence of OP	6.6%	12.2%
Sensitivity (OST=2 or less)	88%	79%
Specificity (OST>2)	32%	51%
Low risk	2.6%	4.0%
Moderate risk	7.7%	16.5%
High risk	14.7%	34.9%

SA096

Radiographic Texture Analysis of Calcaneous Images in Assessing Bone Fragility. T. J. Vokes[1], M. R. Chinander*[2], M. L. Giger*[2], L. B. Dixon*[2], M. J. Favus[1]. [1]Medicine, University of Chicago, Chicago, IL, USA, [2]Radiology, University of Chicago, Chicago, IL, USA.

Radiographic texture analysis (RTA) of spine radiographs has been shown to predict the presence of vertebral fractures elsewhere in the spine. Also, RTA of the hip radiographs predicts bone fragility as measured in the mechanical strength testing of femoral neck specimens excised during hip surgery. The present study examines whether RTA of the heel images obtained using the peripheral densitometer PIXI can differentiate patients with from those without vertebral fractures. The subjects were 121 patients (age 61.7±13.2 years, range 18-92 years; 8 males) referred for densitometry who agreed to participate. BMD of the lumbar spine and proximal femur was measured using Prodigy and BMD and digital radiographic image of the left heel were obtained using PIXI (both from GE Medical Systems). Prevalent vertebral fractures (reduction in vertebral height of at least 25%) were identified using Lateral Vertebral Assessment (LVA) on Prodigy and/or standard radiographs of thoracic and lumbar spine. The PIXI heel images were subjected to computerized RTA yielding Fourier based measures: root mean square variation (RMS - a measure of the magnitude of fluctuation in trabecular texture pattern) and the first moment of the power spectrum (FMP - a measure of the texture pattern's spatial frequency content). 26/121 patients (22%) had vertebral fractures. We performed 3 types of statistical analysis: a) A multivariate logistic regression, which showed that the presence of vertebral fractures was predicted by a combination of texture features, age and T scores of the heel and femoral neck (but not spine). The effect was significant for the texture features (RMS at p=0.032, and FMP at p= 0.019) but not for any of the T scores. When the analysis was restricted to 105 subjects over 50 (21% with vertebral fractures), the results were even more significant (RMS at p=0.02, FMP at p=0.009). b) Receiver operator characteristic (ROC) analysis was used to assess performance of texture features and BMD in distinguishing between patients with and those without fractures. The area under the ROC curve (Az) was 0.56 for heel BMD, 0.51 for RMS and 0.58 for FMP. Combination of the two texture features RMS and FMP yielded an Az of 0.66 while the combination of RMS, FMP and BMD achieved an Az of 0.70. c) Linear regression to examine the relationships between texture features and BMD. A strong correlation was found between the texture features and heel (but not spine or femoral neck) BMD in patients with fractures (R^2 = 0.47, p<0.0001) but not in those without (R^2=0.005, p=0.5). We conclude that RTA may contribute information about bone structure not captured by the BMD measurement alone.

Disclosures: ***T.J. Vokes****, Merck 8.*

Relation Between Disease Activity and Apparent Trabecular Texture at the Wrist in Individuals with Rheumatoid Arthritis. N. J. MacIntyre[1], C. E. Webber[2], J. D. Adachi[3]. [1]Queen's University, Kingston, ON, Canada, [2]Hamilton Health Sciences, Hamilton, ON, Canada, [3]St. Joseph's Hospital, Hamilton, ON, Canada.

This pilot study characterizes the relation between disease activity and apparent radial bone trabecular texture in individuals with rheumatoid arthritis (RA). RA patients diagnosed within the past 8 years (n = 15) and age-matched controls (n = 15) were recruited. A high-resolution image was acquired at the 4% site of the nondominant radius for each subject using peripheral quantitative computed tomography (XCT 960, Stratec). From this cross-sectional image, indices of apparent trabecular texture (average hole size: H_A, maximum hole size: H_M, connectivity index) were determined using in-house developed software. Volumetric bone density (total: ToBD, trabecular: TrBD), bone mineral content (total: ToBMC, trabecular: TrBMC), and bending strength (Strain Stress Index: SSI) were also evaluated at the same radial site using commercial software. For RA subjects, disease activity was characterized by disease duration, counts of the number of active and damaged joints in both upper limbs, and scores on three subscales of the Arthritis Impact Measurement Scales 2 questionnaire (Physical Function Score, Arthritis Impact Score, and Arthritis Pain Score). Between-group differences and relations between disease activity and bone variables were analyzed using ANOVA and Pearson Correlation Coefficient analysis, respectively. Between-group differences were not detected although RA subjects tended to have higher values for H_A, H_M, and lower values for the connectivity index, density, and mass. Active joint count correlated with H_A (r = 0.57, p = 0.03), ToBMC (r = -0.66, p < 0.01), TrBMC (r = -0.55, p = 0.03), and SSI (r = -0.52, p = 0.04). Disease duration correlated with H_M (r = 0.60, p = 0.02). Damaged joint count correlated with TrBMC (r = -0.64, p = 0.01). Physical Function Score correlated with ToBD (r = -0.58, p = 0.02), ToBMC (r = -0.65, p < 0.01), and SSI (r = -0.74, p = 0.001). Arthritis Impact Score correlated with ToBMC (r = -0.54, p = 0.04), and TrBMC (r = -0.51, p = 0.05). No outcome measures correlated with connectivity index or TrBD. These data show that as the number of active and damaged joints in the upper limb increase, the H_A in the trabecular network increases and the bone mass and bending strength decreases at the ultradistal radius. In contrast, the Physical Function Score is related to bone density, mass, and bending strength but not the mineral organization in the trabecular network.

SA098

In vivo 3D-Evaluation of Bone Structure in the Human Forearm; A Time Saving and Non Invasive Procedure. M. Neff[1], M. A. Dambacher[2], P. Rüegsegger[3]. [1]Center for Osteoporosis, Zurich, Switzerland, [2]Univ. Hospital Balgrist, Zurich, Switzerland, [3]Inst. for Biomedical Engineering Univ. and Swiss Federal Inst. of Technology, Zurich, Switzerland.

Purpose: In vivo, till now only bone mass was available quantitatively. The non invasive evaluation of bone structures, which play an important role in the fracture risk prediction, was made qualitatively using high resolution 2D-CT-images (Densiscan 1000, Scanco Medical). Recently quantitative 3D structure analysis became available in vivo with the help of 3D-QCT (Densiscan 3D). Methods: The new system has a 2-dimensional detector array in combination with a 0.15 x 12mm line-focus x-ray tube (effective energy 40keV), enabling the simultaneous acquisition of a stack of 110 tomograms perpendicular to the bone axis with a maximal diameter of 90mm. The radial resolution is 160µm (10% MTF, isotropic voxel size 90µm) and axial 200µm (10%MTF). The tomograms are taken 7mm proximal from the endplate of the distal radius delivering a coverage of a region of about 10mm. The data acquisition time is about 2 minutes and the local skin radiation dose for a whole examination (scout view included) 2.5mGy. With automatic repositioning the reproducibility is <±1% (for structure elements) in mixed collectives. Results: In praxi it is now possible (see graph) to quantify microarchitectural features as number of trabeculae, trabecular and cortical thickness, trabecular spacing and endosteal surface in addition to the separate volumetric BMD of trabecular and cortical bone. Conclusions: Such a characterization will give better insight in pathogenesis, prevention and treatment of primary and secondary osteoporosis. It also improves individual fracture risk prediction; e.g. with the help of finite element analysis.

Assessment of the Tibia in Prepubertal Girls Using Ultrasonic Guided Waves. P. Moilanen, P. H. F. Nicholson*, T. Karkkainen*, Q. Wang*, J. Timonen*, S. Cheng. Univ. of Jyvaskyla, Jyvaskyla, Finland.

The purpose of this study was to compare low frequency guided ultrasonic wave measurements with established ultrasound and bone density measurements in terms of their ability to characterize human long bones. Subjects were 12-14 year-old girls (n=106) who participated in a calcium and vitamin D intervention study. A prototype low frequency pulse transmission device consisting of a uniaxial scanning mechanism and low frequency transducers orientated perpendicularly to the limb was used to measure ultrasound velocities in the tibia. This device recorded the velocity of two propagating waves: a lateral mode (V1) travelling at 3300-4400 m/s and an additional slower mode (V2) propagating at 1500-2000 m/s and which has been shown elsewhere to be consistent with the lowest order antisymmetric guided mode. In addition, commercial ultrasound devices (Omnisense, Sunlight Ltd., QUS-2, Quidel Corp) were used to measure the speed of sound (SOS) in the tibia and the radius, and attenuation (BUA) in the calcaneus. Bone mineral content (BMC), volumetric cortical density (BMD) and cortical thickness (CTh) of the tibia were measured using pQCT, site-matched to the ultrasound measurements. Both V1 and V2 correlated significantly with tibial BMC, BMD and CTh, SOS of the tibia and radius, and BUA of the calcaneus. On the other hand, SOS only correlated with BMD and no correlations were found between SOS and CTh. These results indicate that the prototype device using guided waves reflects aspects of tibial cortical bone geometry in addition to bone density, thereby offering the potential of increased diagnostic information compared to existing tibial ultrasound devices.

The Discrimination Between Cases of Hip Fracture and Matched Controls Is Improved with a Biomechanic Analysis. P. Mayhew*[1], N. Loveridge*[1], N. Rushton*[1], M. Parker*[2], H. Kroger*[3], J. Reeve[1]. [1]University of Cambridge, Cambridge, United Kingdom, [2]Peterborough District Hospital, Peterborough, United Kingdom, [3]University of Kuopio, Kuopio, Finland.

We tested the hypothesis that measures of bending resistance made ex-vivo would discriminate cases of hip fracture from controls better than BMD (BMC/Area), which in vivo typically produces mean case – control differences of – 0.5 Z score units. Peripheral Quantitative Commuted Tomography (pQCT) cross sectional images of the femoral neck were used. The fracture biopsies (n = 19,F) were from subjects that had suffered an intracapsular hip fracture. The control material (n = 22,F) was from post-mortem subjects, with no history of disease known to affect bone and who died in hospital within 14 days of admission. The biopsies were fixed and embedded in methylmethacrylate without decalcification. Serial 0.5 mm thick pQCT cross-sectional images were obtained using the Densiscan 1000, (Scanco AG) and matched for location along the neck. Assuming that the density of methylmethacrylate was a good surrogate for soft tissue density, this was subtracted from each pixel's density and the remaining pixels showing positive densities were mapped on to 2-D images for calculation of 2-D section modulus (SM) and BMD. SM was calculated with respect to distances from the horizontal neutral axis in stance (0 degrees). As shown in the Table the fracture cases had a considerably lower resistance to bending while there was a much less impressive differences in BMD between cases and controls. To simulate the forces experienced during a sideways fall on to the greater trochanter, the model's neutral axis was rotated by –45 degrees. This imposes the greatest compressive and tensile stresses on the superior-posterior and inferior-anterior aspects of the femoral neck respectively. The results for SM were quantitatively similar to those at 0 degrees. We conclude that measures of hip strength such as SM provided greatly improved discrimination between hip fracture cases and controls when scanning was simulated in the AP plane. Rotation of the femoral neck to align the scanning plane so as to measure SM in the fall-loading configuration did not affect discrimination.

Angle of Rotation (degrees)	BMD/Strength Quantity	Cases (mean)	Controls (mean)	Mean Z score Diff**	P
0	BMD	0.547 gm/cm2	0.606 gm/cm2	0.56	0.08

Comparison of BMD and Radiographic Texture Feature Analysis of Spine and Calcaneous in the Prediction of Vertebral Fractures. M. R. Chinander*[1], M. L. Giger*[1], Y. Peng*[1], L. B. Dixon*[1], T. Vokes[2]. [1]Radiology, The University of Chicago, Chicago, IL, USA, [2]Medicine, The University of Chicago, Chicago, IL, USA.

The addition of bone structure information via texture analysis of radiographic images may aid BMD in the assessment of bone strength and fracture risk. While the spine and hip are the anatomic sites of most interest, the assessment of the heel has advantages, namely low dose and efficient scanning in a screening environment. In this study, we compare the performance of BMD and radiographic texture analyses of the heel with those of the spine in terms of predicting the presence of vertebral fracture. Our database consists of fourteen subjects with at least one vertebral fracture and nineteen without a fracture. Spine and calcaneous BMD measurements were performed with Prodigy and PIXI peripheral bone densitometers, respectively. Lateral lumbar spine radiographs were obtained and digitized with 2905 Abe Sekkei (Tokyo, Japan) laser film digitzer to 0.100 mm pixel size. The BMD images from the peripheral bone densitomer were transferred to a Unix workstation for the texture analysis. Regions of interest (ROIs) were selected from the third lumbar vertebra on the digitized spine film and in the central portion of the calcaneous on the PIXI images. Fourier-based texture measures, including the RMS variation and first moment of the power spectrum were computed for each ROI. Receiver operator characteristic (ROC) analysis was used to assess the performance of the features in the task of distinguishing between fracture and non-fracture cases. The combination of the BMD measurements and texture features using linear discriminant analysis was also assessed. Results are summarized in the table. In general, the measurements from the spine performed better than those of the calcaneous. The use of texture analysis to assess bone structure from either the spine radiographs or heel BMD images was able to predict the presence of vertebral fractures about as well as BMD measurements at the same site.

Areas under the ROC curves (Az) for predicting the presence of vertebral fractures

Features	Spine Az	Heel Az
BMD	0.64	0.55
RMS Var., First Moment	0.68	0.58
RMS Var., First Moment, BMD	0.68	0.58

Absence of Marked Seasonal Change in Bone Turnover in a Large Multicenter Cross-Sectional Study. A. Blumsohn[1], K. E. Naylor[1], W. Timm*[2], A. C. Eagleton[1], R. Eastell[1]. [1]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [2]Arbeitsgruppe Medizinische Physik, OPUS Study Group, University of Kiel, Kiel, Germany.

Studies investigating the relationship between season and bone turnover are contradictory. Resolution of this issue is of substantial importance for the use of markers of bone turnover to monitor therapy in routine clinical practice, and for appropriate design of therapeutic and epidemiological studies. No information, is available on seasonality of reliable new serum markers of bone resorption. We investigated the effect of season on serum markers of bone turnover in a large population-based multicenter European study (n=2780 women, Osteoporosis and Ultrasound Study, OPUS). Participants from 5 different European cities (Aberdeen, Berlin, Kiel, Paris, Sheffield) were identified by random selection from registers of local general medical practitioners or lists of the local registry office. Measurements were performed in a randomised order, and included serum β-Crosslaps (sβCTX), procollagen type I N-terminal propeptide (PINP), and osteocalcin (OC). Seasonality was assessed by cosinor analysis with Hotelling's T2-test. Less than one percent of the between person variance was accounted for by seasonality for all markers (n = 2780). There was small but statistically significant summertime increase in OC and PINP in the healthy postmenopausal population after exclusions based on disease or medication use (remaining n = 1226, ages 50 to 80 years; amplitudes 5.6% and 5.4% respectively, $P < 0.001$). There was also a small but statistically significant seasonal trend in PTH with Amplitude 7.1% ($P = 0.038$) and estimated peak on the 9th of March. There was no significant effect of season on serum sβCTX. To assess the practical implications of season for the generation of reference intervals, 95% non-parametric reference limits were calculated by season. There was no major effect of season on reference intervals, but the small summertime increase was statistically significant for OC and PINP (one way ANOVA $P<0.05$), but not for sβCTX. We have been unable to confirm findings of a marked wintertime increase in bone formation and resorption within the general population. The absence of marked seasonality was irrespective of age, menopausal status, or geographical location. The statistically significant summertime increase in bone formation in this and other studies is unlikely to confound clinical interpretation of these measurements.

Biochemical Markers of Type I Collagen Synthesis and Degradation in Monitoring Osteoporosis Treatment with Raloxifene or Alendronate. J. J. Stepan, D. Michalska*, V. Zikan*, J. Vokrouhlicka*. 3rd Department of Internal Medicine, Charles University Faculty of Medicine, Prague, Czech Republic.

The aim of this study was to assess clinical value of biochemical markers of type I collagen synthesis (serum aminoterminal propeptide of type I collagen, S-PINP) and collagen degradation (serum type I collagen cross-linked C-telopeptide beta, S-CTX) in monitoring treatment of postmenopausal osteoporosis with raloxifene or alendronate. The open label study involved 165 postmenopausal women (mean age 63 ± 8 years). Fifty patients were treated for 1 year with raloxifene (60 mg/day), calcium (500 mg/day) and vitamin D (800 IU/day); 65 patients were treated with alendronate (10 mg/day), calcium and vitamin D; and 50 patients received calcium and vitamin D (control group). Premenopausal values were determined in 65 healthy women. S-PINP was measured by a radioimmunoassay (Orion Diagnostica). S-CTX was measured using the Elecsys (Roche). Bone mineral density at the lumbar spine and proximal femur was measured using the QDR 4500A Bone Densitometer (Hologic, U.S.A.). Before treatment, no significant differences in biochemical markers were found between the treatment groups. After one year of treatment with raloxifene, the increase of the spine BMD (1.45 ± 2.56%, n.s.) did not correlate with decrease in S-CTX (-50±16%, $p<0.01$) and S-PINP (-32±20%, $p<0.01$). A significant decrease in S-CTX was observed in 80% of the patients while an increase in BMD exceeding the least significant change was found in only 13/50 patients. After 1 year of treatment, mean S-CTX and S-PINP (345±124 ng/l, and 34±8 ug/l, respectively) was at the range of the premenopausal levels (284±72 ng/l, and 31±9 ug/l, respectively). After 1 year of treatment with alendronate, both S-CTX and S-PINP (99±41 ng/l, and 14±4 ug/l, respectively) were below the premenopausal range ($p<0.01$) and were significantly below the values in raloxifene treated patients. No significant changes of BMD and markers were observed in the control group. In conclusion, after 1 year treatment with raloxifene, markers of type I collagen synthesis and degradation decreased to the mean premenopausal levels. Treatment with alendronate resulted in a significant suppression of both markers below the premenopausal range. Responders to treatment with alendronate could be identified using either BMD or biochemical markers. S-CTX is a candidate marker for monitoring treatment with raloxifene.

Tartrate-Resistant Acid Phosphatase 5b Correlates with Histomorphometric Parameters of Osteoclasts and Bone Resorption in Hemodialysis Patients. P. Chu[1], T. Chao*[1], Y. Lin*[1], A. J. Janckila[2], L. T. Yam*[2]. [1]Medicine, National Defense Medical Center and Tri-Service General Hospital, Taipei, Taiwan Republic of China, [2]Medicine, VAMC, Louisville, Louisville, KY, USA.

Metabolic bone disease is common among patients on chronic hemodialysis (HD). Histomorphometry of bone biopsy is the gold standard for diagnosis and classification of renal osteodystrophy (ROD). Our purpose was to determine if serum tartrate-resistant acid phosphatase (TRACP) 5b activity, an osteoclastic marker of bone resorption, could be used to distinguish HD patients with high turnover hyperparathyroid (HPT) bone disease from other forms of ROD. Fourteen HD patients and six normal males were included for study. All subjects underwent transiliac bone biopsy after dual tetracycline labeling and concomitant biochemical testing for TRACP 5b, intact parathyroid hormone (iPTH), cross-linked C-telopeptides (ICTP), total calcium, phosphorous, and albumin. Bone biopsies were evaluated for static and dynamic histomorphometric parameters of: osteoid volume/bone volume (OV/BV), osteoblast surface/bone surface (OBS/BS), fibrosis surface/bone surface (FbS/BS), erosion surface/bone surface (ES/BS), erosion depth (EDe), osteoclast number/100 mm bone perimeter (NOC/BPM), osteoclast surface/bone surface (OCS/BS), mineral apposition rate (MAR), bone formation rate/bone surface (BFR/MS). Histomorphometry revealed six HD patients to have predominant HPT disease, four to have adynamic bone disease, three to have mixed uremic osteodystrophy, and one to have osteomalacia. All six with HPT had high TRACP 5b (11.97 ± 8.92 U/L) compared to control (3.25 ± 0.59 U/L). All remaining non-HPT cases had TRACP 5b levels at or below the normal mean. iPTH and ICTP levels were also highest in HPT, but were elevated in most other non-HPT patients as well. Significant correlations among histomorphometric and biochemical parameters of bone resorption are shown below: TRACP 5b correlated more strongly with parameters of osteoclastic activity than with evidence of erosion. Further, TRACP 5b correlated more strongly with osteoclasts than did iPTH or ICTP. Serum TRACP 5b is a highly valid biochemical marker for osteoclastic activity in endstage renal disease and, with further study and documentation, may prove to be a useful test to differentiate high turnover HPT bone disease from other ROD.

Spearman's "r" between biochemical and histomorphometric parameters of bone resorption

	NOC/BPM	OCS/BS	ES/BS	EDe
TRACP 5b	.91***	.92***	.50*	.66**

Serum Tartrate-Resistant Acid Phosphatase Isoforms 5a and 5b in Rheumatoid Arthritis. A. J. Janckila[1], D. H. Neustadt*[2], Y. R. Nakasato[2], J. M. Halleen[3], T. Hentunen[3], L. T. Yam*[1]. [1]Medicine, VAMC, Louisville, Louisville, KY, USA, [2]Medicine, University of Louisville, Louisville, KY, USA, [3]Anatomy, Institute of Biomedicine, University of Turku, Turku, Finland.

In many patients with rheumatoid arthritis (RA), total serum tartrate-resistant acid phosphatase (TRACP) protein is elevated while TRACP activity is not. Serum TRACP exists as two related isoforms; non-osteoclastic TRACP 5a and osteoclastic TRACP 5b. Our objective was to determine the significance and source of elevated serum TRACP protein in RA. Thirty-five RA, 32 osteoarthritis (OA) and 16 control subjects were studied. Serum TRACP 5b activity and total TRACP protein were determined by enzyme capture and two-site immunoassay, respectively. TRACP isoforms 5a and 5b were analyzed by non-denaturing polyacrylamide gel electrophoresis (PAGE). Serum bone alkaline phosphatase (BAP), crosslinked N-telopeptides (NTx), and C-telopeptides (ICTP) of type I collagen were estimated as markers of bone turnover. C-reactive protein (CRP) was measured as a marker of chronic inflammation. Macrophages and dendritic cells (DC) were developed from peripheral blood monocytes. Cell lysates and culture supernatants were analyzed for TRACP isoforms by immunoassay and PAGE. In RA, mean TRACP 5b activity was normal (2.55 ± 0.77 U/L vs 2.48 ± 0.71 U/L), but median total TRACP protein was significantly increased (15.81 μg/L vs 9.69 μg/L; $p < 0.001$). In OA TRACP 5b activity and protein were normal. In RA, TRACP 5b activity correlated weakly with ICTP ($r = 0.56$) while TRACP protein levels correlated weakly with NTx ($r = 0.43$). Additionally, TRACP protein, but not TRACP 5b activity correlated significantly with CRP ($r = 0.42$). Macrophage and DC lysates contained TRACP 5b, while tissue culture supernatants contained TRACP 5a. We conclude that elevated total TRACP protein in RA sera was probably due to TRACP 5a and not derived from osteoclasts. Rather, it could be a secreted product of inflammatory macrophages and DC. Serum TRACP 5b activity is further validated as a marker for osteoclastic activity.

Is there a Relationship between Bone Density as Measured by Ultrasound and Foot Loading. I. P. Drysdale, H. J. Hinkley, D. Bird*, N. J. Walters*. British College of Osteopathic Medicine, London, United Kingdom.

Previous studies by the same authors have shown a bilateral difference in Broadband Ultrasound Attenuation (BUA) of the calcaneus, using the McCue Cubaclinical II device, with differences of up to 30 % being reported. Other studies using different equipment and technologies support this. The subjects concerned had no apparent reasons for these differences. The purpose of this study was to further investigate any bilateral differences using different measurement criteria and a new data set. Subjects were excluded if there was previous history of limb disease or bone fracture. The BUA ($dBMz^{-1}$) of 66 subjects was determined for the non-dominant and dominant calcanei, each three times in succession. Both heels were re-positioned between each measurement to allow for anatomical variation and the mean calculated for each foot. Foot pressure was also measured using a Footscan plate (RSscan), with static and dynamic measurements being recorded. In addition leg length, weight and height were recorded. The load of the non-dominant and dominant hindfoot expressed as a percentage of body weight (static), the dynamic pressure load rate in $N/cm^2/ms$ (speed of loading) and the pressure impulse in Ns/cm^2 (total loading over time), were compared to non-dominant and dominant BUA. No significant correlation of BUA with the measured parameters was found except in the case of non-dominant BUA versus non-dominant load rate ($n=54$), $r=0.3$, $P<0.05$.

Quantitative Calcaneal Ultrasound Identifies Men with Prostate Cancer and Androgen Deprivation at Risk for Osteoporosis. P. S. Coates, D. L. Medich*, J. Wagner, J. Ribich, D. L. Trump*, J. B. Nelson*, S. L. Greenspan. University of Pittsburgh Medical Center, Pittsburgh, PA, USA.

Androgen deprivation therapy, the most effective systemic treatment for prostate cancer, is a major risk factor for osteoporosis. Little is known about the use of calcaneal ultrasound to identify bone loss in these men. To identify prostate cancer patients at risk of osteoporosis we measured broadband ultrasound attenuation (BUA) using the Sahara (Hologic, Bedford, MA) and QUS-2 (Metra Biosystems, Mountainview, CA) clinical sonometers and compared this to conventional bone mineral density (BMD) by dual-photon absorptiometry at the PA spine, femoral neck and total hip (Hologic 4500-A, Hologic, Bedford, MA). We studied 95 men in 4 groups; men with prostate cancer 1) not on androgen deprivation, N=23; 2) on androgen deprivation <6 months, N=17; 3) on androgen deprivation >6 months, N=24; and 4) healthy controls, N=31. The groups did not differ in age, height or weight. BUA was lower in men on chronic androgen deprivation using the QUS-2 sonometer than controls ($p<0.01$), with a similar trend using the Sahara. Using both sonometers, BUA was related to BMD at all sites. Duration of androgen deprivation and markers of bone turnover were inversely related to BUA with both instruments. In conclusion, BUA using 2 different instruments is related to BMD, duration of androgen deprivation, and bone turnover markers, and may be useful to identify men on androgen deprivation at risk of osteoporosis. Longitudinal studies are needed to confirm this finding.

	QUS (dB/MHz)	**Sahara (dB/MHz)**

Relationship of Calcaneal Broadband Ultrasound Attenuation and Osteoarthritis of the Lower Limb. H. J. Hinkley, I. P. Drysdale, D. Bird*, N. J. Walters*. British College of Osteopathic Medicine, London, United Kingdom.

Patients with Osteoarthritis (OA) have been reported to have greater bone density, in most cases measured by techniques other than ultrasound. This study investigates the association using Broadband Ultrasound Attenuation (BUA) of the calcaneus. Forty-three postmenopausal women aged 50 to 78 with OA of the lower limb were scanned with the McCue Cubaclinical II bone densitometer. Two measurements on each heel were taken and the minimum BUA used. OA was graded on the ability to walk less than 100m (1), more than 100m (2), more than 500m (3) and more than 1000m (4). The severity of OA was compared with the BUA Zu score and no significant correlation was found. Of the subjects who had unilateral OA there was no significant difference in bilateral BUA. The minimum BUA measure for the OA group was compared to the BUA for an age matched group of normal female subjects, using the students t test. In this study Caucasian post menopausal women with OA of the lower limb, did not have significantly higher levels of bone density at the calcaneus as measured by ultrasound. This supports the findings of a Japanese study involving women suffering OA of the knee.

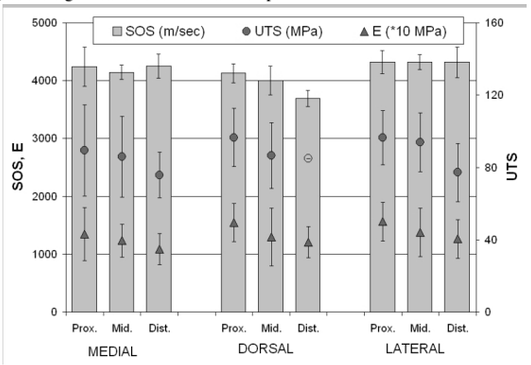
Biomechanical Validation of Quantitative Ultrasound. G. Whan*[1], R. J. Runciman*[1], M. B. Hurtig*[2]. [1]School of Engineering, University of Guelph, Guelph, ON, Canada, [2]Ontario Veterinary College, University of Guelph, Guelph, ON, Canada.

Quantitative Ultrasound (QUS) has previously been explored as a clinical tool for assessing bone properties. Results from these studies have been, for the most part, inconclusive. This extensive comparative study focuses on QUS versus biomechanical strength and stiffness in the equine metacarpus (MC3). In isotropic, homogeneous and pure elastic materials, there is a positive relationship between the speed of sound (SOS) in a material with its Modulus of Elasticity (E). This theoretical relationship is more complex in biological materials. Nine potential clinical sites of interest were identified for testing in this study. The diaphysis of the whole bone was divided into three levels, proximal, mid and distal. Each level was also divided into three sites, medial, dorsal and lateral. QUS readings were taken at the nine sites. QUS measurements were made using a Sunlight Omnisense, manufactured by Sunlight Medical Ltd. Previous investigations with this equipment has shown that QUS measurements are repeatable and reliable on the equine MC3 with and without overlying soft tissue and for various sample temperatures. 3D parallelepiped testing samples were prepared from each of the nine sites from the whole bone. Each sample had a constant testing cross sectional area of 25mm2 of cortical bone. Each sample was tested to destruction under tension. Load was applied using an Inston (Model 4204) outfitted with a 50kN load cell at a rate of 6mm/min. Strain was measured using a modular strain measurement clip. All output data was collected using standard A/D equipment and data collection software. Collected data was analysed to find Modulus of Elasticity (E) and Ultimate Tensile Strength (UTS) of each sample. The correlative relationship between QUS, E and UTS was examined using the statistical analysis program, SAS. Independent correlations were studied as well as the interactions between all the parameters. The medial and lateral proximal sites were found to be unreliable in measuring repeatable QUS data due to the external geometry of the bone. Similarly, the internal geometry of the cortical bone on the distal sites has effected the outcome of the biomechanical testing. Our results indicate an identifiable relationship between QUS, E and UTS. Further analysis is required to investigate the significance of this relationship.



SA117

Bone Mass Phenotypes in Alcohol Preferring Rats. I. Alam*, A. G. Robling, L. G. Carr*, L. Lumeng*, T. K. Li*, C. H. Turner. Indiana University, Indianapolis, IN, USA.

The association between moderate alcohol intake and elevated bone mass has been demonstrated by several epidemiological studies, raising some important issues whether the beneficial effects of alcohol consumption are related to genetics, life style or other factors. It might be that the individuals who are genetically predisposed to drink alcohol also have genetic alleles that promote higher bone mass. Thus, animals selectively bred for alcohol preference might also have higher bone mass even without consuming alcohol. To test this hypothesis, three separate lines of rats [alcohol-preferring (P), high alcohol-drinking 1 & 2 (HAD1, HAD2)] selectively bred based upon high alcohol preference were compared to their non-alcohol preferring control lines [non-alcohol-preferring (NP), low alcohol-drinking 1 & 2 (LAD1, LAD2)] to determine the effects of alcohol preference alleles on bone phenotype. We used growing (3-month old) rats from each of these three lines to characterize volumetric bone mineral density (vBMD), bone mineral content (BMC) and cross sectional area (CSA) at the femoral midshaft and distal metaphysis using pQCT. The P rats exhibited significantly greater (2-12%, $p<0.05$) total and cortical vBMD, BMC, and CSA than the NP rats at the femoral midshaft. At the distal metaphysis, P rats exhibited significantly greater (3-23%, $p<0.05$) values for bone mass in the cortical shell. Conversely, the HAD 1 rats exhibited significantly lower (9-12%, $p<0.05$) total vBMD, total BMC, cortical BMC and cortical area at the midshaft femur than the LAD1 rats. The HAD 1 distal metaphysis exhibited a significantly thinner cortical shell than the LAD1 rats. Similar to the P rats, the HAD2 rats exhibited significantly greater (11-13%, $p<0.05$) total vBMD and cortical area at midshaft and significantly greater (15-27%, $p<0.0001$) total vBMD, BMC and cortical CSA at distal metaphysis than their low-drinking counterparts (LAD2). HAD2 rats also had significantly greater ((5-188%, $p<0.05$) trabecular bone measurements in distal femoral metaphysis, compared to the LAD2 control strain. Our preliminary findings demonstrate an apparent link between alcohol preference and bone mass in some rat strains. P and HAD2 rats have a high bone mass phenotype, while HAD1 rats have a low bone mass phenotype. These findings suggest that P and HAD2 rats have high bone mass genes associated with signals in the brain that make rats prefer alcohol. HAD1 rats do not have high bone mass genes even though they prefer alcohol. Consequently these three different strains of alcohol preferring rats may allow us not only to better understand the association between alcohol preference and bone mass, but potentially to identify new genes linked to BMD.

SA118

Genetic and GH/IGF-I Effects on Vertebral Trabecular Architecture. L. R. Donahue[1], C. J. Rosen[1], R. Muller[2], K. L. Shultz*[1], V. Guido*[1], W. G. Beamer[1], M. L. Bouxsein[2]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Beth Israel Deaconess Medical Center, Boston, MA, USA.

We demonstrated that vertebral trabecular density and structure are polygenic traits and discovered QTLs for vertebral BMD in F2s from a C57BL/6J (B6-low BMD) X C3H/HeJ (C3H-high BMD) cross. To decompose the vertebral BMD phenotype and to determine which aspects are GH/IGF-I dependent or independent, we are utilizing a spontaneous mouse mutation, *little,* with a non-functional GHRHR. We made a congenic strain by backcrossing the *little* mutation from the original B6 background to C3H. In both B6-*lit/lit* and C3.B6-*lit/lit* mice, circulating GH is undetectable, serum IGF-I is low, and femoral BMD (pQCT), areal BMD (PIXImus), femur length, and body mass are reduced compared to *lit/+* mice. Although C3.B6-*lit/lit* mice are of the same body weight as B6-*lit/lit* mice, C3.B6-*lit/lit* mice have higher whole body, femoral, and vertebral BMD. These data suggest both GH/IGF dependent and independent regulation of BMD and indicate that this phenotype needs to be decomposed to understand mechanisms of genetic and endocrine regulation. We have started with vertebral BMD utilizing high resolution microcomputed tomography (μCT) to characterize trabecular bone in a single lumbar vertebra (L5) in 4 month old *lit/+* and *lit/lit* females (mean±SD). These data show that trabecular BV/TV has a strong genetic regulation whereby B6 alleles impart higher BV/TV in both *lit/lit* and *lit/+* mice compared to C3H alleles. Contributing to overall BV/TV are the number, thickness, and spacing of trabeculae. B6 alleles in both *lit/lit* and *lit/+* mice impart greater numbers of trabeculae that are thinner and closer together than C3H alleles. However, the status of heterozygosity for *little* can be seen to effect trabecular thickness regardless of genetic background, but is strain dependent for trabecular number and spacing. These data emphasize the interaction between genetic background and endocrine status. A QTL analysis of F2s from a B6-*lit/lit* x C3.B6-*lit/lit* cross, coupled with data from our B6C3F2s without the *little* mutation will reveal which loci are responsive to GH/IGF-I regulation and which are not.

Bone Mineral Density in 30 Men with Genetic Hemochromatosis and C282Y Mutation HFE Gene Homozygoty. P. Guggenbuhl, Y. Deugnier*, J. Boisdet*, Y. Rolland*, A. Perdriger*, Y. Pawlotsky*, G. Chalès*. CHU, Rennes, France.

Genetic Hemochromatosis (GH) is a genetic disease of iron overload mainly related to the C282Y mutation on the HFE gene. Bone involvement has been recognised only recently. The aim of the study was i- to assess bone mineral density (BMD) and bone remodeling in males with GH; ii- to discuss the influence of iron overload. Patients admitted between September 1995 and July 1997 in our Rheumatology Unit for GH were included. The diagnosis of GH was ascertained on the association of a plasma transferrin saturation > 45% and homozygoty for the Cys282Y mutation; 23 (76.7%) had a liver biopsy. No other condition could explain iron overload. Among the 52 patients screened, 30 males (aged 47±10 years) with GH were considered for the study. Twenty controls were assessed for biological measurements. The results were (mean±SD) : ferritin level was 1508±1365 ng/ml, transferrin saturation was 70.6±21.1%, the hepatic iron concentration (HIC) was 356.3±164.8 µmoles/g. BMD measured by DXA was 0.94±0.15g/cm2 at lumbar spine (LS) and 0.79±0.16 g/cm2 at femoral neck (FN). Osteopenia at LS (Tscore<-1 SD) was observed in 15/29 (51.7%) patients and in 17/28 (60.7%) at FN ; when either LS or FN were considered, osteopenia was found in 21/30 patients (70%). Osteoporosis (Tscore<-2.5 SD) occurred in 6/29 (20.7%) at LS and in 7/28 (25%) at FN ; when either LS or FN were considered, osteoporosis was found in 7/30 patients (23.3%). Three patients (10%) suffered from a vertebral fracture which occurred in 3 of the 6 (50%) osteoporotic patients. There was no significant relationship between BMD and iron saturation, ferritin, PTH and bone remodelling markers, but a significant negative correlation between HIC and BMD at FN (r = -0.49 ; p = 0.019). BMD was positively associated with testosterone at LS (r = 0.342 ; p = 0.07) and with 25 OH vitamine D at LS (r = 0.365 ; p= 0.056) and at FN (r = 0.44 ; p = 0.021). Five patients (16.7%) were hypogonadic; among the 7 osteoporotic patients, 2 (28.6%) were hypogonadic. When the 21 patients with osteopenia were considered, 4 (19.05%) were hypogonadic. There was an increase of bone specific alkaline phosphatase (20.6 vs 11.7 U/l ; p = 0.001) and osteocalcin (23.36 vs 19.5 ng/ml ; p = 0.017) in GH patients vs controls. Conclusion : in our population of 30 males with genetic hemochromatosis and C282 mutation homozygoty for HFE gene, 70% suffered from osteopenia and 23.3% from osteoporosis; a vertebral fracture occurred in 10%. There was no evidence of hypogonadism in the majority of the GH patients, nor low 25-hydroxycholecalciferol levels or PTH 1-84 dysfunction. Biochemical markers of bone formation were found to be increased compared to control and hepatic iron concentration seemed to influence negatively BMD.

SA121

Bone Mass in Rats Is Highly Heritable. Q. Sun[1], S. J. Warden*[1], D. L. Koller*[2], T. Foroud*[2], C. H. Turner*[1]. [1]Orthopaedic Surgery, Indiana University, Indianapolis, IN, USA, [2]Indiana University, Indianapolis, IN, USA.

Rats are the most common animal model for skeletal research. However, mice are most often used for skeletal genetics studies. With the rapid growth in genetic markers and genome sequence information, genetic studies in rats are now quite feasible. One important question remains: Are bone measurements heritable in rats? We studied first (F1) and second (F2) generation offspring from Fischer 344 (F344) and Lewis (LEW) rats to determine the heritability of peak bone mass. F344 and LEW rat strains were chosen because they have been previously demonstrated to differ considerably in bone mass. The study population included 6 month old female F344 (n=16), LEW (n=16), F1 (n=16), and F2 (n=303) rats. Bone mineral content (BMC) was measured using dual energy x-ray absorptiometry (DXA) for L3-5 spine and the whole femur. In addition, high resolution peripheral quantitative computed tomography (pQCT) was used to measure volumetric bone mineral density (vBMD) for L5 vertebrae and the proximal, mid and distal femur. For each phenotype, the environmental variance was estimated as the pooled variance of F344, LEW and F1 rats. Heritability, or the proportion of the variability due to genetic factors, was then calculated as one minus the ratio of the environmental variance estimate to the total variance in the F2 rats, which would be expected to contain both genetic and environmental contributions. Heritability for body weight (BW) was 77%, and for BMC at L3-5 and the femur was 66% and 71%, respectively. When BMC was normalized by BW, the heritability was 47% and 52% for the spine and femur. This finding suggests that a substantial portion of the genetic variability in BMC is under the control of genetic factors different from those genetic factors contributing to total body weight variability. Heritabilities of vBMD measured at the proximal, mid and distal femur were 82%, 80% and 60%, respectively, and the heritability of L5 vBMD was 80%. Consequently, the heritability of bone mass and vBMD in rats is very high, ranging from 60% to over 80%. The observed heritability values are in agreement with those that have been observed in mice and humans. We conclude that, like mice, selected inbred strains of rats will serve as excellent models for studies of skeletal genetics.

Linkage of Femoral Structure QTLs to Chromosomes 3 and 19. D. L. Koller[1], K. E. White[2], G. Liu[2], S. L. Hui[2], P. M. Conneally*[1], C. C. Johnston[2], M. J. Econs[2], T. Foroud[1], M. Peacock[2]. [1]Medical and Molecular Genetics, Indiana University, Indianapolis, IN, USA, [2]Medicine, Indiana University, Indianapolis, IN, USA.

Femoral structure contributes to bone strength and predicts hip fracture risk independently of BMD. We reported an autosomal genome screen in 309 white premenopausal sister pairs (JBMR 16:985-91, 2001). Pelvic and femur axis lengths, and widths of femur head and midshaft, measured from radiographs, demonstrated linkage to regions of chromosomes 3, 4, 5, 17, and 19. To replicate these initial linkage findings, we collected an independent sample of 246 white premenopausal sister pairs and completed a genome screen using 392 microsatellite markers. Multipoint quantitative linkage analysis was performed using Mapmaker/SIBS. We subsequently performed linkage analysis in an expanded sample of 437 white and 201 black sister pairs, which has partial overlap (191 white pairs) with the previously reported genome screen sample (JBMR 16:985-91, 2001). All chromosomal positions (cM) reported here correspond to the Marshfield map coordinates (Am J Hum Genet 63:861-689, 1998). On chromosome 3, the initial sample gave a maximum LOD score of 1.8 at 130 cM with femur head width. The second sample (n=246 white pairs) showed suggestive evidence of linkage with femur head width (LOD=3.3 at 106 cM). In the enlarged sample of black and white sisters (n=638 pairs), a significant maximum LOD score of 4.7 was obtained at 106 cM. Evidence of linkage was also found in this region of chromosome 3 for a second phenotype, femur shaft width, (LOD=3.9 at 112 cM with n=638 pairs). In similar fashion, the independent sample (n=246 pairs) gave a LOD score of 1.3 with femur axis length on chromosome 19 (75 cM). This is in agreement with the result for femur axis length in the initial sample (LOD=2.0 at 80 cM). The LOD score in the enlarged sample (n=638 pairs) for this region of chromosome 19 was 2.6 at 73 cM. For the remaining regions reported in the initial sample (chromosomes 4, 5, and 17), the LOD scores in the independent sample were low (0.7 or less). These findings emphasize the importance of replication of initial linkage findings, and confirm our previously reported linkages to chromosomes 3 and 19.

Is a Factor Score Combining Dual X-Ray Absorptiometry and Ultrasound a Better Phenotype for Genetic Studies? D. Karasik[1], M. T. Hannan[1], D. P. Kiel[1], M. L. Bouxsein[2], L. A. Cupples*[3]. [1]Hebrew Rehab Ctr, Harvard Med Sch Divis on Aging, Boston, MA, USA, [2]Orthopedic Biomechanics Laboratory, BIDMC & Harvard Med Sch, Boston, MA, USA, [3]Biostat, Boston Uni Sch Public Health, Boston, MA, USA.

Genetic factors substantially contribute to variation in bone mineral density (BMD) and quantitative ultrasound (QUS). Many bone characteristics measured by the two methods are similar, but QUS potentially measures features of bone not assessed by BMD. We hypothesize that a score composed of both BMD and QUS may serve as a single indicator of general bone status and represent a useful phenotype for genetic studies of osteoporosis. BMD, QUS and anthropometric measurements were obtained in 1203 persons in 323 pedigrees from the population-based Framingham Osteoporosis Study, along with data on age, sex, alcohol and caffeine intake, smoking status, physical activity, vitamin D and calcium intake, and estrogen use (in females) during 1995-98. BMDs were measured at lumbar spine, femoral neck, trochanter, and Ward's area using a Lunar DPX-L, and broadband ultrasound attenuation (BUA) and speed of sound (SOS) at the calcaneus with a Hologic Sahara. In each sex and generation, we performed principal component analysis of BMD and QUS measures with Varimax rotation and subsequent regression of the resulting composite score on the covariates. Using SOLAR program, we estimated crude and covariate-adjusted heritability (h^2). Correlations between QUS and BMD ranged 0.34-0.45 in both sexes in Original and Offspring Cohorts. The first of the two resulting factor scores (FS1) explained ~65% of the total variation of all six BMD and QUS measurements. Factor loadings for FS1 ranged 0.7-0.9 for BMD and 0.2-0.3 for QUS measures. Loadings of FS1 were extracted for each individual. Multiple regression of FS1 with the covariates revealed that BMI and height were significant predictors of FS1 variation, with age and estrogen therapy significant in Offspring females only. Crude and covariate-adjusted h^2 of FS1 were higher than these of BMD or QUS (Table), suggesting that the composite score may increase genetic signal to noise ratio by providing higher heritability estimates, which may be beneficial for subsequent genetic analysis than either BMD or QUS measures alone. However, additional studies are needed to determine whether FS1 will be a better predictor of skeletal fragility than BMD or QUS.

	Femoral neck BMD	Lumbar spine BMD	BUA	SOS	FS1
h^2crude	0.52±0.05	0.56±0.07	0.50±0.07	0.37±0.06	0.61±0.07
h^2adjusted	0.54±0.06	0.62±0.06	0.51±0.07	0.38±0.06	0.66±0.07

Polymorphic Variation in the Human Vitamin D Receptor Gene: An Association with Muscle Strength in Younger Swedish Women. E. Grundberg*[1], E. Ribom*[2], H. Brändström*[1], Ö. Ljunggren*[1], H. Mallmin*[2], A. Kindmark*[1]. [1]Department of Medical Sciences, Uppsala, Sweden, [2]Department of Surgical Sciences, Uppsala, Sweden.

Bone mineral density (BMD) is regulated by both environmental and genetic factors and known to be associated with muscle strength. Furtermore, muscle strength itself is under strong genetic control, demonstrated in both twin studies and genetic association studies. The polymorphisms of the gene for the Vitamin D receptor (VDR) are commonly studied in relation to BMD and several groups have reported a significant association between BMD and VDR alleles. However, little is known about the genetic influence of VDR on muscle strength. The purpose of this study was to investigate two VDR polymorphisms in relation to BMD and muscle strength in 168 Swedish women. The polymorhisms studied were the single nucleotide polymorhism BsmI and the poly A microsatellite, both situated in the 3´end of the VDR gene. The individuals in the study are part of the Swedish T-score cohort, containing a total of 340 women, aged 20-40, where the BMD data will be the basis for the Swedish reference population of bone density in women. BMD has been measured by dual X-ray absorbtiomtery (DXA) at spine, proximal femur, total body and heel and QUS (Quantitative Ultrasound)at the heel. Also, in 168 individuals quadriceps, hamstrings and handgrip muscle strength have been measured by using a modified Cybex II dynamometer and a JAMAR hydracraulic hand dynamometer. The gene fragments of VDR were amplified by PCR from the individual´s leukocyte DNA and analyzed for genotype. The VDR poly A microsatellite were separated on a polyacrylamidegel using ABI 377 sequencer and fragments < 19 repeats were denoted short (S) and repeats ≥ 19 denoted long (L). The VDR fragments containing the BsmI polymorphism were separated on an agarose gel after restriction digestion using the enzyme BsmI. The genotype frequencies were ss 16%, sL 44%, LL 40 % for the poly A repeat and bb 39%, bB 43 %, BB 18 % for the BsmI polymorphism respectively. Both the genotypes were in Hardy-Weinberg equilibrium and in strong linkage disequilibrium. Significant associations between the two VDR genotypes, ss and BB, and hamstrings strength were observed. However, no significant correlations between BMD at spine, proximal femur, total body and heel and VDR genotypes were found when analyzing 168 women out of 340. The results show that younger women, in this Swedish population based cohort, with shorter poly A repeat, ss, (p=0,041) or absence of the BsmI restriction site, BB, (p=0,0049) in the VDR gene, have significantly higher hamstrings muscle strength, which indicate a strong genetic effect on muscle strength.

SA127

Variations Of Aromatase Gene, Peak Bone Mass And Height In Young Women. J. A. Riancho[1], M. T. Zarrabeitia*[2], A. L. Zarrabeitia*[2], J. Gonzalez-Macias[1]. [1]Internal Medicine, Hospital U.M. Valdecilla, Santander, Spain, [2]Unit of Legal Medicine, University of Cantabria, Santander, Spain.

Aromatase, the enzyme responsible for the synthesis of estrogens from C19-steroids, is expressed in the gonads and a variety of other tissues, including bone. The enzymatic complex includes a unique cytochorme P450 aromatase, the product of CYP19 gene. Spontaneous mutations of aromatase gene result in delayed skeletal maturation in male human subjects, and osteoporosis develops in both male and female aromatase-deficient ArKO mice A common tetranucleotide tandem repeat polymorphism in intron 1 of human CYP19 has also been described as associated with the risk of developing breast cancer, as well as vertebral fractures in postmenopausal women. However, it is unclear if it is due to a low peak bone mass or to an accelerated loss later in life. Therefore, we explored the influence of CYP19 allelic variation on peak bone mass and body size in young women. Fifty one healthy women aged 22-34 years were studied. The polymorphic region was amplified by PCR, allele size was determined in an ABI Prism 310 gene sequencer, and designated as suggested by Healey et al. (Carcinogenesis 2000; 21:189). Bone mineral density (BMD) was measured by DXA with a Hologic machine. Women having CYP19 alleles with 7 or more repeats (n=27) were, on average, 3.1 cm taller (CI 0-6.2; p=0.05) than those with 6 or less repeats (n=23). However, there were no significant differences between both subgroups regarding body weight (56 ±6 vs. 57±7 kg), or BMD at the spine (1.020±0.124 vs. 1.059±0.101 g/cm2) or femoral level (0.816±0.102 vs. 0.861±0.098 g/cm2), whether adjusted by height or not. These results suggest that CYP19 allele variants do not influence peak bone mass in women, but may be associated with differences in body size.

SA128

Aromatase Gene Polymorphisms: Association with Bone Mineral Density and Serum Estradiol Concentrations in Post-menopausal Women. J. Somner[1], J. Cheung*[1], Y. T. Mak*[1], E. Prowse*[2], M. Frost*[2], K. Knapp*[2], I. Fogelman*[2], A. S. Wierzbicki*[1], G. Hampson*[1]. [1]Chemical Pathology, St Thomas Hospital, London, United Kingdom, [2]Nuclear Medicine, Guy's Hospital, London, United Kingdom.

Genetic and environmental factors influence estrogen homeostasis and tissue exposure to estrogen. Aromatase catalyses the conversion of androgens to estrogens. The aromatase gene (CYP19) is a candidate for susceptibility to diseases associated with estrogen exposure. As estrogen plays an important role in osteoporosis we investigated the association between the Valine 80 'G' to 'A' polymorphism in exon 3 of CYP19, bone mineral density (BMD) and serum estradiol concentrations in 253 post-menopausal women aged (mean [SD]) 64.5[9.23] years, cases [osteoporosis] n = 139, controls [normal BMD] n = 114. BMD was assessed at the spine, femoral neck and total hip. Data was analysed by multiple regression analysis including relevant factors such as body mass index (BMI), age at menarche/menopause, exercise, calcium intake, smoking, and alcohol intake. Estradiol values were partially normalised by log transformation. No association was observed between BMD values, 'Z' scores and the CYP 19 genotype in the study population. Allele frequencies were similar between cases and controls (cases AA: 22 % GA: 52.5 %, GG : 25 %, controls AA : 28 %, GA : 53.5 %, GG : 18 %; p= 0.36). However in older women (>10 years since menopause [YSM]) an association (p=0.09) was found between total hip and femoral neck BMD and the CYP 19 genotype after adjustment for other risk factors including family history. The CYP 19 genotype was found to be significantly associated with serum estradiol concentrations (p= 0.002) after adjustment for age at menarche, degree of exercise and BMI. The subjects with the 'AA', 'GA' and 'GG' genotypes were matched for age (mean [SD] years) (AA: 64.7 [8.9], GA: 65 [9.5], GG : 63.2 [8.6]), YSM (16.3 [10], 16.9 [9.6], 16.1 [10.3]), menopausal age (48.5 [5], 48.2 [4.9], 47 [5.3]), BMI (kg/m ^{2}) (25[4.1], 24 [4.5], 25 [4.4]). However those women with the 'AA' genotype had significantly higher serum estradiol concentrations than in the 'GA' group (p=0.08) or 'GG' group (p=0.02). Geometric mean (range) estradiol levels were 17 (2.1-52.8) pmol/L in the 'AA' genotype group; 13.0 (0.8-57.0) pmol/L for 'GA' and 10.0 (0.2-164.0) pmol/L for the 'GG' genotype group. A lower incidence of fractures was seen in subjects with the 'AA' genotype (p=0.07). In conclusion, although the 'G' to 'A' polymorphism was not significantly associated with BMD in our study population except in older women, the CYP 19 genotype was clearly associated with serum estradiol concentrations and may thus be useful as a genetic marker of aromatase efficiency and estrogen synthesis.

SA129

A Single Nucleotide Polymorphism at -238 In The TNF Gene Influences Promoter Activity In-Vitro. J. M. Wilkinson[1], A. G. Wilson*[2], R. Eastell[1], E. Kiss-Toth*[3]. [1]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [2]Division of Genomic Medicine, University of Sheffield, Sheffield, United Kingdom, [3]Cardiovascular Research Group, University of Sheffield, Sheffield, United Kingdom.

Tumor Necrosis Factor (TNF) is a pro-inflammatory cytokine that is thought to play a pivotal role in osteolysis after total hip arthroplasty (THA). We have recently shown that a single nucleotide polymorphism (SNP) at -238 in the TNF gene promoter is associated with development of osteolysis after THA. Possession of the rare 'A' allele at this site is associated with a higher rate of osteolysis after THA versus carriage of the [more common] 'G' allele. The aim of this study was to examine the functional significance of this polymorphism on TNF gene transcriptional activation in a luciferase reporter gene assay. A 691 bp fragment (-585 to +106) of the TNF gene was amplified by polymerase chain reaction and directionally cloned into the PGL3.basic vector (Promega, Madison, WI). Insert sequences were checked using an ABI 377 DNA sequencer (PE Applied Biosystems, Foster City, CA). RAW264.7 murine macrophage-like cells in rapid growth phase were transfected with plasmids containing either the TNF-238G allele or the TNF-238A allele. pTK-RL (Promega), that expresses the Renilla luciferase gene under the control of Herpes Simplex Virus minimal promoter, was used as a transfection control. The cells were then either left unstimulated or were induced using lipopolysaccharide (LPS), phorbol 12-myristate 13-acetate (PMA), human TNF, or LTA (Lypothicaid acid). All transfections were made in triplicate. Luciferase reporter activity was measured after 4 hours and the relative luciferase activity was calculated. Results for unstimulated state and after LPS stimulation are shown in the table below. LTA and TNF stimulation at 0.05µg/mL and 0.2ng/mL, respectively, resulted in greater luciferase expression for -238A versus -238G (P<0.05). Higher concentrations of these agonists, and PMA, did not result in differential luciferase expression between the alleles. The promoter allele TNF-238A results in higher basal and stimulated levels of transcriptional activation in-vitro than the TNF-238G allele. Our data suggest a potential mechanism by which the TNF-238 polymorphism may influence the development of osteolysis after THA.

Mean relative luciferase activity

	TNF-238A Mean (Std.Dev.)	TNF-238G Mean (Std.Dev.)	P-value
Unstimulated	32.1 (2.1)	25.2 (2.4)	0.02
LPS 100ng/mL	43.4 (2.2)	33.0 (1.0)	0.002
LPS 10ng/mL	35.0 (3.7)	31.8 (2.7)	N.S.
LPS 1ng/mL	32.3 (1.6)	27.0 (2.7)	0.04

The MTHFR (*C677T*) Polymorphism and BMD at Menopause: Analysis of the Effects of Bone Size, Body Composition and Physcial Activity. Results from the Danish Osteoporosis Prevention Study. B. Abrahamsen[1], J. S. Madsen*[2], C. L. Tofteng*[3], L. S. Stilgren[1], E. M. Bladbjerg*[4], S. R. Kristensen*[2], K. Brixen[1], L. Mosekilde[5]. [1]Dept. of Endocrinology M, Odense University Hospital, Odense C, Denmark, [2]Dept of Clin. Biochemistry, Odense University Hospital, Odense, Denmark, [3]The Osteoporosis Research Clinic, Hvidovre, Denmark, [4]Dept of Clin. Biochemistry, Ribe C. Hospital, Esbjerg, Denmark, [5]Aarhus University Hospital, Dept of Endocrinology C, Aarhus, Denmark.

We have previously reported an association of the *TT* genotype of the MTHFR polymorphism with a 0.3 SD reduction in BMD at the spine and 0.2 SD at the total hip at the time of menopause, with a normal response to HRT. The mechanism by which this polymorphism affects BMD is unknown, but interference with collagen cross-linking ultimately affecting bone structure has been proposed. Because many inherited disorders of collagen metabolism are associated with reduced growth, the following analysis was undertaken to test for effects on body- and bone size. Body composition and physical activity was also investigated. MTHFR genotyping was done in 1748 healthy post-menopausal Danish women. BMD and body composition was measured using Hologic QDR-1000 and QDR-2000 densitometers. The *TT* genotype was not associated with differences in lean body mass or fat mass. Bone areas did not differ. BMD was lower as previously reported. Participants with the *TT* genotype were very slightly taller, with a trend towards lower BMI but these differences did not reach statistical significance. Physical activity scores were identical in the two groups, with the exception that women with the *TT* genotype spent 35 minutes a week on gymnastics compared with 25 minutes for the rest of the study population (p=0.02).

	TTn=153	CC or CT n=1595	p
Height (cm)	165.3 ± 6.1	164.3 ± 7.2	0.12
Weight (Kg)	64.9	65.7	0.68
BMI (Kg/m2)	23.9	24.2	0.19
L2-L4 area cm2	46.5 ± 4.2	46.1 ± 4.1	0.72
L2-L4 BMD g/cm2	1.00 ± 0.14	1.03 ± 0.14	0.02
Total hip area cm2	37.1 ± 3.5	37.0 ± 3.6	0.72
Total hip BMD g/cm2	0.89 ± 0.11	0.92 ± 0.12	0.01

In conclusion, the significant effects of MTHFR genotype on menopausal BMD are not explained by differences in body composition or bone size. A trend towards greater height and lower BMI in the TT genotype did not reach statistical significance.

SA132

Effect of ER Alpha Gene PvuII-XbaI Polymorpisms on the Development of Hyperthyroidism and Thyroid Hormone-stimulated Bone Loss. E. Bajnok*, I. Takacs, A. Tabak*, C. Horvath, G. Speer*, Z. Nagy, P. Lakatos. 1 st. Department of Medicine, Semmelweis University, Budapest, Hungary.

Genetic background of hyperthyroidism and thyroid hormone-stimulated bone loss have not yet been established. Estrogen is a potent immunomodulatory hormone that may have a role in tumorgenesis as well as in the development of hyperthyroidism. In this study, we investigated the previously described estrogen receptor alpha (ER alpha) gene PvuII-XbaI polymorphisms to test their possible functional contribution to the pathogenesis of hyperthyroidism. Based on former results, we studied the effect of these polymorphisms on bone mineral density (BMD), as well. We genotyped 248 (18-83 years) women: 68 patients with Graves' disease (GD) and 70 with toxic adenoma (TA) and compared the genotype frequencies with 110 healthy controls (C). BMD of 36 GD patients (mean age 49,19 ± 7,15 years), 48 TA patients (mean age 57,52 ± 10,27 years) and 108 control subjects (mean age 54,6 ± 5,4 years) was measured at the lumbar spine and femoral neck. We found the xx genotype to be significantly less frequent in hyperthyroid (HT) patients than in controls. When separating the HT group into GD and TA subgroups, this difference remained significantly only in TA patients (p=0,002). The ER-PvuII genotype distribution was similar in all groups. At the same time, no relationship was seen between these polymorphisms and BMD adjusted for age and BMI at any site in these subgroups. In summary, our data raise the possibility that ER alpha gene XbaI polymorphism might play a role in the development of toxic adenoma.

SA133

Genetic Polymorphisms and Bone Quality in Postmenopausal Women. I. Takacs, C. Horvath, É. Bajnok*, G. Speer*, Z. Nagy, P. Lakatos. 1.st Department of Medicine, Semmelweis University, Budapest, Hungary.

Osteoporosis is a complex disease that is presumably influenced by multiple genes. Part of the genetic effect has been ascribed to the polymorphism in vitamin D receptor gene (VDR), estrogen receptor gene (ER), interleukin-1 receptor antagonist protein gene (IL-1RN) but their genetic implications are still controversial. The majority of studies concentrated on bone quantity rather than bone quality. Recently, bone ultrasound appears to provide non invasive information on bone quality. In this study, we investigated the role of VDR, ER and IL-1RN polymorphisms on bone mineral density (BMD) and bone ultrasound parameters in a group of 53 healthy and 55 hyperthyroid Hungarian postmenopausal women. VDR BsmI., ER, XbaI, and Pvu II. restriction fragment length polymorphisms, as well as IL-1RN variable tandem repeat polymorphism have been determined. BMD was measured at the lumbar spine (L2-4) and femoral neck by DEXA. Women underwent quantitative ultrasonometry (QUS) at the heel. No association could be shown between VDR, ER and IL-RN genotypes and BMD. XbaI. "xx"and PvuII. "pp" alleles were accompanied with ultrasound values reflecting reduced bone quality as compared with other genotypes. Our results raise the possibility that some genetic factors might exert their effects on bone tissue through influencing bone quality.

SA134

Association between Two Types of VDR Gene Polymorphisms and Bone Density in Japanese Women. M. Kubota*[1], S. Yoshida*[2], H. Arai*[3], M. Ikeda*[1], Y. Okada*[1], K. Miyamoto*[3], E. Takeda*[3]. [1]Okayama Prefectural University, Okayama, Japan, [2]Kinki Welfare University, Hyougo, Japan, [3]Clinical Nutrition, Tokushima University, Tokushima, Japan.

[Objective] Bone density is influenced by many factors, which can be broadly divided into genetic and environmental factors. We have previously shown the presence of an M polymorphism at the translation initiation sites in exon 2 of the VDR gene and a polymorphism in the hVD-SIF1 region on the VDR gene promoter. In this study, we analyzed the association of bone density and bone metabolic markers with these two VDR polymorphisms to clarify their usefulness as predisposing genetic markers. [Materials and Methods] 347 healthy Japanese women (20-86 years old) were studied. The polymorphic regions were amplified by the PCR technique; the M genotypes were classified into mm, MM, and Mm by RFLP analysis; and hVD-SIF1 genotypes were classified into WT, MT, and heterozygous type by direct sequencing. The bone mineral density (BMD) (L2-L4) was measured using DXA (QDR-2000). Bone metabolic markers (ALP III and TR-AP activities) were assessed, and body compositions were measured simultaneously. Questionnaires were done on dietary habit and life style. [Results] (1) Subjects were divided by menstrual stage into four groups: pre-menopausal: 153, irregular menopausal: 36, 2-9 years post-menopause: 76, and 10 years post-menopause: 83. The VDR MM, Mm, and mm genotypes frequencies were 12.2%, 52.3%, and 35.5% respectively, while the hVD-SIF1 WT, MT, and hetero type frequencies were 17.6%, 30.5%, and 51.9% respectively. (2) In M polymorphism, the BMD and Z score were significantly higher in the pre-menopausal and irregular group in order of mm>Mm>MM ($p<0.001$). No difference was noted between the 2-9 years and the 10 years group. (3) In hVD-SIF1 polymorphism, the BMD and Z score in the 2-9 years and the 10 years group were high WT > hetero > MT respectively. No changes were observed in the pre-menopause and the irregular group. (4) For BMD, positive correlation with milk ingestion (elementary and junior high school) was observed in pre-menopause and the 10 years group (MM types) and with recent daily product intake was the 10 years group (MM types). In mm types, a positive correlation with BW, body fat mass, BMI. (5) For the BMD relationship, positive correlation with milk ingestion (elementary and junior high school) was observed in irregular group (MT type), and in the 10 years group (WT and hetero types). These results indicate that the association of bone density with two VDR gene polymorphisms varies according to age and menstrual history, and suggest that differential screening for these genetic markers and appropriate nutritional instruction are useful for preventing osteoporosis.

SA135

Novel Polymorphism in the Human Fos Related Antigen-1 Gene Is Associated with Bone Mineral Density in Women from the UK. O. M. E. Albagha*, F. E. McGuigan*, D. M. Reid, S. H. Ralston. Medicine and Therapeutics, University of Aberdeen, Aberdeen, United Kingdom.

Genetic factors are important in the pathogenesis of osteoporosis and regulation of bone mass, but most genes responsible remain to be defined. Linkage studies in families have shown evidence of a quantitative trait locus for regulation of bone mass on chromosome 11q12-13. Fos-related antigen-1 (Fra-1) gene is one of the candidate genes located in this region because of its effect on bone cell function. Recent reports have shown that transgenic mice over-expressing Fra-1 in various organs develop a progressive increase in bone mass leading to osteosclerosis with the observation of enhanced osteoblast differentiation and elevated osteoclastogenesis in vitro (Jochum et al., 2000). We investigated the potential role of the Fra-1 gene in the regulation of bone mineral density (BMD) by screening its coding region for novel polymorphisms and then assessing the potential relationship between the identified polymorphisms and BMD. Mutation screening by DNA sequencing identified a novel C10lT polymorphism located in the first exon (numbers are in reference to GenBank Accession AJ297411). Genotypes were determined by PCR-RFLPs analysis using the EcoRI restriction enzyme. The exon 1 polymorphism was then investigated in relation to BMD in a population-based cohort of 501 perimenopausal women randomly selected from Northeast of Scotland. We found that subjects with the EE genotype (homozygote T variant) had significantly lower lumbar spine BMD (mean Z-score +/- SEM; 0.038 +/- 0.108; n = 82) than subjects without this genotype (0.385 +/- 0.052; n = 419; p = 0.004). A similar trend was observed for the femoral neck BMD but results did not reach statistical significance (p = 0.18). Results for the lumbar spine remained significant (p = 0.007) even after adjustment for confounding factors (such as age, weight, height, menopausal status and HRT use) using general linear model ANOVA analysis. In conclusion, the work presented here is the first to report a significant association between polymorphisms of the human Fra-1 gene and BMD, which suggest that allelic variation at the Fra-1 gene might be important for regulation of BMD, raising the possibility that Fra-1 genotyping could be useful genetic marker for BMD and susceptibility to fractures. However, the exact mechanism by which this polymorphism affects BMD remains to be determined.

SA136

Prostaglandins Increase FGF-2 and FGF Receptor Expression and Nuclear Accummulation in Osteoblasts via Mitogen Activated Protein Kinase. M. G. Sabbieti*[1], L. Marchetti*[2], M. Menghi*[2], S. Materazzi*[3], G. Menghi*[2], L. G. Raisz[4], M. M. Hurley[4]. [1]Dept of Comparative Morphological and Biochemical Sciences, University of Camerino, Camerino, Italy, [2]Dept. of Comparative Morphological and Biochemical Sciences, University of Camerino, Camerino, Italy, [3]Department of Chemistry, University "La Sapienza", Rome, Italy, [4]Medicine/Division of Endocrinology & Metabolism, University of Connecticut School of Medicine, Farmington, CT, USA.

We previously reported that prostaglandin F2a (PGF2a) and the PGF2a agonist fluprostenol (Flup) increased basic fibroblast growth factor (FGF-2) mRNA and protein production in osteoblastic Py1a cells. The present report extends these studies by examining the effects of PGs on FGF receptor (FGFR) mRNA expression, the subcellular localization of FGF-2 and FGFR proteins and the signaling pathway involved. Rat osteoblastic Py1a cells were grown to confluence in Ham's F-12 medium containing 5% fetal calf serum and then serum deprived for 24 h before treatment with PGF2a or Flup for 2 to 24 h. Expression of FGFR mRNA was determined by Northern blot analysis. Py1a cells expressed only one FGF receptor (FGFR2). In the absence of serum, Py1a cells expressed a 4 kb FGFR2 mRNA transcript. Time course experiments revealed that PGF2a caused a 40% and Flup a 60% reduction in FGFR2 mRNA levels at 4 h and both caused an 80 % reduction after 24 h. To investigate in situ localization of FGF-2 and FGFR2 protein, binding patterns of FITC labeled antibodies to FGF-2 and FGFR-2 were examined by confocal laser scanning microscopy (CLFM). Py1a cells expressed low levels of cytoplasmic and nuclear localization for both FGF-2 and FGFR2 protein. Following 24 h of treatment with PGF2a or Flup, FGF-2 and FGFR2 proteins accumulated at the nuclear membrane and were also co-localized in the nucleus of Py1a cells. CLSM studies showed that pretreatment with cycloheximide blocked nuclear labeling for FGF-2 in response to PGF2a. Treatment with SU5402, a specific FGFR tyrosine kinase inhibitor, did not block PG mediated nuclear accumulation of FGF-2 or FGFR2. In contrast, pretreatment with PMA, an activator of protein kinase C (PKC) pathway prevented the nuclear accumulation of FGF-2 and FGFR2 in response to PGF2a. Similar results were obtained by pretreatment with the PKC inhibitor H-7. Cells treated with PGs or PMA showed increased nuclear labeling for the mitogen activated protein kinase, p44/ERK2, compared to control cultures. Pretreatment with PMA blocked both PG and PMA induced ERK2 nuclear labeling. We conclude that PGs stimulate nuclear accumulation of FGF-2 and its receptor by a PKC dependent pathway and suggest a role for p44/ERK 2 in this process.

Glycogen Synthase Kinase-3 (GSK-3) Signaling Is Involved in the Anti-apoptotic Effect of Fibroblast Growth Factor-2 in Human Calvaria Osteoblasts. F. Debiais[1], F. Lasmoles*[1], G. Lefevre*[2], F. Mascarelli*[2], P. J. Marie[1]. [1]INSERM U349, Paris, France, [2]INSERM U450, Paris, France.

Fibroblast Growth Factor-2 (FGF-2) is an important factor controlling osteogenesis. We hypothesized that FGF-2 may control human calvaria osteoblast apoptosis by involving regulation of GSK-3, a component of the APC/axin/beta-catenin complex which is important in determining cell fate. We found that, in both primary human calvaria osteoblasts and immortalized human neonatal calvaria (IHNC) cells, FGF-2 (50 ng/ml, 0-72 hrs) prevented by 50 % ($p<0.05$) DNA fragmentation induced by serum deprivation, as determined by terminal deoxynucleotidyl transferase-mediated nick-end labeling (TUNEL) analysis. This preventive effect of FGF-2 was due to reduction in caspase-2 and effector caspases-3,-6,-7 activity ($p<0.05$) whereas caspases-8 and -9 were unaffected. Western blot analysis of transduction signaling pathways showed that FGF-2 resulted in a rapid (5-15 min) Ser-473 phosphorylation of Akt, a serine/threonine kinase which phosphorylates GSK-3, resulting in phosphorylation and ubiquitin-mediated proteasomal degradation of beta catenin. Accordingly, FGF-2 induced Ser-9 phosphorylation of GSK-3 and beta catenin degradation, suggesting the implication of GSK-3-ß-catenin pathway in the anti-apoptotic effect of FGF-2. In agreement, selective inhibition of GSK-3 phosphorylation by lithium chloride (5-50 mM) or by the GSK-3 inhibitor SB 216763 (1-10 µM) increased caspase-2 and caspases-3, -6, -7 activity and suppressed the inhibitory effect of FGF-2 on caspases activity in serum-deprived IHNC cells. Furthermore, we found that LY 294002 (5-50µM) which inhibits the phosphorylation of phosphatidylinositol-3-kinase (PI-3-K) acting upstream of Akt, blunted the anti-apoptotic effect of FGF-2 and further increased caspase-2 and caspases-3, -6, -7 activity in serum-deprived IHNC cells. In contrast, inhibition of MAPK Erk-1, 2 or MAPK p38 by PD 98059 (25 µM) and SB 203580 (1-10 µM), respectively, did not affect GSK-3 activity or osteoblast survival induced by FGF-2. We conclude that 1) caspase-2, caspases-3, -6, -7 activity and apoptosis induced by serum deprivation are negatively regulated by the PI-3K-Akt-GSK-3 signaling pathway in human osteoblasts 2) FGF-2 reduces caspase-2 and effector caspases activity and apoptosis through selective activation of the PI-3K-Akt-GSK-3 signaling pathway. Thus, GSK-3 plays a critical role in the protective effect exerted by FGF-2 against apoptosis in human osteoblasts.

Parathyroid Hormone Receptor Type 1 (PTHR1)/ Indian Hedgehog (IHH) Expression Is Preserved In The Growth Plate Of Human Fetuses Affected With Fibroblast Growth Factor Receptor Type 3 (FGFR3) Activating Mutations. S. Cormier*[1], A. L. Delezoide*[2], C. Benoist-Lasselin*[3], L. Legeai-Mallet*[3], J. Bonaventure*[3], C. M. Silve[1]. [1]Faculté de Médecine X. Bichat, Inserm U426, Paris, France, [2]Hôpital Robert Debré, Service de Biologie du Développement, Paris, France, [3]Hôpital Necker Enfants Malades, Inserm U393, Paris, France.

Two principal pathways are known to play a key role in regulating endochondral ossification, that mediated by FGFR3 signaling, and that mediated by IHH/PTHR1 signaling. Human chondrodysplasias have been ascribed to mutations in either FGFR3 or PTHR1 genes. However, the involvement of these signaling systems to endochondral ossification has been mostly documented in mouse models. Although both the FGFR3 and IHH/PTHR1 signaling pathways are acting on the same developmental bone process, relatively few studies have evaluated the possible interactions between these two pathways. Analysis of the interplay between these pathways in mouse models expressing different FGFR3 activating mutations has lead to conflicting results owing to the inability of some models to faithfully reproduce the human phenotype. This underlines the importance of studies performed on human tissues. We analysed the femoral growth plates from fetuses carrying activating FGFR3 mutations (9 with achondroplasia, 21 with type 1 thanatophoric dysplasia, and 8 with type 2 thanatophoric dysplasia) and 14 age-matched controls by histological techniques and in situ hybridization using riboprobes for human IHH, PTHR1, type X and I collagen transcripts. We show that bone-perichondrial ring enlargement and increased vascularization of the growth plates in FGFR3-mutated fetuses correlate with the phenotypic severity of the disease. PTHR1 and IHH expression in growth plates, bone-perichondrial rings and vascular canals is not affected by FGFR3 mutations, irrespective of the mutant genotype and age, and is in keeping with cell phenotypes. Our study extends the genotype-phenotype correlation between human growth plate abnormalities and FGFR3 mutations. In addition, our results indicate that in human, FGFR3 signaling does not regulate the main players of IHH/PTHR1 pathway. Furthermore, we show that cells within the bone-perichondrial ring in controls and patients express IHH, PTHR1, and type X and I collagen transcripts, suggesting that bone-perichondrial ring formation involves cells of both chondrocytic and osteoblastic phenotypes.

SA141

Post-natal Defects in Bone Metabolism in Mice Deficient in FGFR3 Signaling. G. Valverde-Franco[1], H. Liu*[1], D. M. Ornitz*[2], R. Poole[3], D. Goltzman[1], J. E. Henderson[1]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Molecular Biology and Pharmacology, Washington University School of Medicine, St Louis, MO, USA, [3]Surgery and Medicine, McGill University, Montreal, PQ, Canada.

Bone development and maintenance of the adult skeleton are regulated by conserved signaling pathways, which are linked to multifunctional growth factors and their high affinity receptors. Fibroblast growth factor receptor 3 (FGFR3) is a receptor tyrosine kinase that binds preferentially to FGFs 2, 9 and 18 and is expressed in a restricted pattern in chondrogenic cells during limb development. Recent evidence suggests that FGFR3 is also expressed by cells of the osteogenic lineage in cranial sutures. Point mutations that result in constitutive activation of FGFR3 have been identified as the cause of a variety of human skeletal disorders that are characterised by short limbed dwarfism and bossing of the skull. Conversely, mice homozygous for targeted disruption of FGFR3 are born with longer bones in the axial and appendicular skeleton and develop severe kyphosis and impaired gait by 4 months of age. The hypothesis on which the current studies were based is that FGFR3 signaling mediates post-natal bone metabolism and maintains skeletal integrity. The absence of FGFR3 signaling would therefore result in osteopenia. We used a combination of non-invasive imaging and classic histology to compare the mineral content, micro-architecture and molecular composition of the bones of young adult wild type and FGFR3-/- male mice. Faxitron x-ray analysis consistently demonstrated kyphosis, lengthening of the humerus, femur and vertebra and loss of mineral in 4-month old FGFR3-/- mice compared with wild type littermates, an observation that was confirmed by bone densitometry measurements. X-ray microtomography, performed by Eric Beulens at Skyscan, Belgium, revealed a substantial loss of cortical and trabecular bone, a significant loss of trabecular connectivity and an increase in the SMI from 1.60 to 2.00 in mutant mice compared with control. Histochemical and immunochemical analyses of the proximal tibia demonstrated sparse trabeculae arising from a disorganised region of hypertrophic chondrocytes that stained heavily for type X collagen. This was associated with an increase in periosteal fibrous tissue, significant thinning of the cortices and failure to down-regulate MMP13 activity in the primary spongiosa. Taken together these observations reveal a previously un-identified role for FGFR3 in post natal bone metabolism and identify it as a potential molecular target to prevent disorders such as ostoporosis, which are associated with low bone mass.

SA142

Prenatal Exposure of IL-1 in Male Rats Have Skeletal Effects. D. Swolin-Eide[1], C. Nilsson*[2], J. Dahlgren*[3], A. Holmäng*[2], C. Ohlsson*[1]. [1]Department of Internal Medicine, Research Center for Endocrinology and Metabolism, Gothenburg, Sweden, [2]Wallenberg Laboratory, Sahlgrenska University Hospital, Göteborg, Sweden, [3]Pediatric Growth Research Center, Queen Silvia Children's Hospital, Göteborg, Sweden.

Interleukin-1 (IL-1) is a multifunctional cytokine that is involved in bone metabolism. Different sorts of stress or hormonal influences, during particular periods of pregnancy, may result in persisting or transient changes. Events occurring early in life or prenatally are able to play important roles in the pathogenesis of diseases in adult age. The aim of the present study was to investigate whether exposure to IL-1β during fetal life has any effect on bone tissue in rat offspring. Pregnant rats were given injections intra peritoneal (1 μ g/rat IL-1β) on day 8, 10 and 12 of gestation. Body weight was recorded from birth to 10 weeks of age. Offspring were sacrificed at 10 weeks of age. No effect on body weight or food intake was seen at any time in the IL-1β -injected group compared with controls. The weights of thymus, muscles, adipose tissues, gonads, spleen and heart were unchanged in the IL-1β -injected group. Interestingly, IL-1β -treated offspring showed reduced vertebral heights and tibial lengths. Furthermore, areal bone mineral density and bone mineral content in the spine, as studied by DXA, were reduced in the IL-1β -injected group compared to control rats. In conclusion, prenatal exposure of IL-1β results in reduced skeletal growth in male offspring.

SA143

Differential Expression of Cytokines and Chemokines in the Interface Membrane of Aseptic Loosened Endoprotheses of the Hip. E. A. Kaiser[1], C. Gentzsch*[1], N. Schultz*[1], J. Plutat*[2], R. Sellckau*[2], J. Wodtke*[2], G. Delling*[1]. [1]Bone Pathology, Center for Biomechanics, Hamburg, Germany, [2]Endoklinik, Hamburg, Germany.

Aseptic loosening of hip endoprotheses is the most common reason for implant failure. Between the implant-to-bone interface a synovial-like tissue that contains macrophages, fibroblasts and vascular endothelial cell develops that effects the loosening of prosthesis. The cells of this interface membrane secrete cytokines, chemokines and growth factors, which could stimulate bone resorption and fibrosis as well as reduce bone formation. To investigate the expression profile of the cytokines and chemokines, we subjected interface membrane samples obtained from 6 patients undergoing revision hip surgery to Clontech Atlas™ Nylon cytokine/receptor cDNA Expression Array. As a control, muscle tissue from the same patients was used. Our results indicate that 9 genes are differentially expressed in at least 3 out of the 6 patients. Interleukin-10 (IL-10), Calgranulin A, B, monocyte chemotactic protein-1 (MCP1), Rantes, tumor necrosis factor receptor (TNFR) 2, human teratocarcinoma-derived growth factor (TDGF1), ribonuclease/angiogenin inhibitor (RAI) and Thymosin beta10 mRNA is upregulated in the interface tissue as compared to control tissue. MCP1 and Rantes, C-C chemokines, as well as IL-10 and TNFR have been reported to be associated with the periprosthetic granulomas, whereas Calgranulin A, B, TDGF1, RAI and Thymosin b10 have been detected for the first time. Some of the corresponding proteins of the newly identified genes have been associated with tumor development and wound-healing adding new aspects to the pathological cell associated condition of aseptic loosening. These results suggest that in addition to recruitment, proliferation and activation of inflammatory cells, an inaccurate activation of mesenchymal cells might also contribute to pathological cell associated condition of aseptic loosening.

Roles of Inflammatory Cytokines in Acquisition of Calcifying Phenotype of Vascular Smooth Muscle Cells. A. Shioi[1], A. Kizu*[2], H. Taniwaki*[3], S. Jono*[2], Y. Okuno*[1], H. Koyama*[2], Y. Nishizawa[2]. [1]Cardiovascular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan, [2]Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan, [3]Internal Medicine, Inoue Hospital, Suita, Japan.

Calcification is a common feature of atherosclerotic lesions, especially in advanced stages of plaque formation. Inflammatory cells such as macrophages and T lymphocytes play an important role in the development of atherosclerotic lesions. By using a coculture model, we have identified tumor necrosis factor-α (TNF-α) and oncostatin M (OSM) as major cytokines derived from macrophages responsible for induction of alkaline phosphatase (ALP) in human vascular smooth muscle cells (HVSMC) in the presence of interferon-γ (IFN-γ) and 1α,25-dihydroxyvitamin D_3 ($1,25D_3$). In this study, we investigated the roles of these factors in acquisition of calcifying phenotype of vascular smooth muscle cells. Only in the presence of IFN-γ, $1,25D_3$, TNF-α, and OSM, ALP activity and its gene expression in HVSMC were increased in a time-dependent manner. ALP-positive HVSMC calcified their extracellular matrix in the presence of 10 mM β-glycerophosphate as evidenced by von Kossa staining and calcium quantification. In vitro calcification by HVSMC was dose-dependently inhibited by the treatment with bisphosphonates such as etidronate. Immunoblot revealed that the expression of SMC phenotypic markers such as α-smooth muscle actin and calponin in ALP-positive HVSMC were decreased compared with control HVSMC. Moreover, the expression of osteoprotegerin was also down-regulated in ALP-positive HVSMC. Since signaling through p38 mitogen-activated protein kinase (MAPK) mediates inflammatory responses to cytokines such as TNF-α, the role of p38 MAPK pathway was investigated with a specific inhibitor, SB203580. SB203580 dose-dependently inhibited ALP induction by these factors. Finally, we examined the expression of ALP in atherosclerotic calcified lesions of apoE-deficient mice. ALP activities were detected in smooth muscle cells around calcified plaque lesions. These data suggest that cytokines derived from macrophages and T lymphocytes may contribute to the development of atherosclerotic calcification.

New Small Molecular Weight Peptide Bone Growth Factor for Fracture Repair. D. R. Sindrey, E. Plawinski*, J. Auluck*. Millenium Biologix Inc., Mississauga, ON, Canada.

Various extraction methods have been applied to bone to extract, isolate, test and identify potential new bone growth factors. Most of these extraction methods, like those used for BMP's, have used conditions to preserve the integrity of the proteins extracted from bone. Using cancellous bovine bone, we have enzymatically extracted a bone growth factor that stimulates new bone formation. This factor has been identified as a 9mer fragment of one of the proteins normally present in the matrix of bone. A small molecular weight peptide, easily produced by peptide synthesis, could prove to be a promising factor for use in the systemic treatment of osteoporosis or local bone fracture repair. This study was conducted to investigate the bone forming ability of the synthetically produced BCSP™ (Bone and Cartilage Stimulating Peptide) P30 in a rat tibia assay as a preclinical development candidate for fracture repair. P30 peptide was dissolved in normal saline at 5 mgs per 100 microliter w/v and combined with a carrier of 1 mg of Skelite™ powder, a synthetic bone biomaterial. Male Wistar rats, weighing 125-200 grams, were randomized and then anaesthetized using Isoflurane. Delivery of the test material was made using a 0.5cc Insulin syringe with an integrated 28G1/2" needle. Test material was deposited onto the periosteal surface of the right medial tibia surface proximal to the knee under the Tibialis cranialis muscle group. The control group was injected with saline plus carrier. Animals received one injection. Tibia were dissected out after 7 days and submitted to DEXA scan, micro CT and demineralized histology sectioning. Particular attention was given to the metaphysis region (injection site) to assess the ability of the material to stimulate local bone formation. After 7 days, one injection of BCSP™ P30 peptide increased local bone formation in the tibia by 16% as measured by BMD (bone mineral density) and 22% as measured by BMC (bone mineral content) in the injection region compared to contralateral limb. Skelite™ carrier alone produced a 5.5% and 6.8% increase in BMD and BMC respectively. Micro CT scans and histology showed a marked increase in bone formation at the periosteal surface in the region of the injection. At dissection tibia appeared normal but notably larger than the contralateral limb. There was no evidence of ectopic bone formation, inflammation, muscle atrophy or bone trauma at the site of the injection. Stimulation of the periosteal lining would suggest a similar effect could be achieved on endosteal surfaces if the peptide was introduced into a fracture or trauma site. The rapid onset of the stimulatory effect would make the BCSP™ P30 peptide a potent site-specific candidate for the treatment of bone fracture and trauma.

Inadequate Copper (Cu) Intake Reduces Serum Insulin-like Growth Factor-1 (IGF-1) and Bone Strength in Growing Rats. Z. K. Roughead, H. C. Lukaski*. Grand Forks Human Nutrition Research Center, USDA-ARS, Grand Forks, ND, USA.

Decreased serum concentrations of IGF-1 are associated strongly with an increased risk of osteoporotic fractures. Although dietary zinc (Zn) has been reported to influence serum IGF-1 directly, the effects of other trace minerals, such as Cu, on serum IGF-1 and bone metabolism have not been elucidated. This study determined the effects of graded intakes (low, marginal and high) of Zn and Cu on serum IGF-1 concentration and measures of bone quality in growing rats. Weanling male Sprague Dawley rats (n=84) were randomly assigned to 12 groups using a 3x4 factorial design and were fed modified AIN-93G basal diets with varying amounts of Cu (0.3, 3, and 10 mg/kg designated as LC, MC, and HC, respectively) and Zn (5, 15, 45 mg/kg designated as LZ, MZ, and HZ, respectively) for 6 wk; a group of rats was pair-fed to each LZ group. No statistical differences were found between the LZ groups and the pair-fed groups in the variables reported. Dietary Zn affected body weights which were highest in the HZ groups ($p<0.0001$). The femur weights were the lowest in the LC groups ($p<0.004$), however, the calcium concentration of the femurs in the LC groups were higher as compared to the HC groups ($p<0.0001$). Dietary Cu influenced femur nitrogen concentration; it was about 10% higher in the LC compared to the HC groups. Although dietary Zn tended to influence serum IGF-1 concentrations ($p = 0.09$), dietary Cu was the primary determinant of this variable ($p<0.0001$). Dietary Cu was also the main determinant of differences in volumetric densities of lumbar vertebras (L4) and femurs, as determined by Archimedes' Principle, and femur breaking strength, as measured by a 3-point breaking test ($p<0.001$) and these variables were the lowest in the LC groups. Compared to the HC groups, serum IGF-1 and femur breaking strength were reduced by 27% and 14%, respectively ($p<0.05$). Serum IGF-1 correlated with both vertebral density and femur breaking strength even after accounting for contributions by body weight (semi-partial $R2 = 0.17$ and 0.15, respectively, $p<0.001$). In summary, low dietary Cu decreased serum IGF-1 concentration and the quality of spinal and long bones in growing rats. The poor quality of bones associated with low Cu intakes may be explained, at least in part, by the decreased serum IGF-1 concentrations. In the presence of graded intakes of Cu, effects of various amounts of dietary Zn were minimal.

Transcription from Promoter 2 of the IGF-I Gene is Increased in Liver of C3H/HeJ Mice that Exhibit Increased Peak Bone Formation. M. L. Adamo[1], C. Ackert-Bicknell[2], L. R. Donahue[2], W. G. Beamer[2], D. Powell*[3], C. J. Rosen[4]. [1]Biochemistry, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA, [3]Lexicon, The Woodlands, TX, USA, [4]St. Joseph Hospital, Bangor, ME, USA.

Insulin-like growth factor-I (IGF-I) is an important osteotrophic agent. Evidence exists supporting critical roles of both circulating and locally produced IGF-I in the acquisition and maintenance of peak bone mass and bone mineral density. Moreover, variation of serum IGF-I within the normal physiological range correlates with bone mineral density. Genetic, non-growth hormone dependent factors contribute to variations of serum IGF-I. Our groups have determined that inbred mouse strains are useful tools for characterizing genetic regulation of the serum IGF-I and bone mineral density phenotype. The C3H/HeJ mouse exhibits significantly higher serum and skeletal IGF-I content and bone mineral density and strength than the C57/Bl6 strain. The increased serum IGF-I is associated with a 2-fold increase in expression of IGF-I mRNA transcribed from the second promoter (P2) in liver and several other soft tissues. We have utilized an antisense RNA probe complementary to contiguous IGF-I gene sequence consisting of the 3' 126 bp of intron 1, the 72 bp of exon 2 and the first 188 bp of intron 2 in RNase protection assays (RPA) to show that levels of correctly initiated P2 premRNA and P2 mature mRNA transcripts are increased by 2-fold in C3H liver compared to C57 liver ($p < 0.05$). P1 premRNA transcripts are not increased, consistent with the lack of significant increase in mature P1 transcripts. As previously reported for rat liver, there is greater animal-to- animal variability in the abundance of premRNA transcripts than in the abundance of mature transcripts in both mouse strains, presumably reflecting the slower turnover rate of mature transcripts. The P2 promoter region was amplified by PCR from genomic DNA from several C3H and C57 mice and several sequence variations were noted in the region between -1350 and +32 (+1 is the first nucleotide of exon 2). In transiently transfected mc3T3 cells, and OVCAR-3 cells that express high levels of P2 transcripts, C3H P2 exhibited greater promoter activity than C57 P2 when comparing clones in which an A residue in C3H P2 replaced a C residue in C57 P2 at position -28. However, two additional clones each of C57 and C3H P2 all showed an A residue at position -28, and there was no difference in promoter activity. We conclude that P2 transcription in liver is increased in C3H mice and we speculate that differences in trans-acting factors binding to the P2 promoter region play an important role in the different rates of transcription.

SA153

Dexamethasone-induced Osteoprogenitor Proliferation and Differentiation in Rat Bone Cells Are Associated with Increased Insulin-like Growth Factor Binding Protein-4 (IGFBP-4) Proteolysis by Pregnancy Associated Plasma Protein-A (PAPP-A). D. Jia, J. N. Heersche*. Faculty of Dentistry, University of Toronto, Toronto, ON, Canada.

Our previous results clearly indicate that dexamethasone (Dex)-induced rat bone cell differentiation is associated with changes in expression of IGF system components. One of these, IGFBP-4, has been shown to consistently inhibit IGF action in a variety of systems, and we have demonstrated that IGFBP-4 mRNA levels are regulated by Dex. In the present study, we evaluated the effects of Dex on IGFBP-4 peptide levels in differentiating bone cells. Osteoprogenitor-containing cells were isolated from explant cultures of vertebrae of 3-month-old rats, cultured and treated with 10 nM Dex or vehicle for up to 20 days. Cell layer proteins were prepared from 6-, 8-, 14- and 20-day cultures and conditioned media (CM) collected from 14-d cultures. Osteoprogenitor-derived bone nodules were visualized by alkaline phosphatase staining of 20-d cultures. Dex stimulated bone nodule formation as reported previously. Western blots showed that cell layer IGFBP-4 levels were lower in Dex-treated cultures than in controls at all 4 time points. Because IGFBP-4 proteolysis has been observed by others in various human and rat cell cultures, we evaluated degradation of recombinant rat (rr) or human (rh) IGFBP-4 by CM using Western blotting. In the absence of IGF-II, a 2-hour incubation with CM from control (CM-Ctrl) and Dex-treated (CM-Dex) cultures both resulted in a small decrease in intact rrIGFBP-4, accompanied by the appearance of a smaller fragment. In the presence of 10 nM IGF-II, the decrease induced by CM-Dex was 2-5-fold greater than that induced by CM-Ctrl. Similar results were observed using rhIGFBP-4. In human fibroblasts, others have identified PAPP-A as the specific IGFBP-4 protease. To determine whether IGFBP-4 proteolysis induced by CM was related to PAPP-A activity, we pre-incubated CM with an anti-human PAPP-A neutralizing antibody before analyzing IGFBP-4 proteolysis. The antibody, which dose-dependently inhibited human PAPP-A-induced rrIGFBP-4 proteolysis, prevented the rrIGFBP-4 from being degraded by CM. Our results demonstrate for the first time that PAPP-A-like IGFBP-4 proteolytic activity exists in rat bone cell cultures and that the activity is higher in CM-Dex than in CM-Ctrl. The findings suggest that the decreased IGFBP-4 levels in Dex-treated cultures likely result from increased IGFBP-4 proteolysis. Since IGFs have been shown to stimulate osteoprogenitor proliferation and differentiation, increased IGFBP-4 proteolysis resulting in an increase in IGF action may be part of the mechanism by which Dex regulates osteoprogenitor differentiation.

Intracellular Osteopontin May be Required for OPN-null Bone Cells to Respond to Pulsatile Fluid Flow. D. T. Denhardt[1], C. C. Kazanecki*[1], L. W. Fisher[2], E. S. Sorensen*[3]. [1]Rutgers University, Piscataway, NJ, USA, [2]Csdb, nidcr, National Institutes of Health, Bethesda, MD, USA, [3]Protein Chemistry Laboratory, University of Aarhus, Aarhus, Denmark.

Osteopontin (OPN) is both a component of the bone matrix, mediating cell attachment and migration, and a cytokine, activating signal transduction pathways via integrins and CD44. There is also an intracellular form associated with CD44 and ezrin. OPN-null mice have superficially normal mineralized tissues despite a general defect both in osteoclast function and in bone resorption/remodeling. For example, they do not lose mineral to the same extent as wild-type mice after ovariectomy or when bones are unloaded. The purpose of this study is to understand why osteoblast/osteocyte-like bone cells in culture do not release NO in response to pulsatile fluid flow (PFF) if they cannot synthesize OPN. The question addressed here is whether OPN acts extracellularly or intracellularly. The approach is to expose bone cells (derived by outgrowth from fragments of the long bones of OPN-/- mice) to PFF while providing OPN either as an exogenously added protein or via infection with an OPN-expressing adenovirus vector. Responsiveness to PFF is assessed by the ability of the cells to produce NO in the first few minutes of exposure to PFF. Slides carrying the cells are placed in a fluid flow chamber and exposed to PFF for 20 min at roughly 18 dynes/cm2. At various times, medium is removed and assayed for nitrite. In contrast to wild-type cells, OPN-/- cells are deficient in their ability to produce NO in response to PFF. The results to date suggest that plating OPN-/- bone cells on recombinant OPN does not restore their ability to produce NO in response to a PFF stimulus. Efforts to restore OPN to the OPN-/- cells using an OPN-expressing adenovirus suggest in contrast that when OPN is synthesized endogenously in these cells, some sensitivity to PFF is restored. Mineralization of primary long bone cells isolated from control and OPN-/- mice was also assessed. The OPN-/- cells did not produce as many bone nodules in culture as control cells, although both cultures did stain similarly for alkaline phosphatase. We have generated clonal cell lines from spontaneously immortalized OPN-/- cells and are currently assessing their ability to mineralize and to respond to fluid flow with and without OPN. In conclusion, current evidence suggests that intracellular OPN is required for the osteoblast/osteocyte-like bone cells in culture to respond to a PFF stimulus as measured by the ability of the cells to produce NO in the first few minutes after the initiation of PFF. In the absence of OPN, bone nodule formation in mineralizing bone cell culture is also modified in that nodule formation is much less focused.

Mechano-sensing By Stretch-activated Calcium Influx Pathways In Human Chondrocytes. A. Miyauchi[1], M. Goto[2], K. Notoya[2], T. Sugimoto[3], Y. Takagi[1], K. Jinnai*[1], Y. Yoshimoto[1], K. Chihara*[3], T. Fujita[4], K. Okabe[5], Y. Mikuni-Takagaki[6]. [1]Medicine, National-Hyogo Chuo Hospital, Sanda, Japan, [2]Pharmaceutical Research Division, Takeda Chemical Industries Limited, Osaka, Japan, [3]Division of Endocrinology/Metabolism, Department of Clinical Molecular Medicine, Kobe University Graduate School of Medicine, Kobe, Japan, [4]Calcium Institute, Osaka, Japan, [5]Cellular Physiology, Fukuoka Dental College, Fukuoka, Japan, [6]Oral Biochemistry, Kanagawa Dental College, Yokosuka, Japan.

Mechanical stimuli, both anabolic and catabolic, are essential in maintaining morphology and function of cartilagenous tissues. The mechanisms of mechanosensing in chondrocytes, however, are not well characterized in human cells, in particular. We compared responses of chondrocytes derived from different species to stretch loading. Human, rabbit and bovine articular chondrocytes were cultured, loaded with fura-2, and distributions of subcellular cytosolic Ca^{2+}, $[Ca^{2+}]i$, were monitored using video image analysis. Stretch loading by swelling the cells with hypoosmotic solution (50% osmolarity) induced a rapid and progressive $[Ca^{2+}]i$, increase in either human(65±6 nM above basal, n=14), rabbit(99±15 nM, n=11) and bovine chondrocytes(126±21 nM, n=10). By depleting intracellular Ca^{2+} stores with thapsigargin, 70% of hypotonically induced $[Ca^{2+}]i$ increase was inhibited in rabbit and bovine chondrocytes. In contrast, more than 90% of the $[Ca^{2+}]i$, increased by exposing human chondrocytes to hypotonic solution, was abolished either by adding Gd^{3+} to the solution or by replacing with Ca^{2+} free media. Moreover, preincubation with thapsigargin inhibited the hypotonically-induced increase by less than 20%. It is suggested that a major source of intracellular Ca^{2+} is the influx of extracellular Ca^{2+} but not the release from intracellular Ca^{2+} stores. A larger $[Ca^{2+}]i$ increase was demonstrated by Ca^{2+} imaging in the submembranous region than in the perinuclear cytoplasm in response to the hypotonic exposure. In human cells, the hypotonically-induced [Ca2+]i increase are more likely to be sustained and oscillatory. Taken together, our results indicate that the hypotonically induced $[Ca^{2+}]i$ increase was primarily caused by an influx of Ca^{2+} through stretch-activated Ca^{2+} channels in human chondrocytes. In conclusion, human chondrocytes may be different from rabbit and bovine cells in sensing stress by stretch-activated Ca^{2+} channels. The SA channels may be involved in human chondrocyte volume regulation and mechanotransduction inherent to the human articular physiology.

Different Response of Human Mandibular Bone Osteoblast and Osteocyte to Mechanical Loading. H. Sekiya[1], Y. Mikuni-Takagaki[2], A. Miyauchi[3], T. Kondoh*[1], K. Seto*[4]. [1]1st Department of Oral &Maxillofacial Surgery, School of Dental Medicine, Tsurumi University, Yokohama, Japan, [2]Oral Biochemistry, Kanagawa Dental Collage, Yokosuka, Japan, [3]Internal Medicine, National Hyougo Central Hospital, Kobe, Japan, [4]1st Department of Oral and Maxillofacial Surgery, School of Dental Medicine, Tsurumi University, Yokohama, Japan.

The aim of this study is to characterize mechanical responses of bone cells as underlying mechanisms of bone regeneration. We compared the response of osteocytes and osteoblasts to low-intensity pulsed ultrasound (LIPUS) and stretching. Primary cells were prepared from human mandibular bone chips removed for a certain clinical treatment of patients who gave consent. We analyzed the effect of mechanical loading on message levels of c-fos, osteocalcin and IGF-I by RT-PCR analysis and Western blotting. The experiments gave us contrasting results: in the response of osteocytes to stretching, the steady-state level of osteocalcin mRNA was unregulated at 1h after the initiation of stretching. In the response to LIPUS, however, there was no upregulation of osteocalcin mRNA in osteocyte. While stretching induced calcium influx into the osteocytic cells, their proliferation was decreased. In the response of osteoblast to LIPUS, the steady-state level of osteocalcin mRNA was upregulated also at 1h after the initiation. In osteoblasts, however, mechanical loading by a low frequency stretching stimulus did not result in any such induction. In this study, we have clearly demonstrated that the high-frequency, LIPUS did not induce any significant responses of osteocyte including Ca2+ influx. Our findings support the notion that the osteocytes are sensitive to deformation of bone, sensing even a low strain magnitude through Ca2+ channels and PKA pathways, while osteoblastic cells in the osteogenic lineage are sensitive to another type of strain through different sensing mechanisms and signaling pathways. It is concluded that at least two entirely different types of mechanotranduction pathways are present in mandibular bone.

Fluid Shear Stress Induces Nuclear Translocation of Beta-catenin in Osteoblasts. S. M. Norvell*, F. Pavalko. Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN, USA.

Mechanical loading of bone produces movement of interstitial fluid over the surfaces of cells of the osteoblast lineage. The resulting fluid shear stress (FSS) is a potent metabolic stimulus for osteoblasts. The biological response of osteoblasts to FSS involves the conversion of the mechanical signal into a molecular signal. In this study, we investigated whether β-catenin functions as a molecular component of FSS-induced mechanotransduction in osteoblasts. β-catenin is a component of cell-cell adherens junctions where it is associated with cadherins. In response to certain stimuli, β-catenin also functions as a signaling molecule when it translocates to the nucleus and promotes gene expression. To examine whether FSS activates β-catenin signaling in osteoblasts, we subjected MC3T3-E1 osteoblast-like cells and primary rat calvarial osteoblasts to 1 hour of 12-dynes/cm^2 laminar FSS or 1 hour of static conditions and measured β-catenin subcellular localization. Immunofluorescence analysis revealed that 1 hour of FSS induced β-catenin nuclear translocation. To dissect the mechanism for FSS-induced β-catenin nuclear translocation, we examined the phosphorylation/activation state of Glycogen Synthase Kinase-3β (GSK-3β). In un-stimulated cells, β-catenin is phosphorylated by active GSK-3β and is targeted for degradation. The activity of GSK-3β itself is regulated by phosphorylation. Phosphorylation of serine 9 is known to inactivate GSK-3β. Analysis of GSK-3β phosphorylation revealed that 1 hour of FSS induced significant phosphorylation of GSK-3β at serine 9 as compared to static controls, which is consistent with FSS preventing phosphorylation of β-catenin and promoting the signaling capacity of β-catenin. To begin to elucidate pathways that β-catenin may regulate in osteoblasts, we investigated whether β-catenin regulates expression of cyclooxygenase-2 (Cox-2) in osteoblasts. To this end, we established MC3T3-E1 cell lines stably expressing a mutant β-catenin molecule that cannot be phosphorylated by GSK-3β and therefore cannot be degraded. Immunofluorescence analysis revealed that the mutant β-catenin molecule localized both to cell-cell interfaces and the nucleus of MC3T3-E1 cells. Cells expressing the mutant β-catenin molecule consistently showed increased levels of Cox-2 protein compared to control MC3T3-E1 cells, demonstrating a potential role for β-catenin in modulation of Cox-2 levels in osteoblasts. In summary, these data suggest that FSS induces β-catenin signaling via a mechanism that may involve GSK-3β, and also demonstrate that β-catenin regulates Cox-2 expression in osteoblasts.

Neither the Microfilament nor the Microtubule Cytoskeleton Is Required for Fluid Shear Stress Induced Increases in Cyclooxygenase-2 and Prostaglandin Release in MC3T3-E1 Cells. S. Norvell*, S. Ponik, F. Pavalko. Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN, USA.

Osteoblasts are mechanosensitive cells that respond to fluid shear stress (FSS) by increasing expression of cyclooxygenase-2 (Cox-2) and increasing prostaglandin release. Additionally, FSS induces reorganization of the actin microfilaments into contractile bundles termed stress fibers. It is thought that the cytoskeleton provides an organized network of fibrils that facilitate the transmission and conversion of mechanical signals into biological responses. In this study, we investigated whether an intact microfilament or an intact microtubule network is necessary for FSS-induced increases in Cox-2 and prostaglandin release in MC3T3-E1 osteoblasts. MC3T3-E1 cells were treated with multiple disruptors of actin filament formation including Cytochalasin B, Cytochalasin D, Latrunculin A and Jasplakinolide or with disruptors of microtubule formation including Nocodozole and Colchicine. Cells were treated with drug for 1 hour prior to the experiment, and were then subjected to 90 minutes of 12-dynes/cm^2 laminar FSS or static conditions in the presence of drug. After cessation of flow, cells were incubated for 30 minutes in 1mL of media in the presence of drug. After 30 minutes, the levels of the prostaglandins PGE_2 and PGI_2 released into the 1mL of media were measured using an enzymeimmunoassay and the cells were lysed in SDS sample buffer for analysis of Cox-2 levels by immunoblot. Neither disruption of the actin cytoskeleton nor disruption of the microtubule cytoskeleton with any drug prevented a significant FSS-induced increase in either PGE_2 or PGI_2 release or Cox-2 protein. These results suggest that neither the microfilament nor the microtubule cytoskeleton is required for FSS-induced prostaglandin metabolism. To rule out the possibility that the presence of either an intact microfilament or an intact microtubule cytoskeleton is sufficient for FSS-induced prostaglandin metabolism, we also disrupted both filament systems and then measured FSS-induced Cox-2 levels and prostaglandin release. Even in the absence of both intact microfilaments and intact microtubules, FSS still induced a significant increase in Cox-2 protein and PGE_2 and PGI_2 release. In summary, neither microtubules nor microfilaments are required for FSS-induced prostaglandin metabolism in MC3T3-E1 cells.

SA163

Osteocyte Formation and Reduced Bone Strength During Rapid Growth. D. Murray*[1], B. Williams*[1], N. Loveridge[2], D. Waddington*[1], C. Farquharson[1]. [1]Roslin Institute, Scotland, United Kingdom, [2]Bone Research Group, Addenbrookes Hospital, Cambridge, United Kingdom.

In response to increased loads during growth, bones increase their diameter by the deposition of circumferential lamellae and the incorporation of primary osteons at the periosteal surface. However, the influence of growth rate on circumferential growth and bone architecture in the immature skeleton is not fully understood. We have compared morphometric and biochemical indices between tibiae from chickens with fast (F) and slow (S) growth potential. Body weight at 42 days was, F=2441g and S=1224g and appositional bone formation rate was F=98.0 and S=68.4 um/day. Bone diameter was greater in the fast growing birds (F=7.16mm, S=5.36mm, P<0.001) and allometric analysis indicated that bone width increased in relation to body weight in both strains. Although bone breaking strength (F=448N, S=270N, P<0.001) and stiffness (F=363N/mm, S=285N/mm; P<0.01) were higher in the fast growing birds after adjustment for body weight the bones were inherently weaker (breaking strength; F=99N, S=181N, P<0.05, stiffness; F=60N/mm, S=220N/mm, P<0.001). To explain these reduced mechanical properties, porosity and ash content were determined. Porosity was elevated periosteally (F=36%, S=27%, P<0.01) but not endosteally. Staining for TRAP and cement lines indicated the increased porosity was not a result of primary osteon remodelling. Increased porosity was due to slower infilling of the primary osteons in the fast strain (F=42.5%, S=27.0%, P<0.01). Osteocyte density within the periosteal interstitial bone was higher in the fast growing strain(F:5.3/mm2, S:1.8/mm2, P<0.01) but unchanged in primary osteons (F:2.73/mm2, S:2.86/mm2, P<0.01).Ash content was reduced in the fast strain (F=45.0%, S=48.0%, P<0.05). In conclusion, fast growth resulted in the expected circumferential expansion to withstand increasing loads. This was accompanied by increased porosity resulting from rapid formation of primary osteons at the periosteal surface and the incapacity of osteoblasts to completely infill the resultant canal. As periosteal interstitial bone of the fast strain had a higher osteocyte density the reduced osteon infilling is unlikely to be due to a decrease in osteoblast numbers. These events suggest that transit through the osteoblast lineage is more rapid at the periosteal surface of the fast strain and while osteoblast precursors are locally available, this has no effect on bone growth. Such increased osteoblast transit times would account for the reduced primary osteon infilling but as osteocyte density within primary osteons was similar in both strains other mechanisms such as increased apoptotic rates may be responsible.

SA164

Low Amplitude Vibration Does Not Induce Osteogenesis in the Mouse Ulna. S. M. Tanaka*, M. I. Alam*, C. H. Turner. Orthopaedic Surgery, Indiana University, Indianapolis, IN, USA.

It is known that the bone strain profile involves not only periodic strain waves at around 1 cycle/s (Hz), but also broad frequency vibration with small amplitude. Others have suggested that low amplitude, high frequency (20-30 Hz) vibration is an osteogenic stimulus for bone tissue. The purpose of this study is to evaluate effects of the broad frequency (0-50 Hz) vibration on new bone formation. Male C57BL/6 mice (16 weeks old) were used for this study. The following types of loading were applied to ulnae of the mice under anesthesia for 30 sec/day for 2 days using a newly developed mechanical stimulator: (1) low

frequency, high amplitude sinusoidal loading at 2 Hz with 3 N peak-to-peak (n=10), (2) broad frequency, low amplitude vibration with 0.3 N of mean amplitude and frequency ranging from 0 to 50 Hz (n=8), and 3) no loading control (n=8). After mechanical loading, new bone formation on the periosteal surface was analyzed histomorphometrically on cross-sections cut from the ulnar midshaft. High amplitude, low frequency (2 Hz) loading significantly increased mineralizing surface (MS/BS, %), mineral apposition rate (MAR, mm/day), and bone formation rate (BFR/BS, mm3/mm2/year) on the right ulnae compared to non-loaded left ulnae. However, no new bone formation was induced by low amplitude, broad frequency vibration. From these results, we conclude that low amplitude vibration does not induce osteogenesis in the mouse ulna even when applied at frequencies of up to 50 Hz.

Effect of Long-duration Spaceflight on Integral and Compartmental Bone Density in the Spine and Hip. T. F. Lang[1], H. Evans*[2], N. Rianon*[3], Y. Lu[1], H. Genant[1], A. Leblanc[3]. [1]Radiology, University of California, San Francisco, CA, USA, [2]Wyle Labs, Houston, TX, USA, [3]Medicine, Baylor College of Medicine, Houston, TX, USA.

Bone loss is a well-established medical risk factor for long-duration spaceflight. Recent DXA studies of the MIR crewmembers demonstrated an average bone mineral loss from the spine and hip of 1.1-1.6%/month, with large heterogeneity between subjects and between skeletal sites in the same subject. However, these studies utilized integral measurements and there is little information on how the bone loss distributes three-dimensionally across the trabecular and cortical compartments. To address this issue, we are performing a study of astronauts making long-duration spaceflights (4-6 months) on the International Space Station, using volumetric quantitative computed tomography (vQCT) to measure changes of cortical and trabecular bone in the hip and spine. Five subjects were imaged in the hip and L1/L2 vertebrae using a helical vQCT protocol (GE Hispeed Advantage, 80 kVp, 280 mAs hip, 140 mAs spine, 3mm slice thickness, pitch=1) before and after missions lasting from 120-165 days. For comparison, the subjects underwent DXA of the spine and hip (Hologic QDR-4500) at the same time points. Hip measures included integral (iBMD), trabecular (tBMD) and cortical (cBMD) bone density, as well as cortical bone mass (cBMC), in the femoral neck and total femur regions. Spine measures included iBMD and tBMD in the vertebral centrum as well as iBMD in a region containing the entire vertebra. We tabulated the average percentage change (standard deviation) in these measures and determined the statistical significance using the paired t-test.

QCT-Femoral neck				QCT-Total femur			
iBMD	tBMD	cBMD	cBMC	iBMD	tBMD	cBMD	cBMC
-5.8(1.5) p<0.001	-11.1(5.2) p<0.01	-3.1(2.5) p<0.05	-4.4 (4.4) ns	-7.6(3.9) p<0.01	-10.2(4.3) p<0.01	-3.5(2.3) p<0.05	-8.6(7.3) p<0.05

QCT-Centrum		QCT-Total Vertebra
iBMD	tBMD	iBMD
-3.7(2.2) p<0.05	-1.2 (1.4) ns	-3.8(2.5) p<0.05

For DXA of L1-L4 and the total femur, the percentage changes were -3.3 (SD=3.2, p<0.05) and -5.6 (SD=1.7, p<0.01) respectively. The relatively small changes observed in the vertebrae were offset by larger proximal femoral changes. There was a trend in the hip data for trabecular losses to exceed cortical and integral losses. Our preliminary data indicate that current countermeasure approaches may be insufficient to prevent serious loss of bone mineral in the hip.

SA167

Effect of Nicotine on Distraction Osteogenesis of the Rat Mandible. A. J. M. Schulten*[1], L. B. Kaban*[2], D. Perrott*[2], J. Glowacki[1]. [1]Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA, [2]Oral and Maxillofacial Surgery, Massachusetts General Hospital, Boston, MA, USA.

Distraction Osteogenesis (DO) has gained clinical acceptance as a surgical technique for bone lengthening, but success is unpredictable. There is need for new approaches to study the biology of DO, especially in compromised settings. Nicotine inhibits soft and hard tissue wound healing in several animal models. We assessed the effects of nicotine (NC) on DO in rats undergoing mandibular distraction. We anticipated that NC treatment would diminish osteogenesis and bone elongation. Mandibular body osteotomies were created between the 2nd and 3rd molars in 25 adult male rats; they were fitted with custom distraction devices. Twenty-four animals underwent gradual lengthening of the right hemimandible using a 3-day latency period, 6-day distraction (0.25 mm twice daily), and 4 weeks of neutral fixation. Twelve of these rats received subcutaneous nicotine pellets (153 mg nicotine; NC group), and twelve received placebo pellets (Vehicle group, Ve). A pilot study showed that these slow-release pellets achieved plasma levels of NC at 60.6 ± 1.6 ng/mL (equal to 1.5 packs/day). One animal underwent acute lengthening (3 mm) and fixation, without implantation of NC or Ve. After removal of devices, specimens were analyzed for radiographic bone fill score, amount of bone advancement, and histological features. Although all animals underwent temporary weight loss following surgery and change to soft diet, subsequent weight gain was similar in NC and Ve. Device distraction of 3.2 mm ± 0.2 was achieved. The mean radiographic bone fill score with NC (2.7 ± 0.9) was 75% of that in Ve (3.6 ± 0.7; p=0.0036). Maintenance of elongation (after removal of the device) in NC was 49% of that in Ve, p=0.0008. With NC, distracted hemimandibles were 1.18 ± 0.84 mm longer than contralateral sides (104.2% ± 3.3; p=0.0014); with Ve, distracted hemimandibles were 2.39 ± 0.33 mm longer (108.5% ± 1.0, p<0.0001). Analysis of the relationship between radiographic bone score and hemimandible advancement showed a significant correlation (Spearman r=0.549, p=0.012). Qualitative histological and enzyme analysis demonstrated less bone, and less osteoblastic and osteoclastic activity in NC. Rather, the gaps contained dense, poorly vascularized scar tissue. The animal with acute advancement showed poor bone fill radiographically and fibrosis by histology, as evidence that gradual distraction was needed to repair a gap this size. This study shows that nicotine inhibits osteogenesis, vascularity, and bone lengthening in mandibular DO wounds. This novel model provides the opportunity to evaluate potential means of enhancing impaired osteogenesis.

Effect of Swimming Exercise on Bone Mineral Density and Trabecular Bone Architecture in Ovariectomized Rats. Y. Joo*[1], T. Sone[2], M. Fukunaga[2], S. Onodera*[1]. [1]Health and Sports Sciences, Kawasaki University of Medical Welfare, Kurashiki, Japan, [2]Nuclear Medicine, Kawasaki Medical School, Kurashiki, Japan.

Weight-bearing exercise is traditionally recommended for improving bone health in postmenopausal women. In this study usefulness of swimming exercise as an alternative to weight-bearing exercise was examined in ovariectomized rats. Ovariectomy (OVX) or sham-operation (SHAM) was conducted to Fisher-344 female rats of the 18 weeks old. Rats in a swimming exercise group (SW-OVX, n = 9; SW-SHAM n = 9) swam for 12 weeks, 5 days/week for 60 min per session. A control group (CON-OVX n = 7; CON-SHAM, n = 9) engaged in no structured exercise. After 12 weeks of intervention, femurs and lumber vertebrae (L1-L4) were analyzed for bone mineral density (BMD) by dual energy X-ray absorptiometry. Cancellous bone in distal femoral metaphysis was analyzed for three-dimensional trabecular bone architecture by microcomputed tomography (micro-CT). BMD and geometrical properties of diaphyseal cortical bone were evaluated in the mid-femoral region by micro-CT. Finally, biomechanical properties of the femurs were analysed by three-point bending (Instron). Bone mineral densities were significantly decreased both in femur and lumber vertebra by OVX. These changes were suppressed by swimming exercise. Trabecular bone width, number, and connectivity were decreased by OVX, whereas the structure model index, i.e. the ratio of rod-like to plate-like trabeculae, increased. These changes were also suppressed by swimming exercise. Femurs of the SW group had greater cortical thickness compared with CON. No significant effect of OVX was observed for mechanical properties of femoral diaphysis. In conclusion, data from this study suggest that the swimming exercise would have some beneficial effects on bone mass, structure, and strength.

The Effects of Weight-Bearing (Running) and Non-weight-bearing (Swimming) Exercise on Bone Development in Growing Rats. R. S. Yang*[1], T. H. Huang*[1], S. S. Hsieh*[2], F. L. Chang*[2], S. H. Liu*[3]. [1]Department of Orthopaedics, National Taiwan University Hospital, Taipei, Taiwan Republic of China, [2]Department of Physical Education, National Taiwan Noraml University, Taipei, Taiwan Republic of China, [3]Institute of Toxicology, National Taiwan University, Taipei, Taiwan Republic of China.

Mechanical loading is an important factor on the bone development. Different exercise will cause various kinds of mechanical loading on bone. In the present study, we investigated the effects of two different exercise modes, swimming vs. running, on rat's bone development.Twenty-nine male Wistar rats (7-wk-old) were randomly divided into three groups: control group (CON, n=10), running group (RUN, n=9) and swimming group (SWIM, n=10). Running exercise was held on the treadmill at a moderate exercise intensity (20m/min in speed) and the swimming trained animals swam with a weight (2% of body weight) attached to their tails. The training protocols were 1hr/day and 5 days/wk for a period over 8 wks. All rats were deeply anesthetized and sacrificed by decapitation after the end of training session. The measured parameters included: 1) wet weight and length of bone; 2) cross-sectional parameters of long bone midshaft; 3) spongy bone histomorphometric analysis; 4) bone mineral density (BMD) and bone mineral content (BMC) by using DEXA (dual energy X-ray absorptiometer). The results showed that exercise training significantly reduced the increment of body weight. Therefore, statistic analysis of one-way ANCOVA was used to correct the effects of body weight on original data and compared the means among groups. In femoral bone mass measurement, two exercise groups (RUN: 1293.4±106.3 mg; SWIM: 1269.5±80.8 mg) showed a higher wet mass than CON rats (1148.3±66.9 mg) (p= .002). Although statistical significance did not reach, SWIM rats were still lower in long-axis values (p= .069) and higher in short-axis values (p= .056) of tibial cross-section. Due to the higher body weight, CON rats were originally higher in BMD and BMC value. After correction of the effects of body weight with covariance analysis, RUN rats had the highest BMD on the proximal tibia and distal femur. The histomorphometric studies showed that exercise groups had a 27% higher bone volume ratio than CON. In addition, RUN rats had a thicker trabecular bone than SWIM rats in proximal tibia, although the significant difference was not found. In conclusion, weight-bearing exercise showed a benefit in increasing BMD on specific sites. Different exercise modes had different adaptation types in tibia cross-sectional geometry and spongy bone. However, swimming training might not provide a sufficient stress for the improvement of BMD and BMC.

***In vitro* Effects of Ribavirin and Interferon alpha-2b on Primary Human Osteoblasts.** R. O. Moreira*[1], M. L. F. Farias[1], F. J. S. Saboia*[1], A. Balduino*[2], L. Boldrini*[2], H. S. H. Martins*[2], R. Borojevic*[3], M. E. L. Duarte[3]. [1]Division of Endocrinology/HUCFF, Universidade Federal do Rio de Janeiro, RJ, Brazil, [2]Dept. of Histology and Embriology, Universidade Federal do Rio de Janeiro, RJ, Brazil, [3]Dept. of Histology and Embriology and PABCAM/HUCFF, Universidade Federal do Rio de Janeiro, RJ, Brazil.

Hepatitis C is a chronic disease that affects approximately 100 million people worldwide. The treatment of hepatitis C with interferon α-2b (IFNα-2b) and ribavirin has already been related with a significant decrease in bone mineral density. The purpose of this study is to investigate the *in vitro* effects of different concentrations of ribavirin and IFNα-2b on human osteoblasts and thus help to define the mechanisms that contribute to the associated bone loss. Accordingly, we exposed primary human osteoblasts obtained by outgrowth of cells from bone chips discarded after orthopedic procedures to ribavirin and/or IFN-α2b. The cells (2.5 x10^4 - 10^5 cells/ml) were cultured in DMEM medium containing 10% FCS and treated with IFN-α2b (0.1-1000 UI/ml), ribavirin (0.01-50 μg/ml) and IFN-α2b (100UI/ml) + ribavirin (0.01-50 μg/ml) respectively. At regular time points, cultures were harvested for posterior analysis. The level of alkaline phosphatase activity (ALP) was determined at 7 and 14 days and the proliferative potential of the cells was assessed by MTT at 3, 4 and 5 days respectively. Cell cycle analysis and apoptosis were ascertained by flow citometry using propidium iodide (PI) at 24 and 48 hours after incubation. In the concentrations used in this study, IFN-α2b did not affect the viability, ALP expression and osteoblast proliferation capacity. In ribavirin and ribavirin+IFN-α2b treated cultures, ALP activity was diminished within 14 days (P<0.001 and P<0.01 respectively) in comparison with IFN-α2b treated cultures. The number of apoptotic osteoblast cells was increased after 48h of incubation with ribavirin in high concentrations (10 and 50 μg/ml). The reduction in cell proliferation was dose-dependent and was detected as early as day 3 in all cultures treated with ribavirin. In conclusion, our experiments demonstrate that ribavirin reduced in a time and dose dependent manner cell proliferation and the expression of osteoblasts markers. Cell apoptosis is likely to be also accelerated by ribavirin. It is possible that localized increase in the levels of this antibiotic may be disruptive to osteoblast mitogenic potential and function. This action may contribute to the loss of bone reported *in vivo*.

Leptin Induces Apoptosis via ERK/cPLA2/cytochrome C Pathway in Human Bone Marrow Stromal Cells. G. S. Kim[1], J. S. Hong*[2], S. W. Kim*[2], J. M. Koh*[1], E. S. Kim*[3], C. S. An*[4], J. Y. Choi*[5], S. L. Cheng[6]. [1]Division of Endocrinology and Metabolism, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Republic of Korea, [2]Asan Institute for Life Science, Seoul, Republic of Korea, [3]Department of Internal Medicine, University of Ulsan College of Medicine, Seoul, Republic of Korea, [4]School of Biological Sciences, College of Natural Sciences, Seoul National University, Seoul, Republic of Korea, [5]Medical Research Institute, Kyungpook National University, Taegu, Republic of Korea, [6]Division of Bone and Mineral Disease, Department of Medicine, Washington University, School of Medicine, St Louis, MO, USA.

Leptin, the Ob gene product, has recently emerged as a key regulator of bone mass. However, the mechanism mediating leptin effect remains controversial. Since the action of leptin is dependent on its receptors, we analyzed their expression in osteoblast-lineage primary human bone marrow stromal cells (hBMSC). Both the short and long forms of leptin receptors were detected in hBMSC. Incubation of hBMSC with leptin significantly decreased the cell viability. This cytotoxic effect was prevented by Z-Val-Ala-Asp-fluoromethylketone, a pan-caspase inhibitor, implicating that leptin-induced hBMSC death was caspase-dependent. Further investigation demonstrated that leptin activated caspase-3 and caspase-9, but not caspase-8, and increased the cleavage of poly (ADP-ribose) polymerase (PARP) and the release of cytochrome C into cytosol. Leptin was found to activate ERK, but not p38 and JNK, and up-regulated cPLA2 activity, the latter was abolished by pre-treatment of cells with the MEK inhibitor (PD098059 or U0126) or cPLA2 inhibitor (AACOCF3). PD98059, U0126, and AACOCF3 also diminished the leptin-induced cell death and caspase-3 activation, implicating that leptin induced hBMSC apoptosis via ERK/cPLA2/cytochrome C pathway, which subsequently activated caspase-9 and caspase-3 and cleaved PARP. To our knowledge, this is the first study demonstrating the detrimental effect of leptin on bone cell development.

Crovidisin, a Snake Venom Protein, Selectively Induced Apoptosis of ROS 17/2.8 Osteosarcoma Cells but not of Rat Primary Osteoblasts. C. H. Tang*[1], R. S. Yang*[2], W. M. Fu*[1], C. Z. Liu*[3]. [1]Pharmacology, National Taiwan University, Taipei, Taiwan Republic of China, [2]Orthopaedics, National Taiwan University Hospital, Taipei, Taiwan Republic of China, [3]Pharmacology, Tzu Chi University, Hualien, Taiwan Republic of China.

Apoptosis, a programmed, physiological mode of cell death, is important in tissue homoeostasis. Crovidisin, a collagen-binding protein, prevents platelet-collagen interaction. In addition, crovidisin expresses matrix metalloproteinase I (MMP-1) activity. Here we report crovidisin, purified from *Crotalus viridis* venom, selectively induced apoptosis of ROS 17/2.8 the osteosarcoma cells but not of rat primary osteoblasts. Immunofluorescence showed that osteoblasts and ROS 17/2.8 exert different pattern of fibronectin (Fn) fibrillogenesis, type I collagen (Cn) and α5 integrin. Immunocytochemistry, western blotting and flow cytometric analysis showed that osteoblasts have more abundant expression that ROS 17/2.8, including Fn, Cn, α5, β1, α2 integrin and focal adhesion kinase (FAK). Crovidisin selectively reduced more adhesion activity of ROS 17/2.8 to Fn or Cn than osteoblasts. Treatment with crovidisin for 24 hr selectively caused the detachment of ROS 17/2.8 but not osteoblasts. However, triflavin, a RGD-dependent disintegrin purified form *Trimeresurus flavoviridis,* did not cause the detachment of either osteoblasts or ROS 17/2.8. Treatment with crovidisin for 36 hr caused the mitochondrial membrane potential loss in ROS 17/2.8 but not in osteoblasts, suggesting that crovidisin is also to induce early apoptosis in ROS 17/2.8. Treatment with crovdisin for 48 hr induced apoptosis in ROS 17/2.8 as examined by propidium iodide and DNA fragmentation analysis. These results suggest that primary rat osteoblasts secrete more matrix and have more integrin expression than ROS 17/2.8 cells. Since the cell-matrix interaction is vital for the cell survival, the crovidisin can bind to collagen and cleave Cn may selectively induce apoptosis of ROS 17/2.8 cells.

Celiac Disease Affects Bone Remodelling: An *in vitro* Study. D. Fortunati*, A. Taranta, M. Longo*, S. Migliaccio, M. L. Bianchi*, M. T. Bardella*, S. Saraifoger*, A. Teti. Experimental Medicine, University of L'Aquila, L'Aquila, Italy.

Gluten intolerance causes celiac disease. This inflammatory disorder of the small bowel is often associated with low bone mass. To assess whether celiac disease directly affected bone formation, human osteoblasts were challenged with sera from three categories of patients: 25 celiac patients on gluten-free diet for at least two years, 17 just-diagnosed, yet untreated celiac patients, and 21 healthy donors. ^{3}H thymidine incorporation revealed that sera from both groups of celiac patients stimulated osteoblast proliferation (p<0.01 vs. controls). Alkaline phosphatase activity and matrix mineralization were mostly increased in osteoblast cultures exposed to sera from untreated celiac patients (p<0.005 vs. controls). These data hint to

an osteoblast stimulation, possibly due to serum factors enhancing their function. However, our observation was not in agreement with those in patients showing reduced bone mass. We therefore hypothesized that osteoclast activity could be increased in celiac patients by serum factors, and that enhanced osteoblast activity could stimulate osteoclast function by released cytokines. Indeed, osteoclast formation and activity was marked increased in human peripheral blood monocyte cultures exposed to sera from celiac patients relative to normal subjects, with a clear-cut acceleration of multinucleated osteoclast differentiation. Notably, RT-PCR analysis of specific cytokines in osteoblast cultures kept in the presence of our sera showed negligible transcriptional expression of TNFalpha and IL-18, and similar mRNA levels for IL-1, IL-6, IL-12 in all conditions, but reduced mRNA levels of osteoprotegerin (OPG) in osteoblasts exposed to sera of celiac patients ($p<0.01$ vs. controls), with consequent alteration of OPG-ligand/OPG ratio. As OPG is a decoy receptor which blocks OPG-ligand stimulatory effect on osteoclasts, we believe that reduction of this factor may contribute to the enhanced bone loss observed in celiac disease.

The RANKL Promoter Is Activated Through Acetylation. J. Rubin[1], T. C. Murphy*[1], L. Zhu*[1], J. W. Pike[2], M. S. Nanes[1], X. Fan[1]. [1]Medicine, VAMC & Emory University, Decatur, GA, USA, [2]Biochemistry, University of Wisconsin-Madison, Madison, WI, USA.

RANKL expression in bone determines the level of osteoclast recruitment and activity. While it is clear that osteoactive substances regulate RANKL mRNA expression, studies of the RANKL promoter have not been particularly informative. For instance, vitD robustly stimulates the endogenous murine gene but has little to no effect on RANKL promoter delivered transiently despite the presence of a vitD consensus sequence. Furthermore, while RANKL expression is restricted to certain cell types, the RANKL promoter appears to be equally active in multiple lineages. This suggests that silencing of an otherwise active promoter might be a predominant control mechanism. To better understand regulatory controls of this important remodeling signal, we first examined endogenous RANKL mRNA levels in ST2 stromal cells. Northern analysis showed that RANKL mRNA was dose-dependently upregulated in the presence of the histone deacetylase inhibitor trichostatin A (TSA). In fact, 6 h TSA treatment raised RANKL mRNA equivalently to that caused by 24 h 10 nM vitD exposure. We next studied the response of five RANKL promoter luciferase constructs of 2020, 1500, 957, 725 and 500 base pairs (bp) from the tsp. Luciferase was measured 48 h after transfection of RANKLpr-luc constructs. There was no apparent tissue specificity (comparing ST2, COS7 and HeLa cells), nor were basal activities different between the five constructs. TSA dose-dependently stimulated -2020bpRANKLpromoter-luc activity maximally to 32 ± 2 fold over basal (basal = promoter activity in absence of TSA). This was significantly higher than TSA's stimulation of a co-transfected SV40-promoter, which peaked at 3-fold over basal SV40 activity. The full TSA effect was present in both the -500bpRANKLpr-luc and the -725bpRANKLpr-luc constructs (34 ± 3 fold and 30 ± 1 fold over basal, respectively). Addition of the next 232 5'-bps (to -957bpRANKLpr-luc) was associated with a significant decrease in TSA effect, to only 20 ± 1 fold over basal. This repression was relieved with inclusion of further 5'-sequence: TSA stimulated the -1500bpRANKLpr-luc construct 31 ± 2 fold. This suggested that the first 500 bp contain a sequence sensitive to acetylation. EMSAs performed with overlapping 150 bp probes representing this RANKLpr sequence revealed numerous bands, none of which was altered by pretreatment with 25 nM TSA. Finally, the -2020bpRANKLpr was extended 3' through the entirety of exon+1: addition of 3'-sequence conferred neither tissue specificity nor response to vitD. Overall, our data suggest that acetylation of histone or transcription factors associated with the endogenous RANKL gene may be involved in its regulation.

SA178

Metabolic Acidosis Stimulates Expression of RANK Ligand RNA. K. K. Frick, D. A. Bushinsky. University of Rochester School of Medicine and Dentistry, Rochester, NY, USA.

Metabolic acidosis increases net calcium efflux from bone, initially through physicochemical and later predominantly through cell-mediated mechanisms. Acidosis decreases bone formation by osteoblasts and increases bone resorption by osteoclasts. Growth and maturation of osteoclasts, which are derived from hemopoietic precursors in the monocyte / macrophage lineage, are dependent on the interplay of a number of factors, including RANKL, M-CSF and OPG produced by osteoblasts. Commitment of precursors to functional osteoclasts is induced by the interaction of the osteoclastic cell-surface receptor RANK with its ligand expressed on the surface of osteoblasts, RANKL. The RANK / RANKL interaction not only initiates a differentiation cascade which leads to mature, bone resorbing osteoclasts but increases their resorptive capacity and survival. To test the hypothesis that metabolic acidosis alters the expression of one or more of these mediators of osteoclastogenesis, we compared RNA expression from neonatal mouse calvariae cultured in acidic (initial pH ~ 7.1 and [HCO3-] ~ 10.6 mM) or neutral (initial pH ~ 7.5 and [HCO3-] ~ 25.1 mM) medium for 24 and for 48 h. Initially using RT-PCR and with subsequent quantitation by Northern analysis we found that metabolic acidosis significantly increased expression of RANKL RNA at both 24 h (2 fold) and 48 h (5 fold) compared to respective controls. There was no alteration of OPG or M-CSF RNA levels with metabolic acidosis. Net calcium efflux from bone was also increased into the acidic, compared to control, medium. At 48 h, net calcium efflux correlated directly with RANKL expression ($r = 0.770$, $n = 15$, $p < 0.001$). The acidosis-induced increase in RANKL would be expected to augment osteoclastic bone resorption and help explain the acidosis-induced increase in cell-mediated net calcium efflux.

Regulation of Target Genes by TGF-ß Inducible Early Gene Through Specific Binding to an SP-1 Binding Site. M. Subramaniam, S. A. Johnsen*, K. Rasmussen*, T. C. Spelsberg. Biochemistry and Molecular Biology, Mayo Clinic & Foundation, Rochester, MN, USA.

TGF-ß is an important autocrine and paracrine growth factor which plays an important role in human osteoblast growth and differentiation. To understand the role of TGF-ß signaling in human osteoblasts and to study the role of downstream target genes, we cloned a TGF-ß inducible early gene (TIEG) from human osteoblasts which acts as a downstream target for TGF-ß signaling. TIEG transcript is rapidly induced within 60 minutes of TGF-ß treatment. TIEG was shown to be a primary response gene induced by selective members of TGF-ß superfamily in human osteoblasts. TIEG encodes a 480 amino acid nuclear protein and has a unique N-terminal end with several SH-3 binding sites. The C-terminal end has three C2 H2 type zinc finger domains with a high homology to several Krüppel transcription factor family members. Further, TIEG is a phosphoprotein and has two Erk1 phosphorylation sites at amino acid residues 97 and 293. It also has potential GSK3 kinase and PDK1 binding sites at residues 93 and 100, respectively. To characterize this protein further and to understand the transcriptional regulation and DNA binding specificity of TIEG protein to DNA, we performed electrophoretic mobility shift assay (EMSA) using an SP-1 consensus sequence (GGG GCG GGG) and a purified TIEG protein produced by a baculovirus expression system. EMSA analysis demonstrated a specific shift when TIEG was incubated with the SP-1 consensus sequence. Competition experiments with excess unlabeled SP-1 duplex DNA competed for TIEG protein binding to SP-1 sequence, whereas the mutant SP-1 duplex DNA did not have any effect on the shift. Further, we were able to supershift this complex with TIEG specific polyclonal antibody suggesting that TIEG protein binding to SP-1 consensus sequence is highly specific. Using gel shift analyses, TIEG showed minimal to no binding to other known zinc finger binding consensus sequences, suggesting TIEG specifically binds to the SP-1 core sequence. We have previously demonstrated that TIEG down-regulates Smad-7 promoter activity. We now demonstrate that TIEG protein binds to an SP-1-like sequence within the Smad-7 promoter. We are now examining whether this SP-1-like sequence represents the target site for the down-regulation of this promoter. In conclusion, we have identified a DNA binding consensus site for TIEG protein which may be utilized in the transcriptional repression of the target gene promoters.

Dlx5 Is a Direct and Specific Target of BMP-signaling, Which in Turn, Triggers Downstream Transcrption Factors, Runx2 and Osterix. M. Lee*[1], Y. Kim*[1], J. Sung*[2], J. M. Wozney[3], H. Kim[4], H. Ryoo[1]. [1]Biochemistry, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea, [2]Orthodontic Dentistry, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea, [3]Genetic Institute Inc, Cambridge, MA, USA, [4]Pediatric Dentistry, School of Dentistry, Kyungpook National Nuiversity, Daegu, Republic of Korea.

Injection of BMP-2 in muscular tissue induces ectopic bone formation. Likewise, BMP-2 treatment not only blocked myogenic differentiation but also induced osteoblastic transdifferentiotion of myogenic C2C12 cells. Previous reports suggested a clue that BMP-2-stimulated Runx2 could play the pivotal role in the transdifferentiation. However, Runx2 expression was induced also by TGF-b1 which could not support osteoblast differentiation in vitro, and Runx2 overexpression by itself could not support osteoclacin expression that was induced by BMP stimulation. Therefore, the induction of Runx2 is not sufficient to explain the BMP-induced transdifferentiation. Here we demonstrated that Dlx5 was specifically expressed in osteogenic cells, and was specifically induced by BMP-2 or BMP-4 signaling but was not by other osteogenic signals including TGF, GDF, FGF, glucocorticoid and Vit.D. Forced expression of constitutive active BMPR-I or BMP R-Smads also stimulated Dlx5 expression even in the absence of BMP-2. Since key transcription factors related to osteoblast differentiation, Dlx5, Runx2 and Osterix, are induced by BMP signaling, the hierarchical regulatory relationship between them would be the next question. Dlx5 induction by BMP was immediate and did not require de novo protein synthesis in C2C12 cells. In contrast, Runx2 or Osterix did require new protein synthesis. Antisense-blocking of Dlx5 completely abrogated both of Runx2 and Osterix expression induced by BMP-2. Dlx5 overexpression strongly enhanced osteogenic marker genes, such as alkaline phosphatase, type I collagen, bone sialoprotein, osteocalcin, even in the absence of BMP-2. On the contrary, neither Runx2- null mutation nor Runx2-overexpression influeced on the Dlx5 or Osterix induction by BMP-2 treatment. Taken together, these results strongly suggest that Dlx5 is the proximal target of BMP signaling that triggers Runx2 and Osterix independently, which in turn, resulted in the bone marker gene expression.

Heterogeneous Nuclear Ribonucleoprotein K Represses Transcription from a CT Element in the Osteocalcin Promoter. J. P. Stains[1], F. Lecanda[2], D. A. Towler[1], R. Civitelli[1]. [1]Div. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA, [2]Histology and Pathology, University of Navarra, Pamplona, Spain.

Heterogeneous nuclear ribonucleoprotein K (hnRNP K) was biochemically purified from a screen of proteins that co-purify with binding activity to the osteocalcin proximal promoter. HnRNP K is a unique member of the heterogenous ribonucleoprotein (RNP) family. Unlike other RNPs, hnRNP K preferentially binds single stranded DNA rather than RNA via 3 repeats of a KH motif. HnRNP K has been implicated as a transcription factor that can transactivate via interaction with a pyrimidine-rich CT element. Because a nearly identical CT-rich element is present in the rat osteocalcin proximal promoter, we tested the ability of hnRNP K to affect osteocalcin promoter activity. Electrophoretic mobility shift analysis (EMSA) of binding of recombinant hnRNP K to a CT-rich element in the -76 to -55 region of the rat osteocalcin promoter reveals that hnRNP K binds single stranded, rather than double stranded oligonucleotide probes. Additionally, hnRNP K antibody can supershift a binding activity present in ROS 17/2.8 nuclear extract using single stranded sense, but not antisense or double stranded -95 to -47 oligonucleotides. Addition of recombinant hnRNP K to ROS 17/2.8 nuclear extract disrupts formation of a DNA/protein complex on double stranded CT element oligonucleotides. The identity of the affected protein/DNA complex is currently unknown, but is under investigation. Luciferase reporter assays demonstrate that overexpresssion of hnRNP K in ROS 17/2.8 cells can repress transcription from the -92 to +32 osteocalcin promoter, which includes the CT element, as well as from a single CT element placed upstream of a RSV minimal promoter. In summary, we have identified hnRNP K as a novel transcriptional repressor acting on the osteocalcin promoter. HnRNP K inhibits osteocalcin gene transcription via two possible mechanisms, 1) modulation of protein-protein interactions that inhibit the formation of a transcriptional complex on the CT element; or 2) binding single stranded CT element *in vivo*, where hnRNP K may act directly as a repressor of transcription.

Identification by cDNA Microarray of Genes Involved in human Mesenchymal Stem Cells Osteogenesis and Mineralization. M. Doi[1], A. Nagano*[2], Y. Nakamura*[1]. [1]Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Tokyo, Japan, [2]Department of Orthopaedic Surgery, Hamamatsu University School of Medicine, Shizuoka, Japan.

Using a culture system that facilitates osteogenic differentiation of bone marrow-derived human mesenchymal stem cells, we analyzed gene-expression profiles during the mineralization process by means of a cDNA microarray system consisting of 23,040 genes. We compared expression profiles of the cells at days 3, 15, and 27 of incubation in media containing either a combination of 0.1mM dexamethasone (Dex), 0.05mM ascorbic acid-2-phosphate (AsAP), and 10mM beta-glycerophosphate (bGP), Dex only, AsAP plus bGP, or medium with no osteogenic supplements. Histochemical detection of alkaline phosphatase and staining by alizarin red S revealed osteogenic differentiation of cells incubated in the presence of all three agents, but not in the other cultures. Comparison of the expression profiles disclosed transcriptional stimulation of 55 genes and repression of 82 genes among more than 20,000 examined. Some of the differentially expressed genes had already been cited for involvement in synthesis of extracellular matrix, in cell differentiation, and in proliferation. For example, within 3 days of incubation, the osteogenesis-inducing medium repressed expression of latent transforming growth factor beta binding protein 2, matrix methalloproteinase 14, myosin regulatory light chain 2, and other genes known to be associated with maintenance of extracellular matrix and muscle structure. After 15 and 27 days, a negative regulator of helix-loop-helix protein called “inhibitor of DNA binding 4” was down-regulated, and we detected up-regulation of methallothionein 2A, osteoprotegerin, and S100 calcium-binding protein A10, all known to have roles in osteogenesis. The set of differentially expressed genes we report here should contribute to a better understanding of the process of mineralization in the matrix surrounding human mesenchymal stem cells.

Characterization of Dexamethasone-Induced Glutamine Synthetase Expression in Human Osteoblastic Cells. A. Olkku*[1], P. V. N. Bodine[2], A. Linnala-Kankkunen*[3], A. Mahonen[1]. [1]Medical Biochemistry, University of Kuopio, Kuopio, Finland, [2]Women´s Health Research Institute, Wyeth-Ayerst Research, Radnor, PA, USA, [3]Biochemistry, University of Kuopio, Kuopio, Finland.

Recently, it has become clear that glutamate signalling is also functional in non-neuronal tissues including bone. Several reports show that human osteoblasts and osteoclasts express diverse glutamate receptors similar to those expressed in the central nervous system. In addition, osteoblasts express a glutamate transporter, GLAST, that is responsible for the cellular glutamate uptake. However, the importance of glutamate and its metabolism in bone cells is currently unknown. Previously, we showed that dexamethasone (Dex), a synthetic glucocorticoid, powerfully induced 12-fold increase in glutamine synthetase (GS) expression in human MG-63 osteosarcoma cells. The glucocorticoid receptor mediated induction needed partly new protein synthesis and was modulated by another potent regulator of osteoblasts, $1,25(OH)_2D_3$. In further characterization of GS in MG-63 cells, the activity of the enzyme was about 15 times higher in 100 nM Dex-treated cells (24 h) compared to the control. A 5-fold increase in GS mRNA level by Dex (3 h) was identified with RT-PCR. Furthermore, the role of GS on glutamate action in these cells was explored by using riluzole, an inhibitor of glutamate release. In our experiments, riluzole-induced accumulation of glutamate alone did not stimulate GS expression implying that the elevated level of substrate is not enough to stimulate GS expression in MG-63 cells. However, given both Dex and riluzole for 24 h, the GS expression was elevated and at the same time, the growth suppressive action of riluzole was diminished. This may indicate that Dex-induced GS expression during riluzole-treatment was able to increase the survival rate of MG-63 cells. The Dex-induction of GS was characterized also in other human osteoblastic cells: in conditionally immortalized preosteoblasts, HOB-03-C5, and mature osteoblasts HOB-03-CE6. In these cells, the Dex-response was slower and weaker than in MG-63 cells, but the induction was determined both on transcriptional and translational levels. Also the enzyme activity was elevated accordingly. GS is an enzyme catalyzing the conversion of glutamate and ammonia to glutamine. In bone, the role of GS is unknown but based on the recently characterized glutamate receptors and transporters, this enzyme may have a central role in glutamate signalling system. Therefore, GS as a regulator of intracellular glutamate concentration can be important in controlling osteoblast proliferation and differentiation, and thereby the development of glucocorticoid-induced osteoporosis.

SA188

Human Osteoblasts Express Functional CXC Chemokine Receptors 3: Their Ligand CXCL10 Induces Alkaline Phosphatase And N-Acetyl-β-D-Glucosaminidase Release. G. Lisignoli*[1], S. Toneguzzi*[1], A. Piacentini*[1], L. Cattini*[1], M. Tschon*[1], S. Cristino*[1], F. Grassi[1], A. Facchini*[2]. [1]Laboratorio di Immunologia e Genetica, Istituti Ortopedici Rizzoli, Bologna, Italy, [2]Laboratorio di Immunologia e Genetica, Istituti Ortopedici Rizzoli, Dip. Medicina Interna e Gastroenterologia, Università degli Studi di Bologna, Bologna, Italy.

Osteoblasts (OBs) represent a bone cell population that contributes to the maintenance of bone homeostasis, and directly or indirectly regulates bone remodeling, growth and mineralization .OBs are not only responsible for matrix deposition, but they also support the differentiation of immune system cells. Chemokines are key mediators of leukocytes recruitment and activation to site of inflammation. These factors interact with specific receptors, thus eliciting different responses (i.e. immunological, enzymatic) in situ. In particular, in the bone tissue they favour the degradation of extracellular matrix and bone remodelling. We investigated the expression of the CXC chemokine receptors in isolated human OBs from post-traumatic patients by RT-PCR and flow cytometry. OBs express high levels of CXC chemokine receptor 3 (CXCR3) and 5 (CXCR5), intermediate level of CXCR1 and CXCR4 but not CXCR2. Functional assays to evaluate the engagment of CXCR3 to its ligand CXCL10 demonstrate that significantly induce the release of N-acetyl-β-D-glucosaminidase, an enzyme involved in endochondral ossification and bone remodelling able to degrade important extracellular matrix components. Moreover, alkaline phosphatase activity, a useful index of matrix formation was also upregulated by CXCL10. Both Bordetella pertussis toxin and neutralizing anti-CXCR3 monoclonal antibodies block CXCL10 induction. We also demonstrated the expression of CXCL10 and CXCR3 in human bone tissue biopsies from post-traumatic patients. These results indicate that CXCR3/CXCL10 receptor-ligand pair may play an important role in OB activity through the specific upregulation of two enzymes which are involved in the bone remodeling process.

SA189

Spatial and Temporal Expression of the Tyrosine Phosphatase, OST-PTP, During Osteogenesis. L. A. Yunker*[1], C. S. Carlson*[2], L. J. Mauro[3]. [1]Grad Program in Molecular Veterinary Biosciences, U of MN, St. Paul, MN, USA, [2]Veterinary Diagnostic Medicine, College of Vet Med, St Paul, MN, USA, [3]Animal Science-Physiology, U of MN, St. Paul, MN, USA.

Osteotesticular Protein Tyrosine Phosphatase (OST-PTP) is the only tyrosine phosphatase currently being studied that appears to be specifically expressed by osteoblasts, is hormonally regulated and is necessary for osteoblast differentiation. Previous studies have examined the in vitro regulation of OST-PTP in primary osteoblasts or cell lines, but little is known about its expression in vivo. To better characterize the regulation of OST-PTP in bone and to further our understanding of its function in osteogenesis, in vivo expression patterns and levels were determined by in situ hybridization and Northern blot analysis. The spatial and temporal expression of the murine OST-PTP (mOST-PTP) gene was compared to markers of bone formation during embryogenesis as well as in tissues formed by endochondral vs. intramembranous ossification. Adjacent paraffin-embedded tissue sections of embryos 11, 12.5, 14,16 and 19 days post-coitum (dpc) as well as neonatal calvaria and long bones were incubated with 35S-labeled riboprobes encoding mOST-PTP as well as Cbfa1, alkaline phosphatase (ALP) and osteocalcin (OC). Northern analysis was performed on embryo, limb and calvarial mRNA. During embryonic development, mOST-PTP mRNA is first detected at 12.5 dpc in the mesenchyme of the skull and several other cranio-facial bones. This highly restricted expression overlaps with that of Cbfa1 mRNA, a transcriptional regulator of osteoblast commitment, which localizes to the mesenchyme of the skull, cranio-facial bones, the clavicle and ribs. By 14 dpc, mOST-PTP expression expands to include most of the cranio-facial

bones, the clavicle, ribs, vertebrae, hip and hindlimb. The relative level of mOST-PTP expression increases at 16 dpc in the ossification centers of the embryo. By 19 dpc, this gene is only observed in the perichondrium of the ribs on the ventral side but continues to be expressed in other areas of ossification. During endochondral ossification, mOST-PTP mRNA is observed in the perichondrium, the periosteum, the surface of the trabecular bone, and along the chondro-osseous junction. Adjacent long bone sections show OC expression restricted mainly to the surfaces of trabecular bone and the periosteal surface of cortical bone. Northern analysis confirms that temporal expression of OST-PTP overlaps with Cbfa1, ALP and OC expression. These results suggest that the OST-PTP gene is expressed in osteoprogenitor cells and that this expression is highly regulated and site-specific in the skeleton during embryogenesis and ossification.

SA190

Analysis of DMP1 Expression During Osteoblast Lineage Differentiation. I. Kalajzic*[1], A. Braut*[1], M. Stover*[1], A. Narayanan*[2], A. George*[2], M. Mina[1], D. Rowe[1]. [1]University of Connecticut Health Center, Farmington, CT, USA, [2]University of Illinois, Chicago, IL, USA.

The osteoprogenitor lineage passes through a number of proliferation and differentiation stages in the process of producing differentiated osteoblasts and osteocytes. Our previous studies have demonstrated that promoter-green fluorescent protein (GFP) transgenes can be used to identify and isolate populations of cells at the preosteoblastic stage (pOBCol3.6GFP positive cells) and at the mature osteoblastic stage (pOBCol2.3GFP) in real time in primary bone cell cultures derived from mice bearing these marker transgenes. This strategy forms the basis for appreciating the cellular heterogeneity of lineage and relating gene function to cell differentiation. Lacking in our model system has been a selective marker at the osteocytic level of differentiation. Based on previous studies in chicken and rat that dental matrix protein 1 (DMP1) exhibits an osteocyte-restricted pattern of expression, we monitored the expression of this protein in murine primary marrow stromal and calvarial osteoblast cultures and in developing bone, calvaria and teeth. In both culture models, a strong DMP1 mRNA signal was detected after the onset of mineralization, 2-4 days after the onset of osteocalcin (OC) mRNA expression. Using in situ hybridization, we confirmed a restricted pattern of DMP1 expression in osteocytes of mouse calvaria and long bones. Osteoblasts on the endosteal and perisoteal surface were negative for DMP1 expression. This data indicate that DMP1 should be a good candidate for identification of living osteocytes using DMP1 promoter-GFP as a marker. Therefore we utilized a 3.0 kb rat DMP1 promoter to drive the coral autofluorescent marker, DS2-red, in a VSV-G pseudotyped retroviral vector. The mature vector contains inactivated LTRs allowing the inserted promoter to drive the marker gene expression in response to its cellular environment. We are currently evaluating DMP1 promoter expression after retroviral infection of neonatal calvarial osteoblast cultures relative to pOBCol2.3GFP and OC-GFP activation. The characterization of DMP1-Red positive cells will be necessary to confirm the value of the DMP1 promoter currently in hand as an osteocyte marker prior to generating transgenic mice expressing the construct.

Developmental Stages of Murine Heterotopic Bone, a Model for Assessing Bone Formation in vivo. Z. Kalajzic*, J. He*, R. Gu*, B. Kream, D. Rowe. University of Connecticut Health Center, Farmington, CT, USA.

Assessing the intrinsic capacity of the osteoprogenitor pathway to form bone in vivo as a consequence of a genetic manipulation or altered gene function is an essential component in somatic gene therapy and functional genomics. We have previously characterized transgenic mice harboring the green fluorescent protein (GFP) gene fused to different fragments of the Col1a1 promoter that activate at defined stages of cell differentiation as judged by its expression pattern in primary cell culture and in intact mouse bone. The pOBCol3.6GFP transgene initiates low-level expression in AP+ fibroblastic shaped cells in culture and within the periosteum (preosteoblastic stage of differentiation) and becomes much stronger in cuboidal shaped cells of the developing nodules and in lining osteoblasts of bone (early osteoblastic cells). The pOBCol2.3GFP transgene expression is restricted to the mineralized nodule in culture and surface osteoblasts on the surface and within bone (mature osteoblast and osteocyte). This study was initiated to determine if the pattern of expression was recapitulated in newly formed heterotopic bone from implanted marrow stromal cells (MSC), a source of cells likely to be available for genetic engineering and functional genomic studies. An FGF-expanded population of MSCs derived from either transgenic mouse were suspended in a neutral collagen solution, heat gelled at 37C and implanted into the dorsal subcutaneous space of C.B-17 Hsd Scid/bg immunodeficient mice. Recipients were sacrificed at days 8, 11, 14, 19 and 24 and the vascularized implant examined in paraffin embedded sections. At day 8 and day 11, the tissue was richly invested with capillaries and cells with a fibroblastic morphology. The pOBCol3.6GFP transgene was activated as elongated, “fibroblast-like” cells which in some regions included a tissue “envelope”. No strong pOBCol3.6+ or any pOBCol2.3+ cells were present at this time. However by day 14, the morphology of pOBCol3.6+ cells in areas of primitive osteoid had became rounded and strongly positive cells, and by at day 19, these areas had well-developed bone with accompanying marrow elements. These same areas are also positive for the pOBCol2.3+ cells but by day 25 when the mature module is formed, the distributions of the two transgenes differ. Strong pOBCol3.6+ cells line the bone surface while the pOBCol2.3+ cells are more prominent within the osteoid. This is the typical pattern of expression in normal bone in these two transgenic lines. This model should be useful to study osteoblast lineage in vivo as well as to examine donor and recipient participation in the process of the new bone formation.

SA193

BMP-2 Inducible Kinase (BIKe) Inhibits Cbfa1 Action on the Osteocalcin Promoter. B. Sanyal*, A. E. Kearns. Division of Endocrinology, Mayo Clinic, Rochester, MN, USA.

BIKe is a novel kinase whose expression is increased during BMP-2 induction of osteoblast differentiation. Overexpression of BIKe in MC3T3-E1 cells attenuates differentiation of these cells to osteoblasts. The mechanism of this effect is not known. Since Cbfa1 is a critical transcription factor for osteoblast differentiation, we investigated whether BIKe can alter Cbfa1 action on the osteocalcin promoter. ROS 17/2.8 cells were transiently transfected with an osteocalcin promoter-luciferase reporter plasmid, a Cbfa1 expression plasmid or control, and either pCMV/BIKe expression plasmid or control pCMV plasmid. BIKe overexpression did not affect luciferase activity generated from endogenous transcription factor action on the osteocalcin promoter. However, BIKe overexpression decreased by 40% the luciferase activity from co-transfection of the Cbfa1 expression plasmid. OSX is a recently discovered transcription factor that is downstream of Cbfa1 in the program of osteoblast differentiation and also is critical for osteoblast differentiation. Analogous transient transfection experiments were performed to assess the effects of BIKe expression on OSX action on the osteocalcin promoter. A pcDNA4.1/OSX expression plasmid or pcDNA4.1 control were transfected into ROS 17/2.8 cells with the osteocalcin promoter-luciferase reporter, and with pCMV/BIKe or pCMV control. Preliminary results indicate no effect of BIKe expression on luciferase activity generated from OSX action on the osteocalcin promoter. Our experiments suggest that BIKe may either directly regulate Cbfa1 action on the osteocalcin promoter, or indirectly by, for example altering interaction with repressors or inhibiting other factors downstream of Cbfa1. Additional experiments are underway to further address these possibilities.

SA194

Thiazide-Sensitive Sodium Chloride Co-Transporter (NCC) in Cryosections of Rat and Human Bone. M. M. Dvorak[1], H. Carter*[2], D. Riccardi*[1]. [1]Physiology, Pharmacology & Toxicology, University of Manchester, Manchester, United Kingdom, [2]Oral Pathology, University of Manchester, Manchester, United Kingdom.

Thiazide diuretics act by inhibiting the activity of the thiazide-sensitive sodium chloride co-transporter (NCC) in the kidney. Such therapy is also associated with an increase in bone mineral density, however, the mechanism for these effects in bone is still unclear. Recent studies have demonstrated the presence of NCC-related transcripts in a rat osteogenic cell line, suggesting that thiazides may have a direct effect on bone cells. To further examine the role of this transporter in bone, expression of NCC was examined by immunocytochemistry, using biochemically intact cryosections of rat bone and biopsies of human mandible. Undecalcified sections from freshly frozen adult rat femora (n = 6) and freshly frozen human mandible (n = 3) were stained using affinity-purified polyclonal antibodies raised against a 110 amino acid segment from the amino terminus of rat NCC. Comparisons were made with known distributions of the bone-specific proteins osteopontin and bone sialoprotein. Our results showed that there was clear NCC-specific immunofluorescence, present in a characteristic punctuate pattern, predominantly in the osteoblasts and osteocytes. In the extracellular matrix of mature lamellar bone, strong immunofluorescence was evident in the regions of reversal lines, while a more general distribution was present in the matrix of primary woven bone. This pattern of expression was confirmed using decalcified paraffin embedded sections of rat femur. We conclude that NCC is present in the cells of osteoblastic origin and in the extracellular matrix of bone. These results suggest a role for this molecule in bone cell function and provide evidence that the effects of thiazide diuretics on bone mineral density may be mediated via direct effects on bone cells. The extracellular distribution of NCC in bone suggests an as yet unkown function for this molecule as an extracellular protein. Further studies characterising the role of NCC in bone metabolism and bone disease are in progress.

SA195

Identifying the ‘Secretome’ of Bone Cells. C. Lanctot, P. Moffat*, P. Salois*, M. Gaumond*, N. St-Armant*, E. Godin*, K. Sellin*, G. Thomas. Phenogene Therapeutiques Inc, Montreal, PQ, Canada.

Secreted and membrane-bound proteins are key players in bone biology. In an effort to discover new bone anabolic agents, we have developed a novel functional genomics tool to identify the subset of cDNAs encoding secreted and membrane-bound proteins (the ‘secretome’). Libraries of cDNA fragments are expressed in mammalian cells from conditionally-defective viral genomes that can be packaged and exported in the culture medium only if the cDNA fragment encodes a secretory signal. Thus, this technology allows the selective retrieval of cDNAs encoding secreted and membrane-bound proteins by simply analyzing the content of viral particles collected from the culture medium of transfected cells. Libraries were constructed from various developing and adult bones as well as from osteoblastic cell models. A total of 9 libraries were screened. 2546 inserts that were retrieved were sequenced; 2473 (97%) contained a putative secretory signal. These encoded 419 unique cDNAs, of which 325 (77%) were previously annotated and 32 specifically associated with skeletal biology. As expected, the known secretome of bone cells was characterized by an abundance of cDNAs encoding proteins involved in secretory processes and matrix deposition. Interestingly, the secretome also included a number of molecules involved in Wnt signaling, consistent with the recently proposed importance of this pathway in osteoblast function. Of the 94 cDNAs encoding proteins of unknown function, 23 (24%) either had no match in databases or contained a secretory signal that could not be predicted from database mining. Expression profiles of these novel cDNAs were determined by Northern analysis on a panel of 52 embryonic and adult tissues. Expression of 9 clones was found to be bone-specific or greatly enriched in bone. Our screening effort has thus identified a number of novel secreted and membrane-bound molecules that may play a role in osteoblast function.

Differential Regulation of Cbfa1 (Runx2) Protein and Activity by Bone Morphogenetic Protein-2 (BMP-2) in Osteoblastic Cell Lines at Various Stages of Differentiation. C. Halleux, B. Fournier*, N. Zamurovic*, H. Keller*, M. M. Susa. Arthritis and Bone Metabolism Therapeutic Area, Novartis Pharma Research, Basel, Switzerland.

Cbfa1 (Runx2) is a master gene regulator of osteoblastic differentiation, as shown by gene deletion and dominant negative construct overexpression in mice. BMP-2 is a known inducer of osteoblast differentiation and was also reported to up-regulate Cbfa1 mRNA levels. However, the exact role of Cbfa1 in the differentiation process remained elusive. Here we examined in detail the steps on BMP-2-induced Cbfa1 pathway in two murine cell lines at various stages of osteoblast differentiation: pluripotent C2C12 cells and pre-osteoblastic MC3T3-E1 cells. Both C2C12 and MC3T3-E1 cell lines responded to BMP-2 by an increase in markers of osteoblast differentiation (alkaline phosphatase, osteocalcin), and by the activation of expected signaling pathway (Smad1, but not Erk phosphorylation). MC3T3, but not C2C12 cultures, also formed mineralized bone nodules. In both cell lines, BMP-2 did not stimulate Cbfa1 type II promoter, but induced its mRNA after 3 days, suggesting an indirect, post-transcriptional regulation. Cbfa1 type I mRNA was expressed, but not regulated. The proteins for Cbfa1 type II (starting with MASNS) and for Cbfa1 type I (starting with MRIPV) were detected by Western blotting in both cell lines. However, BMP-2 induced Cbfa1 type II protein only in MC3T3 cells, but not in C2C12 cells. BMP-2 increased Cbfa1 DNA binding activity in both cell lines, albeit to higher levels in MC3T3 cells. By contrast, the activity of luciferase driven by Cbfa1 response element OSE2 was increased by BMP-2 in C2C12, but not in MC3T3 cells. These findings unravel the unexpected complexity in Cbfa1 regulation by BMP-2: often reported mRNA regulation does not translate into protein up-regulation in C2C12 cells and the protein binding to OSE2 element does not increase reporter gene activity in MC3T3 cells. These data suggest that Cbfa1 OSE2 transcriptional activity can be regulated independently of protein levels at early stages of differentiation, while higher levels of Cbfa1 protein may have OSE2-unrelated functions at later stages of differentiation.

Noggin Arrests Stromal Cell Differentiation In Vitro. E. Gazzerro[1], S. Rydziel[1], L. Priest[1], A. N. Economides*[2], E. Canalis[1]. [1]Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA, [2]Functional Genomics, Regeneron Pharmaceuticals, Inc., Tarrytown, NY, USA.

The activity of cytokines present in the bone microenvironment can be regulated by binding proteins. Noggin is a bone morphogenetic protein (BMP) dependent glycoprotein secreted by cells of the osteoblastic lineage and characterized by binding BMPs specifically, and antagonizing their activity. To define the role of noggin and BMPs in stromal cell differentiation, ST-2 cells were transduced with a retroviral vector (pLPCX) or a vector driving noggin (pLPCX noggin) under the control of the CMV promoter, and cultured for 4 weeks in the presence of beta- glycerophosphate and ascorbic acid. Only ST-2 cells transduced with pLPCX noggin expressed detectable levels of noggin mRNA and protein by Northern and Western blot analyses. The cellular phenotype of wild type, nontransduced cells was not affected by pLPCX alone. ST-2 cells expressed alkaline phosphatase, Cbfa-1, and type I collagen mRNA in the early stages of the culture, and this was followed by the appearance of mineralized nodules. In the presence of cortisol, ST-2 cells did not display osteoblast gene markers, but expressed peroxisome proliferator-activated receptor gamma 2 and adipsin transcripts, indicating a shift towards the adipocytic pathway. pLPCX noggin delayed the expression of osteoblastic gene markers, and prevented the expression of osteocalcin and the development of mineralized nodules. In addition, pLPCX noggin prevented the adipocytic phenotype induced by cortisol. These results indicate a generalized arrest of stromal cell differentiation. ST-2 cells expressed constant levels of type I and type II Cbfa-1/runx-2 mRNA throughout the 4 week culture period and they were not modified by pLPCX noggin. Confirming previous observations, differentiating control cells underwent apoptosis. This event was prevented by pLPCX noggin, indicating survival of undifferentiated cells. Despite a decrease in apoptosis there were fewer cells in pLPCX noggin cultures indicating a decrease in cell replication. In conclusion, noggin overexpression causes arrest of stromal cell differentiation. Since noggin effects may be due to the binding of locally produced BMPs, the results suggest that BMPs are required for overall stromal cell differentiation.

Overexpression of Fra-1 in Primary Human Mesenchymal Stem Cells Induces Osteoblastic Differentiation and Decreases Molecular Markers of Adipogenic Differentiation in vitro. A. Dickason, P. Stevens*, D. Ebert*, N. Jaiswal, A. Houghton. Discovery, Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Fos family members Delta FosB and Fra-1 have both been demonstrated to induce osteosclerosis when overexpressed in transgenic mice. Subsequent data has demonstrated that overexpression of Delta FosB decreases the adipocytic differentiation of pluripotent osteoblast precursors suggesting that this might be one of a number of possible mechanisms by which Delta FosB increases bone formation. However to date the effects of Fra-1 on the adipogenic differentiation of pluripotent human osteoblast precursors has not been described. We therefore performed experiments to determine the effects of Fra-1 on both the osteogenic and adipogenic differentiation of primary human mesenchymal stem cells (MSCs). Myc tagged Fra-1 cDNA was adenovirally packaged by Galapagos Genomics and crude Ad-Fra-1 or control adenovirus used to infect cultures of MSCs at various multiplicities of infection (MOI). MSCs were infected with Ad-Fra-1 at various MOIs and alkaline phosphatase activity measured after 6 days. At higher MOIs of Ad-Fra-1 clear changes in cell morphology were apparent within 3 days, with nodule-like structures composed of cuboidal cells being formed. Alkaline phosphatase assays clearly demonstrated that overexpression of exogenous Fra-1 significantly increased osteoblast differentiation at MOIs as low as 500. MSCs are also able to differentiate into adipocytes when cultured in presence of rabbit serum and 10^{-7}M dexamethasone, as indicated by changes in morphology, increased cellular staining with oil-red O and elevations of mRNAs for the adipocyte marker genes aP2 and lipoprotein lipase (LPL). To determine the effects of Fra-1 on MSC adipocyte differentiation, Ad-Fra-1 and control infected MSCs were cultured in the presence of rabbit serum and Dexamethasone. After 7 days, Ad-Fra-1 infected cells were stained with oil-red O, and aP2 and LPL mRNA measured by Taqman. Microscopic analysis showed no significant difference between control cells and Ad-Fra-1 infected cells in the number of oil-red O stained cells however, both LPL and aP2 mRNA expression levels were decreased in Ad-Fra-1 infected cells compared to control, demonstrating that whilst overexpression of exogenous Fra-1 did not decrease the number of oil-red O stained cells it did inhibit the expression of markers of adipocytic differentiation. In conclusion these data clearly demonstrate that in primary human populations of MSCs, overexpression of Fra-1 induces osteoblast differentiation and decreases the expression of molecular markers of adipocytes, suggesting inhibitory effects on adipogenic differentiation in human cells.

Stage-Restricted and Distinct Expression of Estrogen and Androgen Receptors Requires Osteoblast Differentiation. K. M. Wiren, A. E. Evans*, X. W. Zhang. Oregon Health & Science University, VA Medical Center, Portland, OR, USA.

Both estrogens and non-aromatizable androgens have significant beneficial effects on skeleton homeostasis, but the mechanisms are unclear. Most biologic responses to steroids are mediated through binding to their cognate receptor proteins, and the magnitude of response may reflect the level of expression of the receptor itself. We have investigated the relative expression of both estrogen receptor (ER) isoforms (ERα, ERβ) and androgen receptor (AR) during osteoblastic differentiation. Normal rat primary osteoblastic cultures derived from calvaria by collagenase digestion were grown for up to 35 days either in the presence of ascorbic acid and organic phosphate (differentiation medium) for normal differentiation and without differentiation medium to examine the dependence of receptor expression on osteoblast phenotype. Total RNA or protein was isolated at various timepoints during proliferation, matrix maturation phase, mineralization and late mineralization stages in differentiation medium, and at the same time points in non-differentiating cultures. AR, ERα and ERβ receptor expression was determined by semiquantitative relative RT-PCR and by Western analysis. Stage-specific and distinct patterns for each of the sex steroid receptors were observed throughout normal differentiation. Relative to GAPDH, AR mRNA levels were elevated during proliferation, dropped slightly during matrix maturation, and were again elevated in the mineralization stage. In general, AR protein levels corresponded to the RNA patterns with greater than two-fold elevation in mature osteocytic cultures at day 35. In contrast, ERα expression increased during differentiation and dropped in late mineralizing cultures, but ERβ expression was relatively constant throughout differentiation. Again, protein levels roughly corresponded to these patterns. Interestingly, when osteoblast cultures did not proceed through normal differentiation (in the absence of ascorbic acid), AR, ERα and ERβ mRNA levels did not exhibit these differences in expression. Thus, normal osteoblast differentiation modulates expression of the sex steroid receptors. These results are consistent with the observation that both sex steroids play significant but distinct roles in regulating function and are an important component of osteoblast differentiation.

Proliferation of Serial Passaged MC3T3-E1 Preosteogenic Cells: Effect of Altered Cell Cycle Distribution and ECM Interaction, and Increased Sensitivity to Cell Population Density. W. J. Peterson[1], K. H. Tachiki*[2], D. T. Yamaguchi[3]. [1]GRECC 691/11g, Greater Los Angeles Healthcare System and UCLA School of Medicine, Los Angeles, CA, USA, [2]Research Searvice, Greater Los Angeles Healthcare System and UCLA School of Medicine, Los Angeles, CA, USA, [3]Research Service, Greater Los Angeles Healthcare System and UCLA School of Medicine, Los Angeles, CA, USA.

Many studies have demonstrated that increasing cell passage number or population doubling decreases cell function suggesting that diminished replicative potential of osteoblast progenitors may depress bone formation. While the mechanism of this process is unknown, changes in the cell cycle and characteristics of ECM and/or the ability of cells to respond to growth stimulants may be contributing factors. MC3T3-E1 cells were selected to study proliferation because (a) these cells undergo a complete developmental sequence of proliferation and differentiation in vitro; and (b) we and others have shown that serial passage of these cells leads to dysfunctional proliferative activity, including decrease in the rate of cell proliferation, production of C Fos and incorporation of tritiated thymidine. Cells from passage 25-65 were used to study population doubling, cell cycle distribution, change in cell size and growth on plastic and ECM surfaces. Data are expressed as the mean±SE. Results show: (1) the proliferative potential of MC3T3-E1 cells is determined by the quality of FBS, the number of population doubling or cell passage number and ECM; (2) ECM from low passage (LP) cells fail to stimulate proliferation in LP and high passage cells (HP); (3) ECM from HP cells stimulates proliferation in both LP and HP cells; (4) Increased cell population density decreases the proliferative potential of HP cells but not LP cells; and (5) decreased proliferation of HP cells is associated with an increase in both the percentage of cells in the G2+M phase of the cell cycle and cell size. These results suggest that the decreased cell number in cultures of HP cells may be due to impaired proliferation caused by the high percentage of cells in the G2+M phase of the cell cycle and the sensitivity of HP cells to culture density.

Activation of PPARgamma Is Involved in Osteoblastic Differentiation. Y. Takeuchi[1], M. Fujita*[1], M. Suzawa*[2], K. Nakayama[1], S. Watanabe*[1], S. Kato[2], S. Fukumoto[3], T. Fujita*[1]. [1]Department of Medicine, University of Tokyo School of Medicine, Tokyo, Japan, [2]Institute of Molecular and Cellular Biosciences University of Tokyo, Tokyo, Japan, [3]Department of Laboratory Medicine, University of Tokyo School of Medicine, Tokyo, Japan.

PPARγ is an essential transcription factor for adipocytic differentiation. Osteoblasts and adipocytes derive from common mesenchymal precursor cells, and differentiation of both cells is tightly coordinated. It is shown that activation of PPARγ in common precursor cells promotes adipocytic differentiation. However, it is yet uncertain how PPARγ influences osteoblastic differentiation. The present study was undertaken to address this issue by inhibiting PPARγ actions in common precursor cells for osteoblasts and adipocytes. cDNA for dominant negative mutant of PPARγ (P467L) reported previously was constructed and cloned into pcDNA3 expression plasmid. Mouse stromal ST2 cells, which can differentiate into either osteoblasts or adipocytes, were transfected with P467L or wild type (WT) PPARγ expression plasmid. Several stable transfectants of ST2 cells were selected with G418. In the presence of a PPARγ ligand, troglitazone, the number of Oil-Red O-positive adipocytic cells was higher in WT-ST2 cells and lower in P467L-ST2 cells than that in parental ST2 cells. Alkaline phosphatase activity, an osteoblastic marker, was suppressed in WT cells compared with that in parental cells in the presence and absence of BMP-2. Unexpectedly, ALP activity was also lower in every clone of P467L cells than parental cells. In mouse osteoblastic MC3T3-E1 cells, troglitazone failed to induce adipocytic differentiation but increased ALP activity. All cells examined expressed PPARγ mRNA. These observations indicate that PPARγ activation is involved in osteoblastic differentiation, although it preferentially promotes adipogenesis in common precursor cells for adipocytes and osteoblasts. In particular, PPARγ may stimulate osteoblastic differentiation once their precursors lose potential of adipogenesis. Hence, it is suggested that PPARγ not only plays a pivotal role for adipogenesis if a set of adipogenic genes are transcriptionally responsive to PPARγ but is required for osteoblasts when adipogenic genes are inert.

GFP Expressing Cells Are Useful Tools for Tracing the Fate of Osteoblastic Cells *in vivo*. A. Kadowaki*[1], T. Tsukazaki[1], Y. Shibata*[1], N. Yoshida*[2], A. Yamaguchi[1]. [1]Oral Pathology, Nagasaki University School of Dentistry, Nagasaki, Japan, [2]Orthodontics, Nagasaki University School of Dentistry, Nagasaki, Japan.

Mechanism of differentiation process of osteoblasts from mesenchymal stem cells remains poorly understood *in vivo*, due to lack of suitable experimental models. To establish such experimental models, we employed cell transplantation systems using GFP (Green fluorescent protein)-expressing immortalized cells, which were isolated from GFP transgenic mice (provided by Dr. Masaru Okabe). Osteoblastic cells were isolated from calvariae of newborn GFP transgenic mice. These cells were passaged until 26th, then two kinds of single cell-derived clonal cell lines (GFP-C1, GFP-C3) were established. Characterization of these cell lines was investigated *in vitro*. In addition, we transplanted these cells into back subfascia with rhBMP-2/carrier complex as well as bone defects created on diaphysis of femur in wild type mice (C57 Black6), and monitored the fate of the transplanted cells by detecting GFP fluorescence. Incubation of these cells with rhBMP-2 in culture increased alkaline phosphatase activity with a concomitant expression of mRNAs for osteocalcin and osterix by a dose- and time- dependent manner, though the expression levels of these markers in the cells without rhBMP-2 were under detectable levels. These stimulatory effects of rhBMP-2 on osteoblast phenotypes were more prominent in GFP-C3 than GFP-C1 cells. BMP-2 treatment failed to induce expression of aggrecam mRNA in these cell lines. These results indicated that GFP-C1 and GFP-C3 are osteoblast lineage cells. *In vivo* experiments demonstrated that many GFP-positive cells surrounded mineralized bones and some GFP-positive cells were embedded into mineralized bone matrices when these cell lines were transplanted with rhBMP-2/carrier complexes into back subfascia of wild type mice. Observation by serial sections clarified that GFP-positive cells surrounding mineralized bones retained alkaline phosphatase activity, indicating that the transplanted cells differentiated into osteoblasts *in vivo*. Furthermore, when these cells were transplanted into cortical bone defects, these cells also differentiated into osteoblasts and osteocytse in the newly formed cancellous bones from a relatively early stage. These results indicate that our cell lines are capable of differentiating into bone forming osteoblasts and terminally differentiated osteocytes *in vivo* without exclusion from the regenerative process in the recipient mice. Thus, our osteoblastic cell lines stably expressing GFP are useful tools for analyzing the process of osteoblast differentiation during bone formation as well as bone regeneration.

Effects of Iridoid Glucosides on Osteoblast-like Cell Proliferation and Osteoclast Inhibition. H. Ha[1], J. Ho*[2], C. Kim[1]. [1]Korea Institute of Oriental Medicine, Seoul, Republic of Korea, [2]Graduate School of East-west Medical Sciences, Kyunghee University, Seoul, Republic of Korea.

Bone is a tissue maintaining itself through continuous osteogenesis and osteolysis by osteoblast and osteoclast, respectively. Iridoid glucosides such as geniposidic acid (GA), geniposide (GP), and aucubin (AU) were tested for analyzing their therapeutic efficacy on osteoporosis. The proliferation of osteoblast-like cells (MG-63 and Saos-2) induced by iridoid glucosides was analyzed using a tetrazolium (MTT), alkaline phosphatase (ALP) activity, and [^{3}H]-proline incorporation assays. The inhibition on osteoclast was studied using the coculture method of mouse bone marrow cells and mouse stromal cells (ST-2). As a result, the GA, GP, and AU induced cell proliferation on MG-63 (135% of control) and Saos-2 (153%, 122%, and 131% of control). The ALP activity of AU on Saos-2 was 129% of control, while GA and GP had no effect on the increase in ALP activity. The proline incorporation activities of GA on MG-63 were 120% of control, while GP and AU were not different from that of the control. In addition, GA (IC_{50}: 4.43×10^{-7} M), GP, and AU had an excellent inhibition on osteoclast. In summary, GA participates in stimulation of osteoblast to osteogenesis and suppression of osteoclast activity to inhibit osteolysis.

Overexpression of CHOP, a Dominant-negative C/EBP, Accelerates and Enhances Osteoblastic Differentiation in Stromal Cells. R. C. Pereira, A. M. Delany, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

CHOP, or GAPD 153 (C/EBP zeta), is a member of CCAAT/enhancer binding protein (C/EBP) family of transcription factors, which play a role in cellular proliferation and differentiation. CHOP is unlike others C/EBPs in that it cannot bind DNA; rather it heterodimerizes with C/EBP alpha and beta and serves as a dominant negative inhibitor by preventing their binding to DNA. C/EBPs alpha, beta, and delta are necessary for adipogenesis, and CHOP overexpression inhibits adipogenesis. CHOP is expressed at relatively low levels in preadipocytes but at high levels in the murine stromal cell line ST-2. Recent studies indicate that the C/EBP family of transcription factors plays a role in osteoblast differentiation. We showed that cortisol enhanced the expression of C/EBP beta and delta, and together they down regulate IGF-I transcription in osteoblasts. Conversely, bone morphogenetic protein (BMP) 2 induces osteoblastic differentiation and induces the transcription of CHOP in stromal cells. We hypothesize that CHOP expression aids in the development of the osteoblastic phenotype by antagonizing the activities of C/EBPs important in adipocyte differentiation. Therefore, we examined the role of CHOP in osteoblast differentiation by transducing ST-2 cells retrovirus overexpressing CHOP. Three separate cells lines, consisting of pooled antibiotic resistant cells, were generated and CHOP overexpression was confirmed by Northern blot analysis. Cells were cultured for up to 30 days post-confluence, in the presence or absence of BMP-2. All CHOP over expressing cell lines had higher levels of alkaline phosphatase and accelerated differentiation towards the osteoblastic pathway, as determined by the appearance of alizarin red positive mineralized nodules. This effect was intensified by treatment with BMP-2. These data indicate that CHOP overexpression stimulates osteoblast differentiation. This effect may be due to the dominant-negative effect of CHOP on other C/EBP family members, most importantly C/EBP beta and delta, which contribute to the differentiation of adipocytes.

SA212

Protein Kinase D Mediates Activation of Stress-sensitive MAP Kinases p38 and JNK Induced by Gq Protein-coupled Receptors in Osteoblast-like Cells. J. Caverzasio, J. Lemonnier*, C. Ghayor*. Division of Bone Diseases, University Hospital of Geneva, Geneva, Switzerland.

G protein-coupled receptors (GPCRs) are transducers of the anabolic effect of potent osteotropic factors such as parathyroid hormone, fluoride, prostaglandins and the recently described Wnt glycoprotein. The signaling pathways involved in activation of osteoblasts by GPCRs remains largely unknown. Recent studies reported that GPCRs can induce activation of several mitogen-activated protein kinases (MAPKs) and that the stress-sensitive MAPKs JNK and p38 are probably involved in the regulation of osteoblastic cell differentiation. In this study, we investigated the effect of PGF2alpha (PGF2a), a GqPCR agonist, on activation of MAPKs in MC3T3-E1 osteoblast-like cells and the molecular mechanism by which PGF2a induces activation of JNK and p38. PGF2a (1 microM) activated the three MAPKs Erk, JNK and p38 with different kinetics. Erk activation was rapid, maximal at 5 min and lasted about 10 min whereas activation of JNK and p38 was apparent after 15 min, maximal at one hour and lasted about 3 h. Activation of JNK and p38 but not of Erk was completely blunted by Go6976, a protein kinase C (PKC) and protein kinase D (PKD) inhibitor. PKD is a newly described diacylglycerol-sensitive protein kinase with homology to PKCs and unknown function. To determine the role of PKD in mediating activation of JNK and p38 by PGF2a, we constructed a MC3T3-E1 cell line stably expressing a PKD kinase dead mutant (K612W). In this MC3T3-E1-K612W cell line, activation of JNK and p38 induced by PGF2a was markedly impaired (80-90% inhibition) whereas cell proliferation and Erk activation were normal. Kinetic analysis of PKD activation in normal MC3T3-E1 cells indicated that PGF2a induces a rapid translocation of PKD from the cytosol to a membrane fraction wherein it becomes phosphorylated on several serine residues (p-PKD). Then p-PKD returns in the cytosol. Interestingly, the return of p-PKD in the cytosol correlated with activation of JNK and p38 by PGF2a. This return was blocked by Go6976 likely explaining the blunting effect of this compound on activation of JNK and p38 by PGF2a. In conclusion, GqPCRs in osteoblast-like cells can stimulate Erk, JNK and p38 by different mechanisms. In this study, we demonstrate for the first time that PKD mediates activation of stress-sensitive MAPKs JNK and p38 by GqPCRs in osteoblast-like cells, an observation not yet reported in mammalian cells. The molecular mechanism by which PKD activates JNK and p38 is complex. It involves the translocation of PKD from the cytosol to a membrane fraction for its phosphorylation and activation. Then, activated PKD returns in the cytosol for the stimulation of JNK and p38 pathways.

SA213

Is PKIγ Responsible for Termination of Immediate-Early Gene Expression after Induction by PTH? X. Chen*[1], J. Dai[1], S. A. Orellana*[2], E. M. Greenfield[1]. [1]Orthopaedics, Case Western Reserve University, Cleveland, OH, USA, [2]Pediatrics, Case Western Reserve University, Cleveland, OH, USA.

We have previously shown that rapid termination of immediate-early gene expression following induction by PTH is due to mechanisms that act downstream of receptor desensitization and cAMP degradation. PTH receptor desensitization was blocked with either G protein-coupled receptor kinase 2 (GRK2) antisense transfection or oligonucleotides. However, neither of these approaches increase the time courses of PKA activation, CREB/ATF-1 phosphorylation, and expression of immediate-early genes (IL-6 and *c-fos*) that occurs after induction by PTH in ROS 17/2.8 osteoblastic cells. Moreover, IBMX blocks cAMP degradation but also does not alter the time course of the downstream effects. Since forskolin (FSK) directly stimulates adenyl cyclase, we have now compared the effects of FSK and PTH on ROS 17/2.8 cells. While PTH rapidly and transiently elevates cAMP, FSK acts in a slower but sustained fashion with maximal cAMP levels observed beginning at 30 min and lasting for the 24 h duration of the experiment. Despite this sustained elevation of cAMP, FSK transiently induces the downstream effects with time courses that are indistinguishable from those induced by PTH. Similar results were also observed in osteoblastic MC3T3-E1 cells treated either with FSK or with IBMX plus PTH as well as in fibroblastic NIH3T3 cells treated either with FSK or with IBMX plus isoproterenol. These results further support our conclusion that mechanisms downstream of cAMP degradation are primarily responsible for the termination of immediate-early gene expression in ROS 17/2.8 cells and suggest that this is a general feature of cAMP signaling in mesenchymal cells. One mechanism that may explain the rapid termination of the downstream effects is inactivation of PKA and its translocation out of the nucleus by the protein kinase inhibitor (PKI) family. Consistent with this possibility, western blotting of nuclear extracts showed that the catalytic domain of PKA rapidly translocates into and out of the nucleus. Thus, nuclear levels of PKA are maximal 15-30 min after exposure to PTH and return to baseline levels by 2 h. RT-PCR assays employing positive control mRNAs from murine tissues that express each isoform and sequencing of the PCR products to confirm their identity showed that PKIγ mRNA is strongly expressed in ROS 17/2.8, MC3T3-E1, and NIH3T3 cells, while little or no mRNA encoding the other family members (PKIα and PKIβ) is expressed. These results are consistent with the possibility that PKIγ is involved in termination of PKA activation, CREB/ATF-1 phosphorylation, and expression of immediate-early genes following induction by PTH.

Isolation, Characterization, and Functional Regulation of the CD38 (ADP-ribosyl cyclase) Gene Promoter. L. Sun, M. Lu*, X. Zhang*, E. Abe, M. Zaidi. The Mount Sinai Bone Program and Bronx VA GRECC, New York, NY, USA.

CD38 (ADP-ribosyl cyclase), an enzyme that cyclizes NAD^+ to cyclic ADP-ribose, plays a key role as an NAD^+ sensor in coupling cellular metabolism to Ca^{2+} signaling in both osteoclasts and osteoblasts (J. Cell Biol, 146: 1161, 1999; FASEB J, 16: 302, 2002). Thus, CD38 null mice display an osteopetrotic phenotype characterized by increased bone mineral density, enhanced bone strength, dramatically reduced osteoclastic resorption, and increased osteoblastic bone formation. To study the transcriptional control of the CD38 gene, we examined the regulation of its promoter by Ca^{2+}, protein kinase C (PKC) and cAMP. A 1.8 kb genomic fragment was cloned from a rabbit genomic DNA library using, as a probe, the 280 bp CD38 cDNA fragment that we had cloned previously. Primer extension analysis indicated two transcription start sites consistent with the absence of a TATA box. Sequence analysis revealed several AP-1, AP-4, myo-D, GATA, and SP-1 sequences. MC3T3.E1 cells were then transfected with the CD38 promoter ligated to the luciferase reporter gene. We constructed 9 deletion fragments all of which, except the shortest 41 bp fragment, showed significant luciferase activity. Additionally, there was a marked stimulation of basal activity in the 93 bp fragment. This fragment, containing a GC box and SP1 site, was then analyzed further for its sensitivity to Ca^{2+} (using ionomycin) and PKC (using TPA, H7, and staurosporine). Ionomycin (1 and 10 μM) potently inhibited promoter activity, while PKC activation by TPA (10 and 100 nM) was stimulatory. In contrast, H7 and staurosporine, both potent and specific PKC inhibitors, prevented transactivation of the 93 bp fragment. Notably, H7 or staurosporine did not reverse the ionomycin-induced inhibition of promoter activity suggesting that separate sequences likely mediated the opposing effects of PKC and Ca^{2+}. That the short 41 bp fragment was insensitive to both Ca^{2+} and PKC modulation indicated that the respective regulatory elements resided between –41 and –93 bp upstream of the transcription start site. Furthermore, using forskolin (100 μM), we identified two inhibitory cAMP-sensitive sequences, one between –41 and –93 bp and another between –722 and –931 bp. Finally, neither the full-length promoter nor its shorter fragments responded to interleukin-6 or interleukin-11, both of which utilize the gp130 pathway. Thus, modulation of the expression of the NAD^+-sensing enzyme, CD38, by Ca^{2+}, PKC and cAMP may contribute to the physiological coupling of the intense metabolic activities of the osteoclast and osteoblast to their respective bone-resorbing and bone-forming functions.

SA216

PTHrP Transactivates RANKL Gene through PKA and PKC Pathways on Mouse Stromal Cells. R. Kitazawa, S. Kitazawa. Division of Molecular Pathology, Department of Biomedical Informatics, Kobe University, Kobe, Japan.

Parathyroid hormone-related protein (PTHrP) is thought to act on the osteoblastic cell lineage to promote osteoclastogenesis by increasing RANKL gene expression through the PTH/PTHrP receptor. In a coculture of ST2 cells and bone marrow macrophages, PTHrP (1-34) promoted the formation of TRAP-positive multinucleated cells. Northern blotting demonstrated that PTHrP increased the expression of 2.8 kb transcripts of the mouse RANKL gene by elevating the gene transcription rate assessed by nuclear run-on studies. To identify the post-receptor mechanism conducting PTHrP signaling for RANKL gene expression, we analyzed the mouse RANKL promoter by transient transfection and electromobility shift assay (EMSA). Although the promoter lacked canonical CRE and AP-1 binding sites, a CRE-like sequence (TGAGGTCA -940) and three putative AP-1 binding sites (TGTCTCA -880, TGCCTTCA -730 and TGGCTCA -560) were located upstream of the basic promoter. ST2 cells were transfected with a series of nested deletion constructs of the promoter ligated to a luciferase gene and then treated with human PTHrP (1-34), agonists and antagonists for either PKA or PKC. When transfected with 1.0-2.3 kb constructs, 6 to12-hour treatment with PTHrP increased the promoter activity up to 180%. Forskolin, but not TPA, enhanced the promoter activity; furthermore, H89 abolished the inductive effect of PTHrP and forskolin. When the cells were transfected with a -724-luc lacking a CRE-like sequence, no effect was observed by 6 to12-hour treatment with PTHrP and forskolin. By EMSA, a CRE-like sequence (-940) showed specific binding to the nuclear extract from PTHrP-treated ST2 cells and the supershift with anti-CREB-1 and ATF-2 antibodies. Taken together, TGAGGTCA (-940) could act as a functional CRE. On the other hand, 24 to 48-hour treatment with PTHrP and TPA, but not with forskolin, showed the inductive effect on 1.0-2.3 kb constructs; calphostin C reduced the effect of PTHrP. Neither PTHrP nor TPA showed the inductive effect on -523-luc lacking AP-1 binding site-like sequences. Furthermore, two of the putative AP-1 binding sites, TGTCTCA (-880) and TGGCTCA (-560), showed specific binding to the nuclear protein; the bindings were supershifted with anti-Jun-D and -Fra-2 antibodies. No shifted band was observed with anti- c-Jun, Jun-B, c-Fos, Fos-B or Fra-1 antibodies. We therefore speculated that PTHrP promotes RANKL transcription through the PKA pathway in the early phase and through the PKC pathway (the binding of Fra-2 and Jun-D heterodimer to AP-1 sites) in the later phase.

Osteoblastic Differentiation of Human Bone Marrow Stromal Cells Is Associated with Increased Runx2/Cbfa1 Activity and Phosphorylation without a Change in mRNA or Protein Levels. C. Shui*, T. C. Spelsberg, B. L. Riggs, S. Khosla. Mayo Clinic, Rochester, MN, USA.

Runx2/Cbfa1 has been identified as a "master gene" controlling osteoblast differentiation. However, its role in inducing the osteoblast phenotype has been characterized primarily in rodent systems. Thus, we examined Runx2/Cbfa1 mRNA, protein, and activity levels during osteoblastic differentiation of human bone marrow stromal (BMSC) cells. The human BMSC cells (hMS2-15) were cultured in differentiation medium (DM) [(α-MEM medium plus 10% FBS, 10^{-8} M dexamethasone (Dex), 50 μg/ml L-ascorbate, and 10 mM β-glycerophosphate] for up to 14 days, or in DM with various doses of Dex for 7 days. Semi-quantitative RT-PCR analysis demonstrated that the expression of alkaline phosphatase and osteocalcin mRNAs increased in a time-dependent manner in these cells, and histochemical (alizerin Red-S) staining revealed extensive mineralization at day 14. Type-II Runx2/Cbfa1 mRNA was found to be constitutively expressed in hMS2-15 cells and not altered following incubation in DM; there was no detectable expression of the type-I Runx2/Cbfa1 transcript. Interestingly, despite the absence of any change in Runx2/Cbfa1 mRNA levels during osteoblastic differentiaion of these cells, the activity of Runx2/Cbfa1, as assessed by binding to the osteoblast-specific *cis*-acting element 2 (OSE2), increased markedly at all time-points examined, with the highest activity level seen at day 7. Furthermore, incubation of hMS2-15 cells with 10^{-10}-10^{-7} M Dex for 7 days increased Runx2/Cbfa1 DNA binding activity, but not mRNA levels, in a dose-dependent manner. Similar results were observed in the less differentiated human marrow-derived mesenchymal stem cells (Clonetics, Inc.) following incubation in DM for 7 days. Immunoprecipitation and Western blot analysis revealed that while there was no increase in Runx2/Cbfa1 protein levels with differentiation in hMS2-15 cells, there was an increase in Runx2/Cbfa1 phosphorylation, as detected by specific antibodies against phosphorylated threonine, tyrosine, and serine residues. We conclude that, in contrast to most rodent systems where osteoblastic differentiation is associated with clear increases in Runx2/Cbfa1 mRNA and protein levels, osteoblastic differentiation of human BMSC is associated primarily with increases in Runx2/Cbfa1 activity, without a change in mRNA or protein levels. Our findings also demonstrate that the increase in Runx2/Cbfa1 activity occurs through a post-translational mechanism involving phosphorylation of key residues.

Morphology of the Marrow Sac in Human Bone. An Electron Microscopic Study. L. X. Bi[1], N. Ding*[2], Y. Zhang*[2], R. T. Throndson*[1], W. L. Buford*[1], E. Mainous*[1]. [1]Depts. Orthopaedics & Surgery, University of Texas Medical Branch, Galveston, TX, USA, [2]Hebei Medical University, Shijiazhuang, China.

It is well-known that endosteal osteoblasts are largely recruited from the mesenchymal cells in bone marrow. While clonal technique have shown that bone marrow stromal cells are not all equally osteogenic, those studies do not reveal the anatomical distribution and relative frequency of these populations. One would anticipate that the putatively osteogenic stromal cells would be those that lay closest to the lining of endosteal osteoblasts, and we believe that this population constitutes the sac of epitheleoid-like cells which divides the myeloid and osteoblast populations. TEM/SEM studies show the ubiquity of marrow sacs in laboratory animals, but the situation in man has never been visualized. That was the objective of the present study. Discarded tubular segments of femoral diaphyseal bone were obtained from healthy young (4- 6 yr) male and female patients undergoing femoral shortening surgeries. The specimens were examined by scanning (SEM) and transmission electron microscopy (TEM). The bone was completely covered by a hexagonally packed layer of plump osteoblasts. Their surfaces were studded with many tiny microvillar-like projections, and they displayed numerous intercellular cytoplasmic processes. No osteoclast-like cells were identified. Marrow myeloid elements were always invested in and separated from the endosteal osteoblast lining by a continuous of sac of flattened cells. In the SEM, the sac presented a very distinctive pattern of large flat overlapping auricular-like, lobulate cells which were easily distinguished from the larger populations of medullary hemopoietic cells and the endosteal osteoblasts. TEM studies showed that the marrow sac was 1 or 2 cells thick, that the cells were attenuated with elongated nuclei, and appeared to display intercellular tight junctions. The cells contained few small round mitochondria, few lysosomal bodies and filaments, and sparse rough endoplasmic reticulum. The sac cells lacked basal laminae, but concentrations of collagen fibrils were found in association with their deep medullary surfaces. We conclude that humans share with laboratory animals a broadly similar cellular organization at the bone-marrow interface, but differ interalia in the morphology of the marrow sac cells which envelop the medullary hemopoietic space.

In Search of Blood-Borne Mesenchymal Stem Cells (MSCs) in The Peripheral Blood of Patients Following Long Bone Fractures. G. Li[1], D. Shirley*[2], G. Burke*[2], D. Marsh*[2]. [1]Department of Orthopaedic Surgery, Queen's University of Belfast, Belfast, United Kingdom, [2]Department of Orthopaedic Surgery, Queen's University Belfast, Belfast, United Kingdom.

It is well known that the MSCs reside among the bone marrow can differentiate into functional osteoblasts. The presence of primitive haematopoietic cells in adult peripheral blood has been recognized for long, but there is a controversy as to whether bone marrow MSCs can migrate through the circulation. Few recent studies have suggested the existence of rare numbers of MSCs in normal adult human peripheral blood. This study was to investigate whether the number of MSCs in the peripheral blood changes in the patients with fractures. 15 mls peripheral blood sample was taken from 8 patients (male, age 20-50) with long bone fracture at day 2-3, 5-10, and 14-20 post-fracture. One blood sample was also taken from 4 aged-matched healthy volunteers as controls. The peripheral blood mononuclear cells (PBMNCs) were isolated by centrifugation over a density gradient (1.077 g/ml, Nycomed). Half PBMNCs were immediately spanned onto glass slide and fixed, subject to immunocytochemistry (ICC) with various antibodies of osteoblast-related markers. The remaining PBMNCs were cultured in standard osteogenic medium in 8 well chamber slides. The medium was changed at day 7 and twice weekly thereafter. After 3 weeks, the cells were fixed and used for ICC examinations. The PBMNCs in about two thirds of all the blood samples from fracture patients showed the presence of positive staining for Cbfa-1, BMP-2, BMPR-I or II, Endoglin, Collagen type I, and Vimentin. There was little or no staining of these markers in the PBMNCs from the normal controls. In the fracture patients' PBMNCs culture, numerous fibroblastic cells adhered to the flasks at the first week. The greatest number of adherent cells was found in the blood samples taken at 14-20 days post-fracture. At 3 weeks, these cells were in spindle or round shapes, but did not form colonies. ICC examinations confirmed that some of these cells were positive for all the markers mentioned above, but negative for alkaline phosphatase. We did not observe any fibroblastic cell formation in the PBMNC cultures from the controls. This study has confirmed for the first time that patients with a recent fracture have an increase in the number of circulating MSCs in their peripheral blood. However, it is uncertain where these circulating MSCs come from. Further study is on the way to clarify the links between trauma stimuli and the release of MSCs in circulation. Understanding this phenomenon may provide exciting alternative methods for harvesting skeletal progenitor cells for the treatment of fracture and other skeletal diseases, such as osteoporosis.

SA222

Possible Role of Monocytes in the Retraction of Cells Covering a Bone Surface. S. Perez*[1], W. Beertsen[1], V. Everts[2]. [1]Periodontology, Academic Centre for Dentistry, Amsterdam, Netherlands, [2]Cell Biology, Academic Medical Centre, Amsterdam, Netherlands.

Prior to attachment of osteoclasts to a bone surface, cells covering this surface have to withdraw. The processes involved in this phenomenon are not clear. As a model to study how pre-osteoclasts invade a layer of cells, we added blood monocytes to confluent layers of osteoblasts or fibroblasts. Osteoblasts were isolated by sequential enzymatic digestion from rabbit calvariae, and fibroblasts were isolated from the periosteum of these bones. The cells were cultured until confluence after which isolated rabbit blood mononuclear cells were seeded on top of them. The co-cultures were maintained for up to 15 days. The cultured cells were stained for TRAP activity and the actin filament distribution pattern was visualized by FITC-conjugated phalloidin. In addition we analysed the effect of conditioned media obtained from cultured monocytes or osteoblasts. The following sequence of events was found in the co-cultures: (I) A limited number of monocytes strongly attached to the confluent layer of osteoblasts or fibroblasts (days 1-3). (II) The osteoblasts and fibroblasts then retracted, thus forming cell-free areas (day 4). (III) The monocytes invaded these areas and attached to the surface of the well (days 4-8). (IV) These attached monocytes fused and formed multinucleated TRAP-positive osteoclast-like cells (days 8-15). Osteoblast/fibroblast-free areas were only formed when monocytes were attached to the osteoblast/fibroblast cell layer. The addition of monocyte-conditioned media had no effect on this event. Conditioned media from cultured osteoblasts added to monocyte cultures, however, induced attachment of monocytes and in some instances the appearance of binuclear cells that proved to be TRAP-negative. Multinucleated cells within the cell-free areas showed a dot-like pattern of actin staining, resembling podosomes of osteoclasts. By comparing the co-cultures of osteoblasts with those of fibroblasts, we found that in the osteoblast co-cultures the cell-free areas were 3-4 times larger. Also the number of attached monocytes and multinucleated TRAP-positive cells proved to be much higher (18-fold). Our in vitro observations indicate that cell-cell interactions between monocytes and osteoblasts (or fibroblasts) result in an active retraction of the latter cells. Within the thus formed cell-free areas monocytes adhere, fuse and form osteoclast-like cells. We propose that due to specific cell-cell contacts between both cell types, yet unknown signals are transduced which activate bone-covering cells to withdraw.

Parathyroid Hormone Activates Adhesion in Bone Marrow Stromal Precursor Cells. J. Davies*, T. J. Chambers. Dept of Cellular Pathology, St George's Hospital Medical School, London, United Kingdom.

Bone mass can be increased by parathyroid hormone (PTH), but the mechanisms underlying this phenomenon remain unknown. Osteoblasts derive from multipotential bone marrow stromal precursor cells that form colonies of fibroblastic cells (CFU-F) upon culture ex-vivo. Activation of such stromal precursors is likely to be an early event in the anabolic response of bone to PTH, and indeed induction of c-fos expression occurs in stromal cells adjacent to bone surfaces within an hour of PTH administration. We therefore tested the notion that an early component of the anabolic response of bone to PTH is the activation of CFU-F. To test this, we measured the number of CFU-F that could be extracted from bone marrow soon after administration of an anabolic dose of PTH. We found that a very early response to the administration of PTH to mice is a dramatic reduction, within 3 hrs, in the number of CFU-F that could be extracted from their bone marrow. We then tested whether PTH similarly stimulates adhesion of CFU-F in-vitro. To do this, bone marrow cells were incubated in PTH for varying times. Non-adherent cells were then removed and the adherent cells were incubated for 14 days in PTH-free medium, to assess the number of precursors of CFU-F that had adhered. We found incubation in PTH for 24 hrs caused a substantial increase in the number of CFU-F that formed. This did not seem to be mediated through a PTH-induced increase in Interleukin-6, since Interleukin 6 had no effect on CFU-F numbers when substituted for PTH. Similarly, adhesion was unaffected either by incubation in dibutyryl cyclic AMP, or by inhibitors or donors of nitric oxide. However, CFU-F formation by PTH was strongly inhibited by indomethacin. Our results suggest that a crucial component of the anabolic response of bone to PTH is the activation of previously quiescent osteoblastic precursors.

PYK2-Mediated Signaling Is Involved in Calcitonin-Induced Sealing Zone Detachment in Resorbing Osteoclasts. J. Shyu[1], S. Chung[1], J. Wang*[1], C. Lin*[2]. [1]Biology and Anatomy, National Defense Medical Center, Taipei, Taiwan Republic of China, [2]Microbiology and Immunology, National Yang-Ming University, Taipei, Taiwan Republic of China.

Bone resorption is initiated by adhesion of osteoclasts to the bone surfaces through interactions between the integrin (avb3) and RGD-containing extracellular matrix proteins, such as vitronectin, followed by cytoskeletal rearrangement and formation of the sealing zone, which polarize the cell. Previous results have demonstrated that calcitonin treatments appeared to decrease the motility of isolated osteoclasts, resulting in retraction of the cells from their spread morphologies. It has been shown that adenyl cyclase and phospholipase C might be involved in calcitonin-mediated activities; however, detailed signaling cascades, especially those regarding osteoclast activities, are not well characterized. In the present study, we address the role played by proline-rich tyrosine kinase 2 (PYK2), a cytoplasmic kinase related to the focal adhesion kinase, as a potential effector downstream of the calcitonin pathways. Calcitonin treatments caused retraction and detachment of cultured osteoclasts from the substrates. These detachment events were accompanied by decrease of phosphorylation levels of PYK2. Our results demonstrated that PYK2 might play an important role in mediating calcitonin-induced bone remodeling.

Regulation of the Formation of Osteoclastic Actin Rings by PYK2 Interacting With Gelsolin. W. C. Xiong*[1], Q. Wang*[2], Y. Xie*[1], Q. Du*[1], X. Wu[3], X. Feng*[1], L. Mei*[2], J. M. McDonald[1]. [1]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]Neurobiology, University of Alabama at Birmingham, Birmingham, AL, USA, [3]Pathology, University fo Alabama at Birmingham, Birmingham, AL, USA.

Osteoclast activation is important for bone remodeling and is altered in multiple bone disorders. It requires cell adhesion and extensive actin cytoskeletal reorganization. Proline-rich tyrosine kinase 2 (PYK2), a major cell adhesion activated tyrosine kinase in osteoclasts, plays an important role in regulating this event. The mechanisms by which PYK2 regulates osteoclastic activation remain largely unknown. In this paper, we provide evidence that PYK2, but not its related focal adhesion kinase (FAK), interacts with gelsolin, an actin binding, severing, and capping protein essential for osteoclastic actin cytoskeletal organization. The interaction is mediated via the focal-adhesion-targeting domain of PYK2 and a LD motif in gelsolin's C-terminus. PYK2 phosphorylates gelsolin at tyrosine residues and regulates gelsolin bioactivity including increasing gelsolin binding to phosphatidylinositol lipids and decreasing gelsolin binding to actin. In addition, PYK2 activates phosphatidylinositol 4-kinase, a kinase critical for generation of phosphoatidylinositol lipids. Furthermore, PYK2 increases actin polymerization at the fibroblast cell periphery, which requires gelsolin protein. Finally, PYK2 activation is required for the formation of actin rings in osteoclasts. Taken together, our results suggest that PYK2 is a negative regulator of gelsolin's actin severing and capping activities, revealing that gelsolin is an important mediator by which PYK2 regulates osteoclastic actin cytoskeletal organization.

SA229

Osteoclasts Express Kca Channels Involved in Cell Spreading and Bone Resorption. L. G. Paret*, L. Espinosa*, C. Ojeda*, C. Chenu. Inserm Unit 403, Lyon, France.

Cell movement and spreading involve calcium-dependent processes and ionic channel activation. We previously showed that osteoclast spreading is correlated with spontaneous and oscillatory activation of a calcium-dependant potassium current (Ik_{ca}). We have now characterised the channel involved in this process and investigated its role in osteoclast activity. Rabbit osteoclasts were isolated from long bones and electric recordings were performed using patch-clamp techniques in whole cell and single channel configurations. Three different families of K_{Ca} channels have been described: big conductance channels (BK), small conductance channels (SK1, SK2, SK3) and intermediate conductance channels (IK1 = SK4). The Ik_{ca} was identified as a current generated by a channel with a unitary conductance of approximately 30 pS, within the range of SK4 channels. Pharmacological studies performed in whole cell configuration have shown a high sensitivity of Ik_{ca} to charybdotoxin (specific blocker of BK and SK4 channels), and a lower one to apamin (targeting SK channels). Specific inhibitors of BK channels, iberiotoxin and low concentrations (<5mM) of tetramethylammonium, had no effect on Ik_{ca}. Using RT-PCR analysis, we demonstrated the expression by osteoclasts of mRNA for alpha subunit (Slo) of BK channels and mRNA for SK3 and SK4 channels. The presence of SK4 was further confirmed in mouse osteoclasts and RAW 264 cells differentiated as osteoclasts under the influence of Rank Ligand. Altogether, our results are in favor of an Ik_{ca} generated by SK4 channels. However, we cannot presently exclude that osteoclasts contain nonclassical BK channels with properties modulated by beta regulatory subunits, or SK/BK chimera channels. Blockade of Ik_{ca} by charybdotoxin and apamin significantly inhibit osteoclast spreading and *in vitro* bone resorption, demonstrating a physiological role for this current in osteoclast activity. Using single channel recordings in a cell attached configuration, we showed that extracellular Ca^{2+} regulates K_{Ca} channel activation. This suggests that a Ca^{2+} influx, may be triggered by ryanodine or calcium-sensing receptors, generates a cytosolic Ca^{2+} increase which activates K_{Ca} channels. Our results clearly demonstrate the presence in osteoclasts of K_{Ca} channel, whose activation is involved in the control of membrane spreading and bone resorption, and which may be an SK4 type channel. Work is in progress to investigate the signals that induce Ik_{ca} activation and the interactions of K_{Ca} channels with proteins involved in the regulation of osteoclast spreading.

Calpain Contributes to the Regulation of Osteoclast Attachment and Spreading. M. Marzia*, L. Neff, R. Baron, W. C. Horne. Orthopaedics and Cell Biology, Yale University School of Medicine, New Haven, CT, USA.

Rapid podosome assembly and disassembly is thought to be critical for the high motility of osteoclasts. Calcitonin (CT) inhibits motility, induces marked cellular retraction, and disrupts the actin ring of osteoclasts (OCs), suggesting that CT regulates at least some of the mechanisms responsible for podosome function. Calpains are Ca2+-dependent proteases that catalyse the limited cleavage of specific proteins during regulatory signaling and they are thought to promote cell spreading and locomotion by modifying adhesion sites and by facilitating rear-end detachment. CT receptor (CTR) stimulation leads to an increase in intracellular Ca2+, which might in turn activate calpains. We therefore examined whether calpains might be associated with adhesion structures in OCs and if CT might affect calpain activity. Immunofluorescence analysis of rabbit OCs showed that high levels of mu-calpain were associated with the actin ring. CT treatment induced the rapid (1-3 min) dispersion of the actin ring and the associated mu-calpain, followed soon after by cell retraction (5 min). The actin ring, again with associated mu-calpain, reappeared 20-60 min after the addition of CT. In OCs treated with the calpain inhibitor calpeptin, the actin ring was more prominent and the staining of both F-actin and mu-calpain was more intense than in untreated cells. A second inner ring of individual podosomes was also present in many of the calpeptin-treated OCs. CT still induced the loss of the actin ring in the calpeptin-treated OCs, but the recovery occurred more rapidly than in the control OCs (3-5 min). In addition, CT induced little or no retraction in the presence of calpeptin. Two known substrates of calpain, filamin A and talin were also associated with the OC actin ring, and treatment with CT induced the dispersion of both filamin and talin in parallel with that of the actin ring. The full length forms of both filamin A and talin and as well as high MW cleavage products of both proteins were detected by Western blotting of lysates of untreated OC. The cleavage products were not detected in lysates of calpeptin-treated OCs, suggesting that filamin and talin may be continuously cleaved by calpain in untreated OCs. CT treatment also transiently reduced the amounts of filamin A and talin fragments, with minimum amounts detected at 5 min and recovery to basal levels by 10-20 min. The demonstration that a calpain inhibitor blocks the cleavage of two podosome-associated proteins, filamin and talin, and affects the stability of the actin ring suggest that calpain is involved in the regulation of podosome assembly and/or disassembly. Our results also suggest that calpain contributes to the retraction of OCs in response to CT.

SA232

Dynamin- and Cbl-containing Molecular Complexes Are Present in Podosomes and Are Dissociated by Src Kinase Activation. A. Bruzzaniti, A. Sanjay, L. Neff, R. Baron. Yale University School of Medicine, New Haven, CT, USA.

Osteoclasts grown on bone or dentin develop dynamic actin-containing attachment structures known as podosomes which form the sealing zone and encircle the resorptive space. In osteoclasts derived from transgenic mice lacking c-Src or Pyk2, podosome ring formation is completely abolished, osteoclast migration is inhibited, and the mice exhibit an osteopetrotic phenotype. Following engagement of the vitronectin receptor, the adaptor protein Cbl forms a trimolecular complex with the non-receptor tyrosine kinases Src and Pyk2, and signaling from this complex plays a role in osteoclast attachment and motility. Directly relevant to osteoclasts, a functional link between Src activation, dynamin and the actin cytoskeleton at podosomes was previously demonstrated in BHK cells transformed with v-Src, strongly suggesting a role for dynamin in signaling downstream of integrins. In addition, since dynamin is a multi-domain protein essential for endocytosis and membrane remodeling, it may play a role in osteoclast resorption and in the formation of the ruffled border where endocytosis is a key functional event. In this study, we established that dynamin constitutively participates in functional complexes with Cbl in osteoclasts and when over-expressed in HEK-293 cells stably expressing the vitronectin receptor. Using GST-purified proteins we further show that the proline-rich domain (PRD) of dynamin and the C-terminal domain of c-Cbl, most likely its PRD or acidic domain, are necessary for the two proteins to co-immunoprecipitate in the same molecular complex. Interestingly, while over-expression of activated Src led to the tyrosine phosphorylation of both dynamin and Cbl, Src kinase activity had a dominant negative effect on dynamin-Cbl complex formation. In support of this, dynamin-Cbl association was enhanced following treatment with PP1 (a Src family kinase inhibitor), genistein (a non-specific kinase inhibitor), or by over-expression of a kinase dead c-Src mutant (K295M). The disruptive effects of Src kinase activity on dynamin-Cbl association were abrogated when the known Src SH3 binding site in Cbl was mutated. Thus, phosphorylation of Cbl by Src destabilizes Cbl's association with dynamin, most likely via a similar mechanism to that proposed for the association of UbcH7 with Cbl (Yokouchi et al., JBC, 274:31707, 1999). We propose that dynamin and Cbl coordinately participate in a process that regulates podosome turnover and, thereby, cell motility.

Thyroid Hormones and Vitamine D Coordinately Stimulate Osteoclast Formation Through RANKL Induction. M. Miura*[1], Y. Komatsu[1], K. Tanaka[2], M. Suda*[1], A. Ozasa*[1], K. Nakao*[1]. [1]Medicine and Clinical Science, Kyoto University Graduate Shool of Medicine, Kyoto, Japan, [2]Nutirition Science, Koshien University, Takarazuka, Japan.

Thyroid hormones enhance osteoclast formation and their excess is an important cause of secondary osteoporosis. Using the northern blot analysis, 3,5,3'-Triiodo-L-thyronine (T3) (10^{-8}-10^{-5} M) induced mRNA expression of receptor activator of nuclear factor-kappa B ligand (RANKL), which is a key molecule in osteoclast formation, in primary osteoblastic cells (POB). RANKLmRNA expression was 1.3-1.8 times higher after 24 hours and 2.5-3.0 times higher after 48 hours than the basal expression. In contrast, the mRNA expressions of OPG and M-CSF were unaltered with T3. This effect was amplified in the co-presence of 10^{-8} M of 1-alpha, 25-dihydroxyvitamin D_3 (1,25(OH) $_2D_3$). Although T3 alone did not induce osteoclasts in coculture of bone marrow cells with POB, T3 enhanced 1,25(OH) $_2D_3$-induced osteoclast formation, detected as TRAP-positive multinuclear cells. Thyroxine (T4) (10^{-7}-10^{-5} M) also enhanced 1,25(OH) $_2D_3$-induced osteoclast formation. These data suggested that T4 was locally metabolized to T3 for its action, since T4 was a prohormone with little hormonal activity. Northern blot analysis revealed that the mRNA expression of type-2 iodothyronine deiodinase (D2), which is responsible for maintaining local T3 concentration, was induced by 1,25(OH) $_2D_3$ (10^{-9}-10^{-7} M) dose- and time-dependently until 48 hours in POB and ST2 cells, although the mRNA expression of D2 was undetectable at basal condition. Treatment with 1,25(OH) $_2D_3$ did not show any obvious change in the mRNA expression of ALP. The mRNA expression of D2 was negligible after stimulation by other bone-resorbing cytokines, TNF-alpha or IL-1alpha. Either stimulation of Bt^2cAMP or PTH did not induce the mRNA expression of D2. As treatment with 10 microgram/ml of cycloheximide attenuated the induction of D2 by 1,25(OH) $_2D_3$, this induction mechanism may require de novo synthesis of transacting regulatory proteins. Our data would facilitate our understanding of the mechanism of osteoclast formation by thyroid hormones and suggest a novel interaction between thyroid hormones and 1,25(OH) $_2D_3$.

Contribution of Terminal Prostaglandin E_2 Synthase (PGES) to Bone Resorption. M. Saegusa[1], M. Murakami*[2], K. Matsuda*[1], K. Nakamura[1], I. Kudo*[2], H. Kawaguchi[1]. [1]Orthopaedic Surgery, Univ. of Tokyo, Tokyo, Japan, [2]Showa Univ., Tokyo, Japan.

Prostaglandins (PGs) are potent regulators of bone metabolism. Among the prostanoids that are known to be produced in bone, PGE_2, $PGF_{2\alpha}$, PGI_2 and thromboxane B_2, we confirmed that only PGE_2 has the potency to stimulate osteoclastogenesis and resorbed pit formation on a dentine slice in the coculture of mouse marrow cells and osteoblasts. The major enzymes in the synthesis of PGE_2 are phospholipase A_2, cyclooxygenase-1 or -2 (COX-1, -2), and PGE_2 synthase (PGES) which is the terminal and specific enzyme for PGE_2 biosynthesis. We and another group recently identified two isoforms of PGES, cytosolic PGES (cPGES) and membrane-associated PGES (mPGES). Cotransfection of cPGES and mPGES with COX-1 and COX-2 into HEK293 cells indicated that cPGES was functionally coupled with COX-1 and mPGES was coupled with COX-2 for PGE_2 biosynthesis. Both cPGES and mPGES were shown to be expressed in mouse long bones *in vivo* and cultured primary osteoblasts from mouse calvariae by RT-PCR. In cultured mouse primary osteoblasts, Northern and Western blot analyses revealed that both mPGES and COX-2 were induced by bone resorptive cytokines such as IL-1α, TNF-α and FGF-2. Induction of the mPGES mRNA level peaked at 3-6 h and decreased thereafter, while the maximal protein level was seen at 12 h and maintained up to 48 h. These were later than the COX-2 induction that was transiently seen from 1 to 6 h. mPGES and COX-2 mRNA levels were also shown by RT-PCR/Southern blotting to be induced in mouse long bone and bone marrow *in vivo* by intraperitoneal injection of lipopolysaccharide (0.5-5 mg/kg) dose dependently with maximal effects at 3 h. cPGES and COX-1, however, were expressed constitutively both *in vitro* and *in vivo* without being affected by these stimuli. To determine the contribution of mPGES to bone resorption, we treated coculture of mouse marrow cells and osteoblasts with an antisense oligonucleotide that was confirmed to block mPGES expression. The antisense oligonucleotide not only blocked PGE_2 production measured by ELISA, but also 80-90% reduced osteoclastogenesis and pit formation stimulated by bone resorptive cytokines, while the control oligonucleotide had no effect. Addition of exogenous PGE_2 reversed the inhibition. In conclusion, since mPGES is induced by and mediates effects of bone resorptive stimuli, it may play an important role in physiological and pathological bone resorption. Unlike NSAIDs which inhibit COX activity and suppress not only PGE_2 but also other essential PGs maintaining physiological homeostasis, an inhibitor of this PGE_2 specific enzyme, mPGES, could be a highly selective treatment for bone resorptive diseases with low side effects.

Effects of TNF Alpha on Osteoblasts and Osteoclasts. S. Wada*, S. Suda*, M. Kogawa*, S. Kitahama*, S. Yasuda*, M. Iitaka*, S. Katayama*. Internal Medicine IV, Saitama Medical School, Iruma-gun, Japan.

Recent epidemiological surveys have revealed that diabetes is a risk factor for fractures. This mechanism would be associated with various factors accompanied by diabetes (e.g., insulin deficiency or resistance and/or continuous hyperglycemia). We, therefore, studied the effects of high glucose and TNF alpha on osteoblasts (OBs) and osteoclasts (OCs); TNF alpha has been shown to be a key factor responsible for insulin resistance. The high glucose concentrations (60 mM) did not affect alkaline phosphatase (ALP) activity in mouse primary OBs, whereas treatment with TNF alpha significantly decreased ALP activity and bone formation assessed by von-Kossa staining. Flow cytometric analysis using fluorescein labelled Annexin V revealed that treatment with TNF alpha increased the number of apoptotic OBs but not OC progenitors. When mouse OBs and bone marrow cells were cultured in the presence of PGE2 and 1,25(OH)2D3, OCs were formed under high glucose concentrations (5.6-60 mM), while TNF alpha attenuated PGE2- and 1,25(OH)2D3-stimulated OC formation in the co-cultures. Since this effect was inhibited by antibody against TNF alpha receptor (p55), it seemed that TNF alpha acted on the type 1 receptor. When mature OCs were studied on bone resorbing function, it was found that bone resorption was inhibited by exposure to high glucose (15-60 mM). TNF alpha also inhibited bone resorbing capacity. The effects of decreased bone resorption were, at least partly, due to the deranged actin ring formation of OCs. Although OCs formation and function were modified, treatment with high glucose and TNF alpha did not influence the expression of RANKL and OPG in OBs nor the expression of RANK in OC progenitors. These results indicate that the functions of OBs and OCs could be modified by the factors associated with diabetes. This study suggests that multiple factors or cytokines produced in the microenviroment of bone could affect the cellular function of OBs and OCs, which would be related, to some extent, to low turnover of bone observed in diabetes.

Transgenic Mice Overexpressing Soluble RANKL Exhibit Severe Osteoporosis. H. Yasuda[1], A. Mizuno*[2], T. Kannno*[3], M. Hoshi*[4], O. Shibata*[5], K. Yano*[6], N. Fujise*[7], M. Kinosaki*[8], K. Yamaguchi*[5], E. Tsuda*[6], A. Murakami*[5], K. Higashio*[9]. [1]Institute of Medical Science, Univ. of Tokyo, Tokyo, Japan, [2]Department of Pharmacology,, Jichi Medical School, Tochigi, Japan, [3]Mitsubishi Chemical Safety Institute, Ibaraki, Japan, [4]Iwate Pharmaceutical Plant, Snow Brand Milk Products, Iwate, Japan, [5]Proteome Research Laboratory, Daiichi Pharmaceutical, Tochigi, Japan, [6]Biological Research Laboratories, Sankyo, Tokyo, Japan, [7]Pharmaceutical Division, Snow Brand Milk Products, Saitama, Japan, [8]Pharmaceutical Technology Laboratory, Chugai Pharmaceutical, Shizuoka, Japan, [9]Research Center for Genomic Medicine, Saitama Medical School, Saitama, Japan.

Osteoclast differentiation factor, RANKL, also called ODF, TRANCE, or OPGL, is a key molecule for osteoclast differentiation and activation, and is thought to act as a membrane-associated molecule in bone remodeling. Recent study suggested that soluble RANKL (sRANKL) released from T cell has also some roles in bone resorption. To investigate the physiological and pathological function of sRANKL, we generated two types of transgenic mice overexpressing sRANKL. Mice overexpressing sRANKL ubiquitously from the early developmental stage died at the late fetal stage. Another type of mice, expressing sRANKL only in the liver after birth, grew to be matured with normal body size and weight. However, they exhibited a marked decrease in bone mineral density with aging compared with the non-transgenic littermates. In addition, strength of their femurs was extremely lowered. Histological analysis showed that the trabecular bone mas was decreased at 6 weeks old and was sparse at only 3-4 months old. The number of osteoclasts was significantly increased, while the number of osteoblasts was not altered on the surface of young trabecular bone. These results indicate that excessive production of sRANKL causes osteoporosis by accelerated osteoclastogenesis. The transgenic mouse overexpressing sRANKL in the liver would serve as a useful animal model for studying bone remodeling and evaluating therapeutic agents for osteoporosis.

Transcriptional Program of Mouse Osteoclast Differentiation Governed by the Macrophage Colony-Stimulating Factor and the Ligand for the Receptor Activator of NF{kappa}B. D. Cappellen*[1], N. Luong-Nguyen*[1], S. Bongiovanni*[2], O. Grenet*[2], C. Wanke*[2], M. M. Susa[1]. [1]Arthritis and Bone Metabolism Therapeutic Area, Novartis Pharma Research, Basel, Switzerland, [2]Pharmacogenomics Area, Novartis Pharma Development, Basel, Switzerland.

Cytokines macrophage colony stimulating factor (M-CSF) and the receptor activator of NF{kappa}B ligand (RANKL) induce differentiation of bone marrow hematopoietic precursor cells into bone-resorbing osteoclasts without the requirement for stromal cells of mesenchymal origin. We used this recently described mouse cell system and oligonucleotide microarrays representing about 9,400 different genes to analyze gene expression in hematopoietic cells undergoing differentiation to osteoclasts. The ability of microarrays to detect the genes of interest was validated by showing expression and expected regulation of several osteoclast marker genes. In total 750 known transcripts were up-regulated by more than 2-fold, and 91% of them at an early time in culture, suggesting that almost whole differentiation program is defined already in pre-osteoclasts. As expected, M-CSF alone induced the receptor for RANKL (RANK), but also, unexpectedly, other RANK/NF{kappa}B pathway components (TRAF2A, PI3-kinase, MEKK3, RIPK1), providing a molecular explanation for the synergy of M-CSF and RANKL. Furthermore, interleukins, interferons and their receptors (IL-1{alpha}, IL-18, IFN-{beta}, IL-11R{alpha}2, IL-6/11R gp130, IFN{gamma}R) were induced by M-CSF. Although interleukins are thought to regulate osteoclasts via modulation of M-CSF and RANKL expression in stromal cells, we showed that a mix of IL-1, IL-6, and IL-11 directly increased the activity of osteoclasts by 8.5-fold. RANKL induced about 70 novel target genes, including chemokines and growth factors (RANTES, PDGF{alpha}, IGF1), histamine and {alpha}1A-adrenergic receptors, and three waves of distinct receptors, transcription factors and signaling molecules. In conclusion, M-CSF induced genes necessary for a direct response to RANKL and interleukins, while RANKL directed a three-stage differentiation program and induced genes for interaction with osteoblasts, and immune and nerve cells. Thus, global gene expression suggests a more dynamic role of osteoclasts in bone physiology than previously anticipated.

Carbohydrate Binding Specificity of Osteoclast Inhibitory Lectin. C. Gange*[1], V. Kartsogiannis[2], H. Zhou[2], J. M. W. Quinn[1], M. T. Gillespie[1], K. W. Ng[2]. [1]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [2]Department of Medicine, The University of Melbourne, St. Vincent's Hospital, Fitzroy, Australia.

Osteoclast Inhibitory Lectin (OCIL) is a predicted type II membrane-bound molecule of 207aa containing a C-lectin domain in its extracellular domain which shows structural homology with the type II transmembrane proteins of natural killer (NK) cell receptor group of the C-type lectin super-family. Recombinant protein to the extracellular domain of murine OCIL (mOCIL) inhibits osteoclast formation in vitro. mOCIL, like the NK cell receptors (e.g. Ly49A/C and CD69), does not contain conserved residues for calcium binding however, we report here that mOCIL does exhibit calcium-independent carbohydrate binding with specificity for high molecular weight sulfated sugars. mOCIL bound to high molecular weight sulfated glycosaminoglycans (GAGs) with binding to carrageenan being 3 fold greater than dextran sulfate and 2.3 fold greater than fucoidan. Dose-dependent binding was observed showing saturation at 25ng mOCIL per pmol fucoidan. No significant binding was seen for unsulfated dextran, suggesting that the presence of anionic sulfate groups was important for interaction. Independence of anionic charge alone was observed, since mOCIL did not bind to hyaluronic acid. The low molecular weight sulfated GAGs, chondroitin sulfate A, chondroitin sulfate C, dermatan sulfate, heparan sulfate, heparin, and keratan sulfate showed no specific affinity for mOCIL, while only weak interactions were observed for some monosaccharides. This is consistent with the sugar binding specificity for Ly49A/C and CD69. mOCIL inhibited osteoclast formation in murine bone marrow macrophage precursor (BMMP) cells cultured with M-CSF and RANKL. In BMMPs treated with fucosidase (to remove terminal fucose residues) osteoclast formation was enhanced. mOCIL inhibition of osteoclast formation from such fucosidase treatment was reduced to approximately 50%. In BMMPs treated with neuraminidase as a control (to remove sialic acid residues), the inhibitory action of mOCIL was not ablated and complete inhibition was noted, suggesting that this inhibitory action may be mediated by specific sugar binding. In summary, mOCIL exhibited binding to high molecular weight GAGs that contain anionic sulfate groups. Fucosidase treatment of BMMP cells partially ablated subsequent mOCIL inhibitory action on osteoclast formation, suggesting a role for specific sugar binding in mOCIL inhibition of osteoclastogenesis.

Implication of Cyclooxygenase-2 in Human Osteoclast Differentiation. M. Lora*, R. Samadfam*, S. I. Briand*, A. J. De-Brum Fernandes. Rheumatic Diseases Unit, Université de Sherbrooke, Sherbrooke, PQ, Canada.

We have developed a model of osteoclastogenesis from marrow obtained from human fetal liver that does not require glucocorticoïds, $1,25(OH)_2$ vitamin D_3 or support cells, as other models described in the literature. This model is therefore ideal for studying the roles of cyclooxygenases (COX) in osteoclast development. By determining the number of tartrate resistant acid phosphatase (TRAP) colored cells in the preparation ($TRAP^+$ cells/field of view, corresponding to the surface of a circle of 1 mm diameter), we observed that the inhibition of both COX by indomethacin (100 µM, 58.2 ± 6.2) or ibuprofen (100 µM, 54.1 ± 3.0) as well as the inhibition of COX-2 by DFU (100 nM, 54.5 ± 5.6) or NS-398 (100 nM, 53.0 ± 1.8) doubled the number of $TRAP^+$ cells in our culture when compared to the control (29.6 ± 1.5). The COX-1 specific inhibitor valeryl salicylate (100 µM) had no effect on $TRAP^+$ cell counts when compared to control. Furthermore, we have demonstrated that anti-OPG antibody increased the number of $TRAP^+$ cells just as well as indomethacin (CTRL 17.4 ± 1.8, Indo 30.6 ± 2.5 and anti-OPG 26.4 ± 3.3 $TRAP^+$ cells/field of view). We now know that the RANKL-OPG-RANK system is implicated in our model. We therefore investigated the possibility that the inhibition of COX-2 blocked OPG accumulation in the supernatant which might be responsible for the increase of $TRAP^+$ cells when COX-2 is inhibited. With a sandwich ELISA technique, we have shown that COX-2 inhibition by either NS-398 (100 nM) or indomethacin (100 uM) decrease OPG accumulation in the supernatant and this effect could be reverse by adding exogenous prostaglandins. These results suggests that prostaglandins produced by COX-2 are implicated in osteoclastogenesis (TRAP decrease) and that prostaglandins produced by COX-1 do not seem important for this phenomenon. We can therefore conclude that the prostaglandins produced by COX-2 activity are osteoclastogenesis inhibitors in our system. Pinpoint pharmacological intervention with specific inhibitors of COX may be important elements in understanding and eventually controlling osteoclast differentiation.

Inhibition of Tumor-Induced Osteolysis by Minodronic Acid (YM529) in Nude Mice with Bone Metastases. K. Shibasaki*, S. Tanaka*, N. Katou*, H. Yuyama*, H. Koutoku*, K. Miyata*. Institute for Drug Discovery Research, Yamanouchi Pharmaceutical Co., Ltd., Tsukuba, Ibaraki, Japan.

The effects of minodronic acid (YM529) on osteolysis due to bone metastases of breast cancer were investigated and compared with other bisphosphonates. Metastases were induced by intracardiac injection of the human breast cancer cell line MDA231 into BALB/c nu/nu mice. Test compounds were intravenously given to mice after osteolytic metastases were radiologically defined. Histological examination confirmed that numerous

TRAPase-positive (osteoclastic) cells appeared on the bone surface near the tumor in the breast cancer metastases model. Intravenous administration of minodronic acid or zoledronic acid reduced the number of osteoclasts and the ratio of osteoclast surface to bone surface at each tumor site in a dose dependent manner. The effects of these two compounds were statistically significant at doses of 0.1 mg/kg i.v. In contrast, a dose of 10 mg/kg i.v. was necessary for pamidronate, a currently available bisphosphonate, to cause a significant decrease in the number of osteoclasts and the ratio of osteoclast surface to bone surface. In conclusion, minodronic acid inhibited osteolysis caused by bone metastases of MDA231 cells. Consequently, minodronic acid holds promise as an intravenous treatment for bone lesions arising from metastases of breast cancer to bone. In this model, minodronic acid has the same potency as zoledronic acid and is more potent than pamidronate.

The Promotion Effects Of Sodium Fluoride On Osteoclast Apoptosis Of Adult Intact And Ovariectomized Wistar Rats*. Y. Li[1], Y. Sun[1], F. Yang[1], M. zhu[2], B. Lu[2], M. Qiu*[2]. [1]Biology, Institute of Radiation Medicine, Chinese Academy of Medical Sciences, Tianjin, China, [2]Endocrinilogy, Tianjin Medical University, Tianjin, China.

Fluoride has been shown to increase bone density, possible by reduce the solubility of hydroxyapatite crystals, though the mechanism for this remains unclear. Bone density reflects the comparative rates of osteoclast-mediated bone resorption (bone mineral loss) and osteoblast-mediated new bone formation. The mechanism by which sodium fluoride (NaF) modulates osteoclastic bone resorption also remains unclear. Purpose It has been built a method of osteoclast culture and observation of its' apoptosis in vitro in order to unveil the mechanisms of endemic fluorosis and osteoporosis treatment by fluoride on cellular level. Method Intact and ovariectomized (OVX) rats drank 5mg/L or 15mg/L NaF water desirably. It has been carried out the investigations of osteoclast-like cell (OLC) formation and its' apoptosis in vitro of adult rat modulation by fluoride administrated in vivo and the effects of 5, 10, 15mg/L NaF in culture media on OLC formation and its' apoptosis in vitro. Results [1] The number of OLC in OVX rats was found to be increased, compared to intact rats, two weeks after OVX and still present 6 months after OVX. [2] Both 5 and 15mg/L NaF inhibit intact and OVX rats OLC formation in vitro after fluoride administration of 5 months although the inhibition effect of 5mg/L group was less than latter. However, the inhibition effect of 15mg/L group was obviously even from 2 months after NaF administration. [3] 2 weeks after NaF administration, Fluoride could promote OVX rat OLC apoptosis. From 2nd month after NaF administration both 5 and 15mg/L NaF could promote intact and OVX rat OLC apoptosis. The promotion effects were getting stronger with the time and 15mg/L group's was stronger than that of 5mg/L group. [4] The effects of 5, 10, 15mg/L NaF in culture media on OLC formation inhibition and its' apoptosis promotion were dose-dependent. Conclusion The evidence presented in this paper may explain the reason that the observed reduction in osteoclast numbers is sodium fluoride reduce osteoclast formation and induce its apoptosis.

A TNF-α Peptide-antagonist W9 Inhibits the Soluble RANKL-induced Osteoclastogenesis Stronger Than that Induced by Membrane-bound RANKL. Y. Suzuki*[1], K. Aoki[2], I. Ishikawa*[1], K. Ohya[2]. [1]Section of Periodontology, Department of Hard tissue Engineering, Graduate school, Tokyo Medical and Dental University, Tokyo, Japan, [2]Section of Pharmacology, Department of Hard tissue Engineering, Graduate school, Tokyo Medical and Dental University, Tokyo, Japan.

Therapeutic peptidomimetics that interfere with the TNF/TNF receptor(I) interaction have been developed based on atomic structures deduced from the crystal structures of TNF-α and the TNF-β/TNF receptor(I) complex (Nature Biotechnology 15: 1266-1270, 1997). The cyclized peptidomimetic WP9QY (Tyr-Cys-Trp-Ser-Gln-Tyr-Leu-Cys-Tyr) which engineered to mimic the most critical TNF-α recognition site on the TNF receptor(I) efficiently antagonized the effects of TNF-α binding to the TNF receptor(I). We have already given a presentation at the 21st annual meeting that this TNF-α peptide-antagonist blocks vitamineD_3/PGE_2- and soluble RANKL(sRANKL) - induced osteoclastogenesis *in vitro* (J. Bone Miner. Res. 14: S178, 1999). Recently it was reported that the sRANKL derived from activated T cells might induce osteoclastogenesis under the inflammatory condition. On the other hand, it has already known that vitamin D_3 and PGE_2 iuduce osteoclastogenesis via the trimeric membrane-bound RANKL on osteoblasts, that is supposed to be relevant for the physiological bone resorption. These raised the question whether the inhibitory effect of W9 might be different depending on the stimulants for inducing osteoclasts. To address this question, we performed a standard co-culture experiment using bone marrow cells from ICR mice and primary osteoblasts isolated from calvaria comparing the bone marrow culture stimulated by sRANKL and macrophage-colony stimulating factor. We found that W9 inhibited the sRANKL-induced osteoclastogenesis stronger than that induced by vitamin D_3 and PGE_2. These results suggest that W9 could inhibit the T cell-mediated bone resorption more than the physiological bone resorption which contributes a normal remodeling cycle.

SA251

The Mechanism Of Inhibition Of Farnesyl Diphosphate Synthase By Nitrogen-Containing Bisphosphonates. J. E. Dunford*[1], F. H. Ebetino*[2], M. J. Rogers[1]. [1]Medicine and Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

We and others have recently shown that farnesyl diphosphate synthase (FPP synthase), an enzyme of the mevalonate pathway, is the major molecular target of nitrogen-containing bisphosphonates such as risedronate (RIS). FPP synthase catalyses the condensation IPP and DMAPP to form GPP, then the condensation of GPP with IPP to form FPP. The exact mechanism by which bisphosphonates inhibit FPP synthase are unknown, although the enzyme has 2 binding sites for isoprenoid lipids (IPP and either DMAPP or GPP). Using recombinant human FPP synthase in vitro, we have investigated the mechanism for inhibition of the formation of FPP from GPP+IPP. Enzyme kinetic analysis showed that low concentrations of RIS (<75nM) caused uncompetitive inhibition with IPP but competitive inhibition with GPP, suggesting that RIS binds to the GPP binding site, but also influences the binding of IPP at the other site. At higher concentrations of RIS (>75nM), the inhibition was partially competitive with IPP and noncompetitive with GPP, suggesting that RIS does also bind to the IPP binding site. Further kinetic analysis suggested that more than one molecule of RIS binds to the enzyme, and that this binding occurs in a cooperative manner. We therefore propose that RIS inhibits FPP synthase by binding at the GPP binding site of the enzyme. This then facilitates the binding of RIS at the IPP binding site. The potency for inhibiting FPP synthase may therefore depend on the affinity of the enzyme for the bisphosphonate and the ability of the bisphosphonate to bind to both substrate binding sites in a cooperative manner.

Effects of Membrane Potential on Acid-extrusion via Proton-translocating Subunit (c) of a Vacuolar Type H+-ATPase from Murine Osteoclasts. H. Sakai[1], H. Mori*[2], H. Morihata*[2], J. Kawawaki*[3], A. Shioi[4], M. Kuno[2]. [1]Orthopedic Surgery, Osaka City University, Osaka, Japan, [2]Department of Physiology, Osaka City University, Osaka, Japan, [3]Central Laboratory, Osaka City University, Osaka, Japan, [4]Cardiovascular Medicine, Osaka City University, Osaka, Japan.

A vacuolar type H+-ATPase (V-ATPase) enriched in the ruffled membrane of osteoclasts is a principal H+ secreting mechanism responsible for bone resorption. Although the molecular basis for the V-ATPase is revealed, mechanisms regulating the H+ transport in osteoclasts are yet to be defined well. The membrane potential of osteoclasts could switch between two levels, that is, around –60 and 0 mV. Considering that V-ATP is an electrogenic pump, the acid secretion may be affected by the membrane potential. V-ATPase possesses a trans-membrane domain that contains subunit c (16 kDa) for H+ translocation and subunit a3 (116 kDa) required for localization. In this study, we investigated how the membrane potential affected H+ transport with the two subunits in COS 7 cells transfected with cDNAs encoding the genes. The PCR products of subunit c and a3 were subcloned into pcDNA3.1(+) expression vector and used to transfect COS7 cells. Intracellular pH (pHi) in transformed cells was measured by a co-expressed, pH-dependent marker, GFP. Single-cell RT-PCR analysis confirmed that more than 90% of the GFP-expressing cells overexpressed subunit c and/or subunit a3. Confocal microscopy revealed that the chimeric protein subunit c-GFP and/or subunit a3-RFP (Ds-red) were localized in the cellular and subcellular membranes. In the Na+-free, high-K+ solution, pHi recovered from acid-load induced by washings of NH4Cl in cells transfected with subunit c cDNA, although not in non-transfected cells. The pHi recovery was also brisk even in the Na+- and K+-free solution containing 50 mM TEA-Cl, a K+ channel blocker that could depolarize cells. This pHi recovery was not enhanced by co-transfection with subunit a3 and was not induced in cells transfected with subunit a3 only, suggesting that subunit c, but not subunit a3, was responsible for the depolarization-dependent pHi recovery. Transfection with cDNA for either subunit c or a3 did not alter the resting pHi in the standard extracellular solution. The Na+-independent pHi recovery was not inhibited by bafilomycin A1 (200 nM) in cells transfected with subunit a3 and c. These results suggest that H+ extrusion via subunit c is enhanced by membrane depolarization, which would modify bone-resorbing functions of osteoclasts under different membrane potentials.

Molecular Modeling of the Bisphosphonates (BPs) in Farnesyl Diphosphate (FPP) Synthase. Proposed New Mechanism of Inhibition by Potent Nitrogen Containing Bisphosphonates (NBPs). F. H. Ebetino[1], M. Rogers*[1], J. Dunford*[1], X. Liu*[1], R. Phipps*[1], R. G. G. Russell*[2], G. Mieling*[1], B. Barnett*[1]. [1]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [2]Oxford University, Oxford, United Kingdom.

Although BPs have been successfully utilized clinically for a number of years, only recently has our understanding of the exact antiresorptive mechanism of action of these agents developed. FPP synthase has been shown to be the key biochemical target for the nitrogen containing (N-BPs). To provide improved opportunities for drug design in this field, and to offer clinicians more insight into the potential differences among members of this drug class, we have continued to study the precise chemical and biochemical mechanisms of action of BPs. Minor changes in the side chains of these compounds result in varying potency for FPP synthase inhibition and antiresorptive activity, which suggests that N-BPs interact with their target via a stereochemical recognition event. The relative potency for inhibiting FPP synthase correlates with the known acute *in vivo* potencies of BPs (zoledronate > risedronate > alendronate > pamidronate). These potential interactions in the enzyme can be visualized via molecular modeling techniques, therefore we can now examine the inhibitory interactions that may take place within this enzyme in order to explain exactly how the structure of N-BPs relates to potency. For example, Martin *et al* recently proposed that BPs may inhibit FPP synthase by acting as transition state analogues at the geranyl diphosphate (GPP) binding site. On close analysis of active and inactive structurally-related pairs of BPs, we propose a potentially more specific inhibition due to binding at a predicted isopentenyl diphosphate (IPP) binding site in the enzyme. Docking potent N-BPs such as risedronate in the IPP binding site enables the nitrogen of the N-BP to form a salt bridge with either the diphosphate of GPP or with a N-BP in the GPP site. In the putative IPP binding site, the conformationally restricted, potent N-BP NE-58025 (IC_{50}=110nM, rhFPP) appears to bind in a similar manner to risedronate, whereas the inactive, conformationally-restricted N-BP NE-58086 (IC_{50}=3850nM) is unable to form the salt bridge. In the IPP site, zoledronate appears to form two salt bridge interactions at the imidazole nitrogen, thus explaining its enhanced IC_{50} vs. other N-BPs, whereas alendronate displays greater solvent (water) accessible surface, potentially explaining its lower propensity for FPP synthase inhibition. Work continues to further validate these hypotheses, utilizing enzyme purification and crystallography, but many of the intricacies of the mechanism of action of N-BPs are now becoming clear.

A TNF-α-Related Peptide Inhibits Both Bone Resorption and Inflammation in Collagen-Induced Arthritis. T. Kojima*[1], K. Aoki[2], K. Nonaka[2], R. Murali*[3], M. I. Greene*[3], T. Amagasa*[1], K. Ohya[2], W. C. Horne[4], R. Baron[4]. [1]Section of Maxillofacial Surgery, Tokyo Medical and Dental University, Tokyo, Japan, [2]Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [3]University of Pennsylvania, Philadelphia, PA, USA, [4]Yale University, New Haven, CT, USA.

The peptidomimetic WP9QY (YCWSQYLCY), which was designed to mimic the most critical TNF-α recognition site on the TNF receptor(I), efficiently antagonizes the effects of TNF-α binding to the TNF receptor(I) (Nature Biotechnol. 15: 1266, 1997). We previously reported that this peptide inhibits bone resorption induced by RANKL *in vitro* or by a low calcium diet *in vivo* . Osteoprotegerin, which is a strong antagonist of RANKL but not of TNF-α, has been reported not to inhibit inflammation in the rat arthritis model. Since WP9QY antagonizes both TNF and RANKL in *in vitro* assays, we sought to determine if this peptide would antagonize both cytokines *in vivo* by examining the effect of WP9QY on the inflammatory bone destruction in the collagen-induced arthritis (CIA) model. Male 7 week-old DBA/1J mice were immunized intradermally with bovine type II collagen and boosted similarly at day 21. Mice were divided into three groups; non-immunized control group, immunized group with vehicle injections, and immunized group with peptide injections. The WP9QY peptide (24mg/kg x 8/ day) was administered by SC injections starting before the onset of paw swelling (at day 22, 24, and 26). The arthritis score began to increase in the vehicle-injected group starting at day 25 and reached an average score of 9.6 (12.0 is a full score using this evaluation) at day 38. In contrast, the average score in the peptide-injected group at day 38 was 5.7, indicating that the WP9QY peptide inhibited inflammation. The trabecular bone density of tibial metaphysis, measured by pQCT, was significantly reduced from 261 mg/cm ^{3} in the control group to 210 mg/ cm ^{3} in the vehicle-injected group, and this decrease of bone mineral density was significantly inhibited by the peptide injections (19.6% decrease in the vehicle-injected group vs 6.7% decrease in the peptide-injected group). Histological analysis revealed that WP9QY both blocked the invasive pannus tissue formation in the knee joint and prevented the increase in the number of osteoclasts in the joint area that occurred in the vehicle-injected group. Furthermore, WP9QY reduced the amount of anti-collagen II antibody in serum by 64%. Although the amount of the injected peptide is very high, these results clearly prove the concept that WP9QY peptide inhibits both inflammation and bone destruction that characterizes CIA.

Expression of EP_3 and EP_4 Prostaglandin Receptors in Mature Human Osteoclasts. P. Sarrazin*, I. Fortier*, S. I. Briand*, A. J. De-Brum Fernandes. Rheumatic Diseases Unit, Université de Sherbrooke, Sherbrooke, PQ, Canada.

Prostaglandins are potent, multifunctional and complex regulators of bone metabolism that may increase both bone formation and resorption. PGE_2 is the major prostaglandin produced in bone. Cellular effects of PGE_2 are mediated through specific receptors named EP_1, EP_2, EP_3 and EP_4. Little is known on the distribution of PGE_2 receptors in bone cells, although this knowledge could be important to understand the complex actions of PGE_2 on bone. The objective of the present work was thus to study the distribution of the EP receptors in human osteoclasts and to determine their effects on the presence of lamellipodia and actin rings, cytoskeleton structures necessary for osteoclast motility and bone resorption, respectively. *In situ* hybridization showed that human mature osteoclasts in culture expressed mRNA for the EP_3 and the EP_4 prostaglandin receptors. The presence of the EP_3 and EP_4 receptor proteins was also demonstrated using immunohistochemistry. EP_1 and EP_2 mRNA and proteins were not detected in these cells. We also investigated the expression of the EP receptors in human bone sections. The EP_3 and EP_4 polyclonal antiserum stained osteoclasts from human foetal, osteoporotic and pagetic bone tissues. A concentration dependant decrease of the number of TRAP positive cells with actin ring was observed with increasing PGE_2 concentration (EC_{50} of 1.09 +/- 1.2 nM). Incubation with 11-deoxy-PGE_1, an EP_2 and EP_4 agonist, showed a concentration dependant decrease in the percentage of TRAP positive cells with actin ring (EC_{50}: 14.3 +/- 2.8 nM) and a concentration dependent increase in the percentage of TRAP positive cells with podosomes (EC_{50}: 1.6 +/ - 1.9 nM). 11-deoxy-PGE_1 had no effect on TRAP positive cells with lamellipodia. Butaprost, a selective agonist for the EP_2 receptor, induced no changes in the actin cytoskeleton. Misoprostol, an EP_2 and EP_3 specific agonist, had no effect on the percentage of TRAP positive cells with actin ring but significantly increased the percentage of TRAP positive cells with podosomes (EC_{50}: 1.7 +/- 2.1 nM) and decreased the number of TRAP positive cells with lamellipodia (EC_{50}: 4.2 +/- 1.5 nM). In conclusion, we demonstrated that cultured osteoclasts express functionnal EP_3 and EP_4 receptors, the first implicated in the decrease of lamellipodia and the second decreasing the number of cells presenting actin ring.

Jun Dimerization Protein 2 (JDP2), a Member of the AP-1 Family of Transcription Factor, Mediates Osteoclast Differentiation Induced by RANKL. R. Kawaida*[1], T. Ohtsuka*[1], J. Okutsu*[1], T. Takahashi*[1], Y. Kadono[2], H. Oda[2], K. Nakamura[2], S. Tanaka[2], H. Furukawa*[1]. [1]Biomedical Research Laboratories, Sankyo Co., Ltd., Tokyo, Japan, [2]Department of Orthopaedic Surgery, The University of Tokyo, Tokyo, Japan.

Osteoclasts are multinucleated cells that resorb bones, and are derived from hematopoietic cells of the monocyte-macrophage lineage. Receptor activator of NF-kB ligand (RANKL, also called ODF/TRANCE/OPGL) stimulates both osteoclast differentiation from osteoclast progenitors and activation of mature osteoclasts. However, molecular mechanisms of osteoclast differentiation have yet to be elucidated. To identify genes responsible for osteoclast differentiation, we used a molecular indexing technique. We isolated 10 cDNA clones whose expressions were induced by soluble RANKL (sRANKL) in RAW264.7 cells, a murine myelomonocytic cell line that differentiates to osteoclasts on sRANKL treatment. Sequence comparison analysis revealed that one of them was a mouse homologue of Jun dimerization protein 2 (JDP2), a member of the AP-1 family of transcription factors, containing a basic region-leucine zipper motif. sRANKL-induced up-regulation of this gene was also detected in mouse bone marrow cells during osteoclastogenesis but not in J774A.1 cells which lack oseoclastogenic potential in spite of the fact that they have the same ability to activate the NF-kB pathway as did RAW264.7. To demonstrate the functional role of JDP2 in regulation of osteoclast differentiation, we examined the ability of JDP2 to activate osteoclastogenic pathway. First, infection of mouse primary bone marrow cells with retrovirus expressing JDP2 promoted sRANKL-induced formation of tartrate-resistant acid phosphatase (TRAP)-positive multinuclear osteoclasts. Second, transient transfection experiments of RAW264.7 cells revealed that expression of JDP2 activated promoters for TRAP and cathepsin K genes, which are specific markers for osteoclasts. Our findings suggest that JDP2 may play an important role in the RANK-mediated signal transduction system, especially in osteoclast differentiation.

The Transcription Factor AP-1 Regulates RANKL-dependent Differentiation and Survival in Osteoclasts. F. Ikeda[1], T. Matubara*[1], K. Hata*[1], K. Yamashita*[1], T. Watanabe*[2], T. Kukita[2], K. Yoshioka*[3], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Second Dept of Oral Anat, Kyushu Univ Grad Sch of Dent, Fukuoka, Japan, [3]Div of Cell Cycle Regulation, Cancer Res Inst, Kanazawa Univ, Kanazawa, Japan.

RANK ligand (RANKL) plays an important role in the life cycle of osteoclasts through regulating their differentiation and apoptosis. Recent studies show that RANKL activates the transcription factor AP-1 following propagation of JNK and c-Jun in osteoclasts. These results suggest that the AP-1 signaling plays a role in the regulation of the differentiation and apoptosis in osteoclasts. To test this notion, we used a study model in which soluble RANKL (sRANKL) induced the differentiation of RAW264 murine monocytic cells into tartrate-resistant acid phosphatase-positive multinucleated osteoclast-like cells (TRAP(+) MNC) and promoted the transactivation of AP-1 through JNK and c-Jun activation. To examine the role of AP-1 composed of c-Jun and c-Fos, we introduced a dominant-negative mutant of c-Jun (DN-c-Jun) or c-Fos (DN-c-Fos) into RAW264 cells using a newly-engineered adenovirus system. We found that DN-c-Jun or DN-c-Fos markedly inhibited the transactivation of AP-1 and decreased TRAP(+) MNC formation in sRANKL-stimulated RAW264 cells. DN-JNK1 also suppressed sRANKL-induced activation of c-Jun and TRAP (+) MNC formation. Since recent studies suggest an involvement of AP-1 in induction of apoptosis in various types of cells, we next examined whether the AP-1 affects apoptosis in osteoclasts by assessing for active caspase-3 expression and nuclear fragmentation in mature osteoclasts (OCL) which formed in the mouse bone marrow cultures. sRANKL prevented apoptosis in OCL and prolonged their survival, demonstrating anti-apoptotic effects of sRANKL. On the other hand, DN-c-Jun or DN-c-Fos markedly increased apoptosis of mature OCL even in the presence of sRANKL. Since RANKL activates NF-κB as well as AP-1 in osteoclasts, we studied the role of NF-κB in osteoclast differentiation and apoptosis. Consistent with the previous results, suppression of NF-κB activation using an ubiquitin-resistant mutant of Iκ-Bα (Iκ-BαMut) blocked TRAP(+) MNC formation, suggesting a critical role of NF-κB in osteoclast differentiation. In contrast, the Iκ-BαMut did not inhibit sRANKL-stimulated survival, suggesting an involvement of NF-κB in osteoclast apoptosis is unlikely. In conclusion, our results suggest that the transcription factor AP-1 is critical to osteoclast differentiation. In addition, our results also suggest that the AP-1 has anti-apoptotic actions in contrast to other cell systems. Thus, AP-1 plays diverse roles in RANKL-induced events in osteoclasts.

The Express of Fas, Fasl And Nf-kapab in The Process of Osteoclast-like Cell Apoptosis Effected by Sodium Fluoride*. Y. Sun[1], Y. Li*[1], F. Yang*[1], M. Zhu*[2], B. Lu[2], M. Qiu*[2]. [1]Biology, Institute of Radiation Medicine, Chinese Academy of Medical Sciences, Tianjin, China, [2]Endocrinilogy, Tianjin Medical University, Tianjin, China.

Purpose: In the process of bone remolding, absorption of bone depends on the constant recruit of osteoclast. It has now proved that disappear of osteoclast is the result of itself apoptosis. Our previous experiments showed sodium fluoride in tap water drank by rat ad libitum have promoted the process of osteoclast apoptosis in vivo. Fas is the receptor in the membrane of cells and is related to apoptosis. As it binds to its ligand, the signal of apoptosis is transmitted and cell apoptosis happens. Nuclear factor NF- κB may be participated in tumor necrosis factor activating the pathway of apoptosis and prohibits the apoptosis. This paper reports the expression change of apoptosis signals: Fas, FasL and NF-κB in the course of osteoclast-like cells apoptosis effected by sodium fluoride. Method: C57BR/6 mice spleen cells suspension in α-MEM media containing rmIl-3, rhIl-6, BSA, fetal calf serum and agar cultured at 37ºC and 5% CO2 for two weeks and then the colonies suspension re-cultured in theα-MEM media containing rmGM-CSF for two weeks again. Above cells were induced into osteoclast-like cells by 1,25(OH)2VitD3 in theα-MEM solutions. TRAP staining and scanning electron microscope showed these cells were osteoclast-like cell (OLC). OLCs were co-cultured with sodium fluoride at the concentration of 0, 5, 10 and 15mg/L for a week. The expression of Fas, FasL and NF-κB were examined by immuno-histochemistry. 500 cells were checked under microscope. The cells with dark staining were expression positive and counted the percentage of positive cells. Experiments data are treated with statistics software SPSS. Result: The percentage of OLCs that expressed proteins of Fas and FasL increased with the concentrations of sodium fluoride. The percentage of osteoclast-like cells expressing the NF-κB decreased with the concentration of sodium fluoride. Conclusion: In the process of OLC apoptosis induced by NaF, the expression of Fas and FasL increased and the expression of NF-κB decreased. These changes of the expression presented dose-dependent.

Prevalence of Osteopenia and Osteoporosis in Hispanic Postmenopausal Females. J. R. Talbot[1], M. Goette-Jaime*[2], F. Cons-Molina[3], O. D. Messina[4], E. Schulz[5]. [1]Pan American Ospeoporosis Foundation (PAOF), Oceanside, CA, USA, [2]Baja California University, Mexicali, Mexico, [3]Unidad de Diagnostico Osteoporosis, Mexicali, Mexico, [4]CIRO, Buenos Aires, Argentina, [5]Loma Linda University, Loma Linda, CA, USA.

The prevalence of osteopenia and osteoporosis in the white-Hispanic population remains controversial. For instance, the NHANES has reported a low 10% prevalence of hip osteoporosis in white-Hispanic females in contrast with a 20 % prevalence observed in white-Caucasian females. However, a higher 36% prevalence of osteoporosis has been estimated by Melton in white postmenopausal females (50 to 80+ years of age) from Rochester Minnesota. Recently, has been reported a 20% prevalence of osteoporosis in white-Hispanic females, but the subjects in this study were 20 to 90 years. However, when only postmenopausal females were evaluated the prevalence of osteoporosis increased to 25 - 30%. The aim of this study was to determine the prevalence of osteopenia and osteoporosis in healthy postmenopausal white-Hispanics females from a relatively homogenous menopause age, and geographical area as is Southern California (USA) and Northern Baja California (Mexico). Lumbar spine (L2-L4) and hip BMD/C were performed with a DEXA-Lunar-DPX densitometer in 369 postmenopausal, healthy white-Hispanic females referred by their physician to a bone densitometry center as part of a routine evaluation. Were included in the analysis of these study only healthy females from Southern and Northern Baja California who had their menopause at age 50 ± 1 years. Were excluded from the study females who had any disease or received any treatment that may affect mineral or bone metabolism, scoliosis, vascular calcifications or any other abnormality that may affect DEXA results. Patients with "normal/high" DEXA due to a non-traumatic vertebral fracture were included as osteoporotic (Fractured vertebras were excluded from the analysis). The preliminary results of the prevalence of osteopenia and osteoporosis in 369 postmenopausal Hispanic females showed a mean age of 61 ± 4 years and mean time in menopause of 14.7 years. BMD t-score: normal 19%, osteopenia 49% and osteoporosis 32 %. [Lunar-DEXA results were adjusted to Hologic standards multiplying BMC/D of lumbar spine by 0.9522 and hip by 0.979]. Our preliminary results suggest similar prevalence of osteopenia and osteoporosis in postmenopausal white-Hispanic and white-Caucasian females.

SA266

Effectiveness of Peripheral DEXA in Predicting Fractures and Targeting Treatment in Women aged 60-80. D. M. Reid[1], R. J. Barr*[2], A. Adebajo*[3], W. D. Fraser[4], J. P. Halsey[5], C. Kelsey*[6]. [1]Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]University of Aberdeen, Aberdeen, United Kingdom, [3]Barnsley District Hospital, Barnsley, United Kingdom, [4]Royal Liverpool University Hospital, Liverpool, United Kingdom, [5]Royal Lancaster Infirmary, Lancaster, United Kingdom, [6]Oldchurch Hospital, Romford, United Kingdom.

Purpose To determine the effectiveness of peripheral DXA (PIXI®,GELunar) in the assessment of risk and targeting treatment to prevent future fracture. *Methods* Women aged 60-80 from 5 centres in the United Kingdom attended for a PIXI scan and completed a risk factor questionnaire. Women were designated as high (H), medium(M) or low(L) risk dependent on WHO equivalent T-Scores for the PIXI scanner (T<-1.6 ≈osteoporosis, T<-1 but >-1.6≈osteopenia, T>-1≈normal). 12-24 months later women were followed up by postal questionnaire to determine incident self-reported fractures and treatments for osteoporosis. *Results* Of the initial screened population (n=7604) 74% returned the questionnaire. The proportion of screened women in each risk was H: 24.5%, M: 28.9%, L: 46.6% and this differed significantly from non-responders (H: 26.8%, M: 29.7%, L: 43.5%, $\chi^2 = 7.3$, P=0.026). Of H women 23.4% (n= 323) were on a variety of osteoporosis treatments, including calcium or vitamin D, at baseline(B) rising to 78% at follow-up(F) - see table. More women in the M and L risk groups received treatment at B but the proportions receiving treatment at F changed substantially in the 3 groups ($\chi 2 = 17.71$, P=0.014). Relative risk of all fractures and fractures of hip, wrist and vertebrae were significantly increased in the H and M group compared to L risk. Preliminary analysis did not detect a significant difference in incident total (no treatment -nRx: 8.9%, Rx 8.1%) or hip, wrist and spine fractures (nRx: 3.6%, Rx 3.8%) during 18.6 months follow-up (F). *Conclusions* This study demonstrates that risk assessment by PIXI predicts incident fractures and alters treatment patterns but as yet shows no reduction fracture rates over an 18 month period.

Treatment and Fracture Incidence

	High (n=1377)	Medium (n=1625)	Low (n=2626)
Treatment at baseline (B)	23.4%	25.3%	27.5%
Treatment at follow-up (F)	78.0%	57.2%	17.1%
Never treated (N)	17.4%	33.7%	62.0%
Total Incident Fractures	9.5%	6.1%	3.8%
RR c.f. low (95% CI)	2.5 (1.9 - 3.3)	1.6 (1.2 - 2.2)	
Hip,Wrist, spine only	4.8%	2.7%	1.5%
RR c.f. low (95% CI)	3.2 (2.1 - 4.9)	1.8 (1.1-2.9)

Assessment of Bone Mineral Density in an Elderly Population in the City of São Paulo, Brazil. M. B. R. Camargo*[1], G. L. Saraiva*[1], M. Lazaretti-Castro[1], M. Cendoroglo*[2], L. Ramos*[2]. [1]Endocrinology, Universidade Federal de São Paulo, São Paulo, Brazil, [2]Geriatrics, Universidade Federal de São Paulo, São Paulo, Brazil.

This cross-sectional population-based study examined the association of anthropometric parameters with bone mineral density (BMD) in São Paulo, Brazil. This study was conducted as part of the EPIDOSO Study, the first follow-up study of elderly residents in Brazil. The study started in 1991 and approached 1667 elderly people (above 65 years), living in community in the district of Saúde, in the city of São Paulo. BMD was assessed in 294 elderly women (n =197) with a median age of 77 yo (70 -93 yo) and men (n=97), median of 76 yo (70-88 yo), from the population-based EPIDOSO Study, between 1998 and 1999. For women, median weight was 60 kg (37-97 kg) and median height was 152 cm (136-173 cm). BMI ranged from 15,83 to 38,8 kg/m2 (median 26,8 kg/m2). For men, median weight was 71 kg (49-103,9 kg) and median height was 166 cm (152-180 cm). BMI ranged from 19,6 to 36,03 kg/m2 (median 25,89 kg/m2). Total body composition and BMD at the lumbar spine (L), and femoral neck (N) were measured by dual-energy X-ray absorptiometry, using a HOLOGIC 4500 A. Osteopenia and osteoporosis were defined according to the WHO criteria, irrespective to gender. We examined the correlation (Spearman rank order test) between BMD and the factors: age, sex, weight, height, body mass index (BMI), fat-free soft mass index (FFM) (g of lean mass/height in meters squared) and percentage of fat (% fat). The level of significance was set as $P < 0,05$. Osteoporosis has the highest prevalence at N (45% of men and 53% of women) and osteopenia was found in 39% and 38% of men and women, respectively. On the other hand, only 18% of men and 33% of women had osteoporosis at L, and 34% of men and 35% of women had osteopenia at this site, with no correlation with age for both sexes. The strongest correlation was found between N and weight for both sexes (R=0,45 for men and R=0,51 for women), better than with FFM (R=0,25 and 0,37 respectively) or % fat (R=0,24 and R=0,33, respectively), all of them significant. There was also a weak but significant correlation between N and height (R=0,39 for men and R=0,25 for women). Concluding, we found a high prevalence of osteoporosis on femoral neck for men and women, in a rate of 1,2 women for each man. The best predictor of BMD at N was weight. The measurement of BMD at lumbar spine above 70 yo underestimated the prevalence of osteoporosis in both men and women in our studied population.

SA268

Relationship of Radiogrammetry and Bone Mineral Density using DXA in Normal Reference Data. S. Yang[1], S. Ham*[2], S. Lee*[3]. [1]Radiology, Ulsan University Hospital, Ulsan, Republic of Korea, [2]Ulsan University Hospital, Ulsan, Republic of Korea, [3]Kangnam Hospital, Seoul, Republic of Korea.

Digital X-ray Radiogrammetry (DXR) technique from radiographs of the hand estimate forearm BMD without the use of aluminium wedges. It has been shown to have good correlation to DXA and to have very low precision error. We report the results of a correlation between DXR data and DXA for Korean. The system (Pronosco) calculates BMD using a weighted average of cortical and bone width measurements at the second through fourth metacarpal. The output is an absolute BMD estimate called DXR-BMD. A total of 372 Korean women and 140 men were recruited from the Ulsan and Seoul (only men) area. Women and men with a history of bone diseases, medication impacting bone mineral density were excluded, as were those who had undergone prolonged hospitalisation or immobilisation. They had their non-dominant hand radiographed (50 kvp, 8 mA). DXA for the lumbar region was done with Hologic QDR 4500A in Ulsan and Lunar Expert in Seoul. By using the conversion equation, standardized BMD was taken for the analysis. A total of 349 female and 116 male in whom all the data were available is included the analysis. The means for DXR-BMD at the forearm and DXA at L1-4 were:

		DXR-BMD/ DXA (g/cm^2)	
Age	No.F/M	Female Mean ± SD	Male Mean ± SD

All	349/ 116	0.529±0.066/0.905±0.179	0.580±0.052/1.119±0.188

Correlation coefficients between DXR-BMD and DXA were 0.672 in female ($p<0.01$) and 0.448 in male ($p<0.05$).

The results show that relative to the Korean male population, the Korean females have significantly lower DXR-BMD across the age decades as expected. For women DXR-BMD is more closely correlated with DXA of the L-spine than male. This suggests that bone loss in the peri-menopausal women can also be detected by DXR-BMD accurately. Relatively lower correlation between DXR-BMD and L-spine DXA for male population should be elucidated in the future.

Bone Mineral Density in Healthy Asian Indian Women: Development of a Reference Database and Implications for Diagnosis of Osteoporosis in Indian Women living in the United States. P. G. Reddy*[1], A. Mithal[2], D. Rao[1]. [1]Bone & Mineral Metabolism, Henry Ford Hospital, Detroit, MI, USA, [2]Endocrinology, Indraprastha Apollo Hospital, New Delhi, India.

Genetics and ethnicity are the two most important determinants of bone mineral density (BMD), thereby necessitating the establishment of separate reference databases for different ethnic groups. We sought to establish the first BMD reference database for Asian Indian women so that appropriate comparisons can be made in evaluating individuals of Indian origin for osteoporosis in the United States. Two-hundred and thirteen healthy women, age 20-59 years, were recruited both to establish a reference database to calculate ethnic-specific T-scores and to determine the age-related decline in BMD. Measurements were taken at the lumbar spine, hip, and non-dominant forearm by Hologic 4500 dual energy x-ray absorptiometry. Calcium intake was estimated in all subjects and serum 25-hydroxyvitamin D levels were measured in a subset of 41 subjects. In all age categories BMD in Indians was significantly lower than that of U.S. white women at all relevant measurement sites. The expected age-related decline in BMD was seen at all sites. In 75 young women in the 20-29 age range, the peak adult BMD reference group, BMD results for the relevant sites were as follows: lumbar spine (L1-L4): 0.920 ± 0.097, femoral neck: 0.767 ± 0.090, total hip: 0.839 ± 0.095, and forearm (1/3 radius): 0.590 ± 0.050. Dietary intake of calcium in Indians was also significantly lower than that seen in our clinic (491 vs 697 mg/d; $p<0.01$), and the mean serum 25-hydroxyvitamin D level was 10.2 ± 8.1 ng/ml in a small subset of 41 subjects. BMD results at any measurement site were not related to daily calcium intake or age at menarche, but were significantly related to BMI. Conclusions: At all relevant measurement sites, BMD values were significantly lower in Asian Indian women, compared to U.S. white women, although BMI might explain some of this difference. Until BMD-fracture relationship is established in this ethnic group, it is reasonable to use values from the 20-29 age group (peak adult BMD) to calculate T-scores for evaluating Indians living in the United States. Because of distinct cultural, dietary and genetic features of Asian Indians, it is inappropriate to include them with other Asians in studies of ethnic influence on BMD.

SA271

Race Differences in Bone Density, Cross Sectional Geometry and Bone Strength Measured by pQCT in Young Adult Women. H. J. Kalkwarf[1], N. W. Glynn[2], S. R. Daniels*[3], S. Y. S. Kimm[2]. [1]General & Community Pediatrics, Children's Hospital Medical Center, Cincinnati, OH, USA, [2]Family Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA, [3]Cardiology, Children's Hospital Medical Center, Cincinnati, OH, USA.

Black women have a lower fracture rate than white women. Bone strength is a function of both bone density and bone geometry. The objective of this study was to assess race differences in bone density, cross sectional bone geometry, and bone strength index (BSI) of the radius in a biracial cohort of young women at peak bone mass. We also examined whether race differences in bone measures could be explained by differences in forearm length, muscle area, and grip strength. Subjects were 165 black and 159 white women age 22 ± 1 y. We measured bone density, bone geometry and muscle area of the dominant forearm by pQCT (Norland/Stratec XCT 2000). Measurements were obtained at 2 sites: 4% and 66% from the radial endplate. Total and trabecular bone measurements were obtained at the 4% site. Cortical bone and muscle measurements were obtained at the 66% site. Grip strength was measured by a hand held dynamometer. Black women had greater forearm length (4.2%), muscle area (9.7%) and grip strength (3.4%) than white women ($p<0.05$). At the 4% site, black women had higher total and trabecular BMD. When adjusted for their greater forearm length, muscle area and strength, black women had a smaller bone area. At the 66% site, black women had a greater cortical bone area and thickness, which were due to a greater periosteal circumference. When adjusting for forearm length, muscle area and strength, black women had a smaller endosteal circumference, but there was no difference in periosteal circumference. There was no difference in cortical BMD between black and white women after adjusting for cortical thickness. BSI at the 66% site was greater in black women than in white women, but this difference was no longer evident when adjusting for forearm length, muscle area and strength. These observed racial differences in bone density, geometry and strength may be the underlying factor associated with racial differences in fracture risk later in life.

	Black - White Difference (%)	
Measurement & site	Unadjusted	Adjusted
Trabecular BMD - 4%	14.8*	14.8*
Total bone area - 4%	-2.6	-6.9*
Cortical area - 66%	10.3*	4.4*
Cortical thickness - 66%	9.6*	7.4*
Periosteal circumference - 66%	2.6*	-0.3
Endosteal circumference - 66%	2.8	-6.8*
BSI - 66%	11.2*	0.3

High Parity Is Associated with Greater Bone Size Later in Life. K. S. Wosje*, T. L. Binkley*, B. L. Specker*. EA Martin Program in Human Nutrition, South Dakota State University, Brookings, SD, USA.

Most studies do not find an association between bone health and parity, but there are few studies on the effect of high parity on bone. Female members of the Hutterite Brethren exhibit above normal whole body (WB) and lumbar BMC and bone area (BA) and demonstrate high fecundity. We used cross sectional data to test the hypothesis that high parity is not associated with DXA BMC or pQCT bone parameters among 150 Hutterite women age 30 to 65 y. pQCT measurements were conducted at the 20% and 4% radius sites. 77% of women were estrogen replete. There were 109 women who had previously breastfed (LAC) with average parity 5.5 (range 1 to 10) & 41 women who never breastfed (NoLAC) (n=38 with no live births). LAC and NoLAC were similar in ht, wt, & BMI. WB, lumbar, and hip BMC and BA also were similar between LAC and NoLAC. pQCT 20% radius periosteal & endosteal circumferences and 4% radius total and trabecular densities were similar between LAC and NoLAC. pQCT 20% radius cortical thickness was marginally higher in LAC vs. NoLAC ($p<0.10$) but the effect did not persist in multiple regression models. Cortical density was higher in LAC after controlling for covariates (LSM±SE: 1222±3 vs. 1209±5 mg/cm^3, model $r^2=0.15$, $p<0.05$ for LAC vs. NoLAC). Within LAC, parity was an independent positive predictor of 20% radius periosteal (model $r^2=0.50$, $p<0.05$ for parity) and endosteal (model $r^2=0.37$, $p<0.007$ for parity) circumferences. Adult wt gain {(measured current wt) – (reported wt at age 20-30y)} was marginally higher in LAC compared to NoLAC (14±12 vs. 10±9 kg, $p<0.10$). Parity was positively associated with hip BMC, and WB and hip BA ($P<0.05$ for all), and marginally positively associated with WB BMC and lumbar BA ($p<0.10$) within LAC. Total # months lactating was marginally positively associated with hip BA ($P<0.10$), but not with any other BMC or BA outcomes. In multiple regression, parity independently predicted WB (model $r^2=0.81$, $p<0.001$ for parity), lumbar (model $r^2=0.52$, $p<0.05$ for parity) and hip BA (model $r^2=0.48$, $p=0.01$ for parity). Parity or total # months lactating did not appear in any final regression models predicting BMC. These data show that parity has a positive effect on bone size independently of wt gain or body composition among Hutterite females, but is not associated with BMC or volumetric bone density.

SA273

Bone-Strengthening Medication Use and Low Bone Denisty in Black Elderly Women. D. L. Orwig*[1], N. Brandt*[2], G. Zimmerman*[2], A. L. Smith*[2]. [1]Department of Epidemiology & Preventive Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [2]University of Maryland School of Pharmacy, Baltimore, MD, USA.

Osteoporosis is a problem that affects approximately 10 million individuals plus 18 million who have low bone mass. One of the common risk factors recognized for osteoporosis is Caucasian or Asian ethnicity; thus, African-Americans are often thought to be at low risk for developing this disease; however, urban residents have been found to have lower bone mass and density due to a variety of reasons such as poorer nutrition (calcium and Vitamin D intake), lower body weight, less active lifestyle, higher consumption of tobacco and alcohol, more frequent use of drugs and higher exposure to environmental pollutants which may put urban black elderly women at particular risk for osteoporosis and its consequences. Very little is known about the use of bone-strengthening medications in the black elderly population and this study examined use of these medications as well as bone mineral density (BMD) in a sample of black elderly women attending one of two managed care sites for older adults dually eligible for Medicare and Medicaid. BMD was measured at the heel using a Lunar PIXI provided by Novartis Pharmaceuticals. Use of bone-strengthening medications was based on the electronic medical records and information was obtained on fracture history and other demographics. A total of 72 elderly black women were assessed with an average age of 77, mean education of 8 years and a mean annual income of $6500. According to the manufacturer's normative database for young adult normal, the mean (BMD) for the os calcis is 0.507 gm/cm2 with each standard deviation equaling 0.09. Using 1.0 and 2.5 standard deviations below the mean as the definition for low bone mass and osteoporosis respectively (0.417 gm/cm2 and 0.282 gm/cm2), 18% of subjects had low bone mass while 30% had osteoporosis. The average BMD for the sample was 0.384 gm/cm2. Thirteen percent of the sample had previous fractures reported in the previous 2 years. Of those with low bone density or osteoporosis, only 30% were taking alendronate and/or calcium and vitamin D. More than half of the sample had low BMD and is at risk of suffering its consequences, yet few were taking any bone-strengthening medication in this managed care setting. Osteoporosis and its treatment in this population is under-recognized and it is important as society ages and as the proportion of the population that is black increases that we take a more preventive role in increasing bone density in this vulnerable population.

SA274

Calcium and Vitamin D Influence Bone Density, but not Fracture Risk, in the Caucasian Population of NORA. J. W. Nieves[1], E. S. Siris[2], E. Barrett-Connor[3], M. Zion*[1], S. Barlas*[4], Y. Chen[4]. [1]Clinical Research Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Columbia University, New York, NY, USA, [3]University Of California, San Diego, CA, USA, [4]Merck & Co., Inc., West Point, PA, USA.

Calcium and vitamin D intake are believed to be related to bone health, although, prospective cohort studies and clinical trials have produced varied results. The purpose of this study is to evaluate the relationship between self-reported lifetime calcium intake and current calcium and vitamin D intake and peripheral bone mass and fracture incidence in the subset (n=75,565) of the NORA cohort of postmenopausal Caucasian women who responded to a dietary questionnaire. Dietary questions focused on consumption of milk, ice cream, yogurt and cheese during four time periods of life: childhood, the teenage years, adulthood, and the current time period. An average daily intake of calcium (mg) was calculated for each of the 4 life periods. Supplemental calcium intake and calcium from fortified juice was added to the current daily intake from foods (61% reported some intake of these additional calcium sources). Vitamin D intake was calculated from the intake of milk, fish and supplements and sunlight exposure. Bone mineral density (BMD) was measured by peripheral SXA/DXA at the forearm, heel, or finger, or by ultrasound of the heel. The impact of calcium and vitamin D intake on risk of osteoporosis based on BMD and fracture incidence were evaluated in logistic regression models controlling for age, years from menopause, body mass index, smoking, estrogen, steroid or diuretic use, exercise, alcohol consumption, caffeine intake, level of education, maternal and personal history of fracture, and machine used for BMD. Mean calcium intake for this population was 655 mg per day and was as high as 960mg/day when supplements were added to current intake. An adequate lifetime calcium intake was associated with a reduction in the risk of osteoporosis (OR=0.727; 0.601, 0.880). Current calcium and vitamin D intake at the recommended intake was also associated with a reduction in the risk of having osteoporosis (OR=0.689; 0.614, 0.773). There were 760 fractures in this cohort during one year of follow-up (114 hip; 196 rib; 306 wrist). Fracture risk in the NORA cohort, analyzed with all fractures combined, and hip, wrist and rib fractures separately, was not related to current calcium or vitamin D intake. There was also no association with calcium and vitamin D intake when analysis was restricted to those over 65 years of age. In conclusion, in Caucasian woman calcium and vitamin D intake influence the risk of osteoporosis, but not fracture during one year of follow-up in the NORA cohort.

Pre-conceptional Predictors of Changes in Maternal Skeletal Status during Pregnancy. M. K. Javaid*[1], S. R. Shore*[1], P. Taylor*[2], H. M. Inskip*[1], K. M. Godfrey*[1], C. Cooper*[1]. [1]Medical Research Council Environmental Epidemiology Unit, Southampton, United Kingdom, [2]Medical Physics and Bioengineering, Southampton University Hospitals NHS Trust, Southampton, United Kingdom.

BACKGROUND: During pregnancy, the fetus acquires 30g of calcium for skeletal growth. To meet this demand, calcium metabolism of the mother undergoes several adaptations, including increasing both intestinal calcium absorption and bone resorption. Previous longitudinal studies have recruited women already pregnant or from selective groups intending to become pregnant. As the lifestyle and anthropometric characteristics of these women are unlikely to be representative, we investigated the magnitude of bone loss and its determinants in a longitudinal study of healthy women who were not pregnant at baseline. METHODS: Between April 1998 and April 2001, 8700 women were interviewed at baseline, from these 340, who became pregnant, were entered into the study. At baseline the women completed a lifestyle questionnaire and had their height, weight and skinfold thickness measured. At 11 and 34 weeks pregnancy, the mothers were interviewed and had their skeletal status measured using a calcaneal quantitative ultrasound instrument (Hologic Sahara). RESULTS: During pregnancy, there was a significant ($p<0.001$) reduction in both speed of sound (SOS) and bone ultrasound attenuation (BUA) at the calcaneus [Table 1]. Ankle oedema led to a mean increase of 12% in heel width during pregnancy; however adjusting for this variable did not alter the changes in QUS during pregnancy. We were unable to identify independent pre-conceptional predictors of BUA at either baseline or during pregnancy. Maternal height, parity and reported physical activity were significantly ($p<0.05$) related to baseline SOS. Low maternal parity ($p=0.001$) and low milk intake ($p=0.01$) were also independently associated with greater bone loss during pregnancy. CONCLUSION: These findings suggest that high maternal milk intake before pregnancy may reduce maternal bone loss during pregnancy, as measured calcaneal ultrasound.

Table 1. Changes in QUS and heel width during pregnancy

Calcaneal	Percentage change	Change as Z score	p
SOS	-0.4%	-0.37	<0.001
BUA	-4.5%	-0.31	<0.001
Width	+12.3%	+0.75	<0.001

Does Tea Drinking Affect Bone Density and Risk of Fractures among U.S. Postmenopausal Women with Different States of Hormone Replacement Therapy? Results from the Observational Study in the Women's Health Initiative. Z. Chen[1], M. B. Pettinger*[2], I. A. Hakim*[1], A. Z. LaCroix[2], J. Robbins*[3], B. J. Caan*[4], D. H. Barad*[5], C. Ritenbaugh*[6]. [1]University of Arizona, Tucson, AZ, USA, [2]Fred Hutchinson Cancer Research Center, Seattle, WA, USA, [3]University of California at Davis, Sacramento, CA, USA, [4]Kaiser Permanente, Oakland, CA, USA, [5]Albert Einstein College of Medicine, Bronx, NY, USA, [6]Kaiser Center for Health Research, Portland, OR, USA.

Tea is a rich dietary source of fluoride, and also contains caffeine and flavonoids, which each may influence bone mass and fracture risk in different ways. It has been suggested that hormone replacement therapy (HRT) in combination with fluoride treatment may induce a synergistic effect on bone mass by dissociating bone formation and resorption in postmenopausal women. In this prospective study, we evaluated the association of tea consumption with bone mineral density (BMD), changes in BMD, and risk of fracture among postmenopausal women with different HRT usage. Study participants (N = 91,465) were women from the Observational Study (OS) in the Women's Health Initiative (WHI). Forty percent of the women had never taken HRT, 15% took HRT in the past, and the remainder were current HRT users at the time of enrollment. The average length of follow-up was 4.1 years. Tea consumption was assessed at the baseline using a questionnaire. Fracture events during the follow-up were self-reported, except for hip fractures, which were confirmed by medical record review. A subgroup of the women (N = 4,979) received total body, total hip and lumbar spine BMD measurements on dual-energy x-ray absorptiometry at baseline and during the follow-up. Results showed that the associations of tea drinking with fracture risk varied by HRT usage and fracture site, but in general were not statistically significant. Baseline BMD was not correlated with tea drinking. Interestingly, total body and spine BMD at year three visit and percent changes of total body and spine BMD between baseline and year three visit were significantly related to tea drinking among current HRT users and past HRT users ($p<0.05$), but not among women who never used HRT. Results of our study suggest that tea drinking does not have significant adverse impact on risk of fracture, and HRT and tea may have a synergistic effect on BMD.

See Friday Plenary number F279.

SA280

The Effect of Milk and Calcium on the Age at Menarche. K. Ghatge*[1], J. Russell*[2], J. Cadogan*[1], H. Lambert*[3], M. E. Barker*[1], R. Eastell[3]. [1]Centre for Human Nutrition, University of Sheffield, Sheffield, United Kingdom, [2]Corporate Information and Computing Services, University of Sheffield, Sheffield, United Kingdom, [3]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom.

Calcium supplementation is known to affect the hypothalamic-pituitary-ovarian axis and fat metabolism. It may therefore influence the age at menarche. We analysed data from two supplementation trials in teenage girls. In the first trial 82, 11-12 year old girls were randomised to 1 pint of milk containing 680 mg of calcium or no supplement, daily, for 18 months. In the second trial, 86, 11-12 year-old girls received 792 mg of calcium in the form of calcium citrate malate (CCM) or no supplement, daily, for 18 months. The difference between the supplemented and the control group in both the trials was tested using Tarone-Ware survival analysis. At the beginning of both the studies, there was no difference between the supplemented and the control groups for the mean age of participants and the Tanner stage of puberty. To study the effect of supplementation (milk or CCM) on menarche, the data was analysed for the mean age at menarche and for the length of time between start of the study and menarche. In the milk supplementation trial, there was no difference between the groups for the mean age at menarche as well as for the length of time between start of the study and menarche. In the CCM supplementation trial, the mean age of menarche was marginally different between the two groups (by 4 months) and the time between start of the study and menarche was significantly different between the two groups, $p<0.05$.

Table 1

	Milk supplementation		CCM supplementation	
	Supplement	Control	Supplement	Control
Age at menarche Mean (S.E.)	13.59 (0.11)	13.74 (0.14)	13.03 (0.12)	13.36 (0.14)
	p = 0.5		p = 0.08	
Time between start of study and menarche Mean (S.E.)	0.90 (0.10)	1.14 (0.14)	1.13 (0.13)	1.57 (0.15)
	p = 0.2		p = 0.03	

The CCM supplementation seems to have a positive effect on the time of puberty. The mechanism of action of milk and CCM are different as CCM suppressed PTH whereas milk did not. The mechanism is unlikely to be an influence by leptin as the body weight gain did not differ significantly between the groups in CCM trial. However, the effect may have been mediated via the hypothalamic-pituitary-ovarian axis. Late menarche is a recognised risk factor for osteoporosis; calcium supplementation in childhood may reduce the risk of fracture in later life by accelerating the onset of the menarche.

SA281

The Osteoporosis Population-Based Risk Assessment Trial (OPRA) Comparing Three Strategies for Fracture Prevention. A. Z. LaCroix[1], D. S. M. Buist*[1], T. A. Abbott[2], S. K. Brenneman[2]. [1]Center for Health Studies, Group Health Cooperative, Seattle, WA, USA, [2]Outcomes Research & Management, Merck & Co., West Point, PA, USA.

The OPRA randomized trial compared 3 strategies for allocating bone density screening in the context of an HMO-based fracture prevention program that provided risk factor assessment, personalized feedback and education for all participants. Women aged 60-80 were eligible if they were not taking HRT or other osteoporosis therapy. In the Universal Screening Group, 1986 randomly sampled women were contacted and all were offered BMD testing; 428 women (21.5%) agreed to participate and were tested. In the SCORE Screening Group, 1940 women were sent the SCORE questionnaire and those scoring ≥ 7 were invited for BMD testing; 597 women (30.8%) completed questionnaires and 425 were tested. In the SOF-based Screening Group, 5342 women were sent a SOF-based risk factor questionnaire and those with ≥ 5 risk factors were invited for BMD testing; 2261 (42.3%) completed questionnaires and 150 were tested. Outcomes were evaluated in all eligible participants using intention-to-treat analysis and included: 1) initiation of osteoporosis therapy; 2) hip and other fracture rates; 3) changes in dietary/lifestyle fracture risk factors; 4) osteoporosis knowledge; and 5) satisfaction with the program. Initiation of osteoporosis therapy was slightly higher in the Universal and SCORE groups (21.1% and 20.2%, respectively; vs. 16.7% in the SOF-based group (p-value vs. Universal=0.04). Hip fracture rates were lowest in the Universal group (3.22/1000) as compared to the SCORE (7.95/1000) and SOF-based groups (8.74/1000) but differences were not statistically significant. Rates of all clinical fracture did not differ among the groups. Initiation of calcium supplements was highest in the Universal group (33%) and slightly lower in the other two groups (27-28%). Average values on an exercise scale were highest in the Universal group and lowest in the SOF-based group ($p<0.003$). Knowledge about osteoporosis risk factors differed dramatically with women in the Universal group reporting 57% correct answers as compared with 53% in the SCORE group ($p=0.02$) and 43% in the SOF-based group ($p<0.0001$). Women in all groups reported a high level of interest in seeing a fracture prevention program like this one incorporated into their routine care (82-93%). The degree to which BMD testing was offered to women in a fracture prevention program significantly affected treatment rates, change in modifiable fracture risk factors and knowledge about risk factors. The benefits of bone density testing must be weighed against the costs and competing priorities for prevention of major chronic disease events in older women.

The Modal Distribution of Osteoporotic Vertebral Compression Fracture Types. F. E. McKiernan[1], T. Faciszewski*[2]. [1]Center for Bone Diseases, Marshfield Clinic, Marshfield, WI, USA, [2]Department of Orthopedic Spine Surgery, Marshfield Clinic, Marshfield, WI, USA.

Osteoporotic vertebral compression fractures (VCFs) are distributed bi-modally in the thoracolumbar spine (Osteoporosis Int 3:113, 1993); one peak occurring at the mid-thoracic spine and the other at the thoracolumbar juncture. Recent appreciation of the morphometric variety of osteoporotic VCFs, and in particular the dynamic mobility of many VCFs, led us to consider the possibility that the composition of fracture types of these two modal peaks might differ. Herein we describe the distribution of different fracture types that present for vertebroplasty (VP). Dynamic mobility of osteoporotic VCFs was assessed by comparing preoperative standing lateral X-rays with preoperative supine, cross table-lateral X-rays of the index VCF and was defined as any change in fracture configuration apparent with unaided vision. Non-mobile fractures were considered fixed. Clefts, the gross disruption of cortico-cancellous bone, were sometimes characterized by intravertebral gas on plain radiographs or signal void on short-tau inversion recovery (STIR) sequence magnetic resonance (MR) but were defined as low resistance, confluent reser-

voirs for polymethlymethacrylate (PMMA) at the time of VP. Fifty consecutive patients underwent 56 VP procedures to treat 82 VCFs. There were 33 (66%) women and 17 (34%) men. Twenty-four of 50 patients (48%) had mobile VCFs with clefts. Thirty of their 82 VCFs (34%) were mobile and had clefts. Twenty-two of 30 (73%) mobile, clefted fractures occurred at the thoraco-lumbar junction (T11-L1) whereas only 15 of 52 (29%) fixed fractures occurred at that site ($p< 0.001$). Mobile, clefted VCFs accounted for 59% of all VCFs occurring at the thoracolumbar junction and were infrequent elsewhere (Figure 1). These 82 VCFs were distributed in a bimodal manner characteristic of osteoporotic VCFs. Mobile, clefted VCFs clustered at the thoracolumbar junction whereas fixed VCFs dominated elsewhere in the spine. Thus the composition of the two modal peaks is not homogeneous for fracture type. One peak occurring at the mid-thoracic spine is composed largely of fixed VCFs and is where the concentration of axial load is greatest. The second peak consists largely of mobile, clefted VCFs and occurs at the thoracolumbar juncture where the concentration of dynamic load is greatest.

Under Reporting of Vertebral Fractures and the Importance of Standardized Morphometry. S. A. Jackson*[1], L. Robertson*[2], A. Tenenhouse[3]. [1]Nuclear Medicine, University of Alberta, Edmonton, AB, Canada, [2]Radiology, University of Alberta, Edmonton, AB, Canada, [3]McGill University, Montreal, PQ, Canada.

Evidence today indicates that subtle changes within the spine, consistent with a Grade 1, sub clinical fracture of the vertebra can be measured using health related quality of life instruments. The chronic process of osteoporosis leads to posture changes and lifestyle impact at an early stage. Consequently, it is important to detect vertebral changes in order for a suitable therapy to be prescribed and administered. A lateral radiographic series is the primary diagnostic tool. However, the recognition and reporting of vertebral fractures by this technique is subject to considerable observer variability, which may influence the required lifestyle modification. Data presented is derived from the Canadian Multicentre Osteoporosis Study, which is a large population based prospective study of osteoporosis in the Canadian population. The study involves 9424 subjects, both male and female, from nine centers and seven regions of Canada. Each subject completed an extensive interview to obtain medical, demographic and lifestyle information, and was examined by DEXA of the spine and hip, ultrasound of the heel and for subjects over 50 years of age, lateral spine radiographs. Spinal morphometry of the initial radiographs was performed to evaluate the prevalence of vertebral deformity. A method is utilized to extract reference norms for vertebral shape from a subset of the population data, which is then used to categorize any deformity within the whole data set. Radiologists at each center were instructed to report their findings based on a simple definition of 20% height reduction in any of the three vertebral height ratios. One center with specialist expertise acted as the clinical reference. Using the standardized morphometry and 3 standard deviations (Grade 1) as a limit of normality, the male prevalence of 21.5% was similar to the female prevalence of 23.5%. Using 4 standard deviations (Grade 2) this reduced to 7.3% and 9.3%. While our morphometry method agreed with our expert center to within 1%, reporting of fractures from other sites varied between 7% to 35% for a prevalence of Grade 1 fractures and between 1% to 10% for Grade 2. Under reporting of vertebral fractures appears to be a common phenomena, which has implications for clinical studies and patient awareness. The importance of standardized vertebral morphometry, either by radiography or by DEXA is crucial to the early detection of osteoporotic changes within the spine and consistency of radiographic interpretation.

The Impact of Fractures on the Hospital Care System in Italy: Comparison with Other Commonly Admitted Diseases. E. Romagnoli*[1], V. Carnevale*[2], F. Paglia*[1], S. De Geronimo*[1], J. Pepe*[1], E. D'Erasmo*[1], G. Mazzuoli[1], S. Minisola[1]. [1]Dpt. of Clinical Sciences, "La Sapienza" University, Rome, Italy, [2]Dpt. of Internal Medicine, "Casa Sollievo della Sofferenza" Hospital, S. Giovanni Rotondo, Italy.

We investigated the impact of hip, Colles, humeral and vertebral fractures, as compared to other commonly hospitalised diseases, on the health care of the biggest general hospital ("Umberto I") in Rome, Italy. We examined the discharge forms filled in from 1996 to 1999, according to the 9th International Classification of Diseases. Data on fractures were compared to those related to the following diseases: coronary heart disease (CHD), cerebrovascular disorders (CVD), diabetes mellitus (DM), chronic obstructive pulmonary disease (COPD) and breast cancer (BC). Admissions for hip and humeral fractures decreased progressively during the study period, while the number of patients with Colles and vertebral fractures slightly increased. In all groups of patients mean age of females was significantly higher ($p<0.0001$) than that of males. Male patients with hip fractures showed a hospitalisation stay (20.3 ± 20 days) significantly longer than females (14.2 ± 18.9)($p< 0.0001$), while women with Colles fractures showed significantly ($p< 0.02$) higher length of stay (5.5 ± 6.7 vs 4 ± 4). When patients were divided according to age (over or below 60 years), mean hospitalisation length did not differ between younger and older patients in all groups but Colles fractures ($p<0.001$). Hip fracture in older patients showed a striking in-hospital mortality. In the whole period studied hip fractures accounted for the highest annual (more than 1,000,000 of Euro) and per patient (3,500 to 4,500 Euro) costs. In this group of patients, the number of non-invasive procedures increased year by year. The number of female patients with fractures (and obviously breast cancer) was higher, while the opposite applied to the other disorders. Male patients with fractures, CHD, and CVD were significantly younger than females ($p<0.0001$). When deaths percentage (3.6%) was added to that of patients discharged to other institutions (26.3%), fractures showed the poorest outcome of hospitalisation. Global annual costs showed a gradual increase for BC, COPD, CVD, and CHD from 1996 to 1999. Per patient costs were remarkably and progressively higher for CHD (from 4,000 to 6,000 Euro), followed by fractures (average 3,000 Euro). We observed a progressive increase of surgical and diagnostic procedures employed, particularly for patients with fractures and breast cancer. We concluded that fractures represent a growing but often underestimated burden for hospital care in Italy.

Secondary Causes of Osteoporosis in Patients Registered in the Canadian Database of Osteoporosis and Osteopenia (CANDOO). J. P. Brown[1], G. Ioannidis[2], J. D. Adachi[2], A. Petrie*[2], N. Ferko[2], P. Boulos[2], G. F. Stephenson*[3], C. H. Goldsmith*[2], A. Papaioannou[2]. [1]Laval University, Ste-Foy, PQ, Canada, [2]McMaster University, Hamilton, ON, Canada, [3]Procter & Gamble Pharmaceuticals, Toronto, ON, Canada.

The prevalence of causes of secondary osteoporosis varies with the type of population and referral centre. The primary objective of this study was to determine the prevalence of secondary causes of osteoporosis in tertiary referral centers in adults who have experienced a fracture compared to those who have not experienced a fracture. A case-control methodology was conducted utilizing patient information from CANDOO. CANDOO is designed to prospectively compile comprehensive clinical data in multiple centres across Canada and contains data regarding patient demographics, medications and side effects, female reproductive history, diet and quality of life, bone mineral density measurements, fracture history and laboratory investigations. For the current analysis, CANDOO was searched for women and men over the age of 50 years. Data were collected for 5604 women and 561 men with a mean age of 64 years. Approximately 94% of women were postmenopausal at the baseline visit. Of the 1703 (28%) patients with a fragility fracture within 5 years of baseline assessment, 151 had a hip, 539 a wrist, 741 a vertebral, and 281 a rib fracture, respectively. In our cohort, the prevalence of causes of secondary osteoporosis in adults who have experienced a fracture was 45.9% as compared with 40.1% in non-fracture patients ($p<0.001$). 10.1% of fracture patients had vitamin D levels below normal ranges as compared with 5.6% of non-fracture patients ($p<0.001$). Causes of secondary osteoporosis (1 or more) were higher in men, 288/561 (51.3%) than women, 2319/5604 (41.4%)($p<0.001$). Greater use of oral/inhaled corticosteroids is found in men (27.1%), than in women (13.1%) ($p<0.001$). Of patients with osteoporosis, 12.8% had a lung disorder, 3% had a liver disorder, 2% used anticonvulsants, 0.7% had hyperparathyroidism and 1.1% had monoclonal gammopathy. Hypogonadism was not assessed in men. In our cohort, secondary causes of osteoporosis were higher in fracture patients than non-fracture patients. The most prevalent condition associated with secondary causes of osteoporosis was corticosteroid use.

Intervention Thresholds for Osteoporosis. J. A. Kanis*[1], O. Johnell*[2], A. Oden*[3], C. De Laet*[4], A. Oglesby*[5], B. Jonsson*[3]. [1]WHO Collaborating Centre for Metabolic Bone Diseas, University of Sheffield Medical School, Sheffield, United Kingdom, [2]Malmo General Hospital, Malmo, Sweden, [3]University of Stockholm, Stockholm, Sweden, [4]Institute for Medical Technology Assessment, Rotterdam, Netherlands, [5]Lilly Pharmaceuticals, Indianapolis, IN, USA.

With the advent of effective interventions that decrease the risk of fracture, guidance is required to determine who to treat. Against this background, there is an increasing awareness that intervention thresholds should be based on estimates of fracture probability rather than on BMD alone. The aim of this study was to determine the threshold of fracture probability at which interventions became cost-effective. We modelled the effects of a treatment costing $500 per year given for 5 years that decreased the risk of all osteoporotic fractures by 35 percent followed by a waning of effect for 5 years. Sensitivity analyses included a range of effectiveness and intervention costs. Data on costs and risks were from Sweden. Costs included direct costs and costs in added years of life, but exclude indirect costs due to morbidity. A threshold for cost effectiveness of $60,000/QALY gained was used. Cost of added years were excluded in a sensitivity analysis for which a threshold value of $30,000/QALY was used. In the base case, intervention was cost-effective when treatment was targeted to women at average or higher risk at the age of 65 years or older (see Table). In Sweden, this corresponds to a T-score for BMD close to a diagnostic threshold (T< -2.5 SD) in the absence of other risk factors. A less conservative threshold of BMD was cost effective in the presence of strong risk factors where they contribute to a risk that is responsive to intervention (eg a prior fragility fracture).

Age 10 year probability
(years) RR for hip fracture (%)
50 3.9 1.37
60 1.5 3.18
70 <1 5.60
80 <1 13.0

This analysis provides a framework for defining clinical intervention thresholds that can be justified from a health economic perspective. Of particular importance is that elderly women at moderate risk can be offered intervention. Similar analysis should be undertaken in different regions of the world.

A Recent Trend in the Incidence of Hip Fractures in Tottori Prefecture, Japan. H. Hagino, T. Ryota*, H. Katagiri, T. Okano, K. Yamamoto*. Orthopedic Surgery, Tottori University, Yonago, Japan.

[Purpose] Since the growth of the elderly population will be more marked in Asia than in Europe and North America, great increases in osteoporosis-related fractures are predicted in Asia. If an increase in incidence of these fractures is observed, we may expect the more rapid increase in number of patients with fracture in the future than predicted. The purposes of this study were to present the recent trend in the incidence of hip fractures in Tottori Prefecture, Japan. [Methods] Tottori Prefecture is located in mid western Japan. Its population was 616,399 in 1986 and 613,289 in 2000. The percentage of the total population aged 65 years and over was 14.1% in 1986 and 22.0% in 2000. A survey of all fractures in patients 35 years old and over during 1986-88, 1992-94, and 1998-2000 for hip was performed in all hospitals in Tottori Prefecture, Japan. Registration information included name, gender, age, place of residence, date of fracture, type of fracture, and treatment. Patients residing in other prefectures were excluded. Duplication of cases was checked by the patients' name and address. The age- and gender- specific incidence rates (per 100,000 person-years) were calculated based on the population of Tottori Prefecture in each year. [Results] Registered numbers in patients were 272, 287, 359, 464, 404, 480, 604, 671, and 710 in 1986, 1987, 1988, 1992, 1993, 1994, 1998, 1999, and 2000, respectively. The number of women was more than three times the number of men. The mean age- and gender-specific incidence rates (per 100,000 person-years) for men in 1986-1988 were 174.7, 219.3, and 622.3 in the age groups of 75-79, 80-84 and over 84, respectively, and those in 1992-1994 were 235.7, 322.8, and 655.6, and those in 1998-2000 were 227.7, 392.9, and 832.4, respectively. Those for women in 1986-1988 were 474.4, 756.0, and 1266.7, and those in 1992-1994 were 479.9, 934.0, and 1696.5, and those in 1998-2000 were 489.7, 1146.8, and 2088.7, respectively. The incidence rates showed a significant increase with time. [Conclusion] An increase in the incidence rates of hip fractures was observed from 1986 to 2000 in Tottori Prefecture, Japan.

Management of Osteoporosis in Women Aged 50+ with Osteoporosis-related Fractures. M. J. Gunter*[1], S. K. Brenneman[2], S. J. Beaton*[1], Y. Chen*[2], T. A. Abbott[2]. [1]Lovelace Clinic Foundation, Albuquerque, NM, USA, [2]Merck & Co., Inc., West Point, PA, USA.

Post-menopausal women with a non-traumatic fracture are likely to have low bone mass and are prone to subsequent fractures. Guidelines recommend evaluation and treatment of osteoporosis in post-menopausal women following a fracture. We describe the pattern of diagnosis and treatment of osteoporosis in women age 50+ following an osteoporosis-related fracture. A retrospective cohort study was conducted at a large managed care system located in the southwestern United States. Study subjects were women, age 50+ years, with at least one osteoporosis-related fracture in the calendar years 1996 - 1998 and who were continuously enrolled in the system's health plan for at least 6 months prior to and post fracture. Data were obtained from an administrative claims database. Information on bone-density scans, diagnosis of osteoporosis, and treatment with any FDA-approved medication (including HRT) for osteoporosis was obtained using ICD-9, CPT, and NDC codes.42,041 women ≥ 50 years of age were in the health plan during the study period. 658 continuously enrolled women were identified who had an osteoporosis-related fracture: 189 (29%) hip fractures, 221 (34%) wrist fractures, 127 (19%) vertebral fractures, 116 (18%) rib fractures. In the post-fracture period, 46 (7 %) underwent bone-density testing, 142 (22 %) had a diagnosis of osteoporosis, and 220 (31 %) were treated with at least one of the medications approved for the treatment of osteoporosis. Of the 220 women who had medication claims, 124 (56%) were for HFT and 96 (44%) were for other anti-resorptive agents. Only 80 (16%) were new claims for women who did not have medication claims during the 6 months prior to the fracture. Osteoporosis diagnosis and treatment of postmenopausal-aged women with fractures remain inadequate, despite existing recommendations that osteoporosis be the presumptive diagnosis. There is significant opportunity for improvement in assuring post-fracture follow-up care.

Determining a Clinically Meaningful Difference in a Performance-Based Measure to Assess Recovery from Hip Fracture: The Lower Extremity Gain Scale (LEGS). S. Zimmerman*[1], G. Williams*[2], P. Lapuerta*[2], T. Li*[2], W. Hawkes*[3], D. Orwig[3], L. Wehren[3], J. Hebel*[3], J. Magaziner[3]. [1]University of North Carolina, Chapel Hill, NC, USA, [2]Bristol Myers Squibb, Princeton, NJ, USA, [3]University of Maryland Baltimore, Baltimore, MD, USA.

The Lower Extremity Gain Scale (LEGS) is a validated performance measure of tasks that are often impaired in hip fracture patients. The goal of this analysis is to determine a clinically meaningful difference in LEGS. The analysis used 139 white female patients age 65+ admitted to one of two Baltimore hospitals. Patients were assessed at baseline and 2, 6, and 12 months post-fracture. Average age was 80.2; 55.1% had subcapital fractures. The LEGS score is based on timed performance of 9 activities: walking 10 feet, rising from an armless chair, reaching for an item on the ground, putting on socks, putting on shoes, stepping up and down stairs, and getting on and off a toilet. Each task was scored from 0-4, with higher scores representing better performance. Scores were combined to produce a summary score, ranging from 0-36. Recovery level was determined by the LEGS score, estimated at the point at which the rate of change with time was less than 1% of one standard deviation (SD) of the LEGS. The clinically meaningful difference in the score was evaluated using 2 methods. The anchor-based approach examined the relationships between the LEGS recovery level and age. The LEGS score difference associated with a five year increase in age was considered clinically meaningful. The second, distribution-based, method was determined according to Cohen's effect size. A clinically meaningful difference was defined as a difference in LEGS score with an effect size of .20. According to our model, a difference of approximately 5 years in age corresponded to a difference of 1.6-2.6 points. The SD for LEGS at 12 months was 8.0; thus Cohen's effect size was 0.2-0.32. This suggests a clinically meaningful difference in the LEGS scores for a population in this age range would be 2-3 points. In another anchor-based analysis using by tertiles of grip strength at baseline [<13 kg (weak), >13-18 kg (average), and >18 kg (strong)], the strong group had the best recovery (LEGS score 28.1) in the shortest time (10.1 months). The average group reached a level of 25.4 points in 11.6 months and the weak group reached 22.7 points in 15.5 months. Similar to the age analysis, the strength analysis indicated effect sizes in the range of 0.25-0.3 SD. Both methods suggest that a difference of 2 points in the LEGS score is clinically meaningful. LEGS is the first validated performance measure for use in hip fracture patients and has important potential application in clinical research on interventions to maximize recovery after fracture.

Does Having a Fracture Predict Future Fractures in Men Aged 60 Years and Older. B. Ettinger[1], G. T. Ray*[1], A. R. Pressman*[1], O. Gluck[2]. [1]Division of Research, Kaiser Permanente Medical Care Program, Oakland, CA, USA, [2]Arizona Rheumatology Center, Phoenix, AZ, USA.

Background: It is not known whether fractures in elderly men predict future fractures. We hypothesized in elderly men as in elderly women, that fractures of hip, wrist, humerus, and ankle would indicate osteoporosis and skeletal fragility. **Methods:** We examined fracture incidence among male members of a large health plan in Northern California who were aged 60 years and older and who either had no fracture in 1997-1998 (20% sample), or had a hip, ankle, wrist, or humerus fracture during 1997-2001. Fractures were identified using the health plan's electronic databases containing hospitalization, emergency room, and office visit diagnoses. We used proportional hazards models to compare risk of subsequent fractures of hip, ankle, humerus, or wrist between the different groups, after adjusting for age. Recurrences of the same fracture type were excluded from the analyses. **Results:** During an average of 2.4 years follow-up, the percent of persons in the non-fracture control group having a subsequent first fracture of the humerus, hip, wrist or ankle was .21%, .55%, .40% and .50% respectively. Relative to controls, those with prior humerus fractures were almost 4 times more likely to suffer one of the 3 non-hip fractures (either wrist, humerus, or ankle) (RR, CI; 3.7, 2.4-5.6). Those with prior hip or wrist fractures were about twice as likely to fracture (2.4, 1.5-3.8 and 1.9, 1.2-3.0, respectively). In contrast to men with history of osteoporotic-type fractures, those with prior ankle fracture had no greater risk of subsequent fracture than non-fractured controls (0.8, 0.4-1.6). Stratified analyses of men 60-69 and men over 70 yielded similar results. To test for healthy cohort effect, we used as another control group, men 60 years and older who were treated for closed finger fracture. Their subsequent fracture incidence was similar to the non-fractured controls, and using them as the control group produced similar relative risks. **Conclusion:** We conclude that among elderly men, a recent history of humerus, hip, or wrist fracture is a statistically significant and clinically relevant predictor of future osteoporotic fracture risk, but that a history of ankle fracture is not.

Smoking Is a Risk Factor for Osteoporosis in Men -Longitudinal Study. S. Hagiwara[1], T. Ueda*[2], T. Hayashi*[3], A. Takagi*[2], Y. Mimura*[2], O. Ou*[1]. [1]Matsushita Health Care Center, Moriguchi, Japan, [2]Matsushita Electric Industrial Co.Ltd., Kadoma, Japan, [3]University of Washington, Seattle, WA, USA.

Osteoporosis in men has been focused recently. However, few longitudinal studies are available yet. We evaluated the bone mineral density (BMD) of the heel in Japanese men cross-sectionally and longitudinally. The subject of this study consists of 889 men with the mean age of 41.3 ± 7.5 (SD) years. BMD of the right heel is measured using a Dual X-ray Absorptiometry (DX-2000, Matsushita Industrial Equipment, Japan) at the initiation of this study (Pre) and 5 years thereafter (Post). Smoking habit, alcohol intake in ethanol, and exercise habit are asked using a questionnaire at the time of both examinations. The rate of current smokers is 51.7%, and those with drinking habit and positive exercise habit at Pre are 85.3% and 27.7% of the subject, respectively. The mean alcohol intake is 26.1 ± 24.3 ml in ethanol in a day. Positive exercise habit means that the subjects perform exercise at least 30 minutes in a day per week periodically, regardless of the kind of exercise. The mean BMD at Pre is 0.928 ± 0.093 g/cm^2, and that at Post is 0.910 ± 0.086 g/cm^2. The rate of BMD decrease is -1.8 ± 3.4% for 5 years. As shown in the Table, age, body weight, change of body weight between two measurements, vigorous exercise, daily alcohol intake, and the number of cigarette smoking at Pre are significant determinants for Post BMD ($p<0.001$). The coefficient of determination is 31.6%. In terms of BMD change between two measurements, age, body mass index (BMI) and change of BMI during the observation period are significant factors with the coefficient of determination of 2.6% ($p<0.001$). Cross-sectional analysis also indicates that age, body weight, vigorous exercise, daily alcohol intake, and current smokers are significant determinants for heel BMD ($p<0.001$). The coefficient of determination is 29.7%. These results suggest that smoking is one of the risk factors for heel BMD, and vigorous exercise should be recommended for the prevention of osteoporosis in men.

Multiple linear regression analysis of heel BMD

Independent variables	Regression coefficient	p-value
Age	-0.069	0.029
Body weight	0.543	<0.001
Change of body weight between two measurements	0.066	0.033
Vigorous exercise	0.088	0.004
Daily alcohol intake	0.085	0.008
Number of cigarette smoking	-0.088	0.006
Model R-square	0.316	<0.001

Poor Physical Function Exacerbates the Already Adverse Association between Low Self-reported Physical Activity and BMD in Older Men. J. J. Anderson*[1], D. R. Miller[2], E. A. Krall[1], S. E. Rich*[1], D. P. Kiel[3]. [1]Boston University, Boston, MA, USA, [2]Massachusetts Veterans Epidemiology Resource & Information Center, Boston, MA, USA, [3]Hebrew Rehab Center & Harvard Medical School, Boston, MA, USA.

Both bone density (BMD) and self-reported physical activity decline with age in men over 50, however most previous studies have focused on women. The possible association between physical activity and BMD may also be affected by physical function. We examined the association between self-reported physical activity measured using the Physical Activity Scale for the Elderly (PASE) and BMD at 3 hip sites, adjusting for age and for BMI, in 2 male cohorts: the VA Longitudinal Osteoporosis Research (VALOR) study, and males aged >50 years in the Framingham Osteoporosis Study (FOS). VALOR includes both VA patients (VA-P) and a subgroup of veterans who are not VA patients (non-P). Femoral neck, trochanter and Ward's area BMD were measured using Lunar DPX-L models. In VALOR physical function (pf) was measured using the physical component score (PCS) of the SF-36. In regression analyses (with GEE modeling for VALOR data having up to 3 observations per subject) we assessed associations per population group between PASE (per 50 PASE unit range) and BMD at each site, accounting for age (per 5 year range) and BMI (approximate quintile ranges). We stratified by pf (low pf = PCS <35) within VALOR. The FOS males (n=1126) were aged 50-86 years (median 63) and the VALOR subjects (n=542 VA-P observations, n=522 non-P) were aged 50-91 (median 73). BMI values of 25, 27, 29 and 32 defined approximate quintiles in all groups. FOS and non-P subjects had similar PASE means (157+73, 150+84). VA-P subjects reported less activity (122+83) and also worse pf than non-P (43% vs 10% had low pf). After adjustment for age and BMI categories there were associations between PASE and BMD at all 3 sites among the VA-P (0.7% higher BMD per PASE level, $p<.03$ at each site) and for the FOS subjects (0.6% higher/PASE level at each site, $p=250$ compared with PASE 100-149 by 5-6% per site in FOS, by 3-4% for non-P, and by 2- 4% in VA-P. BMD was lower for PASE <50 compared with PASE 100-149 by 5- 8% across bone sites in VA-P, but did not vary across the lower PASE levels in either non-P or FOS subjects. Among low pf subjects, adjusted BMD was 11-13% lower for PASE <150 vs PASE > 150. These results indicate lower levels of self-reported physical activity are associated with lower hip BMD in older men, and that men with low levels of physical function and lower levels of physical activity have even lower hip BMD, an effect comparable to several decades of normal aging.

Recruitment Design for the Osteoporotic Fractures in Men Study (MrOS). P. E. Mannen[1], J. B. Blank*[2], M. Carrion-Peterson*[3], R. Delay*[4], L. Harper*[5], P. Johnson*[6], E. Mitson*[7], K. L. Stone[1]. [1]Univ of California, San Francisco, CA, USA, [2]Oregon Health and Sciences Univ, Portland, OR, USA, [3]Univ of California, San Diego, CA, USA, [4]Stanford Univ, Palo Alto, CA, USA, [5]Univ of Pittsburgh, Pittsburgh, PA, USA, [6]Univ of Alabama, Birmingham, AL, USA, [7]University of Minnesota, Minneapolis, MN, USA.

The Osteoporotic Fractures in Men Study (MrOS) is a prospective observational study designed to determine risk factors for osteoporosis and fractures in men aged >= 65. Recruitment of participants for this study has recently concluded, and the design of and results from the recruitment strategies will be outlined here. In March and April 2000, recruitment for MrOS began in 6 clinical centers across the US (Univ of Alabama, Birmingham; Univ of Minnesota; Univ of Pittsburgh; Stanford Univ; Oregon Health & Science Univ and Univ of California, San Diego.) The study is directed by an administrative core at OHSU and coordinated by Univ of California, San Francisco. These centers were selected for involvement in this NIH-sponsored investigation based on experience in conducting large, complex studies, and for racial and geographic diversity. At the end of the baseline recruitment period in March 2002, 6,008 participants have been enrolled in the MrOS study, 5% more than the original recruitment goal of 5,700. Minority recruitment has exceeded expectations, as 621 participants (10% of the cohort) listed at least one racial minority background on the study questionnaire (243 African American, 194 Asian). These minority recruitment totals are roughly double the original goals determined at study onset. Recruitment of the "oldest" old, or men age >80, was exceptional, with nearly 18% of the cohort (N=1,060) classified in this age category. All clinical centers completed recruitment on time, with 3 clinics finishing more than 3 months ahead of schedule. Recruitment strategies varied by site, and included DMV, HCFA, voter registration and participant database mailings; community and senior newspaper advertisements; and targeted presentations. A centrally created recruitment brochure enhanced each site's promotional materials. These strategies resulted in an extremely successful recruitment campaign, as response to mass mailings surpassed 10-15% at some sites (compared to a 2-5% expected response rate.) Appointment show rates were an above average 80-90%. Retention so far in the study has been outstanding, as response to one-page follow-up questionnaires mailed every four months has been greater than 99%. Our initial concerns that men would not participate in a study of a "women's disease" were unfounded. Older men, even those over age 80, were enthusiastic about participation. Recruitment for MrOS has been successful.

Femoral Bone Size Among Older Men and Its Relation to Lean and Fat Mass. L. M. Marshall*[1], T. F. Lang[2], J. A. Cauley[3], K. E. Ensrud[4], E. S. Orwoll[1]. [1]Oregon Health & Science University, Portland, OR, USA, [2]University of California, San Francisco, San Francisco, CA, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]VA Medical Ctr & Univ of Minnesota, Minneapolis, MN, USA.

Bone size, a determinant of bone strength, is a component of fracture resistance. Bone size has been shown to be related to body weight. However, body weight is comprised of fat and lean mass, and the association of bone size with body composition is not well characterized. Thus, we examined whether lean mass and fat mass are independently related to femoral cross-sectional area (CSA). The study population included 835 men ages 65 and older from Minneapolis (n=526) and Pittsburgh (n=309) who are participants in the Osteoporotic Fractures in Men study. At the baseline exam, total fat mass (FM) and lean mass (LM) were obtained from DXA, height (cm) and weight (kg) were measured, and leg power (watts) was assessed on a Nottingham Power Rig. Femoral size, defined as the CSA (cm^2), and volumetric BMD (vBMD) were obtained from quantitative computed tomography (QCT) at the femoral neck, the intertrochanteric plane, and the femoral shaft. We used multiple linear regression to examine the independent relations of LM and FM with CSA. The associations are reported as the change in CSA per 7 kg change in either LM or FM, which is about one standard deviation (sd) in the distribution. The mean age (sd) of the study population was 73.3 (5.7) years. The mean (sd) and inner quartile range (IQR) of each CSA was: femoral neck CSA, 13.9 (1.8), IQR 12.6-15.0; intertrochanteric CSA, 36.0 (4.6), IQR 32.9-38.5; and shaft CSA, 9.1 (1.1), IQR 8.4-9.8. After adjustment for city, age, height, vBMD and FM, LM was independently related to each CSA measure (see table).

Change in CSA (95% Confidence Interval) per 7 kg Change in Variable

Variable	Femoral Neck CSA	Intertrochanteric CSA	Shaft CSA
Lean Mass	0.77 (0.62, 0.91)	1.75 (1.38, 2.11)	0.52 (0.42, 0.63)
Fat Mass	-0.11 (-0.23, 0.004)	-0.21 (-0.49, 0.08)	-0.10 (-0.18, -0.02)

FM was inversely related to CSA, but the association was statistically significant only for shaft CSA. The estimates for LM did not change materially when body mass index (kg/m^2) replaced FM in the models. Adding leg power to the multivariable models did not alter the associations of LM with CSA, and leg power was not associated with any CSA measure. In these cross-sectional data among older men, we observed substantial variation in femoral bone size. In multivariate analyses, CSA was independently related to LM but not to FM. Clarifying the mechanism underlying this association could provide insight into bone size regulation among older men and its relation to fracture risk.

SA306

The Clinical Utility of Laboratory Testing in Women with Low Bone Mineral Density. S. A. Jamal[1], A. M. Bayoumi*[2], R. Wagman[3], S. R. Cummings[3], D. C. Bauer[3]. [1]Endocrinology and Metabolism, University of Toronto, Toronto, ON, Canada, [2]General Internal Medicine, University of Toronto, Toronto, ON, Canada, [3]Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA, USA.

Although clinicians often test women with low bone mineral density (BMD) for secondary causes, the utility of routine laboratory testing is unknown. We evaluated the frequency and correlates of abnormal lab tests among 15,371 women from 11 communities in the U.S. who were screened for the Fracture Intervention Trial. Women with femoral neck BMD of 0.68g/cm2 or less (Hologic QDR 2000, Waltham, Mass) had blood drawn for electrolytes, creatinine, urea, complete blood count, alkaline phosphatase, calcium and albumin, random glucose, transaminases, thyroid stimulating hormone and intact parathyroid hormone. Specimen processing was standardized and blood was analyzed at a central laboratory. We classified results outside the reference range as abnormal. The mean age was 69.2 years (± 5.9), and most women (14835 or 97%) were Caucasian. About 1/3 (5381) had normal laboratory tests, 1/3 (5449) had one abnormal result, and the remainder (4541) >2 abnormal laboratory results. The femoral neck T score was <= -2.5 in 5806 (38%) of the women; the remainder had a T score between –1.5 and –2.5. Total body T score was <=-2.5 in 3786 (25%) of the women; the remainder had osteopenia. Compared to women with osteopenia, the prevalence of one or more abnormal laboratory results was slightly higher in women with osteoporosis at the femoral neck (30% vs. 28%; p=0.039) and at the total body (32% vs. 28%; p=0.001). Of the 12,767 women who had spinal radiographs, 2678 (21%) had prevalent vertebral deformities. There was no association between prevalent vertebral deformities and abnormal laboratory results (Odds Ratio [OR]: 1.0; 95% Confidence Interval [CI]: 0.94 to 1.1). Women with osteoporosis at the femoral neck or total body were only slightly more likely to have one or more abnormal laboratory tests (OR: 1.1; 95% CI: 1.0 to 1.2 and OR: 1.3; 95%CI: 1.2 to 1.4) after adjusting for age and weight. Age, weight and the presence of osteoporosis, either at the femoral neck or total body, did not discriminate between women with abnormal and normal laboratory results. Results were similar for women with two or more abnormal test results to women with one or no abnormal test results. We found no clinically important association between abnormalities in a variety of laboratory tests and either low BMD, or vertebral fracture. This suggests that abnormal screening tests in women with osteoporosis are usually incidental findings unrelated to osteoporosis and raises questions about the value of testing for secondary causes in women with osteoporosis.

Computed Posturographic Analysis of Swaying in Aging, Osteoporosis and Degenerative Joint Disease. T. Fujita. Medicine, Calcium Research Institute, Kishiwada, Japan.

Track of the gravity center of the body on standing straight was analyzed by computerized posturography in 136 subjects with osteoporosis and/or degenerative joint disease such as spondylosis deformans and osteoarthritis of the knee. As indices of swaying and postural instability, total length of the track of gravity center (LNG), LNG per unit time indicating sway speed (LNG/T), LNG per unit area estimating sway control mechanism (LNG/A), total area enveloped by the track (ENV), rectangular area covered by the track (REC) and root mean square area of the circle with the radius calculated as a mean of the distance between the center of the track curve and each gravity center (RMS) were measured with the eyes opened and closed by using Gravicorder GS-30 made by Anima Company, Tokyo. For each measurement, the ratio between closed-eye and open-eye values was calculated. Open-eye and closed eye LNG, LNG/T ENv, REC and RMS showed significant positive correlation with age, suggesting an age-bound increase of swaying. While mean lumbar bone mineral density (LBMD) indicating a progress of osteoporosis failed to showed significant correlation with any of these swaying parameters, intraindividual variation of LBMD indicating an advance of spondylotic deformity showed a significant positive correlation with open-eye ENV, REC and RMS and closed-eye RMS. Multiple logistic regression analysis os these swaying parameters on fracture revealed a significant regression of only open-eye REC (p=0.0084,with odd's ratio of 2.87 ; 95% confidence limits : 1.31-6.31). After treatment with 200 mg/day etidronate and 900 mg/day AAA Ca (active absorbable algal calcium), open-eye LNG and close-eye LNG/A, REC and RMS as well as closed-open ratio of LNG, LNG/T, LNG/A, REC and RMS shpwed significant improvements. Aging and spondylotic deformity of the spine is associated with postural instability, whch showed improvement in response to treatment with etidronate and AAA Ca.

Osteoporosis Risk Factors Comparison between Outpatient and Population Screening. A. Defer*. REGO Sachsen/Thüringen, Dresden, Germany.

How do the results of the osteoporosis risk factors analysis differ between women of medical practice and a populations screening? Material and methods: The 11 risk factors of the osteoporosis risk questionnaire of the REGO Saxony & Thuringia were base of the analysis. This questionnaire consists of the following complexes: Bone fractures since the 40^{th} year of life , late menarche , early menopause , low mobility , low consumption of dairy products , falls, abuse of alcohol and nicotine , taking or having taken Cortisone for longer than 6 months , family anamnesis , back pains. 1010 data sets of women were analyzed from the medical practice. These data were subdivided into groups after the bone density diagnosis and into 3 age-groups. Women in the age of 70 to 71 year with an osteoporosis were selected especially for comparison purposes with the population screening analysis. This population screening analysis was carried out in a small town. 50% of the 70-year-old women living there participated with a full risk questionnaire. The percentage frequencies of the data to the 11 risk factors in the different patient groups and in the screening group were compared. Results: Of the 11 risk factors no significant arguments showed Menopause, falls, alcohol and nicotine into relation to the bone density. Clear differences were found at fractures (26% at normal BMD to 50% at osteoporosis) at the menarche (50% to 61%), at the mobility (8% to 17%) and at the milk consumption (10% to 15%) . A positive families case history and back pains are a little more frequent at normal bone density than at osteoporosis (36% to 26% and 95% to85%). Table 1 shows all clear data differences of the comparison in age-groups and between the 70-year-old patients and the 70-year-old women from the screening population analysis. No essential differences were found at the mobility, at falls, at alcohol and nicotine in these groups.

Table 1	Fracture	Menarche	Menopause	Milk	Cortisone	Family	Back pain
Women < 66 years, n=231	39	62	29	11	8	32	88
Women 66-75 years, n=348	55	64	26	16	11	24	86
Women >75 years, n=149	23	28	9	8	5	16	79
Women 70-71 years, n= 75	**47**	**56**	**17**	**16**	**11**	**32**	**92**
women in screening, 70 years, n=86	**26**	**34**	**5**	**2**	**6**	**26**	**65**

Summary: Osteoporosis risk factors can distinguish healthy women from osteoporosis partly. The degree of the distinction possibility is age dependent.

SA312

L-Thyroxine Replacement Accelerates Bone Turnover in Patients with Subclinical Hypothyroidism: Results from a Double-Blind Placebo-controlled Study. C. Meier, B. Müller*, M. Christ-Crain*, M. Kunz*, M. Guglielmetti*, J. J. Staub*, M. Kraenzlin. Department of Medicine, Division of Endocrinology, Basel, Switzerland.

Initiation of L-T4 therapy activates bone remodeling with initial loss of bone mineral density in overt hypothyroidism. Data on the effects of L-T4 replacement on bone turnover and bone density in subclinical hypothyroidism (SCH) are scarce. 61 women (mean age 57.1± 1.3 years) with SCH (mean TSH 11.8± 0.9 mU/L, range, 4.7-46.3 mU/L, with normal thyroid hormones) were randomized to receive either L-T4 (mean dose 85.5± 4.3 µg/d; n=31) or placebo (n=30) for 48 weeks. Physiological L-T4 replacement was guaranteed throughout the whole study period by blinded continuous TSH monitoring and adaptation of L-T4 dose. Thyroid hormones, bone mineral density [BMD; DXA], and biochemical markers of bone formation (Osteocalcin [OC], alkaline phosphatase [ALP]) and bone resorption (C-term. telopeptides type I collagen [CTX], deoxypyridinoline [DPD], pyridinoline [PYD]) were measured at 0, 24 and 48 weeks of treatment. At baseline, thyroid hormones, BMD and biochemical markers were identical in both treatment groups. In L-T4 treated patients (TSH 3.1± 0.3 mU/L) markers of bone formation increased progressively: ALP was changed after 24 weeks (p=0.05) and 48 weeks (p=0.004), whereas OC was significantly increased only after 24 weeks (p=0.03). Markers of bone resorption increased significantly after 24 and 48 weeks: PYD (p=0.003, p=0.016 resp.) and DPD (p=0.003, p=0.014 resp.). In contrast, CTX remained unchanged. The increase of bone resorption markers was more pronounced in premenopausal women and women on HRT (n=17). In the L-T4 group BMD decreased by 1.3% (p=0.006) at the lumbar spine, while femoral BMD remained unchanged. During placebo administration no significant changes of these markers were found. L-T4 replacement in SCH is associated with an increase in bone remodeling as documented by significant changes in markers of bone formation and resorption. Consistent with data in patients with overt hypothyroidism, lumbar bone loss was found in the first year of L-T4 treatment. However, the observed reduction in lumbar BMD is smaller and well within the range of precision error of the method and, thus cannot be interpreted as overzealous treatment effect. Based on this placebo-controlled study with physiological L-T4 replacement, we recommend that patients with SCH (e.g. TSH >10 mU/L) should be treated without concern about adverse effects on skeletal integrity.

SA313

Geometry of the Hipin Relation to Age and Sex -a Cross-Sectional Study in Healthy Adults. N. Nissen*[1], E. Hauge*[2], B. Abrahamsen[1], J. E. Bech-Jensen[3], L. Mosekilde[4], K. Brixen[1]. [1]Dept of Endocrinology M, Odense University Hospital, Odense, Denmark, [2]Institute of pathology, Aarhus University Hospital, Aarhus, Denmark, [3]Osteoporosis Research Clinic, Hvidovre, Denmark, [4]Dept of Endocrinology C, Aarhus University Hospital, Aarhus, Denmark.

The age-related bone loss and increased tendency to fall have been demonstrated as the main factors causing hip fracture, however, neither age-related osteoporosis nor the increased risk of falling sufficiently explains the exponential increase in the incidence of hip fracture. It has been suggested that the geometry of the hip is a predictor for hip-fractures independent of bone mineral density (BMD). The purpose of the present study was to investigate the natural variation of the geometry of the hip in relation to age and sex. Using newly developed software, we measured hip-axis-length (HAL), neck-width (NW), neck-shaft-angle (NSA), and femoral head-radius (HR) from DXA-scans performed on a Hologic QDR-1000 densitometer. The study population consisted of 217 healthy adults, aged 18-82 yrs, recruited at libraries, factories, educational institutions, etc. The effects of age and sex on the measured parameters were investigated using multiple regression analysis (SPSS).

	Hip axis length	Neck width	Neck-shaft-angle	Fem. head radius
Male (n=80)	10.9 +/- 0.8	3.9 +/- 0.4	131 +/- 4	2.6 +/- 0.3
Female (n=137)	9.5 +/- 0.6	3.4 +/- 0.7	130 +/- 4	2.3 +/- 0.2

Data are displayed in centimeters or degrees

We found that HAL depended on sex ($p<0.001$, $R^2=0.08$) but not on age. NW depended only on sex ($p<0.001$, $R^2=0.16$) but not on age. A trend towards increasing NW with age ($p=0.09$) was seen in males but not in females. Age and sex were significantly correlated to NSA ($p=0.05$ and $p=0.02$, $R^2=0.047$). HR is also significant correlated to age and sex ($p<0.01$ and $p<0.001$, R^2 0.34). In conclusion, HAL, NW, HR, and NSA differ between genders. Also, age explained a small proportion of the variation in NSA and HR, however, this may be due to a generation-effect. Supporting previous *ex vivo* findings, NW tends to increase with age in males.

SA315

Racial, but not Sex, Differences in Vertebral Body Volumetric Bone Mineral Density in Asian and Caucasian Women and Men. Y. Duan[1], X. F. Wang*[1], C. H. Turner[2], E. Seeman[1]. [1]Department of Medicine, Austin & Repatriation Medical Centre, Melbourne, Australia, [2]Department of Orthopaedic Surgery, The Biomechanics and Biomaterials Research Center, Indianapolis, IN, USA.

Asians have lower vertebral body aBMD than Caucasians. We hypothesized that the prevalence, and perhaps incidence of vertebral fractures in Asians and Caucasians is similar because of scaling; a reduced muscular loading on a commensurately smaller vertebral body in Asians will produce a similar ratio in load/bone strength – ie a similar fracture risk index (FRI). We studied 94 healthy Asians (Chinese ancestry, 58 females, 36 males) and 396 healthy Caucasians (304 females, 92 males) aged 18 to 43 yrs. Vertebral body (VB) cross-sectional area (CSA), aBMD and volumetric BMD (vBMD, excluded posterior elements) were measured by using dual x-ray absorptiometry by postero-anterior and lateral scanning. We calculated vertebral body compressive stress (load/CSA) and FRI during bending forward. Results (mean ± sem). VB aBMD was 20% higher in Asian men than Asian women because CSA was 26% greater in men than women (10.45 ± 0.25 vs 8.29 ± 0.12 cm2); there was no sex difference in vBMD (0.289 ± 0.008 vs 0.274 ± 0.007 g/cm3, NS), stress (329.5 ± 11.0 vs 316.1 ± 6.2 N/cm2, NS), and FRI (0.32 ± 0.01 vs 0.37 ± 0.02, NS). Similar figures were presented in Caucasian men and women. Compared to Caucasians, VB CSA was 13% higher in Caucasian than Asian men and 15% higher in Caucasian than Asian women. VB vBMD was 13% lower in Caucasian men than Asian men, and 9% lower in Caucasian women than in Asian women. There were no different in load per unit CSA between Asian and Caucasians in either gender. However, both Caucasian men and women had higher FRI than Asian men and women, respectively (men 0.41 ± 0.02 vs 0.32 ± 0.01; women 0.42 ± 0.01 vs 0.37 ± 0.02, both $p < 0.01$). In summary and conclusion, (i) The higher aBMD in Asian men than women is due to the larger bone size, vBMD was no different in Asian men and women (this is true for Caucasian men and women). (ii) The load per unit CSA is no different between genders and races, suggesting that the smaller bone is loaded by a proportionally smaller load. (iii) At peak, Asians achieved a smaller bone size but higher vBMD than Caucasians, conferring a lower risk of vertebral fractures. Whether the higher vBMD in Asians than Caucasians is due to the greater trabecular number, thickness or thicker cortical shell are unknown.

SA316

Young-old Differences in Proximal Femoral BMD and Size in Women. M. Meta[1], A. Yu*[1], J. Keyak*[2], J. Li*[1], H. Genant[1], T. Lang[1]. [1]Department of Radiology, University of California, San Francisco, CA, USA, [2]Department of Orthopedic Surgery, University of California, Irvine, CA, USA.

It is thought by some that structural geometry of the femoral neck changes with age to compensate for the age-related loss of bone mineral and that the higher incidence of hip fracture in women may be related to gender differences in these changes. To examine this issue, we have compared groups of young (mean age 41±3 years) and elderly (75±4 years) healthy Caucasian-American women recruited from the San Francisco Bay Area. To compare BMD and geometric parameters, both groups underwent volumetric quantitative computed tomography (vQCT) of the hip (GE 9800Q, 3-mm slice thickness). Images were processed to measure integral (iBMD), trabecular (tBMD) and cortical (cBMD) BMD of the femoral neck and trochanteric regions of the hip. The geometric parameters included the integral volume (iVOL) of the femoral neck and trochanteric regions, the minimum and maximum cross-sectional area (CSA) along the femoral neck axis. The minimum CSA occurred at the thinnest section of the femoral neck, and the maximum CSA occurred at the thickest intertrochanteric plane. We used analysis of covariance to compare measurements between young and old women adjusting for height and weight differences. Mean values (SD) are tabulated below. BMD units are g/cm^3, volume cm^3 and cross-sectional area cm^2.

	iBMD	tBMD	cBMD	iVOL	CSA
Femoral Neck					
Young	0.331*** (0.04)	0.152*** (0.03)	0.518 ns (0.05)	19.7 ns (4.05)	10.0 ns (1.87)
Old	0.264 (0.04)	0.064 (0.05)	0.516 (0.05)	20.1 (5.44)	10.5 (1.76)
Trochanteric					
Young	0.312*** (0.04)	0.140*** (0.03)	0.564** (0.03)	81.7** (2.8)	25.7*** (3.21)
Old	0.250 (0.04)	0.088 0.03)	0.531 (0.05)	89.9 (2.04)	29.7 (3.2)

*** $p<0.001$, ** $p<0.01$, ns $p>0.05$

In the femoral neck, iBMD and tBMD declined with age, but cBMD and the bone size parameters did not change significantly. In the trochanteric region, all BMD parameters declined with age, but the bone size parameters increased. These data are consistent with an absence in women of an increase in femoral neck size to compensate for decreased BMD. However, the age-related decrease observed in all of the trochanteric BMD parameters was accompanied by an increase in iVOL and CSA. This pronounced inter-site difference may be due to differences in how body weight is supported in the different regions as well as the potential effect of muscle forces, given that the trochanteric region, but not the femoral neck, is an important muscle attachment site.

SA317

Endocortical Remodeling in the Human Femoral Neck: Increased Bone Resorption Surfaces Across the 'Neutral Loading Axis' of Hip Fracture Cases. J. Power*[1], N. Loveridge[1], A. Lyon*[1], N. Rushton*[1], M. Parker*[2], J. Reeve*[1]. [1]University of Cambridge, Cambridge, United Kingdom, [2]Peterborough District Hospital, Peterborough, United Kingdom.

Since periosteal expression of alkaline phosphatase was similar between cases and controls, we hypothesised that the mechanism causing the marked femoral neck cortical thinning associated with hip fracture may be raised endocortical bone loss. Twelve female cases of femoral neck fracture (mean age=81±1.5) and 12 age and sex matched post mortem controls (mean age=81.9±1.9) were included in the study. Samples of their femoral neck bone were embedded in methyl methacrylate, sectioned at 10 microns and stained with Solochrome cyanine R and Goldner's trichrome for the detection of osteoid and resorption surfaces respectively. The table shows the % endocortical osteoid (OS/BS) and eroded surfaces (ES/BS) according to quadrantic region. When the data comprising the individual regions were combined OS/BS in cases (9.4±1.8%) were significantly higher than controls (3.7±0.6; P=0.007; Wilcoxon test). Percentage ES/BS was borderline elevated in the cases (5.5±0.9) compared to controls (3.5±0.4; P=0.053). Endocortical %ES/BS could be normalised by log transformation and was modelled using least squares regression analysis with anatomical region nested within disease category (fracture/control). There was a significant interaction of disease and region (P=0.025) for %ES/BS with significant or borderline higher values in the anterior (P=0.006) and posterior (P=0.074) regions. %ES/BS was not significantly raised in those regions (inferior: P=0.29; superior: P=0.77) bisecting the plane of maximum load. We conclude that endosteal bone remodeling (%OS/BS) is elevated in hip fracture cases. Moreover endosteal resorption surfaces are also elevated in those quadrants subjected to minimum stance-related loading.

	Osteoid surface (%OS/BS)		Eroded Surface (%ES/BS)	
Region	Control	Case	Control	Case
Anterior	3.4±0.7	11.0±2.3*	2.8±0.6	5.3±0.7*
Inferior	3.4±1.0	9.9±3.0*	6.4±1.3	8.3±2.1
Posterior	3.2±0.8	9.1±2.3**	2.6±0.4	4.7±1.0
Superior	4.7±1.3	7.9±1.2	3.3±0.5	4.1±1.1

Changes in Urinary Sodium and Calcium in Response to a Salt Load in African-American and Caucasian Postmenopausal Women. L. Carbone[1], K. D. Barrow*[1], A. Bush*[2], K. Pitts*[3], K. McFadden*[1], A. Kang*[1], F. A. Tylavsky[2]. [1]Medicine, University of TN, Memphis, TN, USA, [2]Preventive Medicine, University of TN, Memphis, TN, USA, [3]General Clinical Research Center, University of TN, Memphis, TN, USA.

The objectives of this study were to examine the response of 24-hour urine sodium (Na) and calcium (Ca) excretion to a salt load of 270 mmoles/day for six weeks and determine if there were ethnic differences in response to the salt load. The participants were healthy, normotensive, estrogen-deficient African-American (n=20) and Caucasian (n=31) women with no history of renal disease. There were no statistically significant differences between the groups (Caucasians vs. African-Americans) for age (65.3 +/- 6.1 vs. 64.3 +/- 6.3 years (mean +/- SD)), height (161.94 vs. 161.87 cm), weight (76.3 vs. 80.7 kg), or BMI (29.1 vs. 30.8 kg/m2). Bone mineral density (BMD in g/cm2) of the total hip was measured using a Lunar DPX, and 24-hour urine samples were collected at baseline and the end of the six-week salt load. African-Americans had higher BMD of the total hip than the Caucasians (1.01 vs. 0.92, p=0.03) with 10% of the African-Americans and 29% of the Caucasians having a T score <-1 (p=0.11). There were no increases in blood pressure or changes in weight in response to the salt load in either group. Both groups had increases in 24-hour Na and Ca excretion (mmoles/gm/TV) in response to the salt load (p<0.01). The percent change in excretion was similar between the ethnic groups for Na (African-Americans 47.3%, Caucasians 66.9%, p=0.21) and Ca excretion (African-Americans 36.2%, Caucasians 35.6%, p=0.54). The absolute change from pre to post salt load are as follows:

	Pre-Salt Load (Mean +/- SD)	Post-Salt Load (Mean +/- SD)	P
African-Americans			
24-Hour Na excretion	119.59 +/- 37.32	169.88 +/- 56.49	<0.01
24-Hour Ca excretion	2.48 +/- 1.33	3.12 +/- 1.54	0.01
Caucasians			
24-Hour Na excretion	129.67 +/- 33.82	210.01 +/- 65.35	<0.01
24-Hour Ca excretion	3.71 +/- 1.72	4.66 +/- 2.00	<0.01

Despite known differences in calcium metabolism, African-American and Caucasian women have similar increases in calcium excretion in response to a salt load. The relationship of salt intake to bone loss and fracture risk in different ethnic groups requires further study.

Disclosures: ***L. Carbone****, Merck 8; Proctor and Gamble 8.*

Source of Body Weight Loss Induced by Gastroplasty in Obese Subjects. C. Petracin*[1], J. P. Devogelaer[2], A. Dysseleer*[1], R. Detry*[3], J. P. Thissen*[1]. [1]Department of Endocrinology, St-Luc University Hospital, Brussels, Belgium, [2]Rheumatology Unit, St-Luc University Hospital, Brussels, Belgium, [3]Department of Surgery, St-Luc University Hospital, Brussels, Belgium.

Gastroplasty is now recognized as a successful method for treatment of morbid obesity. This procedure induces a dramatic body weight loss associated with correction of several co-morbidities. However, the nature of the weight loss has been rarely studied, particularly, the effect on bone mineral content (BMC) has been infrequently studied. To investigate the source of weight loss after gastroplasty, we analyzed the changes in body composition in 12 obese (11 females) subjects aged 23-55 years with BMI ranging from 38 to 50 kg/m2. Body compartments were studied by dual energy X-ray absorptiometry (DXA) before, 3 and 12 months (mo) after surgery. Body weight decreased by 32 ± 3 kg (mean ± SEM) at 12 mo ($p < 0.001$ vs time O) and 60 % of this amount was already lost after 3 mo ($p < 0.001$). Fat mass (FM) decreased by 27.1 ± 3.0 kg at 12 mo ($p < 0.001$), with 54 % of this amount lost already after 3 mo ($p < 0.001$). In contrast, fat-free mass (FFM) decreased only by 5.3 ± 1.1 kg ($p < 0.001$), but 91 % of this amount were already lost after 3 mo ($p < 0.05$). The decrease of FFM represented mainly a decrease in lean body mass (LBM) (4.7 ± 0.8 and 5.2 ± 1.0 kg, respectively at 3 and 12 mo; both $p < 0.001$) and secondarily a decrease in BMC (32 ± 10 and 105 ± 31 g, respectively at 3 mo, NS and 12 mo, $p < 0.001$). Appendicular skeletal muscle contributed for most of the loss in LBM (3.7 ± 0.9 kg out of 5.2 ± 1.0 kg). In conclusion, the body weight loss induced by gastroplasty at 12 mo consisted of 83.9 % of fat mass, 15.9 % of lean body mass (11.6 % of skeletal muscle), but only 0.2 % of bone mineral.

SA320

Substituting Soy Protein for Meat Protein did not Affect Calcium Retention in a Controlled Feeding Study of Healthy Postmenopausal Women. Z. K. Roughead. Grand Forks Human Nutrition Research Center, USDA-ARS, Grand Forks, ND, USA.

The Food and Drug Administration has approved a health claim stating that a daily consumption of 25 g of soy protein, as part of a low fat diet, may reduce the risk of heart disease. Recent studies suggest that soy protein may also protect against postmenopausal bone loss. In contrast, the consumption of meat protein is often cited as a risk factor for osteoporosis. In a controlled feeding study, calcium retention was determined from a diet with meat (CONTROL) and a diet in which 25 g of soy protein (SOY; 2.28 mg aglycone/g protein; Dupont Protein Technologies, St Louis, MO) was substituted for 25 g of meat protein. Healthy postmenopausal women (n=13, age:52-69 y; body mass index: 26.0 ± 5.0; femoral neck BMD Z-score: - 0.98 to1.86) consumed the diets (15% protein; 653 and 740 mg calcium/2200 kcal in the CONTROL and SOY diets, respectively), for 8 wk each, in a randomized crossover design. After 4 wk of equilibration, the entire 2-d cycle menu was extrinsically labeled with Ca-47 radiotracer (as $CaCl_2$) and its retention was monitored for 28 d by whole body scintillation counting. The calcium retention data were modeled by the two-component exponential equation: $y = \beta_1 \exp(-k_1 t) + \beta_2 \exp(-k_2 t)$, where y represents Ca-47 retention, as % of the initial dose, t time in hours, and coefficients β_1 and β_2 the turnover of the radiotracer (%) at rates k_1 and k_2, respectively. The retention curves, modeled for each individual on each diet, had coefficients of determination (R^2) of 0.98 to 0.99.
Table: Retention of Ca-47 radio tracer as measured by whole body counting

Variable[1]	CONTROL	SOY
β_1, % dose	77.4 ± 5.8	78.5 ± 5.5
β_2, % dose	22.7 ± 5.7	21.6 ± 5.5
ln (T_1) (days)[2]	0.43 ± 0.30 (1.5)	0.43 ± 0.28 (1.5)
ln (T_2) (days)[2]	3.8 ± 0.5 (44.7)	3.9 ± 0.5 (49.4)
Retention @ day 7, %	24.4 ± 4.7	23.5 ± 5.6
Retention @ day 14, %	18.2 ± 3.8	17.7 ± 4.5
Retention @ day 21, %	15.9 ± 3.5	15.6 ± 4.3
Retention @ day 28, %	14.1 ± 3.2	14.0 ± 4.1

[1]Mean ± SD, n=12; No significant diet effect (P>0.05). [2]Geometric means.

The fractional retention of the calcium tracer was similar between the CONTROL and SOY diets at all time points (P>0.05, Table). On both diets, >75% of the tracer was eliminated rapidly (biological half-life 1.5 d) indicating the excretion of the unabsorbed isotope and early endogenous losses. The remaining tracer (~20%) was eliminated less rapidly with a biological half-life of 45-49 days. In conclusion, a daily substitution of 25 g of a soy protein isolate for meat protein for 8 weeks did not enhance the efficiency of calcium retention in healthy postmenopausal women. Any beneficial effects of soy protein on bone may be due to mechanisms unrelated to dietary calcium retention.

Impaired Vitamin D Status in Young Israeli Women. R. Hasid*[1], A. Tamir*[1], B. Raz*[2], E. Segal*[3], S. Ish-Shalom[3]. [1]Technion Faculty of Medicine, Haifa, Israel, [2]Endocrine Laboratory, Rambam Medical Center, Haifa, Israel, [3]Metabolic Bone Diseases Unit, Rambam Medical Center, Haifa, Israel.

Vitamin D is an important regulator of bone metabolism. Vitamin D deficiency was frequently reported in the elderly and correlated with increased hip fracture risk. Lifetime deficiency may affect bone health in later years. The aim of this study was to assess vitamin D status in healthy women of reproductive age and to compare between religious, secular and Arab groups. Fifty five women, aged 20 - 44(mean 25±6.2), 23 secular Jewish women, 24 religious Jewish women, and 8 secular Arab women (with western clothing habits) were enrolled in the study. Sunlight exposure, clothing habits, skin types and dietary history were assessed using previously validated questionnaires. Detailed medical history and routine laboratory examination were performed to rule out any disease that could affect vitamin D or bone metabolism. Serum 25(OH)D3 (^{125}I- radioimmunoassay, DiaSorin, Stillwater, Minnesota, USA), bone specific alkaline phosphatase (BAP) and PTH were assessed in the autumn and the spring. Serum 25(OH)D3 < 10 ng/ml was defined as vitamin D deficiency and between 10 - 15 ng/ml as vitamin D insufficiency. Serum 25(OH)D3 concentration of the religious Jewish women was significantly lower in autumn and spring respectively (8.1±4.7, 7.21±5 ng/ml) than of the secular Jewish women (18.9±10.9, 15.22±9 ng/ml). The mean 25(OH)D3 concentration of the secular Arab women was significantly lower than in two other groups (5. 8±2.3, 4.0±1.6 ng/ml). Nevertheless 43.5 % of secular Jewish women had 25(OH)D3 serum levels <15ng/ml in the autumn and 61.9 % in the spring. Compared with the Jewish and Arab secular women, Jewish religious women were significantly less exposed to sunlight (p< 0.0001). A positive correlation was demonstrated between serum 25(OH)D3 and dietary intake of vitamin D only in the autumn in Jewish religious women (r 0.49; p=0.016) and in the spring in Jewish secular women (r 0.47; p=0.034). 25(OH)D3 serum levels were negatively correlated with PTH serum levels (r - 0.51; p<0.0001) and with BAP serum levels (r -0.32;p=0.024). 25(OH)D3 levels were positively correlated with serum calcium (r 0.34;p=0.01) and serum creatinine levels (r 0.535;p=0.002).We conclude that religious Jewish and secular Arab women have markedly low vitamin D serum levels, that may impair bone metabolism. Vitamin D insufficiency is frequent even in secular young women that reside in the city. The need for routine vitamin D supplementation in young women belonging to vitamin deficient groups, and its impact on bone health deserve further investigation.

SA323

The Effects of Long-Term Dietary Restriction on SENCAR, C57BL/6 and DBA/2 Mouse Bone. E. J. Brochmann*[1], M. E. L. Duarte[2], S. S. Murray[1]. [1]GRECC/Medicine, VAGLA/UCLA, Sepulveda, CA, USA, [2]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Long-term dietary restriction (LTDR) prolongs life and reduces the severity of age-related diseases. However, the effects of DR on bone are controversial, with some reporting that LTDR reduces adult bone size and mineral content, while others report that DR has beneficial effects [e.g., increased trabecular BMD is observed after short-term DR in the SENCAR mouse model of rapid bone growth and early-onset bone loss, while LTDR normalizes calcitropic hormone status and bone metabolism in aging Fisher 344 rats (a model of age-related renal failure and bone loss)]. Animal models vary considerably, and this may underlie the disparity in LTDR study results. We tested the hypothesis that the effects of LTDR are strain-specific. Weanling SENCAR, C57BL/6, and DBA/2 mice (models of elevated, low, and indeterminant rates of free radical generation and aging, respectively) were acclimated to a defined test diet for 5 weeks, then randomly assigned to an *ad libitum*-(AL-) or Ca- and P-normalized LTDR feeding group. Body composition and total, vertebral, and femoral BMD and BMC were determined by PIXImus. Data were analyzed by ANOVA, with post-hoc analysis by Fisher PLSD and Scheffe F-testing. Preliminary results for 8-week old control and 5-month LTDR mice are reported. At 8 weeks of age (t_0), total BMD and BMC were affected by strain, with SENCAR > C57 > DBA (p = 0.0001). Post-hoc analysis indicated that strain-dependent differences were significant for all comparisons between any 2 strains (e.g., C57 vs. DBA, C57 vs. SENCAR, etc.). At t_0, vertebral and femoral BMD and BMC were higher in SENCAR than in C57 and DBA mice (p = 0.001), confirming the robust bone growth in young SENCAR vs. C57 and DBA mice. After 5 months of LTDR with diet normalized for Ca and P, total body, vertebral, and femoral BMD and BMC remained higher in SENCAR mice than in C57 or DBA mice ($p \leq 0.01$). LTDR had no adverse effects on total body or vertebral BMC or BMD in any strain. However, LTDR was associated with a significant (p = 0.0001) reduction in femoral BMD and BMC in SENCAR, but not C57 or DBA, mice. Thus, we validated the hypothesis that the response to LTDR is affected by strain. Of interest are the observations that normalizing dietary Ca and P during LTDR had a protective effect on total body, vertebral, and femoral BMD and BMC in two strains (DBA and C57), but it did not protect the SENCAR mouse from femoral BMD or BMC loss at 5 months of LTDR. Thus, there are strain- and site-specific differences in the effects of LTDR on mice, and dietary Ca and P normalization may provide significant protection against DR-induced decrements in BMD and BMC at specific skeletal sites in some animal models.

Synchronization of Bone Remodelling and Improvement of Femoral Neck and Lumbar Spine BMD following Normalization of Cortisol Levels in Cushing's Syndrome. K. Godang*, T. Ueland*, C. Kristo*, J. Bollerslev. Section of Endocrinology, National Hospital, Oslo, Norway.

Both endogenous and exogenous glucocorticoid excess has negative effects on bone and collagen turnover, in part by decreasing bone formation and stimulating bone resorption. Thus, secondary osteoporosis is a known complication of endogenous Cushing's syndrome (CS), and although there have been conducted many cross-sectional studies, there are few studies following patients after treament. The present study was designed to account for this by measuring changes in bone dimensions, bone mineral content and biochemical bone markers in 27 CS patients syndrome (19 with pituitary adenoma and 8 with adrenal tumor; 19 woman, mean age 45 ± 12) following normalization of cortisol levels compared to 27 age-,sex- and BMI-matched healthy controls, also assessed longitudinally. Bone mineral content was uniformly reduced in patients at baseline as was total body bone area. Serum levels of CTX-I were increased while osteocalcin was decreased. Following treatment of CS, femoral neck (FN) and lumbar spine (LS) BMD increased (9.4± 8.9% and 4.8± 6.6% respectively, P<0.001 for both), while a slight decrease was found for the total body BMD (-1.1± 2.2%, P=0.043). Similar changes were observed for BMC, only less prominent. Bone area in the FN decreased (-2.7± 4.4%, P=0.004) and increased in the total body (3.5± 6.7%, P=0.044). Furthermore, these changes where significantly larger than those seen in the control population, where no significant longitudinal changes were observed. As for biochemical bone markers, osteocalcin increased markedly following treatment (272± 201%, P<0.001), while no changes where found for CTX-1 (33± 86%). Moreover, while these parameters were uncorrelated prior to treatment (r=0.07), they were significantly correlated following treatment (r=0.83, P<0.001), indicating synchronisation of bone-remodelling. Finally, changes in LS and FN BMD where significantly correlated with the follow-up period (31± 21 weeks?) before measurement (P=0.68, P<0.001 and r=0.55, P=0.005). In summary, cure of CS is associated with a coupling of bone resorption and formation leading to a marked and continuos increase in bone mass.

Medrysone, a Glucocorticoid that Retains Anti-Inflammatory Efficacy, Has Only Modest Effects on Bone Turnover and Remodeling. K. R. Long*[1], P. Hara*[2], J. L. Lee*[1], V. Shen[2], C. Liu[2], H. Zheng*[2], R. Chott*[1], S. Bain[2], L. M. Olson*[1]. [1]Arthritis and Inflammation Pharmacology, Pharmacia Corporation, Chesterfield, MO, USA, [2]Skeletech, Bothell, WA, USA.

Glucocorticoids (GCs) are widely used due to their impressive anti-inflammatory properties but severe side effects, such as osteoporosis, limit long-term use. GC analogs retaining anti-inflammatory efficacy with reduced effects on skeletal tissues would represent a significant advance over current therapeutic modalities. In this study, a murine model of GC-induced osteoporosis was used to compare medrysone (med), a progesterone analog with GC activity, with prednisolone (pred), a GC known to induce osteopenia. Thirteen-week old male Swiss-Webster mice (n=12/group) were treated orally, twice daily with either vehicle, pred (0.5, 1.5, 5.0 mpk) or med (3, 10, 30 mpk) for 4 wk. The doses of pred and med were selected based on their equivalent efficacies in a murine model of LPS-induced endotoxemia. Weekly body weights (wts) and final thymus wts were recorded. Plasma corticosterone was measured as an indicator of HPA axis suppression. The effects on bone turnover were assessed by measuring bone mineral density (BMD), histomorphometry, and serum biomarkers. Weight loss was observed with both GC-treated groups, but pred-treated mice lost significantly more weight than med-treated mice (P<0.01). Mice treated with either GC showed similar reductions in thymus wts and plasma corticosterone, indicating their comparable effects on these two biomarkers. Pred, but not med, caused dose-dependent decreases in serum osteocalcin, a marker of bone formation. Surprisingly, spinal BMD and distal femur BMD were not significantly affected by either GC. In contrast, femoral midshaft BMD was significantly decreased with GC treatment; greater loss occurred in pred-treated mice (7.5% with 5 mpk, P<0.01) than in med-treated mice (4.3% with 30 mpk). Despite the lack of effect of GCs on distal femur BMD, dynamic histomorphometry at both distal and midshaft femoral sites showed greater suppression of bone formation rates (BFRs) with pred than with med treatment (distal BFR/BS, vehicle, 29.16 ± 7.91; 5 mpk pred, 0.64 ± 0.24, P<0.01; 30 mpk med, 13.64 ± 3.02). In sum, oral delivery of GC caused significant suppression of bone formation as indicated by decreased serum OC, reduction of femoral midshaft BMD, and significant suppression of femoral BFRs at both distal and midshaft sites. Despite comparable effects on LPS-induced endotoxemia, thymus wt, and plasma corticosterone levels, med suppressed bone formation less than pred, suggesting that anti-inflammatory properties of GCs may be distinct from their effects on the skeleton.

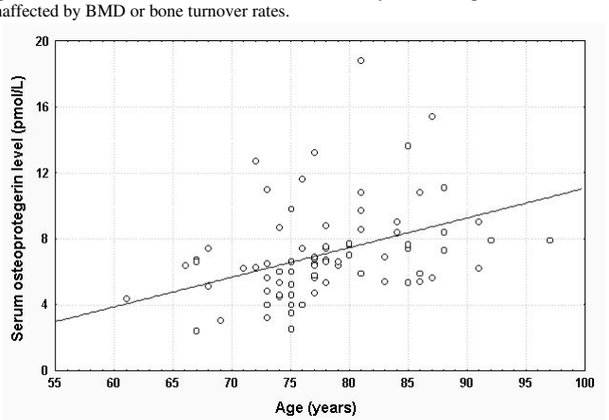
Low levels of Estradiol Protect Bone Mineral Density in Healthy Young Postmenopausal Women. A. Bagur[1], B. Oliveri[1], M. Belotti*[1], D. Yankelevich*[2], F. Sayegh*[2]. [1]Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina, [2]Sección Climaterio, División Ginecología, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina.

Low levels of endogenous estrogens may play a role in the protection of bone mineral density (BMD) in healthy postmenopausal women (PMP). The aim of this study was to evaluate the role of total and bioavailable estradiol and testosterone in the protection of BMD in healthy PMP. Ninety nine PMP women aged 55 to 75 years were included. The BMD of L2-L4, Total Femur (TF) and Total Skeleton (TS) was measured by DXA (Lunar Prodigy). Serum calcium, bone alkaline phosphatase (BAP), crosslaps (CTX), estradiol, estrona and testosterone and urine calcium were measured. Estradiol was measured with a sensitive assay that detects up to 5 pg/ml. Bioavailable sex hormones were calculated. The population was divided in two groups: <65 (Group 1) and >65 years of age (Group 2). The general characteristics of the groups were (mean ± SD): weight 66 ± 11 vs. 65 ± 9 kg (ns), height 1.57 ± 5 vs. 1.52 ± 0.05 m (p<0.001), BMI 26 ± 4 vs. 27 ± 4 kg/m2 (ns), L2-L4 1.01 ± 0.16 vs. 0.95 ± 0.18 g/cm2 (p<0.08, ns), TF 0.90 ± 0.11 vs. 0.82 ± 0.10 g/cm2 (p<0.001), TS 1.04 ± 0.09 vs. 0.98 ± 0.07 g/cm2 (p<0.001). The Groups were also stratified according to estradiol levels: less and more than 10pg/ml. The only significant differences in BMD were found in Group 1 in which estradiol levels higher than 10 pg/ml protected BMD of L2-L4 (+14%, p<0.05) and TS (+3%, p<0.05). BAP and CTX tended to be lower in Group 1 with more than 10 pg/ml of estradiol. The difference was close to reach statistical significance (p<0.07 for both). The highest positive correlations were found in Group 1: estradiol correlated with L2-L4 (r=0.4, p<0.001), TF (r=0.3, p<0.004) and TS (r=0.4, p<0.001), bioavailable estrogen correlated with L2-L4 (r=0.4, p<0.003) and TS (r=0.4, p<0.001), testosterone correlated with L2-L4 (r=0.6, p<0.001), TF (r=0.4, p<0.01) and TS (r=0.6, p<0.001). CTX correlated negatively with estradiol and bioavailable estradiol (r=-0.3, p<0.01 and r=-0.3, p<0.006 respectively). In conclusion, estradiol levels higher than 10 pg/ml, testosterone and bioavailable estradiol are involved in the maintenance of BMD in healthy postmenopausal women under 65 years of age.

SA329

Correlation of Serum Osteoprotegerin Levels with Age but not Hormone Replacement Status in Elderly Women. J. K. Scariano[1], P. J. Garry*[2], R. N. Baumgartner[3]. [1]Pathology, University of New Mexico School of Medicine, Albuquerque, NM, USA, [2]Pathology, University of New Mexico, Albuquerque, NM, USA, [3]Internal Medicine, University of New Mexico, Albuquerque, NM, USA.

The purpose of this study was to investigate the relationship between serum levels of osteoprotegerin (OPG), biochemical markers of bone turnover, PTH, estrone, leptin and bone mineral density (BMD) measurements made of the total and regional skeleton in 84 healthy, elderly postmenopausal women (61 - 97, mean = 78 years). Circulating OPG levels were directly correlated with the age of the subjects (r = 0.50, p < 0.001), intact parathyroid hormone (r = 0.39, p = 0.008), ICTP (r = 0.31, p = 0.04) and serum NTx levels (r = 0.28, p = 0.01). Inverse correlations were detected between OPG with BMD measured at the femoral neck (r = -0.27, p = 0.01) and total skeleton (r = -0.28, p = 0.01). After adjusting for age, however, all of these correlations were diminished. Although 25 women receiving hormone replacement therapy (HRT) had significantly decreased bone resorption markers and increased BMD at all skeletal regions when compared with the 59 women who were not receiving any type of antiresorptive therapy, levels of OPG were not influenced by HRT or circulating estrone. Multiple regression modeling indicated that the only significant determinant of the serum OPG level in elderly women is age, and its secretion is unaffected by BMD or bone turnover rates.



Differences in densitometric, body composition and biochemical parameters in HRT+ or - women

Parameter	HRT + (n=25)	HRT - (n=59)	p value
BMI (k/m^2)	25.7 ± 4.5	25.1 ± 3.0	0. 97
SBMD (g/cm^2)	1.246 ± 0.274	0.981 ± 0.131	< 0.001
FBMD (g/cm^2)	0.833 ± 0.141	0.734 ± 0.024	< 0.01
Estrone (pg/mL)	105.8 ± 131.3	17.3 ± 4.6	0.01
Serum NTx (nmol BCE/L)	14.0 ± 5.6	18.1 ± 11.0	0.009
PINP (μg/L)	33.3 ± 16.1	50.6 ± 25.9	< 0.001
OPG (pmol/L)	7.1 ± 3.6	6.9 ± 3.1	0.55

Elevated Turnover and Osteopenia in Vertebral Bodies of Ovariectomized (OVX) Rabbits. B. L. Pennypacker*[1], P. J. Masarachia[1], M. A. Gentile[1], D. Gilberto*[2], C. Johnson*[2], S. Motzel*[2], G. A. Rodan[1], D. B. Kimmel[1]. [1]Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, PA, USA, [2]Lab Animal Resources, Merck Research Laboratories, West Point, PA, USA.

A non-primate adult animal that displays both Haversian bone remodeling and estrogen deficiency osteopenia would expand opportunities to understand cortical bone behavior in estrogen deficient adult humans. Nine month old New Zealand white rabbits (3.86kg) were ovariectomized (OVX) or Sham-OVXd. OVX rabbits were treated subcutaneously for 26wks with vehicle or 0.2 mg/kg 3X/wk alendronate (OVX+ALN). In-life double calcein labeling (8mg/kg) was done. At necropsy, right femur and second and third lumbar vertebrae (LV) were fixed in 70% ethanol. Bone mineral density (BMD, mg/cm^2) of the central and distal femur and the LV2 and LV3 bodies was measured (dual energy x-ray absorptiometry. 100∝m cross-sections of the mid-femur and 5∝m longitudinal sections of LV3 body were prepared from plastic-embedded specimens. Double labeled surface (MSBS, %) was measured in LV3 cancellous bone. Labeled Haversian canals/mm^2 (lb-HC) were counted in the femur. The three groups were compared (ANOVA with Fisher PLSD). LVBMD was 13% lower in OVX than Sham; LVBMD of ALN-treated OVX rabbits was 79% replete to Sham. No OVX-related differences occurred in the femur. MSBS was ~five-fold higher in OVX than Sham; MSBS of ALN-treated OVX rabbits was 86% replete to Sham. Lb-HC were absent in Sham rabbits, but strongly induced by OVX and strongly suppressed by ALN. Cancellous bone loss occurs in the vertebral body after six months post-OVX in rabbits. This loss is accompanied by increased cancellous and cortical bone turnover. All these changes are suppressed by ALN. Like humans, the adult rabbit has Haversian remodeling of cortical bone and develops estrogen deficiency spinal osteopenia, accompanied by accelerated remodeling of cancellous and cortical bone, all of which are prevented by anti-resorptive therapy.

Group	Sham(N=11)	OVX(N=10)	OVX+ALN(N=12)
LV-BMD	297±34	258±22s	289±29so
LV-MSBS	1.8±2.0	8.8±6.1s	2.8±3.2so
lb-HC	0±0	4.5±4.1s	0.3±0.9so

Mean±SD; s vs. Sham (P<.004); o vs. OVX (P<.02)

SA332

Duration and Severity of the Disease but not Menopausal Status are the Main Risk Factors for Osteoporosis in Primary Biliary Cirrhosis. N. Guañabens[1], A. Parés*[2], I. Ros*[1], L. Caballería*[2], F. Pons*[1], S. Vidal*[1], A. Monegal*[1], P. Peris[1], J. Rodés*[2]. [1]Metabolic Bone Diseases Unit, Hospital Clínic, Barcelona, Spain, [2]Liver Unit, Hospital Clínic, Barcelona, Spain.

Since the clinical spectrum of primary biliary cirrhosis (PBC) has changed in the last years, and the disease is diagnosed usually in postmenopausal women with minor cholestasis, it has been questioned whether PBC itself represents an extra risk for osteoporosis. Therefore this study was carried out to assess the prevalence and risk factors for osteoporosis in an unselected series of 142 women with PBC (age: 54.3 ± 0.8 years) and compared with the prevalence of osteoporosis in the Spanish women. Diagnosis of osteoporosis was established by densitometric criteria (Bone mineral density below –2.5 T-score). Age, duration of PBC, menopausal status, histological stage and severity of liver disease were assessed in all the patients. Prevalence of osteoporosis was significantly higher in PBC (32.4%) than in normal women (11.1%) (RR: 3.83, 95%CI: 2.59 to 5.67, p<0.001). Osteoporosis in PBC was associated with menopausal status (p<0.001), older age (60.2 ± 1.2 vs 51.5 ± 0.9 years, p<0.001), longer PBC duration (4.0 ± 0.6 vs 2.4 ± 0.3 years, p=0.004), advanced histological stage (p<0.001) and high bilirubin (1.96 ± 0.36 vs 1.36 ± 0.29 mg/dl, p=.003), and alkaline phosphatase levels (946 ± 124 vs 634 ± 48 4 u/l),

p=0.005), as well as low albumin (40.9 ± 0.6 vs 42.6 ± 0.4 g/l, p=0.02) and prothrombin index (94 ± 2 vs 99 ± 0.3 %, p<0.001). The stepwise logistic regression analyses identified duration of PBC, age, advanced histological stage and baseline bilirubin > 1.2 mg/dl, but not postmenopausal status as the independent risk factors for osteoporosis. In conclusion, osteoporosis is more prevalent in women with PBC than in general population. Age, duration and severity of the disease but not menopausal status are the main risk factors for osteoporosis in this liver disease.

Skeletal Kinetics at the Lumbar Spine in Postmenopausal Women on Antiresorptive Therapy and Controls Measured by 18F-Fluoride Positron Emission Tomography. M. L. Frost[1], G. J. R. Cook*[2], P. K. Marsden*[1], G. M. Blake[1], I. Fogelman[1]. [1]Radiological Sciences, Guy's, King's and St Thomas' School of Medicine, London, United Kingdom, [2]Department of Nuclear Medicine, Royal Marsden Hospital, London, United Kingdom.

The aim of this study was to compare skeletal kinetics in the lumbar vertebrae in postmenopausal women treated with antiresorptive therapy and controls, measured by 18F-fluoride positron emission tomography (PET). Nineteen women, with a mean age of 65.8 years and a T-score of less than -2 at the spine or hip, had a dynamic PET scan of the lumbar spine after the injection of 180 MBq 18F-fluoride ion. These women were split into two groups: (i) Group 1, women on stable antiresorptive therapy for at least 1 year (n=9); (ii) Group 2, women who were not receiving antiresorptive treatment (n=10). There were no significant differences in mean age, or spine and hip BMD between the two groups. The arterial plasma input function was derived using aorta arterial activity from the PET image. Time activity curves were measured by placing regions of interest over the lumbar vertebrae. A three-compartmental model and non-linear regression analysis were used to calculate the plasma clearance of tracer to bone mineral (K_{bone}) and the clearance of tracer to the whole of the bone tissue (K_{total}). K_{bone} and K_{total} relate to regional mineralisation and formation, and regional blood flow respectively. k2 to k4 were also measured which describe transport between plasma, the ECF compartment and the bone mineral compartment. Mean vertebral K_{bone} was significantly greater in Group 2 (3.35×10^{-2} ml . min^{-1} . ml^{-1}) compared with the mean for Group 1 (2.72×10^{-2} ml . min^{-1} . ml^{-1}), p=0.04. There was no significant difference in K_{total} between Group 1 (1.18×10^{-1} ml . min^{-1} . ml^{-1}) and Group 2 (1.29×10^{-1} ml . min^{-1} . ml^{-1}) p=>0.05. No significant differences were found in k2, k3 or k4. In conclusion, we have shown a direct effect of antiresorptive therapy on skeletal kinetics at the clinically important site of the lumbar spine. The use of 18F-fluoride PET may aid in our understanding of how different treatments for osteoporosis affect regional skeletal metabolism and may provide a useful non-invasive tool to assess novel treatments currently being developed for osteoporosis.

SA335

Effect of Chronic Alcohol Ingestion on Bone Mineral Density in Noncirrhotic Males. Y. Shin*. Endocrinology, Wonju College of Medicine, Wonju, Republic of Korea.

Background: Osteoporosis in men is an important public health problem. Because of the incremental tendency of elderly population and age-specific incidence of fracture, it is evitable that the health burden of fracture will increase. Chronic alcoholism is associated with osteoporosis and other risk factors such as fractures, poor nutrition, leanness, liver disease, malabsorption, vitamin D deficiency, hypogonadism, hemosiderosis, parathyroid dysfunction, and tobacco use. And these risk factors may contribute to the pathogenesis of bone disease in alcoholism. Chronic alcohol intake may reduce bone density but increase bone density. It has been well established that liver disease also induces changes in bone density, and thus it is difficult to distinguish the role of liver disease from that of alcohol itself in bone alterations occurring in patients with chronic alcohol consumption. The purpose of this study is to assess the effect of chronic alcohol consumption on bone mineral density in male chronic alcoholics without liver cirrhosis. **Methods**: We studied 18 chronic heavy drinkers of more than 40 g/day for at least 3 years and age-matched 18 control groups who had drunk alcohol less than 20 g/day. Serum and urinary parameters of bone and mineral metabolism were determined. Bone mineral density(BMD) was measured by dual-energy x-ray absorptiometry at four axial sites(lumbar spine, femoral neck, ward's triangle and trochanter). **Result**: Alcoholic patients drank alcohol 97.6 g/day and control groups drank alcohol 7.2 g/day. Osteocalcin, a marker of bone formation, was slight decreased in alcoholic patients and deoxypyridinoline, a marker of bone resorption, was slight increased but not statistically significant(P>0.05). The levels of free testosterone, estrogen, 25-(OH)-vit D, parathyroid hormone were not different between the two groups. The BMD of ward's triangle and trochanter of femur were significantly lower than controls, and decreased parallel with total alcohol intake amount in lumbar spine of the alcoholics(r=-0.62, P<0.05). **Conclusion**: We suggest that chronic alcohol consumption may induce low bone density on femur ward and trochanter. The large scaled randomized and prospective studies are needed to clarify the pathogenesis of alcohol-induced osteoporosis.

Individual Course of Trabecular Bone Density in Patients Treated with Alendronate. M. Neff[1], M. A. Dambacher[2], J. Schönbächler*[2], H. Radspieler[3], L. Qin*[4]. [1]Center for Osteoporosis, Zurich, Switzerland, [2]University Clinic Balgrist, Zurich, Switzerland, [3]Center for Osteoporosis, Munich, Germany, [4]Chinese University, Hong Kong, Hong Kong Special Administrative Region of China.

Purpose: Evidenced based medicine is based on studies of thousands of patients (Alendronate, Risedronate, Raloxifen) but in our daily practice we do not treat groups of patients, but individuals. We have evaluated the individual course of trabecular bone density in the first year of treatment with 10mg Alendronate. Methods: For this study we used the trabecular bone density evaluated by the high resolution peripheral quantitative Computed Tomography (hrpQCT), parameters: integral, trabecular and cortical bone density separately, reproducibility ± 0,3% in mixed collectives. Patients: 61 postmenopausal osteoporotic women (WHO definition: > -2,5 SD, T-Score, integral bone density). Results: See graph. After one year of treatment with 10mg Alendronate we found in 38% of the patients an increase of trabecular bone density, in 43% a steady state, in 5% a slow bone and in 14% a fast trabecular bone loss. Conclusions: These densitometric data fits the results of the Alendronate one year studies with a reduction of 50-60% fracture rate in the first year of treatment.

Individual Course of Trabecular Bone Density in Patients Treated with Risedronate. H. Radspieler*[1], M. A. Dambacher*[2], M. Neff*[3], J. Schönbächler*[2], L. Qin*[4]. [1]Center of Osteoporosis Munich, Muenchen, Germany, [2]University Clinic Balgrist, Zurich, Switzerland, [3]Center of Osteoporosis, Zurich, Switzerland, [4]Chinese University, Hongkong, China.

Purpose: Evidenced based medicine is based on studies of thousands of patients (Alendronate, Risedronate, Raloxifen) but in our daily practice we do not treat groups of patients, but individuals. We have evaluated the individual course of trabecular bone density in the first year of treatment with 5mg Risedronate. Methods: For this study we used the trabecular bone density evaluated by the high resolution peripheral quantitative Computed Tomography (hrpQCT), parameters: integral, trabecular and cortical bone density separately, reproducibility 0,3% in mixed collectives. Patients: 32 Postmenopausal osteoporotic women (WHO definition: > -2,5 SD, T-Score, integral bone density with or without vertebral fractures). Results: See graph. After one year of treatment with 5mg Risedronate we found in 71% of the patients an increase of trabecular bone density, in 12,5% a steady state, in 9,5% a slow and in 6% a fast trabecular bone loss. The average increase in trabecular bone density was 3,9% for all 32 patients. Conclusions: These densitometrie data fits the results of the Risedronate studies with a reduction of 50-60% fracture rate in the first year of treatment.

Adherence Profile of Etidronate (ETD), Alendronate (ALD) and Hormone Replacement Therapy (HRT) in Patients Registered in the Canadian Database of Osteoporosis and Osteopenia (CANDOO). A. Papaioannou[1], G. Ioannidis[1], R. J. Sebaldt[1], W. P. Olszynski[2], D. A. Hanley[3], A. Petrie*[1], J. P. Brown[4], R. Josse[5], T. Murray*[5], C. H. Goldsmith*[1], J. D. Adachi[1]. [1]McMaster University, Hamilton, ON, Canada, [2]University of Saskatchewan, Saskatoon, SK, Canada, [3]University of Calgary, Calgary, AB, Canada, [4]Laval University, Ste-Foy, PQ, Canada, [5]University of Toronto, Toronto, ON, Canada.

Therapies for osteoporosis must be taken over the longer-term (years) to be effective and to maintain their benefits over time. Potential barriers to long-term patient adherence to osteoporosis therapies may include the development of side effects, other medical reasons, drug costs, and loss of motivation. The purpose of this prospective observational study was to determine the difference in self reported adherence to ETD, ALD, and HRT in a group of patients registered in CANDOO. CANDOO is an observational database designed to longitudinally capture a standardized and comprehensive set of clinical data in patients referred to and followed by collaborating tertiary care centres. CANDOO was searched for women and men who were receiving either ETD, ALD or HRT. All patients may have also been taking concurrent calcium and vitamin D therapy. Patients were excluded if they did not start osteoporosis therapy on or after their first clinical visit and did not have at least one follow-up visit after initiating therapy. A total of 1196, 477, and 294 men and women with a mean age (standard deviation) of 67.0 (8.6), 66.3 (8.4), 60.1 (7.5) years, initiated ETD, ALD or HRT, respectively. At baseline, approximately 23, 27 and 12% of patients had prevalent vertebral fractures and 45, 48 and 37% of patients had prevalent non-vertebral fractures in the ETD, ALD and HRT groups. A Cox proportional hazards regression model was used to assess differences between treatment groups in the time to discontinuation of therapy (days). Several potential covariates such as anthropometric, medications, illnesses, and lifestyle factors were entered in the model. A forward selection technique was used to generate the final model. Hazard Ratios and 95% confidence intervals (CI) were calculated. Adjusted results indicated that ALD users were 42% (95% CI: 16, 73%) more likely to discontinue therapy as compared to ETD users. No significant differences were found between the HRT group and the two bisphosphonate groups. Potential barriers to long-term patient adherence to osteoporosis therapies should be considered prior to the initiation of treatment.

Decrease in Bone Resorption Markers in Response to Risedronate: Relationship to Decrease in Estimates of Bone Turnover Using Bone Histomorphometry. R. A. Hannon[1], R. L. Licence*[1], A. A. Chines[2], E. W. Sod[2], E. F. Eriksen[3], R. Eastell[1]. [1]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [2]Procter & Gamble Pharmaceuticals, Cincinnati, OH, USA, [3]University of Aarhus, Aarhus, Denmark.

Biochemical markers of bone resorption decrease rapidly and to different degrees in response to antiresorptive treatment. It is not known which markers of bone resorption best reflect changes in histomorphometric indices in response to treatment. The aim of this study was to compare changes in bone resorption markers with those in histomorphometric indices in postmenopausal osteoporotic women treated with 5mg risedronate plus 1g calcium per day for 36 months. Histomorphometric indices including activation frequency (AcF), volume-referent bone formation rate (BFR/BV) and bone resorption rate (BRs.R/BV), and mineralised surface (MS/BS) were assessed in bone biopsies obtained at baseline and 36 months from 30 women. Urinary N and C telopeptides of type I collagen (UNTX and UCTX), helical peptide (UHelical) and immunoreactive free deoxypyridinoline (UifDPD) were measured in second morning void urine collected at baseline and 36 months. Change in MS/BS at 36 months correlated (Spearman rank) with change in UNTX ($r = 0.77$, $p = 0.008$) and UHelical ($r = 0.66$, $p = 0.02$). Table shows median percentage changes and 95% confidence intervals at 36 months. The decreases in UNTX, UCTX and UHelical were not significantly different from each other or from changes in AcF, BFR/BV and BRs.R/BV (p=0.3 to 0.7) but were less than the decrease in MS/BS (p=0.02 to 0.07). The decrease in UifDPD was significantly less than the decreases in AcF, BFR/BV, BRs.R/BV and MS/BS ($p = 0.05$ to 0.0002). We conclude that treatment induced changes in dynamic markers such as UNTX, UCTX and UHelical may slightly underestimate the changes in bone histomorphometric indices of bone turnover.

	Median	CI_{upper}	CI_{lower}	n
AcF	-57	-72	-14	12
BFR/BV	-62	-75	0	12
BRs.R/BV	-57	-71	37	10
MS/BS	-74	-87	-37	23
UNTX	-50	-63	-26	20
UCTX	-39	-70	-22	20

Risedronate Reduced the Risk of Nonvertebral Fractures as soon as 6 Months in Postmenopausal Osteoporosis. M. L. Brandi[1], T. J. Harrington*[2], I. Barton*[3], L. G. Ste-Marie*[4]. [1]University of Florence, Florence, Italy, [2]University of Wisconsin, Madison, WI, USA, [3]Procter & Gamble Pharmaceuticals, Staines, United Kingdom, [4]University of Montreal, Montreal, PQ, Canada.

Risedronate has been shown to reduce the incidence of clinical vertebral fractures in as early as 6 months. Although vertebral fractures are most commonly associated with osteoporosis, nonvertebral fractures account for a large proportion of all osteoporotic fractures. The purpose of this analysis was to determine the onset of effect of risedronate (RIS) on nonvertebral osteoporotic fractures. The analysis included data from four studies that ranged in length from 12 months to 3 years. Postmenopausal women were enrolled into the clinical trials on the basis of low lumbar spine BMD and/or the presence of vertebral fracture at baseline. Data were analyzed for patients with a lumbar spine T-score<-2.5 (N=1172) regardless of prevalent vertebral fracture status at baseline (42% had no fractures, 25% had one fracture and 33% had >1 fracture). The effect of risedronate on nonvertebral fracture risk was based on a combined endpoint of hip, wrist, pelvis, clavicle, humerus and leg fractures. Nonvertebral fractures were collected as adverse events in 3-month intervals and were subsequently confirmed by radiograph. All patients received 1g/day calcium and either placebo or risedronate daily. Fracture incidence was calculated using Kaplan-Meier estimates and the treatment effect was determined using Cox proportional hazards regression model. The incidence of nonvertebral osteoporotic fracture in women with low lumbar spine BMD was significantly reduced as early as 6 months (p=0.048). There was a 74% reduction at 1 year (4.5% for control vs 1.2% for risedronate, p=0.001) and the effect was sustained over 3 years. Risedronate 5 mg/d significantly reduces the risk of nonvertebral osteoporotic fractures in as early as 6 months in women with postmenopausal osteoporosis. These findings provide additional support for the rapid onset of anti-fracture effect observed with risedronate treatment at both vertebral and nonvertebral sites.

Effect of Whole Body Vibration on Bone and Muscle Performance. S. B. Torvinen*[1], P. S. Kannus*[1], H. T. Sievänen*[2], T. A. H. Järvinen*[3], M. E. Pasanen*[2], S. A. Kontulainen*[2], A. M. Nenonen*[2], T. L. N. Järvinen*[3], T. Paakkala*[4], M. J. Järvinen*[5], M. I. Vuori*[2]. [1]UKK Institute, University of Tampere, Tampere, Finland, [2]UKK Institute, Tampere, Finland, [3]Medical School, Institute of Medical Technology, University of Tampere, Tampere, Finland, [4]Department of Radiology, Tampere University Hospital, Tampere, Finland, [5]Department of Surgery, Tampere University Hospital, University of Tampere, Tampere, Finland.

Recent animal studies have given evidence that vibration loading may be an efficient way to improve mass and mechanical competence of bone thus possessing great potential for preventing and treating osteoporosis. Randomized controlled human studies are, however, lacking. This randomized controlled trial was designed to assess the effects of an 8-month whole body vibration on mass, structure and estimated strength of bones in young adults. In addition, the effects of vibration on muscle performance and body balance were determined. 56 volunteers (aged 19-38 years) were randomly assigned to either the vibration or control group. The vibration intervention consisted of an 8-month whole body vibration (4-min/day, 3-5 times a week), the stimulus being employed by standing on a vertically vibrating platform. During the 4-min vibration program, the platform oscillated in an ascending order from 25 Hz-45 Hz corresponding to estimated, maximum vertical accelerations from 2-8 g (1 g = 9.81 ms-2). Bone mass, structure and strength at the distal tibia and tibial shaft were measured by pQCT at baseline and at 8 months. Bone mineral content was measured at the lumbar spine, proximal femur, calcaneus and distal radius using DXA at baseline and at 8

months. Osteocalcin, CTx, P1NP and TRAP5b were determined at baseline and at 2, 4, 6, and 8 months. Vertical jump, isometric extension strength of the lower extremities, grip strength, shuttle run, and postural sway-tests were performed at baseline and at 8 months. The vibration intervention succeeded well and was safe to perform but had no effect on bone mass, structure or strength at any skeletal site. Instead, at 8 months a 7.8 % net benefit in the vertical jump height was seen for the vibration group (p=0.003). On the other performance or balance tests, the vibration intervention had no effect. An 8-month whole body vibration intervention had no effect on mass, structure or mechanical strength of bones in young, healthy adults. Except for increased vertical jump height, neither muscular performance nor body balance improved due to vibration. Since the results of this randomized clinical trial were not as positive as those of the recent animal investigations, future human studies are definitely needed before any clinical recommendation for vibration exercise.

The Orthosis Spinomed Improves Posture, Trunk Muscle Strength, and Quality of Life in Women With Vertebral Fractures: Results of a Prospective, Randomized, Cross-over Study. M. Pfeifer, B. Begerow*, H. W. Minne. Institute of Clinical Osteology, Bad Pyrmont, Germany.

Thoracolumbar braces are widely used in the care of patients with vertebral fractures due to osteoporosis. Their usefulness, however, has never been tested under standardized conditions. To our knowledge, this is the first randomized, controlled, prospective, cross-over study to determine the efficacy of an orthosis in the treatment of spinal osteoporosis. In this cross-over study, patients had been randomized into two groups: group A started with an intervention period of six months, while group B served as controls. After 6 months groups changed. Measurements include trunk muscle strength, body sway, angle of kyphosis, pain, and limitations of everyday life and were performed at base-line and every three months thereafter. At base-line, we did not observe any differences between both groups concerning age (p=0.77), height (p=0.90), weight (p=0.84), loss of height (p=0.25) and number of vertebral fractures (p=0.87). Results are presented in Table 1. Spinomed back support improves posture, trunk muscle strength, lung function, body sway, and quality of life in postmenopausal women with osteoporosis and may therefore play an integral part in the rehabilitation process of osteoporotic patients. The efficacy of thoracolumbar braces needs to be further investigated in prospective, randomized and controlled clinical trials.

Initial Values and Changes at 6 Months in 61 Study Subjects

Angle of Kyphosis	Initial Value	Change at 6 Months	P-Value
Group A	74.2 +/- 9.8 (°)	-2.2 +/- 4.1 (°)	0.007
Group B	69.8 +/- 9.9 (°)	+1.4 +/- 4.3 (°)	
Back ext strength	Initial Value	Change at 6 Months	P-Value
Group A	264 +/- 131 (N)	+122 +/- 107 (N)	<0.001
Group B	262 +/- 119 (N)	+ 18 +/- 55 (N)	
Abd flex strength	Initial Value	Change at 6 Months	P-Value
Group A	165 +/- 71 (N)	+66 +/- 61 (N)	0.005
Group N	155 +/- 64 (N)	+25 +/- 41 (N)	
Body Sway	Initial Value	Change at 6 Months	P-Value
Group A	84 +/- 70 (mm)	-14 +/- 45 (mm)	0.045
Group B	78 +/- 37 (mm)	+10 +/- 43 (mm)	
Vital Capacity	Initial Value	Change at 6 Months	P-Value
Group A	83 +/- 21 (%)	+0.5 +/- 13.0 (%)	0.022
Group B	93 +/- 16 (%)	-8.2 +/- 12.9 (%)	
Pain	Initial Value	Change at 6 Months	P-Value
Group A	4.0 +/- 1.1 (Pts.)	-0.9 +/- 1.0 (Pts)	<0.001
Group B	3.9 +/- 1.0 (Pts.)	+0.1 +/- 0.9 (Pts)	
Limi Daily Living	Initial Value	Change at 6 Months	P-Value
Group A	4.8 +/- 1.9 (Pts.)	-1.3 +/- 1.4 (Pts)	0.007

Daily Activity Triples the Efficacy of PTH on Cortical Bone Formation in Adult Female Rat. Y. Mikuni-Takagaki[1], K. Aoki[2], M. Takahashi*[2], K. Ohya[2], M. Itoman*[3]. [1]Kanagawa Dental College, Yokosuka, Japan, [2]Tokyo Medical and Dental University, Graduate School, Tokyo, Japan, [3]Kitasato University School of Medicine, Sagamihara, Japan.

Controlled clinical trials showed that daily subcutaneous injections of low doses of parathyroid hormone (PTH) reduced incidence of osteoporosis-related fractures. While the ovariectomized rats provide an excellent animal model for postmenopausal osteoporosis, no such models are available for disuse osteopenia. The purpose of this study is to confirm our previous observation in isolated rat osteocytes of synergy between PTH and mechanical loading, *in vivo*. Thirty-week-old female Wistar rats were either housed in cages of limited space (RESTRAINED) or allowed free activity (CONTROL) in the institutional standard cages. Rats were injected subcutaneously with 10 μg/kg human PTH (1-34) (Asahi Chemical Co.) or saline three times a week for 6 weeks. Restrained rats were not apparently stressed judged by their serum cortisol levels. Calcein was injected twice for measuring mineral apposition rate (MAR). After measuring tibial BMD by pQCT, histomophometric analysis was carried out by confocal microscopy. As shown in Table I, MAR of RESTRAINED and PTH groups are significantly different (p<0.001) and the difference, 22.7, is much larger than the added differences between RESTRAINED and CONTROL (5.5, not significant) and RESTRAINED and RESTRAINED + PTH (6.4, not significant). Proximal cortical BMD at 6 weeks also showed a significant difference between the RESTRAINED and PTH (p<0.001) in a similar manner. Also confocal microscope images showed larger numbers of brighter periosteocytic calcein labels in PTH group compared to RESTRAINED rats, suggesting that the osteocytic mineralizing activity was upregulated by combined effects of PTH and daily activity of rats. RT-PCR experiments using cortical bone pulverized by CRYO-PRESS showed a significant difference in messages such as collagenase and IGF-I, reported markers of osteocytic response to mechanical environment. From these results, we suggest the critical role of osteocytes in sensitizing bone to PTH during daily activity and propose the combined use of physical stimulation (exercise) and PTH when treating osteoporoticpatients.

Table I. MARx10 (μm/10 days) in tibial cortical bone at the end of the 6-week experiment.

	Mean	SD	SE
RESTRAINED	16.4	3.8	1.9
CONTROL	21.9	3.9	1.9
PTH	39.1	7.6	3.8
RESTRAINED + PTH	22.8	9.3	4.7

SA350

Functional Outcome of Elderly Patients with Vertebral Compression Fractures. J. T. Lin*[1], E. Myers*[2], S. Backus*[3], M. Peterson*[4], A. Poynton*[5], J. M. Lane[5]. [1]Rehabilitation Medicine, The New York-Presbyterian Hospital, New York, NY, USA, [2]Biomechanics, Hospital for Special Surgery, New York, NY, USA, [3]Rehabilitation Medicine, Hospital for Special Surgery, New York, NY, USA, [4]Statistics, Hospital for Special Surgery, New York, NY, USA, [5]Orthopedics, Hospital for Special Surgery, New York, NY, USA.

The purpose of our study was to assess functional outcome using functional tests in a case-control study of osteoporotic patients with and without vertebral compression fractures. The tests were chosen to reliably identify specific deficiencies such as decreased endurance, flexibility, and functional gait performance. Outcome variables were correlated with the presence of fracture and the age of patients. Thirty-one osteoporotic patients with and without compression fracture physically capable underwent functional evaluation in the motion analysis laboratory, including timed up and go, functional reach, six minute walk, and bilateral single limb stance testing. Age of patients and number of fractures were recorded. Patients without compression fractures vs. patients with compression fractures (range 1-5 fractures) had an average age of 68.4 ± 10.5 years vs. 71.7 ± 7.0 years, timed get up and go 8.63 ± 3.30 seconds vs. 10.32 ± 4.98 seconds, functional reach = 11.38 ± 2.84 inches vs. 10.19 ± 2.71 inches, 6 minute walk = 365.02 ± 98.34 meters vs. 333.43 ± 123.05 meters, average right single limb stance = 10.48 ± 6.61 seconds vs. 7.03 ± 7.73 seconds, and average left single limb stance = 11.2 ± 7.29 seconds vs. 7.14 ± 7.26 seconds, respectively. There was a negative correlation between age and ability to perform six minute walk (Pearson correlation = -0.39, p=0.03), average right single stance (Pearson correlation = -0.485, p=0.019), and left single limb stance (Pearson correlation = -0.573, p=0.04). This suggests that age may represent a confounding variable in our analysis. Our preliminary findings suggest that there may not be direct relationships between presence of compression fracture and functional performance. There may be other variables, including the amount of kyphosis or location of fractures, that significantly impact function. A limitation of this study is that patients with severe pain or physical disability were not evaluated. Thus, the subjects with fracture were possibly a healthier subset of fracture patients. Our data should help identify reliable tests in osteoporotic patients with compression fractures to better direct medically-supervised physical therapy programs and to serve as the foundation for future prospective clinical trials, which will further evaluate the relationship between kyphosis and loss of function/impaired performance in kinesiologic measures.

SA351

Results of the Erlangen Fitness and Osteoporosis Prevention Study (EFOPS) -During Year 2 Exercise Effects Level Off at the Lumbar Spine but not at the Proximal Femur. W. Kemmler*[1], K. Engelke*[1], J. Weineck*[2], W. A. Kalender*[1]. [1]Inst. of Medical Physics, Univ. of Erlangen, Erlangen, Germany, [2]Inst. of Sport Sciences, Univ. of Erlangen, Erlangen, Germany.

Several recent exercise studies using high impact training regimes showed beneficial effects on bone. However, many exercise studies, in particular those with larger sample sizes (>50), did not extend over one year. Here we analyzed 2 year results from EFOPS (Erlangen Fitness Osteoporosis Prevention Study) and investigated whether bone mineral density (BMD) changes leveled off after one year of training, similar to observations in interventions using HRT or Bisphosphonates. EFOPS is an ongoing 3-year controlled exercise trial in 137 early (1 - 8 y) postmenopausal women with osteopenia at the lumbar spine or the hip. 86 women (EG) undergo a vigorous high impact/high intensity regime 2-4 times/week (2 joint, 2 home sessions). 51 non-exercising aged, BMI, and BMD matched women serve as control group (CG). Both groups are individually supplemented with Ca and Vit-D. After 2 years 50 women exercising more than 2 times/week and 33 women of the control group remained in the study. %-changes of isometric strength and BMD (measured by DXA) are shown in the tables (mean ± SD) along with corresponding differences for the two groups. In the EG BMD increased or was stable while in the CG BMD significantly decreased during the two years. However, at the spine BMD changes in the EG during year one (+1.3%) differed significantly from year two (-0.6%). Differences between year one and two were also significant for the trunk extensors in the EG. All other differences between variables shown in the table were non significant. Taken together our results show a significant leveling-off effect on BMD at the LS but not at the proximal femur during year 2.

Isometric Strength of the Trunk

Variable (%-changes)	EG (n = 50)	CG (n = 33)	Difference
Trunk extensors year 1	+31.1 ± 19.0***	-0.6 ± 15.7 n.s.	***
Trunk extensors year 2	+6.3 ± 12.4*	-2.4 ± 14.8 n.s.	*
Trunk flexors year 1	+23.8 ± 19.7 ***	-1.4 ± 15.4 n.s.	***

Influence of Hypogonadism and Hormone Replacement Therapy (HRT) on Bone Mass in Adult Women with Thalassaemia Major. G. B. Rini*[1], M. L. Brandi[2], G. Renda*[1], G. Di Fede*[1], G. Cusumano*[1], N. Napoli*[1], D. Bruno*[1], G. Vitale*[1], E. Carmina*[1]. [1]Clinical Medicine, University of Palermo, Palermo, Italy, [2]Internal Medicine, University of Florence, Florence, Italy.

Osteopenia and/or osteoporosis are major causes of morbidity in adult thalassaemic patients. The purpose of the study was to evaluate the influence of hypogonadism and HRT on bone mass in adult women with thalassaemia major. 30 adult women (mean age 28.5 ± 1.3 years, range 21-41) with thalassaemia major were studied. In all patients and in 10 normal controls of similar age (29.5 ± 1 years) blood levels of estradiol, LH, FSH, PTH, osteocalcin, bone alcaline phosphatase (AP) and type 1 collagen C-telopeptides (T) were determined. Hormones were measured by RIA methods while bone markers were determined by ELISA. Bone mineral density (BMD) of the lumbar spine (L1-L4) and of the femoral neck (F) was determined using dual X-ray absorptiometry. 6 patients (mean age 29 ± 2 years) had normal ovarian function. Compared to controls, they had similar blood levels of PTH (21 ± 3 vs 22.2 ± 5 ng/ml in controls), osteocalcin (16 ± 3 vs 18.4 ± 1.5 ng/ml in controls), AP (13 ± 1 versus 14.3 ± 1.5 µg/L in controls) and T (2958 ± 82 vs 3192 ± 315 pmol/L in controls). Their T score (L1-L4 - 1.33 ± 0.37, femoral neck - 0.64 ± 0.36) was lower than in controls, but the difference was significant ($p < 0.05$) only for L1-L4. 24 patients (mean age 28.2 ± 1.5 years) presented hypogonadism. 11 of these patients were never treated by HRT. Compared to controls, they presented similar blood levels of PTH (24.2 ± 3.5 pg/ml) and osteocalcin (23 ± 3.5 ng/ml) but higher levels of AP (21.6 ± 2.5, µg/L, $p < 0.05$) and T (5380 ± 657, pmol/L, $p< 0.01$). They presented a significantly decreased BMD (T score: L1-L4 - 2.44 ± 0.24, $p< 0.01$ vs controls and $p < 0.05$ vs normogonadic patients; F - 1.8 ± 0.22, $p< 0.01$ vs controls and vs normogonadic patients). 13 thalassaemic patients had been treated from a mean of 11 ± 2 years by HRT (conjugated estrogen 0.625 mg/day or equivalent + progestin). Compared to controls, they presented similar levels of PTH (25.8 ± 2.1 pg/ml), osteocalcin (22.2 ± 3.1 pg/ml) but higher levels of AP (23.6 ± 2.9 µg/L, $p< 0.05$) and T (4548 ± 539 pmol/L, $p< 0.05$). In comparison to both controls and normogonadic patients, their T score was significantly ($p< 0.01$) decreased (L1-L4 - 2.66 ± 0.25, F -1.97 ± 0.31). There was not difference in T score and in bone hormones or markers between hypogonadic patients who were treated or not with HRT. In conclusion: 1. hypogonadism is the major, but not the only, factor in determining bone loss in adult thalassaemic women, 2. Low dose HRT is not sufficient to prevent bone loss in adult thalassaemic women. Probably higher estrogen doses or biphosphonates are needed to prevent bone loss in these patients.

SA353

Bone Mineral Density Changes in a One Year Placebo Controlled Double Blind Randomized Trial of Hormone Replacement Therapy in Postmenopausal Systemic Lupus Erythematosus Patients. H. P. Bhattoa[1], P. Bettembuk[1], A. Balogh[1], G. Szegedi*[2], E. Kiss*[2]. [1]Department of Obstetrics and Gynecology, University of Debrecen, Debrecen, Hungary, [2]3rd Department of Internal Medicine, University of Debrecen, Debrecen, Hungary.

Although there are valid concerns regarding the use of exogenous estrogens in women with SLE, there are also potential health benefits to be considered. Several salutary effects of postmenopausal estrogens assume particular importance in SLE where the risks of osteoporosis, exaggerated by menopause (natural or cyclophosphamide-induced) and glucocorticoids, are substantial. We examined the safety and efficacy of hormone replacement therapy (HRT) in postmenopausal SLE patients. We planned a prospective examination of BMD for a year in a placebo controlled double blind study. Postmenopausal SLE women were randomly allocated to placebo or treatment group (50 microgram trans-dermal estradiol). Both groups received 5 mg continuos oral medroxyprogesterone acetate, 500 mg calcium and 400 IU vitamin D3. The patients confirmed to the ACR SLE criteria, T score < -1.0 and had no other disease influencing bone metabolism. Exclusion criteria were: risk factors for thrombo-embolism, serious liver or kidney disease, vaginal bleeding of unknown origin, breast tumor, endometrial carcinoma, and endometriosis. Follow-up visits took place at 3, 6, 9 and 12 months. From the 43 patients that were screened 32 could be included in the study, of whom 15 were in the treatment group and 17 in the placebo group. There was no significant difference between the two groups at baseline with regards to their mean age, disease duration, body mass index, duration of menopause, SLE disease activity index, SLICC, daily and cumulative corticosteroid dose. At the end of the study, 6 and 14 remained in the treatment and placebo group, respectively. In both the groups we found no statistically significant change in BMD during the study period. There was no statistically significant difference in the femur neck values between the two groups during the study period. There was a significant difference in the change in lumbar spine BMD between baseline and the 6th month visit between the two groups (+3,2% (treatment) vs. -1,0% (placebo); $p < 0.005$). Although the dropout rate was high, none was due to disease activation. Although the high dropout rate makes statistical interpretation at the end of the study period difficult, we conclude that HRT can be safely prescribed to postmenopausal SLE patients under strict medical supervision.

Carborane BE360, One of the Carbon-containing Polyhedral Boron-cluster Compounds, Is A New Type of Selective Estrogen Receptor Modulator. C. Miyaura[1], C. Matsumoto*[1], Y. Endo*[2], A. Ito*[1]. [1]Department of Biochemistry, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [2]Tohoku Pharmaceutical University, Sendai, Japan.

Carboranes (dicarba-*closo*-dodecaboranes) are a class of carbon-containing polyhedral boron-cluster compounds having exceptional hydrophobicity, and their features may allow a new medical application as a biologically active molecule that interacts hydrophobically with hormone receptors. We designed carborane compounds with an affinity for estrogen receptor (ER) and synthesized these compounds to search for effective agents to treat osteoporosis. Among several carborane compounds, we noted two compounds, BE120 and BE360. BE120 has a carborane structure with one phenol and is the most potent compound bearing a carborane cage exhibiting a binding affinity for ER. Its binding affinity with ERα is 10-fold greater than that of 17β-estradiol (E2). BE360 has a carborane structure with two phenols, and its ER binding affinities are 1.6-fold to ERα and 0.15-fold to ERβ compared with E2. To examine the estrogenic activity of these compounds in bone, ovariectomized (OVX) mice were given BE120, BE360 or E2 subcutaneously for 4 weeks using a miniosmotic pump. Reduced uterine weight in OVX mice was completely restored by not only E2 but also BE120. However, 1000-fold higher doses of BE360 did not increase the uterine weight of OVX mice. Histological analysis also showed that BE360 did not exhibit any estrogenic activity in the uterus. In OVX mice, the trabecular bone volume of the femoral distal metaphysis was reduced markedly, when measured by DEXA and histological analysis. Treatment with BE120 at 1-30 ng/head/day markedly prevented bone loss in OVX mice, and its effective doses in bone and uterus were similar to those of E2. BE360 at 1-30 µg/head/day dose-dependently restored bone loss in OVX mice to a sham level without estrogenic action in the uterus. Therefore, 1000-fold higher does of BE360 were needed to prevent bone loss in OVX mice compared with that of E2 and BE120. To examine the effects of BE360 in bone in castrated mice, male mice were sham-operated or orchidectomized (ORX) and a subgroup of ORX mice was treated with BE360. Treatment with BE360 at 1-30 µg/head/day prevented bone loss in ORX mice without androgenic action on the sex organs. These results indicate that BE360 binds to ERs and exhibits estrogenic action in bone to prevent bone loss without inducing estrogenic action in the uterus, suggesting its possible application to osteoporosis as a new type of selective estrogen receptor modulator.

Effect of Raloxifene on Bone Mineral Density and Bone Markers in Japanese Postmenopausal Women with Osteoporosis. H. Morii[1], Y. Taketani[1], Y. Ohashi*[1], T. Nakamura*[1], M. Fukunaga*[1], A. Itabashi[1], S. Sarkar*[2], K. D. Harper[2]. [1]Japan Clinical Trial Research Group, Tokyo, Japan, [2]Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN, USA.

Raloxifene (RLX) is a selective estrogen receptor modulator (SERM) that acts as an estrogen agonist on the skeleton and on cardiovascular risk markers but as an antagonist in the endometrium and the breast. The safety and efficacy of RLX has been studied extensively in large, global clinical trials. Study 301J assessed the safety and efficacy of raloxifene 60 mg/day (RLX60) and 120 mg/day (RLX120) in Japanese postmenopausal women with osteoporosis after one year of therapy. 284 postmenopausal women (mean age, 64 years) with osteoporosis (lumbar spine L2-L4 T-score ≤ -2.5 SD) were enrolled in a multicenter, double-blind study that lasted 52 weeks. They were randomly assigned to receive placebo (PL), RLX60, or RLX120. All treatment groups received calcium 500 mg/day and vitamin D_3 200 IU/day. Lumbar spine bone mineral density (BMD) and markers of bone turnover (osteocalcin, bone-specific alkaline phosphatase, NTx/Cr, and CTx/Cr) were assessed at baseline, 12, 24, and 52 weeks and serum lipids (total cholesterol, LDL-C, HDL-C, and TG) were assessed at baseline, 12, 24, 40, and 52 weeks. Ultrasound examinations of the breast and endometrium were performed at 52 weeks. Routine physiological examinations and safety laboratory tests were performed at each visit. Compared to baseline, women taking RLX60 had significant increases in lumbar spine BMD at week 24 (+3.3%, p<0.001). This increase in BMD remained significant through 52 weeks (+3.5%, p<0.001). At 52 weeks, significant increases in BMD from baseline were also observed in the RLX120 group (+2.9%, p<0.001). No change in BMD from baseline was observed in the PL group (0.0%, p = 0.989). By week 52, among women taking RLX, significant reductions were observed in all markers of bone turnover compared to PL (p<0.001), which is consistent with previous observations (Ettinger et al. JAMA 1999; 282:637-45). Compared to PL, women taking either dose of RLX had significant reductions in total cholesterol and LDL-C (p < 0.05) but no change in HDL-C or TG. Overall, there were no significant treatment differences in the proportion of patients who reported at least one adverse event following randomization (p = 0.851). While no episodes of venous thromboembolism were reported, this is a rare adverse event that may not have been seen in this small sample of patients. The results of this study demonstrate that raloxifene is well-tolerated, is associated with early and sustained increases in lumbar spine BMD and has favorable effects on bone turnover markers and lipids in Japanese postmenopausal women.

The Effects of Raloxifene on Bone Mass and Remodeling are not Mediated by a Modulation of Nitric Oxide Synthesis. M. Diaz-Curiel[1], M. Lefort*[2], C. De La Piedra[2], A. Lopez-Farre*[3]. [1]Medicina Interna, Fundacion Jimenez Diaz, Madrid, Spain, [2]Laboratorio Fisiopatologia Osea, Fundacion Jimenez Diaz, Madrid, Spain, [3]Laboratorio de Investigacion Cardiovascular e Hipertension, Fundacion Jimenez Diaz, Madrid, Spain.

Raloxifene (RLX), a selective estrogen receptor modulator, is used in the prevention and treatment of postmenopausal osteoporosis. Recent works show that nitric oxide (NO) is a regulator of bone remodeling, the fall of NO levels increasing bone resorption. The aim of this work was to study if the administration of RLX to ovariectomised rats, an experimental model of postmenopausal osteoporosis, produced any effects on NO pathway, and if its effects on bone mass and remodeling were changed by the administration of aminoguanidine (AG), and inhibitor of the NO-synthase (NOS). Fifty 15 week-old female Wistar rats were ovariectomised (OVX). Thirteen age-and-sex matched rats were sham operated (SHAM). OVX rats were divided in groups: 1) OVX+RLX: received orally 1 mg/kg/day of RLX analogue (LY 139481.HCl,Lilly); 2) OVX + RLX + AG: received RLX and AG (4 g/L in drinking water); 3) OVX: received vehicle. Treatments were followed during 3 months. BMD was determined in the left femur (f) and lumbar spine (l) by DEXA. Osteocalcin (BGP) and C-terminal telopeptide of collagen I (CTX), biochemical markers of bone remodeling, were determined in serum. Inducible NOS (ions) activity and endothelial NOS (eons) expression by Western blot were analysed. OVX presented a significant decrease in l and f BMD and an increase in BGP and CTX respect to SHAM rats. RLX administration decreased bone remodeling and prevented bone loss in OVX rats, and these protective effects were not influenced by AG. Values of eNOS in group (OVX + RLX) were significantly higher than that of SHAM, OVX or (OVX + RLX + AG) groups, whose eNOS levels were similar. However, iNOS levels were similar in all the studied groups. We can concluded that the beneficial effects of RLX on bone mass and remodeling in OVX rats do not seem to by mediated by a modulation of iNOS activity. On the other hand, although the increase in eNOS expression produced by RLX in OVX rats is annulled by AG, the positive actions of RLX on bone does not seem to be influenced by eNOS levels.

Osteogenic Effects of PTH in Osteoblast-like Cells Is Enhanced by Alendronate Pre-Treatment. D. L. Halladay*[1], T. J. Martin[2], J. E. Onyia*[1]. [1]Gene Regulation, Bone and Inflamation, Eli Lilly & Company, Indianapolis, IN, USA, [2]Saint Vincent Institute of Medical Research, Fitzroy, Australia.

Alendronate (ABP) is a treatment for postmenopausal osteoporosis that has been shown to strongly suppress bone turnover, by inhibiting bone resorption and secondarily reducing bone formation activity. While the direct effects of ABP on osteoclasts is well documented, there is limited information on their actions on osteoblasts that may in part explain their ability to reduce bone formation activity. For example, it is not known if ABP pretreatment of osteoblasts could interfere with their ability to express osteogenic genes and/or respond to an osteogenic stimulus such as PTH. Therefore, we examined directly the actions of 1-100 µM ABP on the expression of bone genes (Runx-2 and osteocalcin) in the human osteosarcoma cell-line SaOS-2. SaOS-2 cells stably transfected with a reporter construct containing the luciferase gene driven by either Runx-2 promoter, 6 copies of Runx-2 binding site (p6OSE2-luc) or osteoclacin promoter were analyzed for activity after ABP treatment. To ascertain possible effects of ABP on an osteogenic response, ABP pre-treated and untreated cells were also sequentially challenged with PTH. After 8h, ABP alone had no effect on expression of any gene. After 24h, ABP at 1-100 µM concentrations had a small but significant inhibitory effect (20-25%) on Runx-2, p6OSE2-luc and osteocalcin expression. PTH treatment resulted in a dose dependent increase in the expression of Runx-2 promoter (170-200%), p6OSE2-luc (500%) and osteocalcin promoter (300%). Simultaneous addition of ABP and PTH did not alter any of the PTH stimulatory effects on these osteogenic genes. In contrast, ABP pre-treatment (24h) followed by PTH resulted in a 1.5-2 fold enhanced expression of p6OSE2-luc (to 700-1000%) and osteocalcin promoter (to 400-600%) over PTH alone treatment. Since PTH regulates these promoters in part via the cAMP-PKA pathway, we further examined the effect of forskolin on ABP treated cells. As with PTH, ABP pre-treatment enhanced forskolin's stimulatory effects (2-3 fold enhancement over forskolin alone) on p6OSE2-luc and osteocalcin promoter. Simultaneous addition of ABP and forskolin did not alter any of the forskolin's stimulatory effects on these osteoblast genes. These data are consistent with a direct effect of ABP on osteoblast function and indicate that ABP pre-treated osteoblast-like cells remain responsive to the osteogenic effects of PTH, which are possibly mediated via the c-AMP-PKA signaling pathway. Taken together, these observations imply that regardless of ABP treatment history, osteoblast-like cells remain responsive to PTH.

Biological Activity of Recombinant PTH Analog UGL7841. N. M. Mehta[1], J. P. Gilligan[1], B. Stern*[1], M. V. L. Ray*[1], C. P. Meenan*[1], A. P. Consalvo*[1], E. Miranda*[1], X. Peng*[2], A. Vignery[2], V. Ross*[3], J. F. Whitfield[3], P. Morley[4]. [1]Unigene Laboratories, Inc., Fairfield, NJ, USA, [2]Yale University School of Medicine, New Haven, CT, USA, [3]National Research Council, Ottawa, ON, Canada, [4]ParaTecH Therapeutics Inc., Ottawa, ON, Canada.

Recombinant production of a PTH analog was achieved by direct expression of the peptide in *E. coli.* A fermentation protocol was developed where the glycine-extended peptide was secreted into the conditioned growth medium at levels of approximately 1 g/liter. The secreted peptide was partially purified, amidated *in vitro* at the C-terminus using recombinant peptidylglycine α-amidating monooxygenase, and further purified to homogeneity with an overall yield of >50%. The bioactivity of the recombinant peptide was evaluated *in vitro* by its ability to stimulate intracellular cAMP in ROS17/2 osteosarcoma cells. The ED_{50} values of the recombinant peptide, compared to that of the same peptide obtained by chemical synthesis, were determined to be equivalent (4.1×10^{-9} M and 4.2×10^{-9} M, respectively). The *in vivo* anabolic activity of the recombinant peptide was evaluated in an OVX rat model using 3-month old Sprague-Dawley rats. Subcutaneous injections of synthetic or recombinant PTH analog at 0.6 and 2.0 nmol/100 grams body weight were started two weeks after ovariectomy and then given once a day, 6 days a week for 4 weeks. At the end of the experiment distal femurs were removed, fixed and sectioned. The ability of the recombinant or synthetic PTH analog to stimulate trabecular growth in the cancellous bone of the distal femurs was assessed by bone histomorphometry. Both the recombinant and synthetic peptides were shown to give a statistically significant and dose-dependent increase in femoral trabecular volume and trabecular thickness compared to the ovariectomized vehicle-treated controls. This bioactive recombinant PTH analog is currently being evaluated as an oral therapeutic for the treatment of established osteoporosis.

SA363

Intermittent hPTH Administration Increases Bone Strength in Rat Lumbar Vertebral Body after Ovariectomy with Cortical Bone Mass Increase. S. Arita*[1], S. Ikeda*[1], M. Ito*[2], A. Nishida*[2], T. Nakamura[1]. [1]Orthopedic Surgery, University of Occupational and Environmental Health, Kitakyushu, Japan, [2]Nagasaki University School of Medicine, Nagasaki, Japan.

Ovariectomy (ovx) causes significant bone loss and fragility of bone strength in rats, but the varies can be reversed by treatment with human parathyroid hormone 1-34 (hPTH). To clarify the factor to determine the recover of ultimate strength in rat lumbar vertebra after ovx, we compared the results of skeletal measurements by micro-CT, pQCT and ultimate compression load by mechanical tests on the 5th lumbar vertebra. Female Sprague-Dawley rats (n = 204), 16 weeks of age, were divided into 21 groups. Ten rats were killed at day 0 as the baseline control, the others underwent ovx (n = 125) or sham surgery (n = 69). At 6weeks postsurgery, ovx rats were given subcutaneous injections of hPTH three times a week at respective dose of 0 (vehicle group) and 20micro gram/kg body weight (PTH group) for 12 weeks. Sham groups were administered vehicle only. In PTH group, trabecular bone volume (BV/TV) and trabecular thickness (Tb.Th), measured by micro-CT, increased from day 28 compared with vehicle group. The trabecular bone pattern factor (TBPf) and structure model index (SMI) diminished from day 28 compared with vehicle group. The total bone mineral content (BMC), total bone mineral density, cortical BMC, cortical area and cortical thickness measured by pQCT increased from day 28 compared with vehicle group. Ultimate compression loads increased from day 28 compared with vehicle group. In the early period (0-42 days) of PTH treatment, ultimate compression loads increased by 30.3%, and the late period (42-84 days), it increased by 0.02%. In the early period, cortical BMC was the most significant factor that influenced the ultimate load in PTH group, as assessed by stepwise regression analysis (coefficient of determination [R2]=0.663; p<0.0001). These data suggest that increases in cortical bone mass contributes more than that of trabecular bone mass and structure to recovery of bone strength by intermittent hPTH administration in rat lumber vertebral body after ovx.

Human Parathyroid Hormone 1-34 Prevents Bone Loss in Bile Duct-Ligated Rats. R. Dresner Pollak[1], Z. Ackerman*[1], A. J. Foldes[1], M. Weinreb[2]. [1]Hadassah University Hospital, Jerusalem, Israel, [2]Goldschleger School of Dental Medicine, Tel-Aviv University, Tel-Aviv, Israel.

Reduced bone mass and fractures are common manifestations of primary biliary cirrhosis (PBC) in humans. We have previously demonstrated that bile duct-ligated (BDL) male rats develop osteopenia caused by a decreased rate of bone formation (Ackerman et al. Liver, in press). In this study we evaluated whether the administration of the anabolic agent parathyroid hormone (PTH) 1-34 prevents bone loss in BDL rats. Six month-old Sprague-Dawley male rats were divided into 4 groups: Group 1 underwent sham operation and was treated with a vehicle for 4 weeks. Groups 2-4 underwent BDL operation and, beginning on the 8th postoperative day, were treated for 4 weeks with a vehicle, human PTH (1-34) at 80 μg/kg/day and 40 μg/kg/day, respectively. Animals were sacrificed at the end of the fifth postoperative week. Liver cirrhosis and fibrosis were confirmed in all BDL rats by histology. Bone mineral density (BMD) of the femur and tibia was measured ex-vivo by DXA (Hologic QDR 4500A). In addition, femoral bone mass was measured by ashing. BDL rats had significantly lower femoral and tibial BMD compared to sham operated rats (p=0.02 and 0.001 respectively). BMD in animals treated with high dose PTH was not significantly different from BDL rats. Femoral and tibial BMD in animals treated with low dose PTH was significantly higher than in untreated BDL rats (p=0.009 and 0.003, respectively). Femoral and tibial BMD in BDL animals treated with low dose PTH was significantly higher than in animals treated with high dose PTH (p=0.006, p=0.01, respectively), and not significantly different from sham operated rats. The femoral corrected ash weight analysis confirmed that BDL rats were osteopenic (P < 0.03 vs. sham), and that the low dose, but not the high dose PTH restored bone mass to sham-operated levels (P<0.01 vs. BDL group).

	Sham (n=10)	BDL (n=10)	PTH 80 μg /kg/d (n=8)	PTH 40 μg /kg/d (n=6)
Femoral BMD g/cm^2	0.253±0.009	0.239±0.016	0.241±0.011	0.260±0.010
Tibial BMD g/cm^2	0.197±0.007	0.184±0.007	0.185±0.008	0.201±0.012
Femoral ash weight (mg/mm)	13.1±0.6	12.0±1.1	12.0±0.6	13.5±0.7

Data are mean±SD.

In summary, BDL rats develop osteopenia, which is prevented by treatment with PTH (1-34) at 40 but not 80 μg/kg/day. The shift from the published anabolic effect of the high PTH dose may be related to altered PTH metabolism in BDL rats.

Parsimony with PTH: Is a Single Weekly Injection of PTH Superior to a Larger Cumulative Dose Given Daily? D. M. Black[1], C. J. Rosen[2]. [1]University of California, SF, CA, USA, [2]Maine Center for Osteoporosis, Bangor, ME, USA.

While chronic elevations of endogeneous PTH levels in hyperparathyroidism decrease bone mineral density, intermittent daily administration has the paradoxical effect of increasing BMD at the hip and spine. However, the possibility of other than *daily* administration of intermittent PTH has not been fully explored. Some alternatives to daily use have been tested. Hodsman (JCEM, 1997) tested cyclical use of PTH 1-34 (one month out of three) and found an annual spine BMD increase of 7.5%. Fujita (OI, 1999) conducted a randomized trial to explore a single weekly injection of PTH. In this 1 year study (not placebo controlled), 220 women were randomized to 50, 100 or 200 IU of PTH 1-34 (corresponding to about 15, 30 and 60 microgram (ug)) per week. They found surprisingly large increases in spinal BMD: 4% for the 30 ug dose and 8% the 60 ug dose. Bone formation rose during the first 3 months (about 25% with 60 ug) but by 12 months had fallen to below baseline levels. Bone resorption fell slightly. In the table below, we compare weekly to daily administration of PTH. For daily dosing, we interpolated the 12 month change in spine BMD from the 21 month study of Neer (NEJM, 2001) assuming that the BMD change was linear over time. The bone marker results for daily use are derived from a study PTH 1-34 in men (Kurland, JCEM, 2000). These results suggest that weekly administration of PTH might result in larger increases in BMD than much larger cumulative doses given daily. The similarities in BMD changes occur despite very different patterns of changes in bone markers. In conclusion, the weekly use of lower cumulative dose of PTH could potentially dramatically decrease costs, risks and side effects of PTH while maintaining similar efficacy. While these preliminary data have important limitations (e.g., large variations in the biologic activity of the preparations), they strongly support the value of additional studies to directly compare daily and weekly use of PTH and to explore the mechanisms by which PTH reduces fracture risk.

Comparison of weekly and daily use of PTH 1-34

Study Author(s)	Fujita	Fujita	Neer	Neer/Kurland
Total Weekly Dose	30 ug	60 ug	140 ug	280 ug
Administration	Weekly	Weekly	Daily	Daily
% change @ 1 year				
Spine BMD	+4%	+8%	+5%	+7%
Bone formation	-6%	-15%	NA	+150%
Bone resorption	-15%	-20%	NA	+100-300%

A Single Infusion of the Tumor Necrosis Factor-alpha Antibody Infliximab Suppresses Bone Resorption in Patients with Rheumatoid Arthritis. H. P. Dimai[1], T. Mueller*[2], A. Fahrleitner*[1], J. Hermann*[2]. [1]Internal Medicine, Endocrinology and Nuclear Medicine, Graz, Austria, [2]Internal Medicine, Rheumatology, Graz, Austria.

Rheumatoid arthritis (RA) is a chronic inflammatory disease leading progressively to osteoporosis and bone destruction. Treatment with infliximab, a neutralizing anti tumor necrosis factor-alpha antibody, has been shown to completely abrogate the progression of joint destruction in RA. We sought to investigate the hypothesis that infliximab might also be sufficient to inhibit bone resorption, thus preventing development of osteoporosis. 12 patients (7 females and 5 males; mean age 55 ± 11 yrs; disease duration 11 ± 6 yrs) with RA according to the revised ACR-criteria not responding to treatment with methotrexate were included in the study after given informed consent. Blood was drawn two and one day prior, and one and fourteen days after a single infusion of 10 mg/kg of infliximab. Sera were frozen at –70°C until assay. To evaluate the effect of infliximab on bone turnover we measured a marker of bone formation (i.e.osteocalcin) and a marker of bone resorption (i.e. serum beta-CrossLaps). In addition, we determined serum levels of intact parathyroid hormone (iPTH), interleukin-6 (IL-6) and electrolytes. RA disease activity was evaluated using the disease activity score (DAS). The DAS was significantly lower 24 hours, and 14 days after the infusion, respectively. This clinical improvement correlated significantly with a reduction of serum IL-6-levels (data not shown). More importantly, serum beta-CrossLaps levels decreased significantly 24 hours after the infusion. This effect was still significant 14 days after the infusion, albeit less pronounced. Other markers of bone metabolism investigated, such as OC, iPTH and total serum-calcium (tot Ca), did not change throughout the study period.

	visit-2	visit-1	visit+1	visit+2
DAS	6.5 ± 0.3	6.5 ± 0.3	5.7 ± 0.4*	4.9 ± 0.4**
IL-6 (pg/ml)	27.2 ± 8.6	75.4 ± 29.1	17.6 ± 13.0	11.5 ± 5.6**
beta-CrossLaps (pg/ml)	0.30 ± 0.04	0.29 ± 0.04	0.17 ± 0.03**	0.23 ± 0.04*
OC (ng/ml)	16.9 ± 2.7	19.1 ± 2.7	18.4 ± 2.6	19.6 ± 3.4
iPTH (pg/ml)	48.5 ± 5.7	38.4 ± 7.2	36.0 ± 5.7	52.6 ± 10.8
totCa (mmol/L)	2.3 ± 0.03	2.3 ± 0.02	2.3 ± 0.03	2.3 ± 0.02

*p<0.05; **p<0.001

In this study, infliximab treatment ameliorated disease activity in RA patients, as was already demonstrated in prior studies. It also significantly reduced a biochemical marker of bone resorption in these patients. Therefore, infliximab is not only effective to control disease activity and radiological progression of RA, but it may also be sufficient to prevent generalised bone loss in patients with RA.

Short-term Use of Postmenopausal Hormone Replacement Therapy Reduces the Incidence of Osteoporotic Fractures 10 Years after Withdrawal: The PERF Study. Y. Z. Bagger, L. B. Tankó, P. Alexandersen*, P. Ravn*, C. Christiansen. Center for Clinical & Basic Research A/S, Ballerup, Denmark.

Previous studies have shown that a decrease risk of fractures is evident only in women who have received HRT for at least 5 years. In the present study, we investigated whether a previous short-term course of HRT for 2 years had any anti-fracture effect after withdrawal. We followed up a group of 263 early postmenopausal Danish women who participated in various placebo-controlled HRT clinical trials at our center. Participants were re-examined 5, 11 and 15 years after withdrawal of HRT. Age at baseline was 45-59 years. All women included in this study completed the trials and were re-examined in 2000 and 2001. Those currently taking HRT or other drugs known to influence bone metabolisms were excluded from the calculation. Spine BMD and forearm BMC were assessed at baseline, at the end of HRT and 10 years after withdrawal of treatment. Lateral X-ray of the thoracic and lumbar spine was performed. Vertebral deformities from T4 to L4 were assessed by digital measurement. A more than 20% reduction of the vertebral height was considered as a fracture. Non-vertebral fractures were recorded by standard questionnaire. The mean residual effects of 2 years of HRT on bone mass remained 4.9% at the forearm and about 6% at the spine compared to placebo groups after 5-15 years of withdrawal (Table 1). The number of vertebral fractures in the placebo and HRT groups is shown in Table 2. The risk of vertebral fracture was significantly lower in women who had previously received 2 years of HRT as compared to non-users. Furthermore, using HRT for 2 years after menopause reduced the all-osteoporotic fracture incidence to 0.44 (95% CI, 0.25-0.78, p=0.005) as compared to non-users. These results indicate that a short-term course of HRT administered in the early postmenopausal years offers long-lasting benefits in the prevention of osteoporortic fractures.

Table 1. Mean changes in BMC/BMD% at the end of HRT and after withdrawal of HRT

	Δ mean spine BMD%	Δ mean arm BMC%
At the end of 2 years HRT	6.9%	5.3%
10 years after withdrawal of HRT	6.2%	4.9%

Nasal Calcitonin Increases Spinal Bone Density in Male Osteoporosis without Vertebral Deformity. E. Tóth[1], S. Mészáros*[2], V. Ferencz*[2], E. Csupor*[2], K. Bors*[2], E. V. McCloskey[3], C. Horváth[2]. [1]Rheumatology, Flór Ferenc County Hospital, Kistarcsa, Hungary, [2]1st Department of Medicine, Semmelweis University, Budapest, Hungary, [3]Collaborating Center for Metabolic Bone Diseases, WHO, University of Sheffield, Sheffield, United Kingdom.

The treatment of idiopathic male osteoporosis is still controversial. The aim of our study was to evaluate prospective changes on bone density (BMD) is men with osteoporosis. Patients and methods: Sventy-one men were studied (T score at lumbar spine and femoral neck lower than -2.5) with a mean age of 59±6 years. Men with secondary causes of osteoporosis and vertebral deformity were excluded. 40 patients were randomized to treat with nasal calcitonin (200 IU/day, Miacalcic, Novartis - monthly intermittent doses) plus calcium and Vitamin D replacement while 31 patients were given 1000mg/day calcium and 400NE/day Vitamin D3 only. Bone mineral density of the spine, hip.and forearm was followed by dual energy x-ray absorptiometry (DEXA, LUNAR DPX-L, USA) at baseline and at 18 months of treatment. Results: Calcitonin increased BMD at the spine and hip while no changes were observed in the placebo group. (Tabl. 1). Percent changes of BMD were found as follows (mean ±SD). (Tabl. 2). No fractures occurred in the calcitonin treated group, while 3 patients suffered fractures in the placebo group.Conclusions: Our preliminary results suggest calcitonin to be effective in the management of idiopathic male osteoporosis.

Table 1

ΔBMD mg/cm2	CT (95% CI)	PL (95% CI)	p (CT vs PL)
spine	30 (18-43)	6 (-15-+27)	0,03
hip	23 (11-35)	-8 (-23-+41)	0,001
radius	11 (-17-+81)	11 (-21-+42)	0,99

Table 2

Δ BMD %	CT	PL	p (CT vs PL)
spine	3,5±4,3	0,83±6,4	0,04

A Therapeutic RANKL Vaccine for the Prevention and Treatment of Degenerative Bone Diseases. T. Bratt*[1], V. Nardi-Dei*[2], L. Sonderbye-Kjaerulff*[1], J. H. Rasmussen*[1], C. Lyngso*[1], S. Tanaka[3], M. Hertz[1]. [1]Pharmexa A/S, Horsholm, Denmark, [2]Pharmexa, Horsholm, Denmark, [3]Department of Orthopaedic Surgery, University of Tokyo, Tokyo, Japan.

The TNF family member Receptor Activator of NFκB Ligand (RANKL) stimulates osteoclast differentiation and activation. RANKL and the soluble receptor for RANKL, osteoprotegerin (OPG), together are the critical regulators of normal bone development. Balance of the RANKL - OPG ratio or overexpression of RANKL can be detected during pathological bone destruction in human diseases such as osteoporosis, rheumatoid arthritis (RA), and bone metastasis. Furthermore, neutralizing RANKL is effective at reducing bone destruction in models of osteoporosis, RA, bone metastasis, periodontal disease and reducing markers of bone turnover in a phase I clinical trial of postmenopausal women. We have previously shown that a murine RANKL vaccine could prevent bone loss in a mouse ovariectomy model and ameliorate bone loss and synovial inflammation in a murine RA treatment model (Hertz, M. et al (2001) J.Bone Miner.Res. 16:S222 and Juji,T. et al. (2001). J.Bone Miner.Res. 16:S150.). Here, we demonstrate that human RANKL vaccines can induce polyclonal antibodies that compete with recombinant OPG for binding of human RANKL *in vitro* and that neutralize *in vitro* osteoclastogenesis. Moreover, these vaccines can prevent bone loss in animal models of bone destruction.

Effect of Vitamin K^2 on Cancellous Bone in Orchidectomized and Sciatic Neurectomized Rats. J. Iwamoto[1], J. K. Yeh[2], T. Takeda*[1], S. Ichimura*[3]. [1]Department of Sports Medicine, Keio University School of Medicine, Tokyo, Japan, [2]Department of Medicine, Winthrop-University Hospital, Mineola, NY, USA, [3]Department of Orthopaedic Surgery, National Defense Medical College, Saitama, Japan.

We examined the effect of vitamin K_2 on cancellous bone in orchidectomized and sciatic neurectomized rats. Ninety male Sprague-Dawley rats, 3 months of age, were randomized by stratified weight method into nine groups with 10 rats in each group: baseline controls (BLC), age-matched controls (AMC), AMC+vitamin K_2 administration (K), orchidectomy (ORX), ORX+K, unilateral sciatic neurectomy (NX), NX+K, ORX+NX, and ORX+NX+K. Vitamin K_2 (menatetrenone) was administered orally twice a week at dose of 30 mg/kg each. After 10 weeks of feeding, cancellous bone histomorphometry was performed for the proximal tibia. No significant difference in bone volume (BV/TV) was found between the BLC and AMC groups and between the AMC and AMC+K groups. BV/TV was significantly lower in the ORX, NX, and ORX+NX groups by 49.4 %, 58.5 %, and 65.6 %, respectively than in the AMC group. BV/TV loss in the NX and ORX+NX groups was attributable to increased osteoclast number (N.Oc/BS) and eroded surface (ES/BS) and decreased bone formation rate (BFR/BS), whereas BV/TV loss in the ORX group was associated with increased N.Oc/BS, ES/BS, BFR/BS, and BFR/BV. BV/TV was significantly greater in the ORX+K, NX+K, ORX+NX+K groups by 33.1 %, 20.1 %, and 27.3 % as compared to the respective control group without vitamin K_2 administration. This increase in BV/TV by vitamin K_2 administration was primarily due to increased trabecular thickness (TbTh). The protective effect of vitamin K_2 was attributable to decreased N.Oc/BS and ES/BS and increased BFR/BS in the NX+K and ORX+NX+K groups, whereas it was attributable to decreased N.Oc/BS, ES/BS, and BFR/BV in the ORX+K group. The results of the present study suggest that vitamin K_2 could partially prevent cancellous bone loss by suppressing bone turnover in ORX rats and by suppressing bone resorption and stimulating bone formation in NX and ORX+NX rats.

Alfacalcidol Distributes to Bone Marrow Cells in an Unchanged Form and Converts to Active Forms Locally. N. Hayakawa*, S. Higashi*, A. Shiraishi*, T. Masaki*, E. Hoshino*, S. Matsubara*. Product Research Lab., Chugai Pharmaceutical co., ltd., Tokyo, Japan.

Anti-osteoporosis drug, alfacalcidol [1α(OH)D_3] (ALF), converts to the active form (1α,25$(OH)_2D_3$) at the liver after oral administration. The blood concentration of 1α,25$(OH)_2D_3$ is therefore dominant in the circulation. Recently, we have confirmed that the concentration of pro-drug form (unchanged ALF) was higher in the bone marrow than the plasma and highly distributed in cells on bone surface of adult rats, whereas the 1α,25$(OH)_2D_3$ was dominant in the blood circulation. The distribution of unchanged ALF may be the key to understand the mechanism of the anti-osteoporotic effect. Therefore, in the present study, we examined how bone marrow cells affect on the ALF metabolism in vitro. Bone marrow cells were isolated from femoral bones of male rats (8 weeks old, Wistar-Imamichi) and all the bone marrow cells per femur were seeded in a 35 mm dish with IMDM medium containing [22,23-^{3}H]ALF at a dose of 10^{-8} mol/L. At 4, 24, 48 and 72 h following cultivation, cultured cells were washed and trypsinized to extract radioactivity by 4-5 fold volume of methanol. The radioactivity uptake and the metabolic profiles of ALF were analyzed by liquid-scintillation counting and HPLC analysis, respectively. The radioactivity uptake in the cultured cells reached a maximum after 24 h (about 60 % of dose) and declined up to 72 h (about 40 % of dose). The HPLC analysis of the radioactivity showed that unchanged ALF existed in the cultured cells at the highest ratio during all the time points, while small amounts of 1α,25$(OH)_2D_3$ and some other metabolites were detected. Detailed analysis of the HPLC profiles over the culture period showed that unchanged ALF gradually declined through the all sampling times, whereas 1α,25$(OH)_2D_3$ was evident at 24 h and then maintained its level until 72 h. In summary, the present results demonstrate that, ALF distributed into bone marrow cells might convert to the active form (1α,25$(OH)_2D_3$) gradually and affect bone metabolism for the relatively long period. Therefore, the binding situation between unchanged ALF and vitamin D receptor or the other specific (unknown) binding sites and the induction of converting enzymes in bone marrow cells might be critical.

SA377

Pharmacological Efficacy of Alfacalcidol for the Treatment of Osteoporosis Is Not Achieved by the Use of a Calcium Supplement. A. Shiraishi*[1], S. Higashi*[1], T. Masaki*[1], N. Hayakawa*[1], E. Hoshino*[1], S. Matsubara*[1], M. Ito[2], A. Nishida[2], E. Ogata[3]. [1]Product Research Lab., Chugai Pharmaceutical Co., Ltd., Tokyo, Japan, [2]Department of Radiology, Nagasaki University School of Medicine, Nagasaki, Japan, [3]Cancer Institute Hospital, Tokyo, Japan.

Alfacalcidol [1α(OH)D_3:ALF], the prodrug of calcitriol, has been used for the treatment of osteoporosis in certain countries, including Japan. It is generally agreed that in vitamin D-deficient states, active vitamin D increases bone mass mainly through enhancing intestinal calcium (Ca) absorption. So far, we have reported: 1) ALF has the unique property of suppressing bone resorption while stimulating bone formation in vitamin D-replete rats; 2) ALF acts in bone, at least in part, independently of its effects on calcium absorption and suppression of PTH secretion. In this study, we aimed to assess whether or not a nutritional supply of calcium could be substituted for ALF administration in preventing bone loss due to estrogen deficiency. Eight month-old rats were ovariectomized (OVX) or sham operated. The OVX rats were subjected to ALF administration (0.025, 0.5, 0.1 or 0.2μg/kg, p.o. 5 times a week) or calcium-enriched diets (0.4, 1.4 or 2.5 g/kg, food intake; phosphorus 0.5 g/kg). After 12 weeks of treatment, all rats were sacrificed to harvest the spine, serum, and urine samples. Neither the ALF treatment nor the Ca supplement caused hypercalcemia. Both the ALF administration and the high Ca intake increased the urinary Ca excretion to the maximum level in the same manner, indicating that the intestinal Ca absorption rose to the same extent. In the spine, ALF prevented the decrease in bone mass induced by OVX, and even increased the strength over that of the sham level. Micro-CT analysis also confirmed that the bone-protective effect of ALF was based on an improvement of microstructure in the trabecular bone. In contrast, and of particular interest, with an increase in the Ca intake, there was no change in spinal bone mass and strength despite the range of Ca dosages. In the Ca-treated groups, the dose-dependent changes in urinary deoxypyridinoline excretion and serum osteocalcin level were not observed. Furthermore, excessive Ca intake caused a significant increase in blood urea nitrogen and serum creatinine, and also induced a progressive reduction in urinary excretion of inorganic phosphorus. These results suggested that not only did excessive Ca supplementation have no apparent effect on spinal bone loss in estrogen deficiency, it was also associated with the risk of causing a disorder in the renal function. Consequently, we conclude that ALF has beneficial efficacy for the treatment of osteoporosis, which is not achieved by the use of a Ca supplement.

SA378

Anabolic Effect of Active Vitamin D3 Analog, Alfacalcidol, Is Strongly Related to Bone Strength through Thickening of Transverse Trabeculae. M. Ito[1], S. Higashi[2], A. Nishida[1], A. Shiraishi[2], K. Hayashi*[1]. [1]Radiology, Nagasaki University, Nagasaki, Japan, [2]Product Research Lab. Chugai Pharmaceutical Co., Ltd, Tokyo, Japan.

We previously reported that alfacalcidol (ALF) improves bone strength due to suppression of bone resorption and stimulation of bone formation in ovariectomized (OVX) rats. These pharmacological effects of ALF, however, could not clearly explain the fact that ALF improves bone strength without significantly affecting bone mineral density (BMD). We therefore examined the influence of ALF on microstructure in OVX rats, and investigated the relationship between trabecular microstructure and bone strength. 10-month-old female rats including sham (n=5) and OVX (n=40), were orally administered with ALF at 0, 0.025, 0.05, 0.1mcg/kg BW for 12 weeks. BMD, 3D trabecular microstructure, and bone strength were measured in the lumbar vertebrae, and the histomorphometry was assessed in the femur. We found that 1) Stimulated bone resorption determined by biochemical markers and histomorphometry due to estrogen depletion was dose-dependently inhibited by ALF, and was significantly suppressed at the dose of 0.1mcg/kg. Elevated bone formation markers by OVX did not decrease by ALF treatment and maintained independently of the suppression of bone resorption throughout all the dose range. 2) ALF inhibited decrease in spinal BMD induced by OVX and exerted the maximum effect over the dose range of 0.05-0.1mcg/kg. 3) Bone strength did not increase at the dose of 0.05mcg/kg, but markedly increased at the dose of 0.1mcg/kg. 4) The microstructure dose-dependently improved by ALF. Especially, bone volume (BV/TV) and trabecular thickness (Tb.Th) significantly increased, and trabecular bone pattern factor (TBPf) and structure model index (SMI) significantly decreased. Additionally we found that degree of anisotropy (DA), which determines the ratio of main axes of trabecular direction (vertical and transverse in vertebra) , significantly decreased at the dose of 0.1mcg/kg. To summarize, ALF prevents the loss of trabecular connectivity as indicated by the microstructure indices, such as TBPf and SMI, and, at 0.1mcg/kg, thickens the transverse trabeculae, as evidenced by the decrease of DA. These unique pharmacological effects on trabeculae were considered to be mainly due to the direct anabolic action, while retaining the marked anti-resorptive activity. In conclusion, the anabolic action of ALF appeared to increase bone strength due to thickening transverse trabeculae, in addition to the maintenance of trabecular connectivity due to the suppression of bone resorption. The dose of 0.1mcg/kg ALF markedly improved the trabecular structure and bone strength with minimal increase in BMD.

SA379

Simultaneous Administration of Alfacalcidol and Alendronate at their Subtherapeutic Doses Produces the Inhibition of Bone Loss through Their Synergetic Suppressive Effect on Bone Resorption in Rats. S. Higashi*, T. Masaki*, A. Shiraishi*, N. Hayakawa*, E. Hoshino*, S. Matsubara*. Product Res. Lab., Chugai Pharm. Co., Ltd., Tokyo, Japan.

Both alfacalcidol (ALF) and alendronate (ALN) are reported to prevent estrogen deficiency-induced bone loss by an anti-resorptive effect. The purpose of this study was to clarify the effect of simultaneous administration of ALF with ALN at their threshold doses on bone turnover and OVX-induced bone loss in rats. 40-week-old female Wistar rats, OVX- and sham-operated, were randomized at 12 weeks post-surgery into seven groups (n=5-7); 1) sham+vehicle, 2) OVX+vehicle, 3) OVX+ALF 0.025 μg/kg/day, 4) OVX+ALF 0.1 μg, 5) OVX+ALN 0.3 mg, 6) OVX+ALN 1.0 mg or 7) ALF (0.025 μg) in combination with ALN (0.3 mg). Each drug was administered orally 5 times a week for 12 weeks and thereafter sacrificed. The spinal bone mineral density (BMD) (L2-L4) was measured by dual-energy x-ray absorptiometry every 4 weeks. The rise in urinary excretion of deoxypyridinoline (DPD) induced by OVX was suppressed by both ALF and ALN treatments alone in dose- and time-dependent fashion. The increase in number of osteoclasts determined by histomorphometry of lumbar vertebra (L5) was not ameliorated by ALN but by ALF 0.1 μg/kg ($p < 0.001$ vs OVX) after the 12-week treatment. These results suggest different mechanism of anti-resorption. Moreover, the decrease in DPD excretion by the treatment of ALF 0.025 μg/kg, ALN 0.3 mg/kg, and both administration for 4 weeks were 18% (ns), 24% ($p<0.01$), and 51% ($p<0.001$), respectively, when compared to values of OVX+vehicle group. DPD levels of both-treated group at 4 weeks corresponded to those of ALN 1.0 mg/kg treated group for 4 weeks or of ALN 0.3 mg/kg treated group for 12 weeks. However, elevated bone formation markers by OVX such as serum osteocalcin remained at the same level in either treated group (ns vs. OVX at 4, 8, 12 weeks). The simultaneous administration of ALF and ALN elicited an additive inhibitory effect on bone loss induced by OVX at 12 week, although neither treatment alone elicited obvious effects on spinal BMD. Although doses used in this combination study were below those known to cause severe hypercalcemia and hypocalcemia by ALF and ALN itself, respectively, the decreases in serum calcium (Ca) and urinary Ca excretion in OVX rats were counteracted by the combination therapy and restored to the similar level of sham group. In summary, this study suggests that ALF and ALN are considered to exert additive anti-resorptive activities, and that the simultaneous administration of ALF and ALN at their threshold doses might ameliorate Ca balance and spinal BMD through the prompt beneficial effect on bone turnover.

SA380

Randomized Doubled Blind Twelve Months Study of 1 μg/day of Alphacalcidiol vs Placebo in a High Bone Turnover Postmenopausal Women. G. S. Riera, M. Naressi*, G. Velasquez*, J. Ramos*, B. Herrera*. Medicine, UNILIME. Universidad de Carabobo, Valencia, Venezuela.

Vitamin D metabolites have been used for osteoporosis treatment. Main actions on bone are: mineralization, stimulation of osteoblast and diminish resorption, however available information about action on resorption markers in a prospective double-blind, placebo control trial are scarse. 85 postmenopausal patients with low BMD (T-score between -1 and -3 at L2-L4 or femoral neck) and high turnover (N-telopeptide-NTx-, Tartrate Resistant Acid Phosphatase -TRAP- or Alkaline Phosphatase -AP- 1SD or more above the premenopausal mean) were randomized in a double-blind, placebo control, 12 month trial of 1 μg/day of alphacalcidol vs placebo, according to the principles of the Helsinski Declaration. Exclusion criteria were: secondary osteoporosis, fracture 6 months prior to the study, medication such as TRH, insulin, steroids, diuretics, biphosphonates, calcitonin, raloxifene, antituberculosis drugs and thyroid hormones, allergy to vitamin D. Group A: alphacalcidiol 1μg/day + calcium citrate 500mg/day, Group B: placebo + calcium citrate 500mg/day. Mean age was 61.58 ± 6.69 and 62.4 ± 6.30. Age of menopause was 45.6 ± 5.14 and 46.4 ± 5.5, there were no differences on risk factors between groups. Modest hipercalciuria occurs in 48% (Group A) and 18% (Group B), Calcium supplement was stopped to control this side effect. We did not have hipercalcemia. Drop out rate was 3.5% in the placebo group and

2.4% in the alphacalcidol group. BMD remained stable in both groups. In conclusion the use of alphacalcidiol 1 µg/day during 12 months in postmenopausal women with low BMD and high turnover was very well tolerated and decreased NTx by 27.7%, TRAP by 23.6% and AP by 16%.

Senile Defect in the Renal Activation of Vitamin D. C. Horvath[1], E. Hosszu*[2], S. Meszaros*[1], V. Ferencz*[1], K. Bors*[3], E. V. McCloskey[4]. [1]1st Department of Medicine, Semmelweis University, Budapest, Hungary, [2]2nd Department of Pediatrics, Semmelweis University, Budapest, Hungary, [3]Ferencvaros Osteoporosis Center, Budapest, Hungary, [4]WHO Collaborating Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, United Kingdom.

Vitamin D is formed to active hormone by two steps of activation in the liver and in the kidney. It is supposed that ageing processes of the kidney could deteriorate the vitamin D hydroxylation, too. In our study low-calcium diet was used as a stimulation test estimating the renal vitamin D activating capacity in young and senile people. *Methods:*13 healthy young (between 20-25 ys) and 33 old (70-80 ys) volunteers were involved into the study. They were asked to eat no more than 200 mg calcium daily during 10 days. Serum and urinary calcium, phosphorous, creatinine as well as serum PTH, 25-OHD and $1,25(OH)_2D$ levels were measured before and after the diet period. *Results:*in healthy young people the activated vitamin D level remains normal in a calcium deprivation test (Table, *:p<0,05). Consumption of 25-OHD serum concentration can be observed, however, hypersecretion of parathyroid hormone is not needed to the accomodation. In contrast, elderly people can preserve normal serum level of activated vitamin D only with help of secondary hyperparathyroidism. *Conclusion:* our model suggests that use of activated rather than native vitamin D is rational for supplementation of elder people.

Table

Volunteers	Young	Young	Elder	Elder

2-Methylene-19-Nor-(20S)-1,25-Dihydroxyvitamin D_3 (2MD), an Analog of 1α,25-Dihydroxyvitamin D_3 (VD) Markedly Increases Bone Mass of Ovariectomized (OVX) Rats. L. Plum*[1], X. Ma*[2], M. Clagett-Dame*[2], N. Shevde[2], L. Fitzpatrick[3], J. W. Pike[2], H. F. DeLuca[2]. [1]University of Wisconsin-Madison/Deltanoid Pharmaceuticals, Inc., Madison, WI, USA, [2]Biochemistry, University of Wisconsin-Madison, Madison, WI, USA, [3]Endo/Metabolism Unit, Mayo Clinic, Rochester, MN, USA.

Sicinski et al. (J. Med. Chem. 41, 4662-4674, 1998) demonstrated that 2MD selectively increases the osteoblastic-mediated mobilization of calcium from bone. We made the assumption that 2MD would also selectively increase all activities of the osteoblast including synthesis of new bone. To test this hypothesis, we obtained retired breeder female rats from Harlan Sprague-Dawley. Groups of 12 rats were either sham-operated (controls) or ovariectomized. Two days prior to initiation of drug administration, the animals were switched to a purified diet containing 0.47% Ca, 0.3% P. The OVX groups were provided with 0, 5 pmol 2MD/day, 7 pmol 2MD/day, 32 pmol 2MD 2X/week, or 500 pmol VD 3X/week orally for a total of 30 weeks. Using DPXα, total body bone scans were performed 5 weeks prior to dose administration and after 13 and 23 weeks. Bone mineral density of the right femurs was determined at week 28. Serum calcium was monitored monthly. Approximately two weeks prior to termination, tetracycline and calcein were given to label the skeleton for histomorphometry. At termination, lumbar vertebrae were scanned ex vivo for mineral density. Vertebrae, femurs and tibias were removed for histomorphometry, bone breaking strength and ash determinations. Serum was collected for measurement of biochemical markers of bone formation and resorption. At both 5 and 7 pmol dose levels, 2MD caused a 5-7% increase in total body bone mineral density by 23 weeks. Daily dosing proved to be more effective in increasing bone mineral density than the 2X week regimen. Preliminary estimates are that there is a 25% increase in trabecular bone and a 25% increase in the cortical bone of femur. This took place in the absence of hypercalcemia. In contrast, VD at 500 pmol 3X week caused no appreciable increase in total body bone mass. Results of ash, histomorphometry and bone strength measurements will be reported. The results strongly suggest that 2MD is an anabolic agent for bone that provides significant promise for the treatment of bone loss diseases such as osteoporosis.

Disclosures: ***L. Plum****, Deltanoid Pharmaceuticals, Inc. 1, 3.*

Bone Mineral Density Improvement After Two Years of Intravenous Pamidronate Treatment of Patients with Fibrous Dysplasia. M. S. Parisi*, B. Oliveri, C. Mautalen. Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina.

Intravenous Pamidronate (APD) has proved to be effective in patients with Fibrous Dysplasia (FD) as shown by its effect on bone pain, markers of bone turnover or radiological changes. We report the effect of two years treatment with intravenous APD (180mg, 60mg/day during 3 days, every 6 months) on BMD of affected bones in 10 patients with FD, 7 women and 3 men (mean age 32 years). Clinical symptoms and markers of bone turnover were evaluated every 3 months. BMD of total skeleton and X-rays of FD areas were performed at baseline and once a year. BMD of FD areas was compared with the contralateral side using the region of interest program on the total skeleton scan. At baseline the average difference in BMD of FD areas was –11.2% compared with contralateral side (a significantly greater difference than that observed between left and right sides in healthy controls –0.7% (p<0.02)). Treatment with intravenous APD improved clinical symptoms and significantly decreased values of bone markers. Mean total skeleton BMD increased 2.7% (p<0.05) after 12 months and 4.4% (p<0.05) after 24months. BDM of FD areas Increased 3.8% after 12 months and 8.2% after 24 months compared with 0.3% and –2.9% changes in contralateral side respectively. Average difference BMD of FD areas diminished to –8.4% after 12 months and –2.6% (p<0.02) after 24 months compared with contralateral side. No radiographics changes were observed in FD lesions. Intravenous APD increased BMD of both the total skeleton and Fibrous Dysplasia affected bones BMD. Densitometric follow-up of these patients is a useful tool to evaluate the efficacy of treatment and is more sensitive to detect early changes than radiology.

Association of Molecular Variants in BMP4 with Ossification of the Posterior Longitudinal Ligament of the Spine. K. Furushima[1], T. Tanaka*[1], T. Nakajima*[2], S. Maeda*[3], S. Toh*[1], I. Inoue*[2]. [1]Department of Orthopedic Surgery, School of Medicine, Hirosaki University, Hirosaki, Japan, [2]Division of Genetic Diagnosis, The Institute of Medical Science,, Minatoku, Japan, [3]Department of Orthopedic Surgery, School of Medicine, Kagoshima University, Kagoshima, Japan.

Introduction; Ossification of the posterior longitudinal ligament of the spine (OPLL), which is characterized by heterotopic bone formation in spinal ligaments, is the leading cause of spinal canal stenosis and myelopathy . Although epidemiological and family studies implicate genetic susceptibility in its pathogenesis, the genetic basis of OPLL remains poorly understood. In the previous study extensive non-parametric linkage studies with 126 affected sib-pairs using markers for 64 candidate genes were performed to identify genetic loci relevant to OPLL. Six genes in them, BMP4, PRG1, TGFb3, osteopontin ,PTHR1, and IGF1, showed evidence of linkage by SIBPAL analysis (P<0.05). Among these genes, only BMP4 showed the evidence of linkage by GENEHUNTER (NPL=2.23). In this study we investigated the association of molecular variants in BMP4 gene with OPLL. Methods; For allelic association study, 268 OPLL cases and 168 non-OPLL controls were collected in Japan. Allele frequencies of single-nucleotide polymorphisms (SNPs) were determined by the direct sequencing for the PCR amplicons covering variant sites. Sequencing was performed with BigDye Terminator cycle sequencing with a 377 ABI Prism automated DNA sequencer. Results; Approximately 7.2kb genomic regions in the BMP4 gene were examined in 12 individuals to discover SNPs. Twelve SNPs were identified in the region and performed typing. Among these SNPs no remarkable significance was shown in association study. Next to begin construction of haplotypes from three SNPs (-1578g/a, +518g/t, +5161t/c), which high-frequency of minor allele, we genotyped 268 OPLL cases and 168 non-OPLL controls. Six haplotypes existed in Japanese population. To evaluate the potential that these haplotypes have for identification of a particular mutation or polymorphism, we compared with the haplotype between OPLL and controls. Haplotype of BMP4 gene with GTC have strong difference association. The haplotype of the OPLL patients were lower frequency compared with non-OPLL population. Discussion; Gene expression may change with osteoblast differentiation by the mutation or polymorphism of BMP4 gene. We detected haplotype, which have strong difference between patients and control. A real mutation or polymorphism may play a protective role in the ectopic ossification process. We are going to keep on further research in order to search a real cause polymorphism.

Osteoclastic Dysfunction Leads to Impaired Mechanical Adaptation of Bone Structure in Pycnodysostosis: Transilical Biopsy Study of Two Patients with Defined Mutations Within the Cathepsin K Gene. A. Valenta*[1], P. Roschger*[2], N. Fratzl-Zelman*[2], A. Nader*[2], B. M. Grabner*[2], B. D. Gelb*[3], P. Fratzl*[1], K. Klaushofer[2]. [1]Austrian Academy of Sciences & University of Leoben, Leoben, Austria, [2]Ludwig Boltzmann Institute of Osteology, 4th Med. Dept., Hanusch Hospital & UKH Meidling, Vienna, Austria, [3]Depts. of Pediatrics and Human Genetics, Mount Sinai School of Medicine, New York, NY, USA.

Pycnodysostosis (Pycno) is an autosomal recessive syndrome resulting from mutations in the gene encoding cathepsin K, the major lysosomal protease responsible for efficient matrix degradation in osteoclasts. While Pycno is genetically (Hou, J Clin Invest, 1999) and clinically (osteosclerosis, bone fragility, short stature) well-characterized, little information is available about the bone phenotype at the tissue and material levels. Transiliacal bone biopsies from two unrelated Pycno patients were studied for cellular activity and histomorphometry (Goldner´s Trichrome and Giemsa staining), mean calcium concentration (Ca_{Mean}) by quantitative backscattered electron imaging (Roschger, Bone, 1998), mean thickness (T-parameter) and alignment of the mineral particles within the bone matrix by small angle X-ray scattering (Rinnerthaler, Calcif Tissue Int, 1999). Alterations of histomophometrical parameters are summarized in the Table. Moreover, broad, demineralized fringes containing collagenous matrix were found adjacent to active osteoclasts (more pronounced in patient A). In both samples, residuals of highly mineralized cartilage were present. Mineral concentration and particle thickness were unaffected, but crystal alignment was disturbed, reflecting a disorder in lamellar organization of the bone matrix. We conclude that the bone phenotype in Pycno is caused by a lack of adaptation to mechanical demands due to osteoclastic dysfunction, resulting in increased fragility.

Patient	A (5 yrs/ male)	B (21 yrs/ female)

Molecular Characterization of Osteopetrosis (OP) Using Nonadherent CD14 Peripheral Monocytes Expanded In Vitro. P. J. Orchard*[1], P. H. Schlesinger[2], H. Blair[3]. [1]University of Minnesota, Minneapolis, MN, USA, [2]Cell Biology and Physiology, Washington University Medical School, St. Louis, MO, USA, [3]Pathology, University of Pittsburgh, Pittsburgh, PA, USA.

Genetic alterations in monocytes can produce, osteoclasts defective in many aspects critical to bone turnover. Disruption of CSF-1 signalling, src, ATP6i, ClC-7, cathepsin K, and RANK-ligand cause OP in transgenic mice. However, except for ATP6i and ClC-7, it has been difficult to characterize the basis for osteoclast dysfunction biochemically because cells cannot be isolated. We developed a method to expand precursor cells from peripheral blood and produce human osteoclasts in vitro. Monocytes from OP children or control donors were recovered on ficoll and purified by antibody binding to removal non-CD14 cells (MACS, Miltenyi Biotec, Auburn CA). Non-adherent cells were cultured in DMEM with kit-ligand, IL-1b, and IL-6, 10 ng/ml each, with 15% monocyte-conditioned human serum for 10 days. These uniformly expressed alpha naphthyl acetate esterase when replated in csf-1. Flow cytometry showed cd11, cd34, and cd64 on these cells at constant but low levels. At 10 days, the cells expanded ~10x (5- >20x) allowing recovery of >500,000 nonadherent pre-osteoclasts from 10 ml of pediatric whole blood. Non-adherent cells, ~90% of cells, replated in CSF-1, 10 ng/ml with RANKL, 20 ng/ml, and 25 um bone fragments, expressed tartrate-resistant acid phosphatase and cathepsin K, with 50% of cells multinucleated and expressing osteoclast markers in 5-7 days. Cells were studied for actin distribution, cathepsin K, TRAP, and acid secretion profiles using fluorescence labeling. Bone particles accelerated and increased osteoclastic markers. In four OP lines and nine controls to date, OP osteoclasts showed reduced or absent acid at the attachment site, determined by labeling acid compartments (Lysotracker Red DND, Molecular Probes, Eugene OR). One OP cell line showed potential attachment defect. The other OP cells were identical to controls in spread area and bone attachment, and cells on glass showed typical lysosomal acid transport patterns although in one case OP cells had inclusions consistent with giant lysosomes. However, unlike controls the OP cells attached to bone did not accumulate acid in any case. We conclude that acid secretion defects in OP patients can be characterized using blood monocyte precursors. Other human OP phenotypes will be examined for differentiation arrest, attachment efects, enzyme secretion, and transport. This will subdivide OP, a syndrome, into specific molecular disorder, some of which may be amenable to therapy other than bone marrow transplant.

Efficacy and Predictors of Response to Treatment of Fibrous Dysplasia of Bone with Intravenous Pamidronate. R. D. Chapurlat, P. Hugueny*, P. D. Delmas, P. J. Meunier. INSERM U403, Lyon, France.

Treatment with intravenous pamidronate has been used for a decade in the treatment of fibrous dysplasia of bone (FD), but efficacy and tolerance in the long run (>5 years), and predictors of response to treatment have been not described so far. We examined a series of 58 patients with FD treated using intravenous pamidronate (180 mg every 6 months) up to 12 years to determine clinical, biological and radiological efficacy of treatment with pamidronate, and predictors of response to treatment. So, we measured intensity of pain and the number of painful localizations. We took repeated radiographs of involved bones and defined radiographic response as a substantial thickening of cortices and/or filling of osteolytic lesions. We also measured biochemical markers of bone turnover (serum total alkaline phosphatase [ALP], urinary CTX) before and after courses of treatment. We used repeated measures techniques to analyze data before and after treatment, and linear and logistic regression analyses to determine predictors of response to treatment. Twenty-eight men and 30 women were followed-up for an average 4 years, with a mean age of 30 at onset of treatment. Thirty-eight percent had a monostotic form of FD. Among the 80% of patients who had pain at baseline, we observed a 70% decrease in intensity of bone pain ($p<0.001$) after the first course of pamidronate. This decrease was maintained throughout follow-up, with 60% of patients classified as complete responders and 24% as partial responders. Forty-five percent of patients had a decrease of at least 30% in total ALP after 1 year of treatment, and this proportion was of 64% for urinary CTX. Fifty-four percent of patients were radiographic responders, similarly distributed between monostotic FD and polyostotic FD. The number of localizations, age, and serum phosphate were not associated with radiological response. Men tended to have a better radiological response, but this was not significant (OR = 2.3 [0.8, 6.6]). Similarly, there was no association between radiographic response and biological response, as assessed by total ALP ($p = 0.9$) and urinary CTX ($p = 0.87$). There was also no association between clinical response and radiographic response ($p = 0.38$). Intravenous pamidronate was well tolerated. Three patients had also mineralization defects, for which the main contributor may have been renal phosphate wasting. We conclude that half of the patients with FD treated with intravenous pamidronate exhibit thickening of cortices and/or filling of osteolytic areas, along with significant reduction in bone pain and bone turnover, but prediction of response to treatment is uncertain.

SA393

Abnormal Phosphate Transport in Hyp-Mouse Osteoblasts May Underlie the Inability to Rescue the HYP Phenotype. A. Bhargava*, R. Aravindan, M. K. Drezner. Medicine, University of Wisconsin, Madison, WI, USA.

Recent studies indicate that PHEX mutations underlie X-linked hypophosphatemic rickets. However, efforts to normalize mineralization and rescue the disease phenotype by *in vitro* transfection of *hyp*-mouse osteoblasts or by creation of transgenic mice over-expressing osteoblast promoter-PHEX gene transcripts have failed. The likely reason for failure is absence of PHEX during osteoblast development, prior to osteocalcin and collagen1A1 expression, and consequent lack of enzyme activity requisite to alter an otherwise immutable osteoblast abnormality, which predisposes to aberrant mineralization. Such an occurrence would impair osteoblast function/mineralization and prove refractory to late PHEX expression. To explore this possibility we studied the immortalized SV40 *hyp*-mouse osteoblasts, used for PHEX transfection, and comparable normal cells. We investigated if sodium dependent phosphate (P) transport, a process likely crucial to mineralization, is abnormal in the mature *hyp*-mouse osteoblast and independent of PHEX expression. We plated 40,000 cells per well in 24 well plates and measured active P transport at 4, 7, 11 and 14 days of culture. P transport in *hyp*-mouse osteoblasts was decreased significantly ($p<0.01$) compared to that in normal osteoblasts at each time point by 48.2±2.3%, 32.9±2.4%, 21.5±3.0% and 19.5±3.1%, respectively. Moreover, comparable alanine transport in the normal and *hyp*-mouse osteoblasts indicated that the defect was specific. Further, Lineweaver-Burke plots documented the defect was due not to an altered Km (0.16±0.04 vs 0.19±0.04) but to an abnormal Vmax (29.4±0.9 vs 16.9±1.0 nmoles/mg/10 min; $p<0.001$). Consistent with the apparent decrease in P transporters, semi-quantitative RT-PCR revealed the sodium-dependent P co-transporter (Npt3) concentration in *hyp*-mouse osteoblasts less than in normal osteoblasts at 4, 7, 11 and 14 days of culture. The PHEX independence of this abnormality was indicated by higher P transport in normal osteoblasts before and after PHEX expression, which occurred at 9 days of culture, and the failure of P transport to decrease in normal cells when exposed to conditioned medium from *hyp*-mouse osteoblasts, which contains PHEX substrate(s). These data indicate that defective mineralization in *hyp*-mouse osteoblasts may occur in part due to abnormal P transport, a PHEX refractory event in mature cells. Thus, the failure to rescue the *Hyp* phenotype, either by PHEX transfection or creation of transgenic animals over-expressing osteoblast promoter driven PHEX transcripts, may be due to failure of this gene to normalize osteoblast P transport early in cell development.

SA394

Evidence That PHEX Has a Role in Normal Mineralization. A. Bhargava*, R. Aravindan, M. K. Drezner. Medicine, University of Wisconsin, Madison, WI, USA.

X-linked hypophosphatemia (XLH) is a genetic disease characterized by impaired bone mineralization and hypophosphatemia. Inactivating PHEX mutations underlie the disorder

and contribute, in part, to defective mineralization, likely by failure to degrade putative phosphatonin(s). Whether the PHEX gene product plays a role in normal mineralization, however, remains unknown. Since previous studies revealed *hyp*-mouse osteoblasts produce a mineralization inhibitor in the absence of PHEX, we investigated if osteoblasts from normal mice produce a similar inhibitory factor, the function of which is dictated by PHEX expression. In these studies we used immortalized osteoblasts from SV40 normal (N) and *hyp*-mice and assessed production of a mineralization inhibitor(s) employing co-culture techniques. We plated 10,000 normal osteoblasts in 6 well plates. After 7 days, inserts containing 40,000 normal or *hyp*-mouse osteoblasts, previously cultured for 0 or 7 days, were placed in the wells. We removed the inserts on the 14th day of culture and determined mineralization of normal osteoblasts in the wells by alizarin red staining and ^{45}Ca incorporation. In this manner normal osteoblasts at 7-14 days of culture, inclusive of the mineralization period, were exposed to secreted products of normal osteoblasts 7-14 (Control) or 0-7 days old and *hyp*-mouse osteoblasts 7-14 or 0-7 days old. Not unexpectedly, co-culture with *hyp*-mouse osteoblasts aged 0-7 or 7-14 days impaired mineralization of normal cells. More importantly, co-culture with normal osteoblasts aged 0-7 days likewise impaired the mineralization of normal osteoblasts. This surprising discovery suggests that normal osteoblasts produce a mineralization inhibitor, the functional expression of which disappears with prolonged culture. Moreover, since PHEX was not expressed in *hyp*-mouse osteoblasts but was expressed in normal osteoblasts only after 7 days of culture, the mineralization inhibitory activity of the *hyp*-mouse and normal osteoblasts correlated with absence of PHEX expression. These observations indicate that osteoblasts routinely produce a mineralization inhibitor(s), the function of which is temporally dependent upon absence of PHEX expression. This mechanism may contribute to the regulation of normal mineralization, playing a role in events that characterize the mineralization process, such as mineralization lag time.

Cells in Insert	PHEX Expression	Alizarin Staining	45Ca Incorporation (cpm/mg protein)

Immunohistochemical Detection of FGF-23 Protein in Tumors that Cause Oncogenic Osteomalacia. T. Larsson*[1], R. Zahradnik*[2], R. Marsell*[1], Ö. Ljunggren[1], J. Lavigne[2], H. Jueppner[3], K. Jonsson[1]. [1]University Hospital, Department of Medical Sciences, Uppsala, Sweden, [2]Immutopics Inc, San Clemente, CA, USA, [3]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

Oncogenic hypophosphatemic osteomalacia (OOM) is a rare disease characterized by hypophosphatemia, inappropriately low levels of circulating 1,25 dihydroxyvitamin D_3 and osteomalacia. The disease is most commonly caused by benign mesenchymal tumors that produce, among several other factors, fibroblast growth factor 23 (FGF-23). FGF-23 has been shown to promote *in vivo* renal phosphate excretion through yet undefined mechanisms. Furthermore, patients with autosomal dominant hypophsophatemic rickets (ADHR), an inherited disorder with clinical and biochemical features similar to those of observed in OOM, carry a mutant FGF-23 gene. Current evidence thus suggest that this protein has an important role in the regulation of phosphate homeostasis. To determine whether OOM tumors expressing FGF-23 mRNA also show readily detectable levels of FGF-23 protein, different polyclonal antibodies were raised in rabbits against three different peptides with sequences derived from human FGF-23: [Cys-70]FGF-23(51-69)amide, [Tyr-223]FGF-23(206-222)amide and [Tyr-224]FGF-23(225-244)amide. After affinity purification, all three antibodies detected recombinant human FGF-23 by Western blot analysis. Through immunohistochemical analysis using the anti-[Tyr-224]FGF-23(225-244)amide antibody and through *in situ* hybridizations using full length antisense FGF-23 cRNA as a probe, we showed that abundant amounts of FGF-23 mRNA and protein are present in certain cells of five different OOM tumors. We therefore conclude that the immunohistochemical detection of FGF-23 in OOM tumors is feasible and may help in establishing the diagnosis of tumor-induced hypophosphatemia through analysis of biopsies or surgical specimens.

SA397

The Effect of Supplementation of Inorganic Phosphorus and 1,25-dihydroxyvitamin D_3 on Bone Density on Sporadic Hypophosphatemic Rickets. Y. Imanishi, K. Nakatsuka, K. Kobayashi*, K. Lee*, H. Tahara, H. Goto, E. Ishimura*, M. Inaba, Y. Nishizawa. Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan.

Oncogenic osteomalacia (OOM) is a rare paraneoplastic syndrome that is characterized by hypophosphatemia and low plasma 1,25-dihydroxyvitamin D in association of various types of tumors. Until the responsible tumors were identified and resected, the patients should be treated in combination of pharmacological amounts of inorganic phosphorus and 1,25-dihydroxyvitamin D_3 (1,25-D_3) as sporadic hypophosphatemic rickets. We present two patients with sporadic hypophosphatemic rickets, one was diagnosed as an OOM since the impaired phosphate and vitamin D metabolism completely improved following resection of the responsible tumor (case 1). Another patient was failed to detect any tumors responsible for osteomalacia, and received the combination therapy with inorganic phosphorus and 1,25-D_3 (case 2). Following tumor resection, tubular maximum transport of phosphate (TmP/GFR) was recovered from 0.20 to 1.13 mmol/L, serum phosphate concentration from 0.52 to 1.19 mmol/L on case 1. Suppressed TmP/GFR (0.34 mmol/L) and hypophosphatemia (0.48 mmol/L) were observed at the initiation of the combination therapy on Case 2, and serum phosphate level were kept more than 0.97 mmol/L during the therapy. Bone mineral contents were measured on these patients, before and 1 year after resection of tumor or combined therapy. Lumber spine bone mineral densities were dramatically improved from 0.778 to 1.020 g/cm^2 in case 1, and from 0.448 to 0.962 g/cm^2 in case 2. In conclusion, combination therapy of inorganic phosphorus and 1,25-D_3 is as effective as tumor resection.

False Positive Magnetic Resonance Imaging Skeletal Survey in a Patient with Sporadic Hypophosphatemic Osteomalacia. K. Kobayashi*, Y. Imanishi, K. Nakatsuka, E. Ishimura*, M. Inaba, N. Yoshiki. Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan.

We report a case with adult-onset hypophosphatemic osteomalacia due to renal phosphate wasting, known as tumor-induced osteomalacia (TIO). Biochemical evaluation revealed hypophosphatemia, low tubular maximum transport of phosphate (TmP/GFR), low concentration of serum 1,25-dihydroxyvitamin D, and high serum alkaline phosphatase. Bone biopsies also revealed osteomalacia. In an effort to localize the tumor responsible for TIO, we conducted an whole body Magnetic Resonance (MR) survey. MR imaging showed the presence of tumors in a femoral neck. The lesion appeared as a low-intensity and high-intensity mass in T1-weighted spin echo and T2-weighted turbo spin echo sequences, respectively. Resection of the tumor failed to normalize serum phosphate and TmP/GFR, and pathological analysis revealed bone island. In conclusion, MRI screening might not be as specific as previously thought in localizing the responsible tumor of TIO.

Fanconi's Syndrome in HIV Positive Adults: Report of Three Cases and Literature Review. K. Earle*[1], T. Seneviratne*[1], J. Shaker*[2], D. Shoback*[3]. [1]Dept. of Medicine, UCSF, San Francisco, CA, USA, [2]Dept. of Medicine, St. Lukes Medical Center, Milwaukee, WI, USA, [3]Endocrine Research Unit, VA Med Center, San Francisco, CA, USA.

Fanconi's syndrome results from generalized proximal tubular dysfunction and causes increased excretion of amino acids, glucose, urate, bicarbonate, and phosphate. The syndrome includes osteomalacia, metabolic acidosis, polyuria, and dehydration. We report 3 cases of Fanconi's syndrome in HIV positive patients. Case 1 was a 43 year-old HIV positive woman presenting with multiple painful stress fractures on an antiretroviral regimen of tenofovir, ritonivir, lopinavir, and lamivudine. Laboratory abnormalities included hypophosphatemia, hypokalemia, and metabolic acidosis. Urinary studies revealed phosphaturia, glucosuria, and generalized aminoaciduria. She initially received phosphate supplementation, but after tenofovir was discontinued, her laboratory values corrected. Case 2 was a 39 year-old HIV positive man with hypophosphatemia and bone pain whose symptoms began 6 months after initiation of adefovir. He also demonstrated hypokalemia, metabolic acidosis, and glucosuria. After discontinuation of adefovir and supplementation with phosphate and potassium, his symptoms markedly improved. Case 3 was a 48 year-old HIV positive man who presented with tetany and muscle cramping in the setting of mild renal insufficiency. Medications prior to admission included didanosine, ritonavir, saquinavir, nevirapine, and ganciclovir. Nine months prior, he had taken cidofovir for retinitis due to cytomegalovirus. Although serum creatinine values were improving prior to admission, serum calcium, phosphate, and potassium levels declined progressively until frank tetany precipitated hospitalization. All 3 patients exhibited classic features of Fanconi's syndrome, and all were treated with various antiretroviral regimens. In Case 1, Fanconi's syndrome correlated with use of the antinucleoside tenofovir, which has not been previously reported to cause this complication. A similar compound adefovir has been associated with Fanconi's syndrome in HIV positive patients and is the likely etiology in our second patient. The cause of Fanconi's syndrome in the third patient is unknown. Previous use of cidofovir or the recent onset of renal insufficiency, possibly due to drug-induced interstitial nephritis, may have contributed to proximal tubular dysfunction. Although Fanconi's syndrome is a rare complication of HIV disease and antiretroviral therapy, these cases underscore the need for careful clinical and laboratory monitoring of HIV positive patients so that overt tetany, osteomalacia, and fractures are prevented.

SA402

Treatment of Resistant Paget's Bone Disease with Monthly Clodronate Infusion. P. Filipponi[1], S. Cristallini*[1], G. Policani*[1], B. Frediani*[2], M. F. Schifini*[1], P. Garinei*[1], S. Morlunghi*[1]. [1]Umbertide Regional Hospital, Bone & Mineral Research Unit, Umbertide-Perugia, Italy, [2]University of Siena, Institute of Reumatology, Siena, Italy.

Although there is currently no cure for Paget's disease of bone since its etiology is unknown bisphosphonates have been identified as the best therapy option. They induce a substantial reduction in disease activity with the rider that - while some patients go into long-term remission after a single course of therapy (sometimes for several years) - most pagetics experience a biochemical relapse within 1-2 years. In this study we treated 13 pagetics, who had had unsatisfactory results from prior conventional bisphosphonate therapy, with monthly 300 mg clodronate intravenous infusion. Treatment was continued irrespective of the achievement or not of a positive response (that is, a reduction from baseline in excess bone specific alkaline phosphatase of 50% or more). Of the 13 patients, 11 had an average reduction from baseline in excess bAp of more than 50% during the follow-up, which lasted between 30 and 36 months. Response occurred between 3 and 9 months after the beginning of monthly clodronate infusion, the average length of response being 26.7 ± 2.2 months. Of the 11 responders 6 entered remission: the average duration of remission was 20.0 ± 2.9 months, ranging from 9 to 30 months. At the end of the follow-up 3 of these 6 patients were still in remission, while 2 still had a reduction in bAp excess of over 50%. Of the other 5 responsive patients who did not enter remission 2 were relapsing at the 24th and 30th month, while the other 3 were still responding at the end of the follow-up period. The 2 non-responders also showed an average reduction in bone bAp of over 30%. Pain unrelated to osteoarthritic complications was reduced in 7 of the 11 patients who had complained of pain before treatment began: they were usually the pagetics who had a better biochemical response to treatment. No alterations were detected in routine biochemical tests, including white cell count and renal function. One patient had local irritation at the site of infusion. Monthly clodronate administration could be a useful and safe alternative in the treatment of resistant Paget's bone disease. In a large number of patients bone turnover can be suppressed and, in some, returns to within normal range.

Serum Osteoprotegerin and Serum RANKL in Paget's Disease. R. Nuti, G. Martini, R. Valenti*, S. Giovani*, L. Gennari, S. Salvadori*, B. Galli*. Metabolic Disease Unit, University of Siena, Siena, Italy.

Osteoprotegerin (OPG), a secreted member of tumor necrosis factor superfamily, has been identified as a osteoblast-derived regulator of bone resorption: it acts by neutralizing the receptor activator of nuclear factor-kB ligand (RANKL), a cytokine required for osteoclast formation and activation. It has been demonstrated an increase of OPG with age and higher values in females than males. Moreover, serum OPG levels increase in patients with advanced prostate cancer, while a reduction was found in osteolytic multiple myeloma. To better understand the relationships among serum OPG, RANKL and bone metabolism, we studied a group of 30 patients (16 females aged 60-90 years and 14 males aged 47-88 years) with Paget‘s disease of bone. Eleven women with established postmenopausal osteoporosis were used as control group. Sera were assayed for OPG and RANKL using a sandwich enzyme immunoassay (Osteoprotegerin and sRANKL, Biomedica, Vienna, Austria). Precision inter- and intra-assay was lower than 10%. Serum bone alkaline phosphatase (bALP, Ostase-Tandem, Beckman-Coulter, U.S.A.) and serum cross-linked C-telopeptides of type-I collagen (sCTX, Serum CrossLaps, Osteometer, Denmark) were used as markers of bone formation and bone resorption, respectively. Pagetic patients showed the expected significantly higher values of bALP and sCTX compared to osteoporotic women: 64.2 µg/l ± 20 vs 18.6 µg/l ± 17, p<0.01 and 7916 pmol/l ± 4000 vs 4374 pmol/l ± 3187, p<0.05, respectively. In Paget‘s disease we found significantly higher values of OPG and signicantly lower values of RANKL with respect to osteoporotic women (7.81 pmol/l ± 5.2 vs 4.25 pmol/l ± 2.2, p<0.01 and 3.04 pmol/l ± 1.9 vs 7.6 pmol/l ± 6.8, p<0.01, respectively). The relationship between bone markers was statistically significant (r=0.33, p<0.05), while any correlations were found between OPG, sRANKL and indexes of bone formation and resorption. An inverse but not significant relationship was found as regard OPG and sRANKL (r=-0.13, ns). In conclusion, higher values of OPG, considered as an antiresorptive factor, were found in patients with higher bone turnover due to Paget‘s disease of bone: it could indicate an attempt to counteract the increased rate of bone remodeling. The hypothetic explanation of low serum RANKL observed in pagetic patients involves the inhibitory effect of OPG on RANK system. Moreover, the increased sensitivity of osteoclast precursor to the humoral factor like RANKL , justifies persistence of high bone turnover values found in Paget‘s disease.

Use of Intravenously Pamidronate in Paget`s Sarcoma. Z. Man, R. Fiasche. Centro TIEMPO, Universidad Favaloro, Buenos Aires, Argentina.

The bone`s sarcoma in Paget`s Disease (PD) is the worst complication and does not exist any clear protocol of treatment. When the diagnosis is made, the average of life is no longer than a year. We presented the case of a female of 68 years old with PD in left femur, diagnosed radiologically (Rx) after a fall. Laboratory test and other Rx were asked for, and she was dated 20 days later to initiate processing. In this lapse the annoyances attributed to the fall changed to permanent and severe pain. The leg was edematous and the Rx showed rupture of cortical in the area of the Paget`s bone and also the invasion of soft parts. The laboratory findings were: normal serum calcium, phosphorus, creatinine and red and white blood cells counting, and increased erythrocyte sedimentation (ESR) and more than 5 times higher alkaline phosphatase (AP). Surgical cleaning was performed in the patient, and a replace of the pagetic bone with a nonconventional prosthesis took place, that allowed her to walk . Two months before, and also after the surgery, we treated her with monthly infusions of 90 mg of pamidronate (APD) with supplements of calcium and Vitamin D. The first pulmonary metastasis appeared 12 months after the diagnosis, without worsening her quality of life. In the 18th month we observed a local growth, accompanied with a 10 times elevated AP, which forced us to practice another surgical cleaning. We continued with the same medication until completing 24 months. By that time the patient had deterioration of the conscience and passed away one month later. In our casuistry of 5 cases, 4 passed away before the 8 months (range 3-10 months), in a very bad health and without being able to stop the local recurrence nor the pulmonary metastasis. CONCLUSION: We considered that APD IV in doses of 90 mg per month with supplementation with calcium and vitamin D during all the evolution of the disease, contributed to improve the quality of life of this kind of patient

Trial to Predict Malignancy of Affected Parathyroid Glands in Primary Hyperparathyroidism. Q. Chen*, H. Kaji, R. Nomura*, K. Ikeda, H. Sowa*, M. Yamauchi*, T. Tsukamoto*, T. Yamaguchi, T. Sugimoto, K. Chihara*, M. Kanatani. Endocrinology and Metabolism, Kobe University Graduate School of Medicine, Kobe, Japan.

Primary hyperparathyroidism (pHPT) is included in the common diseases that cause secondary osteoporosis. Parathyroid cancer is rare, but relatively frequent in Japan, compared to Western countries. Surgical parathyroidectomy is the primary choice for the treatment of pHPT, and it is important to distinguish malignant from benign parathyroid tumor in order to determine the surgical indication and operation procedure for pHPT. However, it is not so easy to diagnose parathyroid cancer before the operation. In the present study, we examined the background data, biochemical data and bone mineral density (BMD) of 131 patients with pHPT (111 benign and 20 malignancy) in our institution. BMD of the lumbar spine and mid-radius was measured by dual-energy X-ray absorptiometry. Serum levels of calcium, parathyroid hormone (PTH) and alkaline phosphatase (ALP) were significantly higher in malignant group, compared to benign one. The magnitude of elevation of mid-portion PTH seemed to be greater than that of intact PTH in malignant. Age-, gender- and race-adjusted BMD of mid-radius was significantly decreased in malignant, compared to benign, although that of lumbar spine was not significantly different between two groups, indicating that osteopenia is remarkable in the region which is rich in cortical bone in the patients with parathyroid cancer. On the other hand, serum levels of calcium, ALP and mid-portion PTH as well as age were selected as predictors of malignancy in monovariate logistic regression analysis, although serum level of intact PTH was not selected. In conclusion, mid-radius BMD, which is rich in cortical bone, was lower in malignant, compared to benign in pHPT. Serum levels of calcium, ALP and mid-portion PTH were useful to predict malignancy of affected parathyroid glands in pHPT patients. The fragments of mid-portion or carboxyl-terminal portion of PTH would be predominantly produced from parathyroid cancer.

Lack of Effect of Vitamin D Status on Bone Mineral Density in Italian Female Patients with Primary Hyperparathyroidism. V. Carnevale*[1], S. Minisola[2], A. Scillitani*[3], E. Romagnoli*[2], S. Dionisi*[2], D. Diacinti*[2], E. D'Erasmo*[2], G. Mazzuoli[2]. [1]Dpt. of Internal Medicine, "Casa Sollievo della Sofferenza" Hospital, San Giovanni Rotondo, Italy, [2]Dpt. of Clinical Sciences, "La Sapienza" University, Rome, Italy, [3]Dpt. of Endocrinology, "Casa Sollievo della Sofferenza" Hospital, San Giovanni Rotondo, Italy.

A relative or absolute deficiency of vitamin D is considered a prominent factor determining skeletal damage in patients with primary hyperparathyroidism (PHPT). We investigated the impact of vitamin D status on BMD in PHPT patients. In 62 female PHPT patients we measured serum total and ionised calcium, phosphorus, creatinine, total alkaline phosphatase activity, intact parathyroid hormone (PTH), 25-hydroxyvitamin D (25OHD), together with 24 hour and spot fasting urinary calcium. Bone mineral density (BMD) was measured in 58 patients at lumbar spine and in 56 at femoral neck, Ward’s triangle, great trochanter, intertrochanteric line, and total hip. Patients were studied in the period fron february to june 1999. The associations of all variables with age, 25OHD, and PTH were studied by linear multiple regression analysis, utilising progressively restricted models. Mean 25OHD values of PHPT patients (47.3 ± 2.9 nmol/L) did not significantly differ from those of age-matched healthy women from the same area during winter; 27.4% of patients presented 25OHD values below 30 nmol/L. BMD values showed significant regression with age, 25OHD and PTH (p<0.05 for lumbar spine, femoral trochanter, femoral intertrochanteric line, and total hip; p<0.001 for femoral neck and Ward's triangle). Noteworthy, PTH had a leading role in determining such significance, while no significant regression was found between the parameters studied and 25OHD; this was confirmed by the Pearson’s linear correlation analysis. The progressively restricted models showed sig-

nificant regression of femoral neck, Ward's triangle and total hip BMD with age and PTH ($p<0.05$ to $p<0.01$); significant regression of BMD measured at the intertrochanteric line with PTH ($p<0.05$), and those measured at lumbar spine and great trochanter with age ($p<0.05$ to $p<0.01$)were also found. Our data indicate that the influence of 25-OHD levels on BMD, if any, was overwhelmed by the effects of both PTH excess and age. The latter unequally affected BMD of various measured sites with different composition.

Comparison of Magnesium Metabolism in Patients with Autosomal Dominant Hypocalcemia and Other PTH-Deficient Hypoparathyroidism. S. Watanabe*[1], S. Fukumoto[2], Y. Takeuchi[1], N. Chikatsu[3], R. Okazaki[4], T. Fujita*[1]. [1]Department of Medicine, University of Tokyo, Tokyo, Japan, [2]Department of Laboratory Medicine, University of Tokyo, Tokyo, Japan, [3]Department of Medicine, Hitachi General Hospital, Hitachi, Japan, [4]Department of Medicine, Teikyo University, Ichihara, Japan.

Activating mutations of the calcium-sensing receptor (CaSR) cause autosomal dominant hypocalcemia (ADH). Although patients with ADH are reported to be prone to develop renal dysfunction especially after active vitamin D_3 treatment, there is no clear clinical method to differentiate ADH from other patients with PTH-deficient hypoparathyroidism. Activation of CaSR in kidney inhibits reabsorption of Ca and magnesium (Mg), and hypomagnesemia was reported in patients with ADH. However, it is not clear whether hypomagnesemia is characteristic to ADH. Therefore, to clarify if hypomagnesemia can be a diagnostic marker for ADH, we compared Mg metabolism in PTH-deficient patients with and without mutations in CaSR. Direct sequencing of all coding exons of CaSR and in vitro functional analysis of mutant CaSR detected five patients with ADH (K47N, C131W, P221L, F788E and A843E). In contrast, no mutation was found in other seven patients with PTH-deficient hypoparathyroidism. Serum Mg level was low and fractional excretion of Mg (FE_{Mg}) was high in three of five patients with ADH (C131W, F788E and A843E). In addition, these three patients developed clinical symptoms in or before infancy. On the other hand, serum Mg was normal in two asymptomatic patients with ADH (K47N and P221L) and all seven patients with PTH-deficient hypoparathyroidism without mutations in CaSR. Furthermore, although there was a strong negative correlation between serum Mg and FE_{Mg} in patients with ADH ($r = -0.859$, $p < 0.0001$), this correlation was not significant in patients without mutations in CaSR. These results indicate that serum Mg is not low in all patients with ADH and is mainly determined by tubular Mg reabsorption in patients with ADH. It is suggested that symptomatic patients with more severe activation of CaSR develop hypomagnesemia. Therefore, it is concluded that although lack of hypomagnesemia does not rule out ADH, the presence of hypomagnesemia and high FE_{Mg} in PTH-deficient hypoparathyroidism strongly suggests ADH as a cause of hypocalcemia.

Mast Cells Produce Platelet-derived Growth Factor A (PDGF-A) in Response to Continuous Parathyroid Hormone (PTH). J. D. Sibonga, S. Lotinun, R. T. Turner. Orthopedic Research, Mayo Clinic, Rochester, MN, USA.

Skeletal abnormalities associated with chronic hyperparathyroidism (HPT) are commonly characterized by marrow fibrosis, osteomalacia, and higher indices of bone turnover – including focal bone resorption. A rat model duplicates the histomorphometric traits of HPT following chronic administration of PTH (40 µg/kg) for one week. Lotinun et al. previously reported that a receptor antagonist for PDGF-A, a chemotactic and mitogenic factor for fibroblasts, abrogates the peritrabecular fibrosis and the increase in osteoclast-covered perimeter in this rat model. We performed immunohistochemistry on long bones from this animal experiment to determine the cellular localization of PDGF-A protein in response to continuous PTH. Femora were harvested and fixed in 10% neutral buffered formalin for 18h before decalcification by immersion in 20% EDTA at 4°C. PDGF-A was immunostained using VectorElite peroxidase kit (Burlingame, CA) with a polyclonal antibody (Santa Cruz Biotechnology, Santa Cruz, CA). Mast cells in the bone marrow of rats chronically treated with PTH were intensely positive for PDGF-A. Mast cells were identified by the metachromatic staining of granules with toluidine blue. Rats treated with vehicle alone were largely negative for localization of PDGF-A in mast cells. Continuous PTH increased stem cell factor and histamine H2-gene expression. Stem cell factor is essential to the differentiation of mast cells and the H2 receptor is involved in mast cell degranulation and histamine release. Mastocytosis has been observed both in patients with osteopenia and with chronic renal failure; mast cells are implicated as accessory cells to bone resorption and fibrosis; and PDGF-A gene expression can be induced in cultured mast cells as well as induce mast cell proliferation. These findings suggest that mast cells mediate the fibrosis and focal bone resorption observed in HPT.

Spectrum of Mitochondrial Sequence Variants in Normal and Hyperplastic Parathyroid Glands. J. Costa*, T. Tokura, A. Arnold. Center for Molecular Medicine, University of Connecticut School of Medicine, Farmington, CT, USA.

In the pathogenesis of sporadic parathyroid adenomas, the significance of clonal, homoplasmic mutations of the mitochondrial genome has been strongly suggested by their unusual clustered distribution within genes encoding subunits of the NADH dehydrogenase complex (ASBMR 2001). However, because of the high susceptibility of the mitochondrial genome to mutation, it is unknown whether these somatic mutations might be a frequent occurrence in normal parathyroid cells and perhaps of no direct importance to parathyroid tumorigenesis. Therefore, we performed a rigorous mutational analysis of the mitochondrial genomes of normal and hyperplastic parathyroid glands. Included in this study were 8 independent hyperplastic, apparently polyclonal parathyroids and normal peripheral blood leukocytes from 4 patients, plus 5 normal parathyroid glands and one normal thyroid gland from 5 patients. DNA from each sample was isolated and the entire 16.6kb mitochondrial genome was PCR amplified in overlapping fragments and fully sequenced. The resulting sequences were compared with the standard Anderson public mitochondrial DNA sequence and with the online Mitomap database of previously reported mitochondrial sequence variants. A total of 161 sequence variants were detected, with 36% of changes occurring in the genes encoding subunits of the NADH dehydrogenase complex (which collectively comprise 38.3% of the mitochondrial genome). All sequence variants observed in the hyperplastic parathyroid glands were simultaneously observed in normal control DNA from the same patients and, therefore, were not somatic mutations. Of the nine tumor-specific homoplasmic mutations previously reported in parathyroid adenomas, only one change was represented as a germline base variant; none were found in normal parathyroid DNA. In summary, the mitochondrial sequence variants observed in the normal and hyperplastic parathyroid glands studied were consistent with the typical high level of variability in mitochondrial DNA in human populations. In contrast to observations in parathyroid adenomas, no clustering of sequence variants was observed in normal or hyperplastic parathyroids, nor were somatic mutations found. This genetic evidence supports the potential pathogenetic significance of somatic mitochondrial DNA mutations in parathyroid adenomas.

Enhanced Osteoclastogenesis in Congenital Pseudarthrosis of the Tibia Mediated by the Expression of RANK Ligand. I. Nakamura[1], N. Haga*[2], K. Aoki[3], A. Fukuda*[4], M. Hamazaki*[2], Y. Kadono[4], K. Ohya[3], R. Shiro*[5], M. Kimiduka*[5], H. Okazaki*[4], H. Oda*[4], S. Tanaka[4], K. Nakamura[4]. [1]Orthopaedic Srugery, Yugawara Kosei-Nenkin Hospital, Kanagawa, Japan, [2]Orthopaedic Surgery, Shizuoka Pediatric Hospital, Shizuoka, Japan, [3]Pharmacology, Tokyo Medical and Dental College, Tokyo, Japan, [4]Orthopaedic Surgery, University of Tokyo, Tokyo, Japan, [5]Orthopaedic Surgery, National Rehabilitation Center for Disabled Children, Tokyo, Japan.

The purpose of this study is to examine the possible pathophysiology of congenital pseudarthrosis of the tibia, one of the most controversial pediatric entities in terms of etiopathogenesis, pathology, and treatment. Eight patients with this disease and seven adult patients with post-traumatic pseudarthrosis as a control were reviewed histologically, using pathologic materials. The area of congenital pseudarthrosis was divided into three parts with different morphological features; a highly cellular, fibromatosis area, a cartilagenous area and an osseous area. Interestingly, a marked number of osteoclasts, tartrate resistant acid phosphatase-positive multinucleated cells were detected on the surface of the bone and cartilage, and even in the fibrous area apart from bone surfaces. Bone histomorphometric analysis revealed that in congenital pseudarthrosis, osteoclast number (N. Oc/BS) and osteoclast surface (Oc. S/BS) were 2.66 +/- 0.92 [/mm](mean +/- SD) and 10.67 +/- 4.86%, respectively, while in the case of adult pseudarthrosis, N. Oc/BS and Oc. S/BS were 0.62 +/- 0.33 [/mm] and 2.28 +/- 1.20%, respectively. Furthermore, immunohistochemical study showed that RANK ligand, an essential factor for osteoclastogenesis, was highly expressed not only in the fibroblastic cells but also osteoclasts themselves in congenital pseudarthrosis. RT-PCR analysis also revealed the higher expression of RANK ligand in congenital pseudarthrosis of the tibia than in post-traumatic pseudoarthrosis. Taken together, the enhanced osteoclastogenesis is at least in part involved in the pathophysiology of congenital pseudarthrosis of the tibia. In addition, RANK ligand, an autocrine and paracrine factor for osteoclast differentiation and activation, might be one of the therapeutic targets for this refractory disease.

Decreased Vitamin D Precursor in Skin Following Burns. G. L. Klein[1], T. C. Chen[2], M. F. Holick[2], C. B. Langman[3], M. M. Celis*[1], D. N. Herndon*[1]. [1]University of Texas Medical Branch and Shriners Burns Hospital, Galveston, TX, USA, [2]Boston University School of Medicine, Boston, MA, USA, [3]Children's Memorial Hospital,Northwestern University Medical School, Chicago, IL, USA.

Children who suffer burns greater than 40 percent total body surface area (TBSA) have chronically low serum levels of 25-hydroxyvitamin D(25D) at 2 and 7 yr post-burn. Serum 1,25-dihydroxyvitamin D (1,25D) is normal at 2 yr post-burn but low in approximately half the patients by 7 yr post-burn (Klein et al J Trauma 2002; 52: 346-50). Because sunlight exposure post-burn is not controlled and vitamin D intake is uncertain, it is difficult to explain why patients exposed to sunlight post-burn are vitamin D deficient. The aim of our study was to see if the skin of burn patients had normal quantities of vitamin D precursor, 7-dehydrocholesterol (7DHC). We studied 6 patients(2M, 4F) burned more than 40% TBSA 6-24mo prior. Skin biopsies 0.6 cm were taken from the burn wound and adjacent normal skin, snap-frozen, and analyzed for 7 DHC by straight-phase high performance chromatography. Lumbar spine bone density was obtained by dual energy x-ray absorptiometry(Hologics 4500A), and 25D and 1,25D were analyzed by radioreceptor assays. There were no differences in 7DHC between burn wound and normal skin. All showed a mean of 545 +/- 364 (SD) ng/cm2, or 23 +/- 15% of the normal level of 2352 +/-320 ng/cm2. Preliminary data from UVB light exposure of skin in one biopsy from one of the patients showed a conversion from 7DHC to pre-vitamin D of 5.7% compared to control skin of similar pigment (20%). Serum 25D was normal in 2 patients and at lower limits of normal in 2 others. S1,25D was normal in all patients. Lumbar spine bone density Z-scores were greater than 1 SD below the mean in 2 of 5 patients (40%) and between 0-1SD below the mean in 2 others. Thus skin has low quantities of 7DHC following severe burn whether wound or unburned skin, suggesting a defect in skin cholesterol biosynthesis. Reduced conversion of 7DHC to pre-vitamin D may also be occurring but more studies must be done to confirm this. There is a need for vitamin D supplementation post-burn.

Pubertal Growth Is Normal in Treated Girls With X-Linked Hypophosphatemic Rickets. O. Makitie*[1], A. Doria*[2], A. Daneman*[2], E. Sochett[1]. [1]Pediatric Endocrinology, University of Toronto, The Hospital for Sick Children, Toronto, ON, Canada, [2]Diagnostic Imaging, The Hospital for Sick Children, Toronto, ON, Canada.

X-linked hypophosphatemic rickets (XLH) is characterized by hypophosphatemia, rickets and impaired growth. Treatment with oral phosphate (Pi) and calcitriol results in resolution of the skeletal changes and improved height gain. However, even with optimal treatment many patients do not achieve normal stature. It is not known to what extent pubertal growth contributes to this height deficit. To assess pubertal growth we have reviewed data for patients with XLH who have been followed in our clinic from diagnosis to adult height. The diagnosis was based on hypophosphatemia, subnormal renal tubular Pi reabsorption, elevated plasma alkaline phosphatase activity and radiologic signs of rickets. All the patients were treated with oral Pi and calcitriol since diagnosis, followed 3-monthly and judged to be in good control. Hospital records were reviewed for growth and pubertal development. Individual growth curves were drawn, heights at every full and half year were interpolated and transformed into SD scores (SDS). Height velocities (HV) (over one year) were calculated at these age points. Final height was defined as height after age 16 years when HV was less than 1 cm/year. Predicted adult heights were calculated by the method of Bayley-Pinneau. There were six females and no males with complete growth data. At treatment onset median age was 2.3 yrs and median height -1.4 SDS (range -3.1 - -0.2 SDS). Median prepubertal (at 3-4 yrs before peak HV) height was -2.2 SDS and HV 4.9 cm/yr. Peak HV was reached at median age of 12.8 yrs and was in average 7.6 cm/yr. Median final height was -1.8 SDS. Height SDS improved during puberty in most patients (Table). Mean age at menarche was 13.3 yrs. Predicted adult heights were calculated based on bone age (BA) films obtained at 9.6-12.0 yrs (median 10.6 yrs). In 4/6 patients BA was delayed for more than 1.0 year (1.2-3.5 yrs) and advanced in none of the patients. The predicted adult heights correlated significantly with the achieved final heights ($r=0.98$, $p<0.001$). Our study suggests that in females with XLH (I) height gain and peak HV are normal during puberty, (II) pubertal growth spurt leads to improved height SD score but does not normalize height, and (III) height predictions based on BA films at 10-12 years are accurate.

Pubertal growth in the six females with XLH

Patient #	Prepub.height (SDS)	Adult height (SDS)	Prepub.HV (cm/y)	Peak HV (cm/y)

Bone Mineral Density of the Hip and Spine in Patients with Ankylosing Spondylitis Depending on Nutrition. T. Meurer*, H. Franck*. Center of Rheumatology, Oberammergau, Germany.

Introduction: A sufficient alimentation of vitamine D and calcium is essential in the prevention and treatment of osteoporosis. Patients with ankylosing spondylitis have osteoporosis to a various degree. The aim of our study was to look at the influence of nutrition on bone mineral density in our patients with ankylosing spondylitis. Methods: We included 180 patients with ankylosing spondylitis fulfilled the modified New York criteria. The bone mineral density was measured with DEXA (QDR 4500) at the lumbar spine and right hip. Factors of nutrition were examined by a standardized questionnaire. Results: Positive correlations with bone mineral density were only found with wine consumption. Discussion: No significant correlation between milk and cheese intake with bone mineral density was found in patients with ankylosing spondylitis. Dietetic factors do not seem to influence bone mineral density in patients with ankylosing spondylitis. Only wine consumption seems to have a influence on bone mineral density as is correlated positively in our patients with ankylosing spondylitis.

Hormone Replacement Therapy and the Development of Knee Osteoarthritis in Elderly White Women. A Case-Control Study. J. Brantus*[1], I. Reading*[2], C. Cooper[2]. [1]Centre Hospitalier, Villefranche sur Saône, France, [2]MRC Environmental Epidemiology Unit, University of Southampton, Southampton, United Kingdom.

The goal of the study was to examine the association of hormone replacement therapy (HRT) with knee osteoarthritis (OA) in a population-based case-control study among 321 female cases and 321 age-and sex- matched controls. A total of 321 women listed for knee surgery because of primary OA over an 24 month period were compared with an equal number of controls selected from the general population and individually matched for age and general practice. Information about reproductive variables was obtained by questionnaire administered at interview. The risk of knee OA was not significantly decreased in women who had undergone oophorectomy (OR 0.6, 95% CI 0.3-1.4) and we observed a non-significantly increased risk of OA in women who had undergone a hysterectomy (OR 1.3, 95% CI 0.7-2.6). After adjustment for body mass index (BMI), presence of Heberden's nodes, previous knee injury (all independent risk factors for knee OA), and for other reproductive variables, there was a non-significantly increased risk of knee OA in the women who used HRT for less than 2 years (OR 1.7, 95% CI 0.4-7.3)and in those who used HRT for more than 2 years (OR 1.3, 95% CI 0.6-3.0). When we divided the group according to whether HRT was started before or after the onset of knee pain, long-term (more than 2 years) HRT use was associated with an non-significantly increased risk of knee OA both in the women whose therapy pre-dated pain (OR 1.2, 95% CI 0.5-3.0) and in the women who started the therapy after the onset of knee pain (OR 1.7, 95% CI 0.2-12.4). Age at menarche, age at menopause, oral contraceptives and number of pregnancies were not significantly associated with risk of knee OA. These data show that HRT after 50 increased the relative risk of knee OA. Our results suggest also that risk of knee OA is decreased among women who have undergone unilateral or bilateral oophorectomy and that there is a non-significant increased risk of OA in women who had undergone a hysterectomy. Studies are required to investigate the mechanisms underlying these associations.

Abnormalities in the Replicative Capacity of Osteoblastic Cells in the Proximal Femur of Patients with Osteonecrosis of the Femoral Head. V. Gangji[1], J. Hauzeur*[1], A. Schoutens*[2], M. Hinsemkamp*[3], T. Appelboom*[1], D. Egrise[2]. [1]Rheumatology, Hôpital Erasme, Brussels, Belgium, [2]Nuclear Medicine, Hôpital Erasme, Brussels, Belgium, [3]Orthopaedic Surgery, Hôpital Erasme, Brussels, Belgium.

Aseptic non traumatic osteonecrosis (ON) of the femoral head is a painful disorder which often leads to femoral head collapse due to subchondral fracture.There are multiple mechanisms postulated for ON but none seems to explain entirely the features seen in ON. We postulated that an alteration of osteoblast function might play a role in the physiopathology of ON. In this study we evaluated the ex vivo proliferation rate and differentiation capacity of osteoblasts derived from the intertrochanteric region of the femur and of the iliac crest of 13 patients with ON and compared it with 8 patients with hip osteoarthritis (OA). Nine patients had ON due to corticosteroid therapy; 2 patients had ON due to alcohol abuse. For 2 patients, no aetiological causes could be found. Their ages at diagnosis ranged from 25-68 years. All patients had a normal bone mineral density. The replicative capacity was assessed by the proliferation rate in secondary culture. The phenotypic characterization was evaluated by the level of alkaline phosphatases activity (APA) and the collagen synthesis. The cell doubling time of the osteoblastic cells calculated between 2 and 7 days was found to be significantly increased (10.9±1.1 days) compared to the iliac crest (6.3±0.8 days) (p=0.003) of patients with ON. In patients with OA the cell doubling time was not statistically different in the femur (6.8±1.0 days) and in the iliac crest biopsies (8.0±1.3 days). The cell doubling time of the osteoblastic cells of the proximal femur was significantly increased in ON patients compared to OA patients (p=0.03). There were no statistical differences in APA or in collagen synthesis between the two sites of biopsies or between ON and OA patients. The altered capacities of proliferation of the osteoblastic cell can be responsible of two different events in the pathogenesis of ON; the appearance of ON and the bone repair that occurs after ON. The decrease of osteoblastic proliferative capacities could reflect the disruption of the mechanosensory role of the osteocyte-canalicular network and explain the evolution from marrow edema to established ON. Secondly, an insufficient repair mechanism due to a decrease in bone formation might explain the evolution to a further stage of ON. In conclusion the present study shows that the replicative capacity of the osteoblastic cell is decreased in the proximal femur of ON due to glucocorticoid therapy or due to other causes suggesting a potential role of osteoblast in the pathophysiology of osteonecrosis of the femoral head.

SA426

A Possible Interaction between 3'UTR of Calcitonin Receptor mRNA and mRNA Degradation Factor AUF1. S. Yasuda*[1], Y. Arao*[2], M. Iitaka*[1], F. Kayama*[2], S. Katayama*[1], S. Wada*[1]. [1]Internal Medicine IV, Saitama Medical School, Iruma-gun, Japan, [2]Dept of Health Science, Jichi Medical School, Tochigi, Japan.

We have studied the mechanism of calcitonin (CT) escape phenomenon and the results indicated that desensitization to CT was associated with the down regulation of CT receptor (CTR). Experiments to explore the molecular basis of the CTR gene expression suggested that decreased stability of CTR mRNA was associated with this down-regulation. In a previous report, we showed that there are several AU rich elements in CTR 3' untranslated region (3' UTR) in various species, which should be crucial to regulate stability of CTR mRNA. In this study, we subcloned the 3' UTR of mouse CTR gene using nested PCR technique from mouse brain cDNA library. UV-cross linking analysis revealed that there are several bands showing interactions between the 32P labelled CTR 3'UTR and nuclear protein extracts form mouse co-culture osteoclasts, RAW-derived osteoclasts, MC3T3E1 and NIH 3T3 cells, respectively. Since AUF1 is well known for its regulatory role of mRNA stability, we examined these extracts by AUF1 specific antibodies using western blotting; the results showed that there are some factors specifically interacted with the antibody. When HA-tagged AUF1 cDNA was transfected to NIH3T3 cells, expression of AUF1 isoforms were only observed on P40 and P45 isoforms. To examine specific interaction of AUF1 and CTR 3'UTR, nuclear extracts of AUF1 transfected cells were co-incubated with CTR 3'UTR, and then immunoprecipitated by HA antibody. RNA was extracted form the mixture and RT-PCR analysis with specific primers of the 3'UTR revealed that CTR 3'UTR was clearly bound to AUF1 P45. Specific binding between AUF1 (P40) and CTR 3'UTR was also supported by the finding that mutant P40 did not interact with CTR 3'UTR. When tetracycline dependent LUC reporter gene was co-inserted with CTR 3'UTR to the vector and then transfected into MCF7, it was found insertion of CTR 3'UTR shortened a half life of LUC activity. We are currently investigating whether certain kinase activators and inhibitors could modify the half life of the LUC activity, since we have shown previously that activation of PKA for mouse and PKC for humans are crucial for the signalling through cell surface CTR.

SA427

What Role Does Calcitonin Play in the Diurnal Regulation of Bone Resorption and Plasma Calcium Homeostasis? L. Klein. Biochemistry & Orthopedics, Case Western Reserve Univ. School of Medicine, Cleveland, OH, USA.

The physiologic function of calcitonin (CT) as a regulator of plasma calcium (Ca) homeostasis is considered relatively minor compared to that of parathyroid hormone (PTH) and vitamin D. It is known that multiple organs (thyroid, lung, liver, thymus, intestine) exist as cellular sources for CT, invalidating the athyroid model for chronic deficiency of CT. Due to efficient conservation of Ca in growing species, young dogs were extensively prelabeled with 45Ca from 6 to 12 weeks of age. Two weeks after labeling, dogs were bled every 4 hours for measuring plasma Ca chemically and isotopically. Previously, we showed that bone 45Ca contributes 2/3 of total blood Ca and intestine (dietary Ca) the remaining 1/3, while the total blood Ca remains constant. Thus, 2 different pools of Ca contributed to blood Ca without changing total level of Ca. During 24 hours blood Ca consists of 70% bone Ca (45Ca) and 30% dietary Ca (40Ca) in the early AM(6-8), and fluctuates daily to 40% bone 45Ca and 60% dietary Ca at 5-7PM while the total Ca and ionizable Ca remain constant. The inverse fluctuating relationship between contibutions of bone and dietary Ca in the presence of constant blood Ca suggests a more sensitive regulation of blood Ca homeostasis than heretofore recognized.

Summary of Experimental Data

Diet	Tx/Rx	Plasma Ca (mg/100ml)	Plasma 45Ca (% of Plasma Ca)	Diurnal Rhythm
Normal	None	12	70	Present
Low Ca	None	12	95	Absent
Normal	TPTX	6	20	Absent
Normal + Ca infus.	TPTX	7	10	Absent
Normal	PTX	10	35	Amplitude 1/2
Normal	TX	12	70	Present
Normal	T/Rx	12	70	Present

The reciprocal changes may require one, two or more hormones. Summary of data (cf. Table) showed 2 protocols (TPTX and Ca deficiency) had lost their diurnal rhythm (DR). These protocols were different, 3 different endocrine tissues were removed from TPTX and no tissues were taken from Ca deficiency. Infusion of supplemental Ca to TPTX dog increased blood Ca without initiating DR. In the PTX dogs (-PTH) on normal diet the amplitude of DR decreased in half but otherwise DR was normal. The removal of thyroid or treatment of thyroid with various anti-thyroid drugs did not affect DR. In 1970 H. Copp and T. Care showed that a Ca deficient state in pigs results in a rapid and complete absence of CT in thyroid blood; not seen after thyroidectomy. Since Ca deficiency yields systemic phenomena it would have a similar deficient affect on all organs and tissues in the body. In normal dogs placed on a Ca deficient diet PTH increases slowly, CT decreases rapidly and DR disappears by 8 to 12 hours in the presence of normocalcemia. CT appears to be the primary hormone for initiating DR because it is very sensitive and rapid in action.

Calcitonin Gene-Related Peptide Stimulates cAMP Production, Increases Intracellular Calcium Ion, and Hyperpolarizes Em in Human MG63 Cells. T. Kawase*[1], L. Stehno-Bittel*[2], D. M. Burns[3]. [1]Pharmacology, Niigata University Dental School, Niigata-city, Japan, [2]Cell Biology and Physical Therapy, KU Medical School, Kansas City, KS, USA, [3]Research Service and Biochemistry & Molecular Biology, Kansas City VA Med. Ctr. and KU Medical School, Kansas City, MO, USA.

Calcitonin gene-related peptide (CGRP) is a skeletal neuropeptide that acts on stromal osteoprogenitor cells, pre-osteoblasts, and osteoblasts. To expand our understanding of CGRP action in human osteoblastic cells we examined human MG63 pre-osteoblast-like cells with standard assays and laser-scanning confocal fluorescent microscopy. In the presence of 0.5 mM IBMX CGRP stimulated cAMP formation 15-fold in these immature cells, similar to that reported for lining and osteogenic rodent cells. By a semi-quantitative dual-dye fluorescent single-cell method, we demonstrate that CGRP also elicits a strong dose-dependent mobilization of intracellular calcium ion that is followed after 130-150 seconds by a prolonged smaller diltiazem-sensitive increase in calcium ion concentration. Using two different membrane potential-dependent fluorescent dyes, we also demonstrate delayed hyperpolarization of membrane potential (Em). Unlike previous data obtained from rat UMR106 cells, pharmacological challenges indicate that Em hyperpolarization is cAMP-dependent in human MG63 cells. Specific binding assays,either with radioiodinated-CGRP or by fluorescence polarization assay using Fluo-CGRP indicate that 13,200 sites per cell are present with a Kd of approximately 150 pM. Several independent cellular responses could result from a CGRP receptor that couples to multiple G-proteins. Alternatively, MG63 cells may possess two very similar CGRP receptor subtypes.

SA429

RAMP1 and RAMP3 Expressions after Aortic Stenosis. C. Cueille*, E. Pidoux*, R. Ventura-Clapier*, J. GAREL. Hôpital Lariboisière, Unité 349 INSERM, Paris, France.

CGRP receptors are present in bones. Osteoblasts are known to express this receptor,and the peptidic ligand may be released by nerve endings in bones. Vascularisation is of importance for bone growth (endochondral ossification) and bone repair. Thus, it is tempting to speculate that CGRP signaling through its proliferative effect may participate in conjunction with VEGF to bone angiogenesis. CGRP receptors were recently described by Hagner et al.(2002) in capillaries and small arteries. In the present work, as a model, we have studied the effect of a change in blood flow on CGRP receptor expression in the myocardium. Reduction of blood flow was induced in rats by aortic stenosis, and chronic heart failure (CHF) developped as a consequence of aortic stenosis. CGRP and adrenomedullin (ADM) are known as potent vasodilators in humans, and receptors for both CGRP and ADM were already identified by others in heart. Receptor activity-modifying proteins (RAMPs) determine the ligand specificity of the Calcitonin Receptor-Like Receptor (CRLR); co-expression of RAMP1 and CRLR results in a CGRP receptor, whereas the association of RAMP2 or RAMP3 with CRLR gives an ADM receptor. We have used semi-quantitative RT-PCR and Western-blot analysis to detect and quantify the mRNA and the protein of RAMP1 and RAMP3 in both atria and ventricles of failing hearts 6 months after aortic stenosis in rats. For the first time, we showed, an up- regulation of RAMP1 and RAMP3 mRNAs and proteins in this model of cardiac failure.When accurate comparisons between sham and CHF rats were done for ventricles and atria, RAMP1 appeared 3-fold more abundant in CHF than in sham rats. The mRNA level of RAMP3 was 10-fold increased in atria of CHF animals, whereas a 3-fold induction was observed in ventricles. Western-blot detected the same forms both for RAMP1 and RAMP3 in ventricles and atria, the major form for RAMP1 and RAMP3 was the homodimer. A 10-fold increase in RAMP1 homodimer in atria of CHF rats was observed, whereas RAMP3 homodimer was 28-fold induced. In ventricles of CHF rats, a 10-fold induction of RAMP1 homodimer occurred. No change was observed in mRNAs coding for CRLR, RAMP2, RDC1, and ADM.After congestive heart failure in adult rats, an up-regulation of the CGRP1 receptor (by an increase in RAMP1 that is associated with CRLR) in atria and ventricles, and of ADM receptor (by increased RAMP3 expression that is associated with CRLR) in atria are suggested. These findings support a functional role for CGRP and ADM receptors to compensate the chronic heart failure in rats.

SA430

Effect of Salmon Calcitonin on Aorta Connective Tissue in Elastin-Derived Peptides-Induced Experimental Atherosclerosis. J. G. Gminski*[1], K. Siemianowicz*[1], M. Goss*[1], V. Ciszek-Doniec*[2], T. Francuz*[1]. [1]Experimental and Clinical Biochemistry, Silesian Medical Academy, Katowice, Poland, [2]Women Health Promotion, Silesian Medical Academy, Katowice, Poland.

Salmon calcitonin is accepted by FDA for the treatment of postmenopausal osteoporosis.The main medical problem in postmenopausal women is atherosclerosis-related cardiovascular disease. Elastin is one of the most apolar and the most long-lived protein. In healthy adults the turnover of elastin is slow, but it is enhanced during aging, hypertension, diabetes and atherosclerosis. Elastin-derived peptides (EDPs) - products of hydrolysis of insoluble elastin play an important role in regulation of vascular smooth muscle cells proliferation, migration and atherosclerosis development. EDPs act through calcium ions-mobilizing receptor, stimulate respiratory burst, activate proteolytic enzymes and induce immune response. The aim of this study is to evaluate the effect of salmon calcitonin on the metabolism of connective tissue matrix proteins in EDPs-induced experimental atherosclerosis. 30 male New Zealand rabbits were divided into 3 equal groups: C (control) group were injected with compltete Freund's adjuvant (CFA) while two other groups - E (EDPs) and E+CT (EDPs + calcitonin) were received 1.5 mg of EDPs from porcine aorta + CFA. The E+CT group received s.c. injections of salmon calcitonin 0.5 MRC per day. The experiment lasted for 6 months. Statistical analysis was performed using the ANOVA test, followed by the Newman-Keul's test. The aortas from rabbits of E group developed typical advanced atherosclerotic lesions including fragmentation of elastic fibers and calcification. No such atherosclerotic changes were found in rabbits of C and E+CT groups. A statistically significant decrease in the aorta level of insoluble elastin, the rise of salt- and acid-soluble collagens and the increase of the elastase-like activity were found in the E group when compared with C and E+CT groups. Administration of salmon calcitonin (E+CT) prevented the rise of calcium-bound to elastin content found in E group.

Effect of salmon calcitonin on aorta connective tissue parameters (mean values)

	Controls (C)	EDPs (E)	EDPs + Calcitonin (E+CT)
Insoluble Elastin (mg/g of wet tissue)	218	132	196
Acid- + Salt-Soluble Collagens (mg/g of wet tissue)	85	128	103
Aorta Elastase-Like Activity (ng of eq. elastase/g of wet tissue/24 h)	134	204	151
Calcium-Bound To Elastin (micromole/g of insoluble elastin)	37	96	34

Molecular Cloning and Expression of Equine Calcitonin, Calcitonin Gene-Related Peptide-I, and Calcitonin Gene-Related Peptide-II. R. E. Toribio*[1], C. W. Kohn*[2], G. W. Leone*[3], C. C. Capen[1], T. J. Rosol[1]. [1]Veterinary Biosciences, The Ohio State University, Columbus, OH, USA, [2]Veterinary Clinical Sciences, The Ohio State University, Columbus, OH, USA, [3]Department of Molecular Virology, Immunology and Medical Genetics, The Ohio State University, Columbus, OH, USA.

Abnormal calcium regulation (hypocalcemia and hypercalcemia) is a frequent finding in horses with different pathological conditions (sepsis, endotoxemia, renal failure). In order to investigate the role of the calcitonin gene family in diseased horses we cloned and determined the tissue expression of three transcripts of the equine calcitonin gene family: calcitonin (CT), calcitonin-gene related peptide (CGRP)-I, and CGRP-II. A divergent form of CGRP (CGRP-I) was identified in horses. Equine CT has the greatest homology (>85%) to human, rat and mouse subgroups of calcitonins. Calcitonin carboxyl terminal peptide (katacalcin) homology to other species is low (<38%). Equine CGRP-I (37aa) has low homology (<59%) to CGRPs of other species. The signal and amino terminal peptides for equine CT and CGRP-I were identical, indicating that these peptides are encoded by a gene equivalent to the human *CALC-I* gene. Equine CGRP-II (37 aa) has >80% homology to chicken, human, rat, ovine, swine, and bovine CGRPs. The homology between equine CGRP-I and CGRP-II is low (56%). The high homology of equine CGRP-II and the low homology of equine CGRP-I to CGRP in other species were unexpected findings, because the homology of all known CGRP peptides was reported to be high in mammals. Northern blot analysis revealed that CT mRNA expression was restricted to the thyroid gland; however, RT-PCR revealed that CT mRNA expression was also present in the pituitary gland. CGRP-I and CGRP-II mRNA expression was present in several regions of the nervous system and other tissues of neuroectodermal origin. An unexpected finding was CGRP-I expression in the kidney by both Northern analysis and RT-PCR. Based on these results, CT gene expression in the horse was not restricted to the thyroid gland, and CT may be important in regulating pituitary cell function. CGRPs are widely expressed in tissues of the central and peripheral nervous system. Information from this study will be valuable in developing equine-specific immunoassays to study the role of CT, CGRP-I, and CGRP-II in health and disease, since human assays for serum concentrations of the calcitonin gene family gave variable results.

Dissociation of Functional Response from Cyclic AMP Stimulation in a Substituted and C-terminally Truncated PTH Peptide. R. J. Murrills, B. M. Bhat, P. V. N. Bodine, Y. Kharode, L. Borella, J. J. Yoon*, R. L. Rupert*, V. E. Coleburn*, R. A. Moran*, J. Marzolf*, F. J. Bex. Women's Health Research Institute, Wyeth Research, Philadelphia, PA, USA.

Selective substitution of several N-terminal amino acids can restore and enhance binding and cyclic AMP activity of PTH peptides whose classical binding domain has been truncated or removed entirely and which would otherwise be weak or inactive (Shimizu et al, 2001, Endocrinology 142:3068). One such modified peptide, [Ala^{3,12}, Nle^{8}, Gln^{10}, Har^{11}, Trp^{14}, Arg^{19}, Tyr^{21}] rPTH(1-21), was created by Gardella's group (JBMR 15 Suppl 1:S566, 2000) and termed modified or MPTH(1-21). We were interested to determine whether MPTH(1-21), which is known to potently stimulate cAMP and bind the PTH receptor, would also be active in animal models of osteopenia and in assays downstream of cAMP in the osteoblast. Initial testing in Saos-2 membrane receptor binding and whole cell cyclic AMP assays confirmed that MPTH(1-21) was indeed almost as potent as PTH(1-34) and induced similar levels of cyclic AMP in Saos-2 cells. However, when tested in OVX osteopenic animals at doses (up to 500ug/kg/day sc in mice, 200ug/kg/day sc in rats) that were up to 20 times higher than those routinely used for PTH(1-34), MPTH(1-21) was completely inactive, as assessed by pQCT. To address this result, we tested MPTH(1-21) in Saos-2 cells that had been stably transfected with 15 copies of the cyclic AMP response element (CRE) linked to a Luciferase reporter. In addition, we tested the peptides in an assay of alkaline phosphatase suppression in a conditionally immortalized human osteoblast cell line, HOB-03-C5, which is sensitive to picomolar (physiological) concentrations of PTH. In both of these downstream assays, MPTH(1-21) was much less potent than would be expected from its binding and cyclic AMP profile.

Assay	PTH(1-34)	MPTH(1-21)
Receptor binding*	0.46nM	0.89nM
Cyclic AMP*	0.65nM	1.19nM
CRE-Luciferase*	1.14nM	28.1nM
Alkaline phosphatase	0.04pM	91pM
OVX mouse	Active @100ug/kg	Inactive at 500ug/kg
OVX rat	Active at 10ug/kg	Inactive at 200ug/kg

*Weighted average EC_{50} value from at least 3 side-by-side determinations.

We conclude that, at the doses tested, MPTH(1-21) was inactive in two animal models of osteopenia. Results from two assays downstream of cAMP suggest a disconnect between cAMP and transcriptional and functional responses that may contribute to this lowered in vivo activity.

Whole PTH Assay Does Not Provide Better Discrimination than the Intact PTH in Patients with Secondary Hyperparathyroidism Due to Renal Failure or Vitamin D Deficiency. P. Glendenning, L. L. A. Laffer*, A. A. Musk*, S. D. Vasikaran. Biochemistry, Royal Perth Hospital, Perth, Australia.

Immunoassays for intact PTH (iPTH) detect the whole PTH molecule (1-84) as well as a mixture of different PTH fragments (2-84 to 7-84). The whole PTH (wPTH) assay has been suggested to be the optimal assay to assess parathyroid function as only whole PTH (1-84), which is the biologically active form of PTH, is detected by this assay. We compared the wPTH to the iPTH assay in 208 patients with secondary hyperparathyroidism to examine if the wPTH assay offered any diagnostic advantage over the iPTH assay. EDTA and serum samples were collected over a 2 month period and stored at -20 degrees C. iPTH was measured by immunochemiluminescence immunoassay (ICMA) on the DPC Immulite 2000 and wPTH was measured by ICMA assay on the Nichols Advantage using EDTA plasma. 25 hydroxy vitamin D (25 OHD) was measured in serum by DiaSorin radioimmunoassay. 18 patient samples were collected in parallel to assess sample stability in EDTA plasma compared to serum. 100 patient samples were collected from patients with advanced renal failure (Cr > 300 umol/L) and 90 samples from patients with vitamin D deficiency (25 OHD < 30 nmol/L) and intact renal function (Cr < 100 umol/L). The correlation coefficient was 0.89 between iPTH and wPTH in both renal failure and vitamin D deficient patient groups. Bland Altman analysis indicated the iPTH result was 75% higher than wPTH in renal failure patients but the difference between both PTH assays was constant across all mean values from 5 to 150 pmol/L. In vitamin D deficient patients, Bland Altman analysis indicated that iPTH result was 60% higher than wPTH but the difference between PTH assays progressively increased to over 80% at mean PTH values above 15 pmol/L. Regression of 25 OHD on iPTH and wPTH in vitamin D deficient patients revealed lack of a relationship with the wPTH assay (P=0.32) but near statistical significance for the iPTH assay (P = 0.06). iPTH was 30% lower in serum than EDTA plasma (P < 0.01). wPTH was 8% lower in serum than EDTA plasma (P > 0.05). The wPTH assay is equally useful compared to the iPTH assay in renal failure patients but may be less useful than the iPTH assay in evaluation of vitamin D deficient patients. However, serum and EDTA plasma give comparable results on the wPTH assay but not with the iPTH assay. Thus there may be pre-analytical reasons but no obvious post-analytical reasons to recommend widespread adoption of the wPTH assay.

A Leader Sequence in the PTH mRNA 5'- Untranslated Region (UTR) Regulates PTH Translation. Y. Moz*, R. Kilav*, J. Silver, T. Naveh-Many. Nephrology, Hadassah Hospital, Jerusalem, Israel.

Computer modeling of the PTH mRNA predicts a stable stem-loop structure of the first 19 nt of the 119 nt long 5'-UTR. Secondary structures in 5'-UTRs often regulate translation of mRNAs. To study the effect of the 5'-UTR on PTH mRNA translation, we performed reticulocyte lysate *in vitro* translation of full-length PTH transcripts or truncated transcripts lacking part of the 5'-UTR. Surprisingly, a full-length transcript was not translated either in this system or in a wheat germ translation system. Truncated transcripts lacking from 9 to 33 nt of the 5'-end of the transcript were translated very efficiently. This suggests that there is a regulatory element in this region that prevented translation. There is no parathyroid cell line, so to study this *in vivo* in cells, we transiently transfected HEK293 cells with plasmids containing the CMV promoter linked to cDNAs for the wild type and truncated transcripts. We then measured the levels of PTH mRNA and PTH secreted into the medium. There was no difference in mRNA levels of the wild type and truncated constructs. However, the truncated constructs resulted in the secretion of large amounts of PTH, while with the wild type full-length PTH construct there was no detectable PTH in the medium. Therefore, both in the *in vitro* translation systems as well as *in vivo* in transfected cells the full-length transcript was not translated. This inhibition could be a result of either sequence or structure that is present in the full-length transcript but not in the truncated transcripts. Point mutations and deletions in the 5'-end of the PTH transcript were subjected to in vitro translation in the reticulocyte lysate system to delineate the mechanism of the translation inhibition by the 5'-UTR 9 nt. Our results show that a sequence/structure in the PTH mRNA 5'-UTR prevents PTH translation. This may be a regulatory mechanism to prevent PTH translation of the large amounts of PTH mRNA that are present in the parathyroid cell. In situations, such as hypocalcemia where increased amounts of PTH are synthesized and secreted, there may be a mechanism whereby the inhibition of PTH translation is overcome. This remains to be tested. In the presence of hypercalcemia up to 90% of the PTH protein may be degraded in the parathyroid. Our results suggest that the individual parathyroid cell is able to regulate the amount of PTH synthesized at a number of levels: PTH gene transcription, mRNA stability, translation and PTH degradation.

Modulation of Parathyroid Hormone Dependent Activation of Phospholipase C. Q. Sun*[1], R. W. Katz[2], J. P. Bilezikian[1]. [1]Medicine, Columbia University College of Physicians and Surgeons, New York, NY, USA, [2]Division of Oral Biology, Columbia University School of Dental and Oral Surgery, New York, NY, USA.

Parathyroid hormone (PTH) can activate Phospholipase C (PLC), which hydrolyzes phosphatidylinositol 4,5-bisphosphate to produce inositol 1,4,5-triphosphate (IP), a second messenger involved in many cell activities. PLC isoforms can be preferentially activated by G protein coupled receptors (PLCβ), by non-receptor tyrosine kinases (PLCγ), and by intracellular Ca^{2+}(PLCδ). We hypothesize that prior modulation of PLC function will alter PTH (1-34)dependent IP production. LLC-PK1 kidney cells overexpressing the rat PTH1 receptor were used in these studies. (1) *Regulation by the G alpha protein subtypes*. Mas-7, a $G\alpha_i/G\alpha_o$ activator, suppressed PTH-dependent IP production by 60%. Pertussis toxin, a $G\alpha_i/G\alpha_o$ inactivator, suppressed PTH IP production by 28%. (2) *Regulation by Ca^{2+}*. Exposure to calcium ionophore A23187 increased basal IP levels over time but one hour pre-exposure did not affect PTH dependent IP. In the presence of EGTA, A23187 reduced PTH IP production by 63%. (3) *Regulation by receptor tyrosine kinases*. Epidermal growth factor, insulin, and platelet-derived growth factor did not affect PTH production of IP. (4) *Regulation by phorbol ester or cAMP analogues*. Adding phorbol-12-myristate-13-acetate overnight reduced the PTH dependent production of IP by 46% but cAMP analogues had no effect of PTH activation of PLC. Our results suggest that PTH receptor signal transduction via the IP second messenger system is affected by alterations in $G\alpha_i/G\alpha_o$ activities, by phorbol ester and by calcium ions, but not by receptor tyrosine kinases or by cAMP. Results provide support for the hypothesis that modulation of PLC activity influences PTH peptide signal transduction.

Effect of Low Calcium Diet on Fertility in PTH-Deficient Mice. X. K. Tong*, D. Miao, R. Huo*, D. Goltzman, A. C. Karaplis. Medicine, McGill University, Montreal, PQ, Canada.

We previously reported that targeted disruption of the PTH gene in mice leads postnatally to abnormalities in skeletal development and calcium homeostasis, as well as to decreased fertility in females. $PTH^{-/-}$ mice on a normal diet were hypocalcemic and demonstrated lower serum progesterone level and irregular menstrual cycles. Histological analysis unveiled a marked reduction in the number of corpora lutea present in the ovaries. Here, we examined the effect of a low calcium diet (0.005-0.01%) on the fertility of $PTH^{-/-}$ female mice. On a low calcium diet, animals remained hypocalcemic and were rendered completely infertile. Serum estradiol and progesterone levels were lower than on the regular diet and were associated histologically with uterine hypoplasia, poorly developed ovarian follicles, and complete absence of corpora lutea. Because ovarian follicular and luteal development is dependent on angiogenesis, we next examined the effect of low serum calcium concentration on this process. In the wild type animals, vascular endothelial growth factor (VEGF) and fibroblast growth factor 2 (FGF2) were expressed in the theca layer and in luteal cells, next to the endothelial cells expressing CD31. Wild type animals on a low calcium intake were normocalcemic and showed no change in the expression of VEGF, FGF2 and CD31. In the $PTH^{-/-}$ mice on a normal calcium diet, cells that stained positive for VEGF or FGF2 in the theca layer and in luteal cells were reduced, as were CD31 positive endothelial cells. When $PTH^{-/-}$ mice were placed on a low calcium diet, positive staining for VEGF or FGF2 in luteal cells was completely absent and that in the theca layer was reduced. CD31-positive endothelial cells were also markedly decreased. These findings indicate that a low calcium diet per se has no apparent effect on fertility; however, hypocalcemia reduces fertility in female mice due in part to diminished angiogenic potential of the ovary, a process that is critical for normal follicular and luteal development.

Regulation of OPG/RANK/RANKL by PTHrP Peptides in Human Prostate Cancer Cells. O. A. Ahmadpour, D. W. Burton, S. Tu*, L. J. Deftos. Medicine, University of California and Department of Veterans Affairs, San Diego, CA, USA.

PTHrP is an oncoprotein that regulates the growth and proliferation of many common malignancies. Studies by us and our colleagues have demonstrated that prostatic PTHrP regulates tumor development, growth and progression. We demonstrated previously that PTHrP plays a role in the progression of prostate cancer metastasis to the bone. The identification of the OPG/RANK/RANKL system as the dominant, final mediator of osteoclastogenesis ended a long-standing search for the specific factors produced by preosteoblastic/stromal cells that were both necessary and sufficient for osteoclast development. Since some prostate cancer cells express these proteins, we hypothesized that metastatic prostate carcinomas also utilize the OPG/RANK/RANKL pathway to localize to the bone. We evaluated several prostate cancer cell lines, including 267 B1, 267 B1-XR, DU 145, Dupro-1, PC-3, LNCaP and PPC-1, for the expression of OPG/RANK/RANKL. All cell lines were shown to express these genes by RT-PCR. We next studied the effect of various PTHrP peptides (1-34, 38-64 and 107-139 and 140-173) on the OPG/RANK/RANKL cascade. Using RT-PCR and immunoassays, we demonstrated that PTHrP 1-34 and 140-173 treatment increased OPG expression in 267 B1-XR and PPC-1 cells. PTHrP 38-64 treatment increased OPG expression in PPC-1 cells only. No significant effects on OPG levels by PTHrP peptides were observed in 267 B1, PC-3, DU 145 and Dupro-1 cells. Based on RT-PCR, RANKL expression was increased in PC-3 and 267B1-XR cells with PTHrP 1-34 and 107-139 treatments, respectively. RANKL expression was decreased by PTHrP 1-34 in 267 B1, 267B1-XR, PPC-1 and Dupro-1 cells. No PTHrP peptide treatment effect was demonstrated on RANKL in the other cell lines. RANK expression did not appear to be regulated by PTHrP in the prostate cell lines, with the exception of PTHrP 140-173, which decreased RANK mRNA in 267B1 cells as measured by RT-PCR. In conclusion, these results suggest that PTHrP promotes prostate cancer to spread to bone by regulating the OPG/RANK/RANKL pathway. Future studies may show that PTHrP regulation of the OPG/RANK/RANKL pathway can be used for the treatment of "osteolytic" prostate cancers.

Two-site Immunoassays for Intact PTHrP Isoforms: Confirmation of Specificity and Measurement of Isoform Expression. L. J. Deftos, C. Chalberg*, K. Smith*, Y. Wang*, S. Tu*, A. Gujral, D. W. Burton. Medicine, University of California and Department of Veterans Affairs, San Diego, CA, USA.

Parathyroid hormone-related protein (PTHrP) is expressed in a wide variety of tissues and has pleiotropic effects on bone minerals and cellular growth and differentiation. Many of these actions have been allocated to specific forms of PTHrP that derive from isoform expression and posttranslation modifications by prohormone convertases to generate peptides of distinct biological function. The development of immunoassays specific to the various forms of PTHrP provides information important to understanding the molecular, cellular, and clinical biology of this oncoprotein. Studies of the human specific and full-length isoforms of PTHrP have been limited by the paucity of specific and sensitive immunoassay for them. In this study, we report the development of two-site immunoassays to measure the intact PTHrP isoforms, including PTHrP 1-141 and PTHrP 1-173. Murine monoclonal PTHrP antibody pairs to PTHrP 1-34 and 109-141 and 1-34 and 140-173 were individually identified by clonal selection, confirmed by tracer binding studies, and purified by affinity chromatography. The antibodies were then configured into a plate-based sandwich assay format that utilized E. Coli produced, recombinant PTHrP 1-141 and PTHrP 1-173 as respective standards. The capture antibodies to PTHrP 109-141 and 140-173 and the biotinylated antibody to PTHrP 1-34 were detected with a streptavidin labeled b-D-galactosidase enzyme reaction using the fluorescent substrate, 4-methylumbelliferyl-b-D-galactopyranoside. The PTHrP 1-141 and PTHrP 1-173 immunoassays appropriately identified the corresponding PTHrP isoforms with sensitivities of 0.08 pmol/L and 0.2 nmol/L, respectively, and dynamic ranges over 3 logs. Other control and test PTHrP species did not react in the assays. The fidelity of the assays was further evaluated by measuring conditioned media and cell extracts from lung, prostate, kidney and pancreatic cancer cell lines that were transfected with PTHrP expression plasmids, including prepro-PTHrP1-87, 1-95, and 1-173. The PTHrP 1-141 and PTHrP 1-173 two-site assays respectively demonstrated increased PTHrP levels in the media and cell extracts of the PTHrP 1-173 group but not in the other groups. Some wild-type cells also expressed specific isoform activity. In summary, we developed high-throughput, non-radioactive, fluorescence immunoassays that specifically measure full-length isoforms of PTHrP. In addition to clinical application, these assays can be especially useful for evaluating the isoform expression and processing of PTHrP.

SA445

Amino-Terminal PTHrP Peptides in Lung Cancer Cell Lines Identified by Mass Spectrometry. R. Miller*[1], B. Schilling*[1], D. W. Burton[2], B. Gibson*[1], R. H. Hastings[3], L. J. Deftos[2], V. H. Hook*[1]. [1]Buck Institute for Age Research, Novato, CA, USA, [2]Medicine, University of California and Department of Veterans Affairs, San Diego, CA, USA, [3]Anesthesiology, University of California and Department of Veterans Affairs, San Diego, CA, USA.

Amino-terminal PTHrP (parathyroid hormone-related protein) peptides are derived from proteolysis of the pro-PTHrP precursor and are secreted from lung tumor cells, resulting in the pathophysiological syndrome of hypercalcemia of malignancy. These amino-terminal PTHrP peptides have largely been identified by immunoassays directed towards synthetic PTHrP(1-34). However, since antibodies may recognize several related peptide forms that resemble standard PTHrP(1-34), the primary sequence identity(ies) of such peptides requires direct determination. In this study, the identification of potential amino acid sequences of peptides detected by anti-PTHrP(1-34) from lung cancer cell lines was accomplished by HPLC and MALDI-TOF mass spectrometry. Acid extracts of BEN (courtesy of T.J. Martin) and A549 cells were subjected to HPLC on a C18 column eluted with an acetonitrile gradient. Fractions were immunoassayed for PTHrP(1-34), and elution positions were compared to synthetic PTHrP(1-34). BEN cells contained PTHrP(1-34) that coeluted with standard PTHrP(1-34). However, the majority of PTHrP(1-34) in A549 cells did not coelute with standard PTHrP(1-34). Identification of the HPLC peaks of PTHrP(1-34) were accomplished by Matrix-Assisted Laser Desorption Ionization Mass Spectrometry. In BEN cells, the mass of the PTHrP(1-34) immunoreactivity, 4015 daltons, corresponded to that of PTHrP(1-34). However, A549 cells contained PTHrP(1-34) immunoreactivity that differed from PTHrP(1-34) and is under further investigation. Production of PTHrP(1-34) would be consistent with cleavage of pro-PTHrP at a Lys-Arg site to generate the NH2-terminus of the peptide, and the C-terminus of PTHrP(1-34) could be generated by cleavage at the monobasic Arg-37 site followed by carboxypeptidase trimming. These results demonstrate the identification by mass spectrometry of peptides included within PTHrP(1-34) from lung cancer that can effect serum calcium.

BIM-44058, A Novel PTHrP Analog, Improves Trabecular Bone Microarchitecture In Old Ovariectomized, Osteopenic Cynomolgus Monkeys. J. Legrand[1], C. Fisch[2], R. Forster[2], B. Koller*[3], J. Z. Dong*[4], C. W. Woon*[4], J. R. Claude*[5], M. D. Culler*[4]. [1]Beaufour-Ipsen, Paris, France, [2]CIT, Evreux, France, [3]Scanco, Bassersdorf, Switzerland, [4]Biomeasure Inc., Milford, MA, USA, [5]Faculty of Pharmacy, Paris, France.

BIM-44058, a novel analog of PTHrP1-34, has been shown to effectively restore bone mineral density (BMD) by stimulating bone formation in both ovariectomized, osteopenic rats, and in old, ovariectomized, osteopenic cynomolgus monkeys, two established models of postmenopausal osteoporosis. In order to study the effect of BIM-44058 on the microarchitecture of trabecular bone, vertebrae from old, ovariectomized (OVX) cynomolgus monkeys, in which established osteopenia had been fully reversed by BIM-44058 therapy, were examined using microcomputed tomography (Micro-CT). Old female monkeys (approx. 4 kg) were either OVX or sham-operated (SHAM), and maintained for 10 months to allow development of osteopenia in the OVX animals. The OVX, osteopenic animals were then treated by daily subcutaneous injection of either saline (n=7) or BIM-44058 at the doses of 1 (n=10) or 10 µg/kg/day (n=8) for 10 months. Upon necropsy, the central portion of the L3 lumbar vertebral bodies were analyzed by high-resolution micro-CT. Total bone volume (TV), trabecular number (Tb.N), trabecular thickness (Tb.Th) and trabecular separation (Tb.Sp) and connectivity density (ConnD) were calculated using standardized methods. The trabecular bone volume, and the number and thickness of the trabecular plates and their separation were identical in all groups. The connectivity density, a 3D index of trabecular connectivity, was higher in animals treated with 10 µg BIM-44058/kg/day when compared with both SHAM ($p<0.05$) and vehicle-treated OVX controls. These results demonstrate that the differences of BMD between the groups are not related to a difference in the cancellous bone volume and suggest that daily treatment with BIM-44058 increases bone mass in osteopenic monkeys by increasing bone mineralization. In addition, treatment with BIM-44058 at 10 µg/kg/day improves the trabecular microarchitecture. Similar observations have been reported in postmenopausal women treated for 36 months with daily injections of human parathyroid hormone 1-34, and suggest that BIM-44058 has the potential to reduce the incidence of spinal fractures in patients with osteoporosis by increasing the bone mineralization and correcting the microarchitectural defects that contribute to skeletal fragility.

SA448

Evidence that Bpa19-modified Parathyroid Hormone-related Peptide (PTHrP) Agonist and Antagonist Analogs Crosslink to Distinct Sites in Transmembrane Domain 2 of the PTH/PTHrP Receptor. R. C. Gensure[1], N. Shimizu*[2], J. C. Tsang*[2], H. Jüppner[2], T. J. Gardella[2]. [1]Endocrine Unit and Pediatric Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [2]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

The interaction of parathyroid hormone (PTH) (1-34) and PTHrP(1-36) with the PTH/PTHrP receptor (P1R) is believed to involve two principal components: an interaction between the portion of the ligand spanning residues 15-31 (binding domain) and the receptor's amino-terminal extracellular domain, and an interaction of the amino-terminal portion of the ligand (activation domain, residues 1-14) and the juxtamembrane (J) region of the receptor (the two-domain hypothesis). However, we have recently found that Bpa19-PTHrP(1-36) crosslinks to the P1R within the interval Leu232-Lys240, in transmembrane domain 2 (TM2) of the receptor, with Lys240 being the apparent photo-interaction site, as judged by alanine-scan analysis. Previous studies have indicated that TM2 plays an important role in ligand-dependent and ligand-independent receptor activation, and that mutations at Arg233 in this domain affect the binding of the agonist PTH(1-34) but not the antagonist PTH(3-34). We therefore hypothesized that Bpa19 in an antagonist peptide would crosslink to a different receptor site than would Bpa19 in an agonist peptide. To test this, we prepared the antagonist Bpa19-PTHrP(5-36) and mapped the site of crosslinking to the P1R. This compound crosslinked to the same TM2 interval as did Bpa19-PTHrP(1-36); however, the alanine scan analysis of this interval revealed differences in the effects of the mutations on the crosslinking of the Bpa19-modified agonists and antagonist analogs. The agonist compound crosslinked poorly to the R233A and K240A mutants, whereas the antagonist crosslinked efficiently to these two mutants, but poorly to F238A. Overall, the

data suggest that Bpa19-modified ligands can detect differences between the agonist- and antagonist-occupied states of the P1R; these differences may involve changes in the relative orientation/position of TM2 in active and inactive receptors.

Temporal Regulation of PTH/PTHrP Receptor Coupling to Protein Kinase C Epsilon is Mediated by Changes in Expression of G11-alpha in Chondrocytic Cells. L. P. Lai*, J. Mitchell*. Pharmacology, University of Toronto, Toronto, ON, Canada.

Phospholipase C signaling via the PTH/PTHrP receptor has been shown to be necessary for normal differentiation of chondocytes *in vivo* (Guo, et al., J. Bone Miner. Res. 16:S229, 2001), it is not clear however what role this pathway plays in regulating chondrocyte growth or differentiation. We have examined the ability of PTH to regulate protein kinase C isozymes in the rat chondrocytic cell line CFK2 that progressively express markers of chondrocytic differentiation with time in culture. After nine days in culture the cells express maximal levels PTH receptor mRNA as well as the G proteins $G_s\alpha$ and $G_{11}\alpha$ to which the receptor couples. PTH (10 nM rPTH1-34) stimulates a three-five fold increase in adenylyl cyclase activity and also stimulates the translocation of PKC-α to the plasma membrane and PKC-ε to the nucleus but has no effect on PKC-β1 or PKC-δ. Over the next four days in culture the expression of $G_{11}\alpha$ decreased by 70% but there was no change in the levels of $G_s\alpha$ protein or PTH receptor mRNA. The decrease in $G_{11}\alpha$ was accompanied by a complete loss of the ability of PTH to stimulate PKC-ε translocation, however, adenylyl cyclase activation by PTH was unchanged. The loss of PTH/PTHrP receptor coupling to PKC-ε was accompanied by an increase in inhibition of cell growth and thymidine incorporation by PTH from 15-24% in cells on day 9 to 41-45% on day 13. Stimulation of the cells on both days with the adenylyl cyclase activator forskolin inhibited thymidine incorporation whereas stimulation by the PKC activator PMA increased thymidine incorporation 78-125%. PTH and forskolin both inhibited mRNA encoding collagen type X approximately 36% whereas PMA stimulated the mRNA levels by approximately 30%. These results indicate that the PTH/PTHrP receptor couples to PKC activation through the G protein $G_{11}\alpha$ in CFK2 chondrocytes and similar to chondrocytes *in vivo*, the activation of this pathway modulates PTH regulation of cell growth and differentiation through $G_s\alpha$ and the adenylyl cyclase pathway. Our data also suggest that PTH/PTHrP receptor coupling to the PKC pathway is dependent on $G_{11}\alpha$ expression levels that decrease as the cells progress towards a hypertrophic phenotype.

Expression of Type I PTH/PTHrP Receptors in the Rat Osteoclast and Osteoclast-like RAW 264.7 Cells. P. H. Watson[1], M. Kisiel*[2], E. K. Patterson*[3], A. B. Hodsman[1], S. M. Sims*[4], S. J. Dixon[4], L. J. Fraher[1]. [1]Medicine, University of Western Ontario, London, ON, Canada, [2]Lawson Health Research Institute, London, ON, Canada, [3]Biochemistry, University of Western Ontario, London, ON, Canada, [4]Physiology, University of Western Ontario, London, ON, Canada.

One of the basic tenets of parathyroid hormone (PTH) action is that bone turnover is regulated via the osteoblast PTH receptor. However, evidence has accrued over the past 25 years to indicate that mammalian osteoclasts bind and respond to PTH. Recently, PTH receptor mRNA was found in osteoclasts from humans with primary HPT (JBMR 16:448-456, 2001), and both PTH receptor mRNA and immunoreactivity was detected in osteoclasts isolated from the molting deer antler (JBMR 17:455-464, 2002). In an extension of our studies of PTH receptor localization in rat tissues and cultured bone and kidney cell lines, we have used indirect immunofluorescence (IF) to localize the PTH receptor in isolated rat osteoclasts and the mouse monocyte cell line, RAW264.7, which can be induced to form osteoclast-like multinucleate cells in culture. Rat osteoclasts were isolated from the long bones of newborn rats using methods well established in our laboratories. Freshly isolated osteoclasts were allowed to adhere to 22 mm square glass coverslips for 1 hr before fixation in 4% paraformaldehyde and processing for IF. RAW264.7 cells were cultured on glass coverslips in alpha-MEM with 15% FCS in the presence of 100 nM 1,25-dihydroxyvitamin D-3 +/- 50 ng/ml RANKL. Samples were fixed after 48, 96 and 168 hr to follow the development of multinucleated cells. IF was performed using a PTH receptor antibody previously characterized (JBMR 15:1033-1044, 2000). Rat osteoclasts showed a unique pattern of immunoreactivity for the PTH receptor. Distinct rings of fluorescence were apparent around the osteoclast nuclei with some staining observed within the surrounding filamentous network. No cell membrane staining was detected in any osteoclast. Monocytic RAW 264.7 cells exhibited no immunoreactivity for the PTH receptor. After 48 and 96 hours of culture in the presence of 100 nM 1,25-dihydroxyvitamin D-3, multinucleate cells started to appear in the cultures. These cells exhibited PTH immunoreactivity within the cytoplasm which appeared as focal points and clusters of fluorescence. These data suggest that osteoclasts do indeed express the PTH receptor, albeit in a different pattern than that of osteoblasts and other cell types. The appearance of PTH receptor immunoreactivity in cultures of RAW264.7 cells induced to form multinucleate cells suggests that PTH receptor expression may be a normal element of osteoclast development.

SA454

PTH1R Endocytosis Is not Necessary for Resensitization of cAMP Signaling. A. Bisello[1], W. B. Sneddon[2], P. A. Friedman[3]. [1]Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [2]Pharmacology, University of Pittsburgh, Pittsburgh, PR, USA, [3]Pharmacology, University of Pittsburgh, Pittsburgh, PA, USA.

The parathyroid hormone type 1 receptor (PTH1R) undergoes agonist-induced endocytosis. This process involves interaction of the occupied PTH1R with members of the arrestin family (arrestin2 and arrestin3) at the cell membrane, targeting of the agonist/PTH1R/arrestin complexes to clathrin-coated pits and subsequent internalization. Internalized PTH1Rs can then recycle to the cell membrane in a fully functional state (resensitization). In this study, we investigated whether endocytosis is required for resensitization of the PTH1R. We measured the cAMP activity of PTH1Rs in the presence or in the absence of arrestin- and clathrin-mediated endocytosis. In HEK-293 cells, expression of the C-terminal region of arrestin2 (arrestin2(319-418)), which is the clathrin-binding domain and acts as dominant negative inhibitor of clathrin-mediated endocytosis, reduced internalization of radiolabeled PTH(1-34) by 80%. Real-time confocal fluorescence microscopy monitoring of a green fluorescent protein-tagged PTH1R demonstrated that arrestin2(319-418) abolished PTH-stimulated PTH1R endocytosis. Expression of arrestin2(319-418) did not affect basal or acute cAMP accumulation in response to PTH(1-34). Furthermore, desensitization of PTH-stimulated adenylyl cyclase activity was unaffected by expression of arrestin2(319-418), consistent with normal interaction of wild type arrestins with occupied PTH1Rs. Surprisingly however, inhibition of endocytosis did not prevent resensitization of PTH1Rc: following a first stimulation by PTH(1-34), the PTH1R response to a second challenge with agonist was equivalent to the first irrespective of the expression of arrestin2(319-418). In conclusion, our data show that: 1) PTH-stimulated PTH1R endocytosis in HEK cells occurs almost exclusively via clathrin-coated pits; 2) PTH1R endocytosis is not necessary for resensitization of cAMP signaling; and 3) resensitizing events, such as dissociation from agonist and dephosphorylation, may take place at the cell membrane.

Vitamin D Receptor Null Mice Bone Possesses Increased Potential of Periosteal Bone Formation. N. Inoue*[1], H. Tanaka[1], M. Inoue[1], S. Kato[2], Y. Seino[1]. [1]Okayama University, Okayama, Japan, [2]Tokyo University, Tokyo, Japan.

Vitamin D has been known as an important hormone in bone metabolism, but there is little evidence that shows direct participation of active vitamin D in this process. Vitamin D receptor null mice (VDRKO) have provided lots of information in vitamin D metabolism and the biological roles. VDRKO mice do not show any abnormalities in bone at birth and develop severe rickets after weaning. And calcium supplementation showed apparent cure of rickets. These results suggested that vitamin D may exert its effects on bone via mineral homeostasis and vitamin D might not be essential for bone metabolism. However, even in calcium supplementation, the body fluid environments in VDRKO were not completely normal. For example, they show high serum levels of PTH and $1,25(OH)_2D$. To evaluate the direct function of vitamin D in bone, we previously reported that ectopically implanted VDRKO bone in wild mice showed marked bone formation and this process may involve down-regulation of cbfa1. However, this experimental system is complicated with the contamination of the host cells. Therefore, we confirm our results by implanting bone tissue wrapped with micro-pore filter membrane, and by organ culture experiment in serum-free media. After 2weeks transplantation, both VDRKO femur and calvaria showed significant but less extent increase in bone mineral density compared with wild type bone. This may due to the paucity of blood supply through filter membrane. Therefore, we turned to organ culture experiment. 0-day fetal mouse femora were excised from both VDRKO and wild littermate. Before the start of the culture, we analyzed femora by *f*ÊCT, pQCT and histology. Surprisingly, these analyses clearly demonstrated that there was no difference between VDRKO and Wild type in metaphysis, but in diaphysis and calvaria, bone volume of VDRKO was remarkably increased (1.8 fold) compared to Wild type. And this difference of bone mass was further expanded after 7days culture.Moreover, organ culture in the presence of $1,25(OH)_2D$ (10^{-8} M) showed 86% decrease in bone mineral density in Wild type bone while $1,25(OH)_2D$ did not exert any effects on bone from VDRKO mice. From these results, we conclude that VDRKO bone possesses increased potential of periosteal bone formation and thus vitamin D may play a negative regulating role in periosteal bone formation.

Membrane Effects of 1,25(OH)$_2$D$_3$ Are Intact in VDR(-/-) Mouse Growth Plate Chondrocytes but Effects of 24,25(OH)$_2$D$_3$ Are Modified. B. D. Boyan, V. L. Sylvia, D. D. Dean, Y. Liu*, D. Lopez*, D. B. Dinh*, Z. Schwartz. Orthopaedics, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

1α,25(OH)$_2$D$_3$ (1,25) regulates costochondral growth plate chondrocytes via cell maturation-specific membrane-associated mechanisms in addition to classical nuclear vitamin D receptors (1,25-nVDR). Antibodies generated to a 1,25-binding protein isolated from chick enterocyte membranes (Ab99) block membrane-dependent PKC activation and bind a single band on western blots of plasma membranes from 1,25-sensitive cells. Antibodies to 1,25-nVDR or annexin II do not recognize this band, nor is there evidence of the 1,25-nVDR in the membranes. Whereas cells from the growth zone (GC) respond to 1,25, cells from the resting zone (RC) respond to 24R,25(OH)$_2$D$_3$ (24,25), but no 24,25-specific nuclear receptor has been isolated, suggesting that the 24,25-mVDR is sufficient or that the 1,25-nVDR is used in some way by 24,25. This study tested the hypothesis that the 1,25-mVDR and 24,25-mVDR are distinct from the 1,25-nVDR and that they have physiological significance. Fourth passage RC and GC chondrocytes isolated from VDR(-/-) and VDR(+/+) mice were used for these experiments. 1,25 caused a rapid dose- and time-dependent increase in specific activity of PKC and PLC in GC cells from wild type and knockout mice. In VDR(-/-) cells, 10^{-8}M 1,25 increased PKC 10-fold and PLC 4-fold within 9 minutes. 24,25 had no effect on either enzyme in GC cells and 1,25 had no effect on RC cells at any of the times examined. 24,25 caused a dose-dependent decrease in PKC activity of RC cells from VDR(-/-) mice at 9 minutes but had no effect on PKC in VDR(+/+) RC cells. At 90 minutes, however, 24,25 stimulated PKC activity in RC cells from wild type and knockout mice. These results indicate that in chondrocytes there are three distinct receptors that mediate the effects of 1,25 and 24,25. One is the classical 1,25-nVDR and the others are the mVDRs for 1,25 and 24,25. Lack of the 1,25-nVDR had no effect on the membrane-mediated response to 1,25, indicating that the 1,25-mVDR is a unique receptor. However, the lack of 1,25-nVDRs modified the membrane effect of 24,25, indicating cross talk between these receptors.

Ligand-induced Reverse Trafficking of Vitamin D Receptor (VDR) in Avian and Mammalian 1,25(OH)2-Vitamin D3 Target Cells. D. Capiati*, A. M. Rossi*, R. L. Boland*. Biologia, Bioquimica & Farmacia, Universidad Nacional del Sur, Bahia Blanca, Argentina.

1,25-dihydroxy-vitamin D3 [1,25(OH)2D3; calcitriol], the hormonally active form of vitamin D3, exerts its effects through two different modes of action. In addition to regulating gene transcription via its specific intracellular receptor (VDR, vitamin D receptor), 1,25(OH)2D3 induces, rapid, non-transcriptional responses involving activation of transmembrane signal transduction pathways. The stimulation of second messenger systems suggests that a 1,25(OH)2D3 membrane receptor exists. The presence of membrane-bound VDR was investigated in highly purified plasma membranes isolated from chick embryonic skeletal muscle cells (myoblasts/myotubes) and MCF-7 human breast cancer cells, examining the participation of a ligand-induced receptor translocation mechanism. Using a monoclonal antibody against the nuclear VDR (clone 9A7), it has been observed that short-term treatment (5 min) with 1,25(OH)2D3 induces the translocation of the VDR from the nucleus to the plasma membrane in chick muscle cells. The calcitriol-dependent relocation of the VDR is blocked by genistein, herbimycin or colchicine, suggesting that it is mediated by tyrosine kinase/s and microtubular transport. In MCF-7 cells, the hormone also increased the amounts of VDR associated to plasma membrane after 5 min of treatment. These results support the hypothesis that the classic nuclear VDR may be the receptor that mediates, at least in part, the non-genomic effects of 1,25(OH)2D3 in chick muscle and MCF-7 cells.

A Contribution of the Cellular Environment to the Activation of the Vitamin D Receptor by the Tissue-selective Analog, Ro-26-9228. A. Ismail*, C. V. Nguyen*, S. Peleg. Endocrine Neoplasia & Hormonal Disorders, The University of Texas, M.D. Anderson Cancer Center, Houston, TX, USA.

We have recently shown that the vitamin D receptor (VDR)-mediated transcriptional activity of the vitamin D analog Ro-26-9228 was a 100 times greater in human osteoblastic cell lines (MG-63 and hFOB) than in the human colon carcinoma cell line, Caco-2. The events associated with transcriptional activation of the VDR include binding to its ligand, conformational changes that promote heterodimerization with RXR, and recruitment of coactivators of transcription to the VDR-ligand complexes. These events can be reproduced by in vitro synthesized VDR (ivtVDR), but the experiments with Ro-26-9228 suggested a contribution of the cellular environment to these events. To examine this hypothesis we used ivtVDR incubated with ligand in vitro, or VDR extracted from osteoblastic (hFOB) and intestinal (Caco-2) cells after in vivo incubation with either 1,25(OH)2D3 (1,25D3) or Ro-26-9228. The ligand-bound receptors were tested for their abilities to interact with GRIP, RXR or DRIP by pull-down assays. 1,25D3 had similar potencies (1-10 nM) to induce interactions of VDR from all three sources with these partners of transcription. In contrast, analog concentrations of 100-1000 nM induced interaction of ivtVDR with RXR, GRIP and DRIP, and analog concentration of 10 nM induced interaction of osteoblastic VDR with these partners of transcription. Interestingly, VDR from Caco-2 cells did not interact with these proteins even after incubation with analog concentration of 1000 nM. We hypothesized that the subcellular localization of VDR may contribute to differences in its activation in hFOB and in Caco-2 cells. Therefore, VDR distribution between cytoplasm and chromatin was examined in these cells by subcellular fractionation. We found that in hFOB cells, the unoccupied VDR localized exclusively in the cytoplasm, but VDR from analog- or 1,25D3-treated hFOB cells accumulated in the chromatin. In contrast, in Caco-2 cells, VDR was localized in both the cytoplasm and the chromatin, either in absence or presence of ligand. There was some increase in the amount of VDR associated with chromatin in 1,25D3-treated cells but not in chromatin from analog-treated cells. These results suggest that the ligand-bound VDR translocates from the cytoplasm into the nucleus in hFOB cells, but the translocation mechanism is probably defective in Caco-2 cells. We hypothesize that the VDR-analog complexes in Caco-2 cells are probably associated with a repressor that prevents their interaction with RXR, GRIP and DRIP. Translocation into the nucleus may be required for proper activation of the VDR-analog complexes, or for their release from repression.

SA462

Androgen Receptor Isoforms Differentially Regulate Primary Bone and Skin Cell Metabolism. U. M. Liegibel*, I. Boerscoek*, U. Sommer*, P. Nawroth*, C. Kasperk. Dept. of Medicine, Ruprecht-Karls-University, Heidelberg, Germany.

Steroid hormones, including androgens play a crucial role in the regulation of bone metabolism and in the maintenance of normal bone structure. Two isoforms of the androgen receptor (AR-B and AR-A) are expressed in a number of human tissues including bone. AR-A is the N-terminal truncated form of AR-B, produced by translation initiation at the first internal methionine residue (Met-188) of the same gene transcript. To study the distribution of the AR-isoforms in human bone, we examined their expression in primary human osteoblastic cells (HOC). Western blot analysis revealed that AR-A and AR-B are expressed in male as well as female individuals, independently of the donor's age. Transfection studies with HOC and with primary genital skin fibroblasts (GS-540) derived from a patient with testicular feminization (AR$^-$) were aimed to characterize the physiological role of the AR-isoforms in mesenchymal tissues. AR-B induced mitogenic effects in the presence of DHT (100 nM) in GS-540 and HOC, whereas AR-A as well as the combined transfection of AR-B and AR-A did not have such an effect. Differentiated mesenchymal cell function, as measured by collagen type I synthesis, was not significantly affected by either form, although in GS-540, there was a reproducible tendency of AR-A to enhance collagen type I expression. Using electromobility shift assays, we further examined the binding capacity of AR-B to the ARE consensus sequence in the presence of a peptide coding for the N-terminal sequence (AR-N) of AR-B, missing in AR-A. Binding of AR-B to radiolabeled ARE was reduced in the presence of AR-N, presumably due to the competition of the transactivation domains for co-activating proteins required for stable DNA/protein complex formation. These results are in accordance with the lacking capacity of AR-A to stimulate mesenchymal cell proliferation. In summary, this study shows that (1) the activated AR-B isoform exerts mitogenic effects on bone and skin cells and (2) that the mitogenic effect of AR-B is impaired by the presence of the AR-A isoform. In conclusion, the presence of the AR-A isoform limits the androgen-induced mitogenesis in androgen-responsive tissues.

Identification of Estrogen-Regulated Genes of Potential Importance for the Regulation of Trabecular BMD. S. Movérare[1], M. K. Lindberg*[1], A. L. Eriksson*[1], S. Skrtic*[1], H. Gao*[2], K. Dahlman-Wright*[2], J. Å. Gustafsson*[2], C. Ohlsson[1]. [1]Div. Endocrinology, Dept. Internal Medicine, Gothenburg, Sweden, [2]Dept. Medical Nutrition and Dept. BioScience, Karolinska Institute, Novum, Huddinge, Sweden.

Estrogen is of importance for the regulation of trabecular BMD. The aim of the present study was to search for possible mechanisms of action of estrogen on bone in a non-hypothesized driven manner. Ovariectomized mice were treated with 17β-estradiol. Possible effects of estrogen on the expression of 125 different bone-related genes in humerus were analysed using the microarray technique. Estrogen regulated fifteen of these genes, namely two growth factor-related genes, eight cytokines and five bone matrix-related genes. Seven of the fifteen genes are known to be estrogen regulated, while the remaining eight genes are novel estrogen-regulated genes. Six genes, including IL-1ra, IL-1RII, TGFβ, G-CSFR, LIFR and sIL-4R, were selected as probable candidate genes for the trabecular bone sparing effect of estrogen, as the mRNA levels of these genes were highly correlated ($r>0.8$) to the trabecular BMD. The regulation of most of these six genes was predominantly ERα mediated (4/6) while some genes (2/6) were regulated both via ERα

and ERβ. In conclusion, by using the microarray technique, we have identified three previously known and three novel estrogen-regulated genes of potential importance for the trabecular bone-sparing effect of estrogen.

Melatonin Increases Estradiol-Induced Bone Changes in Ovariectomized Rats. M. Ladizesky*[1], V. Boggio*[2], L. Albornoz*[2], P. Castrillón*[2], C. Mautalen[1], D. Cardinali*[2]. [1]Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina, [2]Departamento de Fisiología, Facultad de Medicina, Universidad de Buenos Aires, Buenos Aires, Argentina.

Estrogen deficiency induces a high turnover on bone remodeling in wich the accelerated bone resorption and formation simultaneously occur with predominance of the former. Recent data suggest that melatonin has an effect on bone remodeling. Since appropiate circulating estradiol levels could be needed for melatonin effects on bone, the present study was underkaten to assess whether estradiol replacement in Ovx rats prolongs the response to melatonin after Ovx. To asses the effect of melatonin on bone metabolism Ovx rats receiving or not estradiol therapy, melatonin was administered in the drinking water (25 ug/ml water) and estradiol (10 ug/kg BW) or vehicle was given s.c. 5 days/ week for up to 60 days after surgery. Dpyr and circulanting levels of serum bone alkaline phosphatase (BAP), as well as CaS and PS, were measurded every 15 days. BA, BMC, BMD and Total Body Fat (expressed as 100g/BW) were measured by DEXA at the end of the experiment. Main factor analysis in a factorial ANOVA indicated that BW and total body fat augmented after Ovx ($p<0.001$), and decreased after melatonin ($p<0.02$) or estradiol treatment ($p<0.001$). Ovx augmented ($p<0.03$) and melatonin ($p<0.02$) or estradiol lowered ($p<0.0001$) Dpyr excretion. This effect of melatonin and estradiol was seen mainly in Ovx rats ($p< 0.001$). The efficacy of estradiol to counteract Ovx–induced bone resorption was significantly increased by melatonin. Melatonin or estradiol lowered BAP in Ovx ($p<0.02$). SP levels decreases after melatonin administration ($p<0.001$) and augmented after estradiol injection ($p<0.001$), overall, melatonin impaired the increase of SP caused by estradiol . Ovx decreased ($p<0.001$), and estradiol increased SCa levels ($p<0.04$), while melatonin augmented SCa in sham rats only ($p<0.005$). On day 60 after surgery, BMD and BMC decreased after Ovx and augmented after estradiol injection. Melatonin augmented BA of spine ($p< 0.01$) and BMC of whole skeleton and tibia ($p<0.04$). The highest values observed were those of rats treated simultaneously with estradiol and melatonin ($p<0.01$). The presents results indicate that: 1- Melatonin treatmentent restored bone remodeling after Ovx 2- The effect of melatonin needed adequate concentrations of estradiol, 3- Melatonin augmented estradiol effects of bone in Ovx rats. 4- A counterregulation by melatonin of the increase in body fat caused by Ovx was uncovered. The melatonin doses employed were pharmacological in terms of circulating levels, but not necessarily for other fluids or tissues.

SA467

Estrogen Inhibits Class II Transactivator and MHCII Gene Expression in Murine Macrophages: A Mechanism by which Estrogen Suppresses Proliferation of TNF Producing T Cells. O. L. Sierra, S. Cenci, Y. Gao, G. Toraldo*, M. N. Weitzmann, R. Pacifici. Division of Bone & Mineral Diseases, Washington University School Medicine & Barnes-Jewish Hospital, St Louis, MO, USA.

One mechanism by which ovariectomy (ovx) increases the number of TNF producing T cells is by enhancing T cell proliferation. The resulting increased production of TNF is crucial for bone loss induced by estrogen (E2) deficiency. However, ovx induced T cell proliferation is not inhibited by in vitro E2 treatment, thus suggesting that E2 regulates T cells via an indirect mechanism. One such mechanism could be downregulation of activation-induced proliferation via repression of the activity of antigen presenting cells (APC). We found that ovx upregulates macrophage APC activity by decreasing their surface expression of MHC Class II (MHCII), which in turn, was due to an increase in the levels of CIITA, the master gene inducer of MHCII. To determine if E2 represses CIITA gene expression by a direct targeting of macrophages, peritoneal macrophages harvested from sham and ovx mice were stimulated with 0.1-10 U/mL of IFNγ, for 24 hrs. MHCII and CIITA gene expression was then examined by RT-PCR and Northern blot analysis. The expression of both MHCII and CIITA mRNAs was 50% higher in unstimulated macrophages from ovx mice than in those from sham controls. Stimulation with IFNγ increased both MHCII and CIITA mRNA levels in a dose dependent manner, in both sham and ovx macrophages. However, at all doses of IFNγ tested, the increase in MHCII and CIITA mRNA was 2 fold higher in ovx macrophages than in sham cells. These data demonstrate that ovx upregulates the responsiveness of macrophages to IFNγ. To further investigate how E2 regulates CIITA and MHCII expression, RAW 264.7 cells, an ER+ murine monocytic line which expresses CIITA in response to IFNγ, were treated with E2 (10^{-8}M) for 24 hours. We found that E2 decreases the expression of both CIITA and MHCII mRNA by ~50%, further demonstrating a direct E2 targeting of these cells. The CIITA gene has 4 promoter regions which confer cell specific gene expression. Since IFNγ induced expression of CIITA in macrophages is mediated by promoter IV, RAW 264.7 cells were transiently transfected with a full length murine CIITA promoter IV-Luc reporter construct. IFNγ induced a 10 fold increase in CIITA-IV-Luc activity which was reduced by E2 by 50%. In conclusion, our data demonstrate that E2 inhibits CIITA transcription in macrophages via a direct mechanism involving promoter IV. Decreased CIITA gene expression results in blunted MHCII expression, decreased macrophage APC activity and decreased activation induced proliferation of TNF producing T cells.

Identification of a Novel Bone Formation Marker (Periosteal Alkaline Phosphatase) to Detect Bone Activity of Androgens in Short-Term Gonadectomized Rats. W. Y. Chang[1], K. Burnett*[1], D. S. Ramirez*[1], J. N. Miner*[2], F. López*[1], H. Viveros*[1]. [1]Pharmacology, Ligand Pharmaceuticals, Inc., San Diego, CA, USA, [2]Molecular and Cell Biology, Ligand Pharmaceuticals, Inc., San Diego, CA, USA.

Fluoxymesterone (fluoxy) and LGD2226, a first generation androgen receptor modulator, prevented orchidectomy (ORDX)-induced reduction in periosteal bone formation rate in Sprague-Dawley (SD) rat tibiae after daily oral administration for 4 months (The Endocrine Society's 83rd Annual Meeting, 2001:abstract P1-497). The goal of this study was to determine whether the effects of an androgen agonist, fluoxy, could be assessed in bone within a shorter treatment duration utilizing two conventional and one new bone biomarker. Two-months-old male SD rats were orchidectomized or sham-operated, and daily administration with fluoxy (1, 10, and 100 mg/kg/day, *po* or *sc*) or vehicle was initiated and continued for the next 2 weeks. Oral and subcutaneous fluoxy stimulated growth of androgen-responsive organs (ventral prostate, seminal vesicle, levator ani, and preputial gland), while it reduced serum luteinizing hormone levels. At doses that were anabolic for the androgen-sensitive organs, fluoxy suppressed serum osteocalcin (OC) and maintained bone-specific alkaline phosphatase (BSALP) to levels comparable to intact rats. To obtain a direct measurement of anabolic effects in bone, periosteal alkaline phosphatase (PAP) was measured by assaying enzyme activity after collagenase digestion of the tibial periosteum. Fluoxy prevented orchidectomy-induced suppression of PAP (osteoblast activity) in a dose-dependent fashion after only 2 weeks of treatment, while our previous histomorphometric results required 4 months of daily oral administration to document this effect. Fluoxy at 100 mg/kg/day (*po*) was able to maintain PAP at levels comparable to intact rats. To determine whether PAP detected fluoxy effects in females, 2 month-old female SD rats were ovariectomized or sham-operated, and daily administration with fluoxy (1, 3, 10, 30, and 100 mg/kg/day, *sc*) or vehicle was initiated and continued for the next 4 weeks. Fluoxy stimulated clitoral gland growth and suppressed serum luteinizing hormone levels. Ovariectomy raised serum OC and BSALP levels as well as PAP. Fluoxy maintained serum OC at levels similar to intact female rats and did not stimulate serum BSALP or PAP beyond the levels induced by ovariectomy. These results indicate that androgen receptor agonists have pronounced effects on rat bone activity and suggest that PAP may be a useful and direct marker of periosteal bone formation that is valuable in identifying activity of compounds in short-term assays.

Impact of Estrogen and Androgen Receptors on Skeletal Metabolism. T. F. Tözüm*[1], M. Oppenlander*[1], C. Chen*[1], D. M. Robins*[2], L. K. McCauley[1]. [1]Dept. Perio/Prev/Geriatrics, University of Michigan, Ann Arbor, MI, USA, [2]Dept. Human Genetics, University of Michigan, Ann Arbor, MI, USA.

The interaction between estrogens and androgens, with their protective effects in bone, and parathyroid hormone (PTH), with its anabolic and catabolic actions, is complex and largely unclear. The purpose of this study was to; 1) characterize skeletal phenotypes of mice deficient in estrogen receptor alpha (ERα), androgen receptor (AR, mutant *tfm*) or both, and 2) determine if ERα and AR alter osteoblast differentiation and PTH response *in vitro*. Gross skeletal analysis, microradiography, DEXA, histomorphometry, cAMP response to PTH, and osteoblast differentiation assays were performed for mice of all 6 possible homozygous genotypes (n=10-17). Loss of ERα resulted in increased long bone lengths in females, but reduced length in males, suggesting loss of ERα reversed sex steroid dependent skeletal dimorphism. The *tfm* mice had the longest bones and similar to males, lengths were reduced with loss of ERα. Loss of AR and/or ERα resulted in a reduction in bone mineral density (BMD) compared to male WT mice suggesting *tfm* mice follow the female gender for BMD. Loss of AR and/or ERα caused a reduction in cortical width of the tibia compared to male WT mice. Loss of ERα was associated with reduced trabecular bone in tibiae of female and *tfm* mice vs. male littermates, suggesting that *tfm* mice follow the female gender for trabecular bone. Primary calvarial osteoblasts of male WT mice were less responsive to PTH via cAMP levels than all other genotypes, indicating the female gender and/or loss of ERα or AR results in increased sensitivity to PTH. There was no difference in mineralization of cells from any genotypes, suggesting neither ERα nor AR intrinsically alter osteoblast differentiation. In conclusion, *tfm* mice follow the male pattern of appendicular skeletal development, but imitate females in bone density and trabecular bone. Further, loss of ERα and/or AR results in increased osteoblast sensitivity to PTH and may explain actions of PTH noted in hypogonadal humans. Finally, these data underscore that sex steroids impact bone development, composition and metabolism differently.

Decreased Renal Expression of Calbindin-D28k in Aromatase Deficient Mice. O. K. Oz[1], K. Howard*[1], A. Thomas*[1], J. E. Zerwekh[2], C. Y. C. Pak[2]. [1]Radiology, UT Southwestern Medical Center, Dallas, TX, USA, [2]Internal Medicine, UT Southwestern Medical Center, Dallas, TX, USA.

Renal calcium uptake is important for maintenance of normal calcium homeostasis. Most studies of calcium transport in the kidney focus on the roles of the hormones vitamin D3 and parathyroid hormone. However, estrogens are known to regulate calcium transport in tissues, such as the intestines and estrogen deficient states are often associated with abnormal urine calcium levels. The mechanisms are incompletely understood. Aromatase catalyzes the biosynthesis of estrogens from androgen precursors. The protein calbindin-D28k is known to be involved in transcellular calcium transport in the distal convoluted tubule. To determine if estrogen deficiency might cause changes in expression of calbindin-D28k we prepared RNA and protein from kidneys of 10-12 week old wildtype and ArKO female mice. Western blotting demonstrated decreased protein levels in extracts from ArKO kidneys. Relative quantitative RT-PCR demonstrated decreased levels of calbindin-D28k mRNA. These data show suggest that the ArKO mouse maybe useful for understanding the role of estrogen in regulating renal handling of calcium. They suggest estrogen maybe involved in the regulation of transcellular calcium absorption in the kidney via effects on the calbindin-D28k protein.

Anabolic Effects of Testosterone on Bone Require the Presence of a Functional Androgen Receptor in Male Mice. L. Vandenput*[1], S. Boonen[2], R. G. Erben[3], E. Van Herck*[1], J. V. Swinnen*[1], R. Bouillon[1], D. Vanderschueren[1]. [1]Laboratory for Experimental Medicine and Endocrinology, Katholieke Universiteit Leuven, Leuven, Belgium, [2]Leuven University Centre for Metabolic Bone Diseases, Katholieke Universiteit Leuven, Leuven, Belgium, [3]Institute of Animal Physiology, University of Munich, Munich, Germany.

Androgens and estrogens may exert nongenomic effects via activation of both the androgen receptor (AR) and estrogen receptors *in vitro*. In order to investigate the relevance of nonAR-mediated androgen and estrogen action in male skeletal metabolism, we have studied testicular feminized male mice (Tfm), which lack a functional AR due to a single base deletion in the N-terminal region of the AR gene. Eight-week-old orchidectomized (ORX) Tfm mice were treated with either testosterone (T, 167 µg/day), 17beta-estradiol (E2, 25 µg/day) or placebo pellets during 4 weeks. E2 stimulated intramedullary bone formation, resulting in a dramatic increase in trabecular bone density (more than 10-fold) and cortical thickness (+ 20%), compared to placebo-treated ORX mice (as determined by peripheral quantitative computed tomography). Moreover, the effects of E2 were not limited to the appendicular skeleton, but were also observed in the axial skeleton, as evidenced by a 152% increase in distal lumbar vertebrae density (calcium content/volume). This anabolic effect of E2 was associated with a significant increase in both endocortical mineral apposition rate (+ 48%) and bone formation rate (+ 69%), as measured by dynamic histomorphometry on femoral cross-sections. In accordance, serum osteocalcin was also significantly higher in E2-treated compared to placebo-treated ORX mice. Furthermore, growth plate width significantly decreased following E2-treatment of ORX mice whereas femur length and periosteal bone formation were not affected. In contrast, treatment of ORX mice with T affected neither trabecular bone density, nor endocortical and periosteal bone formation, compared to placebo-treated ORX mice. However, growth plate width significantly increased following T-treatment, but femoral length remained unchanged. In conclusion, E2 respectively has anabolic effects on trabecular and endocortical surfaces, no effect on periosteal bone, and an inhibitory effect on the growth plate in male mice. In contrast, the aromatizable androgen T did stimulate neither endocortical nor periosteal bone formation in ORX androgen-resistant male mice. These data indicate that the anabolic bone effects of T in male mice are dependent on the presence of a functional AR.

SA475

Sex Steroid Formation in the Tibial Growth Plate and Metaphyseal Bone of the Rat during Development. B. C. J. van der Eerden[1], J. van de Ven*[2], C. W. G. Lowik[3], J. M. Wit*[1], M. Karperien[3]. [1]Pediatrics, Leiden University Medical Center, Leiden, Netherlands, [2]Laboratory of Endocrinology, University Hospital Utrecht, Utrecht, Netherlands, [3]Endocrinology & Metabolic Diseases, Leiden University Medical Center, Leiden, Netherlands.

Estrogens and androgens can have direct effects on bone but it remains unclear what the source is of these sex steroids. We, therefore, surveyed the presence of several key-enzymes involved in androgen and estrogen biosynthesis in the tibial growth plate and metaphyseal bone of growing female and male rats using *in situ* hybridization. We studied the expression of aromatase, type I and II 17β-hydroxysteroid dehydrogenase (type I and II 17β-HSD), steroid sulphatase (STS) and 5α-reductase in the proximal tibia of 1-, 4-, 7-, 16- and 40-week-old female and male rats. In the growth plate, two age-related mRNA expression patterns were distinguished. Aromatase and type I and II 17β-HSD mRNA expression was low or undetectable at 1 week of age. The expression gradually increased at 4 weeks and reached the highest levels during sexual maturation around 7 weeks of age. Thereafter the expression declined but the mRNAs were still detectable at 16 and 40 weeks of age. In contrast, STS and 5α-reductase were expressed at a relatively constant level in all age groups studied. All enzyme mRNAs were detected in late proliferating and early hypertrophic chondrocytes, which we have previously shown to express estrogen and androgen receptors. These data were supported by measuring enzyme activities in chondrocytes collected from tibial growth plates. Aromatase and type I 17β-HSD bioactivity was low or undetectable, respectively, at 1 week of age and was strongly increased during sexual maturation. STS bioactivity did not change with age. There were no apparent differences in expression and bioactivity of the enzymes studied between the sexes. In the tibial metaphysis, STS mRNA was detected in osteoblasts, osteoclasts and some osteocytes in sexually immature 4-week-old female and male rats during development. In contrast, aromatase, type I and II 17β-HSD and 5α-reductase were first detected at 7 weeks of age and thereafter. Like STS, the mRNA expression of these enzymes was confined to osteoblasts, osteoclasts and occasionally in osteocytes. In conclusion, our findings suggest that sex steroid synthesis occurs in the rat growth plate and the underlying metaphyseal bone. The age-related expression of key enzymes involved in sex steroid metabolism suggests that in contrast to sexually immature animals, locally metabolized sex steroids may play a role in longitudinal growth and bone mass accrual during sexual maturation of the rat.

SA476

In Vivo Adverse Effects of Chronic Glucocorticoid and Mineralocorticoid Administration in Rats. Q. Zeng*, J. Hoover*, R. L. Cain*, A. Harvey*, C. Suen*, H. U. Bryant, M. Sato, A. L. Schmidt*, M. D. Adrian*, Y. L. Ma. Gene Regulation, Bone and Inflammation Division, Eli Lilly Company, Indianapolis, IN, USA.

Glucocorticoids are widely used clinical agents due to their robust effects on anti-inflammatory and immunosuppresion. Unfortunately, a number of serious side effects are seen on the long-term glucocorticoid use patients, which limits the therapeutic utility of glucocorticoids. To examine adverse effects, we treated 11-12 months old, retired breeder male Lewis rats with prednisone (Pred) 0.1, 0.5mg/kg/d *p.o*, dexamethasone (Dex) 0.015, 0.075mg/kg/d *p.o*, cortisone (Cort) 0.5, 2.5mg/kg/d *p.o* or desoxycorticosterone (Doca) 0.5, 2.5mg/kg/mo *im* for 6 weeks. These treatment doses are approximately equal to the typically used clinical doses. When compared to vehicle treatments, there was a dose-dependent decrease in the body weight (13-31%), gastrocnemius muscle (12-37%), whole body lean mass (13-23%), whole body fat mass (17-43%) in Dex-treated rats. No body weight change was observed in other treatment groups. Cort and Doca decreased the whole body lean mass but did not significantly change the fat mass. Serum electrolytes (Na, K, Cl, Ca), BUN, creatine (Creat), creatine phosphokinase (CK) and total protein (TP) were elevated in all the treatment groups at days 3 and 7. By end of the 6 weeks study, with the most of these parameters returned to the vehicle control levels in Corti and Pred groups, some parameters were lower (BUN, Cl, Creat, globulin) or higher (TP, A/G) in Dex group, while CK was lower in Doca group. Serum K was decreased in all the treatment groups after 6 weeks treatment. Dex treatment also increased serum cholesterol (39-91%) and glucose (42-116%), however, glucose was returned to the control levels at end of the study. Although a significant reduction in prostate wet weight was seen only in Dex and Doca groups, serum testosterone was significantly decreased by all the treatments except for Cort. No treatment significantly altered the testicular wet weight. In Dex group, but not other treatments, dose-dependent decreases of serum osteocalcin, whole body BMC and BMD were observed. These data suggest that both mineralocorticoid and glucocorticoid impair the regulation of serum electrolytes and sexual hormone production. Glucocorticoids also have impact on protein, serum lipid, glucose and muscularskeletal metabolism.

Failure to Reduce Glucocorticoid Receptor Expression in Bone Following Burn Injury: Possible Mechanism for Steroid-Induced Bone Loss. G. L. Klein[1], S. R. Beavan[2], J. E. Compston[2], W. G. Williams*[1], D. N. Herndon*[1], D. J. Sherrard[3]. [1]University of Texas Medical Branch and Shriners Burns Hospital, Galveston, TX, USA, [2]Medicine, University of Cambridge, Cambridge, United Kingdom, [3]VAMC and University of Washington School of Medicine, Seattle, WA, USA.

Severely burned children develop abnormalities in bone and calcium metabolism, including reduced bone formation and resorption, and reduced growth velocity. Moreover, they exhibit a systemic inflammatory response reflected by elevated circulating cytokines such as interleukin (IL)-1 b and IL-6.Because all but the cytokine elevation can be side-effects of glucocorticoid exposure, the aim of the study was to detect an effect of glucocorticoids on bone in burn patients by determining if there is down-regulation of glucocorticoid receptor (GR) in bone. We studied 7 patients with burn injury greater than 40% total body surface area, ages 7-14 yr and 4 controls, ages 15-20 yr. We obtained a 24-hr urine for free cortisol and iliac crest bone specimens for histomorphometry and for mRNA analysis 3.7 +/- 1.9 (SD)wks post-burn, range 2-8. Bone tissue was analyzed by reverse transcription polymerase chain reaction (RT-PCR)for mRNA expression of GR alpha (the true receptor), GR beta (a possible inhibitor of GR alpha-induced nuclear transcription), osteocalcin, alkaline phosphatase, mineralocorticoid receptor, and IL-1b, all normalized to glyceraldehyde-3 phosphate dehydrogenase (GAPDH).Histomorphometry revealed markedly reduced bone formation in all 7 burn patients, 1.3 +/- 3.4 mcm2/mm2/d, range 0-9, normal 108-576, while urine free cortisol ranged from 4-12 times normal, 371 +/- 147 mcg/d, range 206-629, upper limit of normal 50 mcg/d. ANOVA failed to reveal any significant differences in mRNA expression between burn patients and controls, although there was an inverse correlation between urine free cortisol and GR alpha mRNA in the burn patients, r=-0.74, p< 0.05 and an inverse correlation between urine free cortisol and type I collagen mRNA, r= -0.64.These data indicate that despite marked reduction in bone formation and a marked increase in endogenous glucocorticoid production, there was no proportionate reduction in GR alpha. While it is possible that the small sample size could not detect a statistically significant change from normal, the modest effect of large quantities of endoge-

nous glucocorticoids on GR alpha may leave bone vulnerable to further injury from corticosteroids.It is also possible that a greater down-regulation of GR alpha mRNA was prevented by the IL-1b that was detected in the bone tissue.

Dexamethasone Decreases Bone Mineral Density and Bone Formation in Mice: A Model for Glucocorticoid-Induced Osteoporosis. P. Clément-Lacroix, D. Minet*, C. Belleville*, L. Lepescheux, R. Baron, M. Resche-Rigon. Proskelia, Romainville, France.

The prolonged administration of glucocorticoids (GC) to patients induces significant bone loss and increases incidence of both vertebral and non vertebral fractures. Glucocorticoid-induced osteoporosis (GIOP) in humans is associated with a profound inhibition of bone formation resulting mainly from inhibition of osteoblastogenesis and from increase in osteoblasts and osteocytes apoptosis. Despite several attempts to establish animal models of GIOP, only ewes have been reported to recapitulate the mechanisms associated with GC-induced bone loss in humans. To determine whether a model of GC-induced osteoporosis could be established in mice, 12 week-old C57bl6/J male mice were treated with dexamethasone (DEX) 1 and 5 mg/kg/d subcutaneously injected 5 days/week for 2 months. Bone mineral density (BMD) at both trabecular and cortical sites was measured using Stratec SA+. Tomodensitometry using SCANCO microCT 20 was used for a two dimensional reconstruction of the right tibia and lumbar vertebra at the end of treatment. In contrast to rats, mice body weight was not affected by glucocorticoid administration. DEX 1 and 5 mg/kg induced significant reduction (-67%) in serum osteocalcin, a marker of terminal osteoblastic differentiation, whereas urinary deoxypyridinolin were only transiently decreased at day15. Despite trends towards decreased indices of bone formation (osteoblasts surface, osteoid volume), trabecular BMD or histomorphometric bone volume remained unchanged in DEX-treated animals. A second experiment was then performed, where 4, 8, and 12 week-old C57bl6/J males were implanted with slow release pellet delivering 5mg/kg/d Dexamethasone for 4 weeks. Trabecular BMD decreased by 27%, 17% and 16% at metaphyseal tibia respectively, in 4, 8, and 12 week-old males after continuous administration of dexamethasone. MicroCT analysis revealed that cortical bone mineral density was also significantly reduced in DEX-treated animals. Bone loss was further confirmed by decreased trabecular bone volume (-37% in 4 week-old mice). As previously observed, osteocalcin but not D-Pyr, were significantly reduced at the end of treatment (-68%, -64% and -84%) respectively, in 4, 8, and 12 week-old males. In addition delayed longitudinal growth was observed in 4 week-old mice. Our data suggest that both young and adult male mice may be valid models for GC-induced bone loss. *Bona fide* reduction in bone formation was consistently observed, leading, at least with slow release of glucocorticoids, in decreased bone mass. The impact of GC treatment on bone resorption needs however further clarification.

A Glucocorticoid-Induced Leucine Zipper Protein GILZ Inhibits Adipocyte Differentiation. X. Shi, W. Shi*, B. Song*, Q. Li*, M. Wan, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

In a previous study we showed that glucocorticoid stimulates human bone marrow stromal stem cells to differentiate into adipocytes, and that this action is mediated by the binding of C/EBPδ to PPARγ2 gene promoter and subsequent up-regulation of its gene transcription. Here we report that a glucocorticoid-induced leucine zipper protein (GILZ) inhibits adipocyte differentiation. Unlike C/EBPδ that binds to PPARγ2 promoter and activates its gene transcription in electrophoretic mobility shift assay (EMSA) and transient transfection assay, respectively, GILZ binds to the promoter of PPARγ2, but it represses PPARγ2 gene transcription. Most importantly, the adipocyte differentiation was blocked in GILZ-expressing stable cell lines of C3H10T1/2 mesenchymal and 3T3-L1 preadipocytes. Northern and Western analyses showed that the levels of both GILZ mRNA and protein were strongly and rapidly induced by glucocorticoid dexamethasone. Transient transfection analyses demonstrated that GILZ significantly represses the luciferase-reporter activity driven by the PPARγ2 promoter. In addition, we have mapped the binding site of GILZ to a 40-base pair PPARγ2 promoter fragment that contains a tandem repeat of C/EBP binding sites. These data indicate that GILZ is directly involved in the regulation of PPARγ2 gene expression and glucocorticoid-induced adipocyte differentiation.

Cytokine Production by T Cells from Vitamin D Receptor Knockout Mice. P. Pietschmann[1], E. Kallay*[1], P. Hahn*[2], E. Bajna*[1], M. Willheim*[1], K. Mazzucco*[3], S. Kato*[4], H. S. Cross*[1]. [1]Department of Pathophysiology, University of Vienna, Vienna, Austria, [2]Ludwig Boltzmann Institute of Aging Research, Vienna, Austria, [3]Center for Laboratory Animal Care, University of Vienna, Vienna, Austria, [4]Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan.

1,25(OH)2 vitamin D has a major role in the regulation of calcium homeostasis; in addition to the classical effects a multitude of other action sites of the steroid hormone have been discovered. Cells of the immune system are among the nonclassical targets of 1,25(OH)2 vitamin D. Gene targeted knockout animals provide an interesting possibility to investigate complex regulatory systems that cannot be studied in isolated in vitro experiments. We therefore studied cytokine production by T cells in a vitamin D receptor (VDR) knockout mouse model. In knockout mice and wild type animals cytokine production by CD4+ and CD8+ cells was determined by four color flow cytometry. In the knockout animals, the percentage of CD8+ cells in blood was significantly increased when compared to wild type mice. Moreover, in the blood of the knockouts the frequency of CD8+ cells positive for interferon-gamma was significantly higher than in the wild type animals. Also in the thymus the percentage of CD8+ cells positive for interferon-gamma was significantly increased in the knockout animals. In bone marrow, CD4+ cells positive for interleukin-10 were less abundant in the knockout than in wild type animals. In conclusion, lack of the VDR in mice is associated with significant alterations of lymphocyte subsets, in particular CD8+ cells.

Active Vitamin D Reduces c-Fos and Fra-1 Proteins in Osteoclast Precursors, and Inhibits RANKL-induced Osteoclastogenesis *in vivo* and *in vitro*. H. Takasu[1], M. Okazaki*[1], A. Sugita*[1], N. Kubota[1], E. Ogata[2], K. Ikeda[3], Y. Uchiyama[1]. [1]Fuji Gotemba Res. Lab., Chugai Pharmaceutical Co.,Ltd., Shizuoka, Japan, [2]Cancer Inst. Hosp., Japanese Foundation for Cancer Res., Tokyo, Japan, [3]Dept. of Geriatric Res., Natl. Inst. for Longevity Sci., Aichi, Japan.

We have previously demonstrated that active vitamin D inhibits bone resorption and bone loss in estrogen deficient rats and mice (JBMR 2000, Bone 2002, JBMR 2002). In the present study, we examined the effect of active D in OPG KO mice, which exhibit severe osteoporosis and excessive bone resorption due to super-stimulation of RANKL/RANK signaling. Oral administration of $1\alpha,25(OH)_2D_3$ (0.1μg/kg) to OPG KO mice for 2 weeks reduced urinary excretion of deoxypyridinoline, and treatment for 6 weeks caused an increase in bone mineral density at the femur, suggesting that $1\alpha,25(OH)_2D_3$ inhibits bone resorption by interfering with the osteoclastogenic signaling downstream of RANK. Based on these results, the mechanism of action of active D in osteoclast precursors was further examined using bone marrow macrophage (BMM) prepared from *ddy* mice. $1\alpha,25(OH)_2D_3$ inhibited the differentiation of BMM into osteoclasts in the presence of M-CSF and sRANKL markedly and dose-dependently, and this effect was not observed in BMM from VDR KO mice, pointing to a VDR-mediated action. After surveying a number of active D analogs in this osteoclastogenesis assay, we observed that the osteoclastogenesis-inhibitory activity correlates well with their anti-AP-1 activity (R^2=0.78), but not with VDRE-dependent transcription activation function (R^2=0.08), suggesting the involvement of anti-AP-1 activity in the suppression of osteoclastogenesis. Osteoclastogenic signals downstream of RANK involve activation of JNK, p38MAPK, ERK1/2 and IKK. Phosphorylation and activation of these kinases by RANKL was, however, found not to be inhibited by $1\alpha,25(OH)_2D_3$ even at as high as 10^{-7}M. Western blot analyses revealed that the induction of c-Fos and Fra-1 proteins by sRANKL in BMM was completely inhibited by 10^{-7}M $1\alpha,25(OH)_2D_3$. In conclusion, our data suggest that active vitamin D suppresses RANKL-induced expression of c-Fos and Fra-1 proteins, thereby inhibiting osteoclastogenesis. Thus, anti-AP-1 activity may provide a good screening system for developing and selecting a new type of VDR-based drugs for osteoporosis.

Serum sRANKL Levels Are Inversely Correlated with Serum 25OH-Vitamin D. B. P. Lukert, L. Graves. Medicine, University of Kansas School of Medicine, Kansas City, KS, USA.

The purpose of the study was to test the hypothesis that the OPG/RANKL system is influenced by the nutritional status of vitamin D and that the production of RANKL is increased when the levels of 25OHD are low. Vitamin D deficiency plays a role in the etiology of osteoporosis in postmenopausal women. The sequence of events has been presumed to be: vitamin D deficiency causes poor absorption of calcium, which leads to secondary hyperparathyroidism, which in turn induces bone resorption. The OPG/RANKL system plays a major role in the control of osteoclastic bone resorption and may mediate bone loss in vitamin D deficiency. Twenty-six postmenopausal women presenting to the osteoporosis clinic at our institution for evaluation were studied. The patients were not taking hormone replacement, SERMs, bisphosphonates, calcitonin or steroids. They had normal renal and liver function. At their inititial visit blood was drawn for measuring 25OHD, creatinine and N-telopeptide of type I collagen (NTX, a marker of bone resorption). These samples were preserved at -40 degrees centigrade and subsequently used for measuring sRANKL and osteoprotegerin (OPG) using enzyme immunoassay test kits supplied by Biomedica. The correlations between 25OHD, sRANKL, OPG, OPG/sRANKL ratio, and NTX were examined using Pearson's correlation matrix. Correlations were as follows:
25OHD vs sRANKL r= -0.429 p=.032
25OHD vs NTX r= -0.499 p=.041
sRANKL vs NTX r= 0.425 p=.078
25OHD vs OPG r= -.147 p=.483
Serum sRANKL and NTX levels correlate negatively with serum 25OHD; that is, the lower the 25OHD, the higher sRANKL and NTX. This suggests that bone loss in patients with vitamin D insufficiency is due in part to an imbalance of the OPG/RANKL system which favors bone resorption.

Induction of 25-Hydroxyvitamin D-1alpha-Hydroxylase mRNA by Phosphate Depletion. Y. Taketani[1], M. Nomoto*[1], H. Yamamoto[1], K. Morita[1], M. Isshiki*[2], S. Kato[3], E. Takeda[1]. [1]Clinical Nutrition, University of Tokushima School of Medicine, Tokushima, Japan, [2]Nephrology and Endocrinology, University of Tokyo Faculty of Medicine, Tokyo, Japan, [3]Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan.

25-Hydroxyvitamin D-1alpha-hydroxylase (1alpha-hydroxylase) is a rate limiting enzyme for production of 1,25-dihydroxyvitamin D which is a potent active form of vitamin D. The expression level of 1alpha-hydroxylase is controlled by various hormones or environmental changes. PTH and calcitonin are well-known and well-characterized regulator for the enzyme. On the other hand, phosphate can regulate 1alpha-hydroxylase activity without PTH or calcitonin. However, it has not been clarified how phosphate can regulate the enzyme activity. We investigated the effect of phosphate depletion on the expression of 1alpha-hydroxylase with reference to signal transduction pathway using LLC-PK1 cells. LLC-PK1 cells were cultured with DMEM with 1 mM phosphate and 1% FBS, and then the medium was replaced to DMEM with 0 mM phosphate and 1%FBS. After 2 hours incubation, the cells were subjected to real-time RT-PCR analysis to estimate 1alpha-hydroxylase mRNA level. 1alpha-hydroxylase mRNA level increased after phosphate depletion by 1.3-fold. This effect was abolished in the presence of actinomycin D simultaneously. Furthermore increase of [Ca2+]i by tetraethylammonium chloride also increased 1alpha-hydroxylase mRNA expression. Thus, increase of [Ca2+]i may play an important role in the incuction of 1alpha-hydroxylase. We estimated the elevation of [Ca2+]i after phosphate depletion by modified GFP-based calcium indicator "cameleon" with confocal laser microscopy. After phosphate depletion from 1mM to 0.1 mM, [Ca2+]i was increased by 1.8-fold. This increment was also observed in the absence of extracellular calcium. Thus, phosphate depletion may be involved in the releasing of calcium from intracellular pool. Then we estimated inositol-triphosphate (IP3) production by phosphate depletion. Intracellular IP3 level was also increased by 1.7-fold after phosphate depletion from 1mM to 0.1 mM, by 2-fold from 1 mM to 0 mM. These results suggest that phosphate depletion would be involved in the phospho-inositide hydrolysis and increase of [Ca2+]i from intracellular pool via IP3 receptor to induce 1alpha-hydroxylase gene expression. Furthermore, this phenomenon was observed in opposum kidney cells (OK cells), but not in COS-7 cells. We speculate that phosphate sensor or receptor would exist in the proximal tubular cells and would be coupled with Gq trimeric G-protein.

SA487

Calcitriol Regulates the Expression of Genes Encoding all Three Vitamin D_3-Hydroxylases in the Human Fetal Intestine. C. Theodoropoulos*[1], D. Ménard*[2], C. Demers*[1], E. E. Delvin[1], M. Gascon-Barré[1]. [1]Université de Montréal, Montréal, PQ, Canada, [2]Université de Sherbrooke, Sherbrooke, PQ, Canada.

The human fetal jejunum has been shown to harbour the Vitamin D_3 (D_3) nuclear receptor (VDR_n) and to be responsive to calcitriol (CT) through modulation of proliferation and differentiation processes (Ménard *et al.*, Biol. Neonate, 1995). The aim of the study was to evaluate the presence as well as the effect of CT exposure on the expression levels of the three D_3-hydroxylase gene transcripts (25-hydroxylase, *CYP27A*; 24-hydroxylase, *CYP24*; 1α-hydroxylase, *CYP27B1*) in the human proximal intestine. Specimens from normal fetuses (n=5) ranging from 15 to 20 weeks gestation were obtained following elective termination of normal pregnancies. Intestinal explants were cultured for periods ranging from 6 to 48h with 10^{-7}M CT. All data were compared to those obtained without CT (time 0). Total RNA was extracted and cDNA synthesized by RT-PCR. The cDNA obtained was amplified by radioactive PCR, the signal intensity evaluated by densitometric analyses and expressed in relation to the levels of *GAPDH*. Data indicate that VDR_n and the three D_3-hydroxylases are expressed in all segments of the human fetal small intestine and in the colon. Basal expression levels of VDR_n, and both *CYP27A* and *CYP24* were found to be similar in the proximal, mid and distal jejunum as well an in the proximal and distal colon. In contrast, basal *CYP27B1* expression levels were found to be 65% higher in the colon than in the small intestine ($p<0.05$). *CYP27B1* was also found to be very sensitive to CT with a 31% decrease in its expression levels within 24h of CT exposure to reach a 68% decrease after 48h of incubation in the presence of the hormone ($p<0.05$). Furthermore, CT exposure contributed to a 4 fold increase in the expression of the *CYP24* gene transcript within 24h of exposure whereas ($p<0.05$) the levels of the *CYP27A* gene transcript were decreased by 9% within the first 24h and by 29% after 48h of incubation in the presence of CT ($p<0.03$). VDR_n expression levels were also found to be reduced by 66% 24h following incubation in the presence of CT ($p<0.0006$). These studies clearly show the presence of the D_3-1α and -25-hydroxylase gene transcripts in all segments of the human fetal intestine as well as their regulation by CT. Collectively, the data illustrate that at mid-gestation CT is fully active in the modulation of all D_3-hydroxylases in the human developing intestine.

Post-Transcriptional Defect in the Expression of the Renal 25(OH)D-1alpha-Hydroxylase in Adult Rats. H. J. Armbrecht, M. A. Boltz*, T. L. Hodam*. Geriatric Center, St. Louis VA Medical Center, St. Louis, MO, USA.

The capacity of the kidney to convert 25(OH)D to $1,25(OH)_2D$ declines with age. In addition, the capacity of the kidney to respond to PTH in terms of converting 25(OH)D to $1,25(OH)_2D$ also declines with age. The purpose of this study was to determine whether these age-related changes were due to changes in 1α-hydroxylase mRNA levels. The mRNA levels of the cytochrome P450 component of the rat renal 1α-hydroxylase (CYP1α) were measured by ribonuclease protection assay. Renal $1,25(OH)_2D$ production was measured using isolated renal slices. Studies were performed in young (2 month) and adult (12 month) male F344 rats. In adult rats, serum $1,25(OH)_2D$ levels were decreased, serum PTH levels were increased, and renal production of $1,25(OH)_2D$ was decreased compared to young rats. However, there was no difference in renal CYP1α mRNA levels in the two groups. These basal measurements suggested a refractoriness to PTH in the adult rats. Therefore, the capacity of PTH to increase renal 1α-hydroxylase expression was compared in young and adult rats. Rats of each age group were parathyroidectomized (PTX) and then injected with PTH or vehicle at 48, 24, and 6 hours before sacrifice. PTH significantly increased serum $1,25(OH)_2D$ and renal $1,25(OH)_2D$ production in young rats but not in adult rats. However, PTH increased renal CYP1α mRNA levels to the same levels in both age groups. This was also demonstrated by in vitro studies. In vitro incubation of renal slices from PTXed animals with PTH for 8 hours significantly increased CYP1α mRNA to similar levels in both age groups. However, PTH increased renal $1,25(OH)_2D$ production only in slices from young animals. These studies suggest that the capacity of PTH to increase CYP1α mRNA levels is similar in both young and adult animals. However, the increase in mRNA levels in the adult does not result in an increase in renal $1,25(OH)_2D$ production. This may be due to either a decrease in translation of CYP1α mRNA into protein or else a decrease in functionality of the CYP1α protein in the adult kidney.

Molecules Mediating the Delivery of Substrate 25-Hydroxyvitamin D to the Mitochondrial 1-Hydroxylase. S. Wu, R. F. Chun, J. S. Adams. The Burns and Allen Research Institute and Division of Diabetes, Endocrinology and Metabolism, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, CA, USA.

The synthesis of 1,25-dihydroxyvitamin D (1,25-D) from its substrate 25-hydroxyvitamin D (25-D) is mediated by a mitochondrial enzyme, 1-hydroxylase (CPY1*alpha*; 1-OHase). It is not known how 25-D is translocated from cytoplasm to the inner mitochondrial membrane where the 1-OHase is located. We have previously shown that 1-OHase-expressing human kidney cell line HKC-8 shows a significant 2-fold increase in 1,25-D production when stably transfected with the hsc70-related intracellular vitamin D binding protein-1 (IDBP-1; J Bone Miner Res 16:S556, 2001). We now demonstrate that this increase in 1,25-D synthesis occurs in the absence of any increase in expression of the CYP1*alpha* gene. This suggests that the IDBP-1-mediated 1,25-D production increase may be the result of facilitated transportation of substrate 25-D to the inner mitochondrial membrane 1-OHase. Because IDBP-1 bears no mitochondrial targeting sequence, we have hypothesized that IDBP-1 must co-operate with another molecular chaperone which is targeted to mitochondria. One such candidate is the mitochondrial hsp70, grp75. To test our hypothesis, a panel of hsc70 and grp75 cDNA constructs were transiently transfected into HKC-8 cells and the cells were assayed for their 1,25-D synthetic capacity; HKC-8 cells also constitutively express both IDBP-1 and grp75. The cDNAs used in this study were: 1] wild-type IDBP-1; 2] wild-type grp75; 3] a point mutant of IDBP-1 that abolishes its endogenous ATPase activity; 4] a chimeric IDBP-1 that contains the N-terminal mitochondrial targeting sequence from grp75; 5] a truncation mutant of grp75 in which the mitochondrial targeting signal has been deleted. Results showed that 1,25-D production was significantly increased ($p<0.03$) in cells transfected with wild-type IDBP-1, wild-type grp75 and chimeric IDBP-1 carrying the N-terminal mitochondrial targeting sequence with the latter construct showing the highest increase. The ATPase-mutant IDBP-1 and mitochondrial targeting sequence-deleted grp75 mutant showed a significant reduction ($p<0.01$) in 1,25-D production compared to wild-type IDBP-1 and grp75, respectively. Taken together these results suggest that an ATPase-competent, mitochondrially-targeted, hsp70-related protein is required for translocation of substrate 25-D to the kidney 1-OHase.

1α(OH)D_2 and 1α(OH)D_3 Suppress PTH Secretion by Bovine Parathyroid Cells: Potential Role of Metabolites. A. J. Brown[1], C. S. Ritter*[1], J. C. Knutson[2], S. A. Strugnell[2]. [1]Renal Division, Washington University, Saint Louis, MO, USA, [2]Bone Care International, Madison, WI, USA.

Active vitamin D compounds reduce PTH secretion through a vitamin D receptor (VDR)-dependent repression of PTH gene transcription. 1α(OH)D_3, a vitamin D prohormone with low VDR affinity, was reported to inhibit PTH secretion in cultured bovine parathyroid cells (Nielsen et al, J Am Soc Nephrol 8:578A, 1997), but it was not clear if 1α(OH)D_3 itself or an active metabolite was responsible. In the present study, we have determined the effects of 1α(OH)D_3 and 1α(OH)D_2 on PTH secretion, and examined the metabolism of [^{3}H]1α(OH)D_2 by bovine parathyroid cells. Steady-state rates of PTH secretion were measured after 72-hours of incubation with various concentration of the vitamin D compounds. Both 1α(OH)D_3 and 1α(OH)D_2 suppressed PTH secretion, but at equivalent concentrations were 20 and 40 times less active than 1,25$(OH)_2D_3$, respectively. Incubation of bovine parathyroid cells with [^{3}H]1α(OH)D_2 led to the formation of both 1,25$(OH)_2D_2$ and 1,24$(OH)_2D_2$ as evidenced by co-elution with authentic standards in both normal and reverse phase HPLC systems. The 1,24$(OH)_2D_2$ was detectable at 4 hours, increased to a maximum at 8 hours, and then began to decline. The fall in 1,24$(OH)_2D_2$ was likely due to both: 1) further metabolism by the inducible vitamin D-24-hydroxylase which we have previously characterized in parathyroid cells (Lee et al, Biochemistry 36:9439, 1997; Brown et al, J Cell Biochem 73:106, 1999), and 2) the drop in 1α(OH)D_2 substrate concentration to low levels at which 1,24$(OH)_2D_2$ is not formed efficiently (Strugnell et al, Biochem J 310: 233, 1995). In contrast, 1,25$(OH)_2D_2$ levels in the culture increased linearly with time, suggesting the presence of constitutively active vitamin D-25-hydroxylase not previously reported in parathyroid cells. Whether the suppression of PTH by 1α(OH)D_3 and 1α(OH)D_2 is mediated by these hydroxylated metabolites or through direct effects of the prohormone remains to be resolved.

Carpal Bone Density Measured by the Norland DXA Scanner to Assess Skeletal Maturation in Chinese Boys and Girls. J. M. Wang*[1], H. W. Zhang*[2], Y. L. Liou*[2], F. W. Guo*[2], T. V. Sanchez[3]. [1]Norland Medical Systems, Beijing, China, [2]Hai Dian Hospital of Beijing, Beijing, China, [3]Norland Medical Systems, Socorro, NM, USA.

The assessment of carpal bone density has been shown to be a precise and effective method of assessing skeletal maturation in Caucasian boys and girls (Braillon, PM, et al. Acta Paediatrica. 67:924, 1998). The present study expanded that work to a population of Chinese boys and girls in the Beijing area. A population of 67 males and 83 females between the ages of 5 and 22 years old from Beijing, China underwent examination of carpal bone density on a Norland XR-36 scanner. All scans were performed using Research Scan Software with a point resolution of 1.0 x 1.0 mm and a scan speed of 45 mm/s. All studies in this report were audited and analyzed by the same factory trained operator (JMW). Carpal bone mineral density showed a significant correlation with chronological age in both male (r = 0.9346) and female (r = 0.9442) subjects. Carpal bone density in boys and girls did not differ between the ages of 5 and 12 years. Beyond the age of 12, Chinese males were shown to have progressively greater carpal bone density than females so that by the age of 21 years, females had 81% of the density seen in males. In conclusion, this report examines the relationship between age and carpal bone density in Chinese males and females. Significant relationships are found between age and carpal bone density in both males and females. Furthermore, males over the age of 12 were found to develop significantly greater carpal bone density than females.

Disclosures: ***J.M. Wang****, Norland Medical Systems 3.*

SU002

Faster Differentiation of Human Osteoblasts Due to Increased Donor Age or High-dose Hydrocortisone Treatment Abrogates Increased Type I Collagen mRNA in Response to High-dose 17-beta Estradiol. D. Ireland*, S. Bord, J. Compston. University of Cambridge School of Clinical Medicine, Cambridge, United Kingdom.

Aging, estrogen deficiency and glucocorticoid excess are well-known conditions that predispose to osteoporosis. Estrogen acts on osteoblasts(OBs) according to their stage of differentiation and estrogen receptor (ER) isoform expression. Both increased donor age and hydrocortisone treatment limit cell proliferation by enhancing differentiation. The aim of this study was to determine whether OBs that differentiate at different rates produce similar increases in type I collagen (COL1) mRNA in response to estrogen. Low-passage, human bone-derived OBs (hOBs) from female donors aged one (Young Donor) and 66 years (Old Donor) were cultured for eleven days on collagen in medium containing 10pM 17-beta estradiol (E2, from human serum) plus 200nM hydrocortisone (HC) and 7.5mM beta-glycerophosphate. After two days, 10nM E2 or carrier was added. mRNA from cells harvested on days four and eleven was assayed by real-time RT-PCR. Changes in mRNA levels with time for ERs, COL1 and ALP reflected the faster differentiation of the OD cells. The ERbeta/ERalpha mRNA ratio rose 300-fold ($p<0.001$) in OD hOBs that formed mineralized nodules but fell three-fold in YD hOBs ($p<0.05$) that did not. OD hOBs produced more COL1 mRNA on day four than YD hOBs but the level fell rapidly. In YD hOBs the level of COL1 mRNA continued to rise over the culture period suggesting greater total COL1 synthesis by these cells. Addition of 10nM E2 to YD hOBs resulted in a two-fold increase in COL1 mRNA on day two of E2 treatment ($p<0.05$) and a two-fold decrease in ERalpha mRNA on day nine ($p<0.05$) compared to controls. No comparable changes were seen in OD hOBs. The effect of increased HC on ERs and COL1 mRNA synthesis was then investigated. OD hOBs were cultured for four days in growth medium supplemented with high-dose hydrocortisone (4mM). The ERbeta/ERalpha mRNA ratio rose 37-fold ($p<0.001$) in treated hOBs compared to untreated controls. When 10nM E2 was added to HC-treated and control cells, only the control cells showed decreased ERalpha mRNA (three-fold, $p<0.05$). Since hOB proliferation increases when ERalpha mRNA levels are reduced, ligand-dependent down-regulation of ERalpha transcription slows the rate of cellular differentiation and allows more total synthesis of type I collagen. Rapidly increasing ERbeta/ERalpha ratios in hOBs from older donors and hOBs treated with high-dose HC prevented this down-regulation of ERalpha transcription. Our results suggest that reduced bone formation seen with increasing age and with glucocorticoid treatment may be due to faster differentiation of osteoblasts.

SU003

Congenital Dislocation of Radial Head. S. Singh*, M. Garg*. Orthopaedics, B.P.Koirala Institute Of Health Sciences, Dharan, Nepal.

Congenital radial head dislocation (CRHD) is a debatable entity. CRHD commonly occurs in association with other congenital anomalies in the same limb or in other parts of the body. We came across a case in which no other associated congenital anomaly was found; hence we found it fit to be reported . **Case Report:** A ten-year old girl presented to us with complaints of deformity of both elbows. There was no history of trauma in recent or distant past. On clinical examination of elbow joints the carrying angle at elbow was 40° in both upper limbs. There was no pain or tenderness around elbow joint, forearm and wrists. The movements at elbow joints were painless, but terminal 10° of flexion was restricted. Extension at elbow and supination - pronation in forearm was full. Detailed physical examination did not reveal any other congenital abnormality. There was not functional limitation because of the deformity. **Discussion:** Non-traumatic dislocation of radial head is the most frequent congenital abnormality around elbow. There are controversies regarding the precise definition of its pathogenesis and nomenclature - congenital or developmental. Merv Letts[1] defined developmental dislocation of radial head as any dislocation that results from maldevelopment of the forearm, and congenital radial head dislocation as an entity in which congenital malformation of the extremity is obvious. We believe that debate on whether the dislocation is congenital or developmental is unnecessary, as both types may be a different expression of same genetic defect. Genetic basis of the CRHD is also supported by the fact that this lesion has been seen in identical twins[2] , and as a familial condition occurring in a patient and her daughter[3]. Because of the benign nature of dislocation of radial head and conflicting reports on the results of surgical management of such cases surgical correction of congenital anterior dislocation of radial head is seldom indicated[6,7]. Pain, cosmesis and restricted range of movements (flexion in anterior type, extension in posterior type and ration especially supination) are the usual indications of surgery. Excision of radial head can be done after skeletal maturity has been achieved[8]. Early excision is undesirable in anterior dislocation as instability of proximal radio-ulnar joint permits the radius to displace further and causing increase in the valgus deformity and instability.

SU004

Does Increased Dietary Calcium Enhance The Exercise Effect at Loaded Sites? A Randomised Controlled Study in Boys. S. L. Bass[1], L. Saxon*[1], S. Iuliano-Burns*[2], G. Naughton*[3], C. Nowson*[1], R. Daly[1], E. Briganti*[4], C. Hume*[1]. [1]School of Health Sciences, Deakin University, Burwood, Australia, [2]Dept. Medicine, Melbourne University, Heidelberg, Australia, [3]The New Childrens Hospital, Westmead, Australia, [4]Dept. of Epidemiology and Preventative Medicine, Monash University, Clayton, Australia.

Combining exercise and increased dietary calcium may produce additive or synergistic effects at loaded sites, thus we conducted a single blind, prospective, randomised controlled study to test the following hypothesis: at the loaded sites, exercise and calcium will produce greater benefits than exercise or calcium alone. Eighty-nine boys aged 9.0 (1.1) years (mean (SD)) of Tanner stages 1 or 2 were randomly assigned to one of four intervention groups: 1 - moderate impact exercise+calcium (n = 20), 2 - moderate impact exercise+placebo (n = 21), 3 - low impact exercise+calcium (n = 22) or 4 - low impact exercise+placebo (n = 26). The 9-mth school-based program consisted of 20 min. of moderate or low impact exercise 3 times/wk. Participants also received ~800 mg/day calcium (milk based calcium-fortified foods) or an equivalent food without additional calcium. Total and regional BMC, anthropometry, sexual maturity, dietary calcium intake using a 3-day food record and physical activity levels (questionnaire) were assessed at baseline and post-intervention. Interaction between exercise and calcium was determined by ANOVA (4-group analysis). The main effects were determined by ANOVA (2 group analysis): exercise (groups 1 & 2 vs groups 3 & 4) and calcium (groups 1 & 3 vs groups 2 & 4). ANCOVA was used to control for baseline confounding factors - BMI, sexual maturity, regional bone mineral content, dietary calcium intake and physical activity level. At baseline, no differences were reported between the intervention groups. There was no significant calcium-exercise interaction on BMC gain at any site. For the unadjusted analysis a main effect of calcium was detected at the femur: additional calcium resulted in a 2.6% greater increase in BMC (mean±SE, 3.9±1.2 g, $p<0.01$). A main effect of exercise was detected at the femur and tibia: moderate impact exercise resulted in a 1.9% and 3.2% greater increase in BMC at the femur (2.5±1.2 g, $p<0.05$) and tibia (2.9±1.4 g, $p<0.05$). There was no effect of additional calcium or moderate impact exercise detected for total, lumbar spine, humerus or radius BMC accrual. Similar results were found after adjusting for baseline confounding variables. In conclusion, in pre- and early pubertal boys greater gains in bone mass at the femur may be achieved with short bouts of moderate impact exercise and increased dietary calcium; the effects however, were not synergistic.

SU005

Quantifying The Relationship Between Mechanical Loading and the Skeletal Response in Pre- and Early- Pubertal Girls: A Randomised Controlled Study. L. Saxon*[1], S. Iuliano-Burns*[2], G. Naughton*[3], R. Daly[1], S. L. Bass[1]. [1]School of Health Sciences, Deakin University, Burwood, Australia, [2]Dept. Medicine, Melbourne University, Heidelberg, Australia, [3]The New Childrens Hospital, Westmead, Australia.

Before exercise prescription for bone health can be recommended the relationship between mechanical loading characteristics and the skeletal response need to be quantified. We asked: i) does moderate impact exercise result in a greater gain in BMC than low impact exercise, ii) what are the loading characteristics associated with a moderate and low impact exercise program and does this differ from non-structured play?, and iii) does loading history affect the osteogenic response to a moderate or low impact program? Sixty-eight pre- and early-pubertal girls (aged 8.9±0.2 yrs) were randomised to take part in a moderate or low impact exercise program 3 time/wk for 8.5 mths (as part of an exercise-calcium intervention). The number and type of loads associated with the exercise classes and non-structured play (recess) were assessed from video footage. The magnitude of loads associated with each activity was assessed using a pedar in-sole mobile system. Hours of moderate and high impact organised sport was assessed from a parental assisted physical activity questionnaire. ANCOVA was used to detect differences in BMC gains between exercise groups, adjusting for baseline BMC, change in bone length and calcium intake. Unpaired t-tests were used to compare the differences in the number and magnitude of loads between the moderate and low impact exercise programs and non-structured play. The moderate and low impact exercise programs consisted of ~400 impacts per class, but the jumping, hopping and dynamic activities performed during the moderate impact program produced forces ranging from 2 to 4 x body weight (BW) compared to ~1 BW for the low impact program. Moderate impact exercise resulted in a 2.7% greater gain in BMC at the tibia compared to the low impact exercise. The moderate impact exercise program consisted of fewer low impacts (1-2 BW) and a higher number of moderate impact (2-4 BW) compared to those typically performed during non-structured play. The number of hours of organised sport outside of school positively correlated with gains in BMC ($r = 0.3$, $p<0.05$). There were greater gains in BMC in subjects participating in the moderate versus the low impact exercise programs who participated in 2 to 3 hours of moderate impact sports outside school (2.5% to 4.5% respectively, $p<0.06$ to 0.01). In conclusion, approximately 400 impacts ranging 2-4 BW, 3 times/wk was enough stimuli to result in an osteogenic response in normally active girls; even in those actively involved in moderate impact sports outside school.

SU006

Influence of Ethnicity and Lifestyle Factors on Bone Mass, Size and Architecture in Pre- and Peri- Pubertal Boys. R. Daly[1], D. Newey*[1], S. Bass[1], L. Saxon*[1], S. Iuliano-Burns*[2], E. Briganti*[3]. [1]School of Health Sciences, Deakin University, Melbourne, Australia, [2]Dept of Medicine, Melbourne University, Melbourne, Australia, [3]Dept of Epidemiology and Preventive Medicine, Monash University, Melbourne, Australia.

A number of factors are known to influence the attainment of peak bone mass, including genetics, ethnicity and various lifestyle factors. While ethnic differences in bone mass during growth have been largely explained by differences in bone size, it is possible that lifestyle factors may also contribute to ethnic differences in bone mass, size and architecture. This study examined the influence of ethnicity and the role of lifestyle factors on bone mass, size, architecture and volumetric BMD (vBMD) in pre- and peri- pubertal boys. We measured anthropometry, sexual maturity, exercise and calcium intake in 75 Caucasian and 20 Asian boys aged 8-10 years. Total body, lumbar spine (L3) and femoral neck BMC, BMD, estimated bone volume and vBMD, and lean mass and fat mass were assessed by DXA; heel BUA and VOS were assessed by ultrasound (CUBAClinical). FN and L3 BMC and bone volume were lower in Asian compared to Caucasian boys ($p<0.05$), but no differences were detected for BMD or vBMD (Table). No ethnic differences were observed for TB BMC (height adjusted), BMD, VOS and BUA, or age, height, weight, sitting height, leg length and fat mass. However, Asian boys had lower lean mass (21.9 ± 2.7 vs 23.3 ± 2.9 kg), were less active (organised sport, 1.6 ± 1.3 vs 2.5 ± 1.6 hr/wk) and had lower calcium intakes (572 ± 189 vs 886 ± 372 mg/day) ($p<0.05$).

	L3		FN	
	Asian	Caucasian	Asian	Caucasian
BMC (g)	4.95 ± 0.89*	5.43 ± 0.94	1.91 ± 0.34*	2.12 ± 0.47
Volume (cm3)	17.4 ± 3.3*	19.4 ± 3.4	5.05 ± 0.85*	5.56 ± 1.34
vBMD (g/cm3)	0.287 ± 0.027	0.282 ± 0.029	0.379 ± 0.038	0.386 ± 0.059

*$p<0.05$ vs Caucasians

Univariate analysis revealed that ethnicity, age, exercise, calcium and BMI were independent predictors of L3 and FN BMC ($p<0.2$). Ethnicity (L3 only), age, Tanner stage, exercise and BMI were independent predictors of L3 and FN volume. In multivariate analysis, ethnicity and BMI accounted for 27.4% and 34.4% of the variance in L3 volume and BMC, whereas BMI and age accounted for ~34% of the variance in FN bone volume and BMC. In summary, lower bone mass reported in Asian boys was largely due to a smaller bone size, and not to differences in exercise or calcium intake. There were no ethnic differences in the structural properties of bone. Since bone size has been reported to be a risk factor for fracture, Asian boys may be at increased risk of fracture due to a smaller bone size and not necessarily lower BMD or architectural differences.

SU007

Effects of Calcium, Vitamin D and Cheese Supplementation on Bone Mass Accrual in 10-12-Year-old Girls During Two-year Follow-up. S. Cheng[1], F. Tylavsky[2], A. Koistinen*[3], M. Kemppinen*[1], M. Kemikangas*[1], P. Salo*[1], R. Korpela*[4], A. Lyytikäinen*[1], A. Mahonen[5], M. Alen*[6], H. Suominen[1], H. Kröger[5]. [1]Univ of Jyväskylä, Jyväskylä, Finland, [2]Univ of Tennessee, Memphis, TN, USA, [3]Central Hospital, Jyväskylä, Finland, [4]Valio Oy, Helsinki, Finland, [5]Univ of Kuopio, Kuopio, Finland, [6]PERUNKA-Medical Rehabilitation Center, Jyväskylä, Finland.

The purpose of this double-blinded randomized intervention study (the CALEX-study) was to evaluate the effect of calcium (Cal), vitamin D (VD) and cheese (Che) supplementation on bone mass accrual during a two-year period. The subjects were 10-12-year-old Finnish girls with Tanner stage I-II and with dietary calcium intake <900 mg/day. In wave I, 104 girls were randomly assigned into four groups of which 91 girls [placebo (Pla, n=24), Cal + VD (n=24), Cal + PlaVD (n=20), and Che (n=21)] completed the intervention. In addition, 20 girls who had dietary calcium intake >900 mg/day served as controls (Con). Bone area and bone mineral content (BMC) of the whole body (WB), total femur (TF), and lumbar spine (LS) were assessed using a Dual-energy X-ray Absorptiometry (Prodigy, GE Lunar Corp.). On average, the subjects increased their BMC for 36% in the WB, 33% in the TF and 47% in the LS during the two-year period. When compared to the other groups, the cheese group had a significantly higher increase in BMC at the LS ($p=0.027$), with a trend for significance in the WB ($p=0.083$) and TF ($p=0.081$). Those with a diet >900 mg/day of calcium appeared to have a similar increase in BMC as the groups with Cal and Cal+VD supplementation. The differences in the increases in bone area between the groups disappeared when controlling for changing in height and weight (Table). Based on our analysis for this first wave, it appears that supplementing the diet with cheese or the consumption of foods high in calcium may provide benefits to the skeleton that is not available from supplements alone. These trends will need to be verified as waves II and III complete the study protocol.

%Change	Con	Pla	Cal+PlaVD	Cal+VD	Che
Area					
WB	22.5	22.9	22.0	22.7	23.9
TF	15.3	16.1	15.6	15.7	15.8
LS	24.0	22.4	23.4	23.3	24.0
BMC					
WB	35.5	34.5	34.1	34.1	36.3
TF	32.1	30.8	33.0	30.9	32.4
LS	47.4	43.6	45.8	44.9	49.8

SU008

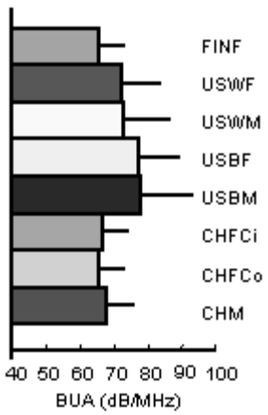
Changes in Bone Size and Mass Are Associated with Changes in Fat Free Mass in 10-12-year-old Girls During Two-year Follow-up. H. Kröger[1], F. Tylavsky[2], M. Kemikangas*[3], M. Kemppinen*[3], A. Koistinen*[4], M. Alen*[5], H. Suominen[3], S. Cheng[3]. [1]Univ of Kuopio, Kuopio, Finland, [2]Univ of Tennessee, Memphis, TN, USA, [3]Univ of Jyväskylä, Jyväskylä, Finland, [4]Central Hospital, Jyväskylä, Finland, [5]PERUNKA-Medical Rehabilitation Center, Jyväskylä, Finland.

The purpose of this study was to evaluate the associations between bone growth and changes in body composition over a two-year period in 10-12-year-old Finnish girls. The subjects were 118 girls with Tanner stage I-II, who participated in an intervention study (the CALEX-study). Fat mass (FM), fat free mass (FFM), bone area (BA) and mineral content (BMC) of the whole body (WB), and BA and BMC of the total femur (TF) and lumbar spine (LS) were assessed using dual-energy X-ray absorptiometry (Prodigy, GE Lunar Corp.). During the two-year period, the girls grew on average 11.9 cm in height (HT) and 10.5 kg in weight (WT), and added 486 g to their WB bone mass. Girls who entered the study in Tanner stage I had a higher increase in HT than the girls in stage II (12.9 vs. 11.0 cm, $p<0.001$). We observed a similar % change of the BMC of the WB and TF for those in Tanner stage I and II at baseline. However, there were larger gains in BA for those in Tanner stage I compared to stage II for the WB (25.5 % vs. 21.4%, $p=0.005$), TF (18.8% vs. 13.0%, $p<0.001$). Girls in Tanner stage II had larger increases in BMC of the LS than the girls in the stage I (43.2% vs. 50.9%, $p<0.001$) with no difference in % change of the LS area (24.0% vs. 23.9%). The changes in BA and BMC of the WB, TF and LS are significantly correlated with the changes in the WT, HT and FFM (r-values ranging from 0.42 to 0.74). The WB area and BMC and TF BMC correlated moderately with the FM. Changes in FFM accounted for about 45% of the variation in the changes of the bone area and mass in WB, about 54% in TF and 26-39% in LS. Our data support the hypothesis that muscle mass (estimated by FFM) has an important role in the gain of bone mass in prepubertal girls.

SU009

Ultrasound Assessment of the Calcaneus in Finnish, USA and Chinese Pre-adolescent Children. L. C. Zou*[1], Q. J. Wang*[2], S. M. Cheng*[2], X. D. Zou*[3], F. Tylavsky[4], L. Carbone[4], E. Helkala*[2], S. Cheng[2]. [1]Guang Zhou College of Physical Education, Guang Zhou, China, [2]Univ of Jyväskylä, Jyväskylä, Finland, [3]Nanning Normal School, Nanning, China, [4]Univ of Tennessee, Memphis, TN, USA.

This study investigated whether there were differences in quantitative ultrasond (QUS) assessment of the calcaneus between Finnish, USA and Chinese preadolecscent children. The subjects consist of 544 children aged 8-12-year-old [Finnish white female (FINWF, n=199), USWF (n=69), US white male (USWM, n=30), US black female (USBF, n=12), USBM (n=8), Chinese female from city (ChFci, n=73), ChF from countryside (ChFco, n=46), ChM (n=111)]. QUS assessment was performed using a QUS-2 scanner at the calcaneus (Quidel Corp). Height (in cm) was measured using a stadiometer and weight (in kg) using a calibrated scale. We found that US children had significantly higher BUA values than the Finnish and Chinese children (Figure). There were no differences in BUA between ChM and ChF or between US males and females. However, black males had the highest value compared to other race and gender groups. After controlling for the differences in age, weight and height among the race and gender groups, the significance remained. Our results confirmed that the black has higher BUA than the whit and Chinese in pre-adolescent children which has been reported in adults. The small sample size of US blacks does not provide the power to correctly estimate differences due to gender. However the absence of gender difference in Chinese and whit children is in agreement with findings observed in bone densitometry assessment in pre-adolescent children.



SU010

Microarchitectural Properties of Subchondral Trabecular Bone of Femoral Head in Osteoporosis and Osteoarthritis. G. Lemineur*[1], B. Brunet-Imbault*[1], R. Jennane*[2], F. Peyrin*[3], A. Bonnassie*[3], C. L. Benhamou[1]. [1]Inserm ERIT-M 0101, Orléans, France, [2]Laboratoire d'Electronique Signaux Images, Orléans, France, [3]CREATIS, Lyon, France.

It has been suggested that subchondral bone changes could be early events of osteoarthritis. To investigate this hypothesis, we have studied six femoral heads from osteoarthritis (OA) and eight femoral heads from osteoporosis (OP). The purpose was to quantify microarchitecture of subchondral trabecular bone in OA, either in an area covered by cartilage (n = 6) or in an area where the cartilage had disappeared (n = 6), and to compare them with 8 OP samples. 3R X-Ray microtomographic images were acquired using a synchrotron source at the ESRF. Each 3D image had a size of 6×6×6 mm^3 with an isotropic voxel size of 10.13 µm. 3D characteristics of the trabecular bone microarchitecture were calculated by the Mean Intercept Length method : bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular spacing (Tb.Sp), trabecular number (Tb.N) and degree of anisotropy (DA).

	OA with cartilage n=6	OA without cartilage n=6	OP n=8
BV/TV	0.221 ± 0.063	0.363 ± 0.035	0.181 ± 0.054
Tb.Th (mm)	0.110 ± 0.019	0.158 ± 0.023	0.114 ± 0.023
Tb.Sp (mm)	0.402 ± 0.083	0.280 ± 0.049	0.538 ± 0.113
Tb.N (mm^{-1})	1.992 ± 0.319	2.320 ± 0.326	1.565 ± 0.244
DA	8.584 ± 12.078	4.006 ± 1.763	4.921 ± 2.351

A statistical significant difference was observed concerning all the parameters ($0.002 < p < 0.01$) between OA samples without cartilage and OP samples, except for DA ($p = 0.44$). The comparison between OA samples with cartilage and OP samples showed no statistical difference ($0.07 < p < 0.61$) except for Tb.N ($p = 0.03$). The comparison between OA samples with and without cartilage showed statistically significant differences for all the parameters ($0.001 < p < 0.01$) except Tb.N ($p = 0.07$) and DA ($p = 0.9$). These data suggest that – significant subchondral microarchitectural changes mainly occur in advanced OA, when cartilage has disappeared – there are no or few anisotropy changes in this region in OA. The increase of Tb.N could be an early OA change, or could be due to a decrease of Tb.N in OP.

SU011

Changes in Calcaneal Ultrasound Attenuation Estimate Changes of Bone Mass and Density in Children. H. Suominen, E. Helkala*, S. M. Cheng*, P. Moilanen*, P. H. Nicholson*, S. Cheng. Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland.

Relatively little is known about the association between changes in quantitative ultrasound (QUS) parameters and changes in bone mineral content (BMC) and density (BMD) in children. We have compared calcaneal broadband ultrasound attenuation (BUA; QUS-2, Quidel Corp) with the BMC and BMD of the whole body (WB), total femur (TF) and lumbar spine (LS) (DXA; Prodigy, Lunar). Subjects (n=91) were girls, aged 10-12 years, who participated in a two-year intervention study to evaluate the effects of calcium, vitamin D and cheese supplementation on the acquisition of bone mass during prepuberty (the CALEX-study). The mean of the CVs for duplicate determinations of BUA was 1.2%. We found that changes in BUA correlated significantly with the changes in BMC of the WB (r=0.317, p=0.002), TF (r=0.276, p=0.009) and LS (r=0.379, p<0.001), and with the changes in BMD of the WB (r=0.583, p<0.001), TF (r=0.460, p<0.001) and LS (r=0.475, p<0.001) during the two-year period. There was also an association between the changes in BUA and the changes in body weight (r=0.279, p=0.007). After controlling the changes in body weight, the correlation remained significant between the changes in BUA and BMD of the WB (r=0.557, p<0.001), TF (r=0.383, p<0.001) and LS (r=0.409, p<0.001). Our study indicates that calcaneal BUA can be used for estimating the bone mass acquisition during growth.

SU012

Effects of Cerivastatin and Parathyroid Hormone on Bone in Male Sprague Dawley Rats. J. Banu[1], D. N. Kalu[2]. [1]Department of Physiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]Dept. of Physiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

It is well established that age-related bone loss occurs in males. The aim of this study is to determine whether cerivastatin and parathyroid hormone (PTH) will prevent age-related bone loss in the tibia and femur of male Sprague Dawley (SD) rats. Nine months old SD rats were divided into 6 groups. Group 1: Baseline controls; Group 2: Age-matched controls; Group 3: Low dose cerivastatin (0.2 mg/kg b wt/d); Group 4: Medium dose cerivastatin (0.4 mg/kg b wt/d) Group 5: High dose cerivastatin (0.8 mg/ kg b wt/d); Group 6: PTH (80 mg/ kg b wt, 3d/wk). Group 1 was sacrificed at the beginning of the study. Groups 2-6 were treated for 6 months. Cancellous and cortical bones were analyzed using pQCT densitometry at the proximal tibial metaphysis (PTM), the neck of the femur and the tibio-fibula junction. PTM: pQCT analyses were done at the tibia fibula junction in the proximal tibial metaphysis. When compared to the baseline controls, the cancellous bone mineral content (Cn. BMC) of the age-matched controls decreased by 44% (p<0.0001) confirming that male SD rats lose bone with age. The Cn. BMC decreased by 58% (p<0.0001), 58% (p<0.0001) and 60% (p<0.0001) in the low, medium and high doses of cerivastatin groups respectively, when compared to the baseline controls while PTH prevented the bone loss seen in the age-matched controls. When compared to the baseline controls, the cancellous bone mineral density (Cn. BMD) of the age-matched controls decreased by 43% (p<0.0001). The Cn. BMD decreased by 55% (p<0.0001), 56% (p<0.0001) and 58% (p<0.0001) in the low, medium and high cerivastatin groups respectively, when compared to the baseline controls while PTH prevented the bone loss seen in the age-matched controls. In the neck of the femur and the tibio fibula junction cerivastatin also did not prevent age-related bone loss in male SD rats while PTH significantly prevented the age-related bone loss. We, therefore, conclude that cerivastatin, in any of the doses tested, did not prevent age-related bone loss, in male SD rats, in any of the different bone sites studied. On the other hand, PTH prevented age-related bone loss in male SD rats in all the different bone sites studied. These findings are in line with our previous observation that cerivastatin did not prevent age-related bone loss in the lumbar vertebra of male SD rats.

SU013

Effects of IGF-I Overexpression in Muscle on Cortical and Cancellous Bones of Female Mice. J. Banu*[1], L. Wang*[2], D. Kalu[3]. [1]Department of Physiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]Dept. of Physiology, University of Texas Health Science Center at San Antonio, SanAntonio, TX, USA, [3]Dept. of Physiology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

It has been hypothesized that increased muscle mass increases strain on bone resulting in increased bone mass. The aim of this study is to determine the effects of increased muscle mass on bone in female mice. A colony of transgenic FVB mice that overexpresses IGF-I in muscle was established. Overexpression of IGF-I brought about increased muscle mass in the transgenic mice. The offsprings of transgenic animals were screened for their genotype and only the heterozygotes and wild type females were used in this study. The animals were scanned at 1.5, 2.5, 3.5, 4.5, 6, 9 and 12 months of age, using a pQCT densitometer. The tibial diaphysis, distal femoral metaphysis and muscle cross-sectional area were analyzed. Body weight and muscle area: The heterozygous animals maintained a significantly higher body weight when compared to the wild type animals. As expected the muscle area in all the age groups was significantly higher in the heterozygous animals when compared to the wild type animals. Tibial Diaphysis: The cortical bone mineral content (Ct. BMC) did not differ significantly between the two groups in any of the age groups studied. Cortical bone mineral density (Ct. BMD) was significantly higher in the heterozygous animals only at 1.5 (7%, p<0.001), 2.5 (5%, p<0.01) and 3.5 months (2%, p<0.01) of age. Distal femoral metaphysis: The heterozygous animals had increased cancellous bone mineral content (Cn. BMC) in all the age groups studied, but this increase was statistically

significant only in the 2.5 months old animals (21%, p<0.01), when compared to the wild type animals. Cancellous bone mineral density (Cn. BMD) did not show any significant differences between the two groups. In conclusion, overexpression of IGF-I in female mice increased the body weight and muscle cross-sectional area. The increase in muscle cross-sectional area was associated with increased bone mass only in the younger animals. As the animals grew older there was no significant difference in bone between the two groups.

SU014

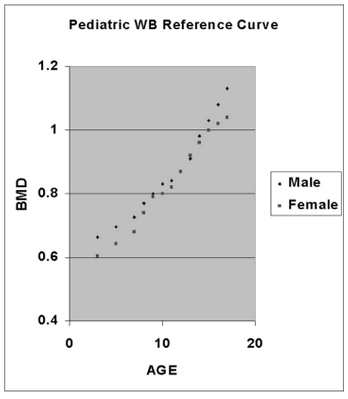
Exercise During Growth and Young Adulthood is Associated With Reduced Fracture Risk in Old Ages. M. K. Karlsson, H. Ahlborg*, K. J. Obrant, F. Nyquist*, H. Lindberg*, C. Karlsson*. Department of Orthopaedics, University Hospital MAS, Malmo, Sweden.

Exercise during growth is associated with increased peak bone mineral density (BMD). However, fragility fractures occur in old age. We asked: (i) are benefits in peak BMD and skeletal structure derived from exercise during growth retained after age 50? (ii) do former athletes have fewer fractures than controls? We compared the prevalence of fractures in 663 former athletes, mean age 69 years (range 50-93), all on national or international level within impact loaded sports during active career, retired from exercise career mean 34 years (range 1-62), and 943 age- and gender matched controls, randomly selected from the computerised national files. BMD was measured in a sub-cohort consisting of 90 former athletes, mean age 67 (range 50-92), retired from exercise career mean 27 years (range 3-65), and 77 sedentary age- and gender- matched controls, by dual energy X-ray absorbtiometry (DXA) and Quantitative Ultrasound Calcaneus (QUS). Data is presented as mean ± SD. The proportion of subjects with fractures was no lower in former athletes than controls over all [172/663 (25.9%) versus 238/994 (25.2%); NS], higher in the former athletes when they were active and less than 35 years of age [126/663 (19.0 %) vs 130/943 (13.8 %); p <0.01] but lower than controls in adulthood, after the age of 35 years [59/663 (8.9 %) vs 115/943 (12.1 %), p < 0.05]. Additionally, the proportion of subjects with low energy related fragility fractures sustained after age 50 [15/663 (2.3 %) vs 38/994 (4.2 %), p = 0.05] as well as distal radius fractures [5/663 (0.8 %) vs 22/943 (2.3 %), p = 0.01] was lower in former athletes than controls. BMD (g/cm2) was higher in the former athletes than the controls (total body 1.24 ± 0.10 vs 1.16 ± 0.09, p<0.001; spine 1.20 ± 0.13 vs 1.11 ± 0.13, p<0.001; femoral neck 0.93 ± 0.15 vs 0.89 ± 0.14, p=0.08). Additionally, bone size (femoral neck area (cm2) 6.17 ± 0.49 vs 5.98 ± 0.41, p<0.01), lumbar spine width (cm) (3rd lumbar vertebrae 4.78 ± 0.38 vs 4.59 ± 0.45, p<0.01) and skeletal architecture evaluated by QUS (SOS (m/s) 1552.6 ± 42.2 vs 1553.0 ± 34.0, p<0.01; Stiffness index 94.0 ± 18.2 vs 87.5 ± 15.5, p<0.05) was higher in the former athletes than the controls. Fracture rates are lower in former athletes than controls, possibly due to residual benefits in skeletal structure attained by vigorous physical activity during growth. We infer that exercise during growth may reduce the burden of fragility fractures in men.

SU015

Pediatric Whole Body Measurements. T. L. Kelly. Hologic, Inc., Bedford, MA, USA.

We report on the development of an algorithm that dynamically adjusts detection thresholds to optimize performance in pediatric subjects weighing between 10 and 40 kg. The Pediatric Whole Body analysis method performs better than the Adult Whole Body method in young children. However, the Pediatric and Adult Whole Body analysis methods provide different results and it is often unclear which method should be used. Further, longitudinal studies and population based studies such as NHANES may employ both analysis methods, complicating the interpretation of changes and the development of reference data. These issues were resolved with an automatic algorithm that dynamically adjusts bone detection thresholds and soft tissue baseline determinations based upon the subject's weight. The thresholds are set such that the Adult Whole Body analysis is employed in subjects weighing more than 41 kg (90 lbs.), representing more than 98% of U.S. adults. Between 40 kg and 10 kg of body weight, bone detection thresholds and soft tissue baseline values are dynamically adjusted downward to provide technically acceptable bone mapping in all regions of the skeleton. Particular attention was given to the arms, legs, and pelvic region to ensure that bone detection was accurate and reliable. Children 3 to 17 years old were analyzed with the technique and reference databases were developed for bone and body composition results. We conclude that this new whole body analysis method will improve the reliability of pediatric whole body determinations, provide congruent results across all age groups, and obviate the need for an alternative analysis method in young children.



SU016

Age Related Changes in Metacarpal Morphometry and Areal Bone Mineral Density in Children Assessed by Digital X-ray Radiogrammetry (DXR). R. L. Ashby*[1], K. A. Ward[1], Z. Mughal[2], J. E. Adams[1]. [1]Department of Clinical Radiology, The University of Manchester, Manchester, United Kingdom, [2]Central Manchester and Manchester Children's University Hospitals NHS Trust, Manchester, United Kingdom.

The purpose of this cross sectional study was to investigate age related changes in metacarpal morphometry and areal bone mineral density (BMD) from hand radiographs of normal children using DXR. This technique analyses the second, third and fourth metacarpals and gives an assessment of the metacarpal index (MCI), cortical thickness (cm) (CT), outer bone width (cm) (BW) and BMD (g/cm^2). Non-dominant hand radiographs of 119 healthy Caucasian children (70 female, 49 male; mean age 11.32 ± 3.61, range 5.42-18.95 years) were assessed using the Pronosco X-posure system ™ (version 2). Subjects were grouped according to gender, pre-pubertal or pubertal status, chronological age in groups (5-8.99; 9-12.99 and 13-19 years), and Tanner pubertal stage (TS) (females only). Females had a higher mean MCI (mMCI) compared to males (p < 0.001). When grouped according to pubertal status, this difference still existed (pre-pubertal mMCI = 0.353 females, 0.328 males, p < 0.05; pubertal mMCI = 0.462 females, 0.401 males, p < 0.01). TS 2 demonstrated a lower mMCI compared to TS 3 (0.344 vs 0.483, p < 0.001). mMCI increased by age group in females (p < 0.01 to < 0.001) only, although mean CT (mCT) and mean BW (mBW) increased with age in both genders (p < 0.05 to < 0.001). Males demonstrated a higher mBW (p < 0.001) but a lower mCT compared to females (p < 0.05). TS 2 had a lower mCT compared to TS 3 (0.120 cm vs 0.171 cm, p < 0.01). Mean BMD (mBMD) increased with age in males and females (p < 0.001). Males (9-12.99 years) had a lower mBMD compared to females of the same age (0.410 g/cm^2 vs 0.433 g/cm^2, p < 0.05). TS 2 had a lower mBMD compared to TS 3 (0.394 g/cm^2 vs 0.514 g/cm^2, p < 0.01). Chronological age, height, weight, MCI, CT, BW, BMD and grip strength (GS) correlated positively (p < 0.05 to < 0.001) with each other. In pubertal males, MCI did not correlate significantly with GS. The Pronosco X-posure system ™ is a useful tool for the study of age and gender related changes in metacarpal morphometry and BMD in children. Such important information concerning growth parameters in normal children can be applied to the study of paediatric conditions associated with increased fracture risk, such as steroid induced osteoporosis.

SU017

Total Body Bone Mineral Content and Parameters of Bone Strength at the Radius and Tibia in Pre-Pubertal Gymnasts and Sedentary Controls. K. A. Ward[1], J. E. Adams[2], S. Roberts*[3], R. L. Ashby*[2], Z. Mughal[4]. [1]Clinical Radiology, University of Manchester, Manchester, United Kingdom, [2]Department of Clinical Radiology, The University of Manchester, Manchester, United Kingdom, [3]School of Epidemiology and Health Sciences, The University of Manchester, Manchester, United Kingdom, [4]Central Manchester & Manchester Children's University Hospitals NHS Trust, Manchester, United Kingdom.

During the pre-pubertal period, physical activity positively influences bone size, geometry, mass and ultimately bone strength. We hypothesised that, compared to controls gymnasts will have higher total body bone mineral content (TBBMC) and stress strain index (SSI), a measure of bone strength, in the radius and tibia. Bone and muscle cross sectional area (CSA) and SSI were measured at the 50% sites from the distal radius and tibia using peripheral quantitative computed tomography in gymnasts (n=28) and controls (n=33). TBBMC was measured using dual energy x-ray absorptiometry. Bone age was assessed from hand radiographs (Greulich & Pyle). There was no significant difference between the chronological or bone age of the gymnasts' vs. controls (mean age 8.9 SD 1.3: 7.6 SD 1.4 years). Controls were taller than gymnasts (3.6cm, p=0.03); weight and BMI were not significantly different. Weekly median activity was 11 hours in gymnasts and 5-6 hours in controls. After adjustment for bone area, weight, height and sex, gymnasts had higher TBBMC than controls (mean difference = 51.91g, p=0.002). After adjustment for weight and sex gymnasts had higher bone strength (SSI = 60.49mm^3, p=0.01), bone and muscle CSA (15.48mm^2, p=0.002; 181.67mm^2, p=0.06 respectively) than controls at 50% distal tibia. At 50% distal radius, gymnasts had higher bone strength parameters than controls (SSI = 16.61mm^3, p=0.002; bone CSA = 4.76mm^2, p=0.009; muscle CSA = 320mm^2, p<0.001). The appendicular skeleton of pre-pubertal gymnasts has adapted to increased loading in comparison to sedentary controls. The 50% mid-cortical sites at the radius and tibia have adapted to withstand the high forces exerted during activity by increasing the bone and muscle CSA and SSI. If the differences in TBBMC between the two groups persist until the end of the growth period then the gymnasts will have achieved a greater peak bone mass, which may contribute to a lower fracture risk in later life.

SU018

Bone Age Assessment by DXA and Standard Radiographs; Comparison with Chronological Age. R. L. Ashby*[1], I. M. Hodgkinson*[1], E. J. Harrison*[1], K. A. Ward[1], Z. Mughal[2], J. E. Adams[1]. [1]Clinical Radiology, Imaging Science & Biomedical Engineering, University of Manchester, Manchester, United Kingdom, [2]Pediatric Medicine, Central Manchester and Manchester Children's Hospitals, Manchester, United Kingdom.

Bone age (BA) or skeletal maturity assessment is important in the evaluation of children with disorders of growth, and when measuring paediatric bone mineral density (BMD). Hand and wrist radiographs are examined and skeletal maturity is classified as a BA according to the methods of Greulich and Pyle (GP) or Tanner-Whitehouse. We hypothesised that 1) assessment of bone age from hand and wrist images generated by Hologic 4500A DXA (DXAi) would be possible and 2) BA from DXAi and BA from a standard hand and wrist radiograph would not differ significantly from chronological age (CA). 55 healthy children mean age 12.8 years (SD 3.3, range 6.3-18.4 years) were studied. The GP method was used to assess the BA of each individual from postero-anterior radiographs (RADi) and DXAi of the left hand and wrist. A paired samples t-test was used to determine whether there was a significant difference between BA assessed from RADi or DXAi and subject's CA. In the age group 6-11.9 years there was a mean significant difference (-1.40 SD 1.08 years, p<0.001) in BA by DXAi compared to CA; in older children (12-18.4years) there was no significant difference (p=0.47). Comparing BA and CA using RADi there were no significant differences in either of the age groups (p=0.10, 6-11 years and p=0.45, 12-18.9 years). This study confirms the feasibility of estimating BA and BMD from DXA. This may be applied to healthy children who have a CA of 12-18.4 years. The inaccuracy in determining BA from DXAi in younger children is likely to be related to the spatial resolution of DXAi limiting image quality and resulting in partial volume averaging errors.

SU019

Longitudinal Follow-up of Bone Mineral Density in Children and Adolescents with Systemic Lupus Erythematosus (SLE). E. von Scheven*[1], J. Shepherd[2], Y. Chen*[2], H. Genant[2]. [1]Pediatrics, University of California, San Francisco, San Francisco, CA, USA, [2]Radiology, University of California, San Francisco, San Francisco, CA, USA.

Chronic illness such as SLE may affect the acquisition of bone mineral during childhood and adolescence. We utilized Dual X-ray Absortiometry (DXA) to detect BMD change in a longitudinal cohort of youth with SLE. Volumetric methods were utilized to control for underlying changes in body size associated with growth. We performed spine DXA (Hologic QDR 4500) to determine APBMD (areal BMD), APBMAD (volumetric BMD, BMC/AP^1.5), Hologic Lat VolBMD (Lat BMC/vol determined by AP and Lat scan dimensions); and whole body (WB) DXA to determine WB BMD, WB BMC (bone mineral content) and WBMAD (bone mineral apparent density). 17 subjects with pediatric-onset SLE (age 8.8-20.4yrs [mean 13.8], 76% female, 6% Caucasian, 33% Asian, 33% Hispanic, 11% African-American and 17% mixed) were evaluated at baseline and follow-up (1.1-2.4 yrs later, mean 1.9). Healthy controls (n=103, age 7.0-21.9yrs, 75% female, 47% Caucasian, 21% Asian, 29% Hispanic and 3% mixed) were evaluated at baseline only. Changes in height and BMD were annualized. Disease duration ranged from 0.17-8.3 yrs (mean 1.6). Prednisone dose (mg/kg) at baseline ranged from 0.0 -0.39 (mean 0.17) and at follow-up 0.0 -1.2 (mean 0.26). Subject's served as their own control for evaluation of unadjusted BMD values. Controls were used to generate age- and weight-adjusted Z-scores for the non-black female subjects. 35% of subjects demonstrated a loss of bone (g/cm^2) by APBMD and 36% by APBMAD. After adjusting for growth (age and weight) this increased to 75% and 83% respectively, reflecting the importance of age and body size in pediatric analysis. The average annualized change of BMD was 0.14 ± 0.04 g/cm^2 (-0.062 to 0.075 g/cm^2) for APBMD and 0.50 ± 3.5 mg/cm^3 (-5.1 to 8.3 mg/cm^3) for APBMAD. After controlling for age and gender, the change in APBMD was significantly associated with increased height (p=0.003) while change in APBMAD was not. Annualized mean [SD] change of Z-score for non-black females was positive for WBMAD (+0.12 [.22]) but negative for all other measurements: WB BMD ¯ 0.10 [.19]); WB BMC ¯ 0.18 [.29]); APBMAD ¯ 0.25 [.18]); APBMD ¯ 0.26 [.35]); and Hologic Lat VolBMD ¯ 0.43 [.67]. This preliminary study suggests that pediatric SLE may be associated with minimal bone acquisition over time. Although on average absolute values of BMD were maintained, evaluation of age- and weight-adjusted Z-scores suggested deficits in the context of expected gains of BMD. Further subjects are needed to confirm these findings and to determine the best modality for longitudinal studies in this population.

SU020

Correlation between Maximal Effect delivered during Fitness Test and Bone Mineral Density. A 3 Year prospective Study in Children and Adolescents. K. Kramme*[1], L. Mortensen*[2], K. Brixen[1], K. Froberg*[3], H. Beck-Nielsen*[1], P. Charles*[2]. [1]Dept of Endocrinology, Odense University Hospital, Odense, Denmark, [2]Dept of Endocrinology, Aarhus University Hospital, Aarhus, Denmark, [3]Institute of Physical Education and Clinical Biomechanics, University of Southern Denmark, Odense, Denmark.

Previous studies have suggested that exercise may be one of the most important modifyable factors for accretion of bone mass in childhood and adolescence. Studies in adults have reported a positive correlation between VO2max and Bone Mineral Density (BMD). VO2max, however, depends on body weight which in itself is closely related with BMD. Here we aimed to evaluate the association between the maximal effect delivered during fitness test (Vmax-f) and lumbar spine (LS) and whole-body (WB) BMD, and the correlation between Vmax-f and the change in LS BMD in children and adolescents.This prospective study comprised 157 females and 149 males aged 8 to 21 years (median 14 years). Participants were tested on an ergometer bicycle, and BMD subsequently measured using a Norland DXA-scanner. The examinations were repeated after 3 years. The relationship between BMD and Vmax-f, body weight, height, age, and sex was evaluated at start (y0) and after 3 years (y3) using multiple backwards regression analysis. Results are shown in the table as partial correlation coefficients.In conclusion, the maximal effect delivered during exercise test correlates significantly and positively with LS and WB BMD in children and adolescents. The performance in the test was significantly and positively correlated with the change in LS BMD during the subsequent 3 years. Our study supports the idea that exercise positively affects accretion of bone mass during childhood and adolescence.

Table

	BMD LS(y0)	BMD WB(y0)	Change BMD LS(y3-y0)

Relationships Between High Resolution Computed Tomography for Architectual Characterization of Human Calcaneus and Histomorphometry. B. Cortet[1], D. Chappard[2], N. Boutry*[3], P. Dubois*[3], A. Cotten*[3], X. Marchandise*[3]. [1]Rheumatology, University-Hospital of Lille, Lille, France, [2]University-Hospital of Angers, Angers, France, [3]University-Hospital of Lille, Lille, France.

The present study aimed to characterize the relationships between several variables reflecting bone microarchitecture assessed by both histomorphometry and high resolution computed tomography (HRCT) at the calcaneus. 24 specimens removed from cadavers were studied. There were 12 men and 12 women (mean age: 78 ± 10 years; range: 53-93). 16 axial sections (1 mm in width and 2 mm apart) were selected for HRCT. One core (11 mm internal diameter) was removed from the superoposterior part of the calcaneus and 6 undecalcified sections (7 microns) were analysed. The histomorphometric analysis was performed on a Leica Quantimet Q570 image analyzer. Features measured by both methods were: BV/TV, trabecular thickness (Tr Th), trabecular number (Tr N), trabecular spacing (Tr Sp), interconnectivity index (ICI), node count (NC), free end count (FEC), node-to-node strut count (NNS), node-to-free end strut count (NFS), free end-to-free end strut count (FFS), marrow space star volume (SV), Euler number (EN) and fractal dimension (FD). R values are shown in the table below (*p<0.05). In conclusion the present study suggests that the correlations found for the 2 methods used (HRCT and histomorphometry) vary according to the features measured. Findings also suggests that several features measured by HRCT reflect bone microarchitecture.

BV/TV	Tr Th	Tr N	Tr Sp	ICI

Medical Conditions in Relation to Bone Mineral Density and Stiffness in Older Men. D. R. Miller[1], E. Krall[2], J. J. Anderson*[3], S. Rich*[1], R. Ferguson*[1], L. Silva*[1]. [1]Chqoer, Veterans Administration, Bedford, MA, USA, [2]Dental Medicine, Boston University, Boston, MA, USA, [3]School of Medicine, Boston University, Boston, MA, USA.

Accelerated bone loss and increased risk of fracture have been associated with a number of common medical conditions in the elderly, including pulmonary, cardiac, metabolic, and gastrointestinal disorders. Generally, these associations have been studied individually and few studies have reported on the independent and compound effects of multiple medical conditions on bone health. This was examined in the VA Longitudinal Osteoporosis Research (VALOR) study using data from 696 male veterans over 50 years of age. Bone mineral density (BMD) at the femur and forearm were measured with dual energy x-ray absorptiometry (model DPX-IQ, Lunar Corp., Madison, WI). Femoral BMD measurements represent averages of right and left hips per subject. Change in BMD with repeat measurements over a period of up to three years are computed as change per year. Bone stiffness at the calcaneus is measured with ultrasonography (Achilles Plus, Lunar). Disease status is determined through self-report of medical diagnoses and diagnostic (ICD-9) codes

from the medical records. General linear modeling was used to estimate associations with various medical conditions, with adjustment for age, body mass index, physical activity, smoking, diet, and other concurrent medical conditions. Femoral BMD was significantly ($p<0.05$) lower (by at least 4%) in men with Crohns disease, rheumatoid arthritis, stroke, transient ischemic attack, congestive heart failure, or cancer. Loss of femoral BMD was also significantly greater in patients with chronic obstructive pulmonary disease. Significantly lower forearm BMD was found in men with these conditions, except for cancer, and was also found in those with diabetes, angina, or syncope. Bone stiffness was lower in men with cardiovascular disease, cancer, Crohns disease, or syncope. The cumulative number of medical conditions was inversely associated with all measures of BMD and bone stiffness, and accounted for a substantial proportion of their variability. Careful examination of the modifying effects of duration of illnesses and their specific pharmacological treatments is in progress. These results document the devastating and independent effects of a number of medical conditions on bone health.

SU023

Long-term Variability of Markers of Bone Turnover in Postmenopausal Women and Implications for their Clinical Utility. The OFELY Study. P. Garnero[1], D. Mulmann*[2], F. Munoz*[3], E. Sornay-Rendu*[3], P. D. Delmas[3]. [1]Synarc, Inserm Unit 403, Lyon, France, [2]INSERM unit 403, Lyon, France, [3]Inserm Unit 403, Lyon, France.

High levels of bone turnover markers is a risk factor for fragility fracture in postmenopausal women, but the variability of their measurement has raised concern about their clinical utility. In this study we investigated the long-term variability of markers in 268 healthy untreated postmenopausal women (1 to 39 yr post menopausal) in the OFELY cohort. A fasting blood sample was collected every yr for 4 yr (5 samples) to measure serum intact osteocalcin (OC) for formation and serum CTX (S-CTX) by automated analyzer for bone resorption. Bone turnover remained stable over 4 years (OC, +1.3%/yr, p=0.003; S-CTX; -0.13%/yr, p=0.7). Women were categorized in tertile (T1, T2 and T3, from lowest to highest) of bone marker levels. Agreement of classification between baseline and 4 yr measurements was moderate (kappa: 0.51 and 0.52, for OC and S-CTX, respectively) with 60% of women remaining in the same group for both markers. However, only 4% and 5% of patients in T3 (high turnover) for OC and S-CTX respectively at baseline were found in T1 (low turnover) after 4 years. Conversely, 10% and 4% of women in T1 for OC and S-CTX respectively were found in T3 after 4 years. Among women in T2 (intermediate bone turnover), 51% and 43% for OC and S-CTX respectively, remained in the same tertile at the second measurement. When the 2 markers were combined, only 2% of women at high turnover at baseline -defined as OC and/or S-CTX in T3- were classified at low turnover 4 years later. We conclude that serum bone turnover markers are stable over 4 years in untreated postmenopausal women. A single measurement of one or two markers accurately classifies most women with a definitively high or low turnover. For those women with intermediate levels (T2), classification may be improved by a second measurement.

SU024

Cyclical Behaviour of Bone Remodelling and Bone Loss in Healthy Women after Menopause: Results of a Prospective Study. G. Mazzuoli*[1], D. Marinucci*[2], E. D'Erasmo*[1], M. Acca*[1], D. Pisani*[1], M. G. Rinaldi*[2], G. Bianchi*[1], D. Diacinti*[1], S. Minisola[1]. [1]Dipartimento Scienze Cliniche, Università La Sapienza, Rome, Italy, [2]Dipartimento Studi Geoeconomici e Statistici, Università La Sapienza, Rome, Italy.

We measured the annual changes of lumbar bone mineral density (BMD) in 238 healthy pre- and postmenopausal women aged 45-74 years providing evidence that bone loss is not monotonic over time but exhibits cyclical damping oscillations. The subjects were divided into groups according to their menstrual status and years since menopause. When the log-linear trend of BMD decrement is transformed into a constant by considering annual percentage changes, the presence of a cyclical component of seven years is evident; by employing a harmonic regression model, the cyclical component is also statistically significant on baseline data. The cyclical behaviour of BMD decrement corresponds to an analogous behaviour of the bone remodelling markers. The results suggest that the lack of oestrogen, acts as a synchronizer on bone remodeling triggering a latent cyclical rhythm of loss of bone persisting throughout the life. The existence of a chronobiological rhythm of bone loss starting after menopause, till now unrecognized, may have important clinical implications.

SU025

Age-related Changes in Cortical Bone Content of Insulin-like Growth Factor Binding Protein (IGFBP)-3, IGFBP-5, and Osteoprotegerin in Postmenopausal Osteoporosis. Possible Connection with Bone Mass. T. Ueland*[1], K. Brixen[2], L. Mosekilde*[3], L. Mosekilde[4], A. Flyvbjerg*[5], J. Bollerslev[6]. [1]Research Institute for Internal Medicine, National University Hospital, Oslo, Norway, [2]Department of Endocrinology C, Aarhus University Hospital, Aarhus, Denmark, [3]Department of Cell Biology, University of Aarhus, Aarhus, Denmark, [4]Department of Endocrinology, Odense University Hospital, Odense, Denmark, [5]Medical Research Laboratory M, Aarhus University Hospital, Aarhus, Denmark, [6]Department of Endocrinology, National University Hospital, Oslo, Norway.

Serum levels of growth hormone (GH), insulin-like growth factor (IGF)-I decline with increasing age, while osteoprotegerin (OPG) increases. IGFs as well as OPG are abundant in bone matrix and are important local regulators of bone metabolism mediating the effects of many upstream hormones (e.g. estrogen). Thus, they may explain some of the decrease in bone mass found in post-menopausal osteoporosis. We measured cortical and trabecular bone content of IGF-I, IGF-II, IGF binding proteins (IGFBP)-3, IGFBP-5, osteoprotegerin (OPG), osteocalcin and total protein in combined extracts obtained after ethylenediamine tetratacetate and guanidine hydrochloride extraction in 60 postmenopausal women aged 46.9 to 74.4 yrs (mean, 63.0 yrs), who had suffered a distal forearm fracture and had low BMD in the spine or hip (z-score < 0). Calcium was determined after HCl hydrolysis. We found significant age-related increases of IGFBP-3 ($r=0.35$, $p<0.01$), IGFBP-5 ($r=0.59$, $p<0.001$) and OPG ($R=0.36$, $p<0.01$) in cortical bone, significantly inversely correlated with femoral neck BMD (IGFBP-5, $r=-0.28$, $p<0.05$; OPG, $r=-0.42$, $p<0.01$). A correlation between age and OPG was also detected in trabecular bone ($r=0.27$, $p<0.05$). No age-related changes were detected for IGF or IGF-II. In conclusion, we found age-related increases in cortical bone matrix levels of OPG, IGFBP-3, and IGFBP-5 in post-menopausal women. These changes could potentially represent both compensatory and inhibitory mechanisms by regulating anabolic actions of IGFs, in addition to IGF-independent effects. As for OPG our findings probably represent compensatory responses to increased osteoclastic bone resorption.

SU026

Cut-Off Value Determined for Osteoporosis in Japanese Women by Using Quantitative Ultrasound. K. Yoh*[1], H. Ohta[2], H. Kishimoto*[3], I. Gorai[4], J. Hashimoto[5], Y. Nakatuka*[6], S. Yosimoto*[7], K. Makita*[8]. [1]Orthopedic Surgery, Hyogo College of Medicine, Nishinomiya, Japan, [2]Tokyo Women's Medical Univ, Tokyo, Japan, [3]Sanin Rosai Hospital, Yonago, Japan, [4]Yokohama city Univ., Yokohama, Japan, [5]Osaka Univ., Osaka, Japan, [6]Osaka City Univ., Osaka, Japan, [7]Hyogo Chuo Hosp., Sanda, Japan, [8]Keio Univ., Tokyo, Japan.

The aim of this study was to evaluate the cut-off value for osteoporosis in Japanese women, by using Quantitative Ultrasound (QUS). The QUS technique is widely used in diagnosis, health check and monitoring of therapy. At present there are more than 2,500 QUS devices installed in Japan. In the case where QUS is used for the purpose of diagnosis and health check as well as dual energy X-ray absorptiometry (DXA), there is a need to consider differences in race and province. For this reason, normative data of speed of sound (SOS) using the handy QUS device (FURUNO CM-100, Japan) was reported in IBMS 2001 by us. A total of 1207 Japanese women aged 20-95 years (mean age: 57) were, after signing an informed consent, enrolled to perform the present study from six centers and three provinces in Japan. They were selected in a random manner with no subject having serious bone metabolism disease. The SOS of all subjects was measured at the right calcareous using the CM-100, and the bone mineral density (BMD) was measured at the lumbar spine (L2-L4) using DXA (Norland: XR-26/36, Hologic: QDR-2000 and Lunar: DPX). After measuring lumbar BMD, we divided the subjects into three categories according to the Japanese diagnostic criterion for osteoporosis proposed the Japanese Society for Bone Mineral Research in 1996. (This criterion defines those people with a BMD value of less than 70% (corresponding to T-score: -2.5SD) of young adult mean (YAM) as having osteoporosis, 70%-80% of YAM as low bone mass and more than 80% (corresponding to T-score:-1.5SD) of YAM as normal, respectively.) According to the cut-off value of lumbar BMD based on the above criterion, 312 of the 1207 women were categorized as osteoporosis, 302 women as low bone mass and 593 women as normal, respectively. Referring to the cut-off value of lumbar BMD, the cut-off value of SOS for osteoporosis, low bone mass and normal corresponded to 1481m/s, 1491m/s and 1506m/s, respectively. As a result of the sensitivity and specificity curve analysis on SOS, the cut-off value of the point of intersection was 1487m/s. This cut-off value, 1487m/s, is equivalent to 72% of YAM of lumbar BMD. This data showed that the cut-off value of SOS using CM-100 is highly compatible with the cut-off value of lumbar BMD using DXA. In conclusion, SOS measurement using the CM-100 gives good performance for diagnosis of osteoporosis as well as DXA. The CM-100 is a useful tool for clinical application.

SU027

Decreased Bone Formation in Ataxia Telangiectasia Mutated (ATM) Knockout Mice. A. Hishiya*[1], M. Ito[2], K. Ikeda[1], K. Watanabe[1]. [1]Dept. Geriatric Res., Natl. Inst. for Longevity Sci., Obu, Japan, [2]Dept. Radiology, Nagasaki Univ. School of Medicine, Nagasaki, Japan.

ATM is a member of PI-3 kinase family proteins, encoded by the gene, Atm, responsible for premature aging syndrome, ataxia telangiectasia (AT). This protein kinase is known to play critical roles in DNA replication and repair. Accelerated carcinogenesis induced by irradiation as well as growth retardation has been observed in Atm knockout (ATMKO) mice. AT is also recognized as a genomic instability syndrome, sharing the symptoms with accelerated senescence in human and mouse. Here, we have found that the bone phenotype of ATMKO is similar to that of bone loss in disuse and/or aging. ATMKO in 129/Sv and its age-matched heterozygous mutant (+/-) and wild-type (+/+) animals were used for experiments. At 10 weeks of age, there is no significant difference in body weight between KO and control (+/- or +/+) mice. Growth retardation of KO mice is pronounced at 14 weeks of age. The fifth lumber vertebra and tibia from these mice were subjected to micro-CT analysis and bone histomorphometry, respectively. Significant decrease in BV/TV was already observed in KO mice at 10 weeks. The difference between KO and control animals was more pronounced at the age of 14 weeks. Furthermore, bone mass was decreased along with aging of KO mice, whereas it was increased in controls. Both BFR/BS and Oc.S/BS were significantly lower in KO mice than in control mice at 10 weeks of age. To determine the cellular basis of the bone phenotype, we employed in vitro osteoclastogenesis and colony formation assays using bone marrow cells from KO and control mice. Although there was no significant decrease in osteoclast formation from M-CSF-dependent bone marrow cells of KO mice, CFU-F, CFU-OB, and CFU-Adip were markedly reduced in KO mice, comparing with bone marrow cells from control mice. These data suggested a possibility that osteopenic phenotype in ATMKO is caused by dysfunction of osteoblast lineage.

SU028

The Design and Baseline Participant Characteristics of Osteoporotic Fractures in Men (MrOS) – a Large Observational Study of the Determinants of Fracture in Older Men. E. Orwoll[1], J. Blank[1], E. Barrett-Connor[2], J. Cauley[3], S. Cummings[4], K. Ensrud[5], C. Lewis[6], P. Mannen*[4], R. Marcus[7], K. Phipps[1], M. Stefanick*[7], K. Stone[4]. [1]Oregon Health & Science University, Portland, OR, USA, [2]University of California, San Diego, San Diego, CA, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]University of California, San Francisco, San Francisco, CA, USA, [5]VA Medical Ctr & Univ of Minnesota, Minneapolis, MN, USA, [6]University of Alabama, Birmingham, Birmingham, AL, USA, [7]Stanford University, Palo Alto, CA, USA.

Although osteoporosis is common, there is insufficient information concerning the characteristics and risk factors for fracture in men. Osteoporotic Fractures in Men (MrOS), a prospective cohort study, was designed to provide a better understanding of the problem. About 6000 U.S. men ages of 65 years and older were recruited in early 2000 at 6 sites (Birmingham, Minneapolis, Portland OR, Pittsburgh, Palo Alto, San Diego), primarily by mass mailings to population-based lists. Additional participants are being recruited in Sweden and Hong Kong. Study information is collated at a data coordinating center (UCSF). At the baseline examination, each participant completed detailed questionnaires regarding medical history, physical activity, diet, and lifestyle and demographic characteristics. Skeletal assessments are made with DXA, ultrasound, femoral and vertebral QCT, and vertebral radiographs. Serum and DNA has been collected. Data from the baseline examination for 5437 participants is presented here. The mean age is 73 yrs, with 43% $\geq$75 yrs. 10% are minorities, including 210 African Americans, 173 Asians, 100 Hispanics, and 55 American Indians. The population is generally educated (53% completed college) and healthy (86% rated their health as relatively good/excellent). 82% are currently married. There are few current smokers (3%) but 59% smoked previously, and 64% use alcohol at least occasionally. The mean (range) BMI is 26.9 kg/m^2 (17-51), and subjects report a mean weight increase of 10 kg since age 25. 33% have a history of fracture in a parent (father 15%, mother 22%). 17% of the participants reported a non-traumatic fracture since age 50, and 2% reported a fracture within the last 12 months. As measured by DXA, mean (range) total hip BMD is 0.951 gm/cm^2 (0.31 - 2.06) and total spine BMD is 1.06 gm/cm^2 (0.47 - 2.1). Men are followed with brief questionnaires mailed every 4 months to ascertain falls and fractures, and a mid-study questionnaire. After an average of 4.5 years, men will return for a final study visit to assess change since baseline. With this data, the risk of fracture will be examined. MrOS should provide information essential for the understanding and management of osteoporosis in men.

Periosteal Bone Formation and Resorption are Both Active at the Femoral Neck: Mechanisms for Change in Bone Size. E. Orwoll[1], S. Orwoll[1], S. Kohama*[1], G. Evans[2], R. Turner[2]. [1]Oregon Health & Science University, Portland, OR, USA, [2]Mayo Clinic, Rochester, MN, USA.

The femoral neck is a common site for fracture. It is critical to understand the factors that influence its biomechanical strength. Femoral neck size is a fundamental determinant of fracture resistance and it has recently been appreciated that change in femoral neck size occurs not only during growth but also with aging. The cellular mechanisms involved in mediating change in bone size have not been studied but clearly provide an opportunity to better understand fracture risk and to identify possible methods to change bone size therapeutically. To describe the remodeling events that occur on the periosteal surface of the femoral neck we studied specimens from double tetracycline labeled rhesus macaques. 5 animals of a variety of ages (2-12 yrs) were sacrificed; proximal femurs were carefully removed intact, preserved in 70% alcohol and prepared for histomorphometric analyses. Sections through the femoral neck were examined to determine periosteal osteoblast and osteoclast activity. Bone formation was clearly present on periosteal surfaces in all animals. 3 animals were more completely analyzed. The osteoid surface was 13% (range 8.5-20.7), the extent of double-labeled surface was 5.4% (2.5-7.0) and the mineral apposition rate was 0.5 um/day. At this rate of bone formation, the femoral neck diameter would increase at a rate of ~0.015mm/yr and the cross sectional area would be expected to increase at a rate of ~1%/year. In addition, extensive surface based osteoclastic activity was also apparent. The extent of eroded surface was 15.6% (7.2-24.7). Resorption pits contained multinucleated osteoclasts that stained positively for acid phosphatase. Resorption activity apparently arose on the periosteal surface as there was no evidence that it resulted from extension of intracortical remodeling processes (tunneling). These results document the previously unrecognized presence of surface-based remodeling at the femoral neck in adult non-human primates. In addition to bone formation, bone resorption was an active part of periosteal activity. The rates of bone formation and bone resorption are sufficient to result in biomechanically meaningful changes in femoral neck geometry. In light of the importance of femoral neck geometry in the determination of bone strength, remodeling at this site may play an important role in the determination of fracture risk. Moreover, the presence of both osteoblastic and osteoclastic activity provides the opportunity to target therapies designed to reduce the loss of bone, or to increase bone formation, at the femoral neck and thus to reduce likelihood of fracture.

Soy Consumption and Bone Mineral Density in Chinese Perimenopausal Women. S. C. Ho[1], J. Woo*[2], S. Lam*[2], Y. Chen*[2], A. Sham*[2]. [1]Department of Community & Family Medicine, The Chinese University of Hong Kong, New Territories, Hong Kong Special Administrative Region of China, [2]CUHK, HK, Hong Kong Special Administrative Region of China.

Recent interest has been shown in the potential beneficial effects of phytoestrogens on bone health. As the early years of menopause are a period of rapid bone loss, and the risk for osteoporosis increases substantially, the habitual intake of soy protein and isoflavones may play a role in the retardation of bone loss in Asian women during the postmenopausal years. This study aims to investigate the relation between soy intake and bone mass in Chinese women within the first 12 years postmenopausal. We estimated the dietary intake of soy foods and other key nutrients, including dietary calcium, using the quantitative food frequency method. Bone mineral density (BMD) was measured with a dual energy x-ray densitometre (Hologic 4500A). Soy isoflavone consumption was categorised as quartiles of intake and related to BMD at different sites. We did not observe differences in BMD among the intake quartiles in women within the first 4 years since menopause. We noted generally higher BMD values with increasing soy protein intake quartiles among women 5 to 12 years postmenopause. Women belonging to the highest intake quartile had a mean intake of 19.8 ± 13.3 g/day with a range from 9.6 to 76.9 g/day. We observed a statistically significant difference between the mean BMD values at the intertrochanter and trochanter areas among women belonging to the highest and lowest soy intake quartiles. The BMD values of women from the first and fourth intake quartiles differed by about 3.5% to 7.1% at the various hip sites, while no difference was observed for the spinal BMD. The chi-square test for trend showed a significant trend ($p < 0.05$) in the increase in mean BMD values at the intertrochanter and the total hip areas among subjects with increasing quartiles of soy intake. The results remained similar after adjusting for body weight and years since menopause in the multiple linear regression analysis. Soy protein intake, together with the two variables, accounted for about 24 to 28% of the variances of the BMD values for the hip and the total body. This study of early Chinese postmenopausal women demonstrated that soy intake had a small but significant effect on the preservation of BMD after the initial years of rapid bone loss. The effects of phytoestrogens on bone health should be further explored in populations with habitual dietary soy intake, taking into account the different stages of menopausal effect.

Bone Morphogenetic Protein-2 (BMP-2) Induces Distinct Effects on Human Osteosarcoma Cell Proliferation, Differentiation and Apoptosis. E. Haÿ*, D. Modrowski, S. Le Mee*, P. J. Marie. INSERM U349, Paris, France.

We previously showed that BMP-2 promotes normal human osteoblast apoptosis through a Smad-independent, protein kinase C-dependent signaling pathway. In this study, we investigated the effects of BMP-2 on cell proliferation, differentiation and apoptosis in three human osteosarcoma (SaOS2, MG63, OHS4) cell lines. We found that rhBMP-2 (50-1000 ng/ml, Genetics Institute) increased alkaline phosphatase activity (ALP) in SaOS2 and OHS4 cells, but not in MG63 cells, with a maximal effect at 200 ng/ml. Similarly, rhBMP-2 (200 ng/ml) increased the expression of ALP, Cbfa1/Runx2 and N-cadherin mRNA and protein levels in SasOS2 and OHS4 cells, but not in MG63 cells, as shown by RT-PCR and western blot analyses. In contrast, rhBMP-2 inhibited cell proliferation in MG63 and SaOS2 cells, but not in OHS4 cells. More interestingly, rhBMP-2 (200 ng/ml) increased apoptosis in MG63 and SaOS2 cells, but not in OHS4 cells, as demonstrated by TUNEL analysis. In both MG63 and SaOS2 cell lines, rhBMP-2 stimulated caspase-9 and caspases-3, -6, -7 activity, but not caspases-2 and -8 activity. Moreover, the pro-apoptotic effect of BMP-2 in MG63 and SaOS2 cells was inhibited by calphostin C (2 µM), a selective inhibitor of protein kinase C activity, showing that BMP-2 induces apoptosis in responsive human osteosarcoma cells through a PKC-caspase-9-caspase-3, -6, -7 pathway. Transient transfection of MG63 and SaOS2 cells with a vector containing a rat BMP-2 cDNA also increased ALP and Cbfa1/Runx2 mRNA expression and induced pro-apoptotic effects, as found with exogenous rhBMP-2. These data show that 1) BMP-2 induces distinct effects on cell proliferation, differentiation and apoptosis in human osteosarcoma cell lines, depending on their stage of differentiation, 2) BMP-2 promotes apoptosis in responsive osteosarcoma cells by activating PKC and caspase-9 and caspases-3, -6, -7 activities and 3) BMP-2 overexpression reproduces the same effects as exogenous BMP-2 in responsive cells. This study suggests that exogenous BMP-2 or promotion of endogenous BMP-2 by specific agents may be useful to promote cell death of human osteosarcoma cells.

Regulation of the Cloned Aggrecan Gene Promoter by Osteogenic Protein-1 (OP-1, BMP-7). L. C. C. Yeh*[1], J. C. Lee[2]. [1]Biochemistry (MC7760), University of Texas Health Science Center, San Antonio, TX, USA, [2]Biochemistry (Mail Code 7760), The University of Texas Health Science Center, San Antonio, TX, USA.

Osteogenic Protein-1 is a member of the bone morphogenetic protein subfamily of the transforming growth factor-β superfamily and induces formation of new bone and cartilage. Previous studies have demonstrated that OP-1 stimulates the synthesis of aggrecan, a major extracellular matrix component. To investigate the molecular mechanism of transcriptional regulation of the aggrecan gene by OP-1, we constructed a clone containing a 1 kb region of the 5'-upstream sequence of the mouse aggrecan gene fused to the promoterless luciferase reporter gene in pGL2-Basic vector. Several promoter deletion constructs were also generated by unique restriction endonuclease digestion or by PCR. These DNA constructs were used in transient transfection studies using C2C12 cells. An inhibitory element of the basal transcription activity was detected in the aggrecan promoter. To examine effects of OP-1 on the promoter activity, transfected cells were treated with solvent control

or different concentrations of OP-1 for 24 h. OP-1 stimulated the 1-kb promoter construct in a dose-dependent manner with a maximum stimulation of about 2-fold. Subsequent studies with the various deletion constructs revealed that a 100 bp region was essential for the up-regulation of the aggrecan by OP-1. In summary, we identified an OP-1 response region in the promoter of the mouse aggrecan gene. The information will be useful in additional studies on the nature of transcriptional regulation of the aggrecan gene by BMPs in general and OP-1 in particular.

Expression of Bone Morphogenetic Proteins and Ectopic Bone Induction by Native and Primary Cultures of Rat Growth Plate Chondrocytes. R. Dhanyamraju*, J. Sipe*, H. H. T. Hsu, H. C. Anderson. Department of Pathology & Laboratory Medicine, University of Kansas Medical Center, Kansas City, KS, USA.

Endochondral bone formation is a very highly coordinated event involving many regulatory factors, which eventually leads to the replacement of cartilage with bone. The maturation of cartilage is thought to be promoted by BMPs, 1,25-OH_2 Vit D_3, retinoic acid, c-myc, ascorbic acid and *Ihh*. In this study, we report the expression of BMPs by primary cultures of rat growth plate chondrocytes. Further, we attribute the osteoinductivity of rat growth plate chondrocytes to the presence of BMPs in them. Chondrocytes were obtained from collagenase-digested tibial and femoral growth plate cartilage of 4 week old rachitic rats. The isolated chondrocytes were plated as monolayers at a density of 0.5 X 10^6 cells/35 mm plate and grown for 17 days in BGJ_b medium supplemented with 10% FBS and 50 µg/ml ascorbic acid. Immunohistochemistry with anti-BMP 2, 4 and 6 showed that BMP expression was associated with maturing hypertrophic central chondrocytes. Expression of BMP-2, 4 and 6 in primary cultures of rat growth plate chondrocytes suggests that BMPs might have a role in the differentiation of chondrocytes. The observation that rat growth plate chondrocytes expressed BMPs *in vivo* and in primary cultures led us to investigate whether these cells would be osteoinductive when implanted subcutaneously in Nu/Nu mice. Soluble bone inducing agent (BIA) was extracted from freeze-dried, native rat growth plate chondrocytes in 4M Gu-HCl and bioassayed for osteoinductivity by subcutaneous implantation in Nu/Nu mice. Our bioassay results showed that freeze-dried extracts of chondrocyte implants were capable of ectopic bone initiation by host mesenchymal cells as revealed by light microscopy and high alkaline specific activity. In conclusion, native and primary cultures of rat growth plate chondrocytes express BMP-2, 4 and 6 and are osteoinductive in subcutaneous implants in mice.

SU034

Effects of Radiation on Ex Vivo Gene Therapy-Directed Osteogenesis. B. Nussenbaum*, R. B. Rutherford, T. N. Teknos*, K. J. Dornfeld*, P. H. Krebsbach. University of Michigan, Ann Arbor, MI, USA.

Craniofacial defects commonly arise from ablative cancer surgery, and autologous bone grafts are used for reconstruction. To avoid donor site morbidity, innovative bone regenerative strategies are being investigated using protein, cell, or gene therapy. Because radiation remains a common post-operative treatment for head and neck cancers, it is critical to determine if these new approaches are effective in healing defects that are challenged by therapeutic doses of radiation. The purpose of this study was to determine if radiation affects the ability of ex vivo gene therapy to heal bone critical sized defects. Dermal fibroblasts derived from Fisher rats were transduced ex vivo using an adenoviral vector containing the cDNA for BMP-7 (AdCMV-BMP-7) for 24 hours at 1000 PFU/cell. Two million cells were loaded onto a 9 mm diameter collagen sponge. Nine mm calvarial defects were created in 200 gm Fisher rats. Either a transduced cell-seeded sponge or an inlay calvarial bone graft was placed in the defect. Two weeks post-operatively, either no radiation or a single 12 Gy radiation dose was delivered to the operated area, and the tissue was harvested 4 weeks later. For the bone graft specimens, histology was used to determine degree of healing at the wound margins. For the gene therapy specimens, histomorphometry was used to determine the defect surface covered with bone, defect area, and percent of defect filled by new bone. Statistical analysis using the unpaired t-test was performed. None of the inlay bone grafts in radiated (n=5) or non-radiated (n=5) rats had gross or histologic evidence of complete healing at the wound margins. For the gene therapy groups, gross estimation revealed near-100% defect healing including the wound margins in the non-radiated defects (n=3), while the radiated defects (n=10) had variable amounts of bone production (30-90%) with incomplete fusion at the margins. Comparison of these 2 groups revealed a statistically significant difference favoring the non-radiated group for mean percentage of defect surface covered by bone (90% vs. 65%, $p<0.02$), and mean percentage of defect area filled by new bone (47% vs. 32%, $p<0.02$). In conclusion, BMP-7 ex vivo gene therapy successfully regenerated bone in rat calvarial critical sized defects despite receiving a therapeutic dose of radiation. Both qualitatively and quantitatively, the defects were not as well healed at 4 weeks post-radiation when compared to the non-radiated rats. The free inlay bone grafts did not heal at the wound margins independent of radiotherapy, which suggests that BMP-7 ex vivo gene therapy was more effective for healing calvarial defects in this defect model.

Stimulation of BMP Signal in Osteoblasts by Dexamethasone and Testosterone but not by Estradiol. K. Nakayama[1], S. Watanabe*[1], S. Fukumoto[2], Y. Takeuchi[1], T. Fujita*[1]. [1]Department of Medicine, University of Tokyo, School of Medicine, Tokyo, Japan, [2]Department of Laboratory Medicine, University of Tokyo Hospital, Tokyo, Japan.

Steroid hormones, such as glucocorticoid and sex steroids, are involved in bone formation. However it is largely unknown how steroid hormones affect osteoblastic functions at this moment. Bone morphogenetic proteins (BMPs) play a pivotal role for osteoblastic differentiation and bone formation. Thus, it is speculated that there are some interactions between BMP signal and steroid hormones. Since BMPs regulate the transcription of their target genes through Smad proteins, some steroids may affect the transcriptional activity of Smads. We, therefore, investigated actions of glucocorticoids, testosterone and estrogen on BMP signal at the transcriptional level. Because mouse Smad6 promoter has at least one BMP responsive element, we used a reporter plasmid called mS6-lux that has mouse Smad6 promoter in the upstream of Luciferase gene to detect BMP signal. We introduced mS6-lux into mouse osteoblastic MC3T3-E1 cells and treated them with 10 nM dexamethasone (DEX), 10 nM 17β-estradiol (E2) or 10 nM dihydrotestosterone (DHT) for 48 hours in the presence or absence of 100 ng/ml BMP-2, followed by luciferase assay. We also measured alkaline phosphatase (ALP) activity of similarly treated MC3T3-E1 cells. The activities of mS6-lux and ALP in MC3T3-E1 cells induced by BMP-2 were enhanced by DEX and DHT but not by E2. None of them had significant effects in the absence of BMP-2. These results indicate that the stimulatory effect of DEX and DHT on osteoblastic differentiation is at least partially mediated via the enhancement of BMP signal by these steroid hormones. This may explain the reason why physiological amounts of glucocorticoid are essential for the osteoblastogenesis. More importantly, since E2 failed to mimic the positive effect of DHT, androgen receptor (AR) but not estrogen receptor (ER) may be directly involved in the osteoblastogenesis and bone formation. Recent studies demonstrate a crucial role of ER activation by E2 for the suppression of bone resorption both in female and male. However, our observations suggest that testosterone has some stimulatory actions on bone formation via AR activation which may result in the enhancement of the transcriptional activity of BMP-regulated Smads.

SU036

Articular Chondrocyte Maturation Is Induced By Shifting Signaling Pathway Dominance from TGF-β to BMP. M. J. Zuscik, J. F. Baden*, T. J. Sheu*, E. M. Schwarz, R. J. O'Keefe, J. E. Puzas, R. N. Rosier. Orthopaedics, University of Rochester, Rochester, NY, USA.

Maintenance of the articular surface depends on the function of articular chondrocytes (ACs) which produce matrix and are constrained from undergoing terminal maturation. Under unique circumstances, such as in osteoarthritis, these unknown molecular constraints are lost and ACs recapitulate the maturational process that occurs during endochondral ossification. The aim of this study was to identify these unknown suppressive constraints, with the goal of understanding the molecular processes at work during inappropriate stimulation of AC hypertrophy. To address this aim, a novel cell model was developed which utilizes 5-azacytidine (Aza) to induce maturation in cultured ACs. Aza, an s-triazine nucleoside used to treat leukemias, is known to un-mask expression of silenced genes in a number of cell models by replacing cytidine in the DNA, thus blocking the suppressive effect of cytidine methylation on gene transcription. ACs, which do not spontaneously express markers of maturation such as type X collagen (colX), indian hedgehog and alkaline phosphatase, were induced to express these markers by an 8 day treatment with 15 µg/ml Aza. Since it is well established that TGF-β and BMP-2 regulate the respective suppression or induction of chondrocyte maturation, we hypothesized that this Aza-induction of maturation was facilitated via a shift in signaling dominance from TGF-β to BMP. We tested this hypothesis i) by comparing Aza effects with those induced by over-expressing the BMP-2 signaling molecule smad1 or by blocking signaling through the TGF-β smads (2 and 3) using a dominant negative (Δ) approach, ii) by examining the impact of Aza on the expression of the TGF-β smads (2 and 3), the BMP-2 smads (1 and 5), and the ubiquitin E3 ligase smurf2, a protein that initiates the degradation of smad2 and 3, and iii) by using a pulse/chase method to measure the rate of smad2 and 3 degradation following Aza treatment. We found that i) over-expression of smad1, Δsmad2 or Δsmad3 mimicked Aza by inducing expression of the hypertrophic marker colX, ii) Aza-treated ACs displayed less smad2 and 3 protein and increased smad1, smad5 and smurf2 protein, and iii) Aza mimics smurf2 by accelerating smad2 and 3 degradation. These data indicate that Aza induction of AC maturation is facilitated by driving BMP signaling dominance via up-regulation of smad1 and 5 and via increased degradation of smad 2 and 3 by smurf2. We suggest that inappropriate maturation of ACs, such as in osteoarthritis, may be due to dis-regulation of the delicate balance between these pathways leading to the dominance of BMP signals and concomitant maturation.

SU037

Regulation of Osteoblastic Differentiation by BMP Inhibitors. A. Nifuji[1], Y. Ohyama*[1], K. Miyazono*[2], M. Noda[1]. [1]Dept. Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Dept. Molecular Phathology, The University of Tokyo, Tokyo, Japan.

The balance between BMP and BMP inhibitors is crucial for proper skeletal cell differentiation. There are several types of BMP inhibitors including noggin, chordin, tsg, gremlin, Cerberus, Dan, smad6 and smad7. Many of those inhibitors are known to be expressed in the skeletal tissues in development. However, it is not clear whether each BMP inhibitor is functionally equivalent to block skeletal cell differentiation. To address this point, we investigated how and when each BMP inhibitor functions as regulator of osteoblast differentiation by using an adenovirus constructs expressing noggin, smad6 and smad7. When we infected adenovirus expressing noggin into MC3T3 E1 cells at moi250, the increase in alkaline phosphatase (ALP) activity induced by the addition of ascorbic acid and beta glycerophosphate was blocked. Mineralized nodule formation estimated by Von Kossa and Alizarin red staining did not differ between Lac Z-infected and noggin-infected cells at moi 250, suggesting that noggin blocked at the early stage rather than maturation stage of osteogenic differentiation. In contrast to noggin, when we infected adenovirus expressing smad 6, both ALP activity and mineralized nodule formation were blocked when compared with lacZ-expressing adenovirus. Similar results were obtained by using smad 7 expressing adenovirus. These data suggest that the effects of secreted BMP inhibitors on osteoblastic differentiation are not equivalent to those of intra-celluar BMP inhibitors.

SU038

Hoxc-8 C-terminal Domain Sufficiently Inhibits BMP-induced OPG Expression. S. Bai*, M. Wan, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Two transmembrane proteins, RANKL and RANK, mediate the cell-cell contact between osteoblasts and osteoclast precursor cells which is required for osteoclast differentiation and maturation. Osteoprotegrin (OPG) is an osteoblast-secreted decoy TNF receptor. It binds to RANKL, blocks the interaction between RANKL and RANK, and then inhibits osteoclast differentiation and maturation. BMPs stimulate OPG transcription. Previously, Hoxc-8 was identified as a transcriptional repressor on the OPG promoter. Smad1, one of the BMP signal specific effectors, interacts with Hoxc-8, dislodges Hoxc-8 from its binding, and stimulates OPG expression. Hoxc-8 was also identified as interacting with Smad6, one of the inhibitory Smad proteins, through its hexapeptide motif. However, the repressive domain of Hoxc-8 and its transcriptional repressive mechanism remained unclear. To address this question, we mapped Hoxc-8 and identified that the N-terminal domain of Hoxc-8 acts as its transactivation domain while the highly conserved domain within Hox proteins, including its hexapeptide motif, homeodomain and the C-terminal domain (Hoxc-8PHC), mediates its repressive activity. Overexpression of the Hoxc-8 N-terminal domain and the hexapeptide motif (Hoxc-8NP) stimulates OPG promoter activity while Hoxc-8PHC represses OPG promoter activity. Acetylation state of core histones plays a critical role in gene transcription regulation. Hoxc-8 was identified to interact with HDAC-1. To examine the mechanism of Hoxc-8PHC repressive activity, we performed an immunoprecipitation assay and identified that Hoxc-8PHC interacts with HDAC-1, indicating that Hoxc-8PHC recruits HDACs to the OPG promoter to inhibit OPG expression. To test the activity of Hoxc-8PHC on endogenous OPG expression in human bone marrow stromal cells, we generated Hoxc-8PHC expression retrovirus. Overexpression of Hoxc-8PHC inhibited BMP-stimulated endogenous OPG expression in human bone marrow stromal cells. These findings demonstrate that Hoxc-8PHC is the repressive domain of Hoxc-8. In summary, the finding of different functions of Hoxc-8 domains on OPG expression regulation helps us to understand the mechanism of BMP signaling and Hox proteins in bone cell differentiation and will provide us a scientific basis to develop potential clinical therapies.

SU039

Dlx5 Stimulates Osteoblast Differentiation in the Presence of Noggin, an Inhibitor of BMP Signaling. I. Erceg*, I. Marijanovic, M. S. Kronenberg, I. Kalajzic*, T. Tadic*, A. C. Lichtler. Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Previous studies from our laboratory and others have demonstrated that the homeodomain protein Dlx5 is present in differentiated osteoblasts, is induced by BMPs, and can induce osteoblastic differentiation. This suggests that Dlx5 may be an important mediator of BMP induction of osteoblastic differentiation. To test this hypothesis, we blocked the function of endogenous BMP in a primary in vitro chick calvarial osteoblast differentiation system using noggin, and supplied exogenous Dlx5 using an unregulated RCAS retroviral expression vector. Our hypothesis predicted that blocking BMP action would inhibit osteoblastic differentiation, as has been demonstrated previously, and that Dlx5 expression would stimulate expression of osteoblastic markers. We used an RCAS vector of subtype A to express noggin, and a subgroup B RCAS vector to express Dlx5. RCAS-noggin alone strongly inhibited differentiation, as expected. Expression of Dlx5 in the presence of noggin consistently induced higher levels of osteocalcin mRNA, although induction was not to the levels observed with Dlx5 alone. Our results suggest that Dlx5 is a significant mediator of BMP induction of osteoblast differentiation. However, it appears that BMPs may induce one or more other factors that cooperate with Dlx5 to induce the full expression of the osteoblast phenotype.

Mechanisms of BMP2-Induced Heterotopic Bone Formation. A. Davis[1], E. Olmsted-Davis[1], Z. Gugala*[2], K. Moran*[2], R. Lindsey*[2], E. Shore[3], F. Kaplan[3], F. Gannon[4]. [1]Pediatrics/CAGT, Baylor College of Medicine, Houston, TX, USA, [2]Orthopedic Surgery, Baylor College of Medicine, Houston, TX, USA, [3]Orthopedic Surgery, University of Pennsylvania, Philadelphia, PA, USA, [4]Orthopedic Pathology, Armed Forces Institute of Pathology, Washington, DC, USA.

Bone morphogenetic protein 2 (BMP2) belongs to a family of growth factors which induce both orthotopic and heterotopic bone formation, and is currently being developed for clinical use in bone healing. However, little is known about the mechanism by which BMP2 induces this process. We have developed a mouse model to identify the key factors necessary for BMP2 -induced bone formation as well as the initial events that occur upon delivery of the BMP2 protein. In this model, cells transduced to express and secrete BMP2 were injected directly into the muscle and the progression of bone formation was then followed histologically. This model system utilized a novel adenovirus type 5 vector, Ad5F35BMP2, containing a CMV-BMP2 cDNA within the E1 region, but has an adenovirus type 35 fiber replacing the normal adenovirus type 5 fiber. Comparison of this virus to the traditional Ad5BMP2 vector demonstrated enhanced virus uptake and a higher level of BMP2 expression. A correlation was found between bone formation and the level of BMP2 expression. The results also demonstrated that delivery of the BMP2 by mesenchymal stem cells is not required for bone formation since other fibroblastic cells transduced to express similar levels of BMP2 can induce bone formation as effectively. Immunohistochemical analysis using an antibody specific to human cells demonstrated that the majority of cells in the newly forming bone were recruited from the murine host, rather than from the transduced human cells used to deliver BMP2. Histological analysis demonstrated that one of the first events is the appearance of fibroblast-like cells in between the muscle fibers, leading to edema, and eventually new vessel formation in the tissues. This process led to destruction of muscle fibers with subsequent proliferative expansion of both fibroblastic and chondrocytic-like cells outward with eventual engulfment and death of the skeletal muscle. This degeneration of muscle fibers resembled the early phases of fibrodysplasia ossificans progressiva.

CREB and Smads Interact at the Smad 6 Promoter. A. M. Ionescu*, E. M. Schwarz, J. E. Puzas, R. N. Rosier, R. J. O'Keefe. Orthopaedics, University of Rochester, Rochester, NY, USA.

BMP's are known stimulators of chondrocyte maturation. Smad6, an inhibitor of the BMP signaling, was examined as a potential target for the inhibitory effects of PTHrP on chondrocyte maturation. PTHrP and BMP-2 effects were examined on the 3GC2-lux reporter in embryonic upper sternal chondrocyte cell cultures. This reporter is a 3X repeat of a 22 bp sequence derived from the BMP responsive region of the Smad6 promoter. The promoter contains a Smad binding site with adjacent sequences similar to CRE sites previously described in the osteocalcin and Ubx promoters. BMP treatment caused 4.1-fold and PTHrP a 4.2-fold stimulation of luciferase activity, while in combination, the effects were additive. Mutation of the Smad site abolished BMP responsiveness without altering PTHrP effects, suggesting that PTHrP induces the reporter independent of Smad signaling. PTHrP induction of the Smad6 promoter was blocked with dominant negative CREB (A-CREB), while co-transfections with dominant negatives specific for c-Fos, JunD, ATF-2, and CREB had no effect on reporter activation. Furthermore, gain of function experiments through co-transfection with either wild type CREB, constitutively active CREB or PKA expression vector had a stimulatory effect on the reporter in both control and PTHrP treated cells. EMSA was performed using the Smad6 BMP-responsive promoter oligonucleotide. In cultures transfected with wild type Flag-CREB, binding was enhanced 5 fold as compared with nuclear extracts from control samples. Flag-Creb binding was inhibited by anti-Flag antibody. PKA/CREB signaling was found to enhance BMP signaling; co-transfection with PKA or CREB cdna slightly increased BMP driven luciferase activity while A-CREB decreased the BMP effect from 12.6 to 7.5 fold. The findings demonstrate the requirement of CREB for maximal activation of the Smad6 reporter. However, CREB is not a direct target of BMP signaling since BMP-2 did not increase CREB activity at either of two CREB responsive reporters, one driven by multiple consensus CREs and the other driven by a Gal4 response element sensitive to CREB transactivation. In contrast, PTHrP induced both reporters. The functional importance of CREB in BMP-mediated activation of Smad6 expression was examined. BMP-2 stimulated Smad6 expression 13 fold at two-hours. However, in cultures infected with a replication competent retrovirus expressing ACREB, Smad6 induction was reduced 50% while control viral infection had no effect. The findings demonstrate that CREB acts in association with Smads to induce transcription at the Smad6 promoter. Induction of Smad6 is a potential mechanism involved in the inhibition of differentiation by PTHrP.

SU042

***In Vivo* Retroviral (MLV)-mediated BMP-2/4 Hybrid Gene Therapy Markedly Enhances Callus Formation in the Rat Femoral Fracture Model.** C. H. Rundle, N. Miyakoshi*, Y. Kasukawa, S. T. Chen*, M. H. C. Sheng*, J. E. Wergedal, K. H. W. Lau, D. J. Baylink. J.L. Pettis VAMC, Loma Linda, CA, USA.

Serious injuries, such as bone fractures, constitute a highly significant health problem that is projected to increase over the next several decades. In this study we tested whether 1) a murine leukemia retrovirus (MLV) vector could target transgene expression to the fracture site, and 2) if this application of gene therapy could safely promote fracture healing. Regarding the first hypothesis, because retroviruses transduce proliferating cells and there is a burst of periosteal cell proliferation at the fracture site shortly after bone fracture, MLV vectors should specifically target the fracture site for transgene expression. The transgene we applied was the bone morphogenetic protein (BMP)-2/4 hybrid gene. We chose the BMP-4 gene because it undergoes a considerable increase in expression during normal fracture healing. We found that using the BMP-2 signal sequence significantly enhanced and prolonged the secretion of mature BMP-4 in stromal cells transduced with the BMP2/4 hybrid gene, as compared to the native BMP-4 gene. Twelve week-old male Fischer 344 rats underwent femoral fracture and were divided into groups of 4 animals receiving lateral injections of either 1) MLV-BMP-2/4 transgene, or 2) MLV-B-galactosidase marker transgene (control). Examination by Faxitron and pQCT during healing revealed that BMP-2/4 therapy produced dramatic and significant increases ($p<0.02$) in the cross-sectional areas of calluses at days 7 (1.78-fold), 14 (2.86-fold) and 28 (2.87-fold). These calluses showed significant increases ($p<0.02$) in the bone mineral content at days 14 (5.65-fold) and 28 (3.11-fold). This bone formation suggested successful MLV targeting of BMP-2/4 gene function, and was confirmed by strong immunocytochemical staining for BMP-4 expression at the fracture site. All fractures displayed qualitatively normal bone histology. To examine the long-term response to this therapy, two control and two BMP-2/4 MLV-treated animals were monitored for 70 days. At this time, Faxitron X-rays revealed almost complete remodeling of the new bone in the fracture callus in both groups. Histologic studies showed there were no immune infiltrates in any fracture tissues, suggesting that MLV was nonimmunogenic. PCR analysis of DNA isolated from extraskeletal tissues, including the gonads, failed to detect transgene sequence at any time, indicating that this therapy was safe. In summary, we have demonstrated for the first time that the MLV-based retroviral vector is safe and effective for the introduction of BMP-2/4 gene expression to a fracture site, where it promotes greater fracture callus formation.
